

The Etiology of Cancer

1

SECTION A

The Genetic Basis of Cancer

JAIME F. MODIANO

This is an exciting and rapidly evolving time in the field of cancer genetics. Although it has been clear for several decades that cancer is a disease driven by the accumulation of genetic abnormalities,^{1,2} new technologies are rapidly unraveling nuances in how heritable traits influence epigenetics and the tumor environment. Meticulous reductionist research done since the early 1960s helped identify hundreds of genetic abnormalities that are peculiarly associated with specific cancers, and more recent advances allowed for full sequencing of tumor genomes.³⁻⁶ The information from these experiments has reinforced current concepts and provided insight into new areas of research. This chapter will focus on contemporary information to provide context for the genetic basis of cancer and how interactions between genes and environment impact the origin, progression, and response to therapy of hematopoietic tumors. It is probably reasonable to say that the next decade will represent a new “golden age” of discovery in cancer genetics, when many of the apparent conflicts from our traditional (reductionist) experimental approaches will be resolved by integration of data from epidemiologic, molecular, and clinical studies into a more holistic understanding of the biology of cancer.

Genes and Cancer Risk

To understand cancer, one must first realize that cancer is neither a single nor a simple disease. Rather, the term *cancer* describes a large number of diseases whose only common feature is uncontrolled cell growth and proliferation. An important concept that is universally accepted is that cancer is a genetic disease, although it is not always heritable. Tumors arise from the accumulation of mutations that eliminate normal constraints of proliferation and genetic integrity in a somatic cell. Among other causes, mutations can arise following exposure to environmental mutagens such as cigarette smoke, ultraviolet irradiation, and others. In fact, changes in cancer incidence over the course of the twentieth century, many reflecting behavior patterns (e.g., lung cancer in smokers), infectious diseases (e.g., stomach cancer in people infected with *Helicobacter pylori*), or exposure to special cultural factors such as urbanization or diet (e.g., increasing breast cancer rates in the second and subsequent generations of Asian-American women), underscore the significant influence that the environment exerts on the genetic make-up of any individual. Nevertheless, it would be incorrect to assume that the environment is wholly responsible for most tumors; most associations of cancer and exposure to potential environmental carcinogens other than

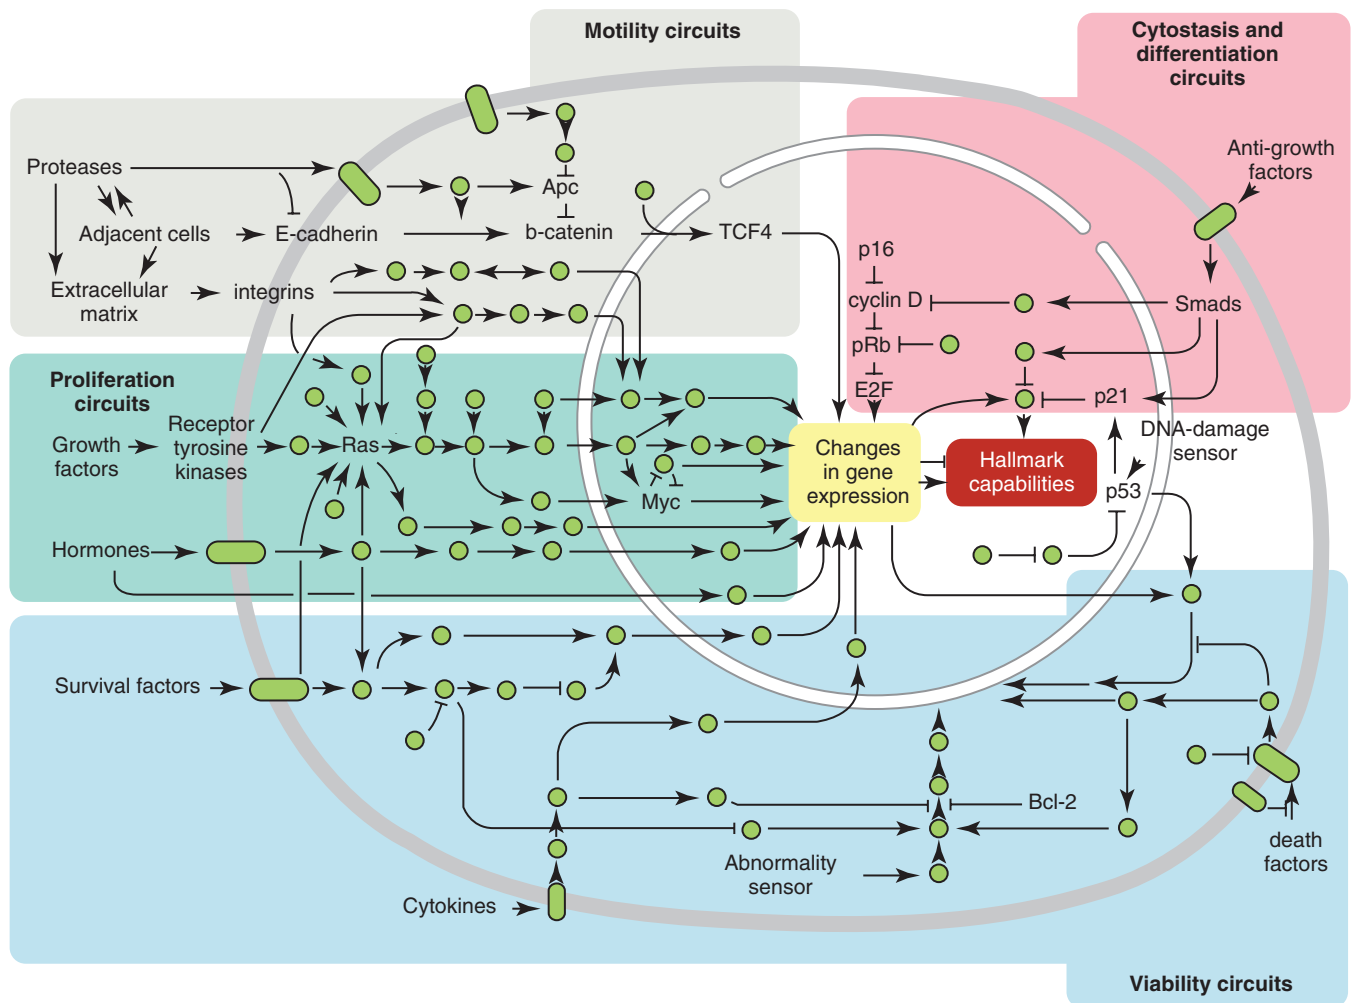

tobacco products and ultraviolet or gamma irradiation are relatively weak.

Rigorous experimental evidence now supports a number of “intrinsic mutagens” that interact in complex and sometimes unpredictable ways with environmental triggers to promote cancer. For example, it is clear now that oxygen free radicals that result from chronic inflammation can act as procarcinogenic mutagens. An equally important and perhaps less well-recognized “mutagen” is the inherent error rate of enzymes that control DNA replication, which introduces from 1 in 10,000,000 to 1 in 1,000,000 mutations for each base that is replicated during each round of cell division. Most mammalian genomes comprise 2 to 3 billion base pairs, so every time a cell divides, each daughter cell is likely to carry at least a few hundred mutations in its DNA. Most mutations, whether caused by extrinsic or intrinsic factors, are silent; that is, they do not hinder the cell’s ability to function. However, others can disable tumor suppressor genes or activate proto-oncogenes that respectively inhibit or promote cell division and survival. Thus it can be said that “being alive” is the single largest risk factor for cancer.

Heritable Cancer Syndromes

The existence of genetic predisposition to cancer is illustrated by well-defined heritable cancer syndromes.⁷ Over 200 such syndromes have now been defined.⁸ Even though they account for only 5% to 10% of all human cancers, studies of families with these syndromes provided many of the initial clues to understanding the genetic basis of sporadic (nonheritable) cancers. Although inheritance is recessive, these familial cancer syndromes show dominant patterns of inheritance and many have high penetrance.⁸ All but two of the known familial cancer syndromes are due to mutations that inactivate tumor suppressor genes. As originally proposed by Knudson in his “two-hit” hypothesis from studies in children with retinoblastoma,⁹ individuals at risk are obligate heterozygotes (they inherit a mutant allele and a wild-type allele). As it happens, homozygous mutations in critical growth regulatory genes usually cause embryonic lethality; however, in the case in which a single allele is affected, the mutation is present in every cell in the body. Given the rate of spontaneous mutation as described, the probability that the second, wild-type allele will be inactivated in at least one cell is extremely high, therefore facilitating tumorigenesis. This process is called *loss of heterozygosity* (LOH).

A curious observation worth noting is that different mutations in a single gene can predispose individuals to distinct cancer syndromes, whereas independent, single mutations of different genes can result in virtually the same disease, or at least diseases with indistinguishable phenotypes.⁷ This is not surprising when we consider that commonly affected genes are multifunctional and parts

• **FIGURE 1-1** Intracellular signaling networks regulate the operations of the cancer cell. An elaborate integrated circuit operates within normal cells and is reprogrammed to regulate hallmark capabilities within cancer cells. Separate subcircuits, depicted here in differently colored fields, are specialized to orchestrate the various capabilities. At one level, this depiction is simplistic because there is considerable crosstalk between such subcircuits. In addition, because each cancer cell is exposed to a complex mixture of signals from its microenvironment, each of these subcircuits is connected with signals originating from other cells in the tumor microenvironment. (Redrawn from Hanahan D, Weinberg RA: *Hallmarks of cancer: The next generation*, Cell 144:646–674, 2011, with permission.)

of complex, interactive networks or circuits^{10,11} (Figure 1-1). Thus a mutation may only alter gene function along one biochemical pathway, leaving its interactions with other pathways intact. Moreover, mutations that contribute to most sporadic cancers are restricted to a small subset of genes,¹² many of which also are associated with heritable cancer syndromes. These observations have given rise to competing contemporary theories on the origins of cancer, which are addressed later in this chapter.

At least one heritable cancer syndrome (renal carcinoma and nodular dermatofibrosis [RCND] of German shepherd dogs) has been described in dogs.¹³ The heritable factor (or *RCND* gene) for this syndrome maps to dog chromosome 5 (CFA 5) and specifically to the folliculin gene, which was recently described as the heritable factor for the corresponding human disease (Birt-Hogg-Dube syndrome).¹⁴ It is probable that other syndromes comparable to those that are described in humans will eventually be identified in companion and laboratory animals, but it is unlikely that these will account for more than 5% to 10% of all cancer cases.

Genetic Influence in Sporadic Cancers

Unlike diseases due to single gene defects, cancer is a complex, multigenic disease. The “initiation, promotion, and progression” model was among the first to propose a sequential progression of mutations that could account for cancer.^{15,16} In this model, a genetic event would endow a somatic cell with limitless replicative potential or another growth or survival advantage from other cells in its environment (initiation). Alone, this would not be sufficient to give rise to a tumor, as the cell would remain constrained by environmental factors. A second event would further add to the cell’s ability to outcompete its neighbors in this environment, leading to its potential expansion into a recognizable tumor mass (promotion). Finally, a third event would reinforce the cell’s malignant potential (invasion, tissue destruction, and metastasis), leading to clinical disease (progression). It is important to note that an “event” is not

equivalent to a single mutation but rather is more likely to represent a series of mutations that act in concert to alter the cell's functional and morphologic phenotype. Although this model is overly simplistic and technically flawed (experimental evidence clearly shows that mutations are stochastic and do not occur in step-wise fashion),¹⁷ it is nevertheless useful to convey the events that lead to carcinogenesis and it remains the foundation for our current understanding of cancer genetics and cancer evolution.

Both the environment and the individual's peculiar genetic background influence cancer risk and the natural history of tumors. This is especially clear in mice, in which the relative rate of spontaneous cancers and the susceptibility to chemically induced cancers differ according to the genetic background of various inbred strains.¹⁸ Similar evidence exists for humans; for example, the risk of habitual smokers to develop lung cancer was found to be tightly linked to a unique allele encoding the alpha-3 subunit of the high affinity nicotinic receptor¹⁹⁻²¹ and was later extended to this and other loci where additional nicotinic receptor subunits are encoded.²² An association between lung cancer arising from habitual tobacco use and activity of cytochrome P450 enzymes also had been observed repeatedly for many years, and there are indeed P450 alleles (e.g., CYP1B1²³) that also are associated with lung cancer. Together, these findings illustrate the complex relationship between genetics, environmental exposures, and probability to define cancer risk, prevention, and treatment. Specifically, alleles encoding "higher risk" nicotine receptors appear to modulate nicotine signaling, which in turn is responsible for embedding smoking behaviors and consequently exposure to dozens of potent carcinogens.^{22,24} Nicotine metabolism itself by P450 enzymes also influences tobacco use; however, conversion of tobacco-specific nitrosamines to mutagenic forms by highly active P450 enzymes modulates risk of transformation.²⁵ Each component of risk is incremental and their interactions are not predictable. It is likely that similar relationships will be operative for many, if not most, common cancers of humans and domestic animals; defining these interactions will be a major emphasis of research during the coming decades.

There also is evidence to suggest that in some cases mutations are "directed" due to the presence of a "mutator phenotype," in which the factors that control DNA replication and repair are prone to more errors than would be expected by simple random events. This leads to different rates of cancer predisposition, which would be higher than the mean in individuals bearing this "mutator phenotype," and might explain why not all people or animals exposed to similar environmental carcinogens develop the same forms of cancer at the same rate.²⁶ Recent information obtained from massive parallel full genome sequencing of tumor/normal pairs in diffuse large B-cell lymphoma suggests that the mutator phenotypes may be acquired and may involve genes that mediate both DNA repair and chromatin organization.^{5,6} It is important to note, however, that this does not exclude the possibility that mutator phenotypes also might be heritable.

In dogs and other domestic animals, the coexistence of genetic isolates in closed populations we call "breeds," along with animals of mixed breeding, lends itself to study how a relatively homogeneous background influences cancer in out-bred populations. Preliminary data from whole genome association studies suggest there are distinct heritable traits that segregate with common cancer phenotypes in dogs.^{27,28} One common finding—and a pervasive obstacle for the completion of these studies—has been the observation of "fixed" risk alleles, making an association between individuals in the breed and disease challenging. Nevertheless, even though at the time of this writing none of these studies were yet published in the

peer-reviewed literature, the reader should be alert for upcoming studies that will likely document specific risk genes for histiocytic sarcoma, transitional cell carcinoma, osteosarcoma, hemangiosarcoma, lymphoma, mammary cancer, and melanoma, among others, in susceptible dog breeds, and with the recent advent of the feline genome sequence,²⁹ possibly in specific cat breeds as well.³⁰ It remains to be seen if these traits will be shared between closely related breeds or whether they contribute to risk independently among different breeds.³¹

Perhaps as important, dogs are the first species in which genetic background has been shown to mold tumor genomes and tumor gene expression profiles.³²⁻³⁵ This knowledge, together with the demonstration that causal, pathognomonic genetic abnormalities are conserved in homologous human and canine cancers,³⁶ opens a new area in which the precise contribution of heritable traits to sporadic cancers can be identified by using comparative systems approaches. These observations also indicate that we must assess "risk" far beyond the conventional idea of "tumor development," as heritable traits might influence risk by modulating the probability of initiating events, the probability of promoting events, or the probability of progression through the interactions between the tumor and its microenvironment.³⁴ A useful illustration of this concept is the occurrence of prostate cancers in men: virtually all men over 60 years of age will die *with* prostate cancer, but only a minority will die *from* prostate cancer, indicating that the major factors that influence the disease are not those that mediate transformation (at least as defined by morphologic appearance and anatomic organization), but instead those that dictate the biologic behavior of the transformed cells in the host.

Another important conceptual advance in this regard was the identification that spontaneous canine tumors had highly conserved (homologous) aberrations that had been previously characterized in human tumors. The prototypical example is a structural aberration resulting from a balanced chromosomal translocation that creates a fusion gene comprised of most of the *BCR* gene (located on chromosome 22 in humans and on chromosome 26 in dogs) and a truncated form of the *ABL* gene (coincidentally located on chromosome 9 in both humans and dogs) in chronic myelogenous leukemia (CML).³⁶ Both translocations give rise to a derivative chromosome, the Philadelphia (Ph) chromosome in humans and the Raleigh chromosome in dogs, as illustrated by the canine form in Figure 1-2. Numeric aberrations (changes in DNA copy number) are similarly conserved among species, as illustrated by deletions of the *RB1* locus, including the associated tumor-suppressing micro-RNAs in chronic lymphoid leukemias³⁶ and the *INK4* locus in T-cell malignancies,³⁷ as well as copy number gains such as *Runx2* amplification in osteosarcoma.³⁸

The development of these specific tumors from cells harboring such mutations may not be at all surprising, but why would *homologous*, highly conserved pathologic rearrangements, deletions, or amplifications occur in cells from organisms separated by more than 40 million years of evolution? Is it possible they are evolutionarily related on a mechanistic basis? For example, rearrangements of the immunoglobulin heavy chain locus and the *MYC* locus are thought to be due to recognition of *MYC* flanking sequences by the recombinase enzyme system.³⁶ No such mechanism is known to be operative for other defined sites, so these other mutational events could occur stochastically, with their recurrent characterization across multiple species being the result of the selective advantage provided by the acquired gene to a cell of a highly specific lineage under highly specific conditions. This notion fits with Duesberg's hypothesis that aneuploidy precedes genetic instability.^{39,40} Although

FIGURE 1-2 Conserved cytogenetic rearrangement in canine chronic myelogenous leukemia (CML). **A**, Photomicrograph of a peripheral blood smear from a dog with CML (Diff-Quik stain; original magnification $\times 1600$). Scale bar = 10 μm . **B**, Comparative ideograms showing corresponding regions for HSA 9q34 and HSA 22q11 on canine chromosomes 9 and 26. Orange and green spots indicate the location of canine ABL and BCR. A horizontal blue line on each ideogram identifies the location of the predicted breakpoints on CFA 9 and CFA 26, below which the two regions would be exchanged to form the aberrant derivative chromosomes. **C**, Schematic representation of the predicted derivative CFA 9 and derivative CFA 26 that would be produced by such a reciprocal translocation, with the derivative 26 (*der 26*) showing co-localized signals from ABL and BCR. **D**, Fluorescence in situ hybridization (FISH) analysis of metaphase preparations and interphase nuclei in normal canine leukocytes using canine BAC clones representing canine ABL and BCR on CFA 9 (orange spots) and CFA 26 (green spots), respectively. Inset shows enlarged, single metaphase chromosomes for CFA 9 and 26 correctly oriented. **E**, Hybridization of the same two BAC probes to metaphase chromosomes and interphase nuclei of a canine CML. Heterozygous co-localization of these two BAC clones to the derivative chromosome 26 is evident in the metaphase preparation and co-localization of one green and one yellow spot is also evident in the two interphase nuclei. Inset shows the derivative CFA 26 enlarged and correctly oriented (compare to predicted *der 26* in **C**). **F**, Interphase nucleus from the same case of CML showing the presence of an apparent homozygous 9/26 translocation event, with both yellow and green spots showing close association. Scale bars = 8 μm . (Redrawn from Breen M, Modiano JF: *Evolutionarily conserved cytogenetic changes in hematological malignancies of dogs and humans—man and his best friend share more than companionship*, Chromosome Res 16:145–154, 2008, with permission.)

it is impossible to rule out this argument, the implication would be that such mutational events are phenomenally common, and since they are not otherwise observed frequently in other cells where their occurrence was neutral makes this highly unlikely. Another possibility is that they are related to the nuclear anatomy of the cell and specifically caused by proximity of chromosomal regions, cellular stress, inappropriate DNA repair (or as mentioned previously, recombination), and DNA sequence and chromatin features.⁴¹ A third most intriguing possibility is that cellular genomes are reverting to a conformation that was found in a common ancestor (thus the high affinity and specificity between the rearranged chromosomal segments leads to the same recurrent event in many patients) but lost during the process of chromosomal reorganization in evolution, or that these sites represent targets for gene deletions or duplications that have been repeatedly advantageous to species

under conditions of natural selection and so have become embedded in their contemporary descendants.

The clinical relevance of shared evolutionary and genetic origins should not be lost on physicians, veterinarians, or scientists. Shared origins mean shared biologic behaviors, thus supporting the rationale to apply the same therapies that have been developed for human patients to treat companion animals and vice versa. The best evidence for shared biologic behaviors comes from four recent studies of osteosarcoma, in which gene expression profiling documented overlapping characteristics of this disease in humans and in dogs.^{35,42–44} Specifically, the use of biased breed cohorts and isolated tumor explants allowed our group to filter genetic noise and stromal signatures to achieve pathologic stratification of osteosarcomas from three independent dog cohorts and five independent human cohorts into prognostically significant groups.³⁵

The Hallmarks of Cancer

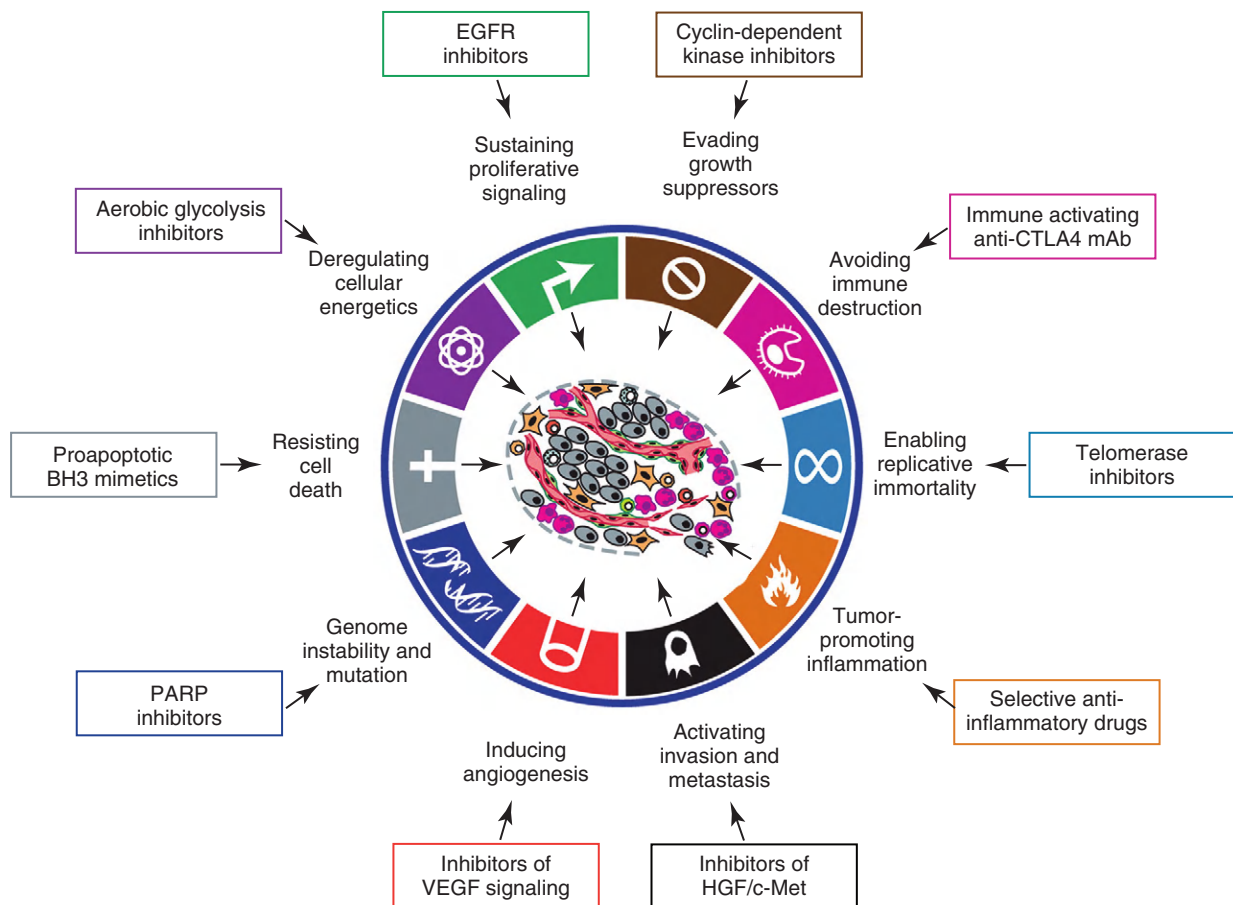

Thirty years of research culminated in the year 2000 in an insightful and thorough review paper by Douglas Hanahan and Robert Weinberg that synthesized our knowledge into six essential, acquired characteristics necessary for cellular transformation.⁴⁵ These characteristics included (1) self-sufficiency in growth signals, (2) insensitivity to antigrowth signals, (3) the ability to evade apoptosis, (4) limitless replicative potential, (5) sustained angiogenesis, and (6) the capacity to invade tissues and metastasize. The importance of this paper was less in describing a list of events and more in the synthesis of these events because the concepts proposed by Hanahan and Weinberg created a paradigm shift in our understanding of cancer. Some of the important concepts that were clarified include: No single gene is universally responsible for transformation; five or six mutations are the minimum probable number required to endow the cancer phenotype (an observation that has since been confirmed experimentally³); each step is regulated by multiple interactive biochemical pathways,¹⁰ and thus mutations of different genes along a pathway can result in equivalent phenotypes and, conversely, mutations of the same gene can result in different cancers with distinct biology; tumors behave as tissues; and the

interactions between the tumor and its microenvironment are major drivers of cancer behavior.

In early 2011, Hanahan and Weinberg updated the hallmarks of cancer in a new review that will likely be even more influential than the first.¹¹ In this “next generation,” the hallmarks of cancer were refined and reassessed, and new “enabling characteristics” (genome instability and mutation and tumor-promoting inflammation) and “emerging” hallmarks (deregulating cellular energetics and avoiding immune destruction) were added to the paradigm. The impact of this unifying conceptualization of cancer genetics and this level of understanding are clearly evident when we consider how they have influenced the design, development, implementation, and success of new cancer therapies (Figure 1-3). A summary of the information with added refinements is provided later, and the reader is referred to the original manuscripts for details, since space constraints preclude an extensive review herein.

Self-Sufficiency of Growth Signals

Arguably, the most important event in neoplastic transformation is the capability of cells to sustain chronic proliferation. Under normal conditions, cells communicate with each other and integrate environmental signals by sensing cues and gradients. For example,

• **FIGURE 1-3** Therapeutic targeting of the hallmarks of cancer. Drugs that interfere with each of the acquired capabilities necessary for tumor growth and progression have been developed and are in clinical trials or in some cases approved for clinical use in treating certain forms of human cancer. Additionally, investigational drugs are being developed to target each of the enabling characteristics and emerging hallmarks, which also hold promise as cancer therapeutics. The drugs listed are but illustrative examples; there is a deep pipeline of candidate drugs with different molecular targets and modes of action in development for most of these hallmarks. *EGFR*, Epidermal growth factor receptor; *PARP*, poly ADP ribose polymerase; *VEGF*, vascular endothelial growth factor; *HGF*, hepatocyte growth factor. (Redrawn from Hanahan D, Weinberg RA: *Hallmarks of cancer: The next generation*, Cell 144:646–674, 2011, with permission.)

migration, metabolism, and proliferation of mature hematopoietic cells are regulated in autocrine and paracrine fashions by locally secreted cytokines. The same cytokines may travel systemically and act in an endocrine fashion. Generally, the cytokines work by binding transmembrane receptors, which in turn initiate signaling cascades that culminate in transcriptional changes that allow the cell to adapt its behavior to match the environmental signal. The activity of these cytokines, their receptors, and the corresponding signaling molecules are finely tuned. The system can be shut down when the concentration of the cytokine falls below a threshold that can stably bind the receptor, when the receptor ceases to be expressed, or when signaling molecules are downregulated or otherwise inactivated. However, mutations in even one of the molecules involved in regulating these pathways can provide sustained growth signals in the absence of the initiating cytokine. Among many examples, there is a translocation between chromosome 2 and chromosome 5 (t(2;5)) that is present in almost half of human anaplastic lymphomas. The translocation creates a fusion protein between the nucleophosmin gene (*NPM1*) and the anaplastic lymphoma kinase gene (*ALK*), which aberrantly activates the Jak2/STAT5 signaling pathway⁴⁶ that is normally responsive to various interleukins (IL), including IL-2, IL-3, and IL-6. The genes that encode the normal growth-promoting proteins (such as *ALK*, *Jak2*, and *STAT5*) are called *proto-oncogenes*; the mutated versions that allow cells to gain self-sufficiency from the environmental signals are called *oncogenes*. It is important to note that not all growth-promoting genes have the capacity to become oncogenes and that the outcomes of oncogenic activation are most commonly senescence or apoptosis, unless there are additional events that promote stable transformation and survival.

Insensitivity to Antigrowth Signals

In addition to the hallmark capability of inducing and sustaining positively acting growth-stimulatory signals, cancer cells must also circumvent powerful programs that negatively regulate cell proliferation; many of these programs depend on the actions of tumor suppressor genes. To maintain homeostasis, cells also must integrate antigrowth signals from the environment. Quiescence in non-hematopoietic cells is enforced by signals delivered by contact inhibition.⁴⁷ Hematopoietic cells, on the other hand, utilize cell-cell contacts to maintain interactions within the niche and to regulate the timing and intensity of hematopoiesis, inflammation, and immunity.⁴⁸

“Stop” signals are usually delivered and integrated by the products of tumor suppressor genes, which derive their name largely from the observation that their inactivation facilitates tumor formation. Tumor suppressor genes balance the activity of growth-promoting proto-oncogenes and tend to act in tandem with these in most biochemical pathways. Loss of function of one or more tumor suppressor genes occurs in virtually every cancer, with inactivation of *p53*, *RB1*, *PTEN*, or *CDKN2A* each seen in more than 50% of all tumors. Each of these pathways may contribute to the pathogenesis of bone marrow-derived tumors in companion animals, and their dysfunction also may be predictive for outcomes.^{49–52}

Evasion of Cell Death

Apoptosis, or programmed cell death, is the imprinted outcome for every cell in multicellular organisms. Survival requires support from extrinsic (environmental) factors, as well as precise balance of cellular energetics and metabolism. Bone marrow-derived cells normally undergo apoptosis when concentrations of survival

factors (e.g., stem cell factor, IL-3, IL-7) or nutrients are limiting or when there are severe disruptions to cellular bioenergetics.⁵³

Evasion of apoptosis is an essential acquired feature of all cancers, and it can result from loss of proapoptotic tumor suppressor genes such as *p53* or *PTEN* or by gain of function of antiapoptotic genes, such as *BCL2*. Gain of function of *BCL2* in humans is generally associated with indolent, follicular lymphomas that carry t(14;18) translocations that juxtapose *BCL2* and the immunoglobulin heavy enhancer locus (*IGH*). These tumors are seen rarely in domestic animals, but evasion of apoptosis may be an important mechanism in the pathogenesis of indolent tumors seen more commonly in these species.

A more recent concept in the cell death field is autophagy—a process that tumor cells have efficiently coopted as a means to survive under adverse conditions.⁵⁴ As part of the autophagy program, intracellular vesicles termed *autophagosomes* surround intracellular organelles and fuse with lysosomes. There, the organelles are broken down and then are channeled to form new molecules that support the energy-producing machinery of the cell, allowing it to survive in the stressed, nutrient-limited environment that defines most cancers.

Tumor cells also must avoid death by anoikis or loss of integral cell-to-cell or cell-to-matrix contacts.⁴⁷ Absent these physiologic death pathways, the body often reacts to the anatomic and physiologic disruptions caused by cancer cells by targeting these cells for destruction through inflammatory pathways. This is but one pathway that leads to necrosis, since it appears that the process of necrosis also might be regulated genetically, providing another mechanism that favors survival of the whole (organism or tumor) over survival of the one. We are probably on the edge of an explosion of new findings that will further nuance our perception of how evasion (or inciting) of these cell death mechanisms contributes to neoplastic transformation and tumor progression.

Limitless Replicative Potential

Immortalization is another essential feature of cancer. The genetic program limits the number of times a cell is able to replicate, the so-called *Hayflick limit*, and when this limit is reached, replicative senescence is induced. Induction of replicative senescence does not induce death; cells maintain energetic homeostasis and remain functional, but they undergo significant genetic changes characterized by telomere erosion. Cells that are able to replicate must maintain the integrity of telomeres, which are “caps” made of repetitive DNA sequence that protect chromosomes from destruction. Solid tumors acquire immortalization predominantly by activation of the telomerase enzyme system and the consequent maintenance of telomere integrity. In hematopoietic cells, telomerase activity seems to be retained longer than in other somatic cells, so it is possible this facilitates immortalization in lymphoma and leukemia.⁵⁵ The role of immortalization and the importance of telomerase (both to maintain telomere length and to maintain other biochemical functions that are essential for cell survival) are well established; however, the role of replicative senescence has recently been questioned because improved technology has allowed researchers to circumvent this process in normal cells.¹¹ Mouse models complicate the story due to significant differences in telomere length between rodents and humans, so this is an area in which other models such as companion animals might provide clarity in the future.⁵⁶

Sustained Angiogenesis

The process of angiogenesis requires the coordinated action of a variety of growth factors and cell-adhesion molecules in endothelial

and stromal cells. So far, vascular endothelial growth factor-A (VEGF) and its receptors comprise the best-characterized signaling pathway in tumor angiogenesis.⁵⁷ VEGF binds several receptor tyrosine kinases, including VEGF receptor-1 (VEGFR-1 [Flt-1]) and VEGFR-2 (KDR, Flk-1). VEGFR-2 is the major mediator of the angiogenic effects of VEGF. However, VEGFR-1 is expressed by some tumor cells and may mediate chemotactic signals, thus potentially having a role in cancer growth. The expression of VEGF is upregulated by hypoxia and inflammation. The transcription factor hypoxia-inducible factor-1 α (HIF), which is part of a pathway that also includes regulation by the von Hippel-Lindau (VHL) tumor suppressor gene, is a major regulator of VEGF expression. Under conditions of normal oxygen tension, VHL protein targets HIF for degradation; under low oxygen conditions, HIF increases as VHL-mediated degradation is reduced, allowing for upregulation of VEGF. Other signaling molecules also contribute to angiogenesis, including platelet-derived growth factor- β (PDGF- β) and its receptor (PDGFR), and the angiopoietins. PDGF- β is required for recruitment of pericytes and maturation of new capillaries. Recent studies also document the importance of tumor-derived PDGF in recruitment of stroma that produces VEGF and other angiogenic factors (Figure 1-4).

Folkman proposed a role for angiogenesis in cancer more than 30 years ago,^{58,59} but this idea took time to gain traction in the scientific community. Even after the importance of angiogenesis was recognized, the prediction was that this process would impact solid tumors but would be relatively unimportant for tumors of the blood and lymph (lymphoma, leukemia, and multiple myeloma). The first clues that this notion was mistaken came from unexpected benefits of patients with chronic lymphocytic leukemia (CLL) treated with antiangiogenic compounds,⁶⁰⁻⁶² followed by similar success for some patients with multiple myeloma.^{63,64} More recently, a European study showed that different histologic types of human non-Hodgkin's lymphoma show different patterns of angiogenesis, and these can predict outcomes for some of the most aggressive tumors, such as peripheral T-cell lymphomas.⁶⁵ One study has shown that microvessel density is similarly correlated with the aggressive behavior of canine lymphoma,⁶⁶ and similar findings have been reported for other blood-derived and solid tumors of dogs, such as mast cell cancer and mammary cancer.^{67,68}

The concepts of how neoangiogenesis contributes to cancer also are undergoing refinement. For example, it is apparent now that clinical trials of antiangiogenic drugs have largely failed because their design was based on incomplete knowledge and thus incorrect assumptions. Perhaps the most informative example is the history of Bevacizumab (a humanized anti-VEGF antibody), which received approval to treat various cancers between 2004 and 2010 after it was shown to confer improved quality of life, albeit with modest survival benefits for patients. On December 6, 2010, the Federal Drug Administration (FDA) issued a press release (<http://www.fda.gov/newsevents/newsroom/pressannouncements/ucm237172.htm>) that announced the withdrawal of the indication for bevacizumab in treatment of metastatic breast cancer, stating that "... the drug has not been shown to be safe and effective for that use." The FDA press release also stated, "The agency is making this recommendation after reviewing the results of four clinical studies of Avastin (bevacizumab) in women with breast cancer and determining that the data indicate that the drug does not prolong overall survival in breast cancer patients or provide a sufficient benefit in slowing disease progression to outweigh the significant risk to patients. These risks include severe high blood pressure; bleeding and hemorrhage; the development of perforations (or

FIGURE 1-4 A few of the molecular and cellular players in the tumor/microvascular microenvironment. **A**, Tumor cells produce VEGF-A and other angiogenic factors, such as bFGF, angiopoietins, interleukin-8 (IL-8), placenta growth factor (PlGF), and VEGF-C. These stimulate resident endothelial cells to proliferate and migrate. **B**, An additional source of angiogenic factors is the stroma, which is a heterogeneous compartment, comprising fibroblastic, inflammatory, and immune cells. Recent studies indicate that tumor-associated fibroblasts produce chemokines such as SDF-1, which may recruit bone marrow-derived angiogenic cells (BMC). VEGF-A or PlGF may also recruit BMC. Tumor cells may also release stromal cell-recruitment factors, such as PDGF-A, PDGF-C, or transforming growth factor ($TGF-\alpha$, $TGF-\beta$). A well-established function of tumor-associated fibroblasts is the production of growth/survival factor for tumor cells such as EGFR ligands, HGF, and heregulin. **C**, Endothelial cells produce PDGF- β , which promotes recruitment of pericytes in the microvasculature after activation of PDGF receptor- β (PDGFR- β) factor. VEGF-A, Vascular endothelial growth factor-A; bFGF, basic fibroblast growth factor; SDF-1, stromal cell-derived factor-1; HGF, hepatocyte growth factor; PDGF, platelet-derived growth factor; EGFR, epidermal growth factor receptor. (Redrawn from Ferrara N, Kerbel RS: Angiogenesis as a therapeutic target, *Nature* 438:967–974, 2005, with permission.)

'holes') in the body, including in the nose, stomach, and intestines; and heart attack or heart failure."

Indeed, the preponderance of data suggest that antiangiogenic therapies will benefit cancer patients by promoting vessel normalization, reversing the anatomic and hemodynamic dysfunction created by the tumor microenvironment, disabling some of the intrinsic advantages that this provides for cancer cells, and allowing better penetration of drugs. Vascular normalization relies on restoring the balance among all the blood vessel-forming constituents from the bone marrow and the stroma, including pericytes, myeloid-derived cells, and endothelial progenitors, all of which contribute—and respond to—the "angiogenic switch," whereby previously quiescent tissues trigger formation of new blood vessels associated with tumor growth.

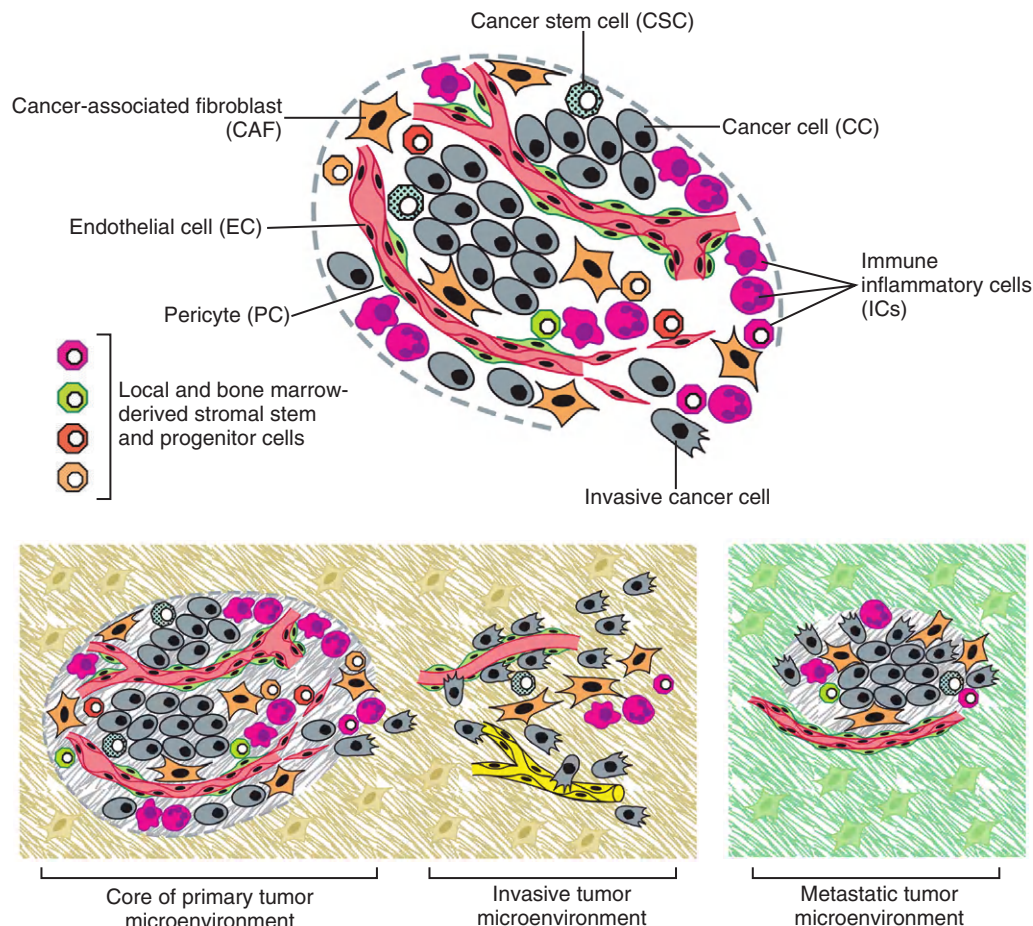

Invasion and Metastasis

The role of genetic events in invasion and metastasis is still incompletely understood. The classic model of metastasis proposed by Fidler suggests a step-wise acquisition of assets that enables cells to leave the primary tumor site, travel through blood or lymph, invade stroma in favorable locations, and thus become reestablished at distant sites.⁶⁹ More recent work suggests that most tumors possess the ability to dislodge cells that travel to distant sites, and the ability of such cells to survive in capillary beds may be the most important step in the metastatic process.⁷⁰⁻⁷⁴

Bone marrow–derived cells have intrinsic properties that allow them to travel throughout the body, traffic through all major organs, and home to areas of inflammation. Thus bone marrow–derived tumors are inherently metastatic. Nevertheless, hematopoietic tumors that are cytologically indistinguishable can have distinct and preferential tissue distribution. We do not fully understand what events make leukemic cells stay in the peripheral circulation,

while cells from corresponding lymphomas (or myeloid sarcomas) with virtually identical molecular signatures stay confined to lymphoid or visceral organs.

In epithelial neoplasms that account for the majority of tumors in humans, the epithelial-to-mesenchymal transition (EMT) has received increasing attention for its role in metastasis. EMT is a developmental program that progenitor stem cells use during morphogenesis and can be physiologically reactivated during wound healing. It remains unclear whether EMT is equally (or less) important in sarcomas more commonly seen in domestic animals, in which the cells of origin seem to retain EMT capabilities to a greater extent. Similarly, there is increasing evidence of interactions between cancer cells, the “initiating” population in the tumor (cancer stem cells [CSCs]), mesenchymal stem cells (MSCs), tumor-associated fibroblasts, inflammatory cells, and angiogenic cells, which may be responsible for invasive behaviors and possibly for survival in hostile environments that exist at distant sites (Figure 1-5).

• **FIGURE 1-5** The cells of the tumor microenvironment. *Upper*, An assemblage of distinct cell types constitutes most solid tumors. Both the parenchyma and stroma of tumors contain distinct cell types and subtypes that collectively enable tumor growth and progression. Notably, the immune inflammatory cells present in tumors can include both tumor-promoting, as well as tumor-killing, subclasses. *Lower*, The distinctive microenvironments of tumors. The multiple stromal cell types create a succession of tumor microenvironments that change as tumors invade normal tissue and thereafter seed and colonize distant tissues. The abundance, histologic organization, and phenotypic characteristics of the stromal cell types, as well as of the extracellular matrix (*hatched background*), evolve during progression, thereby enabling primary, invasive, and then metastatic growth. The surrounding normal cells of the primary and metastatic sites, shown only schematically, likely also affect the character of the various neoplastic microenvironments. (Not shown are the premalignant stages in tumorigenesis, which also have distinctive microenvironments that are created by the abundance and characteristics of the assembled cells.) (Redrawn from Hanahan D, Weinberg RA: *Hallmarks of cancer: The next generation*, Cell 144:646–674, 2011, with permission.)

Adaptive Evolution and the Tumor Microenvironment

There is a bidirectional flow of information between the tumor and the microenvironment, with each helping to mold the other into functional growing tissue that can evade or withstand attack by the host.⁷⁵ Our previous reference to a “selective growth advantage” that is reminiscent of Darwinian selection is not accidental. The clonal evolution theory⁷⁶ addresses the significance of sequential genetic changes providing growth and survival advantages, but to this we must add the fact that, in addition to these self-sufficient events that influence growth and survival, tumor cells must also evade “predators” (e.g., inflammation and the immune system^{77,78}). In essence, the interaction of the tumor with its microenvironment and ultimately with the host is in fact subject to Darwinian laws of evolution, albeit in an accelerated time scale.⁷⁹ This is evident in the ability of tumors to modulate stromal cells to support their own growth by providing a suitable matrix and an abundance of nutrients, while maintaining antitumor responses at bay.

As is true for other selective environments, tumors that outgrow the capability of their immediate surroundings to support their growth must alter that environment to suit their needs or identify other favorable locations where they can become established. The tumor microenvironment was recently shown to exert a significant effect on the complement of genes expressed by incipient tumor cells.⁸⁰ In this case, the microenvironment was modified by gamma irradiation and the tumor was derived from orthotopic implants of chimeric Trp53-deficient mammary epithelial cells. The magnitude of change was not unlike that observed by our group when comparing the influence of breed on gene expression by canine hemangiosarcoma cells, although in our case the expression profile was maintained in a cell-autonomous fashion (i.e., *ex vivo*).³⁴ Again, the behavior of carcinomas and sarcomas may differ, and for the latter, recent experiments from our group using canine hemangiosarcoma xenotransplantation models suggest that alterations in the microenvironment might favor not only the efficiency of tumor implantation but also the extent to which the microenvironment contributes to the composition of the tumor as a whole. Incipient sarcoma cells, in turn, can reside as quiescent inhabitants of distant microenvironments themselves modulating growth, morphology, and behavior of microenvironment constituents in the process of metastatic dissemination (Figure 1-6).

Emerging and Enabling Hallmarks

Genomic Instability

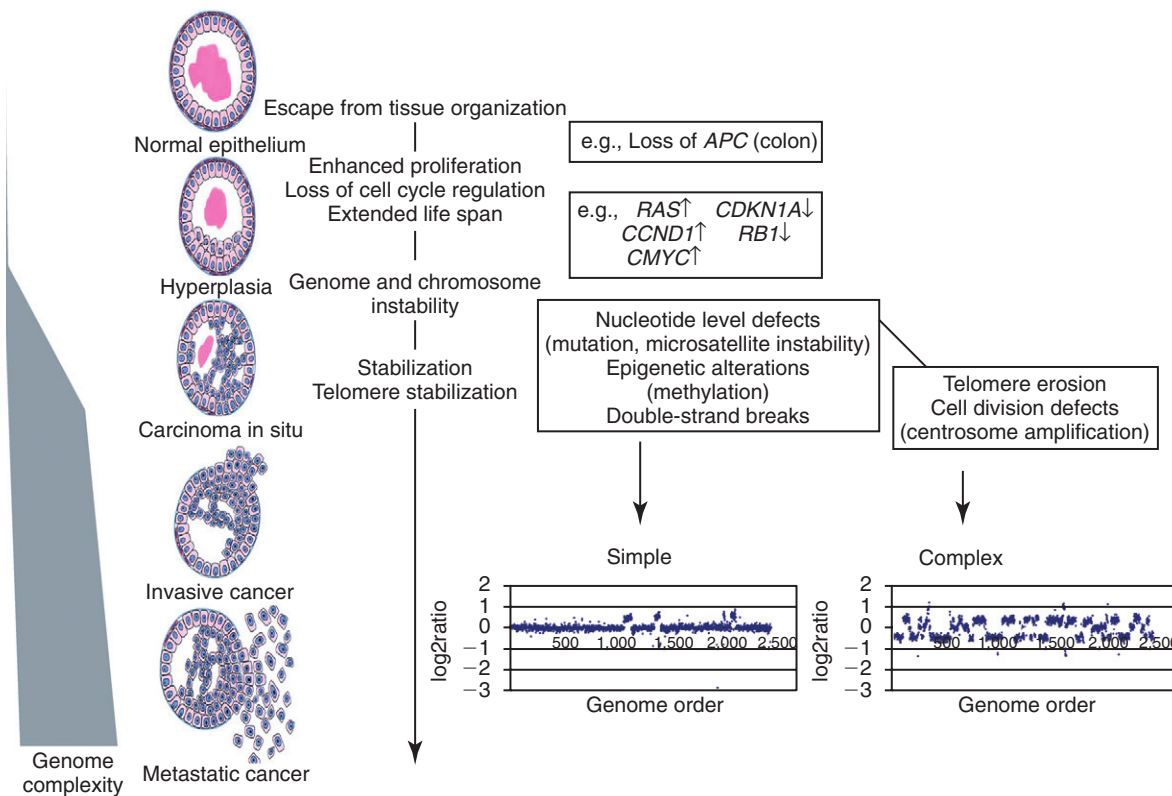

The concept of genomic instability is not new but was incorporated as an “enabling hallmark” into the updated Hanahan and Weinberg model. Step-wise clonal evolution is satisfying because it can be correlated with discrete pathologic changes in tumor progression, especially for epithelial tumors where such progression can be seen in lesions that go through stages of hyperplasia, atypical hyperplasia (dysplasia), adenoma, carcinoma in situ, invasive carcinoma, and metastatic carcinoma (Figure 1-7). However, analysis of tumor genomes even in early stages usually shows aneuploidy (abnormal DNA copy number), as well as chaotic changes indicative of multiple numeric and structural DNA abnormalities. Similar abnormalities first noticed by Boveri more than 100 years ago in studies of sea urchin cells led him to formulate the “aneuploidy theory” of cancer.⁸¹ We know now that aneuploidy is especially evident in solid tumors; based on this, Loeb proposed the existence of the “mutator

• **FIGURE 1-6** Incipient canine hemangiosarcoma cells in the spleen of a mouse after subcutaneous tumor xenotransplantation. SB canine hemangiosarcoma cells (5×10^4) harboring a firefly luciferase gene were injected subcutaneously in the flank of immunocompromised mice. Tumors were detectable at the local site within 14 days of injection. After 48 days, the mice were humanely sacrificed and systemic tissues were examined for the presence of luciferase-expressing (tumor) cells. The photomicrograph shows immunohistochemical staining for luciferase in a frozen section of spleen from a representative mouse. Cells with red staining in the cytoplasm represent luciferase-positive canine hemangiosarcoma cells (arrows). Similar events were seen in other organs both by immunohistochemistry and by *in vivo* imaging. These incipient cells did not show evidence of organization into a tumor, suggesting a critical mass had not yet been reached, or possibly, that the primary subcutaneous tumor suppressed metastatic growth. In other mice, however, the incipient cells appeared to “instruct” organization of the resident spleen microenvironment into fulminant hematopoietic tumors. Magnification 200 \times with hematoxylin counterstain. (Experiment, staining, and image courtesy AM Frantz, EB Dickerson, TD O'Brien, and JW Wojcieszyn.)

phenotype” in which cells are predisposed to undergo multiple mutations, some of which inevitably lead to cancer (see earlier).²⁶ Some tenets of his hypothesis appear to be correct, although perhaps in different circumstances than Loeb originally envisioned, because they might relate to increased activity of polymerases with low fidelity under conditions in which the rate of DNA damage (and consequently mutations) is higher than the expected background from normal DNA replication (e.g., in lung epithelial cells from heavy smokers). However, direct measurements of mutation rates of sporadic tumors are much lower than those predicted if a “mutator phenotype” was operative in these tumors.¹² Indeed, the minimum number of mutations that are required for clinical onset of cancer in solid tumors based on sequencing of solid tumor genomes is 15 to 25,⁴ but this may apply to tumors with chaotic karyotypes, as the number of mutations identified in a cytogenetically stable leukemia was significantly smaller.³

Still, genetic instability is a hallmark of most tumors, and while it can be partly explained by increased errors in DNA replication and chromosomal segregation in cells that are rapidly dividing, other mechanisms are clearly operative, involving telomeres and

• **FIGURE 1-7** Schematic representation of chromosomal evolution in human solid tumor progression. The stages of progression are arranged with the earlier lesions at the top. Cells may begin to proliferate excessively owing to the loss of tissue architecture, abrogation of checkpoints, and other factors. In general, relatively few aberrations occur before the development of in situ cancer. As indicated, a sharp increase in genome complexity (the number of independent chromosomal aberrations) in many (but not all) tumors coincides with the development of in situ disease. The types and range in aberration number varies markedly between tumors, probably owing to the specific failures in checkpoint or damage surveillance that are present, as illustrated by the whole-genome array comparative genomic hybridization (CGH) profiles of HCT116, a mismatch repair-defective cell line, and T47D, a mismatch repair-proficient cell line. The copy number profiles of HCT116 and T47D are labeled as “simple” and “complex,” respectively, to distinguish between tumor genomes with few or many copy number changes. The spectrum of aberrations in in situ lesions is similar to those found in more advanced malignancies. Thus an early increase in chromosomal aberration composition is followed by more modest chromosomal evolution. (Redrawn from Albertson DG, Collins C, McCormick F, et al: *Chromosome aberrations in solid tumors*, Nat Genet 34:369–376, 2003, with permission.)

telomerase.^{12,79,82–85} Although many of these changes are not “recurrent” and appear to be random products of instability, some may in fact contribute to proliferative crisis.⁸⁶ It is possible that the initiation events for many tumors occur early in life during highly proliferative stages of tissue growth and remodeling (e.g., prior to closure of the growth plates in bone cancer), but they become evident later in life when a last series of mutations allows the transformed cell to reach this crisis stage. As we alluded earlier, hematopoietic tumors seem to avoid the chaotic chromosomal instability associated with solid tumors. We do not fully understand the reasons for this, although it may be partly due to intrinsic protective mechanisms associated with the proliferative rate of bone marrow precursor cells.

Tumor-Promoting Inflammation

The role of inflammation in cancer has received considerable attention in the past 10 years. Although our understanding of this phenomenon remains incomplete, it clearly met the criteria for inclusion as an “enabling hallmark” into the updated Hanahan and Weinberg model. The importance of inflammation was inferred from the earliest microscopic studies of cancer, but it was a seminal

paper by Dvorak in 1986, in which he described tumors as “wounds that never heal,”⁸⁷ that provided synthesis for the recurrent observation that tumors were often infiltrated by inflammatory cells of the innate (granulocytes, histiocytes, and macrophages) and the adaptive (lymphocytes) immune systems. Mechanistic distinctions remain to be defined between inflammation that favors tumor growth and inflammation that retards growth or eliminates the tumor,^{88–90} but we can say confidently that inflammation contributes to tumor growth and survival by supplying factors that sustain proliferation; factors that limit cell death; proangiogenic factors; extracellular matrix-modifying enzymes that facilitate angiogenesis, invasion, and metastasis; and other signals that lead to activation of EMT and other hallmark-facilitating programs.¹¹ As noted earlier, inflammatory cells also release notably reactive oxygen species that are actively mutagenic for nearby cancer cells, accelerating their genetic evolution toward states of heightened malignancy.⁹¹

Reprogramming Energy Metabolism

In the early years of the twentieth century, Otto Warburg observed that cancer cells preferentially utilized glycolytic (anaerobic) rather

than oxidative (aerobic) pathways to generate energy even under conditions of normal or high oxygen. This metabolic peculiarity of cancer cells, called the *Warburg effect*, seems to be driven by activated oncogenes and/or by loss of tumor suppressor genes that provide cancer cells with selective growth and survival advantages by conferring the hallmark capabilities of cell proliferation, avoidance of cytostatic controls, and attenuation of apoptosis. The reliance of cancer cells on glycolysis can be further accentuated under the hypoxic conditions. In fact, Warburg-like metabolism seems to be present in rapidly dividing embryonic tissues, suggesting a role in supporting large-scale biosynthetic programs that are required for active cell proliferation.

Cancer cells do not seem to enable the Warburg effect universally. Rather, much like other cells with high energetic demands, they seem to sort out into lactate-secreting (Warburg) and lactate-consuming cells, providing an efficient, albeit homeostatically disturbed, energy environment. Furthermore, it seems that oxygenation is not static in tumors but instead fluctuates temporally and regionally due to the instability and chaotic organization of tumor-associated neovasculature. Altered energy metabolism is proving to be as widespread in cancer cells as many of the other cancer-associated traits that have been accepted as hallmarks of cancer. This realization raises the question of whether deregulating cellular energy metabolism is therefore a core hallmark capability of cancer cells that is as fundamental as the six well-established core hallmarks. In fact, the redirection of energy metabolism is largely orchestrated by proteins that are involved in one way or another in programming the core hallmarks of cancer. When viewed in this way, aerobic glycolysis is simply another phenotype that is programmed by proliferation-inducing oncogenes and the designation of reprogrammed energy metabolism as an emerging hallmark seems most appropriate.

It is worth noting that this characteristic of tumor cells provides at least one important diagnostic advantage. Upregulation of the major glucose transporter, GLUT-1, is seen in virtually all tumors, making the cells efficient glucose scavengers. This can be exploited to image tumor cells noninvasively with precision by visualizing glucose uptake using positron-emission tomography (PET) with a radiolabeled analog of glucose (^{18}F -fluorodeoxyglucose [^{18}F -FDG]) as a reporter. The combination of PET with computed tomography (PET-CT) is now one of the most robust means to evaluate composition of tumors, minimal residual disease, and tumor-specific objective responses in patients receiving conventional and experimental therapies.

Evading Immune Destruction

Burnet and Thomas proposed the concept that the immune system can recognize and destroy incipient tumors (cancer immunosurveillance) in the 1950s.⁷⁸ However, the hypothesis was far ahead of its time, and technologic obstacles impeded proof, so the theory fell into disfavor. In recent years, the immunosurveillance theory has gained traction anew because data strongly suggest that the immune system helps to maintain tumors at bay, and thus tumors must evade the immune response to survive. In its recent incarnation, the theory has been refined to incorporate the concept of immunoediting, in which the immune system destroys strongly antigenic tumor cells, providing weakly antigenic cells a survival advantage.⁷⁸ Experimental evidence for this concept includes differences between tumors grown in immunocompetent (only weakly antigenic tumors survive) and immunocompromised mice (no selection against strongly antigenic tumors is observed), but it is unknown if immunoediting is operative in spontaneous cancers.

That the tumor microenvironment forms and maintains an immunosuppressive barrier provides more compelling evidence for the role of the immune system to limit tumor growth and metastasis. This immunosuppressive barrier includes cellular factors such as regulatory T cells (Tregs), myeloid-derived suppressor cells (MDSCs), and MSCs. Tregs, MDSCs, and MSCs can attack distinct and complementary antigen-specific (Tregs) and nonspecific (MDSCs and MSCs) facets of immune effector cell activation and function. Soluble factors, including transforming growth factor- β (TGF- β) and immunoglobulins, also contribute to the immunosuppressive barrier directly by disabling immune effector cells and indirectly by “educating” tumor-associated stromal cells, which in turn promotes secretion of stromal-derived factors that recruit additional inflammatory cells (tumor macrophages) and endothelial cells that further accelerate tumor growth.⁹² This is an active area of basic and clinical research in which companion animal oncology has been at the forefront, for example, through the generation and approval of the first active gene-based therapeutic cancer vaccine for canine melanoma.⁹³

Epigenetic Events

Another observation is that events leading to cancer need not necessarily be caused by mutational events but instead can be caused by epigenetic changes. Epigenetic events are those that can alter phenotype without changing the genotype. Two well-characterized epigenetic mechanisms regulate gene expression. Gene silencing can occur by methylation of CpG residues in promoter regions, as well as by histone deacetylation. Both of these events interfere with the transcriptional machinery and repress gene expression. The effects of global changes in methylation or deacetylation (e.g., by inactivation of DNA methylases or histone deacetylases) remain incompletely understood, but silencing of specific genes by methylation is implicated in numerous cancers of humans and animals.^{2,94-96} One important observation is that most (or all) genes that are subject to silencing by methylation in specific cancers (e.g., *CDKN2A* in T-cell leukemia) are commonly inactivated by mutation or deletion in other cancers (e.g., *CDKN2A* in melanoma).

As is true for mutations, gene regulation by epigenetic methylation can occur sporadically or it can be heritable. Silencing of some tumor suppressor genes in sporadic cancers occurs more frequently by epigenetic methylation than by mutation or deletion. These different mechanisms of gene silencing are not equivalent, as they each result in specific tumor phenotypes. For example, data from our laboratories indicate that loss of canine chromosome 11, with resultant deletion of the *INK4* tumor suppressor locus containing the *CDKN2A*, *CDKN2B*, and *ARF* genes, and methylation of *CDKN2A* are each associated with morphologically distinct types of T-cell lymphoma that have a different clinical presentation and prognosis.^{37,51}

Genomic imprinting presents a unique example in which heritable epigenetic changes influence cancer predisposition. Genomic imprinting refers to a pattern of gene expression that is determined by the parental origin of the gene; in other words, unlike most genes in which both parental alleles are expressed, only one allele (specifically derived from the mother or from the father, depending on the gene) of an imprinted gene is expressed and the other one is permanently repressed. Epigenetic changes in Wilms' tumor and in heritable colon cancer (among others) alter the expression of the imprinted allele, leading to loss of imprinting that causes *overexpression* of the insulin growth factor-2 (*IGF2*) gene.^{2,97}

• **FIGURE 1-8** Multiple facets to cancer stem cell (CSC) self-renewal. Increasing evidence is emerging to support the notion that CSC self-renewal decisions can be guided by the activation of several pathways, including Wnt, Notch, Hedgehog, and others. A CSC may autonomously trigger the appropriate signaling cascade to maintain self-renewal with minimal niche support. It is likely that some CSCs need the appropriate microenvironment to provide the stimuli for uncontrolled self-renewal. Finally, some cancer cells have lost the capacity to self-renew regardless of stimulating molecules and hence cannot initiate a tumor. (*Reprinted from O'Brien CA, Kreso A, Jamieson CHM: Cancer stem cells and self-renewal, Clin Cancer Res 16(12):3113–3120, 2010, with permission.*)

Cancer Stem Cells

The paradoxical nature of some cancers gave rise to the notion of a “cancer progenitor” or a CSC as far back as the 1960s. The best illustration for this concept was CML, where the bulk of the tumor consists of terminally differentiated neutrophils that are incapable of recreating the malignancy. However, it was apparent that there were multipotent stem cells in this tumor population. In 1994, Dick’s group proved conclusively that another type of leukemia, acute myelogenous leukemia (AML), was a hierarchically organized disease in which a small number of cells that were undetectable by conventional methods could be isolated from patients and made to recapitulate the full spectrum of the disease in an animal model.⁹⁸ This gave rise to the CSC or “tumor-initiating cell” hypothesis, which is based on the concept that tumors are hierarchically organized into a subpopulation of cells that retain or acquire the capacity for self renewal and are capable and responsible for initiating and maintaining the tumor (Figure 1-8).⁹⁹ Another subpopulation of cells that consists of the CSC progeny undergo partial to complete differentiation and lose the capability to support the tumor, albeit they still contribute to the morbidity of cancer. This hypothesis fundamentally altered the way we understand cancer but also gave rise to a debate regarding how widely this model applies. The competing hypothesis is based on a model where all the cells in a tumor possess an equal capacity for self-renewal and is commonly referred to as the *stochastic model*. According to this model, the process of cancer is driven entirely (or almost entirely) by environmental selection of favorable mutations; this model would necessarily predict that cancer is an inevitable outcome for multicellular organisms, and few, if any, long-lived animals would reach reproductive age.¹⁰⁰ Thus this model must, by necessity, invoke the existence of protective mechanisms that are independent of cancer risk (e.g., efficient DNA repair mechanisms and immune surveillance).

It is possible that the two models represent a continuum dependent on the extent to which CSCs undergo asymmetric versus

symmetric divisions. Under conditions in which CSC divisions are primarily asymmetric, few CSCs would be apparent and the population would achieve a hierarchical organization, whereas under conditions in which CSCs underwent symmetric divisions, virtually every cell in the tumor would have CSC-like properties and the organization would be more consistent with a stochastic model. The prevailing opinion is that CSCs exist and are characterized both by peculiar phenotypes and defined sets of mutations of a small number of genes.^{101–103} Other mutations then endow their progeny with limited or extensive capacity to undergo programmed differentiation, thus resulting in the distinct clinical phenotypes that characterize acute and chronic leukemias or high-grade and low-grade solid tumors. The origin of CSCs is among the most important contemporary topics of investigation. CSCs may arise from mutations that occur in bona fide stem cells, they may arise by “de-differentiation” of somatic cells that acquire mutations that endow them with stem cell–like properties, or they may develop by fusion of a transformed cell and a bone marrow–derived stem cell.¹⁰⁴ In companion animals, putative CSCs have been identified in hemangiosarcoma, osteosarcoma, brain tumors, and possibly lymphoma.^{105–108}

As is true for the rest of cancer genetics, information in this field is rapidly evolving. Large-scale bioinformatics and conceptual advances are integrating the CSC theory into the mainstream of cancer research and biology, as well as into the design for new diagnostic and therapeutic strategies. For example, it appears that much like hematopoietic stem cells, the CSC niche favors oligoclonality and some genetic diversity. Thus clonal competition can ensue, giving rise to heterogeneous tumors and maintaining a reservoir of cells that can reestablish the tumor when a therapy effectively kills the predominant CSC clone and its progeny. Similarly, clonal competition can facilitate distant spread by selection of cells with different capabilities. An extreme example may be the potential for a single tumor cell (or a small population of oligoclonal cells in a tumor) to give rise to histologically distinct tumors—an event we have observed in xenotransplanted sarcomas.

Summary

The genetic basis of cancer is now beyond question. It is estimated that at least five to seven mutational events are required for overt malignant transformation, and genomic instability seems to be necessary to establish a self-renewing population of cells (possibly CSCs) whose progeny expand to cause clinical disease. Ultimately, a subpopulation endowed with metastatic properties that is drug resistant leads to death of the cancer patient. The rate and the flow of information is such that we predict the coming decade will see transformational changes in our perception of how genes interact with the macroenvironment at the organismal level and with the microenvironment in tumors. Although it is possible that cancer in higher vertebrates is an inevitable consequence of evolution,¹⁰⁹ improvements in our understanding of fundamental mechanisms that account for malignant transformation and tumor progression will allow us to design strategies to improve quality of life and outcomes for cancer patients.

■ SECTION B

Chemical, Physical, and Hormonal Factors

CAROLYN J. HENRY

In 1978, the United States Congress ordered development of the first Report on Carcinogens (RoC), a document designed to educate the public and health professionals on potential cancer hazards. The document is now required by law to be released every 2 years by the Secretary of the Department of Health and Human Services. The twelfth edition of the RoC, released in 2011, lists 240 potential carcinogens, of which 54 are categorized as *known to be human carcinogens* and 186 are categorized as *reasonably anticipated to be human carcinogens*.¹ Although no such report exists for companion animals, one could reasonably assume that there would be considerable overlap between such a list and the potential carcinogens found in the RoC. The 2005 RoC was the first to include neutrons, x- and gamma-radiation, and viruses (human papillomavirus, hepatitis B virus, and hepatitis C virus). Although the list of carcinogens reportedly associated with cancer in companion animals is less extensive, this section will address chemical, physical, and hormonal factors that have been linked to carcinogenesis in pet animals. Viral carcinogenesis will be addressed in a separate section (see Section C below).

Chemical Factors

Environmental Tobacco Smoke

Despite ample evidence that secondhand smoke increases the risk of lung cancer in people,^{2,3} the data for this effect in companion

animals are less compelling. One case-control study involving dogs with lung cancer from two veterinary hospitals showed only a weak relationship between living with a smoker and development of lung cancer, and the risk did not increase with an increased smoke exposure index.⁴ However, evidence for a relationship between exposure to environmental tobacco smoke (ETS) and development of other malignancies in companion animals is mounting.

Based on human data suggesting that smoking may increase the risk of non-Hodgkin's lymphoma,^{5,6} Bertone et al examined the relationship between ETS exposure and development of feline lymphoma.⁷ In a case-control study of 80 cats with malignant lymphoma and 114 control cats with renal disease that presented to Tufts University School of Veterinary Medicine (TUSVM) between 1993 and 2000, the relative risk of lymphoma for cats with any household ETS exposure was 2.4. As has been reported for male smokers,⁸ the risk of lymphoma increased with increases in either duration or quantity of exposure. More recently, an Italian study of environmental risk factors for development of cancer in domestic animals demonstrated that ETS exposure increased the risk of lymphoma in dogs.⁹

Hypothesizing that inhalation and ingestion of carcinogenic compounds in ETS during grooming might also predispose cats in smoking households to development of oral squamous cell carcinoma (SCC), Bertone et al examined ETS and other environmental and lifestyle risk factors in cats with SCC.¹⁰ The study examined a population of 36 cats with histologically confirmed oral SCC and a control population of 112 cats with renal disease, all presenting to TUSVM between 1994 and 2000. Exposure to ETS was associated with a twofold but statistically insignificant increased risk of oral SCC.¹⁰ Interestingly, in a separate report, the investigators showed that SCC tissue from cats exposed to any ETS were 4.5 more likely to overexpress p53 and those from cats with 5 years or more of ETS exposure were 7 times more likely to overexpress p53.¹¹ Although the findings did not reach statistical significance, the collective work of this group provides an intriguing suggestion that both ETS and mutations in the p53 gene may play a role in the etiology of feline oral SCC.

Pesticides, Herbicides, and Insecticides

In 1991, investigators at the National Cancer Institute (NCI) completed a case-control study to examine the relationship between exposure of dogs to the herbicide, 2,4-dichlorophenoxyacetic acid (2,4-D), and development of lymphoma.¹² Dogs with a histologically confirmed diagnosis of lymphoma during a 4-year period were identified through the computerized medical record information from three veterinary teaching hospitals. Each case animal was age-matched with two control animals. The first control group consisted of dogs diagnosed with tumors other than lymphoma during the same time period and the second control group was a nontumor group, selected from all other dogs presenting to the hospital for conditions deemed unrelated to chemical exposure. Owners were questioned about household use of and potential pet exposure to commercial lawn care and owner-applied herbicides. A positive association was found between exposure to owner-applied 2,4-D or the use of commercial lawn care services and the development of canine lymphoma. The risk of lymphoma development doubled when owners applied 2,4-D liquid or granules to the lawn four or more times a year. After these findings were reported, an independent review panel was convened to assess the validity of the NCI study.¹³ This panel voiced concerns about the original study design, data analysis, and interpretation, concluding that a relationship between 2,4-D exposure and the development of canine lymphoma

could not be established based on the reported data. In response, the original investigators reanalyzed their data, addressing many of the concerns raised by the scientific review panel.¹⁴ In their second study, Hayes et al used a more stringent definition of exposure to 2,4-D, including only cases in which the owner applied 2,4-D as the sole herbicide and did not use other lawn chemicals or lawn care services. Their second report did not show a statistically significant association between exposure to 2,4-D and development of lymphoma.¹⁴ However, they concluded that their results did indicate a dose-response relationship between disease incidence and number of yearly 2,4-D applications by dog owners. In a subsequent study conducted by researchers at Michigan State University, the original 1991 data was again reanalyzed using the more stringent definition of exposure and completing a dose-response analysis. The study, which was funded by a chemical industry task force, showed no dose-response relationship between number of 2,4-D applications and the occurrence of canine lymphoma.¹⁵ Although increased urinary excretion of 2,4-D has been demonstrated in dogs exposed to herbicide-treated lawns, a direct link between such exposure and development of lymphoma has not been shown.¹⁶ A 2011 case-control study conducted in Italy was designed to assess the effect of residential exposure to environmental pollutants on the risk of developing lymphoma.¹⁷ The investigators were unable to demonstrate an association between exposure to pesticides (which by their definition included herbicides) and development of lymphoma. They did, however, find that living in industrial areas and owner use of chemicals such as paints and solvents were significantly and independently associated with lymphoma.

Canine transitional cell carcinoma (TCC) of the urinary bladder is another malignancy that has been linked to environmental carcinogens including insecticides and herbicides. In a case-control study of 59 dogs with TCC and 71 age-matched and breed size-matched control dogs with other neoplasms or chronic disease, investigators compared the two populations to assess the effect of obesity, exposure to sidestream cigarette smoke and chemicals, and use of topical insecticides on risk of TCC.¹⁸ They reported an increased risk of TCC in dogs treated with topical insecticides, with an enhancement of this risk in overweight or obese dogs. In the aforementioned study of risk factors for oral SCC in cats, Bertone et al reported a significantly increased risk of oral SCC in cats that wore flea collars.¹⁰ However, newer topical spot-on flea and tick products have been evaluated in Scottish terrier populations due to the breed's predisposition for development of TCC of the urinary bladder and have not been shown to increase the risk of TCC.¹⁹ Other studies of Scottish terriers have suggested that exposure to lawn and garden care products containing phenoxy herbicides, including 2,4-D, 4-chloro-2-methylphenoxy acetic acid (MCPA), and 2-(4-chloro-2-methylphenoxy) propionic acid (MCPP), is associated with an increased risk of TCC.²⁰ Although it has been difficult to prove a link between phenoxy herbicides and development of lymphoma or TCC, attempts to limit exposure of pets to these products is advised.

Cyclophosphamide

The cytotoxic alkylating agent, cyclophosphamide, has been implicated in the development of urinary bladder cancer in people and dogs.²¹⁻²³ A known potential side effect of cyclophosphamide therapy is sterile hemorrhagic cystitis, which may develop due to the irritating effects of the drug's metabolite, acrolein, on the bladder mucosa. Although the specific etiology is unknown, it is speculated that chronic inflammation secondary to acrolein exposure is the underlying event that leads to bladder cancer in some

patients that have undergone cyclophosphamide therapy. The author has had the experience of treating a dog for lymphoma that was found to have concurrent but clinically occult TCC of the bladder prior to initiation of cyclophosphamide chemotherapy. If an abdominal ultrasound had not been performed on this dog as part of the initial staging procedures prior to chemotherapy, the bladder TCC may have been diagnosed at a later date and incorrectly attributed to administration of cyclophosphamide. This exemplifies the danger of assuming a causal relationship for potential carcinogens, especially in animals that have a prior malignancy.

Rural versus Urban Environment

Although several reports have identified differences in cancer incidence between companion animals living in urban versus rural settings, the underlying cause for these differences is unclear. An increased incidence of some canine cancers, including lymphoma, tonsillar SCC, and nasal carcinoma,^{17,18,24,25} has been reported in urban/industrial settings as compared with rural settings. However, the coexistence of multiple environmental carcinogens in the same setting makes discerning the "smoking gun" a difficult task. Nonetheless, the study of animals as sentinels of environmental health hazards has been recommended and provides supportive evidence for carcinogenic risk assessment across species.²⁶⁻²⁹ Results of a hospital-based case-control study conducted in Naples, Italy and nearby cities with known high levels of illegal waste dumping suggest that living in these sites of waste emission increases the risk of cancer development in dogs but not cats. This may relate to reduced exposure of cats to environmental carcinogens, as they are often exclusively indoor pets.⁹

Physical Factors

Sunlight

The relationship between sunlight exposure or ultraviolet irradiation and subsequent development of skin cancer is one of the better known examples of physical carcinogenesis. Recognized for its role in human SCC induction, sunlight has also been implicated as a cause of SCC in domestic animals and livestock—an implication that is strengthened by a clear dose-response relationship shown in both epidemiologic and experimental studies.²⁸⁻³¹ In particular, light skin pigmentation and chronic sun exposure are associated with the development of facial, aural, and nasal planum SCC in white or partially white cats and may also play a similar role in some cutaneous SCC lesions in dogs. The portion of the ultraviolet spectrum most likely to be responsible for nonmelanotic skin lesions in people and animals is ultraviolet B (UV-B), which is in the range of 280 to 320 nm.²⁸ Cumulative long-term exposure to UV-B may induce skin tumors directly through genetic mutations, including mutations in p53, and indirectly by impairing the response of the immune system to tumor antigens.^{28,32,33} Pets are at greatest risk of exposure to UV-B during the midday hours and should be protected from this exposure, especially if they are a lightly pigmented breed.

Trauma/Chronic Inflammation

Chronic inflammation may lead to cellular mutations that in turn cause neoplastic transformation. In four dogs with chronic pigmentary keratitis, neoplastic lesions of the cornea, including three SCC and one squamous papilloma, were reported.³⁴ Although the underlying etiology of the keratitis could not be confirmed, the neoplastic transformation was likely related to chronic inflammation. Earlier

reports have linked feline eye tumors to ocular trauma that induces secondary uveitis and lens rupture (see Chapter 31).³⁵ Unlike the corneal tumors reported in dogs with pigmentary keratitis, the ocular lesions in cats were intraocular sarcomas. Despite the varied histology, the underlying etiology in all cases was thought to be related to inflammatory changes. Another companion animal malignancy thought to be associated with inflammation is vaccine-associated feline sarcoma (VAFS). This tumor type and its etiology are discussed in detail in Chapter 21.

Magnetic Fields

More than a quarter century ago, a potential link between chronic low-dose exposure to magnetic fields and development of childhood cancer was proposed.³⁶ Since then, multiple studies have been conducted in an attempt to discern links between magnetic fields and a variety of human cancers ranging from hematopoietic malignancies to breast cancer. The extremely low frequency (<60 Hz) magnetic fields in question are ubiquitous in today's society and are generated by household appliances, industrial machinery, and electrical power lines. Since pets share our environment and have similar exposure to magnetic fields, a similar risk of cancer development has been presumed for companion animals. In a 1995 study, the risk for development of lymphoma was found to be highest in dogs from households with the highest measured exposure to magnetic fields.³⁷ The risk was related to both duration and intensity of exposure and was highest for dogs that spent more than 25% of the day outdoors. In the following year at the request of Congress, a report was published by the National Research Council (NRC) that reviewed over 500 studies on the subject of cancer risk and exposure to electromagnetic fields.³⁸ The report concluded that, although a weak association has been shown between development of childhood leukemia and exposure to electromagnetic fields, no clear evidence exists to suggest that exposure to electromagnetic fields is a true threat to human health. To the author's knowledge, no reports on the possible link between magnetic fields and cancer in companion animals have been published since the 1995 report, although the magnetic field debate continues in the human literature. The NRC report suggested that other factors, including air quality and proximity to high traffic density, may be more likely environmental causes of cancer than low frequency magnetic fields.

Radiation

The first report of cancer development after therapeutic irradiation in a dog dates back over 25 years, when orthovoltage radiation was considered state-of-the-art.³⁹ At that time, the term *malignant transformation* was used to describe the development of epithelial malignancies at the site of prior irradiation for acanthomatous epulides in four dogs. Following a review of more recent cases with megavoltage irradiation, the author of the original report has since suggested that the concept of malignant transformation should be discarded, in that the occurrence of second tumors was not likely due to a true transformation of epulides into carcinomas.⁴⁰ Rather, the relatively high rate of carcinomas at previously irradiated sites for epulides is a result of less effective forms of irradiation or misclassification of the tumor type. Radiation carcinogenesis is considered the cause of second tumors arising in radiation fields. In human oncology, most tumors occurring in heavily irradiated treatment fields are mesenchymal, rather than epithelial, in origin.⁴¹⁻⁴³ Several reports of sarcomas occurring in sites of prior radiation can be found in the veterinary literature, as well,^{39,44-46} with the most recent being a retrospective review of 57 dogs undergoing definitive megavoltage radiation therapy with ⁶⁰Cobalt

photons for acanthomatous epulis.⁴⁰ In the latter report, McEntee et al describe the development of a second tumor (one sarcoma and one osteosarcoma) in 2 of the 57 irradiated dogs, occurring 5.2 and 8.7 years after the initial treatment, respectively. The overall incidence of second tumors was lower in their study than in previous reports (3.5% versus up to 18%).^{39,47} The fact that no epithelial tumors were reported may indicate a more efficient targeting of a subpopulation of malignant epithelial cells by megavoltage radiotherapy, as compared to orthovoltage. The report suggests that the risk of second tumors at sites of radiation therapy is primarily of clinical concern for young dogs expected to enjoy long-term survival. Second tumors have also been reported in at least six people who have undergone stereotactic radiosurgery.⁴⁸ As this radiation technique becomes more commonplace in veterinary medicine, the possibility of second tumors may need to be considered in companion animals undergoing stereotactic radiosurgery.

Surgery and Implanted Devices

The development of sarcomas at the site of metallic implants has been reported in people, dogs, and laboratory animal models.^{49,50} However, it is often difficult to discern if sarcoma development is related to fracture fixation devices or to other factors, including wound healing complications and osteomyelitis. The largest veterinary study examining the relationship between metallic implants and tumor development in dogs was published in 1993 by Li et al.⁵⁰ The authors reported on 222 dogs that developed tumors of any kind after fracture fixation, compared to 1635 dogs that underwent fracture fixation without subsequent tumor development. They concluded that use of metallic implants was not a risk factor for bone tumor development. Other types of implants and foreign materials related to surgery are sporadically implicated in carcinogenesis in human and veterinary case reports. Published examples include one dog that developed a myxoma at the site of a subcutaneous pacemaker and another that developed a jejunal osteosarcoma associated with a surgical sponge presumably not retrieved during an abdominal surgery 6 years prior.^{51,52}

Asbestos

Asbestos exposure is a known risk factor for development of mesothelioma in people.⁵³ In fact, an estimated 60% to 88% of all cases of human mesothelioma are attributable to asbestos exposure.⁵³ A similar association has been found for dogs whose owners have an asbestos-related occupation or hobby.⁵⁴ This association was further supported by a study in which significantly more asbestos bodies were found in dogs with mesothelioma than in control dogs.⁵⁵ Pericardial mesothelioma was reported in five golden retrievers with histories of chronic idiopathic hemorrhagic pericardial effusion, suggesting that other factors, including breed predispositions and chronic inflammation unrelated to asbestos exposure, may be involved in the etiology of mesothelioma affecting the pericardium.⁵⁶

Hormonal Factors

Estrogen and Progesterone Canine Mammary Cancer

Canine mammary cancer is a well-established model of hormonal carcinogenesis in domestic animals (see Chapter 27). The most common neoplasm of female intact dogs, mammary tumors affect approximately 260/100,000 dogs in the United States each year.^{57,58} Dogs spayed before their first estrous cycle have a greatly reduced risk of developing breast cancer, with the risk rising to 26% for dogs

that are spayed after their second estrus.^{59,60} Mammary tumors primarily affect late middle-aged (9 to 11 years) female intact dogs, with an increased incidence beginning at approximately 6 years of age.⁶¹ Sexual steroid hormones likely have their primary effect on target cells during the very early stages of mammary carcinogenesis in dogs; thus, the protective effect of spaying is lost with time.⁶²⁻⁶⁸ In addition to the influence of ovarian hormones on breast cancer development, the use of medroxyprogesterone acetate (progestin and estrogen combination) products to prevent estrus or to treat pseudopregnancy has been linked to an increased incidence of mammary tumor development in dogs.⁶⁹⁻⁷¹

Progestin-induced growth hormone (GH) excess in dogs originates in the mammary gland. Within the mammary gland, the gene encoding GH may act in an autocrine/paracrine fashion, effecting cyclic epithelial changes and, perhaps, carcinogenesis. Research to determine the mechanism of progestin-induced mammary GH expression in dogs has led to the cloning and cellular localization of the canine progesterone receptor (PR).⁷² The investigators concluded that within the same mammary gland cell, the activated PR may transactivate GH expression and function as a prerequisite transcription factor. However, this regulation may be lost during malignant transformation. Mammary GH expression has been reported in people as well, suggesting that evaluation of links between this hormone and mammary carcinogenesis may have implications for both species.^{73,74}

Feline Mammary Cancer

Both estrogen and progesterone are thought to play important roles in feline mammary carcinogenesis, although the underlying mechanisms are less clear than for dogs. Prior studies have shown that intact female cats and those cats that are exposed regularly to progestin are at an increased risk for mammary cancer development. The literature also suggests that, as is the case in dogs, ovariectomy may be protective against feline mammary gland tumor development in cats.^{57,75-77} In one study, cats ovariectomized at 6 months of age had an approximate sevenfold reduction in risk of mammary tumor development compared to intact cats.⁵⁷ What has been lacking in the veterinary literature is an epidemiologic study of cats with age-matched controls for comparison to specifically investigate the effects that spaying and age of spay have on the risk of feline mammary carcinoma development. Overley et al attempted to address these issues in a retrospective study that compared a population of 308 cats with biopsy-proven mammary carcinoma diagnosed between 2000 and 2001 and a control population of 400 female cats not diagnosed with mammary tumors but from the same biopsy service population as the affected cats. Cats from the two groups were frequency-matched by age and year of diagnosis.⁷⁷ The study reported a 91% reduction in risk for those spayed prior to 6 months of age and an 86% reduction in risk for those spayed prior to 1 year of age, compared to intact cats. Although the study was retrospective in nature and relied on questionnaire data from a survey with a 58% response rate, the manuscript is the first published report attempting to age-match controls and evaluate age at time of spay as a risk factor for mammary tumor development in cats. Although further epidemiologic evaluation and prospective assessment are needed to confirm these findings, the reported results provide some justification for recommending ovariohysterectomy prior to 1 year of age in cats.

Lymphoma

Surveillance, Epidemiology and End Results (SEER) data indicate that non-Hodgkin's lymphoma is approximately 50% more common

among men than women.⁷⁸ Although a similar male predisposition is reported for canine lymphoma, the underlying role of gender in lymphoma etiology remains elusive. The author and others undertook a population-based study using the Veterinary Medical Database (VMDB) to determine the relationship between gender and development of canine lymphoma.⁷⁹ Data from 1980 to 2000 were retrieved from the VMDB and sorted by gender and reproductive status. In the statistical analysis, spayed or neutered dogs diagnosed with lymphoma were compared to intact dogs seen each year in each gender category. The VMDB included nearly 15,000 lymphoma cases in a population of over 1.2 million dogs. These data suggest that intact females were significantly less likely to develop lymphoma than were other gender groups. Based on this initial data, we propose that further examination of the role of estrogen in the development or prevention of canine lymphoma is warranted.

Androgens/Testosterone Perianal Adenoma

Perianal adenoma is androgen dependent and occurs primarily in intact male dogs, whereas perianal adenocarcinoma occurs in both intact and castrated males. Perianal adenomas may also develop in female dogs secondary to testosterone secretion from the adrenal gland.⁸⁰ The majority of these tumors in male dogs resolve after castration, a fact that lends further support to the assertion that androgens are involved in the etiology of this tumor (see Chapter 22).⁸¹

Prostate Cancer

Although there is a well-established link between presence of testosterone and development of benign prostatic hyperplasia (BPH) in dogs and man, prostatic cancer risk is not higher in intact dogs compared to those that are castrated.⁸² To the contrary, neutered dogs have been shown to be at increased risk. Castration is likely not an initiating event, but is thought to favor tumor progression.⁸³⁻⁸⁶ A clear relationship between age at castration and risk of prostate cancer development is yet to be determined (see Chapter 28).

■ SECTION C

Cancer-Causing Viruses

DENNIS W. MACY AND CAROLYN J. HENRY

Both DNA- and RNA-containing viruses are known to cause cancer. An initial step in malignant transformation of normal cells by most tumor viruses is integration of all or part of the viral DNA (or DNA copy of retroviral RNA) into the host cell genome. For some viruses, specific viral genes (oncogenes) have been identified that lead to malignant transformation when expressed in normal cells. Other viruses, through the process of integration, activate the expression of normal cellular genes, leading to overexpression or inactivation of genes, resulting in cellular transformation or uncontrolled growth.¹

Tumor-Causing Viruses of Dogs

Papillomaviruses

Papillomaviruses are oncogenic, contagious, and infectious and have been described in several animal species.² Papillomaviruses are considered species specific, and isolates of humans, cattle, and dogs lack serologic cross-reactivity.² However, cross-infection with other species can occur. For example, the coyote can be infected with dog isolates, and bovine papillomaviruses type 1 and type 2 have been reported to infect horses.³ In addition, bovine papillomaviruses have been isolated from tumors in cats, indicating a unique cross-species infection in a dead-end host.⁴

Four or possibly more papillomaviruses infect dogs and are responsible for a wide spectrum of clinical syndromes. Papillomaviruses of the family Papovaviridae produce benign, mucocutaneous, and cutaneous canine papillomas and in rare cases transform into SCCs.^{5,6}

The canine papillomaviruses are naked DNA viruses; they are larger than the canine parvoviruses but similar in structure. Electron microscopy has been used to detect the virus in infected tissues. Like other papillomaviruses, canine papillomaviruses are resistant, acid stable, and relatively thermostable.⁷ Only a limited sequence homology exists between the DNA sequences of papillomaviruses of different species, but substantial sequence homology exists between isolates from any given species.²

Pathogenesis

Papillomas develop subsequent to introduction of papillomavirus through breaks in the epithelium. Different viruses derived from the same species are believed to correlate with the type of clinical

• **FIGURE 1-9** Multiple papillomatosis in the oral cavity of the dog.

disease produced by the virus (i.e., oral versus cutaneous isolates). However, this feature of papillomaviruses has yet to be proven for the dog, and experimentally, ocular isolates have produced oral papillomas.⁸⁻¹² The presence and location of mature, complete viruses on the surface of papillomas are believed to aid its transmission to adjacent epithelial tissues.² In contrast to other oncogenic or transforming DNA viruses, papillomaviruses rarely integrate into the cellular genome and remain episomal.²

Infection of epithelial cells results in a marked increase in cellular mitosis and hyperplasia of cells with a strand of spongiosum, with subsequent degeneration and hyperkeratinization.¹³ Clinical evidence of hyperplasia and hyperkeratinization usually manifests 4 to 6 weeks after infection.¹³ Canine papillomas generally persist for 4 to 6 months in the mouth and 6 months to 1 year on the skin before undergoing spontaneous regression, and multiple warts generally regress simultaneously.¹³ Although antibodies are produced against the papillomavirus, antibody levels do not appear to correlate with either growth or regression of the papilloma; the mechanism of induction or regression remains unknown, although it is thought in most cases to be associated with cellular immunity.¹⁴ The development of multiple papillomavirus-associated epidermal hematomas and SCC in situ in a dog after treatment with prednisone and cyclosporine has been reported.¹⁵

Clinical Features

Papillomas may be referred to as warts, verruca vulgaris, squamous cell papillomas, or cutaneous papillomatosis. Papillomas caused by the papillomavirus usually are multiple and frequently infect young dogs. In the dog, multiple papillomatosis most frequently is seen in the oral cavity, involving the labial margins, tongue, pharyngeal mucosa, hard palate, and epiglottis (Figure 1-9).¹⁴ Four to 8 weeks after infection, small, pale, smooth, elevated lesions appear; these quickly develop a cauliflower-like appearance, with fine, white fronds extending from the surface of the lesions. Multiple sites of susceptible tissue in the oral cavity appear to be affected early in the course of the disease; as many as 50 to 100 tumors may be present at the time of diagnosis.¹⁴ The primary complaints of owners of infected dogs are halitosis, ptyalism, hemorrhage, and difficulty eating. Most oral cavity papillomas start regressing after 4 to 8 weeks. However, some oral lesions may show incomplete regression, and some have been known to persist up to 24 months.¹⁴

• **FIGURE 1-10** Solitary ocular papilloma in a dog.

• **FIGURE 1-11** Multiple cutaneous papillomatosis in the inguinal region of a dog.

Ocular papillomas, which are less numerous than the oral type, appear on the conjunctiva, cornea, and eyelid margins (Figure 1-10). Ocular papillomas also occur less often than oral lesions.¹⁴ Experimentally, viruses isolated from ocular lesions can produce oral papillomatosis, although whether this occurs in nature is unknown.⁸ Ocular papillomatosis most frequently occurs in dogs 6 months to 4 years of age, but it occasionally is reported in older dogs.

Multiple cutaneous papillomatosis is thought to be of viral origin (Figure 1-11); however, evidence suggests that it is not the same strain of papillomavirus that produces oral papillomatosis in the dog.⁸ Multiple skin papillomatosis affects a much broader age range of canine patients, and regression of the lesion is prolonged, sometimes taking years.¹⁴ A rare form of cutaneous papillomatosis, in which the lesion appears in the interdigital areas of the pad, has been described in greyhounds, particularly young ones (12 to 18 months of age).¹² Canine pigmented plaques have been associated with papillomaviruses in miniature schnauzers and pugs.¹⁶ The lesions may or may not regress and are considered premalignant.

Although papillomatosis should be considered a benign disease, in rare cases, oral and corneal papillomas have transformed into SCCs.^{5,6}

Treatment

Most clinicians elect not to treat papillomatosis because of the lack of proven efficacy of recommended treatments and the expected

spontaneous regression of these tumors. However, if the number of papillomas increases or if the animal has significant difficulty eating, owners often request treatment. Surgical excision, cryosurgery, laser surgery, or electrosurgery for just a few lesions has resulted in regression of the remaining papillomas, presumably through immunologic mechanisms.^{14,17,18} The exact mechanism by which regression of papillomas occurs is unknown. Serum from dogs in which papillomas have undergone spontaneous regression not only fails to produce tumor regression when administered to infected animals, it actually enhances existing tumor growth. However, administration of immune lymphocytes from dogs in which tumors have regressed has been shown to enhance regression.⁷ This effect may be a result of induction of blocking antigen-antibody factors, which may impede cytotoxic lymphocyte action on target cells. CD4 lymphocytes activate macrophages and have been shown to inhibit the virus in dogs.⁷ Interferon also has been tried, with some success (1 to 3 million IU/m² given subcutaneously three times a week [Monday-Wednesday-Friday]), and chemotherapy of resistant lesions has produced variable results.¹⁹ Corticosteroids should be avoided because they are thought to contribute to the dissemination of papillomas.²⁰

Most systemic chemotherapeutic agents (e.g., bleomycin, vincristine, cyclophosphamide, and doxorubicin) have failed to cause regression of papillomas. However, etretinate (1 mg/kg given orally daily) has been effective in some dogs with persistent papillomas.^{21,22} Topical or intralesional compounds containing 5-fluorouracil (5-FU) have been used in both humans and dogs to treat papillomas. In the past, autogenous wart vaccines have been recommended but have proved of little value in the treatment of resistant papillomatosis of the dog.¹⁴ In at least one study, papillomavirus vaccines have been shown to prevent the development of oral papillomas in the dog; however, cutaneous neoplasms at the injection sites have been attributed to administration of the vaccines.^{11,23,24}

Tumor-Causing Viruses of the Cat

Papillomaviruses

Feline viral papillomatosis is a rarely recognized condition caused by a papillomavirus specific to the cat. The feline isolates *Felis domesticus* papillomavirus type 1 (FdPV-1), FdPV-JM, and FdPV-MY are genomically very similar to canine isolates but are considered species specific.²⁵ Papillomavirus-associated lesions have been reported in six species of felids besides the domestic cat: the mountain lion, Florida panther, bobcat, Asian lion, snow leopard, and clouded leopard.^{26,27} Unlike in the domestic cat, in which the lesions commonly affect areas of haired skin, papillomas in exotic species most often are found in the oral cavity, similar to those in the dog.^{26,27} Despite the clinical similarities, genetic and antigenic studies indicate that each species of felid is infected by a unique papillomavirus.

Pathogenesis

In cats, as in other species, papillomas are believed to develop after the virus is introduced through lesions or abrasions in the skin. Unlike in the dog, most feline case reports involve older cats (6 to 13 years of age), although papillomavirus lesions have been reported in kittens 6 to 7 months old.^{28,29} As in other species, impaired T-cell function likely plays a significant role in lesion formation. Papillomas in cats that are receiving immunosuppressive therapy or are infected with the feline immunodeficiency virus (FIV) support this hypothesis.

Although papillomas most frequently are benign lesions, recent studies have associated the papillomavirus with SCCs and other malignant neoplasms in cats³⁰; specifically, papillomavirus has been isolated from 30 of 63 squamous cell carcinoma in situ skin lesions. Through the use of polymerase chain reaction (PCR) techniques, papillomaviruses have been found in 17 of 19 and 9 of 12 fibropapillomas in cats.^{31,32} Although a cause-and-effect relationship has yet to be proved for carcinoma in situ, Bowen's disease, fibropapillomas, and papillomaviruses, the evidence is compelling.³⁰⁻³² Over 100 papillomaviruses occur in humans and are believed responsible for cervical cancer, between 25% and 60% of SCCs of the oral cavity, and rarely even some that occur on the skin surface.³³

Bovine papillomaviruses may also play a role in the pathogenesis of feline cutaneous fibropapillomas. In a study of 20 cats with fibropapillomas, more than half were known to have exposure to cattle, and all were within an area with dairy farms.³¹ In one isolate, the nucleotide sequence was similar to that of the bovine papillomavirus. Injection of that isolate back into bovine skin resulted in asymptomatic infection. Also, although papillomaviruses generally are species specific, an association between bovine papillomavirus types 1 and 2 has been suggested as causes of equine sarcoids.³⁴

Clinical Features

Lesions in the cat differ from those in the dog because they are more like plaques than warts. The plaques are several millimeters in diameter, may be white or pigmented, and are scaly or greasy. Also, lesions in the cat usually affect haired skin rather than the mucous membrane locations common for oral and ocular papillomas of the dog and wild felids.^{26,27}

Diagnosis

Definitive diagnosis depends on histopathologic, immunohistochemical, or electron microscope (EM) examination of excised lesions. Histologic features include proliferation of all cell layers with little or no inflammation. Typically the epidermal hyperplasia is accompanied by acanthosis, hypergranulosis, hyperkeratosis, and ballooning degeneration of cells of the stratum spinosum and stratum granulosum. Amphophilic cytoplasmic inclusion structures may be present in cells of the upper stratum granulosum. EM findings in the lesions include intranuclear particles within keratinized cells in the superficial epithelial strata of the plaques. Immunohistology can be performed on sections using band-reactive, genus-specific antiserum. Interestingly, the histologic features of the feline fibropapilloma are very similar to those of equine sarcoids, with characteristic fibroblastic proliferation, hyperplasia of epidermis, and rete ridges.³¹ PCR also has demonstrated papillomavirus DNA in the lesions.

Treatment

Surgical excision is generally used; however, parenteral alpha interferon has been suggested as an alternative. *Medications containing 5-FU that are used in humans and dogs should NOT be used in cats.* Imiquimod 5% cream (Aldara) is a novel immune-response modifier (IRM) that has been used in humans with Bowen's disease and has recently been used in cats with the same disease. Although 41% of cats treated with imiquimod developed some level of toxicity, most adverse events were manageable.³⁵

Retroviruses

Retroviral infections are considered the number one infectious cause of morbidity and mortality in the domestic cat. Before the vaccine was developed and routine testing and control measures

became widespread, the feline leukemia virus (FeLV) was associated with one-third of deaths in cats.^{36,37} The cat is believed to be affected by the largest number of retroviruses of any companion animal, and these viruses produce a wide spectrum of diseases, including cancer.³⁸⁻⁴⁰

The cat has both endogenous and exogenous retroviruses. The endogenous retroviruses generally are considered nonpathogenic, are present in the host DNA, and are passed from generation to generation genetically, as are other chromosomal genes. The exogenous retroviruses include both pathogenic and nonpathogenic viruses and are passed horizontally and vertically between cats. Pathogenic exogenous retroviruses include FeLV and FIV.⁴¹ The exogenous RNA sequences of FeLV play the most important role in tumorigenesis in the cat.⁴⁰ Another pathogenic retrovirus, the feline sarcoma virus (FeSV), arises from the combination of exogenous FeLV and proto-oncogenes in the cat's genome.⁴² Feline syncytium-forming virus (FeSFV), also called the *feline foamy virus*, is a nonpathogenic exogenous retrovirus.³⁶

FeLV is believed to have been contracted from the ancestral rat approximately 10 million years ago.⁴³ The ancestral source of other retroviruses is unknown. The three pathogenic retroviruses of clinical importance are FeLV, FIV, and, in rare cases, FeSV.

Feline Leukemia Virus

The retrovirus FeLV belongs to the subfamily oncornavirus, or tumor-producing RNA viruses. Like other retroviruses, it has a single strand of RNA and an enzyme, reverse transcriptase (RT), that synthesizes DNA from the virus RNA template. Nondomestic felids, including the cheetah and bobcat, can be infected by FeLV; however, it is not considered enzootic in wild felids except for European wild cats in France and Scotland.^{44,45}

The basic FeLV proteins include the envelope proteins and the core proteins, several of which are important clinically. Two envelope proteins, the P15E and the GP70 glycoproteins, have particular clinical significance.⁴⁶⁻⁴⁸ P15E is thought to be one of the mediators of immunosuppression in FeLV-infected cats.⁴⁹ The glycoprotein of the envelope GP70 may contain three subgroup antigens, A, B, and C.^{50,51} An individual cat may have combinations of viruses with these subgroup viral antigens. Considerable antigenic variation exists within subgroups, which can affect the biologic properties of the individual isolates or strains of FeLV.^{40,50} These subgroup antigens bind the virion to receptors on the surface of cells. The specific characters of these proteins also predict the pathogenicity, host range, infectivity, and other biologic properties of the virus.^{40,50} The antibodies produced against envelope proteins can be neutralizing and thus can prevent infection. Envelope proteins are very important components of FeLV vaccines.

Core proteins (capsids) include P15C, P12, P10, and P27. P27 is quite soluble and can be found in large amounts in the cytoplasm of cells and bodily fluids, such as tears and serum.⁴⁶⁻⁴⁸ P27 is the antigen that is detected in immunofluorescent assay (IFA) tests and enzyme-linked immunosorbent assays (ELISAs), which are commonly used in the diagnosis of FeLV infection.⁵¹

Transmission

FeLV is an enveloped virus and is considered very fragile. Desiccation rapidly reduces the amount of viable virus in saliva, and inactivation occurs in 1 to 2 hours. In exudates or blood, the virus may be viable for only 48 hours (at 37° C) or 1 to 2 weeks (at 22° C).⁵² Like most retroviruses, FeLV is rapidly inactivated by heating and most disinfectants.⁴⁷ Given these characteristics, environmental contamination (e.g., examination tables, cages, and waiting rooms)

is unlikely to be a potential source of FeLV infection.⁴⁰ Although saliva may contain up to 100,000 virus particles per milliliter, prolonged, intimate contact with infected cats usually is required for transmission. The factors most frequently incriminated in the transmission of FeLV are licking, biting, grooming, and sharing of litter pans, food bowls, and water dishes. Intimate contact is enhanced in catteries and multiple-cat households, where infection rates may be very high.⁴⁹

Although cats may be infected with FeLV subgroups A, B, or C or other recombinants, only subgroup A has been found in cell-free fluids and is thought to be associated with natural transmission of FeLV. Subgroups B and C and other recombinants are more cell associated and are not thought to be transmitted in nature.⁵³⁻⁵⁶

Before vaccines and routine testing became available, the overall prevalence of FeLV infection in the United States was estimated at 1% to 3% of the population.^{38,39} The prevalence of FeLV infection was less than 1% in single-cat households and as high as 30% in multiple-cat households.⁵⁷ The incidence of FeLV-positive test results in sick cats in the United States was approximately 11.5%.⁵⁸ Several studies have reported a decline in the prevalence of FeLV by as much as 50% over the past 20 years.^{37,59,60}

The FeLV subgroups are characterized by their cross-interference with homologous but not heterologous subgroups of FeLV and by their host range and other factors. All naturally infected FeLV cats have subgroup A, 50% of infected cats have a combination of subgroups A and B, and 1% of infected cats in nature have a mixture of subgroup C either as AC or ABC.^{38,58,61}

The relevance of subgroups in strains is essential to an understanding of the biodiversity of the clinical disease caused by FeLV infection. Although subgroups A, B, and C maintain 85% genomic homology, cats infected with various combinations of these subgroups may manifest vastly different diseases.

Subgroup A has a variety of strains that range from nonpathogenic to very pathogenic.⁶² Although most strains of subgroup A have limited pathogenicity, their pathogenicity increases dramatically if they are present with other subgroups.

Subgroup B is created when subgroup A recombines with endogenous FeLV envelopes at sequences already in the feline genome.⁶³⁻⁶⁵ Each recombination is unique, resulting in many strains of FeLV-B. The combination of subgroups A and B is more contagious and pathogenic than subgroup A alone.^{58,61,62} Cats infected with subgroups A and B often develop thymic lymphoma and myeloproliferative disease.⁶³

Subgroup C arises from the mutation of subgroup A.⁶⁶ Cats may be infected with a combination of C and other subgroups, although these combinations are uncommon and are found in only about 1% of naturally infected cats. FeLV-C is antigenically similar to the associated membrane antigen (feline oncornavirus-associated cell membrane antigen [FOCMA]), and cats carrying FeLV-C have developed severe erythroid hypoplasia and anemia and usually die within 1 to 2 months.⁵³ Further complicating the biodiversity of subgroups and strains is the fact that subgroups A and B can recombine with proto-oncogenes such as MYC or TCR, producing FeLV-MYC or FeLV-TCR.³⁶ Both of these recombinants are considered more potent tumor producers than their nonrecombinant FeLV parent. Another subgroup, T, is highly cytolytic for T lymphocytes and causes severe immunosuppression.⁵⁴⁻⁵⁶

The Rickard strain of FeLV (FeLV-R), although similar to MYC-containing recombinant strains in its ability to produce mediastinal lymphoma rapidly, does not recombine with the MYC gene.^{36,67} Instead, it obtains some of the biologic effects by integrating adjacent to the C-MYC gene, causing its overexpression.³⁶

Feline Oncornavirus-Associated Cell Membrane Antigen

FOCMA is a protein found on the surface of FeLV and FeLV-induced neoplasms but not on nonneoplastic feline cells.^{68,69} FOCMA is detected serologically when cells expressing it react to immunoglobulins produced in cats that have regressed FeSV-induced fibrosarcoma or FeLV infection. The presence of FOCMA antibody is determined by the ability of the serum to react with FL74 cells, a transformed infected feline lymphocyte line.⁷⁰ Antibodies to FOCMA protect against neoplastic and myeloproliferative disease. Some FeLV vaccines contain FOCMA and elicit an anti-FOCMA response.⁷¹ The relative importance of this in preventing disease in vaccinates is unknown.

Neoplastic Diseases Caused by Feline Leukemia Virus

We have much to learn about the genetic basis for the vast diversity of tumor types produced by FeLV and its recombinants. We now know that FeLV, through one or another of its recombinants, may cause virtually any hematopoietic neoplasm in the cat. The only hematopoietic neoplasms not yet associated with FeLV in nature are mast cell leukemia, eosinophilic leukemia, plasma cell tumors, and polycythemia vera.³⁶

Although FeLV infection is considered the most significant infectious cause of morbidity and mortality in cats, only 20% of cats persistently infected with FeLV develop lymphoid cancer.^{72,73} The cat has the highest incidence of hematopoietic neoplasms of domestic animals, and the prevalence of lymphoma ranges from 44 to 200 cases per 100,000 cats, six times the rate of this disease in humans.³⁶ Twenty years ago, 70% of lymphomas in cats were believed to be caused by FeLV.

Some cancers are more commonly associated with FeLV infection than others. Large, granular lymphoma and globular leukocyte tumors usually test negative for FeLV,^{74,75} whereas 70% to 90% of cats with nonlymphoid hematopoietic neoplasia (myeloproliferative disease) test positive for FeLV.³⁶ The percentage of lymphomas that test positive for FeLV also varies, depending on the anatomic location of the tumor.⁷⁶⁻⁷⁸ Cats with spinal, mediastinal, ocular, and renal lymphoma frequently tested positive for FeLV prior to routine vaccination (more than 70%).⁷⁹ Extranodal sites such as lymphomas of the nasal cavity and the alimentary form of lymphoma frequently test negative for FeLV infection.³⁶ Over the past 20 years, the multicentric FeLV-positive form has declined in young cats, and the FeLV-negative alimentary form in older cats has increased.⁸⁰⁻⁸² Although the alimentary form most often is FeLV negative, as assessed by IFA and ELISA testing, some of these lesions have been shown by PCR to be FeLV positive, which suggests that the disease may be related to previous FeLV exposure.

Although not all lymphomas are caused by FeLV, the relative risk of developing lymphoma is 62 times higher in FeLV-positive cats, and cats that are FeLV negative but that have had previous exposure to FeLV have a fortyfold increase in the risk of developing lymphoma.⁸³ Most spontaneous lymphomas of cats that test positive for FeLV arise from T cells, whereas FeLV-negative lymphoma frequently is of alimentary or B-cell origin.^{84,85} The time from infection to tumor development varies and may depend on the age at which the cat is infected or on other factors, such as strain, anatomic location, and viral subgroup.³⁶ The range from the time of experimental infection to tumor production is 1 to 23 months (mean, 5.3 months).^{86,87} The younger the cat when infected with FeLV, the shorter the time to the development of neoplastic disease.

Some cats infected with FeLV die of immunosuppressive disease before tumors have a chance to develop.

Treatment of Feline Leukemia Virus Infections

Although no effective treatment exists to eliminate established FeLV infection in cats, a variety of antiviral and biologic response modifiers have been used to manage retroviral infections in cats and humans. The mainstay of therapy for cats infected with FeLV or other retroviruses is supportive care.⁸⁸⁻⁹⁰ Maintaining hydration and nutritional status not only prolongs life but also enhances the patient's quality of life. The cat should be kept in a humid environment to reduce the chance of water loss. Appetite stimulants and placement of gastrostomy tubes may facilitate nutritional therapy. The cat's requirement for B vitamins is eight times that of the dog, and dietary concentrations must be maintained to maintain appetite. Semimoist cat foods often contain propylene glycol, which can shorten red blood cell survival. These foods, although often quite palatable, should not be used for the nutritional management of cats infected with FeLV.⁸⁹ Many cats with FeLV are anemic, but administering erythropoietin is not helpful because endogenous erythropoietin levels usually are 20 times normal.⁹¹

Biologic-Response Modifiers

A variety of biologic-response modifiers (BRMs) has been used in cats infected with FeLV,⁹²⁻¹⁰⁰ but none has shown benefit in controlled trials. A few of the most popular are discussed here.

Interferons have been studied extensively for the management of FeLV infection, but the results have been mixed. In one study, oral and parenteral doses of either human recombinant interferon- α or bovine interferon failed to alter the viremia or result in clinical improvement. However, some uncontrolled studies have shown improvement in the clinical status of cats treated with oral interferon- α .⁹⁹ Controlled trials are needed to establish the true efficacy of these products. Orally administered interferon probably is inactivated by gastric acid in the stomach. Parenterally administered interferons from other species (i.e., bovine and human) are likely to have temporary activity because of the production of neutralizing antibodies.

Carrisyn (Acemannan) is a BRM designed to enhance macrophage phagocytosis and cell killing. Viremic cats treated with carrisyn have been reported to improve clinically; however, the studies reporting these results have not been well controlled, and the observed benefit may be due to the natural waxing and waning clinical course commonly observed in FeLV-positive cats.¹⁰⁰

Lymphocyte T-cell immunomodulator (LTCI) has recently become commercially available for the treatment of cats infected with FeLV and FIV. The true efficacy of this product, if any, awaits the results of controlled trials in cats.¹⁰¹

The apparent positive effect of many of the BRMs, which, in fact, may be due to the anabolic effect observed with some of these cytokines, is thought to be based on endorphin release rather than a direct effect on the viral infection.

Reverse Transcriptase Inhibitors

Drugs that inhibit RT and retrovirus integration into the host cell have been evaluated for their potential use in the treatment of FeLV-positive cats. The drugs evaluated include suramin (a polyionic dye used to treat filariasis in humans), nucleoside analogs (AZT, DDC, DDA, and PNEA), glucose homopolymers, dextran sulfate, phosphonate, and others.¹⁰²⁻¹⁰⁵ More detailed descriptions of these therapies are provided elsewhere.^{102,105} In general, most of these agents have shown efficacy *in vitro* against FeLV, the human

immunodeficiency virus (HIV), and in some cases, FIV. Most of these drugs result in some reduction in viremia *in vivo*, but none are capable of reversing established viremia, although some may prevent viremia if administered prophylactically. Most of these drugs cause significant toxicities at the dosages needed to produce antiviral effects and therefore have not gained popularity in clinical practice. AZT (zidovudine) is the most widely studied RT inhibitor.¹⁰⁶ AZT inhibits FeLV reverse transcriptase when administered at a dosage of 10 to 20 mg/kg in daily divided doses. AZT prevents viremia if given within 72 hours of exposure to FeLV. The antiviral effects of AZT appear to be synergistic with interferon.^{107,108} Reversal of established experimental FeLV viremia through adoption transfer of lectin/IL-2-activated lymphocytes, interferon- α , and AZT has been reported.

Prevention and Control

The most effective means of preventing FeLV infection is to eliminate contact with viremic cats. The test and removal program is the most effective means of controlling FeLV in multiple-cat households.¹⁰⁹ The program consists of closing the household or cattery to new cats, testing the remaining cats every 3 months, and removing all animals that test positive. When all cats test negative for two consecutive sessions, the facility is determined to be FeLV free. New cats may enter the household or facility only after a 3-month quarantine and two negative FeLV tests. The test and removal system has been shown to reduce the incidence of FeLV in a variety of settings and geographic locations.¹⁰⁹

Prevention by Vaccination

Vaccinations help control or eliminate many infectious diseases in veterinary medicine. The first commercial FeLV vaccine was introduced in 1985. Since then, seven FeLV vaccine products from six companies have been licensed for sale to veterinarians in the United States. Despite the fact that FeLV vaccines have been available for a decade, a survey of US veterinary teaching hospitals in 1991 found that only two of the 22 teaching hospitals considered FeLV vaccination to be part of their routine feline preventive medicine program.¹¹⁰ The principal concern has been the perceived lack of efficacy of the FeLV vaccines. Some studies of available vaccines have reported efficacies ranging from 0 to 100%.¹¹¹ In addition to efficacy questions, it has been established that soft tissue sarcomas may develop after FeLV and rabies vaccination.¹¹²

FeLV vaccination issues are discussed elsewhere.⁷¹ However, several comments regarding FeLV vaccines should help practitioners decide whether to use FeLV vaccines in their practice. FeLV vaccines may contain two or three subgroup antigens. Because only subgroup A is transmitted contagiously between cats, vaccines need only to contain subgroup A. Their primary means of protecting against tumor development is preventing persistent viremia. If a vaccine protects against persistent FeLV infection, it need not contain FOCMA. The value of FOCMA in FeLV vaccines has yet to be proved. Vaccines should protect against a variety of strains of subgroup A, and none of the available vaccines contain more than one strain of subgroup A. Differences in published comparative studies of vaccine efficacy probably are related to differences in vaccine strains and to the challenge strains used. Vaccines that contain adjuvants enhance immunity but at the expense of producing local inflammatory reactions at the injection site.¹¹³ These local reactions may lead to the development of soft tissue sarcomas. However, the development of soft tissue sarcomas after vaccination, either with rabies or FeLV vaccines, is thought to occur in only 1 in 1000 to 1 in 10,000 vaccinates.¹¹² Nonadjuvanted FeLV vaccines

have shown little or no inflammatory reaction 21 days after administration.¹¹³ A canarypox-vectored FeLV nonadjuvanted vaccine is available that stimulates both cellular and humoral immunity without significant injection site inflammation. Clinical discretion should be used when recommending FeLV vaccines.

The American Association of Feline Practitioners (AAFP) does not consider FeLV vaccine a core vaccine, and only cats at significant risk should be vaccinated. Cats under 12 weeks of age have an 85% chance of becoming persistently infected, whereas cats over 6 months of age have only a 15% chance of becoming persistently infected after challenge. Age-acquired immunity of adult cats is associated with improved macrophage function and reduced viral receptors on target tissues. Annual vaccination of adult cats also appears to be a questionable practice, given age-acquired immunity and the risk of vaccine-associated sarcomas.

Feline Sarcoma Virus

FeSVs are true hybrids that result from the rare recombination of FeLV DNA provirus with cat proto-oncogenes. Cats have at least 30 proto-oncogenes.^{36,114,115} Proto-oncogenes have many biologic functions; when they are altered and activated inappropriately, they are called *oncogenes*, which can play a key role in the development of cancerous phenotypes. Proto-oncogenes can be activated by mutations that produce chromosomal translocations such as those that may be associated with inflammation and vaccine-associated sarcomas, or by incorporation into a retrovirus, such as FeLV.¹¹⁴⁻¹¹⁶ When FeLV-derived DNA inserts near a proto-oncogene and takes up the proto-oncogene into the FeLV provirus, formation of FeSV results. In the process, part of the FeLV GAG gene, most of the FeLV envelope gene, and all of the pole genes are lost.¹¹⁵ The loss of these vital components makes FeSV dependent on FeLV as a helper virus for replication. Cats that have FeSV always test FeLV positive. Because several different recombinations may recur with several different proto-oncogenes, each recombination is a unique event, and each isolate is distinct.¹¹⁶ Despite this phenotypic heterogeneity, the recombinations transform fibroblasts, and all produce fibrosarcomas.

Natural transmission of FeSV between cats has not been described, and as with other FeLV recombinants (e.g., FeLV-B), transmission of the recombinant product is not thought to occur in nature. Some cats are capable of rejecting transformed cells and producing FOCMA antibody.^{90,91} FOCMA is important in the experimental response of cats to FeSV because it has been associated with tumor regression and failure to develop tumors.^{117,118} Cats that fail to develop antibodies against FOCMA die quickly of fast-growing sarcomas.¹¹⁹

Clinical Features of Feline Sarcoma Virus and Induced Fibrosarcomas

Only 2% of fibrosarcomas of cats are virally induced.⁴² In contrast to the solitary, slow-growing, nonvirally induced sarcomas seen in older cats, FeSV-induced tumors are multicentric and are found most frequently in young cats.¹²⁰ They are characterized by rapid growth, including doubling times as short as 12 to 72 hours.³⁶ This rapid growth often is accompanied by superficial ulceration. Lesions frequently occur at sites of previous bite wounds.³⁶ Metastasis to the lungs or other organs occurs with approximately 30% of virally induced fibrosarcomas in cats. Hypercalcemia was observed in association with multicentric fibrosarcomas in one cat with FeSV.³⁶ Virally induced fibrosarcomas are always FeLV positive; this helps differentiate them from vaccine-associated sarcomas, which have growth characteristics similar to those of virally

induced tumors. Cats with multicentric FeSV-induced tumors have a very poor prognosis. Doxorubicin, vincristine, vinblastine, lomustine (CCNU), and radiotherapy have been used to treat vaccine-associated sarcomas in the cat.¹²¹ Although radiotherapy often is used in combination with surgery, recurrence both within and outside the treatment fields is common.

Feline Immunodeficiency Virus

FIV, which is classified as a retrovirus in the subfamily Lentivirinae, is distinct from other retroviruses that infect cats. Like other retroviruses, FIV is an enveloped, single-stranded RNA virus in which the RNA is copied into the DNA in the infected host by RT in the virus.

The nucleotide sequence of several FIV isolates has been determined, and genetic homology falls between 36% and 97%. Despite this homology, significant differences in pathogenicity and infectivity exists between FIV strains.^{122,123} Although lentiviruses are known to infect wild felids, they are antigenically distinct from domestic cat isolates; they also are well adapted to their host and seldom cause clinical disease.

Transmission

FIV is present in all bodily fluids of infected cats, similar to FeLV, but at much lower concentrations. FIV is mainly cell associated and is present in relatively low concentrations in the blood, although high amounts can be found in the saliva.^{124,125} FIV is not thought to be very infectious and is mainly transmitted through biting during cat fights.^{126,127}

Feline Immunodeficiency Virus–Associated Neoplasms

The prevalence of neoplasms in FIV-positive cats ranges from 1% to 62%.^{83,128,129} Lymphomas and myeloid tumors (myelogenous leukemia, myeloproliferative disease) and a few carcinomas and sarcomas are the neoplasms most commonly linked to FIV infection. One study found that cats infected with FIV and FeLV are 5.6 times more likely to develop lymphoma or leukemia than if they had been infected with either virus alone. Cats with combined infections had a 77.3% greater likelihood of developing lymphoma or leukemia than noninfected cats.⁸³ Lymphoreticular neoplasms have been linked to HIV infection in humans and simian immunodeficiency virus (SIV) infection in nonhuman primates. In contrast to FeLV-associated lymphomas, FIV-associated lymphomas most often develop in extranodal sites and occur in older cats (mean age, 8.7 years).⁸³ Myeloproliferative disease also has been observed in cats naturally and in cats experimentally infected with FIV.^{83,130,131}

Although lentiviruses such as FIV have not been thought to be oncogenic in themselves, they are markedly immunosuppressive and affect normal immunosurveillance of cancerous cells. FIV-positive cats with lymphoma have extremely low CD4 lymphocyte counts.¹²¹ SCCs of the skin have been linked to FIV infection in two geographic areas, California and Colorado, but this association is believed to be due to a co-risk behavior (outdoor cats) rather than to any direct viral contribution to tumor development.^{132,133} Other reports have linked FIV infection to oral SCC, mammary carcinoma, fibrosarcoma, myeloproliferative disease, and histiocytic mast cell disease.^{128,134,135} The nature of these associations awaits further investigation.

Treatment

The same treatment considerations in the management of cats with FeLV can be applied to the treatment of FIV-positive cats. The most

widely applied treatments have been the RT inhibitors and interferon (see the earlier discussion on the treatment of FeLV). As in the treatment of FeLV, FIV-positive cats remain positive despite these therapies. A single inactivated FIV vaccine has been licensed for use in domestic cats. However, this is an adjuvanted vaccine, and it may be associated with an increased risk of vaccine-associated sarcoma. The primary concern with the vaccine is that it generates antibodies that cross-react with the currently recommended antibody-based diagnostic test for FIV infection. PCR-based tests are not currently considered reliable for diagnosis of FIV, and antibody-based testing remains the gold standard. It is important to note that the AAEP does not recommend the use of an FIV vaccine in domestic cats.

Comparative Aspects

The association between human viruses and certain cancers has been established on the basis of epidemiologic, clinical, and molecular studies.¹ Human T-cell leukemia virus (HTLV-1) has been linked to adult T-cell leukemia. The human papillomavirus (HPV) is associated with cervical cancer. The Epstein-Barr virus (EBV) is related to the development of Burkitt's lymphoma and nasopharyngeal carcinoma, and human hepatitis B and C viruses are associated with hepatocellular carcinoma. The human herpes virus (HHV) is implicated in the development of Kaposi's sarcoma.

Tumor Biology and Metastasis

David J. Argyle and Chand Khanna

Cells of multicellular organisms form part of a specialized society that cooperate to promote survival of the organism. In this society, cell division, proliferation, and differentiation are strictly controlled and a balance exists between normal cell birth and the natural cell death rate.¹ Derangement of these normal homeostatic mechanisms can lead to uncontrolled proliferation or loss of the ability to die, leading to a normal cell taking on a malignant phenotype.

Cancer in animals is well documented throughout history but has taken on significance over the past hundred years for a number of reasons. Studies on chicken, feline, and bovine retroviruses have made significant contributions to our overall understanding of carcinogenesis through the discovery of oncogenes and tumor suppressor genes.² Further contributions to our understanding of viral oncogenesis have come from studies of the DNA papilloma viruses in cattle and horses, complementing research into cervical cancer in women.³⁻¹⁰ This complementary cancer research has paved the way for the development of programs of research in comparative medicine that has benefits for both humans and the veterinary species. In this chapter we summarize the current understanding of the molecular mechanisms of cancer development and metastasis.

Normal Cell Division

Within an animal, all cells are subject to wear and tear, making cellular reproduction a necessity for maintenance of the individual. Reproduction of the gametes occurs by the process of meiosis, whereas reproduction of somatic cells involves two sequential phases known as *mitosis* and *cytokinesis*. Mitosis is nuclear division, and cytokinesis involves the division of the cytoplasm, the two occurring in close succession. Nuclear division is preceded by a doubling of the genetic material of the cell during a period known as interphase. As well as a copying of the chromosomes, this period is characterized by marked cellular activity in terms of RNA, protein and lipid production. The alternation between mitosis and interphase in all tissues is often referred to as the *cell cycle*. The phases of the cell cycle are shown in Figure 2-1.

Interphase (G1, G2, and S phases) is the longest phase of the cell cycle. During interphase, the chromatin is very long and slender; however, it shortens and thickens as interphase progresses. The first phase of mitosis is referred to as *prophase* and sees the first appearance of the chromosomes. As the phase progresses, the chromosomes appear as two identical sister chromatids joined at the centromere. As the nuclear membrane disappears, spindle fibers form and radiate from the two centrioles, each located at opposite poles of the cell. The spindle fibers serve to pull the chromosomes to opposite sides of the cell.

During *metaphase*, the spindle fibers pull the centromeres of the chromosomes, which become aligned to the middle of the spindle,

often referred to as the *equatorial plate*. During *anaphase*, the centromeres split and the sister chromatids are pulled apart by the contraction of the spindle fibers. The final stage of cell division is *telophase*, characterized by the formation of a nuclear membrane around each group of chromosomes, is followed by cytokinesis or separation of the cytoplasm to produce two identical diploid cells. Progression through the cell cycle lasts approximately 12 to 24 hours.

The Cell Cycle

The cell cycle comprises four phases (M phase, S phase, G1, and G2) (see Figure 2-1). Nonproliferating cells are usually arrested between the M (mitosis) and S (DNA synthesis) phases and are referred to as G0 cells. The majority of cells in normal tissues are in G0. Cells are stimulated to enter the cell cycle in response to external factors including growth factors and cell adhesion. During the G1 phase of the cell cycle, cells are responsive to mitogenic signals. Once the cell cycle has traversed the restriction point (R) in the G1 phase, cell cycle transitions become autonomous.

Progression through the cell cycle is mediated by the sequential activation and inactivation of a class of proteins called *cyclin-dependent kinases* (CDKs).^{11,12} CDKs consist of an inactive conserved catalytic core and are regulated at the following three levels:

1. CDK activity requires the association with regulatory subunits known as *cyclins*. The level of CDK remains constant throughout the cell cycle; however, the concentration of cyclins varies in a phase-specific manner during the cell cycle. The periodic synthesis and destruction of cyclins provides the primary level of cell cycle control (see Figure 2-1).
2. The activity of cyclin/CDK complexes is also regulated by phosphorylation. Activation of CDK/cyclin complexes requires phosphorylation by CDK-activating kinases (CAK); meanwhile the phosphorylation at threonine and serine residues suppresses activity.
3. CDKs are also tightly regulated by a class of inhibitory proteins known as CDK inhibitors (CDKI). CDKIs can block G1/S progression by binding CDKs/cyclin complexes and can be classified into the following two groups:
 - a. INK4A family (p15^{INK4b}, p16^{INK4a}, p18^{INK4c} and p19^{INK4d}). These act primarily on cdk4 and cdk6 complexes and prevent the association with cyclin D (see later discussion).
 - b. CIP/KIP family (p21^{Cip1}, p27^{Kip1}, and p57^{Kip2}). These are less specific and can inactivate various cyclin/CDK complexes.

The first class of proteins induced in G1 following mitogenic stimulation of the cell cycle is the class D cyclins, which in turn activate CDK4 and CDK6. Cyclin D-CDK complexes cause phosphorylation of the substrate retinoblastoma protein (Rb), which results in dissociation of the transcription factor E2F from the Rb protein. The phosphorylation status of Rb plays a critical role in

• **FIGURE 2-1** The cell cycle and its control. The cell cycle is divided into four phases (G1, S, G2, and M) and G0, which represents cycle-arrested cells. Cells are stimulated to enter the cell cycle in response to external factors, including growth factors and cell adhesion molecules. During G1, cells are responsive to mitogenic signals. Once the cell cycle has traversed the restriction point (R) in the G1 phase, the cell-cycle transitions become autonomous. Progression through the cell cycle is mediated by the sequential activation and inactivation of the cyclin-dependent kinases (CDKs). Control of CDK activity is through their interaction with specific cyclins (D, E, A, B) and with specific CDK inhibitors.

regulating G1 progression, and Rb is the molecular device that serves as the R point switch. Phosphorylated Rb releases E2F enabling transcription of numerous E2 responsive genes involved in DNA synthesis, and unphosphorylated Rb remains associated with E2F, thereby inhibiting cell cycle progression. During G1 progression, activation of E2F also leads to induction of cyclin E. Cyclin E associates with CDK2 and the cyclin E-CDK2 complex maintains Rb in the phosphorylated state and is essential for cells to enter the S phase of cell cycle. At the G1/S phase transition, E2F induces cyclin A. During early S phase, cyclin D and E are degraded and cyclin A associates with CDK2 and CDK1; this kinase activity is essential for entry into S phase, completion of S phase, and entry into M phase. Mitosis is regulated by CDK1 in association with cyclins A and B causing phosphorylation of cytoskeletal proteins, including histones and lamins. This tight regulation on cell cycle progression prevents uncontrolled passage of normal cells through the cell cycle. The corollary of this is that loss of these control mechanisms can be a driving event in the development of cancer.

Cellular Responses to DNA Damage

When normal cells are subjected to stress signals, radiation, DNA damage, or oxygen depletion, the majority of cells have the ability to cause cell cycle arrest in G1, S, and G2 or enter programmed cell death (apoptosis) or both. Within cells, numerous surveillance systems called *checkpoints* function to recognize and respond to DNA damage. Cell cycle checkpoints occur in the G1 phase in response to DNA damage, during S phase to monitor the quality of DNA replication and the occurrence of DNA damage, and during

the G2/M phase to examine the status of the spindle. The DNA damage-induced checkpoint mediated by the tumor suppressor protein p53 is the most well studied. The p53 protein plays an important role in maintaining genomic stability and forms part of a stress response pathway to various exogenous and endogenous DNA damage signals, including gamma irradiation, ultraviolet (UV) irradiation, chemicals, and oxidative stress.

p53 Functions as a Genomic Guardian

The p53 response to stress may be mediated by DNA-dependent protein kinase (DNA-PK) or by the ATM kinase and leads to phosphorylation of the N terminus of p53. In normal cells, p53 is short lived; however, phosphorylated p53 is stabilized and can then function as a transcriptional regulator binding to sequences and transactivating a number of genes, including p21.^{13,14} p21 has a high affinity for G1 CDK/cyclin complexes and acts as a CDKI inhibiting kinase activity, thereby arresting cells in G1. By holding cells in G1, the replication of damaged DNA is prevented, and the cell's own DNA repair machinery has the opportunity to repair damage prior to reentering the active growth cycle (Figure 2-2).

The cellular levels of p53 protein are regulated by the product of another gene MDM2 (mouse double minute 2 oncogene).¹⁵ The principal role of MDM2 is to act as a negative regulator of p53 function. One mechanism for MDM2 to downregulate p53 is to target p53 for degradation. The p53 protein is maintained in normal cells as an unstable protein, and its interaction with MDM2 can target p53 for degradation via a ubiquitin proteasome pathway. MDM2 can also control p53 function by suppressing p53 transcriptional activity. MDM2 is a transcriptional target of p53, and expression is induced by the binding of p53 to an internal promoter within the *mdm2* gene. MDM2 can in turn bind to a domain within the

• **FIGURE 2-2** p53 is involved in cell cycle control. The p53 response to stress may be mediated by DNA-dependent protein kinase (DNA-PK) or by the ATM kinase and leads to phosphorylation of the N terminus of p53. In normal cells, p53 is short lived; however, phosphorylated p53 is stabilized and can then function as a transcriptional regulator binding to sequences and transactivating a number of genes, including p21 and Bax. Consequently, the cell cycle is arrested or the cell undergoes programmed cell death (apoptosis). This is a defense mechanism that allows for repair or death (if the cell is irreversibly damaged). The cellular levels of p53 protein are regulated by the product of another gene mouse double minute 2 oncogene (MDM2). The principal role of MDM2 is to act as a negative regulator of p53 function. One mechanism for MDM2 to downregulate p53 is to target p53 for degradation. The p53 protein is maintained in normal cells as an unstable protein, and its interaction with p53 can target p53 for degradation via a ubiquitin proteasome pathway. MDM2 can also control p53 function by suppressing p53 transcriptional activity. MDM2 is a transcriptional target of p53, and expression is induced by the binding of p53 to an internal promoter within the MDM2 gene. MDM2 can in turn bind to a domain within the amino terminus of p53, thereby inhibiting the transcriptional activity and G₁ arrest function of p53 by masking access to the transcriptional machinery.

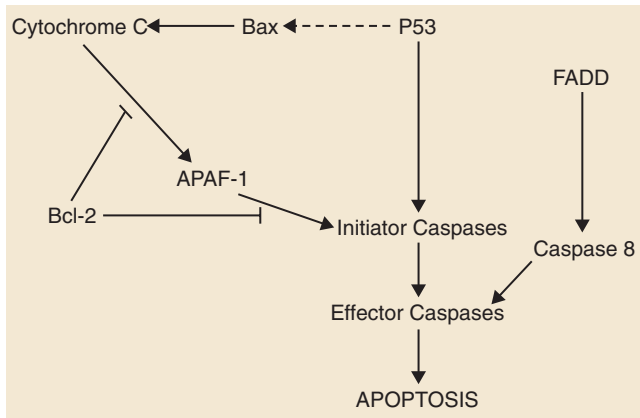

amino terminus of p53, thereby inhibiting the transcriptional activity and G₁ arrest function of p53 by masking access to the transcriptional machinery (see Figure 2-2).¹⁶

Cell Death

In contrast to necrosis, apoptosis is a distinct type of cell death most often characterized as the “programmed” self-destruction of cells that occurs in disease states, as well as part of the normal physiologic cell turnover. Whereas necrosis is characterized by swelling of the cell and lysis, in apoptosis there is cellular and nuclear shrinkage followed by fragmentation and subsequent phagocytosis. These morphologic features of apoptosis result from a number of apoptosis effectors (i.e., caspases) and regulators (particularly the Bcl-2 protein family). The molecular mechanisms involved in apoptosis are shown in Figure 2-3.^{17,18} Apoptosis provides a controlled mechanism for eliminating cells that are irreversibly damaged and involves an adenosine triphosphate (ATP)-dependent activation of cellular pathways, which move calcium from the endoplasmic reticulum to the cytoplasm and activation of endonucleases. As noted previously, some of these pathways are mediated through caspases. However,

a wide variety of signals can initiate an apoptotic response, including Fas ligand (CD95 or FasL) and its interaction with the Fas receptor, tumor necrosis factor (TNF) and its receptor interaction, and certain oncogenes. The Fas and TNF receptors are members of the death receptor family. These transmembrane proteins with cysteine rich extracellular domains and intracellular regions share a common structure termed the “death domain.” The proapoptotic ligands for these receptors are homotrimeric peptides that are either soluble or expressed at the surface of the adjacent cell. Ligand-induced receptor clustering promotes the binding of a soluble cytosolic adapter protein called *Fas-associated death domain* (FADD), which itself contains a death domain as well as a caspase binding site, to the clustered death domains of the receptors. This leads to activation of caspase 8 and downstream activation of effector caspases for apoptosis.

Where cells are damaged and are unable to repair DNA, p53 expression can upregulate p21 and cause cell cycle arrest or can aid in directing the cell into programmed death or apoptosis through upregulation and expression of Bax (a proapoptotic Bcl-2 family protein) and also through priming of caspases. In this, the

• **FIGURE 2-3** The mediators of apoptosis. A wide variety of signals can initiate an apoptotic response, including Fas ligand (CD95 or FasL) and its interaction with the Fas receptor, tumor necrosis factor (TNF) and its receptor interaction, and certain oncogenes. The Fas and TNF receptors are members of the death receptor family. These are transmembrane proteins with cysteine rich extracellular domains and intracellular regions that share a common structure termed the *death domain*. The proapoptotic ligands for these receptors are homotrimeric peptides that are either soluble or expressed at the surface of the adjacent cell. Ligand-induced receptor clustering promotes the binding of a soluble cytosolic adapter protein called *Fas-associated death domain* (FADD), which itself contains a death domain, as well as a caspase binding site, to the clustered death domains of the receptors. This leads to activation of caspase 8 and downstream activation of effector caspases for apoptosis.

expression of p53 can also downregulate expression of the Bcl2 gene itself (a prosurvival, negative regulator of apoptosis).

Summary

The cell cycle ensures a regulated process so that each cell can complete DNA replication before cell division occurs. The cell responds to growth and environmental signals through the cell cycle. Components of the cell cycle that have a stimulatory effect include the cyclins and the CDKs. The negative influences come from a series of checkpoints that respond to external stimuli. These include tumor suppressor genes such as p53 and Rb and also genes involved in DNA repair. The process of DNA replication is also subject to the introduction of errors, and this is closely monitored by a class of enzymes called *DNA repair enzymes*. Consequently, there are a number of safeguards within the cell cycle to ensure that normal cells are produced during division and that the DNA is accurately replicated. The next section will describe how these systems are overcome to produce a malignant cancer cell.

From Normal Cell to Cancer Cell

It is difficult to define a cancer cell in absolute terms. Tumors are usually phenotypically recognized by the fact that their cells show abnormal growth patterns and are no longer under the control of normal homeostatic growth controlling mechanisms, including apoptosis. Although the range of mechanisms involved in the development of tumors and the spectrum of tissues from which tumors are derived is diverse, they can be classified into the following three broad types:

- **Benign tumors:** Broadly speaking, these tumors arise in any of the tissues of the body and grow locally. Their clinical significance is the ability to cause local pressure, cause obstruction, or form a space-occupying lesion, such as a benign brain tumor. Benign tumors do not metastasize.
- **In-situ tumors:** These are often small tumors that arise in the epithelium. Histologically, the lesion appears to contain cancer cells, but the tumor remains in the epithelial layer and does not invade the basement membrane or the supporting mesenchyme. A typical example of this is preinvasive squamous cell carcinoma (SCC) affecting the skin of cats, which is often referred to as *Bowen's disease*.
- **Cancer:** This refers to a malignant tumor that has the capacity for both local invasion and distant spread by the process of metastasis.

Multistep Carcinogenesis

Cancer is the phenotypic end result of a whole series of changes that may have taken a long period of time to develop. Indeed, recent studies that have sequenced the genome of pancreatic and brain tumors have identified 63 and 60 genetic alterations on average in each cancer, respectively. From this large list of genetic alterations, there are a small number of commonly mutated genes that are “drivers” of the cancer phenotype.^{19,20}

The application of a cancer-producing agent (carcinogen) to tissues does not lead to the immediate production of a cancer cell. After the initiation step produced by the agent, there follows a period of tumor promotion. This promotion may be caused by the same initiating agent or by other substances, such as normal growth promoters or hormones. The initiating step is a rapid step and affects the genetic material of the cell. If the cell does not repair this damage, then promoting factors may progress the cell toward a malignant phenotype. In contrast to initiation, progression may be a very slow process and may not even manifest in the lifetime of the animal. Each stage of multistep carcinogenesis reflects genetic changes in the cell with a selection advantage that drives the progression toward a highly malignant cell. The age-dependent incidence of cancer suggests a requirement for between four and seven rate-limiting, stochastic events to produce the malignant phenotype.²¹

These sequential events in tumor formation are a consequence of changes at the genetic level. Over the past 25 years, cancer research has generated a rich and complex body of information revealing that cancer is a disease involving dynamic changes in the genome. Seminal to our understanding of cancer biology has been the discovery of the so-called *cancer genes* or *oncogenes* and *tumor suppressor genes*. Mutations that produce oncogenes with dominant gain of function and tumor suppressor genes with recessive loss of function have been identified through their alteration in human and animal cancer cells and by their elicitation of cancer phenotypes in experimental models.

Oncogenes

The RNA tumor viruses (retroviruses) provided the first evidence that genetic factors play a role in the development of cancer. The initial observation came in 1910 when Rous demonstrated that a filterable agent (later classified as a retrovirus and termed *avian leukosis virus*) was capable of producing lymphoid tumors in chickens.²² Retroviruses have three core genes (*gag*, *pol*, and *env*) and an additional gene that gives the virus the ability to transform cells. Retroviral sequences that are responsible for transforming properties are called *viral oncogenes* (v-onc). The names of these genes are

• **TABLE 2-1** Functional Classification of Tumor Oncogenes

ONCOGENE	NAME	ABBREVIATION
Growth factors	Platelet-derived growth factor	PDGF
	Epidermal growth factor	EGF
	Insulin-like growth factor-1	ILGF-1
	Vascular endothelial growth factor	VEGF
	Transforming growth factor- β	TGF- β
	Interleukin-2	IL-2
Growth factor receptors	PDGF receptor	PDGFR
	EGF receptor	EGFR, erbB-1
	ILGF-1 receptor	ILGF-1R
	VEGF receptor	VEGFR
	IL-2 receptor	IL-2R
	Hepatocyte growth factor receptor	met
	Heregulin receptor	neu/erbB-2
	Stem cell factor receptor	Kit
Protein kinases	Tyrosine kinase	bcr-abl
	Tyrosine kinase	src
	Serine-threonine kinase	raf/mil
	Serine-threonine kinase	mos
G-protein signal transducers	GTPase	H- <i>ras</i>
	GTPase	K- <i>ras</i>
	GTPase	N- <i>ras</i>

	Transcription factor	jun
	Transcription factor	myb
	Transcription factor	myc
	Transcription factor	rel

GTPase, Guanosine triphosphatase.

derived from the tumors in which they were first described (e.g., *v-ras* from rat sarcoma virus).

Viral oncogenes were subsequently shown to have cellular homologues called *cellular oncogenes* (c-onc). Later, the term *proto-oncogene* was used to describe cellular oncogenes that do not have transforming potential to form tumors in their native state but can be altered to lead to malignancy.²³ Most proto-oncogenes are key genes involved in the control of cell growth and proliferation and their roles are complex. For simplicity, their sites and modes of action in the normal cell can be divided as follows (Table 2-1):

- Growth factors
- Growth factor receptors
- Protein kinases
- Signal transducers
- Nuclear proteins and transcription factors

Growth Factors

Growth factors are molecules that act on the cell via cell surface receptors. Their contribution to carcinogenesis may be through

excessive production of the growth factor or where a growth factor is expressed in a cell but does not normally function in that cell.

Growth Factor Receptors

Several proto-oncogene–derived proteins form a part of cell surface receptors for growth factors. The binding of ligand to receptor is the initial stage of delivery of mitogenic signals to cells. Their role in carcinogenesis may be through structural alterations in these proteins.

Protein Kinases

Protein kinases are associated with the inner surface of the plasma membrane and are involved in signal transduction following ligand-receptor binding. Structural changes in these genes and proteins lead to increased kinase activity that can have profound effects on signal transduction pathways.

Signal Transduction

The binding of an extracellular growth factor to the membrane receptor leads to a series of events by which the mitogenic signal is transduced to the nucleus of the cell. Essential to this signaling is the successive phosphorylation of signaling intermediaries or the second messengers such as guanosine triphosphate (GTP) and proteins that bind GTP (G-proteins). During signal transduction, GTP is converted to guanosine diphosphate (GDP) by the guanosine triphosphatase (GTPase) activity of G-proteins. A group of proto-oncogenes called *Ras* encode proteins with GTPase and GTP-binding activity and, in the normal cell, help to modulate cellular proliferation. Mutations in the *Ras* proto-oncogene can contribute to uncontrolled cellular proliferation.

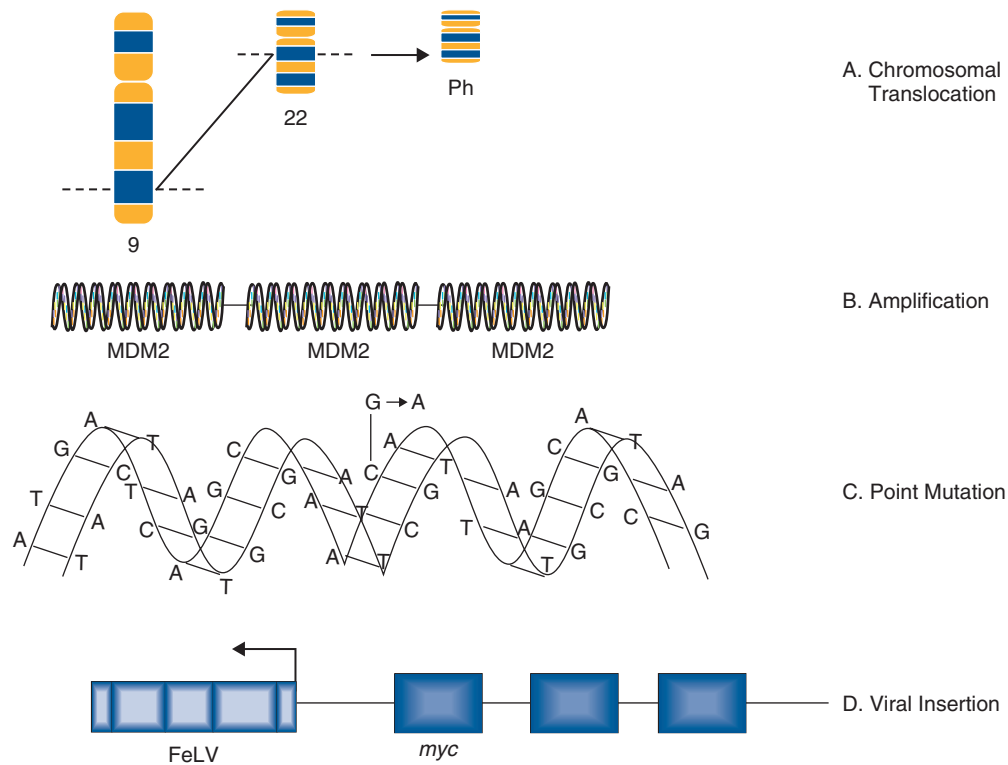

Nuclear Proteins and Transcription Factors

Nuclear proteins and transcription factors encode proteins that control gene expression. These proto-oncogenes may have a role in cellular proliferation. Not surprisingly, changes in transcription factor activity may contribute to the development of the malignant genotype.

Mechanisms by which Oncogenes Become Activated

The advent of recombinant DNA technology has allowed scientists to unravel a number of mechanisms by which the normal products of proto-oncogenes can be disrupted to produce uncontrolled cell division. The conversion of a proto-oncogene to an oncogene is a result of somatic events in the genetic material of the target tissue. The activated allele of the oncogene dominates the wild-type allele and results in a *dominant gain of function*. This means that only one allele needs to be affected to obtain phenotypic change; this is in contrast to tumor suppressor genes in which both alleles have to be lost for phenotypic change. The mechanisms of oncogene activation are outlined in the following list and are shown in Figure 2-4.²³⁻³⁰

- **Chromosomal translocation.** Where proto-oncogenes are translocated within the genome (i.e., from one chromosome to another), their function can be greatly altered. The classic example in human medicine is the chromosomal breakpoint that produces the Philadelphia chromosome found in chronic myelogenous leukemia (CML). This involves the translocation of the c-abl oncogene on chromosome 9 to a gene on chromosome 22 (bcr). The point at which two genes come together is referred to as a *chromosomal breakpoint* (or *translocation breakpoint*). The BCR/

• **FIGURE 2-4** Methods of oncogene activation. Oncogenes can be activated by chromosomal rearrangements (e.g., BCR/ABL-induced leukemia), gene amplification (e.g., amplification of MDM2 in some sarcomas), point mutations (e.g., changes in nucleotide sequence that alters protein production), or by viral insertions (e.g., the insertion of feline leukemia virus [FeLV] at the *myc* locus in FeLV-induced lymphomas).

ABL hybrid gene produces a novel transcript whose protein product has elevated tyrosine kinase activity and can contribute to uncontrolled cellular proliferation. Transgenic mice for this chimeric gene develop lymphoblastic leukemia and lymphoma. Since this gene product is directly linked to CML formation, it is a logical target for tyrosine kinase inhibitors in the treatment of chronic myeloid leukemia in humans (CML).

- **Gene amplification.** Quantitation of gene copy number is possible by a number of molecular techniques, including comparative genomic hybridization, genotyping arrays, and Southern hybridization. Amplification of oncogenes can occur in a number of tumor types and has been demonstrated in childhood neuroblastoma, where the *myc* proto-oncogene (nuclear transcription factor) is amplified up to 300 times. Gene amplification is possibly the most common mechanism of proto-oncogene activation. A further example is the MDM2 proto-oncogene, which has been identified in dogs and horses, and has recently shown to be amplified in a proportion of canine soft tissue sarcomas.³¹
- **Point mutations.** These are single base changes in the DNA sequence of proto-oncogenes leading to the production of abnormal proteins. Point mutations can arise through the actions of ionizing radiation, chemical carcinogens, or errors in DNA replication and repair. A mutation in a proto-oncogene or the transcriptional machinery that controls its expression may disrupt homeostasis and result in sustained proliferation signals or a failure to respond to negative feedback signals. A classical example is the Ras proto-oncogene in which point mutations are a consistent finding in a number of human tumors. K-ras mutations have also been identified in canine lung tumors. Mutations in the Erb-B (epidermal growth factor receptor) gene have been

shown in a number of human cancers to lead to ligand-independent activation. Erb-2 mutations have been identified in canine mammary tumors.

- **Viral insertions.** The discovery of oncogenes was a direct result of studies on tumor-causing viruses. In some circumstances, proto-oncogene function can be damaged by the insertion of viral elements. Occasionally, novel retroviruses are isolated from leukemias or sarcomas in animals that have been viremic with a leukemia virus for some time. These viruses induce tumors very rapidly when inoculated into members of the species of origin and are referred to as *acutely transforming oncoviruses*. The prototype of the acutely transforming virus is the Rous sarcoma virus (RSV) isolated from a fowl in 1911. Subsequently, many more have been isolated from animals infected with avian, feline, murine, or simian oncoviruses. These viruses are generated by a rare recombinatorial event between the leukemia virus with which the animal was originally infected and a cellular proto-oncogene. In this, part of the viral genome is deleted and replaced with the cellular oncogene. The virus then becomes acutely transforming because this oncogene is now under the transcriptional control of very efficient viral promoters. This then allows infection of a cell and insertion of this continuously expressed oncogene into the cellular genome leading toward rapid progression and malignancy. Evidence suggests that these acutely transforming viruses are not transmitted naturally, but all events occur in the individual animal. Because the virus has itself lost some of its own genetic material, it is defective for replication. However, they are spread throughout an animal by the provision of help from the normal leukemia virus, which provides the missing proteins in co-infected cells.

In addition to acutely transforming mechanisms, retroviruses can activate cellular oncogenes by integrating adjacent to them. A good example of this is the *myc* gene, which is frequently activated in feline T-cell lymphomas. In one mode, the virus integrates adjacent to the oncogene and transcription initiation in the viral long terminal repeat (LTR) proceeds into the adjacent oncogene, producing a hybrid mRNA. In a second form, the enhancer of the virus overrides the regulation of the *c-myc* transcription from its normal promoter.

Tumor Suppressor Genes

Changes in genes can lead to either stimulatory or inhibitory effects on cell growth and proliferation. The stimulatory effects are provided by the proto-oncogenes as described. Mutations or translocations of these genes produce positive signals leading to uncontrolled growth. In contrast, tumor formation can result from a loss of inhibitory functions associated with another class of cellular genes called the *tumor suppressor genes*. The discovery of these genes began by observations of inherited cancer syndromes in children, in particular studies of retinoblastoma. In the early 1970s, epidemiologic studies of both retinoblastoma and Wilms' tumor led Knudson to propose his "two hit" theory of tumorigenesis.

Retinoblastoma Forms the First Clues to the Existence of Tumor Suppressor Genes

Retinoblastoma occurs in two forms, a sporadic form and an inherited form (accounting for 40% of cases).³² In the inherited form, the mode of inheritance is autosomal dominant and about half the children are affected by the condition. Knudson's model required the retinoblastoma tumor cells (in either sporadic or inherited forms) to acquire two separate genetic changes in the DNA before tumor development. The first or predisposing event could be inherited through the germ line (familial retinoblastoma) or it could arise *de novo* in somatic cells (sporadic form). The second event occurred in somatic cells. Thus, in sporadic retinoblastoma, both events arose in the retinal cells. However, in familial retinoblastoma, the individual had already inherited one mutant gene and only required a second hit in the remaining normal gene in somatic cells.

The mode of inheritance of retinoblastoma is dominant with incomplete penetrance. However, at the cellular level, loss or inactivation of both alleles is required to change the cells' phenotype. The retinoblastoma gene codes for Rb, which was previously described as a normal cellular gene involved in control of the cell cycle. Rb is described as a tumor suppressor and, in a cell with only one normal allele, that allele usually produces enough tumor suppressor product to remain normal. Generically, mutations in tumor suppressor genes behave very differently from oncogene mutations. Whereas activating oncogene mutations are dominant to wild type (they emit their proliferating signals regardless of the wild-type gene product), suppressor mutations are recessive. Mutation in one gene copy usually has no effect, as long as a reasonable amount of wild-type protein remains. Consequently, some texts refer to tumor suppressor genes as recessive oncogenes.

More recently, Knudson's hypothesis was confirmed when the Rb gene was cloned and characterized. The retinoblastoma tumor suppressor Rb is the principal member of a family of proteins that also encompass pRb2/p130 and p107. Rb plays a central role in regulating cell cycle progression in G1. Indeed, disruption of Rb function has been found to be a common feature of many human cancers not only retinoblastoma. Rb function can be abrogated by point mutations, deletions, or by complex formation with viral

oncoproteins such as SV40 large T antigen and adenoviral E1a protein. The function of additional proteins associated with the Rb pathway are also subjected to deregulation in human cancers, including overexpression of D type cyclins, overexpression of CDK4, and downregulation of the CDKI cell cycle inhibitor p16.

Although loss of cell cycle control via the Rb pathway occurs commonly in many human tumors, little is known about the role of Rb, cyclin D, CDK4, and p16 in domesticated animal tumors.

The p53 Tumor Suppressor Gene

P53 is a gene whose product is intimately involved in cell cycle control. Its discovery by Sir David Lane in 1979 marked a major milestone in cancer research and has allowed greater understanding of molecular mechanisms of cancer and identified potential targets for therapeutic intervention.

The p53 protein has been described as the guardian of the genome by virtue of its ability to push cells into arrest or apoptosis, depending on the degree of DNA damage. Thus the p53 tumor suppressor gene plays an important role in cell cycle progression, regulation of gene expression, and the cellular response mechanisms to DNA damage. Under normal physiologic conditions, wild-type p53 can bind specific DNA sequences and regulate transcription of a number of genes involved in cell cycle progression and apoptotic pathways including p21^{waf1/cip1} and bax (see Figure 2-2). The p53-mediated mechanisms are responsible for tumor suppression and prevent accumulation of potentially oncogenic mutations and genomic instability. Failure by p53 to activate such cellular functions may ultimately result in abnormal uncontrolled cell growth leading to tumorigenic transformation.³³⁻³⁶

p53 is the most frequently inactivated gene in human neoplasia, with functional loss commonly occurring through gene mutational events, including nonsense, missense and splice site mutations, allelic loss, rearrangements, and deletions. However, p53 function can also be abrogated by several nonmutational mechanisms, including nuclear exclusion, complex formation with a number of viral proteins, and through overexpression of the cellular oncogene MDM2.

The homologs of p53 and MDM2 have both been identified in domestic animal species and a number of studies indicate that this gene also has a central role in the progression of veterinary cancers.³⁷⁻⁴¹

Cancer Arises through Multiple Molecular Mechanisms

The advances in our understanding of normal cell biology and the processes that lead to malignancy have increased dramatically over the past 30 years. The last decade has shown us that transformation of a normal cell into a malignant cell requires very few molecular, biochemical, and cellular changes that can be considered as acquired capabilities.^{42,43} Further, despite the wide diversity of cancer types, these acquired capabilities appear to be common to all types of cancer. An optimistic view of increasing simplicity in cancer biology is further endorsed by the fact that all normal cells, irrespective of origin and phenotype, carry similar molecular machineries that regulate cell proliferation, differentiation, aging, and cell death.

We have discussed that tumorigenesis is a multistep process and that these steps reflect genetic alterations that drive the progression of a normal cell into a highly malignant cancer cell. This is supported by the finding that genomes of tumor cells are invariably altered at multiple sites. The spectrum of changes range from subtle

point mutations in growth regulatory genes to obvious changes in chromosomal complement.

Cancer cells have defects in regulatory circuits that govern cellular proliferation and homeostasis and survival. A model has been proposed that suggests that the vast array of genetic abnormalities associated with cancer are a manifestation of eight alterations in cellular physiology that collectively contribute to malignant growth. First proposed in 2000 and updated in 2011, these “hallmarks” of cancer constitute an organizing principle for rationalizing the complexities of cancer and are underpinned by two overarching themes: *genome instability* and *chronic inflammation*.^{42,43} The eight acquired characteristics can be summarized under the following headings (see Figure 1-3):

- Self-sufficient growth
- Insensitivity to antigrowth signals
- Evasion of programmed cell death (apoptosis)
- Limitless replicative potential
- Sustained angiogenesis
- Reprogramming energy metabolism
- Evading immune destruction
- Tissue invasion and metastasis

In addition, cancer exhibits another dimension of complexity in that they contain an array of “normal” cells that contribute to the acquisition and maintenance of the cancer hallmarks by creating the tumor microenvironment. The next section is an overview of these traits and the strategies by which they are acquired in cancer cells. The process of metastasis requires angiogenesis and invasion, as such the traits of sustained angiogenesis, and tissue invasion and metastasis will be collectively reviewed under a final section on metastasis.

The Hallmarks of Cancer

In the preceding section, we have described the normal cell and the role of oncogenes and tumor suppressor genes in cell cycle control and regulation. In one sense, cancer is a very common disease in animals and humans, but in fact the development of cancer is a rare event. When one considers the number of cells in the body, the proliferation and regulation of these cells and the potential for malignant transformation, then the development of a single cancer is rare. This is because of the cell's own natural defenses against progression toward the malignant phenotype. The ability of the cell to effect DNA repair or initiate cell death is a defense mechanism against malignant transformation and serves to maintain cellular homeostasis. Each of the acquired capabilities described previously represents a breach in a cell's homeostatic mechanisms. However, the biology of cancer cannot be understood by simply considering the phenotypic traits of the cancer cell. Rather the cancer phenotype is defined by the interactions between the cancer cell, the tumor microenvironment, and the enabling effects of fundamental genomic instability and chronic inflammation.

Self-Sufficiency in Growth Signals

Normal cells require mitogenic stimuli for growth and proliferation. These signals are transmitted to the nucleus by the binding of signaling molecules to specific receptors, the diffusion of growth factors into the cell, extracellular matrix components, or cell-to-cell adhesions or interactions. As previously discussed, many oncogenes act by mimicking normal growth signals. Tumor cells are not dependent on external mitogenic stimuli for proliferation and sustained growth but are self-sufficient. The liberation from dependency on exogenous signals severely disrupts normal cellular

homeostasis. Arguably, the most fundamental trait of cancer cells is their ability to sustain chronic proliferation. By deregulating these signals, cancer cells become masters of their own destinies, promoting signaling (typically through intracellular kinase domains) to promote progression through the cell cycle, increases in cell size, increases in cell survival, and changes in energy metabolism.

The cancer cell can acquire this capability in the following ways:

- They may produce growth factor ligands themselves.
- They may induce stromal cells to produce such ligands.
- There may be an increase in receptor concentration on the cell surface that leads to receptor homodimerization or heterodimerization, making the cell hyperresponsive to ligands.
- There may be structural alterations in the receptor to support ligand-independent firing.
- Constitutive activation of the signaling pathway (downstream of the receptor). A good example of this is the constitutive activation of the PI3-AKT pathway, through mutations in the catalytic subunit of the PI3 kinase.
- Disruptions in negative-feedback mechanisms that attenuate proliferative signaling, such as the following:
 - Mutations in the *Ras* gene compromise the Ras GTPase activity, which acts as a negative-feedback mechanism to ensure the effects of *Ras* are only transitory.
 - *PTEN* is a tumor suppressor protein that counteracts PI3 signaling. *PTEN* loss has a similar effect to constitutive PI3 activation and promotes tumorigenesis.

Although the acquisition of growth signaling autonomy by cancer cells is conceptually satisfying, it is in fact too simplistic. One of the major problems of cancer research is to focus on the cancer cell in isolation. It is now apparent that we must also consider the contribution of the tumor microenvironment to the survival of cancer cells. Within normal tissues, paracrine and endocrine signals contribute greatly to growth and proliferation. Cell-to-cell growth signaling is also likely to operate in cancer cells and may be as important as some of the autonomous mechanisms of tumor growth. It has recently been suggested that growth signals for the proliferation of carcinoma cells are derived from the tumor stromal elements (e.g., cancer or carcinoma-associated fibroblasts [CAFs]). It is therefore possible that the survival of tumor cells not only relies on the acquisition of growth signal autonomy but may also require the recruitment or modulation of stromal cells to provide these growth signals.

Insensitivity to Antigrowth Signals or Evading Growth Suppressors

Within the normal cell, multiple antiproliferative signals operate to maintain cellular quiescence and homeostasis. These signals include soluble growth inhibitors that act via cell surface receptors and immobilized inhibitors that are embedded in the extracellular matrix and on the surface of nearby cells. The signals operate to push the cell either into G0 or into a postmitotic state (usually associated with the acquisition of specific differentiation-associated characteristics) and are thus intimately associated with cell cycle control mechanisms. Cells monitor their external environment during the progression through G1 and, on the basis of external stimuli, decide whether to proliferate, become quiescent, or enter into a postmitotic state.

Most cellular programs that negatively regulate cell growth and proliferation depend on the actions of tumor suppressor genes. At the basic level, most of the antiproliferative signals are funneled through the Rb protein and its close relatives. Disruption of Rb

allows cell proliferation and renders the cell insensitive to antiproliferative signals such as that provided by the well-characterized transforming growth factor- β (TGF- β).³² The Rb protein integrates signals from diverse extracellular and intracellular sources and can control cell cycle progression. The other major tumor suppressor is p53, which integrates intracellular signals and can promote either cell cycle arrest or apoptosis (depending on the degree of cellular stress or damage). However, the effects of p53 expression are highly context dependent. Loss of Rb or p53 is associated with the malignant phenotype through the cell's ability to evade antigrowth signals.

In addition to tumor suppressor gene loss, cells can also evade antigrowth signals by the following alternative cellular programs:

- Another characteristic of the cancer cell is the evasion of contact inhibition. Cell-to-cell contact in most normal cells results in an inhibitory signal against further cell proliferation. The role of this mechanism in vivo has been thought to be to maintain tissue homeostasis. In cell culture, contact inhibition is abrogated in cancer cell monolayers, leading to their indefinite expansion. NF2 and LKB1 genes are considered tumor suppressor genes that are involved in this process and loss of these genes in vivo may promote loss of contact inhibition that contributes to the progression of cancers.
- Although TGF- β has antiproliferative effects in cancer, it is now, however, appreciated that the TGF- β pathway can be corrupted in the later stages of malignancy and can contribute to cancer progression. In this late effect, TGF- β is found to activate a cellular program termed *epithelial-to-mesenchymal transition* (EMT) that promotes invasion and metastasis (see later).

Evading Cell Death: The Roles of Apoptosis, Autophagy, and Necrosis

The growth of any tumor depends not only on the rate of cell division but also the rate of cellular attrition (mainly provided by apoptotic mechanisms). Basic molecular and pathologic studies of tumors have confirmed that acquired resistance toward apoptosis and other types of death is a hallmark of all types of cancer.

Cancer cells, through a variety of strategies, can acquire resistance to cell death and apoptosis. One of the most common ways is through loss of function of the tumor suppressor protein p53. Loss of p53 protein function occurs most often through mutation but can also be via sequestration or inactivation of the protein by viral proteins or by amplification of other oncogenes such as MDM2. Removal of normal p53 function leads to failure of the cells' sensor mechanism for DNA damage. When the cell suffers an insult such as UV radiation, hypoxia, or exposure to DNA-damaging agents, signals are funneled through p53 to cause either cell cycle arrest or apoptosis. Failure of this mechanism can contribute to the progression of the cell toward malignancy and promoting the accumulation of additional genetic defects that are not corrected at defined checkpoints in cell cycle progression.³⁵

The mechanisms involved in apoptosis are now well established, as are the strategies by which cancer cells evade its actions. However, recently there have been conceptual advances involving other forms of "programmed cell death" as a barrier to cancer development. A notable example is the emerging role that autophagy plays in cancer development. *Autophagy* is a normal cellular response that operates at low basal levels in cells but can be induced in states of cellular stress such as nutrient deficiency. In autophagy, there is controlled breakdown of cellular organelles that yields energy and cellular substrates that can be used for a variety of cellular functions. Recent

evidence suggests that autophagy may be involved in both tumor cell survival and, paradoxically, tumor cell death, depending on the cellular state. The link between apoptosis and autophagy suggests that autophagy may represent another barrier for cells to overcome before they can attain malignancy. In contrast, it has also been shown that irradiation or cytotoxic drug treatment in late-stage tumors may promote autophagy, leading to cells attaining a state of reversible dormancy. The situation seems to suggest that autophagy is a barrier to tumor development in early disease but, in late stage disease, may allow cancer cells to survive severe cellular stress.⁴⁴

In both autophagy and apoptosis, the process does not lead to the release of any "proinflammatory" signals. In contrast, the process of necrosis, observed in larger tumors, causes release of signals that support an influx of inflammatory cells. For many years, this has been considered to be a positive event, helping to expose the immune system to tumor antigens and promote immune destruction. However, recent evidence suggests that some phenotypes of inflammatory macrophages can actually support tumor growth through fostering of angiogenesis, cancer cell proliferation, and invasion. Consequently, our understanding of macrophage phenotypes in cancer progression is an area of active research.

Limitless Replicative Capacity

Over 30 years ago the pioneering observations of Hayflick established that when normal human or animal cells are grown in culture, they demonstrate a finite replicative lifespan. That is, they are capable of a finite number of cell divisions, after which they undergo what has been termed *replicative senescence* and are incapable of any further cell division. The mechanism underlying the replicative clock that monitors this process has been the subject of intense research. This process has further evoked considerable interest as it is also one of the mechanisms that must be overcome to establish the immortal phenotype that is characteristic of the cancer cell.⁴⁵⁻⁴⁷

In mammalian cells, the DNA is organized into chromosomes within the nucleus and these are capped by specialized DNA-protein structures known as *telomeres*. The major function of these structures is protection, but they are progressively eroded at each cell division because of the inability of DNA to completely replicate itself. The result is that there is progressive telomeric attrition as cell populations double. After an estimated 50 cell divisions, cells enter an irreversible (and prolonged) state of cellular senescence (sometimes referred to as *mortality stage 1* [M1]). This period is characterized by arrest of proliferation without loss of biochemical function or viability. At the end of this period, cells exhibit altered morphology and chromosomal instability, a state often referred to as *crisis* (mortality stage 2 [M2]) (Figures 2-5 and 2-6). Thus telomeric attrition is intimately involved with the aging of cells. Cancer cells must overcome replicative senescence and take on an immortal phenotype.

It has now been demonstrated in human tumors and, more recently, tumors of the dog, that telomere maintenance is a feature of virtually all cancer types.⁴⁶⁻⁵³ Tumor cells succeed in telomeric maintenance by the expression of the enzyme telomerase. From studies on cellular senescence, expression of the enzyme telomerase has emerged as a central unifying mechanism underlying the immortal phenotype of cancer cells and has thus become the most common marker of malignant cells. Telomerase is a ribonucleoprotein enzyme that maintains the protective structures at the ends of eukaryotic chromosomes, at the telomeres. In humans, telomerase expression is repressed in most somatic tissues, and telomeres shorten with each progressive cell division. In contrast, telomerase

• **FIGURE 2-5** Telomeric attrition in cultured cells. In mammalian cells the DNA is organized into chromosomes within the nucleus, and these are capped by specialized DNA-protein structures known as *telomeres*. The major function of these structures is protection, but they are progressively eroded at each cell division because of the inability of DNA to completely replicate itself. The result is that there is progressive telomeric attrition as cell populations double. After an estimated 50 cell divisions, cells enter an irreversible (and prolonged) state of cellular senescence (sometimes referred to as *mortality stage 1* [M1]). This period is characterized by arrest of proliferation without loss of biochemical function or viability. At the end of this period, cells exhibit altered morphology and chromosomal instability, a state often referred to as *crisis* (*mortality stage 2* [M2]).

• **FIGURE 2-6** The end replication problem. Telomeric attrition arises because of the inability of chromosomes to completely replicate their extreme 5' ends (end replication problem).

activity is a common finding in many human malignancies, resulting in stabilized telomere length. The telomerase complex consists of an RNA subunit that contains a domain complementary to the telomeric repeat sequence TTAGGG and a catalytic protein component. The catalytic protein component acts as a reverse transcriptase and can catalyze the addition of telomeric repeats onto the ends of chromosomes, using the RNA subunit as a template. It is now well documented that the level of telomerase in malignant tissue compared to normal tissue is much higher, and this differential is greater than that for classic enzymatic targets such as thymidylate synthase, dihydrofolate reductase, or topoisomerase II.

Telomerase biology is complex, and the mechanisms by which telomerase becomes reactivated in tumor cells is the subject of intense research. However, this represents an exciting opportunity for further understanding the complex biology of cancer and also the identification of completely novel targets for therapy.

Reprogramming Energy Metabolism

The sustained growth and proliferation of a cancer requires a corresponding adjustment of energy metabolism to ensure this growth can be fueled. Under normal conditions, cells respire aerobically in that they metabolize glucose to pyruvate with a net gain in energy as ATP.⁴³ Cancer cells can undergo a “metabolic switch” so that glucose is metabolized to lactate, in the presence or absence of oxygen, causing a net energy deficit. There is a corresponding upregulation of glucose transporters (e.g., GLUT-1), which increases uptake of glucose into the cytoplasm. This process is exploited in positron-emission tomography (PET) imaging as tumors will preferentially uptake a radiolabeled analog of glucose (¹⁸F-fluorodeoxyglucose [FDG]). This metabolic switch is sometimes referred to as the *Warburg effect* (Figure 2-7).⁵⁴

It is difficult to appreciate the survival advantage of this mechanism. One hypothesis is that the switch allows the diversion of glycolytic intermediates into other biosynthetic pathways that support the production of new cells. This is supported by the observation that the Warburg effect can also be detected in growing cells in the embryo. An expansion of the theory of reprogramming of energy metabolism in cancer suggests that cancer cells are advantaged by a flexibility in their ability to derive ATP. This may come from a number of metabolic pathways that derive ATP from glucose metabolism under aerobic and anaerobic conditions but may also include efficiencies in metabolizing amino acids and lipids toward ATP and other biomolecule synthesis. Such metabolic flexibility may be necessary during primary tumor development but even more so during metastatic progression (see next section).

Metastasis

Metastasis is defined as the dissemination of neoplastic cells to discontinuous secondary (or higher order) sites, where they proliferate to form a macroscopic mass. Implicit in this process is the presence of a primary tumor. Metastases are not a direct extension of the primary tumor and are not dependent on the route of spread (i.e., hematogenous versus lymphatic versus peritoneal dissemination). The process of metastasis is believed to occur through the completion of a series of step-wise events. In order for this process to occur, a cancer cell must leave the site of the primary tumor, pass through the tumor basement membrane, and then through or between endothelial cells to enter the circulation (extravasation). While in the circulation, tumor cells must be able to resist anoikis (programmed cell death associated with loss of cellular contact), evade immune recognition and physical stress, and eventually arrest at distant organs. At that distant site the cell must leave the circulation and survive in the hostile microenvironment of the foreign tissue. These secondary sites are believed to be primed to receive metastatic cells through effects that are directed and mediated by the primary tumor itself (premetastatic niche). This distant site may be the eventual target organ for metastasis or may be a temporary (sanctuary) site. In either case, the cancer cell is thought to lie dormant for a variable and often protracted period of time before moving to its final location. Following a break in dormancy, cells receive signals to proliferate, create new blood vessels (angiogenesis) or co-opt existing blood vessels, and then successfully grow into a measurable metastatic lesion. It is likely that further progression is associated with the repetition of this process resulting in the development of metastases from metastases. As such, the steps outlined here continue not only after the detection of the primary tumor but also after the detection of metastases. From a therapeutic perspective, it is therefore never too late to target the biologic steps

• **FIGURE 2-7** In normal tissues, cellular respiration in the presence of oxygen allows the production of a net gain in energy through metabolism of glucose to pyruvate. The *Warburg effect* in cancer cells refers to a metabolic switch that causes cancer cells to preferentially metabolize glucose to lactate irrespective of oxygen status, leading to a net loss of energy in the form of adenosine triphosphate (ATP).

associated with metastatic progression as a means to improve outcomes for patients. The basic tenets of this model of metastasis have been intact for over 40 years; however, a greater understanding of biologic principles associated with each metastasis process is emerging.⁵⁵

Metastasis-Associated Genes and Metastasis Suppressor Genes

Cancer cells are not unique in their ability to complete the individual steps required for metastasis (Figure 2-8). For example, leukocytes and neuronal cells have the ability to invade tissue planes and cross vascular barriers. Several types of leukocytes demonstrate the phenotype of intermittent adherence to vascular endothelium and are able to resist anoikis. It is also true that stem cells of various phases of differentiation are able to perform many of these steps during development and in the adult.⁵⁶ What is unique about metastatic cells is that each must be able to perform all the steps required for successful metastasis. An extension of this argument is that the genetic changes that permit the metastatic process are not unique to a metastatic cancer cell; however, the metastatic cancer cell must have the appropriate set of genetic changes available to complete all the steps of the metastatic cascade.

Literally hundreds of genes and their resultant proteins have been suggested to contribute to the development of cancers and to their eventual ability to metastasize. It is possible for a single genetic change in cancer to contribute many of the metastasis-associated processes or for several genes to work together toward a single metastasis-associated process. Metastatic cancers may achieve the metastatic phenotype through distinct constellations of genetic and “epigenetic” events that in their respective sums complete the list of necessary metastasis-associated processes needed for successful metastasis. Two classes of genes have been broadly defined as contributing to the metastatic phenotype. These include metastasis promoting genes^{57,58} and metastasis suppressors.^{59,60} These genes have functions in normal development and physiology (i.e., cell migration, tissue invasion, and angiogenesis discussed earlier) that

are subverted by the cancer cell in the acquisition of the metastatic phenotype.

The use of high through-put and genome-wide investigations has uncovered many putative metastasis-associated genes in cancer. It should be noted that many metastasis-associated genes have functions that also contribute to tumor formation and progression. Several of these metastasis-associated genes have been validated in canine and feline cancers.^{61,62} For example, the metastasis-associated gene *e3rin* was identified using genomic approaches in murine and human studies of metastasis.⁶³ *E3rin* is a membrane-cytoskeleton linker protein that functionally and physically connects the actin cytoskeleton to the cell membrane. The degree of *e3rin* expression in the primary tumor of dogs with osteosarcoma was shown to predict a more aggressive course of disease, defined by metastasis to the lung. Furthermore, recent studies have confirmed the connection between *e3rin* and protein kinase C (PKC) signaling in murine, canine, and human osteosarcoma cells.^{64,65}

Metastasis suppressor genes have been identified in several human cancers. These genes are thought to also have normal functions in the regulation of motility, invasion, and angiogenesis. The loss of these genes is not thought to be associated with the formation of tumors; however, their loss is thought to contribute to specific steps in the metastatic cascade. The characterization, biology, and clinical impact of metastasis suppressor genes have been recently reviewed elsewhere.⁶⁶ The loss of reduced expression of metastasis suppressors has not been documented in canine or feline cancers at this time.

The following sections provide descriptions of the critical metastasis-associated processes (see Figure 2-8). Examples of genetic changes or resulting protein changes that contribute to each process is highlighted in each section, with particular emphasis on those with demonstrated associations with veterinary malignancies.

Intravasation

Following the successful growth of the primary tumor, intravasation of a cancer cell into the vascular or lymphatic circulation is the first step required during the metastatic cascade. The process of

• **FIGURE 2-8** The metastatic cascade. The metastatic cascade describes a set of discrete steps that cells must move through as a part of the process of metastasis. This complexity begins with the recognized complexity associated with primary tumor development in which tumor cells must proliferate, resist apoptosis, and develop interactions with many host cells in the microenvironment. Subsequent steps then allow metastatic cancer cells to enter and survive in the circulation. Cells then arrest at distant locations, extravasate, and survive in the microenvironment of the distant locations. Arrest of cells may be at the eventual secondary organ where metastasis becomes clinically evident or cells may initially arrest at a “sanctuary site” where they may lie dormant before moving on to the eventual secondary site. The cellular programs that result in a break of dormancy are not well understood. Survival of cells at these sites of dormancy or the eventual secondary site is a significant hurdle for metastatic cells to overcome. Indeed, the majority of cells that arrive at distant locations are unable to survive in these distant locations. At secondary sites, tumor cells may proliferate and progress following the development of the angiogenic phenotype. It is likely that successful metastatic lesions at secondary sites are then the source of subsequent metastases within these secondary sites.

intravasation requires that a tumor cell be motile and able to digest, modulate, or escape the extracellular matrix.⁶⁷⁻⁶⁹ The specific mechanisms used by cancer cells to invade and intravasate include the classical model of enzymatic degradation of the extracellular matrix referred to as *mesenchymal invasion* (see later discussion on *epithelial-mesenchymal transition*). Unlike mesenchymal invasion, tumor cells may also develop so-called *amoeboid invasion*, in which they individually slip between fibers of the extracellular matrix without evidence or a need for enzymatic degradation.⁷⁰ Finally, a distinct method termed *collective invasion* refers to the en masse regional extension of a tumor into surrounding tissues.⁷¹ Such collective invasion is observed clinically in dogs with oral SCC and biologically high-grade/histologically low-grade fibrosarcoma. The low rate of distant metastasis associated with collective invasion suggests a lack of functional attributes necessary for true distant metastasis. It is likely that individual metastatic tumors may utilize distinct invasion programs at distinct points during metastatic progression. Not surprisingly, studies with intravital imaging (single cell imaging of cancer cells in animals) have demonstrated that only a minority of the cells in the primary tumor develop any of these forms of invasion.^{72,73} Efforts are underway to define the genetic features of this minority population.^{74,75}

In the classic mesenchymal form of invasion, matrix proteases and metalloproteases (MMPs) are believed to be necessary for the invasive phenotype. Expression of members of this enzyme family have been found in most human and several canine and feline malignancies, including canine osteosarcoma.⁷⁶⁻⁷⁹ The activity of MMPs in osteosarcoma and mast cell cancers has been correlated with grade and metastatic propensity.^{79,80} Similar correlative studies have been undertaken in human patients.⁸¹ The importance of MMP activity during this early step in metastasis prompted the development of pharmacological inhibitors of MMPs. Anticancer activity of these agents in preclinical animal models and in sporadic human patients was evident; however, in randomized trials, the activity of MMPs was not observed.^{82,83} The failure of these clinical trials may be explained at many levels and does not refute the importance of invasion as a critical step for a metastatic cell. Rather, these results suggest potential redundancy in the types of invasion (mesenchymal versus amoeboid) that may exist within a given cancer.^{84,85} Recent evidence also suggests that the expression of matrix-degrading enzymes and other growth factors may not be necessary in the tumor cells themselves but may be provided by inflammatory cells (i.e., macrophages) recruited by the growing tumor.⁸⁶

Epithelial-Mesenchymal Transition

Observed primarily in the context of epithelial malignancies, the ability of tumor cells to engage in the early steps in the metastatic cascade has been linked to a transcriptional program referred to as *epithelial-mesenchymal transition* (EMT).⁸⁷ This transcriptional program has been largely ascribed to the effects of a family of transcription factors, including twist, snail, and slug.⁸⁸ Activation of these and other EMT transcription factors is not necessarily associated with a morphologic change in the cancer cell but may be associated with a loss of polarity (apicobasal) in epithelial cells, a greater proportion of cells losing cell-to-cell contacts similar to mesenchymal cells (observed *in vitro*), cell motility, and invasion. In the “mesenchymal” state, suggested by EMT, epithelial cancer cells (similar to cells involved in embryogenesis) develop the phenotypic ability to undergo invasion, migration, and intravasation.⁸⁹ Interestingly, cells that are able to take on these “mesenchymal” features share signaling programs and other phenotypes with tumor-initiating cell populations.⁹⁰ Opponents of the EMT hypothesis are most critical of the use of the term *transition*, which suggests a switch in the phenotype of individual cells from an epithelial to a mesenchymal form. It is, however, reasonable and generally agreed that the effects of EMT transcription factors contribute to the early phenotypes needed for metastatic progression. Limited data also exist that suggest a need for mesenchymal cells to take on attributes of epithelial cells (likely later during metastatic progression) for successful metastasis, the so-called *mesenchymal-epithelial transition* (MET). For epithelial cancers, MET is also understood to be a final step in EMT, in which following the activation an invasive phenotype and colonization of a distant site cells will revert to their original epithelial phenotypes.

The process of intravasation concludes when a cancer cell successfully enters the vascular or lymphatic circulations. Tumor cells may enter the circulation through established blood vessels, small arterioles, venules, lymphatics, or through tumor-associated (or lined) blood vessels, in a process referred to as *vasculogenic mimicry*.⁹¹ For larger vascular structures, the process of intravasation requires penetration of adventitial cells, including pericytes; digestion of the vascular basement membrane; and penetration between or through endothelial cells.⁹² Penetration of the tumor-associated vasculature may be easier than invasion through normal vessels and may only require transit from the extracellular environment between endothelial cells into the circulation.

Survival in the Circulation (Resisting Anoikis)

Frisch and Francis reported the induction of apoptosis after disruption of the interaction between epithelial cells and the extracellular matrix.⁹³ This phenomenon was termed *anoikis*, from the Greek word for homelessness. In normal tissues, anoikis is a mechanism for maintaining tissue homeostasis and integrity.⁹⁴ For the metastatic cancer cell, survival during dissemination requires resistance to anoikis. In normal tissues, anoikis is prevented by two systems: cell-matrix anchorage and cell-cell interactions.⁹⁵ Anchorage of cells to the extracellular matrix is mediated primarily by transmembrane receptors referred to as *integrins*. Formation of active heterodimers trigger an intracellular cascade resulting in activation of effectors of growth and survival.⁹⁶ Integrin family members have been identified in canine sarcomas and lymphomas.⁹⁷⁻¹⁰² Cell-cell anchorage in many epithelial tissues is mediated by cadherins, a family of calcium-binding glycoproteins. Intracellularly, cadherins form complexes with members of the catenin protein family that

link them to the actin cytoskeleton, as well as survival-promoting signal transduction cascades.¹⁰³ Loss of either cell-cell or cell-matrix interaction in normal cells triggers the activation of the caspase proteases, the hallmark of apoptotic cell death. Metastatic cancer must resist this contact-dependent death in order to be successful and do so through two nonmutually exclusive mechanisms. The first is by maintaining cell-cell contacts with other tumor cells (homotypic interactions) or with host cells such as platelets and inflammatory cells (heterotypic interactions) during metastatic progression. Both homotypic and heterotypic interactions generate intracellular signals that prevent the initiation of anoikis. Additionally, cancer cells may overexpress proteins that directly inhibit anoikis. For example, the integrin pair $\alpha_v\beta_3$ is frequently overexpressed in malignancy, including prostate cancer and melanoma.^{104,105} This overexpression subverts the need for ligand binding and results in the generation of survival signals.¹⁰⁶ Proteins reported to be involved in resistance to anoikis include Trk B, focal adhesion kinase (FAK, the immediate effector of integrin signaling), galectin-3, and TGF- β , among others. Certainly more molecular mediators of anoikis resistance have been identified and reviewed elsewhere.¹⁰⁷ These molecules may be valuable antimetastasis targets for novel therapy.

Evasion of the Immune System

At all stages of metastatic progression, metastatic tumor cells must evade detection and destruction by the immune system. The ability of the host immune system to recognize and destroy tumor cells (immunosurveillance) was first proposed by Paul Ehrlich in 1909. Molecular support of the theory of immunosurveillance has come with studies of mice deficient in immunomodulatory and proinflammatory molecules such as interferon- γ (IFN- γ), interleukin-12 (IL-12), and perforin. Mice deficient in these molecules are known to develop tumors more readily than wild-type mice. Clinical evidence for immunosurveillance against cancer was first reported by Coley over 100 years ago. Through the administration of bacteria, Coley's toxin, Coley was able to induce fever and tumor regression in patients with cancer. Evidence in dogs with osteosarcoma further supports the potential value of cancer immunotherapy.¹⁰⁸ Indeed, survival times in dogs who develop bacterial infection at the site of a limb salvage surgery are significantly longer than in dogs who do not develop infection. Interestingly similar parallels may be seen in human osteosarcoma patients. In immunocompetent hosts, it is believed that immunosurveillance removes a large number of cancer cells from the primary tumor, from the circulation, and at distant metastatic sites. Cancer cells employ a wide variety of mechanisms to effect this evasion. The mechanisms for immunosurveillance and evasion from immunosurveillance by cancer are reviewed elsewhere and are summarized in Chapter 13 of this text.¹⁰⁹

Modification of the immune system to treat cancer continues to be an attractive therapeutic strategy.¹¹⁰⁻¹¹² Clinical trials based on this concept have been reported throughout the veterinary literature in dogs with melanoma, soft tissue sarcoma, hemangiosarcoma, osteosarcoma, and others, using a variety of immune-based therapies.¹¹³ Indeed, this principle has been the basis for the development and approval of a therapeutic vaccine directed against a melanoma antigen in dogs with melanoma.¹¹⁴

Arrest in Target Tissues

The arrest of circulating tumor cells at distant sites is thought to occur by two distinct but potentially overlapping mechanisms. These include size-dependent “trapping” of tumor cells within the lumen of small vessels (capillaries and veins) in the target organ,

and/or receptor mediated interaction involving the tumor cell and the host vasculature.¹¹⁵ Data supporting the “trapping” phenomenon comes from single-cell imaging studies in which metastatic cancer cells were observed to primarily arrest at distant vascular beds as a result of size-dependent restrictions of large tumor cells in small blood vessels.^{116,117} This work was primarily conducted for metastasis to the liver and more recently metastasis to the brain.¹¹⁸ This trapping phenomenon suggests that the site for metastasis from a primary tumor is largely guided by the location of the first (small vessel) vascular bed encountered by a tumor cell. Alternatively, several groups have suggested the role of specific adhesion molecules as being necessary for initial tumor arrest in the microenvironment of the secondary metastatic sites.¹¹⁹⁻¹²¹ It is likely that both of the mechanisms play a role in the initial seeding of distant metastatic target organs. The dominant mechanism of arrest may be primarily defined by tumor type or target organ.

Early Survival at Distant Sites

Once the cancer cell or cancer embolus has arrested at its distant sites, it may immediately move out of the circulation into the target organ or may stay within the circulation.¹²² In either location, the cancer cell must survive in a new microenvironment. Early survival of metastatic cells at secondary sites is a significant hurdle for the cancer cell. Several studies have shown the ability of cancer cells to arrest at multiple organs in the body. Within hours, the number of remaining cells is dramatically reduced and within days, the number of viable cells may be as low as 0.1% of the original number of cells, even for the most aggressive cancer models.^{63,123} The organ selectivity for cancers is to a large extent defined by the organs in which a cancer cell can survive following initial arrest. The “seed and soil” hypothesis first articulated by Paget and then more recently by Fidler et al suggests that the success of a cancer, or metastasis, is defined by interactions between the seed (tumor cell) and the soil (the tumor microenvironment). Arrest of tumor cells in target organs may or may not be receptor mediated (discussed earlier); however, adhesion requires receptor-ligand interactions. Contributors to these steps include the cell adhesion molecules (CAMs). Multiple CAMs have been identified and are named based on their cell specificity (e.g., N-CAM for neural and L-CAM for liver). CD44 is a specific adhesion molecule (H-CAM for homing), initially identified as the receptor for the matrix component hyaluronate acid on hematopoietic cells. Expression of splice variants of CD44 on tumor cells has been demonstrated to correlate with poor prognosis in a wide variety of human tumors from acute myelogenous leukemia (AML) and Hodgkin’s disease to breast and colon cancer and osteosarcoma.¹²⁴ Chemokines are a class of chemotactic cytokines that function in leukocyte trafficking and function. In metastasis, chemokines may also contribute to the metastatic process through enhanced metastatic cell survival.¹²⁵ Chemokines may be active in the recruitment of a leukocytic infiltrate to intravasated, circulating tumor cells, therein creating an embolus that can better resist shearing stress associated with circulation or through the generation of matrix degrading proteins at the distant metastatic site.

The Premetastatic Niche and Modulation of the Microenvironment

It is increasingly clear that the sites (microenvironments) of successful secondary metastasis are modulated by the presence of a primary tumor and then by the arrival of metastatic cells at the secondary site. The concept of the premetastatic niche suggests that

a primary tumor modulates the microenvironment of a secondary site before the arrival of most metastatic cells.¹²⁶ The modulation of the premetastatic niche appears to be accomplished by primary tumor-induced mobilization and recruitment of specific primarily bone marrow-derived cells (bone marrow niche) to the secondary microenvironment.¹²⁷ These bone marrow-derived cells are myeloid in origin and express the vascular endothelial growth factor receptor (VEGFR). Interestingly, the sites of metastatic tumor arrest appear to preferentially include sites in which these myeloid-derived cells were first recruited. Furthermore, targeting these VEGFR-positive cells using pharmacologic and genetic tools has effectively prevented metastatic development in murine models.¹²⁷ Ongoing studies will likely uncover greater complexity of the populations of cells recruited to the premetastatic niche and potentially therapeutic targets for antimetastatic therapy (see Figure 1-5).

Following survival at the distant site, the tumor cell must proliferate and modulate its new environment. In most cases, it is believed that cancer cells extravasate from the circulation and then proliferate in the new organ. However, it is also possible for proliferation to occur within blood vessels, in a process referred to as *intravascular metastases*, and then expand out into the local tissue before further proliferation occurs.¹²⁸ In both situations, modulation of the new environment is necessary for appropriate growth and progression of the metastatic lesions. It is now recognized that part of this modulation is based on tumor-induced changes in the stroma.^{129,130} These stromal changes may result in the production of growth factors or signals that are used by the tumor for further growth. These stromal cell-derived growth factors provide important signals for tumor cell proliferation and progression, including angiogenesis. The importance of tumor-stromal interaction has suggested that the “induced” tumor-stroma may be a credible target for novel cancer therapeutics.¹³¹

Angiogenesis

It is now well accepted that the development of new blood vessels from endothelial progenitors (vasculogenesis) or from existing blood vessels (angiogenesis) is required for cancer progression and metastasis.^{132,133} Endothelial cells or endothelial progenitors are activated by tumor-derived growth factors and result in new capillaries at the tumor site.¹³⁴ In healthy tissue, endothelial cell proliferation is controlled by a balance between protein factors that activate endothelial cells and those that antagonize activation. Malignant tumors provide signals that result in endothelial cell survival, motility, invasion, differentiation, and organization. These steps are required to create a supportive vasculature for the tumor. In many ways, these required endothelial processes share parallel features with the processes required for the success of a metastatic cancer cell itself. The creation of new blood vessels requires the tumors to recruit circulating endothelial cells to their site, presumably through the release of growth factors such as vascular endothelial growth factor (VEGF). Circulating endothelial cells must survive at their new site with the help of survival signals (e.g., thrombospondin-I [TSP-I]) and form vascular tubes that then reorganize to sustain blood flow. The resulting vasculature of cancers is typically aberrant with often poorly organized and chaotic vascular structures that are leaky, with limited adventitial development and excessive branching.¹³⁵ Once developed, this angiogenic phenotype (the result of the angiogenic switch) is associated with a diverse pattern of ongoing angiogenesis and neovascularization. This ongoing process is likely complex and involves a wide variety of tumor and microenvironmental-derived growth factors and signaling molecules. Adding to this complexity, it is likely that certain

phases of cancer progression are associated with and require periods of antiangiogenesis. Indeed, these hypovascularized states may directly contribute to the progression of certain cancers.¹³⁶

Many lines of evidence support the importance of angiogenesis in the biology of metastasis. The vascularity of a primary tumor (measured by microvessel density) has been correlated with metastatic behavior for most human and many veterinary tumors. The expression of angiogenesis-associated growth or survival factors and their receptors (i.e., VEGFR) in serum and in tumors, respectively, has also been correlated with outcome; more recently, functional imaging studies using magnetic resonance imaging (MRI) and other means has provided correlates of vascularity with poor outcome.^{137,138} The strength of this biologic argument has supported the development of a number of novel therapeutic agents with antiangiogenic activities. These agents have moved through discovery and development and are now approved drugs for cancer (see Section C in Chapter 14).

Metastasis from Metastases

For most solid tumors the appearance of a single metastatic nodule is followed shortly by the development of additional metastases within the same target organ and tertiary sites. It is unlikely that these metastatic sites all emerge from distinct and unique clones within the primary tumor and nearly simultaneously progress through the metastatic cascade to yield synchronous metastases at the distant site. It is reasonable and perhaps more likely that metastases develop from other metastatic sites. In this hypothesis a small number of successful clones colonize distant sites. As these clones move through progression to become successful metastases, the process of metastasis continues, resulting in metastasis from metastases. Although data supporting this hypothesis are limited, the implication for the treatment and management of cancer patients is substantial. If true, the process of metastasis from metastases would suggest that all steps in the metastatic cascade occur continuously, both before and after detection of metastases in patients. As such, all of the steps in the metastatic cascade may be targets for future therapeutic intervention.

Ongoing Controversies and Areas of Research in the Field of Metastasis

Does the Metastatic Propensity for Tumors Emerge Early or Late in the Biology of Cancer?

The development of the metastatic phenotype has been traditionally believed to be a process that happens late in carcinogenesis. In this model, referred to as the *progression model*, the genetic changes responsible for primary tumor development are in most cases distinct and precede those steps that result in the metastatic phenotype.^{139,140} The progression model argues that the metastatic phenotype is acquired within a small fraction of cells within the heterogeneous primary tumor. Support for the progression model came from work by Fidler and others, who demonstrated the ability to select for rodent cancers with greater metastatic potential, through the serial passage of metastatic tumor nodules back to naïve mice. This selection phenomenon suggested that a minority of tumor cell clones within a primary tumor were endowed with the metastatic phenotype and that this small proportion were enriched in the metastases compared to the primary tumor. Application of the progression model would suggest that a period of time exists between primary tumor development and acquisition of the full metastatic phenotype. This model was thought to be the basis of the improved outcome associated with early detection of cancers

and the belief that effective and definitive therapy was most likely if a diagnosis was made early. Work from Ramaswamy et al provided data to support an alternative model,⁵⁷ “the early oncogenic model” for metastasis. This alternative suggests that the genetic events that contribute to initial primary tumor development are the same or emerge at the same time as the events that contribute to the metastatic phenotype. As such, the early oncogenic model suggests that the biology of a cancer is defined early and may not be something that can be reduced through the early identification of a cancer. This is not to say that early detection of a cancer is not helpful for a patient, but rather that bad cancers may be “born” bad. This model may explain the phenomenon of the unknown primary tumor, wherein metastatic disease is detected without an apparent primary tumor.

To add complexity to the question of emergence of the metastatic phenotype, there is increasing evidence that host (genomic) differences can influence metastatic behavior of cancers, without necessarily influencing primary tumor growth.^{141,142} Using a genetically engineered mouse model of mammary cancer, Hunter et al have been able to identify specific host genes that influence metastatic behavior of tumors.^{141,143,144} These findings have several important implications. First, they suggest that individuals might be predisposed to aggressive metastatic progression before the development of a tumor. In addition, it suggests that there may be families in the population that are at high risk, not necessarily for tumor development, but for aggressive metastatic course once a tumor develops. Most importantly, if a significant part of a patient’s metastatic risk is encoded within the patient’s constitutional genome rather than within the mutated tumor genome, it may be feasible to identify those individuals at high risk for metastatic disease at the time of diagnosis of the primary tumor, or potentially before. This finding may be particularly relevant in the field of veterinary oncology, in which breed-associated genomic differences may explain the more aggressive course of disease seen in some dogs compared to others. Taken together, the risk for metastatic progression is in part defined by the genetics of the patient, genetic changes that develop early in the process of tumor development, and the subsequent and incremental emergence of aggressive metastatic cells.

Where Is the Inefficiency in Metastatic Inefficiency?

As devastating as the metastatic process is, it is equally inefficient. Estimates of this inefficiency in animal models suggest that less than 1% of cancer cells that successfully enter the circulation are able to survive at distant sites.¹⁴⁵ The true metastatic inefficiency of human cancers is likely to be much lower. In most studies to date, it does not seem that entry of cancer cells into the circulation is the major barrier for successful metastases. Recent studies have identified high numbers of circulating tumor cells in cancer patients who are free of metastatic disease. The clinical importance of high circulating tumor cell numbers is not clear¹⁴⁶; however, it appears that for some cancers, high circulating numbers of cancer cells do not necessarily correlate with risk for metastasis. Butler and Gullino estimated that between 1 to 4×10^6 cells/g of tumor enter the systemic circulation each day in human cancers.¹⁴⁷ These data suggest that, although intravasation is necessary for metastasis, it is not sufficient nor is it process limiting. After removal of the primary tumor, these circulating cell counts drop and in many cases, no gross metastases develop. Although arrest at target organs may be a limitation for some cancers, the successful early survival of cancer cells at distant sites appears to be a major hurdle for successful metastases and therefore is a significant contributor to metastatic

inefficiency. Metastatic cancer cells appear to be highly vulnerable to death (metastatic inefficiency) early after their arrival at a secondary site. The microenvironment of the secondary site is distinct from that of the primary tumor site and the initial tissues of origin of the cancer cell. These differences include changes in oxygen tension, pH, growth factor availability, and cellular binding partners. Collectively, these changes represent unique stresses to metastatic cancer cells. Successful metastatic cells must recognize, adapt, and endure these stresses in order to survive. Furthermore, appropriate modulation of the secondary microenvironment before the cancer cells arrive (premetastatic niche) and as a result of early and effective interaction with stromal and inflammatory cells within the new environment allow select populations of cells to survive and proliferate. The duration of this initial vulnerable state during metastatic progression may extend for the entire period of dormancy (see later). It is also likely that metastatic cells must successfully pass through additional vulnerable states later during metastatic progression. Targeting metastatic cancer cells during these vulnerable states may be an effective treatment strategy for cancer metastasis.¹⁴⁸

What Is Dormancy and Where Do Dormant Cells Reside?

In spite of effective control of the primary tumor and aggressive multiagent and multimodality adjuvant therapy, the risk for metastases to distant sites remains high for several cancer histologies. Since most patients are free of gross metastases at the time of diagnosis, the development of metastases is presumed to emerge from microscopic cells that are not identifiable at the time of initial patient presentation.¹⁴⁹ The location, size, angiogenic state, and proliferative/apoptotic state of these microscopic cells are largely unknown. Indeed, these dormant cells may exist as single cancer cells or microscopic clusters, they may exist in a quiescent (outside the cell cycle) or in a balanced state of proliferation and apoptosis, they may lie dormant in the eventual secondary metastatic tissue site (i.e., the lung) or persist in sanctuary sites (i.e., the bone marrow). Recent insights gleaned from the tumor-initiating (cancer stem cell) model may provide further support for the hypothesis that metastatic cells are capable of residence in transient sites like the bone marrow, where they may rest in a dormant state before being recruited into the metastatic cascade. The signals that induce these presumed small populations of cells to break dormancy and emerge into gross metastases likely also involve tumor cell microenvironment interaction.^{150,151}

The Enabling Characteristics

As previously suggested, the hallmarks of cancer have been defined as functional capabilities that allow cancer cells to survive, proliferate, and disseminate. The fact that these critical hallmarks can be attained within a single cancer is explained by two key enabling characteristics of cancer: genome instability and tumor-promoting inflammation.

Genome Instability

The majority of the acquired hallmarks of cancer require changes in the genome through mutation, amplification, or chromosomal translocation. However, the process of random mutation is inefficient because of the complex and fastidious maintenance mechanisms of the normal cell that monitor DNA damage and regulate repair enzymes. As such, it is actually difficult to explain why cancers arise in animals at all because the acquisition of all traits

would seem an impossible task. To explain this, it may be argued that genomes must attain increased mutability or genome instability in order to overcome the redundant homeostatic mechanisms that ordinarily prevent the emergence of a cancer cell.^{1,2}

The following mechanisms have been suggested that may support the development of genomic instability⁴³:

- Defects affecting various components of the DNA-maintenance machinery (caretakers of the genome), which may involve mutations in caretaker genes.
- The loss of telomeric DNA, which may cause karyotypic instability and chromosomal changes (amplification/deletion).
- Inactivation of tumor suppressor genes through genetic (mutation) or epigenetic (DNA methylation/histone modifications) mechanisms.

Tumor-Promoting Inflammation

For decades it has been recognized that tumors contain inflammatory and immune cell infiltrates that have classically been considered to be an attempt by the immune system to eradicate the tumor. However, recent evidence suggests that tumor-associated inflammation may paradoxically have a tumor-promoting effect. Inflammation can contribute to neoplastic progression through one of the following various mechanisms.^{43,152,153}

- The supply of growth factors and growth signals to the microenvironment that promote angiogenesis, cell proliferation, and invasion.
- Induction signals that support the process of EMT.
- Fostering the progression of premalignant lesions to fully blown cancer.
- The production of reactive oxygen species that are mutagenic.

Many of the cells that contribute to this are components of the innate immune system, particularly macrophages with a specific, cancer-promoting phenotype. Specifically, they form part of the tumor microenvironment that supports the maintenance of the cancer phenotype (see Figure 1-5).

The Pathway to Cancer

The eight acquired capabilities of cancer cells and the two overarching enabling characteristics of genome instability and tumor inflammation have been outlined. It is important to stress that the pathways by which cells become malignant are highly variable. Mutations in certain oncogenes can occur early in the progression of some tumors and late in others. As a consequence, the acquisition of the essential cancer characteristics may appear at different times in the progression of different cancers. Furthermore, in certain tumors, a specific genetic event may, on its own, contribute only partially to the acquisition of a single capability, while in others it may contribute to the simultaneous acquisition of multiple capabilities. However, irrespective of the path taken, the hallmark capabilities of cancer will remain common for multiple cancer types and will help clarify mechanisms, prognosis, and the development of new treatments.

The Tumor Microenvironment

Over the past 10 years, tumors have been increasingly considered as organ systems similar to the tissues from which they derive. This is in contrast to a reductionist view of cancer biology, which considers the tumor as just a mass of tumor cells. In reality, the tumor is a complex system containing cancer cells and supporting cells, which all contribute to the maintenance of the malignant population and support ultimate dissemination and metastasis.

Consequently, the major players in the cancer “organ system” are as follows:

- Cancer cells and cancer stem cells (CSCs)
- Endothelial cells
- Pericytes
- Immune cells
- Tumor-associated fibroblasts

Cancer Cells and Cancer Stem Cells

The concept that a cancer can arise from any cell in the body, along with the stochastic model of tumorigenesis, has recently been challenged.^{154,155} Although tumor heterogeneity is a well-established concept, a new dimension to heterogeneity has been established that suggests that a tumor may contain a hierarchical structure similar to many normal organ systems. Recent evidence suggests the existence of CSCs (sometimes termed *tumor-initiating cells*), which form the founder cell population for a tumor (see Figure 1-8). It was first extensively documented for leukemia and multiple myeloma that only a small subset of cancer cells are capable of extensive proliferation. For example, when mouse myeloma cells were obtained from mouse ascites, separated from normal hematopoietic cells, and put in clonal in vitro colony-forming assays, only 1 in 10,000 to 1 in 100 cancer cells were able to form colonies. Even when leukemic cells were transplanted in vivo, only 1% to 4% of cells could form spleen colonies.¹⁵⁶⁻¹⁶¹ Because the differences in clonogenicity among the leukemia cells mirrored the differences in clonogenicity among normal hematopoietic cells, the clonogenic leukemic cells were described as leukemic stem cells. It has also been shown for solid cancers that the cells are phenotypically heterogeneous and that only a small proportion of cells are clonogenic in culture and in vivo.¹⁶²⁻¹⁶⁵ For example, only 1 in 1000 to 1 in 5000 lung cancer, ovarian cancer, or neuroblastoma cells were found to form colonies in soft agar. Just as in the context of leukemic stem cells, these observations led to the hypothesis that only a few cancer cells are actually tumorigenic and that these tumorigenic cells could be considered as CSCs. Although the field and concept of CSCs is a controversial one, CSCs may prove to be a common constituent of many, if not all, cancer types. Features of the CSC model also fit well with a view of metastasis in which only a small number of cells within a tumor have the ability (and plasticity) to endure the stresses of metastatic progression, survive during a dormant period, and then progress, proliferate, and differentiate into the complex heterogeneous metastatic lesion.

If tumor growth and metastasis are driven by a small population of CSCs, this might explain the failure to develop therapies that are consistently able to eradicate solid tumors.^{154,155} Although currently available drugs can shrink metastatic tumors, these effects are usually transient and often do not appreciably extend the life of patients. One reason for the failure of these treatments is the acquisition of drug resistance by the cancer cells as they evolve; another possibility is that existing therapies fail to kill CSCs effectively.

Stem cell populations in human cancers have been identified in breast, bone, brain, colon, pancreas, liver, ovary, and skin.^{154,155} The actual origin of CSCs within solid tumors has not been clarified and may actually vary between tumor types. In some tumors, it may be that the resident adult or somatic stem cell may serve as the tumor-initiating cell, and in other tumors, the initiating cell may be the resident progenitor or transit-amplifying cell. A characteristic of the CSCs is that they undergo asymmetric division and self-renew, providing a continual resident population of highly resistant cancer cells.

Existing cancer therapies have been largely developed against the bulk population of tumor cells because they are often identified by their ability to shrink tumors. Because most cells with a cancer have limited proliferative potential, an ability to shrink a tumor mainly reflects an ability to kill these cells. It seems that normal stem cells from various tissues tend to be more resistant to chemotherapeutics than mature cell types from the same tissues. If the same is true of CSCs, then one would predict that these cells would be more resistant to chemotherapeutics than tumor cells with limited proliferative potential. Even therapies that cause complete regression of tumors might spare enough CSCs to allow regrowth of the tumors. Therapies that are more specifically directed against CSCs might result in much more durable responses and even cures of metastatic tumors. In veterinary oncology, putative stem cell populations have been identified for breast, bone, brain, and liver.^{154,155,166-168} Interestingly, stem cell populations appear to have altered DNA repair pathways, which may explain their resistance to conventional drugs. Identification of these populations, coupled with the availability of microarray and microRNA array technology, is allowing the identification of potential therapeutic targets.

Recent research has linked the acquisition of CSC characteristics with the EMT program, described previously in the section on metastasis.¹⁶⁸ Cells that undergo EMT also take on characteristics reminiscent of the CSC phenotype. For example, they have the ability to self-renew and may support the ability of cells to colonize outside of the primary tumor. One may speculate that the signaling processes that support EMT may also serve to maintain the CSC population within a tumor and may also suggest plasticity in CSC populations.

Endothelial Cells

Much of the heterogeneity in tumors is found in the stromal compartment, and many of these cells are endothelial cells, which form the tumor-associated vasculature. VEGF and fibroblast growth factor are prominent signaling pathways in formation of these vessels. More modern sequencing techniques have also identified new pathways that may represent important signaling systems for neoangiogenesis and may represent therapeutic targets (e.g., notch signaling).

Pericytes

Pericytes are mesenchymal cells that wrap around the endothelial tubing of the blood vessels. Pericytes are considered a major cell type supporting the tumor vasculature.

Immune Inflammatory Cells

As described previously, an environment of chronic inflammation is an important enabling characteristic that supports the acquisition of cancer-related traits. Cells of the innate immune system are particularly crucial for the maintenance of the tumor environment. In particular, tumor macrophages with a specific pro-tumor phenotype can enhance cellular proliferation, invasion, and neoangiogenesis.

Cancer-Associated Fibroblasts

Cancer-associated fibroblasts comprise the supporting structure for many tumors but can also promote invasion, cell proliferation, and neoangiogenesis.⁴³ The importance of the various cell types that make up the tumor microenvironment cannot be overstated. Although there is a complex signaling network between and within cancer cells that maintains the cancer phenotype, superimposed on top of this are the complex signaling networks between stromal

components and stromal cells and cancer cells. Although we have considered earlier the potential evolution of cancer cells as they evolve from early disease to late-stage disease, it is quite possible that there is a similar evolution in the supporting structures that is dictated by the cancer itself. For example, incipient tumors may recruit stromal elements, which in turn reciprocate by promoting cell proliferation and angiogenesis. Evolution of the cancer population may then in turn feed back on the stromal population to further reprogram them to support the growing tumor. This of course could be extended to show the role of the stroma in promoting invasion and metastasis. These mechanisms underpin the complexity of understanding cancer pathogenesis as the process is highly dynamic and context dependent.

Summary and Future Directions

In this chapter we have sought to simplify as far as possible the mechanisms of carcinogenesis. It is clear that genomic instability and an environment of chronic inflammation support and provide a basis for the acquisition of the eight fundamental cancer characteristics. The identification of these pathways is providing excellent clues to the underlying mechanisms in cancer and the identification of potential therapeutic targets. However, despite our ability to make small molecules or antibodies, which aim at key targets in cancer survival, we are still a long way from a cure. The reasons for this are many but include the inherent tumor heterogeneity (in part supplied by the existence of tumor stem cells), the continual tumor evolution, and the immense and underestimated contribution of the tumor microenvironment. It is clear that multiple approaches will be required to maximize any possibility of therapeutic benefit.

The Pathology of Neoplasia

3

E.J. EHRHART, DEBRA A. KAMSTOCK, AND BARBARA E. POWERS

Veterinary pathologists play a critical role in the management of neoplasia of companion animals by providing accurate diagnostic information to clinicians so that a prognosis can be determined and adequate treatment provided. The clinician needs to have knowledge of the pathology of neoplasia to understand neoplastic conditions and the limitations of histopathologic assessment in the diagnosis of neoplasia. Both the pathologist and the clinician must work together to determine optimal treatment for the patient because the diagnosis and treatment of neoplasia in veterinary medicine have become more complex. No longer is it adequate to simply determine if the tumor is benign or malignant. The tumor type needs to be identified as accurately as possible, and tumor subtypes should be identified if prognostically significant. Grading of tumors is increasingly important because the behavior of some tumors can be predicted by the grade of the tumor. In addition, the assessment of margins for completeness of surgical removal is very important. In some cases, the histologic assessment of tissue treated preoperatively is important in predicting treatment outcome. Special procedures such as immunohistochemistry (IHC), electron microscopy (EM), flow cytometry, or polymerase chain reaction (PCR) may be advantageous in some cases to correctly identify tumor type or subtype or to predict clinical behavior of certain tumors. Classification of neoplasia in veterinary medicine is becoming more commonly applied, and systems have become more advanced with application of molecular markers for more accurate classification and prognostic information. For example, a recently upgraded histopathologic classification and grading system for canine mammary tumors has been reported to better prognostically evaluate tumors and standardize studies for cross-comparison.¹ As more is learned about the diagnosis and treatment of neoplasia in veterinary medicine, newer predictive/prognostic classifications and grading schemes will continue to be developed.

Sample Handling

The biopsy sample should be visually inspected by the clinician to help determine that the appropriate tissue was obtained. If the biopsy was a needle core or incisional specimen, the sample should be of sufficient size and consistency so that it remains intact in formalin and does not become lost in processing. Samples less than 1 mm³ are usually inadequate, although a needle core sample 1 mm wide but at least 5 mm long can be sufficient. If the biopsy samples are needle core samples, more than one core of tissue should be obtained, if possible.

Very small samples can easily be lost during shipping or in processing because sample shrinkage during fixation and processing is imminent. Given these precautions, some techniques can be utilized to maximize the chances that the sample will make it through the process. Samples less than 3 mm in size can be placed

on paper (surgical glove paper is appropriate) before fixation. These samples will be tacky and adhere to the paper. Very small or pale samples can be circled with pencil to draw attention to the samples at the histology laboratory. The paper can then be folded around the sample, and the entire package can be placed in formalin for fixation and shipping. Alternatively, commercially available screened tissue cassettes can be used to house the sample during fixation and shipment. The sample is placed in the screened cassette at the time of surgery, and the cassette with the sample is placed directly into formalin for fixation. These techniques decrease the chance for small samples to be lost in larger formalin containers. Extremely small samples can also be dyed with India ink or other commercially available dyes to assist in the identification of the sample. Samples containing excessive blood, mucus, or necrotic material may not be diagnostic, and the biopsy procedure may need to be repeated. If the specimen was an excisional sample, the entire sample should be submitted if feasible, and margins of concern should be identified with suture or ink. For very large samples such as large splenic tumors, representative sections such as peripheral versus central or different-colored or textured areas can be submitted. Visualization by an experienced person is extremely important when selecting the sample so that viable tissue is selected. Usually it is best to submit at least three to five sections of large lesions in case some portions of the tumor have excessive distortion, necrosis, or inflammation. When taking representative samples, the tumor and normal tissue interface should be included so assessment of tumor invasiveness into normal tissue can be determined. Tissue samples should be handled gently because compression during biopsy sampling and excessive use of electrocautery, cryosurgery, or laser surgery can cause specimen artifact, which can prevent a definitive diagnosis from being made.²

The sample needs to be preserved in fixative. The most widely used fixative is 10% neutral buffered formalin, which is readily available and frequently supplied in individual specimen containers by most laboratories. During excessive cold conditions, samples can freeze during shipment and cause significant destructive tissue artifact. Addition of 20% ethylene glycol or ethanol to the formalin can prevent freezing and maintain tissue integrity. Prior to immersion in fixative, larger samples may need to be sliced, facilitating adequate fixation; however, one side such as the deep edge should be left intact rather than slicing all the way through the sample so that orientation and margin assessment are not lost. Slices less than 1 cm thick should be avoided because curling and distortion of the tissue during fixation can result. The volume of tissue to fixative should approximate 1 : 10. In cases in which this volume ratio is not feasible because of large tumor size, multiple representative sections can be obtained. It is advisable to save the remnants of the sample, if possible, in case these first sections are not adequate for a diagnosis. When mailing large samples, use of smaller volumes of

fixative is acceptable if the specimen has been in the recommended initial volume for at least 12 hours.³

Sample containers must be properly labeled (on the container, not just the lid) prior to submission to the laboratory. During transportation by mail, courier, or unpacking at the laboratory, paperwork can be inadvertently separated from the sample container, and unless the container is properly labeled, samples could become mixed. Most important, adequate history, including signalment, pertinent clinical findings, radiographic findings, and pertinent treatment, should be provided to the pathologist. A drawing of the sample indicating the position of the tissue on the animal is helpful in some situations, especially when margin determination is needed. If margins or areas of special clinical interest are marked (labeled) on the sample, a clear description of these labels, margins, or areas should be present in the submission form. A proper history is crucial for accurate diagnosis; without this the pathologist can be severely handicapped. The end result might be an inaccurate diagnosis, culminating in an inaccurate prognosis and improper treatment.^{2,4}

After arrival at the laboratory, the specimens are catalogued and assigned an identification number, visually examined, trimmed to fit into processing cassettes, processed into paraffin blocks, sectioned, and stained. These procedures are performed by trained technicians and automated laboratory equipment. In most laboratories, tissues are trimmed into cassettes on the day of arrival, processed overnight, and completed slides are ready for examination by the pathologist 24 hours after receipt. Hard tissue such as bone needs to be decalcified prior to sections and thus will take longer to process. Larger samples incompletely fixed, extremely bloody samples (e.g., spleen), or samples with abundant fatty tissue (e.g., mammary gland) may require additional time for fixation. This additional time is vital to assure fatty tissue at the margin of the surgically excised sample remains intact during trimming, processing, and sectioning. In the process of trimming in or sectioning on the microtome, margins could become distorted and orientation may be lost, in which case reexamination of the gross specimen by the pathologist may be necessary. Most laboratories will hold remnant wet tissues in formalin for 7 to 60 days in the event further examination or sectioning is needed. Most laboratories file paraffin blocks and glass slides indefinitely, permitting review of previously submitted tissue on a given patient or retrospective studies on a series of cases.

Although infrequent, frozen sections can be made during operative procedures to provide the surgeon with a more rapid diagnosis. Samples are quick-frozen, sectioned on a cryostat, fixed, stained, and examined within 20 to 35 minutes. This technique is often conducted during surgery to assist with intraoperative decisions and thus requires a diagnostic laboratory and facility on site. However, these tissue sections are inferior to those processed routinely into paraffin, and as a result diagnostic accuracy is not as high and is proportional to the experience of the pathologist interpreting frozen sections. Furthermore, only a few veterinary institutions provide this service. This procedure may be helpful in establishing the identity of the tissue, adequacy of surgical margins, or adequacy of the tissue for more routine processing. Sometimes a provisional diagnosis can be made or at least a distinction between benign and malignant processes can be determined. The frozen-section diagnosis is always confirmed by routine histopathologic assessment of a paraffin-embedded section, often using the same tissue sample.⁴

Molecular techniques are now routinely applied as diagnostic tests in veterinary medicine. Some of these such as PCR and IHC

have been developed and characterized for use on formalin-fixed, paraffin-embedded samples. Once processed, these tissues are often viable indefinitely for these tests, although the time prior to fixation, the time in fixation, and the storage time can negatively affect test sensitivity. These factors need to be determined for individual tests, and their effect needs to be considered in interpretation of results. IHC on formalin-fixed tissues requires only unstained, routine sections on slides appropriate for IHC. Exposure to sunlight or extremes of temperature should be avoided. Requirements particular to individual testing laboratories should be determined prior to submitting samples for these tests. PCR requires thick sections (10 to 20 μm) to assure adequate DNA or RNA amounts. These are typically allowed to roll up during microtome sectioning and can be sent to the testing laboratory at room temperature in an air-tight container. Acquiring specifics of the test material needed and shipping requirements prior to collecting the sample or requesting the test is often beneficial and avoids frustration for the owner, submitter, and testing laboratory.

Terminology

Numerous terms associated with tumors or suspected tumors are encountered in the description of the features of a tissue sample. A clear understanding of this terminology is imperative to understand the implications of the histopathologic findings. A clinician's responsibility extends beyond collection of the tumor and treating the patient. A clinician has a responsibility to interpret the histopathology report, to identify details that might help subclassify a tumor beyond the base of tumor identification, and to assist in determining a tailored treatment protocol for individuals. A firm grasp on terminology is required for this interpretation and to discuss details of the tumor with the pathologist.

A *tumor* is any tissue mass or swelling and may be neoplastic or not, although this term today more typically is a generic term used to describe any neoplasm. *Neoplasia* is the abnormal growth of a tissue into a mass that is not responsive to normal control mechanisms and may be benign or malignant. Growth of this mass is not affected when the inciting stimulus is removed. *Cancer* refers to a malignant neoplasm.⁵ All neoplasms arise in normal tissue and thus are composed of parenchymal and stromal cells—some can also incite secondary inflammation. Their differentiation state can be assessed with histopathology and is based on the appearance of the tumor cells, their organization, and their association with the supporting stroma. Differentiation is controlled at the molecular level by gene expression. Normal reversible processes of *hyperplasia* (a nonneoplastic increase in the number of cells present) and *atrophy* (a decrease in the number of cells present) are also composed of parenchymal cells and stroma. Their retention of near-normal architecture, just as well-differentiated neoplasms retain normal architecture, can make differentiation of the two processes difficult. At times, only removal of the inciting stimulus and time can distinguish between hyperplasia and well-differentiated cancer. One definition of cancer is a proliferation of a clonal population of cells that is no longer responsive to tissue homeostatic mechanisms. Molecular techniques to determine a clonal expansion of cells by their similar DNA sequence structure could help separate these conditions or identify occult cancer prior to tissue distortion at a microscopic level. These tests are few, but more are currently being developed, specifically for use in canine and feline lymphomas.⁶ *Metaplasia* is the abnormal transformation of a differentiated tissue of one kind into a differentiated tissue of another kind and not a neoplastic condition. Metaplasia should reverse or not progress

with cessation of the chronic inciting stimulus. An example is squamous metaplasia in the prostate gland, where normally columnar epithelium becomes squamous under the influence of estrogen. Metaplastic cells can be targets for carcinogenesis if continued carcinogenic promotional events occur (e.g., bronchial squamous metaplasia in human smokers). In such cases, metaplasia often progresses and acquires dysplastic changes. *Dysplasia* is abnormal tissue development and can be a feature of neoplasia, but it is not necessarily a neoplastic condition. Dysplasia such as epithelial dysplasia in the oral cavity can be a preneoplastic condition. *Anaplasia* is a loss of differentiation or atypical differentiation and is a feature of many, but not all, malignancies.

Terms associated with cellular or growth features are frequently encountered in descriptions of neoplasia. *Pleomorphism* is the occurrence of multiple forms, shapes, and sizes of cells and nuclei (cellular and nuclear pleomorphism respectively). *Anisocytosis* and *anisokaryosis* are greater than normal variations in cell and nuclear size, respectively. Round or polygonal cell shapes are usually associated with epithelial or hematologic tumors, whereas spindle cell shapes are usually associated with mesenchymal tumors. A *scirrhous* or *desmoplastic* response is an abundant fibroblastic proliferation with collagen formation that occurs in some malignant invasive cancers. *In situ* refers to a malignancy, usually limited to lesions of epithelial origin, that has not yet become invasive or invaded beyond the natural confines of its basement membrane.^{2,4,5}

For each type of tumor, specific terminology is used to denote the origin of the tumor and whether the tumor is benign or malignant (Table 3-1). In basic terms, although benign tumors can cause tissue distortion, they typically do not have a high mortality. In contrast, malignant tumors (cancer) are more destructive of tissues and will often ultimately lead to death if the patient is left untreated. There are exceptions to these rules. Tumors can develop from any normal tissue type; therefore there are a considerable number of different tumor types. As more is learned about certain tumors, names and subclassifications may change, creating some confusion. More recent advances in molecular techniques applied to tumors have allowed additional subclassification of tumors beyond the histologic realm. More focused techniques such as IHC, targeted PCR for genetic alterations and mutations, and flow cytometry for cell surface markers can be applied once specific alterations in tumor types have been identified and determined to be markers in a specific tumor or tumor subtype. Broad encompassing techniques for large genomic, proteomic, and more recently metabolomic fingerprinting of tumors are used as discovery tools to scan for alterations that define subclasses of tumor types previously unidentified by more traditional methods. The identification of genetic mutations, varied cell surface receptor expression, altered signaling pathways, or altered cellular metabolic response to these genetic modifications may identify unique fingerprints for a tumor, which, combined with traditional histologic methods, might allow subclassification that is more accurate at identifying a tumor's behavior and its response to tailored cancer treatment (see Chapter 8).

Benign tumors of epithelial origin are termed *adenoma*, *papilloma*, or *epithelioma*. Benign tumors of mesenchymal origin are designated by the suffix *-oma* after the tissue type (e.g., fibroma, osteoma). Malignant tumors of epithelial origin are termed *carcinoma* or *adenocarcinoma* if forming glands and ducts, whereas malignant tumors of mesenchymal origin are termed *sarcoma*. In some cases, the *-oma* suffix is used when the tumor is malignant, as in malignant melanoma and lymphoma. *Leukemia*, a malignant neoplasia of blood cells (occasionally referred to as “liquid tumors”) in hematopoietic tissues and usually in the blood, has no benign

counterpart, although a leukemoid reaction is a nonmalignant condition that mimics leukemia.^{2,4,7} Although nomenclature for human cancer can often be applied to animal cancer, all nomenclature cannot be directly applied across species due to differences in tumor types and tumor behavior. Similarities and differences must be taken into account when considering whether nomenclature can have cross-species application. For example, direct comparison of canine mammary gland tumors to those of the human mammary classification system have identified differences that require an independent classification system.⁸

Histologic Features of Neoplasia

Despite recent advances in a number of areas of pathology, including molecular techniques, evaluation of tissue by light microscopy remains the standard technique for tumor diagnosis.³ Neoplasia has certain histologic features that distinguish it from hyperplasia or inflammation, and there are features that distinguish benign from malignant neoplasia. In some cases, these features can be difficult to observe. Definitive diagnosis of malignant versus benign versus inflammation or hyperplasia may not always be possible. In these cases, a repeat biopsy, either immediately or after a period of clinical observation, may facilitate a definitive diagnosis.

When inflammation is present, the cellular features of reactive fibroblasts and reactive endothelial cells can be misleading.^{2,9} However, in reactive tissue with inflammation, the fibroblasts and endothelial cells usually are oriented perpendicular to one another (reactive granulation tissue) and usually a substantial amount of inflammation relative to reactive tissue is present. When granulomatous inflammation occurs, large reactive and epithelioid macrophages can be mistaken for tumor cells, but the pattern of tissue involvement and presence of other inflammatory cells helps rule out neoplasia. In some tumors, especially those with surface ulceration or necrosis (e.g., some synovial cell and soft tissue sarcomas), an extensive amount of inflammation can obscure neoplasia but is considered a secondary process.

Benign tumors may be most difficult to distinguish from hyperplasia (Table 3-2) because both have a proliferation of well-differentiated cells that are easy to identify. There is a distortion or loss of normal tissue architecture in benign neoplasia, and usually the tumor grows in an expansive manner, causing compression rather than invasion of adjacent tissue. These tumors are often defined by a fibrous tumor capsule. Hyperplasia tends to retain normal tissue orientation and does not compress adjacent tissue. It often lacks a fibrous capsule. In general, if allowed to grow, benign neoplasia will attain a larger size than a hyperplastic lesion. In some instances, such as thyroid gland adenoma versus adenomatous hyperplasia of the thyroid gland in cats or sebaceous gland adenoma versus sebaceous gland hyperplasia the distinction between benign tumor and hyperplasia is not clinically important.

Features that distinguish malignant from benign neoplasia include more dramatic loss of tissue organization, increased anisocytosis and anisokaryosis, increased nuclear and cellular pleomorphism, increased and variable nuclear:cytoplasmic ratio, abnormal nuclear chromatin, increased mitotic figures, increased and abnormal mitotic figures, abnormal large and/or multiple nucleoli, increased necrosis, amount and character of the supporting stroma, and invasiveness of malignant tumors (see Table 3-2). With invasion, individual cells or groups of tumor cells infiltrate extensively into surrounding tissue, may invade into vascular or lymphatic spaces, and may invoke a scirrhous or desmoplastic response characterized by an excessive fibrous reaction. A further feature of

• **TABLE 3-1** Nomenclature of Common Tumor Types in Veterinary Medicine

TISSUE OR CELL OF ORIGIN	BENIGN	MALIGNANT
Epithelial		
Squamous	Squamous papilloma	Squamous cell carcinoma
Transitional	Transitional papilloma	Transitional cell carcinoma
Glandular	Adenoma, cystadenoma	Adenocarcinoma
Nonglandular	Adenoma	Carcinoma
Mesenchymal		
Fibrous tissue	Fibroma	Fibrosarcoma
Fat	Lipoma, “infiltrative lipoma”	Liposarcoma
Cartilage	Chondroma	Chondrosarcoma
Bone	Osteoma	Osteosarcoma, multilobular osteochondrosarcoma
Muscle (smooth)	Leiomyoma	Leiomyosarcoma
Muscle (skeletal)	Rhabdomyoma	Rhabdomyosarcoma
Endothelial cells	Hemangioma	Hemangiosarcoma
Synovium	—	Synovial cell sarcoma
Mesothelium	—	Mesothelioma
Melanocytes	Benign melanoma, melanocytoma	Malignant melanoma, melanosarcoma
Peripheral nerve	—	Malignant schwannoma, neurofibrosarcoma, peripheral nerve sheath tumor
Uncertain origin*	—	Malignant fibrous histiocytoma, hemangiopericytoma
Hematopoietic and lymphoreticular		
Lymphocytes	—	Lymphoma with subclassifications and leukemic forms
Plasma cells	Cutaneous plasmacytoma	Multiple myeloma, plasmacytoid lymphoma
Granulocytes	—	Myeloid leukemia
Red blood cells	—	Erythroid leukemia
Macrophages	Histiocytoma	Histiocytic sarcoma (malignant histiocytosis)
Mast cells	—	Mast cell tumor†
Thymus	Thymoma, encapsulated	Invasive thymoma
Brain		
Glial cells	Astrocytoma, oligodendroglioma	Astrocytoma, glioblastoma multiforme, oligodendroglioma
Meninges	Meningioma	Malignant meningioma
Gonadal		
Germ cells‡	Seminoma, dysgerminoma	Seminoma, dysgerminoma
Supportive cells‡	Sertoli cell tumor, granulosa cell tumor	Sertoli cell tumor, granulosa cell tumor
Interstitial cells‡	Interstitial (Leydig) cell tumor, thecoma, luteoma	Interstitial (Leydig) cell tumor

*Pathologists disagree about the origin of these tumors; some feel they are a class of peripheral nerve sheath tumors or perivascular wall tumors.

†Theoretically, all mast cell tumors are potentially malignant, but grade 1 mast cell tumors are clinically benign.

‡Unfortunately, the terminology of these tumors does not distinguish between benign and malignant forms.

• **TABLE 3-2** Histologic Features of Hyperplasia and of Benign and Malignant Neoplasia

HISTOLOGIC FEATURE	HYPERPLASIA	BENIGN NEOPLASIA	MALIGNANT NEOPLASIA
Overall differentiation	Normal	Disorganized, but well differentiated	Disorganized, well to poorly differentiated
Cell and nuclear pleomorphism	None	Minimal	Moderate to marked
Mitotic index	Variable, usually low	Usually low	Often high
Nucleoli	Normal	Normal	Large and/or multiple
Amount of necrosis	None	Usually minimal	Minimal to abundant
Tissue demarcation	Blends with normal tissue	Expansive and/or compressive	Invasive

• **TABLE 3-3** Molecular Features Underlying Grading Criteria

GRADING CRITERIA	UNDERLYING MOLECULAR MECHANISMS
Mitotic index	Cyclins, cyclin-dependent kinases (CDKs), proliferating cell nuclear antigen (PCNA), Ki67, bromodeoxyuridine (BrdUrd), labeling index (LI)/growth fraction (GF)
Percent necrosis	Inflammatory mediators, including eicosanoids (prostaglandins), cytokines (interleukin [IL], tumor necrosis factor alpha [TNF- α]), microvessel density (MVD)
Invasiveness	Matrix metalloproteinases (MMPs), plasminogen activators (PA), integrin expression, CAM (cell adhesion molecules)
Stromal reaction	Transforming growth factor beta (TGF- β), platelet-derived growth factor (PDGF), basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), MVD mediators
Nucleolar size	RNA transcriptional activity, silver staining nucleolar organizing regions (AgNORs)
Overall cellularity	Growth fraction, apoptosis factors (i.e., FasL, caspases), tumor doubling time
Inflammatory (lymphoid) response	TNF- α , interferon gamma (IFN- γ), IL-2, increased MHCII, intercellular adhesion molecule (ICAM)

malignancy is destruction of the normal tissue or obliteration of normal tissue architecture. Evidence of lymph node or more widespread metastasis obviously distinguishes malignant from benign tumors.^{2,4,10} However, in certain tumors, histologic features do not correlate with behavior (e.g., canine histiocytoma and benign plasmacytoma). Both have histologic features of malignancy but are clinically benign. Histologically low-grade, yet biologically high-grade, fibrosarcomas of the canine head have histologic features of a benign condition but are clinically malignant.¹¹ Similarly, bronchial carcinomas in cats will retain organized epithelial structures composed of well-differentiated ciliated pseudostratified columnar epithelium even at distant metastatic sites, including the digit, eye, heart, and kidneys.¹² In these instances, knowledge of clinical history and tumor behavior is needed to distinguish benign from malignant neoplasia.

Generally, a pathologist makes the diagnosis of tumor versus reactive tissue and sometimes tumor type at relatively low magnification after evaluating the overall tissue pattern and behavior with respect to adjacent normal tissue. Higher magnification is then used to confirm the low magnification impression, to classify tumor type if not already done, and to assess nuclear features and mitotic index. Immediate use of high magnification is a mistake because very reactive tissue and inflammation, especially when macrophages are present, may be mistaken for neoplasia. For this reason, a definitive diagnosis may be difficult to establish with small samples or with samples that lack some normal tissue. There are numerous instances such as with osteosarcoma, mast cell tumor, transitional cell carcinoma, some soft tissue sarcomas, and squamous cell carcinoma in which histologic features are sufficiently distinct to make a definitive diagnosis on a small sample if the tumor was sampled correctly. In other cases such as with lymphoma or granulomatous inflammation, small samples may be inadequate to establish a final diagnosis because the overall cellular pattern and interaction with normal tissue is an important diagnostic feature.

Grading and Staging of Neoplasia

In certain tumors, grading the degree of malignancy is predictive of biologic behavior,^{2,4,10} and, in the future, quite likely the behavior of more tumors will be shown to be related to histologic grade. Grading of tumors is somewhat subjective, and reproducibility between pathologists can be variable.¹³ Despite this limitation, in one study of 440,000 cases of cancer in humans, interobserver variation did not have a sufficient impact to alter the relationship

between grade and outcome.¹⁴ A recent international study applying the World Health Organization (WHO) system of lymphoma classification to canine lymphomas demonstrated a reproducibility of 83% to 87% if the classification entities were well described and illustrated for reference by those applying the classification system. With preparative training of those using the system and careful application to well-described criteria, a high level of accuracy can be achieved in diagnosing canine lymphoma or any other disease entity.¹⁵

Another difficulty is that tumors are heterogeneous, and patterns as well as features of increased malignancy may vary from area to area. If heterogeneity is present, the most malignant areas are usually assessed for grading purposes. Sampling variation with small biopsy samples can dramatically affect the representation of different components in a heterogeneous tumor; therefore, if the sample is small, accurate grading is not possible and grades should be interpreted with caution.

Features of tumors that are often evaluated to assess grade include (1) degree of differentiation, (2) mitotic index (number of mitotic figures per 10 high-power 400 \times fields), (3) degree of cellular or nuclear pleomorphism, (4) amount of necrosis, (5) invasiveness, (6) stromal reaction, (7) nucleolar size and number, (8) overall cellularity, and (9) lymphoid response (Table 3-3). Of these features, mitotic index, amount of necrosis, and nucleolar features are the only objective, quantifiable features that can be quantified with manual counting, computerized morphometry, or chemical quantification.^{2,4,10} Often, in determining a grade, individual features are scored, and then each score is added to obtain a total tumor score. The tumor scores are then separated into ranges that are associated with a tumor grade. Current grading scales are efficient, cost-effective, and involve no new technology. As the identification of molecular markers for tumor subtypes and prognostic or predictive parameters progresses and as the techniques become more time and cost efficient, yielding quicker turnaround times and easier application, they will become more routine and, likely, a valuable component of updated grading systems.

The quantifiable criteria previously mentioned for tumor grading have more recently been assessed with image analysis (computerized analytical morphometry). The use of image analysis allows for a more objective, repeatable measure decreasing interobserver variation and bias. Examples of this methodology demonstrate nuclear features such as nuclear area, mean diameter, and perimeter that correlate with mast cell tumor histologic grade, which is predictive of tumor biologic aggressiveness.^{16,17} Currently,

the routine application of computerized morphometry is not practical for routine use in diagnostic pathology due to time and effort restrictions, but it is only a matter of time before automation overcomes these limitations.

The rationale behind the effectiveness of tumor grade is the indirect assessment of molecular features. Many of the histologic criteria used in grading scales probably reflect the underlying molecular mechanisms (Table 3-4). One example would be the correlation between tumor necrosis evaluated in many tumor grades and the underlying mechanism of tumor microvessel density (MVD) and factors that affect the density of these vessels. Lack of adequate tumor vessel density will result in tumor hypoxia and thus tumor necrosis. An underlying mechanism of tumor vessel density includes the vascular endothelial growth factor (VEGF) signaling pathway. Studies have demonstrated the strong association of MVD and VEGF expression with tumor grade and biologic tumor aggressiveness.^{52,53} Another example involves the induction of hypoxia-inducible factor-1 α (HIF-1 α) by hypoxic tumor cells. The HIF-1 gene product is the alpha subunit of transcription factor HIF-1 (<http://www.ncbi.nlm.nih.gov/gene/3091>). HIF-1 α is a regulator of the cellular response to hypoxia by activating transcription of many genes involved in energy metabolism, angiogenesis, apoptosis, and other genes whose protein products increase oxygen delivery or facilitate metabolic adaptation to hypoxia. HIF-1 α thus plays an essential role in angiogenesis and pathophysiology in the hypoxic environment present in many rapidly growing tumors. HIF-1 α overexpression in brain, breast, cervical, esophageal, oropharyngeal, and ovarian cancers is correlated with treatment failure and mortality, as well as tumor progression.⁵⁴

Tumor grade may correlate with survival, metastatic rate, disease-free interval, or with frequency and/or speed of local recurrence. Tumors in which grade or histologic features have been determined to be prognostic for biologic behavior in dogs include mast cell tumor¹⁸⁻²¹; lymphoma^{24,25}; dermal, oral, and ocular melanoma^{26,29,54,55}; mammary gland carcinoma^{1,35}; synovial cell sarcoma^{39,40}; multilobular osteochondrosarcoma^{43,44}; hemangiosarcoma⁴⁷; nonhematogenous sarcoma and fibrohistiocytic nodules of the spleen^{48,49}; transitional cell carcinoma of the urinary bladder⁵⁰; squamous cell carcinoma of the tongue⁵¹; lung carcinoma^{33,34}; appendicular osteosarcoma^{42,56}; mandibular osteosarcoma⁴⁵; chondrosarcoma⁴⁶; and soft tissue sarcoma^{31,32,57} (see Table 3-3). In humans and dogs with soft tissue sarcoma, the histologic grade is more important than the tumor type.^{2,32,58} Tumors whose grade or histologic features are predictive of biologic behavior in cats include lung carcinoma³⁴ and mammary gland carcinoma,³⁸ with conflicting reports regarding feline mast cell tumor and fibrosarcoma^{22,23,59,60} (see Table 3-4).

Grading systems have not been well established for some malignant tumors, yet the pathologist can make an assessment of presumed biologic behavior based on the overall degree of tumor differentiation. In these cases, the terms *well differentiated*, *moderately differentiated* or *poorly differentiated* may be suggestive of a low-grade, medium-grade, and high-grade malignancy, respectively.⁶¹ This type of assessment is most commonly done for squamous cell carcinomas, some sarcomas, and carcinomas of the mammary gland, salivary gland, gastrointestinal tract, liver, exocrine pancreas, and perianal gland. Tumor grading probably will become even more widespread and important in the future, especially as novel analytical techniques and molecular tumor markers are included. Not only can prognosis be determined based on tumor grade and differentiation, but also treatment may be modified to apply more aggressive therapies to tumors of higher grade.

The pathologist also may assist in staging of cancer by assessing tumor size, depth of tumor invasion, the presence of tumor in regional lymph nodes, and identification of tumor in distant sites. This information is needed to stage tumors into the *T* (tumor size and/or invasion), *N* (nodal involvement), and *M* (distant metastasis) system.¹⁰ Cytologic assessment of draining lymph nodes has been shown as a sensitive alternative to histopathology for lymph node metastasis needed for staging.⁶² For some tumors such as bladder cancer in humans, tumor staging is based largely on depth of tumor invasion into the bladder wall.^{2,4} This may prove to be useful in cases of bladder cancer in pets and has been shown to correlate with tumor grade in dogs.⁵⁰ In both processes of tumor grading or tumor staging, these procedures are useful only if they have been shown to correlate with clinical behavior.

Assessment of Tumor Margins

Tumor margin assessment is an essential part of the pathology report whenever curative-intent surgical excision is attempted.³ It may be the best determinant of adequate surgical treatment and may serve as a predictor of treatment outcome.⁶³ Grossly, the surgical margin can be defined as the margin beyond which tissue remains in the surgical bed or any region of the biopsy specimen adjacent to or contiguous with tissue that remains in vivo.⁶³ Microscopically, the surgical margin is the region between the neoplastic process and the surgical edge of the biopsy specimen. Margin assessment should be performed for both benign and malignant lesions, although detailed characterization of the margin (e.g., objective measurement, tissue constituents, viability) is typically more critical for malignancies. Obtaining accurate surgical margin information on the pathology report is critically dependent on (1) specimen handling and information submitted by the clinician, (2) method of tissue trimming at the diagnostic laboratory, and (3) observations reported by the pathologist.

Appropriate assessment of the surgical margin is at the onset critically dependent on information provided by the submitting clinician and moreover by appropriate tissue demarcation (e.g., inking) prior to submission. Inking is superior to other methods of denoting surgical margins (e.g., suture placement) because surgical ink is visible at both the gross and microscopic levels.^{4,64} At the gross specimen level, the surgical ink impacts the regions of the specimen that are obtained by laboratory personnel during trimming for microscopic examination. At the microscopic level, assuming appropriate corresponding information was provided on the submission form by the clinician (e.g., yellow ink = deep margins, black ink = lateral margin), the ink allows the pathologist to appropriately assess and report the margins relative to a specific region. Surgical ink should only be placed on regions of the specimen that are *true* surgical margins or of specific concern to the clinician. The ink should also be allowed to dry (typically 5 to 10 minutes) prior to placement into a fixative (e.g., 10% neutral buffered formalin) to prevent the ink from washing off or unintentionally coating insignificant areas.⁶³

Once at the laboratory, the specimen will be trimmed routinely with guidance from the information provided on the submission form and based on any tissue markings. If desired and if it enhances communication, annotated sketches or images of the specimen may also be submitted. The most common method of trimming for routine specimens is known as the *cross-sectioning method*. The mass is bisected along its short axis, after which each remaining half is bisected along its long axis, creating quarter sections. Ultimately, this method is perpendicular sectioning and allows for margin

• **TABLE 3-4** Neoplasia with Grades or Histologic Features Having Prognostic Significance

TUMOR TYPE	GRADES GIVEN	FEATURES OF IMPORTANCE	REFERENCES
Mast cell tumor, cutaneous (dog)	I, II, III 2-tier: High, low SQ: High, low	Cellularity, nuclear:cytoplasmic ratio, cell morphology, mitotic index, depth, necrosis, granularity Mitotic index, karyomegaly, multinucleation, bizarre nuclei Mitotic index ≤ 4 , >4 ; invasiveness; multinucleation	18, 19 20 21
Mast cell tumor, cutaneous (cat)	Well and poorly differentiated, histiocytic	Cellular and nuclear pleomorphism, mitotic index	22, 23
Lymphoma	Low, intermediate, high	Architecture, mitotic index, nuclear size, morphology, T-cell/B-cell immunophenotype	24, 25
Dermal melanoma	Well and poorly differentiated	Mitotic index: $\geq 3/10$ hpf	26, 27
Oral and lip melanomas	Well and poorly differentiated	Mitotic index: $\geq 3/10$ hpf	28
Anterior uveal melanoma (cat, dog)	I-VI (or early, moderate, advanced); benign, malignant (dog)	Mitotic index, extent of invasion	29, 30
Soft tissue sarcoma (dog)	1, 2, 3 or mitotic index >9 ,* mitotic index <9 *	Overall differentiation, mitotic index, necrosis	31, 32
Lung/pulmonary carcinoma (dog)	1, 2, 3	Overall differentiation, nuclear pleomorphism, mitotic index, necrosis, nucleolar size, fibrosis, invasion	33, 34
Lung/pulmonary carcinoma (cat)	Moderately and poorly differentiated	Organization, pleomorphism, pulmonary and vascular invasion	34
Mammary gland carcinoma (dog)	System 1: Well, moderately, and poorly differentiated grades System 2: Grades I, II, III	Invasion, nuclear differentiation, lymphoid response Tubule formation, nuclear pleomorphism, mitotic index, simple carcinoma versus other, lymph node metastasis	35-37
Mammary gland carcinoma (cat)	System 1: Well, moderately, and poorly differentiated grades System 2: Grades I, II, III	Differentiation, cellular pleomorphism, mitotic index Same as system 2 for dog	37, 38
Synovial cell sarcoma	1, 2, 3 Histiocytic or nonhistiocytic Myxoma or nonmyxoma	Nuclear pleomorphism, mitotic index, necrosis CD18± Abundant myxomatous matrix	39-41
Primary and metastatic osteosarcoma (dog)	I-III	Tumor pleomorphism, mitoses, tumor matrix, cell density, necrosis, vascular invasion	42
Multilobular osteochondrosarcoma	1, 2, 3	Borders, lobule size, organization, mitotic index, nuclear pleomorphism, necrosis	43, 44
Mandibular osteosarcoma	1, 2, 3	Nuclear pleomorphism, mitotic index, necrosis	45
Appendicular chondrosarcoma	1, 2, 3	Tumor pleomorphism, mitoses, tumor matrix, cellularity, necrosis, architecture	46
Hemangiosarcoma	1, 2, 3	Overall differentiation, nuclear pleomorphism, mitotic index, necrosis	47
Nonlymphoid, nonangiomatous splenic sarcomas	Mitotic index 0-9,* mitotic index >9	Mitotic index	48
Fibrohistiocytic nodules of spleen	1, 2, 3	Proportion of lymphocytes and multinucleated cells, mitotic index	49
Transitional cell carcinoma	1, 2, 3	Cytoplasmic and nuclear variation, nuclear placement, nucleolar size/number, mitoses	50
Squamous cell carcinoma	1, 2, 3	Overall differentiation, mitotic index, nuclear pleomorphism, invasion, stromal reaction	51

*Sum of mitoses in ten 400× fields.

evaluation at four lateral and four deep regions of the specimen.⁶⁵ Additional techniques exist that can increase the region of marginal tissue evaluated although increased costs may also be incurred. These techniques include “parallel” sectioning, “modified” sectioning (a combination of parallel and cross-sectioning), and “tangential” sectioning.⁶³ An additional method for evaluating excisional completeness is to evaluate the “tumor bed,” which is the in vivo tissue that was adjacent to or contiguous with the excised specimen. Small regions/scrapings from the tumor bed may be submitted in addition to the excised mass but should be submitted in a separate container and clearly specified that it is “tumor bed” tissue. If neoplastic cells exist within the tumor bed tissue, this indicates presence of residual disease in the patient.

Specimens come in all shapes and sizes, thus no one blanket trimming method can be recommended. Additionally, each method has advantages and disadvantages. The most important fundamental aspects of trimming to recognize are that the regions selected for microscopic examination (1) adequately represent the mass lesion for diagnosis and (2) are the most appropriate for margin evaluation for that specific specimen. It is essential for clinicians to understand the various trimming methods that exist and the methods by which their own specimens are being trimmed, to have an understanding of the percentage of marginal tissue that is evaluated relative to the entire surgical margin, and to recognize that they can greatly influence the region of the tissue examined microscopically through inking and information provided on the submission form.

Assuming tissue demarcation, specimen submission, and tissue trimming have all been appropriately performed, microscopic reporting of the surgical margins should be clear, concise, and thorough, furnishing the clinician with essential information such that they can make informed decisions and recommendations regarding further management of the cancer patient. Thorough microscopic evaluation of the tissue margin should include (1) a description of the neoplastic cells closest to the margin (e.g., individual cells, nests of cells, cells at the periphery of the mass itself); (2) an objective measurement (via stage or ocular micrometer) from the tissue edge to the closest neoplastic cell (this parameter is precluded for tangentially trimmed sections); and (3) a description of the tissue constituents (e.g., adipose tissue, dense connective tissue, skeletal muscle) and quality of these constituents (e.g., normal, necrotic, inflamed) composing the margin because different tissue types provide variable barriers against invasion and infiltration of neoplastic cells.⁶³ Objective measurements may be provided in any appropriate metric (e.g., micrometers, millimeters), but the metric used should remain consistent for all margins reported for a given specimen. Vague and ambiguous terminology such as *clean*, *dirty*, *close*, or *narrow*, should be avoided, since these are subjective and introduce interpretative variability.

Microscopic evaluation of surgical margins to assess excisional completeness is not a perfect science but is approached to provide the best possible assessment. If surgical resection is determined to be complete by microscopic evaluation, the chance of local recurrence is reduced, but by no means is local tumor control guaranteed. Recurrence of soft tissue sarcomas in humans has been shown to occur in about 10% of cases in which margins were deemed complete⁶⁶; a similar situation likely exists in veterinary medicine. Additionally, “complete excision” of local disease does not address the potential for systemic or metastatic disease and thus in no way can confirm a disease-free state.

Many tumor-specific (especially canine soft tissue sarcoma and mast cell tumor) studies have been performed with the goal of correlating surgical margins to clinical outcome.^{32,67-73} To this end, it is

important to note that tissue shrinkage subsequent to formalin fixation does occur and the degree of shrinkage varies relative to tissue type.⁷⁴⁻⁷⁷ For cutaneous biopsies, shrinkage can occur up to 30%.^{75,77} Additionally, tissue shrinkage is impacted by inherent postexcisional tissue retraction, as well as dehydration steps during processing. These changes may result in reported surgical margins that appear to be significantly less than the clinician believed were obtained at surgery.

Assessment of Treatment Response

Sometimes histologic assessment of preoperative treatment response may help predict outcome and could even alter subsequent therapeutic options. Assessment of preoperative therapy is most common with osteosarcoma and soft tissue sarcoma. Percent tumor necrosis is the most commonly used parameter to quantify the impact of presurgical chemotherapy or radiation therapy. In dogs with osteosarcoma, percent tumor necrosis is a good predictor for local recurrence following limb-sparing surgery subsequent to neoadjuvant radiation therapy and/or chemotherapy. Tumor necrosis rates of 90% or more, between 80% and 90%, and below 80% are associated with 91%, 78%, and 28% local control rates, respectively.^{78,79} In humans, the percent of tumor necrosis in osteosarcoma following preoperative chemotherapy is also predictive for survival, and poor responders may be treated with more aggressive alternative chemotherapeutic regimes.⁸⁰ In soft tissue sarcomas, percent tumor necrosis has been used to assess presurgical therapy in humans⁸¹ and could be done in companion animals.

The effect of previous treatment also may be evaluated histologically when there is progressive growth of tissue in an area treated previously with radiation, surgery, chemotherapy, or photodynamic therapy. In these cases, distinguishing between reactive tissue and neoplasia is important but also may be extremely difficult. Inflammation, fibrovascular proliferation (granulation tissue), or epithelial hyperplasia (if applicable) is usually present in the area. Furthermore, especially after radiation therapy, the area may contain some bizarre reactive cells, including fibroblasts (called *radiation atypical fibroblasts*) with many features of malignancy, although these cells are not neoplastic.⁸² If tumor cells are identified, the clinician may wish to know if these cells are viable, dead, or rendered viable but sterilized (reproductively dead) by radiation or chemotherapy. Distinction between a viable and dead cell is often possible, but determining if a cell is viable but sterilized, or nonclonogenic, is not possible with routine microscopy. However, the presence of numerous mitotic figures in a viable-appearing tumor is suggestive of active regrowth.

Molecular techniques hold promise in identifying the adequacy of treatment and/or treatment response. Use of PCR to identify residual circulating lymphoma cells in dogs during clinical remission holds promise as an early indicator of tumor reoccurrence prior to clinical and histologic/cytologic identifiable disease. New techniques that identify large portions of the tumor's genomic expression (gene expression microarrays) and molecular phenotype (tissue microarrays, protein microarrays, and mass spectrometry) can identify tumor gene and phenotypic profiles that are predictive of a tumor's biologic behavior, a tumor's response to treatment, or early tumor recurrence.

Special Procedures

Approximately 90% of oncologic cases in humans can be diagnosed by light microscopy using hematoxylin and eosin (H&E) stains.³ This likely approximates the situation in veterinary medicine as

well. In the remaining 10% of cases, special stains or special procedures such as IHC or EM may help. IHC, flow cytometry, or other molecular techniques may also be useful in predicting tumor behavior or may help in distinguishing benign from malignant tumors (see Chapter 8).

Special Histochemical Stains

Histochemical stains consist of chemical substances that, when applied to tissue sections, result in a direct chemical reaction with tissue constituents. For all intents and purposes, routine H&E is a histochemical stain; however, many additional special histochemical stains exist. In veterinary oncologic pathology, these stains are most commonly used to assist in the diagnosis of certain poorly differentiated tumors.¹⁰ Toluidine blue and Giemsa are two of the more common histochemical stains that aid in the identification of mast cell granules in poorly differentiated mast cell tumors. Periodic acid–Schiff (PAS), another histochemical stain, is often used in feline and ferret mast cell tumors because the granules in these species are often better visualized with PAS.

Silver stains such as Pascual's, Grimelius, or Sevier-Munger can aid in the identification of neuroendocrine tumors. Sudan black and Oil Red O stains are specific for lipid and thus may aid in the diagnosis of poorly differentiated liposarcomas or lipid-rich variants of some carcinomas and other tumor types.^{83–86} It should be noted that these stains must be performed on nonprocessed tissue because exposure to xylene during processing will dissolve lipid components. A melanin bleach or iron stain (Prussian blue) may help distinguish between melanin and hemosiderin, respectively, in suspected cases of melanoma. Masson's trichrome or other trichrome stains may be used to identify collagen fibrils; this can help differentiate certain mesenchymal tumors, such as those derived from muscle (leiomyomas, leiomyosarcomas, rhabdomyoma, rhabdomyosarcomas), and those that produce collagen matrix (fibromas, fibrosarcomas). It is important to keep in mind, however, that muscle-derived tumors may have a small amount of collagen inherent in the surrounding microenvironment, and poorly differentiated fibrosarcomas may produce only minimal, if any, collagen. Phosphotungstic acid hematoxylin (PTAH) can aid in differentiating a rhabdomyosarcoma from leiomyosarcoma or other tumor as it enhances visibility of the cytoplasmic cross-striations present in skeletal muscle. Alcian blue stain may help identify ground substance glycosaminoglycans that may be seen in some neurofibrosarcomas or myxosarcomas. Mucicarmine stain or PAS is useful in mucosal tissues for identifying poorly differentiated carcinomas, whereas PAS is also helpful in the diagnosis of granular cell tumor as it reacts with the intracytoplasmic lysosomes.

With the advancement of IHC (discussed later), many histochemical stains have lost popularity but are still available and useful in the appropriate setting. Silver staining of nucleolar organizer regions (AgNOR) is an additional histochemical stain that has been shown to be prognostically relevant in canine malignant lymphoma⁸⁷ and mast cell tumors.⁸⁸

Immunohistochemistry

Immunohistochemistry (IHC) can aid the classification of several tumors in veterinary medicine and is a widely used diagnostic technique. IHC is a staining procedure that employs commercial antibodies to identify specific cellular and extracellular molecules *ex vivo*, such as cytoplasmic intermediate filaments, secretory substances, and cell surface markers. IHC can be performed on frozen sections or specimens routinely fixed in formalin and processed into paraffin blocks. The tissue sections are incubated with primary antibodies to specific cell proteins (the antigens). These sections

with bound primary antibody are then exposed to secondary antibodies directed against the primary antibody. The secondary antibodies are linked to peroxidase or avidin-biotin peroxidase complexes. The peroxidase catalyzes a reaction in the presence of dye that precipitates at the site of the complex and is visible with light microscopy.^{3,89} As an alternative, alkaline phosphatase enzyme systems are also available. Commonly used immunohistochemical stains include those for intermediate filaments, such as vimentin for mesenchymal cells, cytokeratin for epithelial cells, and desmin or actin for muscle cells (myocytes).^{3,90–92} A list of common diagnostic IHC markers used in veterinary oncology and the respective tumor types in which their use is indicated is provided in Table 3-5.

IHC can also be useful in determining cellular proliferation or the tumor growth fraction that may carry prognostic relevance.¹¹⁶ This can be done using Ki-67 and PCNA staining, markers of multidrug resistance (e.g., P-glycoprotein),¹³⁶ or altered proto-oncogenes such as p53, CD117/c-Kit, p21, Rb, and PTEN.^{137–139} Other markers that have been explored as potential prognostic markers via IHC in a variety of veterinary tumor types include VEGF, cyclooxygenase-2 (COX-2), epidermal growth factor receptor (EGFR), human epidermal growth factor receptor-2 (HER2), urokinase plasminogen activator (UPA), and heat shock proteins (HSPs), among others. As the realm of IHC in veterinary medicine continues to advance, so too will the discovery of tumor-specific diagnostic markers, as well as markers for prognostic (biologic aggressiveness) and predictive (response to therapy) utility.

Although IHC can be a valuable tool, some complicating factors exist. A negative stain does not exclude a certain cell type as technical difficulties or tumor cell dedifferentiation, causing loss of expression of expected proteins/markers, may result in a negative stain. One of the more common technical problems that can cause negative staining is prolonged formalin fixation that results in excessive cross-linking of the antigenic components or loss of soluble proteins into the fixative. Antibody-specific antigens (epitopes) that have been masked by protein cross-linking can often be “unmasked” by pretreating sections with trypsin or pepsin or by using heat-induced epitope retrieval (HIER) techniques.⁸⁹ Decalcification of tissue may also result in alteration of target proteins so that they are no longer recognized by the respective antibody; however, the type and duration of decalcifying solution may mitigate these deleterious effects.⁸⁹ Areas of tissue necrosis, autolysis, hemorrhage, section drying, and sometimes collagenous matrix components can cause excessive nonspecific background staining. A skilled pathologist who is familiar with the IHC stain should be asked to differentiate background stain from tumor-specific stain and to navigate technical difficulties. Additionally, IHC does not distinguish between neoplastic and nonneoplastic tissue, normal, or hyperplastic. For example, normal bladder mucosal epithelium (urothelium), urothelial hyperplasia, and urothelial carcinoma (transitional cell carcinoma) would all be immunopositive for cytokeratin. The differentiation between neoplastic and nonneoplastic is made via routine H&E light microscopy based on hallmark features of neoplasia (e.g., loss of organization, cellular atypica, invasion). IHC is an ancillary diagnostic tool that aids in determining histogenesis for poorly differentiated tumors. Considerable cross-reactivity of staining in different tumor types may occur because some markers lack specificity and can be found in a variety of cells or tumors (e.g., S-100 in melanomas, cartilage, and certain epithelial cells).^{3,140} Because most tumor markers have limitations, the best and most reliable results may be obtained by using a panel of IHC stains wherein both marker-specific immunopositive and immunonegative results may be anticipated (e.g., rhabdomyosarcoma should be immunopositive for vimentin and desmin but

• **TABLE 3-5** Common Diagnostic Immunohistochemical Markers/Panels and Respective Tumor Types in Cats and Dogs

TUMOR TYPE	MOLECULAR MARKER(S)	LOCALIZATION/EXPRESSION	PROTEIN FAMILY/FUNCTION	COMMENTS	REFERENCES

Lymphoma, B-cell	CD18 ⁺ , CD3 ⁻ , CD79a ⁺ , Pax5 ⁺ ‡	CD18, CD3e, CD79a = PM Pax5 = N	CD18 = Integrin $\beta 2$ chain CD3e = Transmembrane protein (epsilon chain) of the T-cell receptor complex CD79a = Transmembrane protein (alpha chain) of the B-cell receptor complex Pax5 = Transcription factor involved in the development and differentiation of B-cells	At the time of this writing, Pax5 immunopositivity in feline B-cell lymphoma is not reported in the literature but has been anecdotally observed by the authors.	112-115

Lymphoma, T-cell	CD18 ⁻ , CD3 ⁺ , CD79a ⁻ , Pax5 ⁻	CD18, CD3e, CD79a = PM Pax5 = N	As above	Pax5 is also known as <i>BSAP</i> , a member of the highly conserved paired box (PAX)-domain family of transcription factors and is encoded for by the <i>Pax5</i> gene.	112-115
Lymphoma, null cell	CD18 ⁻ , CD3e ⁻ , CD79a ⁻ , Pax5 ⁻ (and exclusion of other round cell tumors)	CD18, CD3e, CD79a = PM Pax5 = N	As above		112
Mast cell tumor	Tryptase ⁺ (C-kit/CD117) [§]	Tryptase = Cyto	Tryptase = Mast cell-specific protease enzyme	<i>Histochemical</i> stains Toluidine blue and Giemsa are more commonly used to confirm mast cell origin. Tryptase IHC is fairly uncommon but is available if other diagnostic parameters are unrewarding.	116, 117
Melanocytic neoplasms (melanotic and amelanotic)	Melan-A ^{+/} PNL2 ^{+/+} Tyrosinase ^{+/+} TRP-1 ^{+/+} TRP-2 ^{+/+} Vim ⁺ S-100 ^{+/+}	Melan-A = Cyto PNL2 = Cyto Tyrosinase = Cyto TRP-1&2 = Cyto Vim = Cyto S-100 = N & Cyto	Melan-A = Melanocyte antigen recognized by T-cells (melanocyte lineage-specific protein) PNL2 = Unknown Tyrosinase = Melanocyte differentiation protein involved in melanin synthesis TRP-1&2 = Glycoproteins involved in melanin synthesis Vimentin = IFPs S-100 = Calcium flux regulator	Melan-A/MART-1 PNL2 is melanocyte-specific save for myeloid cells, especially neutrophils	118-124
Neural astrocytic tumors (astrocytoma, glioblastoma, oligoastrocytoma)	GFAP ⁺ S-100 ^{+/+}	GFAP = Cyto S-100 = N & Cyto	GFAP = IFP S-100 = Calcium flux regulator	Astrocytomas are glial tumors like oligodendrogliomas; however, oligodendrogliomas are negative for GFAP.	94, 125, 126
NE tumors	Chromogranin A [¶] Synaptophysin ⁺ NSE ⁺	Chromogranin = Cyto Synaptophysin = Cyto NSE = Cyto	Chromogranin = Soluble protein extract of neurosecretory granules in NE cells Synaptophysin = Gp and integral component of the NE secretory granule membrane NSE = Glycolytic isoenzyme involved in various reactions	NSE lacks NE specificity as it is found in a number of other normal and neoplastic cell types but is considered useful in combination with other NE markers.	93, 127, 128
Plasma cell tumor	MUM-1/IRF4 ⁺ CD18 ^{+/+} CD3e ⁻ CD79a ^{+/+} (Pax5 ⁻)	MUM-1 = N CD18, CD3e, CD79a = PM Pax5 = N	MUM-1 = Transcription factor involved in lymphoid differentiation. CD18, CD3e, CD79a Pax5 = As above	In humans, plasma cell neoplasms, multiple myeloma, and plasmablastic lymphomas typically are negative for Pax5; however, currently, similar tumors have not been evaluated in dogs.	129, 130

(continued)

• **TABLE 3-5** Common Diagnostic Immunohistochemical Markers/Panels and Respective Tumor Types in Cats and Dogs (continued)

TUMOR TYPE	MOLECULAR MARKER(S)	LOCALIZATION/EXPRESSION	PROTEIN FAMILY/FUNCTION	COMMENTS	REFERENCES
Rhabdomyosarcoma	Vim ⁺ Desmin ⁺ Myoglobin ^{+/−} SMA [−]	Cyto	Vim, Desmin, & SMA = IFPs Myoglobin = Iron-binding protein exclusively in skeletal muscle	Myoglobin is typically a late-stage marker and thus may be negative in poorly differentiated rhabdomyosarcomas. Myo-D1 and myogenin are also skeletal muscle-specific markers but are not routinely used. PTAH is a histochemical stain that may assist in highlighting cyto cross-striations of skeletal muscle.	93, 131, 132
Sarcoma	Vimentin ⁺ Cytokeratin [−]	Cyto	IFP		93-95
Thyroid tumor: Follicular epithelial origin (follicular carcinoma)	Thyroglobulin ⁺ TTF-1 ⁺ Calcitonin [−] Chromogranin A [−] Synaptophysin [−] NSE [−]	Thyroglobulin = Cyto TTF-1 = N Calcitonin = Cyto	Thyroglobulin = Heavily glycosylated protein providing iodination sites for the production of thyroid hormones TTF-1 = Nuclear transcription factor specific to thyroid tissue save for pulmonary epithelium Calcitonin = Polypeptide hormone secreted by thyroid C-cells; counteracts effects of PTH by reducing blood Ca ²⁺		133-135
Thyroid tumor: C-cell/ parafollicular cell origin (medullary C-cell carcinoma)	Thyroglobulin [−] TTF-1 ⁺ Calcitonin ⁺ Chromogranin A ⁺ Synaptophysin ⁺ NSE ⁺	As above	As above		133-135

This table provides common diagnostic immunohistochemical markers utilized in veterinary oncologic pathology. For a complete list of cell-specific markers available for use in veterinary samples, visit www.ihc.sdsstate.org. Immunohistochemical stains should always be interpreted in conjunction with routine (hematoxylin & eosin [H&E]) histopathologic evaluation and in the presence of appropriately stained positive and negative control tissues.

BSAP, B-cell-specific activator protein; *Cyto*, cytoplasmic; *DOG1*, discovered on gastrointestinal tumor 1; *EC*, endothelial cell; *Factor VIII-RAg/vWF*, factor VIII-related antigen/von Willebrand factor; *GFAP*, glial fibrillary acidic protein; *GIST*, gastrointestinal stromal tumor; *Gp*, glycoprotein; *IFP*, intermediate filament protein; *IHC*, immunohistochemistry; *MKS*, megakaryocytes; *MUM-1/IRF4*, multiple myeloma 1/interferon regulatory factor 4; *N*, nuclear; *NE*, neuroendocrine; *NSE*, neuron-specific enolase; *PECAM1*, platelet endothelial cell adhesion molecule; *PM*, plasma membrane; *PTH*, parathyroid hormone; *PTAH*, phosphotungstic acid hematoxylin; *RTK*, tyrosine kinase receptor; *SMA*, smooth muscle actin; *TRP*, tyrosinase-related protein; *TTF-1*, thyroid transcription factor-1; *Vim*, vimentin.

*Generic marker for tumors of epithelial origin.

†A well characterized diagnostic marker for GISTs in humans and, at the time of this writing, under investigation for veterinary application by one of the chapter authors (BEP).

‡At the time of this writing, reported only in the dog; however, anecdotally observed in feline lymphoma by the authors.

§c-kit/CD117 is *not* diagnostic for mast cell tumors because it is not mast-cell specific, but it has been shown to carry prognostic relevance in canine cutaneous mast cell tumor based on its cellular localization/expression pattern determined via immunohistochemistry.¹⁶

||Rare positivity in amelanotic melanomas.

¶Generic markers for tumors of neuroendocrine (NE) origin. A panel of all three markers is strongly recommended because NE tumors may be positive for only one of the three.

#Generic marker for tumors of mesenchymal cell origin.

immunonegative for smooth muscle actin) rather than relying on a single stain. Additionally, IHC stains can *only* be appropriately interpreted in the presence of appropriate species-specific controls. For example, if one seeks to support the diagnosis of or immunophenotype an intestinal lymphoma in a cat, the appropriate positive control tissue that must be run simultaneously would be a section of normal feline lymphoid tissue (e.g., lymph node, spleen, tonsil, or other). It must be of feline origin and contain normal lymphoid tissue in order for the pathologist to confirm that the IHC stain was successfully performed and to appropriately interpret the immunoreaction of the test tissue. Similarly, a negative control that consists of the test tissue treated either with nonspecific antibody or omission of the primary antibody must also be run to assist in ruling out background/nonspecific staining. Finally, IHC can be a powerful tool providing information that could not otherwise be determined on routine microscopy alone (e.g., confirmation of tumor histogenesis); however, an IHC stain should never be interpreted in and of itself but rather should always be evaluated in conjunction with routine light microscopic findings and knowledge of relevant clinical information.

Electron Microscopy

EM involves preserving very small representative tumor samples (1×1 mm) in special fixatives such as glutaraldehyde, processing tissue into epoxy-based plastic blocks, and sectioning at $1 \mu\text{m}$ for thick sections to determine the adequacy of the sample and inclusion of appropriate tumor cells. Subsequently, sectioning is done at about 600\AA , stained with heavy-metal-based stains, and examined with the aid of the electron microscope. Samples fixed in formalin can be used, although the quality of the subsequent sections is less than ideal. EM may help identify certain specific features, such as intercellular junctions or basal lamina in epithelial cells, melanosomes in melanocytic cells, mast cell granules in mast cells, neurosecretory granules in neuroendocrine cells, or mucin droplets in certain epithelial cells. These features are useful in distinguishing carcinomas from lymphomas and identifying melanomas, mast cell tumors, and neuroendocrine tumors. Unless a specific feature is sought, however, EM will be no more useful than a higher magnification of a tumor that could not be diagnosed with the light microscope. Furthermore, EM is not useful for distinguishing benign from malignant cells in many cases because the magnification is too high and the tumor pattern in the tissue is not evident.^{4,10} Not all veterinary diagnostic laboratories have the technical support and equipment needed for EM.

Flow Cytometry and Polymerase Chain Reaction

Flow cytometry is an analytic procedure that can be used to evaluate cell suspensions obtained from suspected neoplastic masses or fluids. In human medicine, this procedure is frequently used to diagnose and occasionally to monitor for the recurrence of various tumors, such as bladder carcinoma. Use of flow cytometry for humans is especially useful for detecting neoplastic cells in the urine of bladder cancer patients and in the evaluation of cell suspensions of suspected leukemia and lymphoma. In solid tumors, the cells must first be dissociated to create a single cell suspension. Cell suspensions are stained with specific fluorochromes, passed through the flow cytometer chamber, and analyzed and sorted by use of a focused laser beam. The most routine analysis is to determine DNA content or ploidy of the cells. Malignant cells may be diploid (normal DNA content) or aneuploid (nondiploid), but

normal tissue, benign tumors, and reactive tissues are usually diploid. Occasionally, however, benign tumors and reactive tissue can be aneuploid. In some instances, aneuploidy may be prognostically significant and can be predictive of survival time. Flow cytometry also can be used to evaluate S-phase distribution or cell cycle time if the tumor is sampled at appropriate times after injecting the patient with bromodeoxyuridine (BrdUrd).¹⁴¹

Flow cytometry has been used to evaluate tumors in dogs and is becoming a more routine diagnostic procedure combined with other tests, including histopathology and cytopathology, immunocytochemistry, and PCR. In the earliest report, various canine tumors were characterized for DNA ploidy.¹⁴² In subsequent studies, tumor cell heterogeneity, comparisons of primary and metastatic tumors, and the positive predictive value of kinetic parameters in canine osteosarcomas were evaluated.^{143,144} Other studies have indicated the value of flow cytometry in predicting the behavior of various canine tumors, including lymphomas,^{145,146} myeloproliferative disease,¹⁴⁷⁻¹⁴⁹ mammary gland tumors,¹⁵⁰ melanomas,¹⁵¹ osteosarcomas,¹⁴³ and plasmacytomas.¹⁵² Flow cytometry can also be useful for analyzing abnormal populations of white blood cells in blood or fluid, helping to distinguish lymphoma from reactive processes. As samples to be evaluated by flow cytometry are often cell suspensions derived from tumor masses, a correlate sample from the same site or same specimen should always be taken for histopathologic assessment. Histologic correlation is necessary because flow cytometry cannot distinguish a benign from a malignant diploid tumor, nor can it always identify tumor type.³ Currently the use of flow cytometry in diagnostic medicine to identify tumor subtypes, occult disease with a leukemic component, or cell surface prognostic markers is crossing over from investigational to practical diagnostic veterinary medicine.

PCR is a technique now commonly used to distinguish lymphoma from reactive processes by evaluating for the presence of antigen-receptor rearrangements (PARR) to determine clonality. The PCR is used to amplify DNA encoding the antigen-binding region of lymphocytes, and a clonal or single-size product indicates malignancy. In an early study, 91% of lymphomas were identified by this technique.⁶ This technique also accurately identified B- or T-cell immunophenotype. Currently, air-dried aspirates, fresh, or formalin-fixed tissue can be used for this technique. Mutations resulting in internal tandem duplication in exon 11 of the *c-Kit* gene, CD117 or stem cell growth factor receptor, have been identified as a mutation constitutively activating this tyrosine kinase receptor, resulting in a more aggressive biologic behavior in canine mast cell tumors.^{153,154} PCR is currently used to identify this mutation in a diagnostic setting as a biologic marker of prognosis.

Clinical-Pathologic Correlation and Second Opinions

Sometimes the pathologist cannot make an accurate diagnosis without clinical correlations.^{2,4} This is especially true for some primary bone tumors or secondary tumors involving bone. Diagnosis of a surface or juxtacortical osteosarcoma is based on both radiographic and histologic features. An osteoma may be difficult to distinguish from reactive bone without a corroborative radiograph. A synovial cell sarcoma may be difficult to distinguish from other sarcomas or even inflammatory or immune-mediated joint disease unless there is radiographic or gross evidence of joint involvement and bone invasion. An acanthomatous epulis may be difficult to distinguish from a fibrous epulis unless there is bone

invasion in the former that cannot be identified without appropriately deep biopsy samples that include underlying bone. The best example of the need for clinical and pathologic correlation is with histologically low-grade yet biologically high-grade fibrosarcomas of the canine head in which the histologic appearance is of benign fibrous tissue, but the clinical presentation is an aggressive invasive mass, often recurrent after conservative surgery, causing bone destruction.¹¹ These examples demonstrate the necessity for an accurate history with pertinent clinical results being provided to the pathologist along with the biopsy sample. In some cases, photographs of the tumor site or inclusion of radiographs or radiographic findings are most helpful.

Before any major treatment is undertaken or if a pathology diagnosis is not consistent with clinical presentation, a second opinion should be requested from the pathologist. In human medicine, a review of mandatory second-opinion surgical pathology at major hospitals revealed 1.4% to 5.8% major changes in diagnosis that resulted in change of therapy or prognoses. It was concluded that despite the extra cost, mandatory second opinions should be obtained whenever a major therapeutic endeavor is considered or if treatment decisions are based primarily on the pathologic diagnosis.¹⁵⁵⁻¹⁵⁷

The two major categories of errors that may occur at the pathology laboratory are technical errors and errors in interpretation of the tissue.⁶¹ Technical errors may occur if the histotechnologist improperly labels specimens, tissue blocks, or slides or fails to process all the critical tissue submitted by the clinician. If tissue is improperly processed because of equipment malfunction or because it is poorly sectioned, artifacts can occur that make the tissue specimen impossible to interpret. Errors in interpretation by the pathologist may occur in difficult cases. If a pathology service staffed by physicians is used, certain tumors such as histiocytoma, mast cell tumor, transmissible venereal tumor, or perianal gland adenoma may be misdiagnosed, as these do not have a human counterpart. Many pathologists will obtain opinions from other pathologists when confronted with difficult cases, just as clinicians will seek second opinions on difficult radiographs or clinical problems. *The clinician should never hesitate to ask for a second opinion nor should the pathologist be offended by the request.* Each pathologist approaches a section differently and in some cases, one approach might prove more accurate than another. A second or even third pathologist can offer a different perspective on a difficult case, offer an alternative diagnosis, confirm the primary pathologist's diagnosis, or confirm that an accurate diagnosis is not possible. Since the patient's treatment options or decisions regarding euthanasia are often based on the final pathology diagnosis, it is not at all unreasonable for the clinician to request a second opinion. A misdiagnosis can result in costly, ineffective, and untimely treatments that can cause undo discomfort for patients. They can result in unnecessary surgery, unnecessary chemotherapy or radiation therapy, insufficient treatment resulting in cancer progression, and, worst of all, unwarranted euthanasia. Considering these possible scenarios, second opinions are not only prudent but highly recommended.

The clinician needs to have knowledge of the pathology of neoplasia to understand neoplastic conditions and understand the limitations of histopathologic assessment in the diagnosis of neoplasia. In the case of tumor diagnosis, histopathologic assessment of a thin slice of tissue may not always be an exact science. The pathologist and the clinician must work together to establish the most appropriate diagnosis so that proper treatment can be initiated.

Epidemiology and the Evidence-Based Medicine Approach

LESLEY M. BUTLER, BRENDA N. BONNETT, AND RODNEY L. PAGE

Epidemiology has been traditionally defined as the study of the distribution and determinants of disease in populations. Although historically epidemiologic methods were primarily used for the investigation of outbreaks and/or epidemics of infectious disease, the philosophies, attitudes, methodologies, and application of epidemiology are in fact more broadly applicable to research and clinical practice, regardless of species, disease, or discipline. Evidence-based medicine (EBM) is an approach to the practice of health care that is now well-accepted in the human and veterinary fields. Using the EBM approach involves a commitment to base all decisions on the best available evidence and to be explicit about the level and quality of evidence on which decisions are based. Much of the underpinning of EBM, including study design and interpretation, are also facets of epidemiology. Extensive literature is available on EBM and evidence-based practice in the human field (e.g., The Cochrane Collaboration [<http://www.cochrane.org/about-us/evidence-base-health-care/webliography/books/ebhc>]).

The EBM approach can and should be applied to all interventions, including diagnosis and prognosis, and choice of preventive and clinical therapies applied to individuals, as well as decisions about health policy or control programs for populations. Pathophysiology forms the basis of our understanding of health and disease, but this knowledge, even combined with clinical acumen and experience, is not sufficient grounds for decision making across the spectrum of activities of health professionals. In order to have confidence that our interventions will be beneficial, we need to understand that personal and expert opinion are only anecdotal evidence, unless they are based on a valid appraisal of available evidence from the literature. In addition to embracing the philosophy of EBM, all clinicians must develop the knowledge and skills such as information management, critical appraisal, and causal reasoning that are needed to assess evidence in order to determine that their chosen interventions are both efficacious and effective (see glossary of terms in Table 4-1). Unfortunately, especially in veterinary medicine, there are many gaps in our evidence base, both in terms of validity and relevance of published studies.

In veterinary medicine, in general, and in certain specialties, including oncology, the trend has been toward a heightened sophistication of practice, including the use of advanced technologies in diagnostic testing (e.g., state-of-the-art imaging techniques and molecular characterization of tumors) and therapeutic interventions (e.g., interventional surgery and targeted, small molecule chemotherapy). This trend has been due in part to the presumption that most clients want care for their pets at more or less the level they themselves receive. Therefore many approaches and interventions have been adopted from human medicine and applied to animals despite considerable gaps in evidence as to their efficacy and/or effectiveness in the veterinary clinical situation. Additionally, even where a sufficient quantity of studies is present, the

quality and consistency of reporting is frequently inadequate to allow systematic review or adequate comparison between studies.¹ This issue is not unique to oncology and has spawned efforts to improve the reporting of veterinary studies, with a longer term goal of improving the quality of work.¹⁻⁴ For example, the *Journal of Veterinary Internal Medicine* has initiated an effort to develop guidelines to improve the quality of reporting of therapeutic intervention studies in companion animals (e.g., the Companion Animal Reporting Expectations and Standards [CARES; Ken Hinchcliff, personal communication]) that are similar to the Consolidated Standards of Reporting Trials (CONSORT) guidelines used in the human field.⁴ To approach a level of care in veterinary oncology truly similar to that in humans, there will need to be an increased focus on EBM, and the CARES reporting guidelines represent an initial step toward better clinical evidence. Further information and articles pertinent to challenges of applying EBM in practice can be found on the website of the Evidence-Based Veterinary Medicine Association (<http://www.ebvma.org>) and the Centre for Evidence-Based Veterinary Medicine (<http://www.nottingham.ac.uk/cevm/index.aspx>).

In this chapter, we will focus on quantifying the occurrence of cancer (incidence, prevalence) and risk factors for cancer (causal reasoning, associations). An evidence-based approach to diagnosis, prognosis, and selection of therapeutic interventions will be proposed, although other authors in this text will present specific details of diagnosis, prognosis, and therapy for specific cancers. Rather than presenting an exhaustive or systematic review of the literature in this chapter, we will highlight relevant literature. Our aim is to provide a guide for the application of epidemiologic principles to oncology, in general and for clinical practice.

Measures of Disease Occurrence

Complete and accurate cancer surveillance data are the foundation needed to make appropriate conclusions about the burden of disease, to make recommendations for cancer prevention and control, and for the design of analytic studies to identify causal associations between exposures and cancer risk. Here we cover the measures used to quantify cancer occurrence such as incidence, prevalence, and proportional measures and the types of data used to calculate them.

Incidence

Incidence, or the number of newly diagnosed cancer cases divided by the total population at risk over a specified period of time, is the most useful disease occurrence statistic for comparison between populations over time. Incidence data are especially valid when they are generated from a large population-based cancer registry with histologically confirmed cases and complete ascertainment of

• TABLE 4-1 Glossary of Terms

TERM	DEFINITION	COMMENTS
Efficacy	How well a treatment works in those who receive it (e.g., correct formulation, dose).	May be proved in laboratory studies or clinical trials.
Effectiveness	How well a treatment works in those to whom it is offered.	Studies must occur in the environment and under conditions and with patients typical of those to whom it will be offered in practice.
Compliance	How closely a treatment protocol is followed.	Influenced by clinician, client, patient, formulation, duration, and so forth.
Coherence	How well findings reflect our understanding of biologic relationships/pathophysiology.	Limited by our current understanding.
Consistency	The extent to which new findings agree with previously published findings.	Limited by the current literature, traditional approaches, funding, and so forth.
Experimental studies	Traditional research approach done in a laboratory or highly controlled environment.	Potential for high validity, generally lower relevance to the clinical situation.
External validity	The extent to which a study's findings can be extrapolated to a wider population. Similar terms include relevance and generalizability.	A function of the study population, methods, data collection, treatments, and so forth.
Incidence rate	The rate at which new events occur in a population: $\frac{\text{Number of new events in a specified period}}{\text{Number of individuals at risk during this period}} \times 10^n$	Cancer incidence rates are available from population-based data (e.g., cancer registry data) or prospective (cohort or longitudinal) studies.
Internal validity	The extent to which a study's findings are likely correct for that study population.	Likelihood that systematic bias is responsible for the study findings reduces its validity (e.g., due to bias in selecting study participants, measuring the exposure, and confounding).
Observational studies	Epidemiologic studies that use existing comparisons in the species of interest in its "natural" environment (often client-owned animals, perhaps in veterinary practice settings).	Examples: (1) Case-control study: Researcher observes/describes exposures in individuals selected based on presence/absence of the outcome; (2) Cohort study: Individuals with different exposures are followed and incidence of outcome(s) is observed.
Randomized controlled trial (RCT)	<i>Randomized</i> refers to the random allocation of exposure. <i>Controlled</i> refers to appropriate comparison groups (e.g., placebo or standard treatment). <i>Trial</i> is generally conducted in a clinical setting.	Researcher exerts control over which individuals receive which treatments or exposures and observes outcomes.
Prevalence	The number of events in a given population at a designated time: $\frac{\text{Number of events at a designated time}}{\text{Number of individuals at risk at the designated time}}$	Taking the number of canine cancers that are observed in a clinic or several clinics during a designated period of time and dividing by the total number of patients seen during the same period is a proportional measure, <i>not</i> prevalence.
Proportional morbidity or mortality	The number of events (e.g., disease, death) in a limited population (e.g., animals presenting to the clinic, total deaths) at a designated time.	Proportional measures are used when the underlying population at risk is not known.

the population at risk within a defined geographic area or theoretically from large prospective, longitudinal or cohort studies.

Cancer incidence data has been provided from several population-based cancer registries (Table 4-2). Estimates of canine cancer incidence range from 99.3 to 272.1 per 100,000 dog-years.⁵ Variation in estimates may be due in part to differences in actual cancer risks and/or variation in the base population. These registries included information from all cancer cases identified within a specified geographic region from a well-defined and enumerated population. One of the earliest, well-known cancer registries for

companion animals was the California Animal Neoplasm Registry.^{11,13} This comprehensive effort began in 1963 with the goal of identifying all neoplasms diagnosed over a 3-year period among animals living in the San Francisco Bay Area Counties of Alameda and Contra Costa. The denominator was estimated by conducting a survey in a probability sample of households in Alameda County to derive the age, sex, and breed distribution of pets and to determine whether the household had used veterinary services. Additional information on former and existing cancer registries for companion animals has been comprehensively reviewed.^{14,15}

• **TABLE 4-2** Characteristics of Population-Based Companion Animal Cancer Registries and Cancer Incidence

REGISTRY	PERIOD	CASES/POPULATION AT RISK	INCIDENCE/PREVALENCE
Genoa Registry of Animal Tumors ⁵ (Genoa, Italy)	1985-2002	3303/107,981; 1,943,725 dog-years	Males: 99.3/100,000 dog-years; females: 272.1/100,000 dog-years, for total tumors (malignant and benign).
Animal Tumor Registry ⁶ (Venice, Italy)	2005	2509 dogs; 494 cats/296,318 dogs; 214,683 cats	282, 143 and 140/100,000 dogs for total, malignant and benign tumors, respectively; 77, 63, 14/100,000 cats for total, malignant and benign tumors, respectively.
Danish Veterinary Cancer Registry (DVCR) ⁷	2005-2008	1523 dogs/dogs registered in the Danish Dog Registry as of August 2006	Breeds with standardized morbidity ratios ≥ 2 : Boxer, Bernese mountain dog, and West Highland white terrier. Measures for all dogs were not provided.
Norwegian Canine Cancer Registry ^{8,9} (Oslo, Norway)	1990-1998	14,401 tumors/census of dogs in Norway in 1992-93 ¹⁰	Boxers: 28 and 14/1000 dogs per year for total and malignant tumors, respectively. Bernese mountain dogs: 10 and 4/1000 dogs/year for total and malignant tumors, respectively.
California Animal Neoplasm Registry (CANR) ^{11,12}	1963-1966	1624/80,006 dogs 448/54,786 cats	381.2/100,000 dogs over 3-year period. 155.8/100,000 cats over the 3-year period.

Prevalence

Cancer prevalence information from population-based registries is also useful for surveillance and comparison between populations. Prevalence is the number of total cancer cases divided by the number of dogs in the population at risk at one point in time. For example, the prevalence of canine cancer in April 2005 was 143 per 100,000 dogs in an Italian population (see Table 4-2).^{5,6}

Feline cancer prevalence has been reported from a population-based registry in Italy as 63 per 100,000 cats⁶ (see Table 4-2). These data were based on a telephone survey conducted among 214,683 residents of two provinces in northern Italy over a 3-year period starting in 2005. Earlier prevalence data for feline cancers have ranged from 51.9/100,000 cat-years from the California Animal Neoplasm Registry^{11,13} to 470.2/100,000 cat-years from the Tulsa Registry.¹⁶

In addition to population-based cancer registries, cancer occurrence data are abundantly available from veterinary teaching hospital databases as well as insurance databases. A caution to be noted when interpreting cancer occurrence information from hospital-based registries is that the size and characteristics of the underlying population at risk are not known¹⁷; thus neither true incidence nor prevalence measures can be calculated. Instead, the proportional morbidity ratio (PMR) is used to quantify cancer occurrence. For example, the PMR for a particular tumor type among a single breed is calculated as follows:

$$\frac{(\# \text{ tumor type in breed} \div \# \text{ total tumors in breed})}{(\# \text{ tumor type in all other breeds} \div \# \text{ total tumors in all other breeds})}$$

Proportional measures are *not* to be interpreted as prevalence or incidence of cancer occurrence. As an example, Craig et al presents proportional statistics from a necropsy database and concludes that golden retrievers have an increased “risk” of tumors similar to that for Boxers.¹⁸ However, only the proportion of dead dogs that had cancer are available in that study, and these data cannot be used to estimate risk. Although proportional measures, such as those presented in a recent article by Fleming et al,¹⁹ have some

usefulness for describing patterns within a breed, they are very risky to use for comparison across breeds in which population-based measures are unavailable and the degree of referral bias is unknown. In addition, in those data, 40% of deaths were unable to be classified pathologically and the unclassified proportion showed extreme variation across breed (e.g., from 16% to 60%). Using a subset of data from Bonnett et al, a study with information on the population at risk and data from the recent Veterinary Medical Database (VMDB) study, Figure 4-1 shows a comparison between proportional mortality ratios and true mortality rate.^{19,20} For golden retrievers, 30% of deaths (before 10 years of age in the Swedish insurance population) were due to cancer. For Leonbergers and Boxers, the proportional mortality was 28% and 37%, respectively. Proportional values for these three breeds may be similar, but, in fact, Leonbergers and Boxers have a risk for death due to cancer (before 10 years of age) that is almost four times as high as that for golden retrievers (approximately 200 deaths per 10,000 years-at-risk versus 55 [$p > 0.05$]). Irish wolfhounds and Bernese mountain dogs have an equal risk (approximately 300 deaths due to tumors per 10,000 dog-years at risk [DYAR]), but tumors account for over 40% of deaths in Bernese mountain dogs and only 22% in Irish wolfhounds. Note that these are deaths before 10 years of age. Comparing the proportional mortality values between the two studies, values for Bernese mountain dogs are very similar (42%, 45%), perhaps because almost all dogs of this breed would die before 10 years of age, whereas the values for golden retrievers are somewhat different (30%, 50%). Of course, there may be true differences between the two study populations and/or the differences may be influenced by referral bias and the high proportion of unclassifiable deaths in the VMDB study.

To further illustrate this example, using just the breeds in Figure 4-1 and data from the Swedish insurance database, if one ranked the breeds based on actual numbers of dogs that died due to tumors (e.g., perhaps how an oncology clinician would perceive the “risk,” based on dogs that present to a specialty clinic), golden retrievers would be number one because they are one of the more numerous breeds in this population. Likewise, if one ranked the breeds by the

• **FIGURE 4-1** Comparison of true mortality rate and proportional mortality for selected breeds. The 95% confidence intervals for mortality rates overlap for breeds with the same number (e.g., mortality risk in Labrador retrievers and golden retrievers was not different from that for all breeds combined). (Data from Bonnett BN, Egenvall A, Hedhammar A, et al: Mortality in over 350,000 insured Swedish dogs from 1995-2000: I. Breed-, gender-, age- and cause-specific rates, *Acta Vet Scand* 46(3):105-120, 2005*; and Fleming JM, Creevy KE, Promislow DE: Mortality in North American dogs from 1984 to 2004: An investigation into age-, size-, and breed-related causes of death, *J Vet Intern Med* 25(2):187-198, 2011.†)

proportion of dead dogs that had tumors (e.g., similar to what would be reported in analysis of postmortem data), the top three would be Bernese mountain dogs, Boxers, and golden retrievers. So, in these examples, as has been frequently reported in the United States, based on proportional statistics, golden retrievers would be labeled as being one of the highest risk breeds. However, in looking at the true incidence based on these Swedish data, they do not have an increased risk compared to all breeds. There is likely considerable misunderstanding of the occurrence of cancer in dogs in the United States due to the lack of accurate incidence data and confusion about the interpretation of proportional statistics. Of course, where a breed is very common, like the golden retriever, and given that a considerable proportion of them die of cancer, that will represent an important population burden of disease, even if they are not truly the “highest risk” breed. Additionally, the Swedish data only include dogs up to 10 years of age; it is unknown how the statistics would look if dogs of all ages were included. As the authors (Bonnett et al) discuss, for cancer (or any cause of death) that occurs at older ages, a dog must live long enough to experience it (i.e., not die at a younger age due to any other cause) and deaths before 10 years of age are relevant to focus on for cancer prevention.²⁰

Sources of Information on Cancer Occurrence

One of the largest clinic-based databases is the VMDB.²¹ This database was started in 1964 by the National Cancer Institute, includes patient data from 26 university teaching hospitals in the United States and Canada, and contains over 7 million records from all species covering the full range of diagnoses, including cancer. This database is a widely used source of cancer surveillance information for companion animals; however, as was discussed previously (and presented in Figure 4-1), there is no information on the base population in these studies and only proportional measures can be calculated. Given that the data sources are teaching hospitals, patients, and diseases may not be typical of those seen in the general population. Therefore the results generated from passive surveillance such as the VMDB are likely to be influenced by referral bias. This type of selection bias affects estimates of disease frequency if the monitored clinics or hospitals have a predominance of patients that were referred for more specialized care. In fact, in a recent analysis using VMDB medical records from November 2006 to October 2007 for 9577 dogs and 4445 cats, it was concluded that substantial referral bias may exist.²² The authors suggested that the accuracy of

*In total, there were over 350,000 insured Swedish dogs up to 10 years of age contributing to over one million dog-years at risk (DYAR) during 1995 to 2000 and a total of 43,172 deaths. Of these, 31,057 (72%) had a code for cause of death; however, of these, 6.8% were unclassified as to system or process.

†The authors use the term *relative frequency* but it is proportional mortality. There is no knowledge of total deaths in the referent population, but there were 80,306 deaths that met their inclusion criteria recorded in VMDB. Of these, 5750 were initially dropped because there was no cause of death recorded and 26,442 more were unclassifiable as to pathologic process, therefore, for approximately 40% of eligible deaths, cause was unknown. There was great between-breed variation (e.g., Bernese Mountain dogs had 16% and miniature dachshunds had 60% unclassified for pathologic process, not including those initially excluded). It is very likely that there is bias in types of disease, age, and other factors influencing whether a cause of death is recorded.

prevalence estimates measured from the VMDB could be improved by statistical adjustment on the basis of geographic proximity to the university teaching hospitals.²²

Two well-established insurance databases are from the United Kingdom²³ and from Sweden.^{20,24,25} A notable limitation of these databases is that not all cases are histologically confirmed. The benefits and limitations of these data have been discussed extensively in the literature.²⁶ From the U.K. database, using data from 1997 through 1998, cancer incidence among 130,684 dogs at risk was 747.9 per 100,000 dog-years.²³ From the Swedish data, the overall mortality rate for cancer was 50 per 10,000 dog-years-at-risk (which equates to 500 per 100,000).²⁰ The limitations with the Swedish data are that deaths are mainly in dogs 10 years of age or younger and it is unknown whether the diagnosis has been validated by histology.¹⁷ Osteosarcoma incidence rates were 6.1 and 5.0 dogs per 10,000 dog-years for males and females, respectively,²⁷ and among females, breast cancer incidence was 111 dogs per 10,000 dog-years.²⁸ Comparison across breeds within the Swedish data is quite informative, given that the limitations occur equally across breeds. Crudely comparing overall mortality rates for cancer, Bernese mountain dogs were approximately 6 times more likely to die of cancer compared to all dogs, combined (306 versus 50 per 10,000 DYAR, respectively).²⁰ Where it was possible to do more sophisticated analyses, Bernese mountain dogs were shown to be 17 times more likely to die of cancer, compared to baseline, and adjusting for age, gender, and breed.²⁵ Even if specifics of the population may not be the same as other populations, data such as these are important for identifying high-risk breeds. Comparison across populations and over time is needed, with due consideration of data issues.

Studies on Swedish insurance data have presented statistics on morbidity and mortality in cats.^{29,30} As with dogs, the diagnoses are made by veterinarians, but further details are unavailable. The overall age-standardized mortality rate for death due to cancer in insured Swedish cats (generally <12 years of age) was 37 per 10,000 cat-years at risk (95% confidence interval [CI]: 28, 46). The most common types of cancer in the Swedish data were mammary, stomach/intestinal, and lymphoma. Siamese breeds were at increased risk of death due to neoplasia; mammary cancer was the most common type,³¹ in agreement with an earlier study.³² Differences between populations and data are no doubt affected by differences in various factors (e.g., spay/neuter rates and age structure of the populations). Further study of neoplasia in cats is needed.

Notwithstanding the previous discussion on the relative paucity of population-based, histologically-confirmed data on the incidence of cancer, there is no doubt that certain breeds are at high risk for cancer (e.g., the Bernese mountain dog, flat-coated retrievers, Boxers, and Scottish terriers). In the section that follows, we will present an overview of known and suspected risk factors for specific cancers, including breed-specific risks, which is not strictly limited by the level of evidence or quality of studies or data but that reflects the current state of knowledge. An important concern for the future, however, is that without true incidence data we are limited in our ability to track changes in occurrence over time, as proportional measures are influenced both by changes in the numerator and denominator. In other words, an increase in the popularity of a breed may lead to its apparent overrepresentation in proportional cancer measures; a change in the distribution of breeds may affect cancer prevalence, without any actual change in breed risk. Without incidence measures, it would be impossible to accurately evaluate the effectiveness of programs aimed at preventing or controlling disease.

Factors Associated with Cancer Risk

Observational studies are the tools of epidemiology used to identify and characterize the determinants of cancer risk. Information from descriptive studies such as case series may help to generate hypotheses but is not adequate as a basis for evidence-based cancer prevention strategies. Results from case series are also no longer accepted for publication in at least one major veterinary medical journal.⁴ Analytic observational studies such as case-control and cohort designs, on the other hand, are used to test research hypotheses, and when well-designed, can provide valuable information for cancer prevention strategies.

The case-control study design is the most commonly used observational study design in veterinary epidemiology research and in cancer epidemiology research in general. This is the most efficient study design, in terms of cost and time, when evaluating associations with relatively rare outcomes, such as specific cancers. Unfortunately, as data collection is often retrospective, many potential sources of bias must be considered. The features of an ideally conducted study (e.g., with the least opportunity for systematic bias) include the complete ascertainment of all newly diagnosed cases with histopathologic confirmation of primary tumors and a random (or matched) selection of controls from the same base population as the cases. In a population-based case-control study design,^{33,34} we can assume that if a control subject had been diagnosed with the tumor of interest, that control would have been a case in the study (i.e., the controls are from the same base population as the cases). The goal of the control group is to represent the exposure experience of the base population. For this reason, we are not interested in selecting the “healthiest” subjects as our comparison group.

In a hospital-based case-control study, both cases and controls are selected from the same hospital(s). The limitation with this design is that we cannot generalize the study results to a clearly defined base population. This design, however, is valid and can still provide meaningful results. When using this design, it is preferable to randomly or systematically sample from the non-case population and to not include animals that have been diagnosed with other cancers.^{35,36}

In a prospective cohort study, a group of animals is defined on the basis of exposure and followed over time to compare the incidence of disease (or other specified outcome) among the exposed and unexposed groups. The results obtained from a prospective cohort study are advantageous to results obtained from a case-control study for many reasons. One primary advantage is that we can assume temporality, or that the exposure came before the disease, when associations are observed from prospectively collected data. Systematic errors due to selection bias (e.g., referral bias) and differential recall bias (e.g., misclassification of exposure by disease status) are also not major concerns when interpreting results from a well-performed prospective cohort study. However, regardless of the observational study design, nondifferential exposure misclassification will be a major concern and the possibility and extent of misclassification should be considered when interpreting observational study results. Methods by which exposure misclassification can be reduced include using a precise and accurate questionnaire that has been properly validated or incorporating the use of biomarkers of exposure into the study design. There is a need for more longitudinal (as opposed to retrospective), preferably population-based studies in veterinary oncology.

To estimate the magnitude of an association between an exposure and a cancer type, the relative risk, or risk ratio (RR), and odds

ratio (OR) are calculated from data collected from cohort studies or cross-sectional and case-control studies, respectively. The RR is calculated as follows:

$$\text{RR} = \frac{\text{Incidence among exposed subjects} \div \text{Incidence among unexposed subjects}}$$

where incidence is the number of events divided by total animal-time of follow-up. The OR can be used to estimate the RR when incidence data are not available. The OR is calculated as follows:

$$\text{OR} = \frac{(\text{Number exposed cases} \div \text{number unexposed cases}) \div (\text{number exposed controls} \div \text{number unexposed controls})}$$

The RR and OR are similarly interpreted. A value greater than 1.0 indicates that the exposure is positively associated with disease (increases risk), whereas a value less than 1.0 indicates that the exposure is inversely associated with disease (decreases risk). A value of 1.0 indicates no association between exposure and disease. The 95% CI indicates the precision of the RR or OR, and if the 95%

CI includes 1.0, we interpret the RR or OR to be statistically non-significant. It must be remembered, however, that statistical significance does not necessarily equate with clinical importance. For the latter, the magnitude of the effect is also important to consider. Table 4-3 shows suggested guidelines for interpretation of risk estimates. When considering whether to implement preventive measures or health interventions at the population level, the following, in addition to the risk estimate, are also relevant: Prevalence of the factor (i.e., likelihood of exposure) and the prevalence of the disease. These values are used to estimate the attributable risk or risk-reduction measures.

Findings from all observational studies are influenced by systematic error to some degree because there is inherent bias in the methods used to select the study population, measure exposures, and identify the outcome. The opportunity for any one study to report an association that is due in part to chance is a real concern, even with the use of valid study design methods and statistical analyses. Confidence in the evidence for a particular association is strengthened when it is observed repeatedly in multiple populations and with the use of more and more rigorous study design methods. Metaanalysis is a technique whereby results from multiple, similar studies can be combined to increase the power of findings. Several examples are available from the human literature relating to nutritional risk factors associated with pancreatic, breast, and colon cancer.³⁷⁻³⁹ Unfortunately, in small animal oncology, studies have neither been performed nor reported consistently enough nor are there an adequate number of studies conducted to support metaanalyses at this time. Notwithstanding these limitations, Table 4-4 presents risk factors, including breed risks, for some of the more common cancers in dogs and cats for which there are at least reasonable estimations of association.

The identification of modifiable risk factors for canine cancers is the first step in eventually reducing incidence. Table 4-5 presents analytic studies used to test hypotheses that selected factors were

Text continued on page 78.

• **TABLE 4-3** Guidelines for Interpreting Clinical Relevance from Odds Ratios or Relative Risk Measures

INVERSE ASSOCIATION ≈ DECREASED RISK	CLINICAL RELEVANCE	POSITIVE ASSOCIATION ≈ INCREASED RISK
1.0	Not evident	1.0
0.7 to <1.0	Weak	>1.0 to 1.5
0.5 to <0.7	Moderate	>1.5 to 2.0
0.3 to <0.5	Strong	>2.0 to 3.5
<0.3	Very strong	>3.5

• **TABLE 4-4** Commonly Diagnosed Cancers and Suspected Risk Factors

CANCERS	SUSPECTED RISK FACTORS
Common Canine Cancers	
Mammary carcinoma	Obesity, high dietary fat intake, late age at spay, and some breeds (e.g., English Springer spaniel, Pointer, Poodle, Boston terrier, Dachshund, German shepherd, Chihuahua)
Osteosarcoma	High weight, high height, early castration/spay, some breeds (e.g., Irish wolfhound, Saint Bernard, Great Dane, Rottweiler, Irish setter, Doberman Pinscher, golden retriever, Labrador retriever, Leonberger)
Transitional cell carcinoma of the urinary bladder	Being neutered, exposure to phenoxy-acid containing herbicides, frequent flea dipping, some breeds (e.g., Scottish terrier, Beagle, Shetland sheepdog, Wirehaired fox terrier, West Highland white terrier)
Mast cell tumors	Some breeds (e.g., Boxer, Rhodesian ridgeback, Vizsla, Boston terrier, Weimaraner, Chinese Shar-Pei, Bullmastiff, Dutch pug, Labrador retriever, American Staffordshire terrier, golden retriever, English setter, English pointer)
Lymphoma	ETS, exposure to chemicals containing 2,4-dichlorophenoxyacetic acid, some breeds (e.g., Bullmastiff, Boxer, Scottish terrier, Gordon setter, Irish wolfhound, Basset hound, golden retriever)
Common Feline Cancers	
Lymphoma	FeLV, FIV, environmental tobacco smoke
Sarcoma	Vaccine injection
Cutaneous squamous cell carcinoma	Solar irradiation

ETS, Environmental tobacco smoke; FeLV, Feline leukemia virus; FIV, feline immunodeficiency virus.

• **TABLE 4-5** Selected Observational Studies of Canine and Feline Cancers by Type of Exposure

EXPOSURE	MAIN FINDINGS	STRENGTHS/LIMITATIONS
ETS		
Reif, 1998 ⁴⁰	Positive trend for number of packs smoked by owner and increased risk of canine nasal cancer among long-nosed (dolichocephalic) dogs.	Strengths: Evaluation of nose size as an effect modifier with biologic plausibility; collected information on potential confounders. Limitations: Use of controls with cancer.
Reif, 1992 ⁴¹	Statistically nonsignificant positive association for living with ≥ 1 versus no smokers and canine lung	Strengths: High participation rates among cases and controls. Limitations: Use of controls with cancer; limited statistical power.
Marconato, 2009 ³⁴	Any ETS exposure was positively associated with canine lymphoma, compared with no exposure.	Strengths: Population-based study design. Limitations: Use of controls with cancer; limited ETS exposure information was collected.
Bertone, 2002 ⁴²	Strong, statistically significant association for any household ETS exposure and malignant lymphoma in cats. Statistically significant trend reported for a stronger association with increasing years of ETS exposure.	Strengths: Statistical power to evaluate trends; cases confirmed by biopsy; respectable response rate among the cases and controls (>65%); use of a detailed questionnaire to assess ETS and other environmental exposures. Limitations: No clear biologic mechanism for the observed association.
Bertone, 2003 ⁴³	Clinic-based case-control study had ETS exposure positively associated with feline oral SCC. Overall, results do not support a causal relationship between ETS exposure and feline SCC.	Strengths: Cases confirmed by biopsy; good response rates; use of a detailed questionnaire (see previous entry). Limitations: Prevalence of ETS exposure was low; limiting the statistical power to evaluate more than two levels of exposure.
Pesticides		
Hayes, 1991 ⁴⁴	Any use of chemicals containing 2,4-dichlorophenoxyacetic acid (2,4-D) positively associated with canine malignant lymphoma, compared with no use. Lymphoma risk increased with greater number of applications of 2,4-D-containing chemicals.	Strengths: Complete ascertainment of newly diagnosed cases; high participation rates among cases and controls; collected extensive information on chemical use on lawns/yards (self-applied and commercially applied). Limitations: One control group comprised of dogs with other cancers. NOTE: This and other limitations were addressed in subsequent analyses.
Glickman, 1989 ⁴⁵	Residence location within one mile of a marsh (where chemicals were used for mosquito control) positively associated with canine TCC of the urinary bladder. Receiving flea dips more than two times/year versus no use was positively associated with TCC.	Strengths: Collected information on numerous sources of chemical exposure, including residential location to industries, pesticide use, flea/tick treatments. Limitations: 45% of control dogs had malignant neoplasia; information was not collected on individual dog exposure to the marsh or on specific chemicals used around the house/yard.
Glickman, 2004 ³⁵	Access versus no access to phenoxy herbicide-treated lawns/yards positively associated with TCC of the urinary bladder among Scottish terriers. No	Strengths: Collected information on brand name and active ingredients for household, lawn, and garden chemicals; results were specific for phenoxy herbicide exposure. Limitations: Limited statistical power to conduct subgroup analyses.
Raghavan, 2004 ⁴⁶	Use of topical flea/tick products (e.g., shampoos, dips, powders, sprays, and collars) not associated with TCC of the urinary bladder among Scottish terriers.	Strengths: Collected detailed information on use of flea/tick products (e.g., type, brand, pattern of use) Limitation: 24% of control dogs had cancer; numbers for cases and controls were not presented by exposure level.
Environmental Pollutants		
Bettini, 2010 ⁴⁷	Pulmonary anthracosis (high versus none) positively associated with canine lung cancer risk.	Strengths: Histologic confirmation of primary diagnosis of lung cancer; exposure assessment determined by histologic scoring of anthracosis; strong biologic mechanism supporting the a priori hypothesis. Limitations: Small number of cases limited the statistical analyses.

• **TABLE 4-5** Selected Observational Studies of Canine and Feline Cancers by Type of Exposure (continued)

EXPOSURE	MAIN FINDINGS	STRENGTHS/LIMITATIONS
Marconato, 2009 ³⁴	Living in geographic areas exposed to toxic waste positively associated with canine cancer risk (all tumors and lymphoma), compared with living in an unexposed area. No associations observed for	Strengths: Population-based study design, histologic confirmation of cases; odds ratios were adjusted for age, sex, and breed. Limitations: Same eligibility criterion (i.e., living at same address for 2 years prior to enrollment) was not applied to controls.
Gavazza, 2001 ⁴⁸	Living in an industrial neighborhood was positively associated with canine lymphoma risk, compared with living in any other neighborhood. Use or storage of paints and solvents was positively	Strengths: Histopathologic or cytologic confirmation of cases; information was collected on potential confounders. Limitations: Very low prevalence of exposed cases and controls; only univariate analyses were conducted.
Bukowski, 1998 ⁴⁹	Cumulative kerosene or coal heat exposure was positively associated with sinonasal cancer risk.	Strengths: High participation rate; covariate information was compared between respondents and nonrespondents; histopathologic confirmation of cases. Limitations: Use of controls with cancer.
Endogenous/Exogenous Sex Hormones		
Sonnenschein, 1991 ⁵⁰	Earlier age at spaying was inversely associated with canine mammary cancer. Trend of decreasing risk was observed for younger age at spaying.	Strengths: Cases were limited to mammary carcinoma or adenocarcinoma. Limitations: Controls may not be representative of the base population.
Ru, 1998 ⁵¹	Neutered dogs, regardless of gender, had a greater risk of osteosarcoma, compared to intact dogs.	Strengths: Histologic or radiologic confirmation; large study size; collected information on potential confounders. Limitations: Medical conditions of the controls were not clearly described.
Glickman, 2004 ³⁵	Neutered status versus intact was a risk factor for TCC of the urinary bladder among Scottish terriers.	Strengths: Cases were histologically confirmed. Limitations: Small study size did not permit for analyses by age at neutering.
Dias Pereira, 2008 ⁵²	No overall association was observed for COMT genotype and canine mammary cancer risk. Older age at mammary cancer diagnosis was observed by COMT genotype.	Strengths: Strong biologic rationale for research hypothesis; cases were histologically confirmed. Limitations: Very small numbers in subgroup analyses; selection methods were not provided; information was not collected on potential confounders (e.g., hormone-related exposures).
Cooley, 2002 ⁵³	Neutering prior to 1 year of age increased risk of canine osteosarcoma among Rottweilers, regardless of gender. Incidence rates decreased with later age	Strengths: Radiographic or histologic confirmation of cases; retrospective cohort study design. Limitations: Low participation rate.
Stovring, 1997 ³³	MPA use was positively associated with canine mammary cancer.	Strengths: Population-based study design; histologic confirmation of cases. Limitations: Information was not collected on details of MPA use (e.g., frequency, dose, age at first use).
Teske, 2002 ⁵⁴	Castration was positively associated with canine prostate cancer risk, compared with intact status.	Strengths: Strong biologic plausibility. Limitations: Only cytology was used to make cancer diagnosis.
Bryan, 2007 ⁵⁵	Neutered versus intact status was a risk factor for the following canine cancers: TCC of the urinary bladder, prostate carcinoma, prostate adenocarcinoma, and TCC of the prostate.	Strengths: Histopathologic confirmation of cases; included analyses by histologic subtype. Limitations: Statistically nonsignificant measures were not presented.
Misdorp, 1991 ⁵⁶	Ovariectomy was inversely associated with feline mammary cancer risk. Regular administration of progestogens increased risk. No association was observed for irregular progestogen administration or for parity.	Strengths: Histologic confirmation of cases; collection of detailed exogenous progestogens (frequency, brand, type); large study size. Limitations: Cases and controls were selected over different time periods.

(continued)

• **TABLE 4-5** Selected Observational Studies of Canine and Feline Cancers by Type of Exposure (continued)

EXPOSURE	MAIN FINDINGS	STRENGTHS/LIMITATIONS
Overley, 2005 ⁵⁷	Intact versus neutered status was a risk factor for feline mammary cancer. Cats spayed before 1 year of age were at lower risk of mammary cancer than those spayed after 6 months of age. There was no risk benefit in cats spayed after 2 years of age.	Strengths: Histologic confirmation of cases; large study size. Limitations: Univariate analyses were performed, although detailed information was collected on exogenous hormone use, parity, and number of litters; large amount of missing data due to veterinarian nonresponse.
Diet		
Perez Alenza, 1998 ⁵⁸	Higher intake of red meat (as percentage of total calories) was positively associated with canine mammary carcinoma risk. No differences were observed for intake of fruits and vegetables, or biomarker levels of selenium, retinol, or individual fatty acids.	Strength: Used biomarkers of exposure; multivariable analyses included covariates for body conformation. Limitations: Use of a retrospective study design is not recommended for evaluating biomarkers of exposure and cancer risk because of possible disease and/or treatment effects on the biomarker measurement.
Sonnenschein, 1991 ⁵⁰	Higher intake of fat and table food (as percentage of total calories) was inversely associated with canine mammary carcinoma. No associations were observed with protein or carbohydrates intake.	Strengths: Cases and controls were matched by age, spay status, and breed size, thus reducing the opportunity for confounding by these factors; the dietary assessment tool was validated using a 7-day food record. Limitations: Study size was too small to evaluate diet-cancer associations in subgroups.
Raghavan, 2005 ⁵⁹	Vegetable intake (≥ 3 versus 0 times/week) was inversely associated with TCC of the urinary bladder in Scottish terriers. A trend was observed with greater servings of vegetables per week and decreased risk of TCC. No association was observed	Strengths: Histopathology and/or cytology confirmation; use of a comprehensive dietary questionnaire; multivariable analyses. Limitations: Used a volunteer population; 61% of the cases were deceased at the start of the study; 24% of control dogs had neoplastic diseases.
Body Size		
Perez Alenza, 1998 ⁵⁸	Obese body condition at 1 year of age and at 1 year before diagnosis was positively associated with canine mammary cancer, compared with normal or underweight body condition at the same time points.	Strengths: Objective measurements of weight and height were collected at presentation; body conformation was determined by a clinician at presentation. Limitations: Height, weight, and body conformation at 1 year of age and 1 year before diagnosis were based on owners' reports.
Sonnenschein, 1991 ⁵⁰	Spayed dogs that were thin at 9 to 12 months of age had a lower risk of mammary cancer. Intact dogs that were not overweight in adulthood had a lower risk of mammary cancer.	Strengths: Cases were limited to mammary carcinoma or adenocarcinoma; designed to assess a timely hypothesis that early life factors are related to mammary cancer risk. Limitations: Controls may not be representative of the base population; subgroup analyses did not have ample statistical power to calculate precise measures.
Weeth, 2007 ³⁶	BCSs ≥ 6 were inversely associated with canine cancer risk (all cancers, sarcomas, and carcinomas), compared with BCSs of 4 to 6. BCSs < 3 were inversely associated with canine sarcoma risk, compared with scores of 4 to 6.	Strengths: Very large study size; 9-point BCS determined by physical examination; analyses were conducted by cancer type (sarcoma, carcinoma, round cell tumors) Limitations: Selection of cases and controls depended on availability of BCS in medical records; the inverse associations with higher BCS may be due to reverse causation.
Ru, 1998 ⁵¹	Height (> 61 versus < 35.5 cm) and weight (> 45 versus < 23 kg) were positively associated with canine osteosarcoma risk, after adjusting for age and standard weight and height, respectively. Longer length of hind limbs and front limbs was positively	Strengths: Histologic or radiologic confirmation; large study size; collected information on potential confounders. Limitations: Medical conditions of the controls were not clearly described; a proxy measure for height was used; there was a large percentage (22.5%) with missing weight information.

• **TABLE 4-5** Selected Observational Studies of Canine and Feline Cancers by Type of Exposure (continued)

EXPOSURE	MAIN FINDINGS	STRENGTHS/LIMITATIONS
Glickman, 2004 ³⁵	Greater weight was positively associated with TCC urinary bladder risk in Scottish terriers, comparing	Strengths: Cases were histologically confirmed. Limitations: Weight and height information was based on owners' reports.
Vaccines/Injection Site		
Kass, 2003 ⁶⁰	Cats with sarcomas at a vaccine injection site (n = 662) were compared with cats with basal cell tumors or noninjection site sarcomas (n = 473). Univariate analyses showed no difference in the vaccine type (FVRCP, rabies, FeLV) between cases	Strengths: Histologic confirmation of cases and controls; collected extensive vaccine information (date of injection, manufacturer, type, brand, site of injection). Limitations: Cases were identified on a volunteer basis from participating clinics; heterogeneous sarcoma case group.
Kass, 1993 ⁶¹	In 345 cats diagnosed with fibrosarcoma, 53.6% had tumors at the vaccine injection site. The time from FeLV vaccination to tumor diagnosis was significantly shorter among cats that had tumors at	Strengths: Biopsy-confirmed diagnoses; vaccination history was validated by veterinarian; collected vaccination details allowing for analyses by type of vaccine, time since vaccination and location of injection site. Limitations: Differential missing data by exposure status.
FeLV/FIV		
Hutson, 1991 ⁶²	Among 1160 cats identified from an oncology referral and a general practice clinic, 2.5% were FIV positive. Of the FIV-positive cats, 62% were	Strengths: Descriptive information of neoplasia among FIV-positive cats. Limitations: No evident population base; only count data were presented.
Gabor, 2001 ⁶³	Among 101 cats with lymphosarcoma, 50% were FIV positive. These cats were more likely to be male domestic crossbreeds.	Strengths: Histopathologic confirmation of cases; FIV antibodies were determined using Western blot. Limitations: Convenience study population was used.
Shelton, 1990 ⁶⁴	Coinfection with FIV and FeLV was present in 14.4% of 353 cats collected in several US cities. FIV and FeLV infection were strongly associated with risk of leukemia or lymphoma. A very imprecise positive	Strengths: FIV antibodies were determined using ELISA and Western blot. Limitations: Base population and subject recruitment methods were not well defined; low prevalence of coinfection among controls limited statistical power.
Solar Irradiation		
Dorn, 1971 ⁶⁵	Among white cats, the observed incidence of SCC of the skin was greater than the expected incidence ($p < 0.001$). For SCC of the mouth-pharynx, white	Strengths: Population-based study population. Limitations: Amount of sun exposure was not quantified; the number of cats with SCC of the mouth-pharynx was small (n = 29).

ETS, Environmental tobacco smoke; SCC, squamous cell carcinoma; TCC, transitional cell carcinoma; COMT, catechol-O-methyltransferase; MPA, medroxyprogesterone acetate; BCS, body condition score; FeLV, feline leukemia virus; FIV, feline immunodeficiency virus; FVRCP, feline viral rhinotracheitis-calicivirus-panleukopenia; ELISA, enzyme-linked immunosorbent assay.

either associated with an increased or decreased risk of canine and feline cancers. Characteristics of the study design and analytic methods are highlighted as strengths and weaknesses. Studies with the strongest level of evidence included several characteristics related to study design (e.g., hypothesis-driven, population-based, large study size, validated exposure assessment) and results (e.g., a precise measure of association, a modest-to-strong magnitude of association, statistically significant measure of association, statistically significant trend between exposure level and magnitude of association).

Highlighted Findings from Observational Studies

In this section, we discuss risk factors for which there is relatively strong evidence, those which relate to key issues in animal or human oncology, and those for which important controversies need to be addressed by further research. These categories coincide with those shown in Table 4-5.

Environmental Exposures

The identification of environmental exposures that are related to canine cancer risk have a broad public health interest, given the shared environments of companion animals and their owners, as well as similar etiology of some cancers.⁶⁶ In a recent review, a historic perspective is provided on how studies in pet populations have informed human health with respect to the specific exposures of air pollution, environmental tobacco smoke (ETS), and pesticides.⁶⁷ The shared etiologic characteristics of cancers such as lymphoma, osteosarcoma, and mammary cancer also support the utility of looking to both pet and human populations to investigate environmental-cancer associations.⁶⁸

There is experimental evidence for an underlying biologic mechanism for the compounds of cigarette smoke to have a causal relationship with canine carcinogenesis.^{69,70} There are few observational studies that were designed to specifically evaluate associations between ETS exposure and canine cancer risk.^{40,41} There is support for a positive association (3.4-fold increased risk) between ETS and lymphoma³⁴ and sinonasal cancers⁴⁰ but not for lung cancer.⁴¹ In a clinic-based case-control study, household ETS exposure was strongly associated with feline lymphoma.⁴² The OR for any exposure, compared with no exposure was 2.4 (95% CI: 1.2, 4.5), and statistically significant trends were reported for more years of ETS exposure, more smokers in the household, and number of cigarettes smoked per day in the household. In contrast, there is only weak observational evidence for ETS as a risk factor for oral squamous cell carcinoma in cats.⁴³ In summary, avoiding ETS exposure may reduce the risk of lymphoma in cats and dogs and the risk of sinonasal cancers in dogs.

Pesticides are a heterogeneous group of chemicals, some of which are known human and canine carcinogens.⁷¹⁻⁷³ Dogs may be exposed to pesticides in the home, in the yard/garden, and upon application of flea and tick treatments. The most consistent observational evidence for pesticide exposure as a cancer risk factor is for phenoxy acid-containing herbicides and lymphoma risk, both in humans and dogs.⁷⁴ These data, however, have not been deemed strong enough to establish causality.⁷⁵ In a large case-control study ($n = 491$ cases and $n = 945$ controls) by Hayes et al, any use of pesticides that contained dichlorophenoxyacetic acid (2,4-D) was associated with a 30% increased risk of lymphoma, compared to no use.^{44,76} Although modest, the positive association also demonstrated a dose-dependent effect, in which more frequent use of

2,4-D pesticides resulted in a stronger positive association with lymphoma risk (p for trend < 0.02). Additional support for 2,4-D and canine bladder cancer risk is from the result of a small case-control study in Scottish terriers.³³

Residential proximity to environmental hazard-containing sites has been used to estimate chemical exposure and canine cancer risk in several observational studies.^{34,45,48} A 2.4-fold increase in risk of lymphoma was observed among dogs living in the cities containing illegal waste sites, compared to dogs living in other cities.³⁴ No association was observed with mast cell tumors or breast cancer. Mortality due to cancer is also higher among human populations living near the same waste sites, compared with the general population.⁷⁷ Chemical mixtures that have been identified at hazard waste landfills include organic solvents, polychlorinated biphenyls, and heavy metals and can reach human and pet populations through contaminated air, water, and/or soil⁷⁸ and have been causally related to adverse human health effects, including childhood lymphoma.⁷⁹ The biologic plausibility and the observational findings from Marconato et al³⁴ both help strengthen the evidence that living near the waste sites increases risk of canine lymphoma.

Exposure misclassification is a primary limitation of using geographic proximity as a marker of exposure to an industrial or waste site because it may or may not be a good proxy for individual-level exposure. For example, a validation study would need to be conducted that provides information on whether dogs that live close to an industrial site are necessarily exposed at higher levels to environmental hazards, compared to dogs that live further from the site. Misclassification of exposure that does not differ by disease status (e.g., nondifferential misclassification) typically results in an underestimate of the exposure-cancer association, although there are situations when the observed association results in an overestimate of the true association.^{80,81}

Hormones and Neuter Status

Hormones may act as either growth factors or inhibitors, depending on the sex of the dog and the tissue type.^{53,82,83} For some cancers, such as breast, less exposure to sex hormones is protective, whereas for others, such as osteosarcoma and prostate cancer, less exposure increases risk. Neuter/spay status and age at neuter/spay are the most commonly used measures of endogenous hormone exposure. Given the widespread recommendation for early spay/neuter, especially in North America, this is a topic in need of further study.

In a mammary cancer case-control study by Sonnenschein et al, there was clear evidence that spayed dogs were at lower risk of mammary cancer.⁵⁰ In particular, the earlier age at which dogs were spayed the lower their mammary cancer risk, compared to dogs that were not spayed. This finding has been supported by other observational studies of spay status and mammary cancer risk.⁸⁴

Contrary to human epidemiologic and experimental evidence,^{85,86} exposure to sex hormones such as androgens may be protective for canine prostate cancer.⁸⁷ From two case-control studies using large veterinary teaching hospital databases, neutered dogs had a 2.8- and 3.4-fold increased risk of prostate cancer compared with intact dogs.^{54,55} The apparent opposite associations between hormone exposure and prostate cancer risk in men and dogs are likely due to the higher rate of androgen-independent tumors in dogs than in men.^{88,89}

Neuter status is also a risk factor for osteosarcoma and transitional cell carcinoma of the urinary bladder,^{35,51,53,55} regardless of sex.^{51,53} Cooley et al conducted a retrospective cohort study in 1999 among 683 Rottweilers and used a self-administered questionnaire

to test the hypothesis that neuter/spay status was related to the development of osteosarcoma.⁵³ The owners were identified through eight national Rottweiler breed specialty clubs and had a purebred Rottweiler that was alive on January 1, 1995. The participation rate ($[\text{number of participants}] \div [\text{total number of invited owners}] \times 100$) was 49%. This low participation rate suggests that selection bias may have influenced the results of this study. In other words, the participants of the study are likely to have systematic differences compared with those who did not participate. However, a strength of this study is the ability to calculate incidence because the total number of dog-months of observation were estimated retrospectively among dogs that were neutered/spayed and those that were not. During a total of 71,004 dog-months of observation, there were 86 cases of osteosarcoma. Collectively, the findings of a positive association between neuter/spay status and osteosarcoma from both case-control and cohort studies, as well as the biologic plausibility of the association, provide strong evidence that neutering/spaying dogs, regardless of sex, increases risk of osteosarcoma.

Risk Factors in Cats

In cats, the epidemiology of injection-site sarcomas has been well studied. A recent review provides information on the current epidemiology, etiology, and clinical knowledge of feline injection-site sarcomas (FISS).⁹⁰ Kass et al conducted one of the first epidemiologic studies investigating the hypothesis that vaccinations were related to feline fibrosarcoma risk in the early 1990s.⁶¹ A main finding of this study was the shorter time interval from vaccination to FISS compared with the interval from vaccination to noninjection site fibrosarcomas. This finding was not supported by a second, larger case-control study conducted by Kass et al.⁶⁰ Although there is no doubt that the phenomenon of FISS exists, the administration of an injection itself is not sufficient to cause development of FISS. The component causes (e.g., the nature of vaccines and adjuvants in the injected material and the role of the resulting inflammatory reaction), in addition to the physical injection that leads to the development of FISS, are not well characterized. Further epidemiologic research designed with due consideration of the challenging methodologic issues is needed to identify the various factors associated with FISS.⁹¹

Cats infected with the feline immunodeficiency virus (FIV), the feline analog to the human immunodeficiency virus (HIV), are at increased risk of certain cancers.⁹² FIV is a lentivirus typically transmitted by biting.⁹³ Lymphomas, particularly those of B-cell origin, are the most commonly diagnosed neoplasia among FIV-infected cats. Persistent feline leukemia virus (FeLV) infection is also known to have a strong role in feline neoplasia development,⁹⁴ and coinfection with FIV and FeLV may have synergistic effects on feline neoplasia risk.⁶⁴

Diagnosis and Screening

As mentioned previously, numerous guidelines have been produced for the human medical literature (e.g., <http://www.cochrane.org/about-us/evidence-base-health-care/webliography/books/reporting>). One of these describes an approach to complete and accurate reporting of studies of diagnostic accuracy (Standards for Reporting of Diagnostic Accuracy [STARD]).^{95,96} The application of this and another instrument in the veterinary field has been discussed.⁹⁷ Unfortunately, relatively few diagnostic interventions in veterinary medicine have been examined or evaluated as fully, in terms of reliability, accuracy, efficacy, and effectiveness, as is needed

to support EBM practices. Guidelines for prognostic studies in veterinary oncology have also been reported.⁹⁸

It may also be appropriate to use clinical trial methodology to evaluate the outcomes of diagnostic tests, for example, whether the animal is better off for having had the test performed.⁹⁹ In addition, recommendations about diagnostic tests and screening programs may have both positive and negative impacts beyond any individual, on populations of animals and owners. Although new, sophisticated diagnostic tests used in humans are being evaluated for use in companion animals, it is important to remember that beyond the benefit in a specific case, efficacy and effectiveness of tests should consider the broadest aspects of cost benefit. In human oncology, there has been much discussion about the problems inherent in certain widely applied screening processes and the consequences of false positives and negatives (e.g., prostate specific antigen test for prostate cancer¹⁰⁰). Due to space constraints, we cannot expand on this crucially important area of cancer epidemiology.

Therapeutic Interventions

A recent review highlighted that the quality of reporting of oncology studies in dogs and cats published in the *Journal of Veterinary Internal Medicine* has not improved appreciably in the past 10 years and that quality of reporting is highly correlated with the rate of positive outcomes (i.e., well-described studies are more likely to report positive effects of a treatment).¹⁰¹ This may also be exacerbated by the fact that the profession increasingly depends on corporate contracts for funding of research, and, in addition to this having a major impact on which treatments are investigated, there may also be underreporting of studies in which either beneficial effects were not seen or there were deleterious side effects. As mentioned previously, efforts are underway to produce reporting guidelines for companion animal intervention studies. However, guidelines for appropriate study design for clinical trials have been widely available for many decades, and the need for appropriate trials in oncology has been specifically advocated (see Chapter 17).¹⁰² Longer-term analyses of survival following diagnosis and treatment, including both outcome and cost-benefit analysis, are needed to provide the information that owners and veterinarians need to choose the best options, with due consideration of quality-of-life issues.

Although there are good examples of randomized, controlled, blinded trials in veterinary oncology,^{103,104} essentially all studies have some limitations in terms of either quality (validity) or relevance (extrapolation to other situations). For example, because many trials are performed on clients at specialty practices or veterinary teaching hospitals, animals have passed through numerous filters in order to be available for the study (e.g., referral, have a willing and capable owner, live long enough to have a confirmed diagnosis). Although this may improve the validity of the study (e.g., by increasing compliance and reducing loss to follow-up), it reduces the relevance to, for example, primary practice. Therefore clinicians must be able to apply the rules of evidence to determine both the quality and relevance of information for their specific situation and patients. Other authors in this text will present current information on treatments for cancer, and a further review of the literature is beyond the scope of this chapter. Hopefully, the quality of the veterinary literature will continue to improve over time, and the application of appropriate reporting guidelines and production of evidence-based reviews will assist clinicians to interpret and apply published information.

Knowledge Gaps and Future Directions

Even though systematic reviews and metaanalysis may not be currently possible, evidence-based reviews of the existing oncology literature in dogs and cats are needed to further elucidate what we know about breed risks, other risk factors, appropriate use of diagnostic and screening aids, therapies, prognoses, and so forth, and to identify the most crucial gaps in our knowledge. Appropriate assessment of existing oncology prevention and treatment strategies is also needed.

With increasingly available genomic information, our understanding of breeds and breed risk may change.^{105,106} It is especially important to recognize the value of studying populations from different areas or countries. There are important differences and similarities in genetics (across and within breeds), environments, diets, and activities that will inform cancer etiology and management. Such complex relationships will only be fully understood by a multidisciplinary approach using various methodologies and study designs. These should include more population-based, longitudinal observational studies.^{33,34,107} Although these may not yield results for many years, relying solely on traditional approaches (case-control studies and clinical trials of invasive or risky treatments) is not an effective strategy to reduce the population burden of cancer. In addition and beyond the scope of this chapter, there are important complex issues of human-animal interactions, in general and specifically related to the field of oncology. Thus there is a need for an increased understanding of the social and emotional factors underpinning many aspects of this diverse field.¹⁰⁸

Paraneoplastic Syndromes

PHILIP J. BERGMAN

5

Paraneoplastic syndromes (PNSs) are neoplasm-associated alterations in bodily structure and/or function that occur distant to the tumor. They are a diverse group of clinical aberrations that are associated with the noninvasive actions of the tumor. In many situations, the PNS parallels the underlying malignancy; therefore successful treatment of the tumor leads to disappearance of the PNS. Alternatively, recurrence of the PNS after successful treatment signals tumor recurrence and often significantly precedes clinically detectable tumor.

PNSs are often the first sign of malignancy, and the PNS may be a hallmark of a certain tumor histology. Therefore an understanding and appreciation for the types and causes of these syndromes are paramount for early cancer detection and appropriate therapy. In addition, a PNS may result in greater morbidity than that associated with the actual tumor.

The causes of PNSs are quite variable; they are usually caused by the production of small molecules (e.g., hormones, cytokines, or peptides) that are released into the circulation to cause effects at distant sites or by immune cross-reactivity between malignant and normal tissues. Some PNSs are due to functional mutations that result in overexpression of the small molecule in question, whereas many nonendocrine PNSs have no known etiology. PNSs are recognized commonly in both human and companion animal cancer patients.¹ Box 5-1 summarizes the most common PNSs of dogs and cats and the tumors associated with them.

Gastrointestinal Manifestations of Cancer

Cancer Cachexia and Anorexia

An important systemic effect of cancer in animals is profound malnutrition and wasting. The weight loss and metabolic alterations observed in cancer patients despite adequate nutritional intake are termed *cancer cachexia*, whereas alterations observed as the result of poor nutritional intake are termed *cancer anorexia*. The clinical outcome of either cancer cachexia and/or anorexia is a progressive wasting (Figure 5-1). The weight loss endured by these patients is more than a simple cosmetic abnormality as human patients with cancer cachexia can have significantly reduced survival times, and many patients are unable to undergo appropriate therapy because of their poor clinical status.

Cancer cachexia occurs frequently in human oncology, with estimated incidences from 40% to approximately 90% of hospitalized patients.^{2,3} Importantly, cancer cachexia accounts for approximately 20% of cancer deaths.^{4,5} The incidence of cancer cachexia in veterinary oncology patients is presently unknown, although this

author believes that an estimated incidence of cancer cachexia in dogs is realistically 10% or less. For example, only 4% of dogs presenting to an academic oncology center were found to have cachexia, although referral bias likely results in some reporting artifact.⁶ The metabolic alterations associated with this PNS usually occur before weight loss is detected in both human and veterinary cancer patients.^{3,7-11} These metabolic alterations may last for some time after the patient is tumor free making it difficult for the clinician to reverse the weight loss.^{8,10} A plasmid-DNA-mediated approach utilizing growth hormone-releasing hormone (GHRH) in dogs appears to increase insulin-like growth factor-1 (IGF-1) levels (a measure of GHRH activity) and may represent a mechanism for attenuating cancer cachexia.¹²⁻¹⁵

In the clinical evaluation of a veterinary patient for the possibility of cancer cachexia/anorexia, a detailed history and physical examination are crucial. The prognostic importance of the presence of cancer cachexia in human cancer patients cannot be overstated because many studies show that this PNS is the only or one of very few independent multivariate negative prognostic factors for a variety of malignancies.^{2,3} A more detailed discussion of this syndrome is found in Chapter 15, Section B.

Protein-Losing Enteropathy

Protein-losing enteropathy (PLE) is a syndrome whereby excessive serum proteins are lost into the gastrointestinal (GI) tract, leading to hypoproteinemia.¹⁶ The hypoproteinemia seen in cancer patients can be due to impaired synthesis and/or increased loss into the GI tract or urine (see Renal Manifestations of Cancer later in this chapter). Once the loss of proteins becomes greater than the body's ability to synthesize them, serum protein levels begin to decrease. The half-life of many serum proteins is long, and patients with hypoproteinemia caused by PLE or some other cancer-related protein loss may represent long-standing protein loss.^{2,16} PLE is thought to result from an increase in mucosal serum protein permeability because of mucosal erosion, ulceration, or lymphatic obstruction.

The diagnosis of PLE is made by noting hypoproteinemia on serum chemistry evaluation with subsequent exclusion of severe malnutrition and liver disease. Confirmation of the diagnosis is made in humans with PLE by alpha-1-antitrypsin detection,¹⁷ but this methodology has not been validated in veterinary medicine.¹⁸ In addition, nuclear scintigraphy appears to be a reliable methodology for the diagnosis of PLE.¹⁹ The incidence of PLE as a PNS is unknown in veterinary medicine but is likely to be rare. The treatment for PLE consists of treating the primary malignancy; however, those patients with a lymphangiectasia-related PLE may also be treated with medium-chain triglycerides that do not undergo transport by intestinal lymphatics.

• **FIGURE 5-1** Dog with lymphoma and secondary severe cachexia. Cancer cachexia can be a common paraneoplastic syndrome (PNS) in dogs and cats. The weight loss noted in cases of paraneoplastic cancer cachexia occurs despite adequate nutritional intake. The metabolic alterations associated with cancer cachexia usually occur before clinical signs of the inciting malignancy appear and unfortunately may continue after the patient is successfully treated for the tumor.

Gastroduodenal Ulceration

The most common cause of PNS-associated gastroduodenal ulceration is mast cell tumor (MCT). The excess histamine seen in MCTs stimulates gastric H_2 receptors, leading to increased gastric acid secretion. Clinical manifestations of mucosal damage and/or ulceration with gastric vessel thrombosis occur in association with gastric hyperacidity. Plasma histamine concentrations are elevated in approximately 75% of dogs with macroscopic MCT, although only 30% have GI signs.^{20,21} Abnormally elevated plasma histamine concentrations have also been found to be a negative prognostic factor in dogs with MCT.²¹ Symptomatic therapies such as proton-pump inhibitors, H_2 blockers, misoprostol, sucralfate, and rehydration may be helpful in combating PNS-associated gastroduodenal ulceration. MCTs are covered in greater detail in Chapter 20.

An additional cause of PNS-associated gastroduodenal ulceration is gastrinoma (gastrin-secreting non-islet cell pancreatic tumor). Although these tumors are relatively rare, they have been reported in both dogs and cats.²²⁻²⁶ Gastrinomas can be associated with vomiting, lethargy, anorexia, blood loss, and abdominal pain. Many of these features are also seen in humans with gastrinoma-related Zollinger-Ellison syndrome. Gastrinomas are covered in greater detail in Chapter 25.

Endocrinologic Manifestations of Cancer

Hypercalcemia

The most common cause of hypercalcemia in the dog is cancer. A variety of tumors have been associated with hypercalcemia of malignancy (HM), and neoplasia is diagnosed in approximately two-thirds of dogs^{27,28} and one-third of cats with hypercalcemia.²⁹ Lymphoma is the most common cause of HM (10% to 35% occurrence). Other tumor types associated with HM in dogs and cats include anal sac apocrine gland adenocarcinoma ($\geq 25\%$), thyroid carcinoma, multiple myeloma (20%), bone tumors, thymoma, squamous cell carcinoma, mammary gland carcinoma/

adenocarcinoma, melanoma, primary lung tumors, chronic lymphocytic leukemia, renal angiomyxoma, and parathyroid gland tumors.³⁰⁻⁴⁰ The causes of HM are varied and include ectopic production of parathormone (PTH) or PTH-related peptide (PTH-rp) by the tumor, extensive and usually multifocal lytic bone metastases, primary hyperparathyroidism, tumor-associated prostaglandins ($PGE_{1/2}$), interleukin-1- β (IL-1 β , previously known as osteoclast-activating factor [OAF]), transforming growth factor- β (TGF- β), and receptor activator of nuclear factor kappa-B ligand (RANKL).^{2,34,41-46} Interestingly, TGF- β 1 regulates the mRNA stability of PTH-rp.⁴⁷ The HM seen in lymphoma and anal sac apocrine gland adenocarcinoma is commonly caused by tumor-associated PTH-rp.^{48,49} PTH-rp is a 16-kDa protein with significant sequence identity to PTH, suggesting it may act and function like PTH. In addition to HM, other hypercalcemia differential diagnoses include “lab error” (lipemia and hemolysis), acute renal failure, hypervitaminosis D, hypoadrenocorticism, and granulomatous disease.

In addition to ensuring the hypercalcemia is not due to lipemia or hemolysis, it is important to interpret the calcium value in relation to the level of serum albumin if ionized calcium determination is not available. Two commonly utilized correction formulas that controversially attempt to account for the level of serum albumin follow:

$$\text{Adjusted calcium (mg/dL)} = [\text{Calcium (mg/dL)} - \text{albumin (g/dL)}] + 3.5$$

or

$$\text{Adjusted calcium (mg/dL)} = \text{Calcium (mg/dL)} - [\text{total serum protein (g/dL)} \times 0.4] + 3.3$$

Similarly, an increase in the free ionized fraction of calcium can occur with acidosis. Acidotic HM patients may have an increase in clinical signs of hypercalcemia when compared to nonacidotic HM patients.

The primary clinical manifestations of HM are due to renal function impairment. Severe HM (calcium > 18 mg/dL) should be considered a *medical emergency*. An inability to concentrate urine is the initial manifestation of hypercalcemia and is due to decreased responsiveness to antidiuretic hormone (ADH) at the distal tubule; the calcium then decreases renal blood flow and glomerular filtration rate (GFR) as the result of severe vasoconstriction. Calcium salt deposition in the renal parenchyma may also contribute to renal azotemia, although this is uncommon. The urinary epithelium may then undergo degeneration, and in severe cases, necrosis results in exposure of the basement membrane of the renal tubule. The situation worsens as the patient becomes polyuric and polydipsic, resulting in progressive dehydration. In addition to effects on the renal system, severe HM may cause constipation, hypertension, twitching, weakness, shaking, depression, vomiting, bradycardia, stupor, and possibly coma and/or death.

When HM is diagnosed, appropriate steps for identification of the underlying neoplasm cause are necessary, and if azotemia accompanies HM, appropriate therapy to support renal function should be instituted quickly. The diagnostic evaluation of HM should begin with procedures used in the staging of lymphoma (as outlined in Chapter 32, Sections A and B) in addition to a rectal palpation and examination for anal sac apocrine gland adenocarcinoma. If these diagnostics do not confirm the specific cause of the HM, then the aforementioned hypercalcemia differential diagnoses

should be considered and appropriately pursued. Dogs and cats with HM will typically have low PTH and high PTH-rp concentrations; however, the cause of the HM can usually be delineated with appropriate diagnostics before the return of PTH/PTH-rp assay results and such tests may not be routinely needed. Since HM is a potential medical emergency, the primary goal is elucidation of the underlying cause in order to institute the appropriate therapy for the specific tumor. Symptomatic therapy must be judiciously utilized while searching for the underlying cause of the HM. The premature administration of symptomatic therapy that includes the use of corticosteroids prior to the confirmation of the cause of the HM can have serious consequences. If lymphoma is the underlying cause of the HM, the use of corticosteroids may interfere with the ability to confirm a diagnosis, necessitating either additional diagnostics and/or waiting to determine if the lymphoma reappears after glucocorticoid withdrawal. In addition, glucocorticoids may induce resistance to other chemotherapy agents with a decrease in the ability to induce a complete remission, as well as a decrease in the length of survival.⁵⁰ Therefore the use of corticosteroids in cases of undiagnosed hypercalcemia is strongly discouraged.

Symptomatic therapies that promote external loss of calcium, increase renal excretion of calcium, and inhibit bone reabsorption may be utilized in HM patients. The severity of clinical signs and associated hypercalcemia determine the preferred therapy (Box 5-2). The use of 0.9% NaCl intravenously (IV) is recommended for management of existing dehydration and to expand the extracellular fluid volume, increase GFR, increase calciuresis and natriuresis, and decrease calcium reabsorption by the kidneys. Once rehydrated, the loop diuretic furosemide with continued normosaline diuresis can be utilized to potentially inhibit calcium reabsorption

in the ascending loop of Henle. If the cause of the HM is determined, corticosteroids can be extremely effective as adjunct therapy for HM by their inhibition of PGE, OAF (IL-1 β), vitamin D, and intestinal calcium absorption. Corticosteroids can also be cytotoxic to lymphoma cells, the most common cause of HM. The most common therapies utilized in the treatment of HM are outlined in Box 5-2. In rare cases that are unresponsive to these symptomatic therapies and treatment of the underlying cause, other treatments such as calcitonin, bisphosphonates, or gallium nitrate may be utilized.⁵¹ Bisphosphonates have become the standard of therapy for human nonhumoral HM because of their potent inhibition of bone resorption without affecting tubular calcium reabsorption.⁵² The use of bisphosphonates in dogs and cats appears to be a promising treatment for hypercalcemia but requires additional study.^{53,54} In the future, treatment options for refractory HM may include osteoprotegerins, more potent bisphosphonates, anti-PTH-rp antibodies, noncalcemic calcitriol analogs, distal tubule calcium reabsorption inhibitors, RANKL antagonists, and new bone resorption inhibitors.^{52,55}

Hypoglycemia

The most common cause of cancer-induced hypoglycemia (<65 to 70 mg/dL serum glucose) in the dog is insulinoma (beta-islet cell tumor), and the reader is directed to Chapter 25 for a discussion of insulinomas.⁵⁶ Nonislet cell tumors can also serve as sources of ectopic hormone production with resultant hypoglycemia in dogs and humans. Nonislet cell tumors with PNS hypoglycemia have been most commonly associated with hepatocellular carcinomas; however, lymphoma, hemangiosarcoma, oral melanoma, hepatoma, plasma cell tumor, multiple myeloma, smooth muscle tumors (leiomyoma and leiomyosarcoma), mammary tumors, renal tumors, and salivary gland tumors have also been reported.⁵⁷⁻⁶² The hypoglycemia of extrapancreatic tumors has interestingly been associated with low insulin levels, whereas pancreatic beta-islet cell tumors (insulinomas) induce hypoglycemia by excessive circulating insulin levels. Nonislet cell tumors may induce hypoglycemia by increased tumor utilization of glucose, decreased hepatic glycogenolysis or gluconeogenesis, or the secretion of insulin or IGF-1 and IGF-2. Additional mechanisms include upregulation of insulin receptors, increased insulin binding by M proteins in myeloma, and increased production of somatomedins.^{2,63} The differential diagnoses of hypoglycemia include insulinoma, nonislet cell tumor hyperinsulinism, nonislet cell tumor, hypoadrenocorticism, starvation, sepsis, liver dysfunction, and laboratory error (lack of timely serum separation). Tumors associated with extrapancreatic hypoglycemia are often extremely large and therefore radiographs/ultrasound of the abdomen and/or thorax may be helpful. Exploratory laparotomy may be necessary if a space-occupying mass is not identified. Provocative testing via glucagon or glucose tolerance testing may be useful in cases when the diagnosis is uncertain. The reader is directed to Chapter 25 for an extensive discussion of the clinical consequences, diagnosis, and therapy of tumor-induced hypoglycemia.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

Syndrome of inappropriate secretion of ADH (SIADH) is a PNS widely recognized in lung, head, neck, and many other tumors in humans^{1,2}; however, it continues to be essentially unrecognized in veterinary oncology. SIADH has been reported in dogs associated with heartworm disease, congenital hydrocephalus, and granulomatous amebic meningoencephalitis.⁶⁴⁻⁶⁶ In addition to

BOX 5-2 Treatment for Hypercalcemia of Malignancy

Elimination of the inciting tumor is the primary goal for all categories of hypercalcemia.

Mild Hypercalcemia and Minimal Clinical Signs

Rehydration with normosaline (0.9% NaCl)

Moderate Hypercalcemia and Clinical Signs

Rehydration with normosaline (0.9% NaCl)

Continue normosaline diuresis (urine output >2 mL/kg/hr)

Furosemide (1-4 mg/kg every 8-24 hours IV or PO)

NOTE: Only use after patient is fully rehydrated.

Prednisone (1 mg/kg daily to BID PO)

NOTE: Only use after diagnosis obtained (see text).

Severe Hypercalcemia and Severe Clinical Signs

ONCOLOGIC EMERGENCY

See moderate hypercalcemia treatments

For refractory cases:

Bisphosphonates

Pamidronate (1-1.5 mg/kg IV every 2-3 weeks)

Salmon calcitonin (4-10 MRC units/kg SQ daily)

Mithramycin (25 μ g/kg IV 1-2 times/week)

NOTE: Sclerosing agent and hepatotoxin at higher doses—rarely used.

NaCl, Sodium chloride; IV, intravenous; PO, by mouth; BID, twice a day.

PNS-associated SIADH, chemotherapy agents and other drugs (vincristine, cyclophosphamide, cisplatin, thiazides, morphine, and chlorpropamide), pulmonary and/or central nervous system (CNS) infections, and a variety of other conditions can cause SIADH.^{67,68} The initial finding in SIADH patients is hyponatremia. In addition to hyponatremia, serum hypo-osmolality, hypernatruresis, urine hyperosmolality, and euvoemia with normal renal, thyroid, and adrenal function is noted.^{2,67} Although most human SIADH patients are asymptomatic, clinical signs can develop due to hyponatremia that result in CNS signs such as fatigue, anorexia, confusion and potentially seizures. The treatment of choice for PNS-associated SIADH is removal of the underlying cause. In addition, water restriction, demeclocycline (ADH antagonist), and hypertonic sodium chloride may be useful in SIADH cases.⁶⁹

Ectopic Adrenocorticotrophic Hormone Syndrome

The ectopic production of adrenocorticotrophic hormone (ACTH) or ACTH-like substances is the second most common PNS reported in humans.² This PNS is associated with small cell lung tumors, pancreatic tumors, and a wide variety of other human tumors.^{2,67} In the dog, this PNS is reported to occur in primary lung tumors and a single case of an abdominal neuroendocrine tumor.^{70,71} The predominant active molecules in this PNS are ACTH, ACTH precursors, endorphins, enkephalins, and melanocyte-stimulating hormone (MSH).^{2,67} All result in excessive production of steroids from the adrenal glands resulting in clinical signs similar to those seen in hyperadrenocorticism (Cushing's disease). Invariably, tumors that cause this PNS are dexamethasone insuppressible. The diagnosis of this PNS is made by the concomitant presentation of Cushing's-like signs with an abnormal dexamethasone suppression test and a localizable tumor. The treatment of choice is removal of the underlying cause by surgical extirpation of the tumor. When necessary, the medical therapy for this PNS centers on inhibiting cortisol production by mitotane or ketoconazole. The use of selegiline (Anipryl) in the management of this PNS in dogs has not been evaluated to date in veterinary medicine.

Hypocalcemia/Hyperglycemia

Paraneoplastic hypocalcemia and hyperglycemia are extremely rare. Tumors associated with lytic bone metastases and tumors that secrete calcitonin (medullary carcinoma of the thyroid) are the most common causes of human PNS hypocalcemia.² A variety of nonthyroid cancers such as breast cancer, GI cancer, carcinoids, and lung cancer in humans have been reported to secrete calcitonin.⁷² Most cases of PNS hypocalcemia are asymptomatic, although human patients may have neuromuscular irritability and/or tetany. A gingival vascular hamartoma in a 4-month-old kitten has been reported to be associated with PNS hyperglycemia, and the hyperglycemia resolved within 24 hours on removal of the tumor.⁷³ Treatment of choice for either PNS is eradication of the primary tumor whenever possible, calcium infusion in severe hypocalcemia cases, and diabetes-like support for severe hyperglycemia cases.

Hematologic Manifestations of Cancer

Hypergammaglobulinemia

Monoclonal gammopathies can be common in animals and people with cancer and they are termed *M-component disorders*.^{1,2,74-76} The

hypergammaglobulinemia seen as a PNS is due to the excessive production of proteins from a monoclonal line of immunoglobulin (Ig)-producing plasma cells or lymphocytes. When production of these Igs, partial Igs, heavy chains, and/or light chains becomes extreme, clinical signs of hyperviscosity (ataxia, depression, dementia, cardiac disease and/or failure, seizures, and coma), tissue hypoxia, bleeding (poor platelet aggregation, platelet coating with Igs, and release of platelet factor III), and/or ocular disorders (e.g., papilledema, retinal hemorrhage, detachment) may occur. These proteins may be identified by performing a protein electrophoresis on the serum and/or urine.⁷⁶ Similarly, light chain production may be detected in the urine as Bence-Jones proteins. In addition to the hypergammaglobulinemia PNS seen in plasma cell tumors (multiple myeloma and extramedullary plasmacytoma), lymphomas, lymphocytic leukemias, and primary macroglobulinemia can also cause this PNS.^{75,76} Further discussion of plasma cell tumors, myeloma and lymphoma/leukemia can be found in Chapter 32.

Anemia

Anemia is one of the most common PNSs seen in veterinary and human oncology. Approximately 20% to 25% of human cancer patients have PNS anemia, and although the exact incidence of PNS anemia in veterinary oncology is unknown, it is thought to be a significant problem.⁷⁷ There are numerous possible causes for PNS anemia in veterinary oncology patients, and the vast majority are due to either anemia of chronic disease (ACD), immune-mediated hemolytic anemia (IMHA), blood loss anemia, or microangiopathic hemolytic anemia (MAHA).

ACD is extremely common in veterinary and human oncology patients with disseminated and/or metastatic tumors. This anemia is due to disordered iron storage and metabolism, shortened red blood cell (RBC) lifespan, and occasionally decreased bone marrow response.⁷⁷ The anemia seen in ACD is normocytic/normochromic, and evaluation of the bone marrow does not suggest significant problems with cellularity. Treatment of choice is removal of the tumor.

IMHA can be triggered by tumors in animals and humans. Immune mechanisms then result in the premature destruction of RBCs.⁷⁸ The diagnosis of PNS IMHA is typically established by a Coombs' slide agglutination test, and many patients will have concurrent spherocytosis and a regenerative anemia. The treatment of choice is removal of the tumor; however, if this is not immediately possible, the use of immunosuppressive dosages of prednisone (1 to 2 mg/kg daily to two times a day by mouth [BID PO]) may be indicated if a diagnosis has been established. Similar to non-PNS IMHA, the use of additional agents such as azathioprine (1 to 2 mg/kg daily for 4 to 7 days, then 0.5 to 1 mg/kg every 48 hrs PO), cyclosporine, cyclophosphamide, and others may be necessary for complicated IMHA cases.⁷⁸⁻⁸¹

Blood loss anemia can be a sequela to many types of cancer. Due to decreased hemoglobin content, the RBCs in blood loss anemia are microcytic/hypochromic. In addition, decreased serum iron, increased total iron-binding capacity, and poikilocytosis may also be noted.^{82,83} The blood loss may be readily apparent in some patients (e.g., bleeding splenic tumor or bleeding superficial tumor), whereas others may not have a readily identifiable source for the loss (e.g., GI tumors). The treatment of choice is removal of the tumor, although severe anemia may necessitate blood transfusions. The use of oral and/or injectable iron may be a useful adjunct therapy.

MAHA is a secondary phenomenon to hemolysis and is typically due to fibrin deposition and/or endothelial damage.⁷⁷ The most common causes of MAHA are PNS disseminated

intravascular coagulation (DIC) and RBC shearing as the result of hemangiosarcoma.^{77,80} Schistocytosis and hemolysis are common indicators of ongoing MAHA. While any tumor can cause DIC and subsequent MAHA, hemangiosarcoma is most common.⁸⁴ The treatment of choice is removal of the tumor; however, additional ancillary treatments such as aggressive supportive therapy and transfusions may be useful.

Chemotherapy-induced anemia can be quite common in people because of more aggressive chemotherapy protocols²; however, this is rarely seen in veterinary patients.^{77,82,83} The degree of anemia seen in veterinary cancer patients undergoing chemotherapy is generally mild, with typical packed cell volumes hovering in the 28% to 32% range for dogs and 24% to 28% range for cats. This anemia rarely necessitates therapy and resolves on discontinuation of the chemotherapy protocol.

A relatively uncommon cause of PNS-associated anemia is myelophthisis (bone marrow invasion/crowding out), and it is most commonly caused by leukemias.² Another uncommon cause of PNS-associated anemia is bone marrow hypoplasia resulting from hyperestrogenism. Sertoli cell tumors in the male dog and granulosa cell tumors of the female dog are commonly associated with hyperestrogenism, and anemia is a common presenting feature.⁸⁵⁻⁸⁷

Erythrocytosis

Erythrocytosis is a relatively uncommon PNS. Tumors that have been associated with PNS erythrocytosis include renal tumors (primary and secondary), lymphoma (including renal origin), lung or liver tumors, cecal leiomyosarcoma, nasal fibrosarcoma, and transmissible venereal tumor (TVT).^{62,88-93} The erythrocytosis seen in cancer patients can be due directly to overproduction of erythropoietin, indirect excess erythropoietin from renal hypoxia, or increased production of hypoxia-inducible factors such as HIF-1.⁹⁴ Interestingly, some tumor suppressor genes (TSG) are important proteosomal regulators of HIF-1, which may explain some of the vascular diseases seen in human patients with certain TSG mutations.⁹⁵ Other differential diagnoses for polycythemia include arteriovenous shunts, severe dehydration, hyperadrenocorticism, polycythemia vera (primary polycythemia), and a variety of cardiac and/or pulmonary diseases.

It is important to differentiate primary and secondary causes of erythrocytosis. Polycythemia vera is a myeloproliferative disorder resulting in clonal proliferation of RBCs with splenomegaly and possibly pancytosis most commonly associated with acquired recurrent mutation in JAK2.^{1,2,96} Secondary polycythemia results from decreased arterial oxygen saturation. PNS erythrocytosis is best treated by removal of the erythropoietin-producing tumor whenever possible; phlebotomy can be a useful temporary adjunct therapy. Unfortunately, the volumes typically needed for a therapeutic phlebotomy in PNS erythrocytosis cases necessitates administration of fluids and potentially readministration of plasma. The use of hydroxyurea (40 to 50 mg/kg divided BID PO)⁹¹ as a chemotherapeutic agent for polycythemia vera has been previously recommended; however, this author has noted limited benefit with use of this agent.

Neutrophilic Leukocytosis

Increases in the number of circulating neutrophils have occasionally been associated with a variety of tumors in humans and dogs. Unfortunately, a leukemoid reaction of this nature can be difficult to distinguish from a true leukemia without extensive diagnostics. Neutrophilic leukocytosis has been reported in dogs with lymphoma, renal carcinoma, primary lung tumor, rectal polyp, and

metastatic fibrosarcoma.⁹⁷⁻¹⁰⁰ The exact mechanism of PNS leukemoid reactions is unknown; however, the production of a colony-stimulating factor such as granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF) is considered likely. Reports have documented tumor-produced G-CSF and GM-CSF in dogs with primary lung tumor and renal transitional cell carcinoma, whereas tumor-produced G-CSF has been documented in a cat with dermal adenocarcinoma and suspected in a cat with pulmonary squamous cell carcinoma.¹⁰¹⁻¹⁰³ This PNS is generally of minimal clinical significance, and normalization of the PNS is possible following removal of the inciting tumor.

Thrombocytopenia

Thrombocytopenia in human and veterinary cancer patients is typically secondary to chemotherapy administration; however, the incidence of thrombocytopenia in tumor-bearing dogs prior to chemotherapy administration has been reported to be as high as 36%.⁸⁰ Dogs with lymphoproliferative tumors have been reported to have thrombocytopenia in 58% of cases.¹⁰⁴ Dogs with Sertoli cell tumors (or occasionally seminomas) that excessively produce estrogen are also prone to thrombocytopenia.^{85,87} Twenty percent of the cases of thrombocytopenia in cats have been reported to be due to cancer, most commonly associated with lymphoma.¹⁰⁵

Numerous mechanisms for PNS thrombocytopenia are possible and include platelet destruction, sequestration, or consumption and/or decreased platelet production. The most common tumors associated with PNS thrombocytopenia are vascular tumors of the spleen and tumors infiltrating the marrow, such as lymphoma or leukemias.¹⁰⁶ Immune-mediated thrombocytopenia (ITP) is an additional significant cause of thrombocytopenia.¹⁰⁷ The treatment of PNS-associated thrombocytopenia is removal of the inciting tumor; however, adjunctive therapies such as intravenous fluids, plasma, and heparin may be beneficial. For those cases secondary to ITP, the use of immunosuppressive drugs such as corticosteroids (≥ 2 mg/kg PO daily) and azathioprine (2 mg/kg PO daily then 0.5 to 1 mg/kg PO every other day) may be necessary.

Coagulopathies and Disseminated Intravascular Coagulation

Alterations in hemostasis can be common in human and veterinary cancer patients. PNS coagulopathies are most commonly associated with tumors that cause thrombocytopenia, thrombocytosis, DIC, platelet dysfunction, changes in platelet aggregation, or hyperheparinemia (due to MCT).^{108,109} Trousseau's syndrome is a carcinoma-associated human coagulopathy that appears to be related to excess production of hypoxia factors leading to angiogenesis and a procoagulant state.¹¹⁰ PNS-associated DIC has been reported to be the cause of consumptive thrombocytopenia in almost 40% of DIC cases,⁸⁰ suggesting this PNS may be an important clinical syndrome based on the potentially devastating morbidity and mortality associated with DIC. The diagnosis of DIC is made when the patient has thrombocytopenia, prolongation of activated partial thromboplastin time (aPTT), elevated fibrin degradation products (FDP), and hypofibrinogenemia.^{80,111,112} A reduction in serum antithrombin III levels appears to be one of the most reliable and prognostic measurements for the presence of DIC.^{104,113,114}

The incidence of DIC in dogs with malignant tumors is approximately 10%.¹¹⁵ A variety of tumors have been associated with DIC; hemangiosarcoma is the most common in dogs. Other associated tumors include inflammatory mammary gland tumors,

thyroid carcinomas, primary lung tumors, and intraabdominal carcinomas.^{113,115-117} DIC has not been evaluated as a prognostic factor in veterinary cancer patients to date; however, the presence and severity of DIC in human cancer patients is a significant negative prognostic factor. Although not specifically related to DIC, the hyperheparinemia associated with MCTs can be associated with prolonged bleeding times and poor hemostasis during and after biopsy or surgery.²⁰

Miscellaneous

Thrombocytosis is a common PNS in humans with lymphomas and leukemias, although it is rarely noted in veterinary oncology. Myeloproliferative disorders appear to be the most common cause of PNS thrombocytosis in dogs and cats.¹¹⁸⁻¹²⁰ Important differential diagnoses include causes of primary thrombocytosis such as inflammatory processes, some hemolytic anemias, posthemorrhage, iron deficiency, and postsplenectomy.

PNS eosinophilia is rarely reported in veterinary medicine. Dogs with mammary tumors, leiomyosarcoma, T-cell lymphosarcoma (LSA), or fibrosarcoma and cats with a variety of tumors (lymphoma, sarcomas, MCT, and bladder tumors) have been reported to have tumor-associated eosinophilia.¹²¹⁻¹²⁵ In addition, eosinophilic effusions have been documented in dogs and cats with cancer and nonneoplastic conditions.¹²⁶ The cause of eosinophilia in these cases is poorly understood; however, the production of eosinophilic substances such as GM-CSF, various interleukins (e.g., IL-5, -13, and -17), and eotaxins are likely. PNS eosinophilia should be distinguished from eosinophilic leukemia and hypereosinophilia syndrome. The treatment for PNS eosinophilia is removal of the inciting tumor; PNS-associated eosinophilia is typically of little clinical significance.

Although lymphocytosis can be noted with various lymphocytic neoplasms and reactive nonneoplastic conditions, it is rarely noted as a PNS. T-cell lymphocytosis has been recently reported as a PNS in association with thymoma in a dog.¹²⁷

Platelets may play a role in cancer progression and metastasis attributable to platelet aggregation-mediated augmentation of tumor cell extravasation, survival, and angiogenesis. Platelet aggregation was investigated in a study of 59 dogs with cancer.¹⁰⁹ When compared to control dogs, the platelets of dogs with cancer exhibited significantly higher maximum aggregation, higher adenosine triphosphate (ATP) secretion, and shorter delays in the aggregation response. In addition to aiding the metastatic process, platelet hyperaggregation may also lead to thromboembolism.¹²⁸

Cutaneous Manifestations of Cancer

A wide variety of cutaneous syndromes are associated with malignancies in humans,¹²⁹ whereas relatively few are noted in veterinary medicine.¹³⁰ For example, Sweet syndrome is a human PNS associated with hematologic and solid tumors that causes acute febrile neutrophilic dermatosis but has not been reported to date in veterinary patients.¹³¹ As with any PNS, cutaneous-associated PNS lesions may precede, coexist with, or follow the diagnosis of the underlying tumor.

Alopecia

Pancreatic carcinoma has been reported in cats as the cause of a progressive, nonscarring PNS alopecia.¹³²⁻¹³⁵ The alopecia is acute, bilaterally symmetric (ventrum and limbs), and ventrally

glistening. The hair easily epilates from nonalopecic areas and histologically exhibits severe follicular and adnexal atrophy with absence of stratum corneum in many areas, including the foot pads. Clinical signs include anorexia, weight loss, lethargy, and difficulty walking and/or standing, which is most likely due to the aforementioned foot pad histologic changes. In two reports, a similar presentation was noted in cats with bile duct carcinoma.^{134,136} The cause of this PNS is presently unknown.

Cutaneous Flushing

When the skin episodically turns various shades of red because of changes in cutaneous blood vessel vasodilation, it is termed *cutaneous flushing*. Intermittent or paroxysmal cutaneous flushing can be associated with pheochromocytoma (see Chapter 25).^{2,137,138} This PNS has also been reported in a dog with primary lung tumor and concomitant intrathoracic MCT.¹³⁹ Dogs that undergo MCT degranulation may also have cutaneous flushing. Important non-neoplastic diagnoses to rule out for this PNS include drug reactions, demodicosis, and systemic lupus erythematosus. In addition to pheochromocytoma, humans may experience cutaneous flushing caused by Zollinger-Ellison syndrome, carcinoids, leukemias, renal cell carcinoma, and many other conditions.^{2,140}

Nodular Dermatofibrosis

Nodular dermatofibrosis (ND) is a well-recognized PNS of multiple, slowly growing cutaneous nodules in dogs with bilateral renal cysts or cystadenocarcinomas (Figure 5-2).¹⁴¹⁻¹⁴⁴ The nodules are

• **FIGURE 5-2** Diffuse nodular dermatofibrosis (ND) in a German shepherd dog. The nodules are composed of extremely dense but well-differentiated collagen tissue (collagenous nevi) and are found predominately on the limbs, although the head and trunk may be affected in advanced cases.

composed of dense but well-differentiated collagen tissue (collagenous nevi) and are found predominately on the limbs, although the head and trunk may be affected in advanced cases. ND appears to be inherited in an autosomal dominant fashion and is most commonly seen in middle-aged German shepherd dogs.^{141-143,145} The ND-associated mutation was mapped to exon 7 of the Birt-Hogg-Dube (BHD) locus on canine chromosome 5, which is the same locus for a phenotypically similar human disease.¹⁴⁶ Intact females with ND are also at increased risk for the development of uterine leiomyomas, and the BHD mutation appears to be homozygous lethal.^{143,146,147} The pathogenesis of ND is unknown; however, the BHD mutation in humans leads to a novel protein called *folliculin*, which may be related to the mTOR pathway.^{148,149} Currently, there is no effective therapy for the underlying tumor; however, palliative therapy via surgical removal of nodules may be utilized in cases in which the nodules are ulcerated, cosmetically displeasing, or interfering with function.

Necrolytic Migratory Erythema/ Superficial Necrolytic Dermatitis

Superficial necrolytic dermatitis (SND) is a rare PNS in humans and dogs characterized by circinate and gyrate areas of erosive blistering and erythema as the result of glucagonomas (glucagon-secreting pancreatic alpha-cell tumors).^{2,150-153} Marked fissuring, ulceration, and crusting of foot pads have also been noted in dogs. Nonneoplastic differential diagnoses for SND include hepatic disease and diabetes mellitus. Necrolytic migratory erythema, metabolic epidermal necrosis, diabetic dermatopathy, and hepatocutaneous syndrome are terms that have been previously used to describe SND. This PNS resolves in people after surgical extirpation of the glucagonoma, although the prognosis may be poor in dogs due to multiple postoperative complications.¹⁵⁴ Octreotide (2 to 3 µg/kg BID) has been reported to successfully treat paraneoplastic SND.¹⁵⁵ Although not specifically related to hepatocutaneous syndrome, a dog with sarcomatoid renal cell carcinoma and paraneoplastic hepatopathy with similarities to Stauffer's syndrome in humans has been reported.^{152,156}

Miscellaneous Syndromes

The number of recognized cutaneous PNSs in humans easily reaches into the dozens; however, the specificity of which we are able to delineate similar PNS in veterinary oncology is limited.¹³⁰ Ischemic necrosis of the digits and/or feet is a common human PNS associated with lymphoma, adenocarcinoma, and occasionally other malignancies.¹⁵⁷ Symmetric cutaneous necrosis of the hind feet has been reported in a cat with multicentric follicular lymphoma.¹⁵⁸ Interestingly, the necrosis was not associated with a neoplastic infiltrate and thrombotic/vasculitic causes were not seen histologically, suggesting it was of paraneoplastic origin.

Malassezia-associated dermatitis was first reported in a cat with paraneoplastic alopecia from a metastatic exocrine pancreatic carcinoma.¹⁵⁹ A study of over 500 feline skin biopsies found fifteen (2.7%) of the submissions contained *Malassezia* organisms. Ten of the 15 cats also had neoplasia, suggesting that *Malassezia* yeast in feline skin biopsies should prompt a clinical workup for neoplasia.¹⁶⁰

Pemphigus vulgaris (PV) is a dermatopathy characterized by intraepidermal bullae and erosions of the skin and oral mucosa.^{161,162} In humans, paraneoplastic PV (PPV) can be associated with lymphoma, Kaposi's sarcoma, and various carcinomas.² PPV has been reported in association with mediastinal lymphoma and splenic

sarcoma in dogs.^{163,164} Canine paraneoplastic pemphigus may be an excellent comparative model to human pemphigus PNS.¹⁶⁵ Recent reports suggest that paraneoplastic pemphigus is due to circulating IgG autoantibodies against desmoglein 3 across species.^{161,166,167}

Erythema multiforme has been associated with thymoma in a dog.¹⁶⁸ The erythema multiforme resolved after thymectomy, suggesting it was paraneoplastic in origin and may be similar to feline thymoma-associated exfoliative dermatitis.^{169,170} The variety noted in miscellaneous reports should serve as a reminder that there are likely many other uncharacterized cutaneous PNSs in veterinary oncology.

Renal Manifestations of Cancer

Human and veterinary cancer patients alike can develop important renal complications. Most are iatrogenic in nature and include chemotherapy-related toxicity (e.g., cisplatin), antibiotic toxicity (e.g., aminoglycoside), and contrast-associated nephropathy. In addition, infiltrative diseases such as lymphoma can have renal consequences. Biochemical alterations that can lead to nephrotoxicity include tubular precipitations from hypercalcemia, protein casts, glomerulopathies due to amyloidosis and/or membranous glomerulopathy, and fluid and electrolyte disorders due to hypercalcemia, hyponatremia, and acute tumor lysis syndrome. Nephrogenic diabetes insipidus may be a renal PNS in dogs with intestinal leiomyosarcoma.¹⁷¹

Approximately 6% to 10% of human cancer patients have significant glomerulonephritis and protein loss in the urine.^{172,173} Similarly, 11% of humans with nephrotic syndrome have a concurrent diagnosis of cancer.¹⁷⁴ The most common malignancies associated with PNS glomerulonephritis in humans are carcinomas of the lung and GI tract.¹⁷⁵ Immune complexes are thought to play a central role.^{176,177} The prevalence of glomerulonephritis in veterinary cancer patients is unknown; however, immune complex glomerulonephritis has been reported in a dog with polycythemia vera and a dog with lymphocytic leukemia.^{178,179}

Neurologic Manifestations of Cancer

Greater than 50% of human cancer patients have a mild degree of neuromuscular dysfunction (myopathy and/or peripheral neuropathy); however, the frequency of a specific neurologic PNS is low.^{1,2,180-182} Human neurologic PNSs are separated into anatomic categories (brain, spinal cord, peripheral nerve, muscle, neuromuscular junction). The prevalence of neurologic PNSs in veterinary medicine is unknown, and presently there are examples of neurologic PNSs reported in the dog for the brain, peripheral nerves, and neuromuscular junction.¹⁸³⁻¹⁸⁹ Many non-PNS causes of neurologic complications from cancer such as metabolic encephalopathy, brain metastasis, cerebrovascular incidents, neurotoxicity from radiation and/or chemotherapy, and neurologic infections due to altered immunity are possible.

Myasthenia Gravis

Myasthenia gravis (MG) is an acquired or congenital disorder of the neuromuscular junction that results from a failure of synaptic transmission. Antibodies to nicotinic acetylcholine receptors (nAChRs) can be documented in dogs with MG and are useful in the diagnosis and follow-up.^{183,190} In a similar fashion, Lambert-Eaton syndrome in humans occurs as the result of calcium-channel

autoantibody formation from predominately lung tumors, which then result in an MG-like syndrome caused by poor calcium influx from the presynaptic neuromuscular junction.^{191,192}

The most common cause of acquired MG in the dog is thymoma, although it has also been reported in association with osteosarcoma, lymphoma, and bile duct carcinoma.^{184,193-199} The clinical signs revolve around intermittent mild-to-severe muscular weakness, exercise intolerance, dysphagia, and megaesophagus (and possible secondary aspiration pneumonia). Rapid clinical improvement and decreases in nAChR antibodies have been noted after surgical extirpation of thymoma.^{194,200} The use of immunosuppressive doses of prednisone (>2 mg/kg PO daily) may be a useful adjunct in the treatment of paraneoplastic MG.¹⁹⁵

Peripheral Neuropathy

Peripheral nerve lesions that are the result of cancer are a relatively common event in humans and animals. When nerve fibers were analyzed from dogs with a wide variety of malignancies, a significant percentage of abnormal findings such as demyelination, myelin globulation, and axonal degeneration were noted in some specific malignancies.¹⁸⁵ Tumors associated with large numbers of peripheral nerve changes included primary lung tumors, insulinoma, MCT, thyroid adenocarcinoma, melanoma, and mammary tumors.¹⁸⁵ In contrast, clinically apparent PNS of the peripheral nerves in veterinary medicine is rare. Tumors associated with PNS peripheral neuropathy in dogs and cats include primary lung tumor, leiomyosarcoma, undifferentiated sarcoma, hemangiosarcoma, mammary tumor, multiple myeloma, lymphoma, and insulinoma.^{185-187,201-203} A multisystemic PNS in humans caused by plasma cell dyscrasia or tumor is termed *POEMS syndrome* for polyneuropathy, organomegaly, endocrinopathy, *M* protein, and skin changes. The treatment for paraneoplastic peripheral neuropathy is removal of the inciting tumor.

Diencephalic Syndrome and Miscellaneous Neuromuscular Syndromes

Diencephalic syndrome is a PNS seen in infants with rostral hypothalamic tumors that undergo extreme emaciation despite normal to increased caloric intake.² All cases occur in association with a tumor in the diencephalic region that secretes excess growth hormone. Only one case has been reported in the veterinary literature to date (affecting a 3-year-old Doberman pinscher).¹⁸⁸ Similar to human cases of diencephalic syndrome, this dog had extreme emaciation despite increased caloric intake with a growth-hormone producing astrocytoma in the diencephalic region. The cause for the lack of acromegalic and accelerated growth signs in this case is unknown.

Miscellaneous Manifestations of Cancer

Hypertrophic Osteopathy

Hypertrophic osteopathy (HO) is a syndrome characterized by periosteal proliferation of new bone along the shafts of long bones in response to malignant and nonmalignant diseases (Figure 5-3). HO has been present in the medical literature for over 25 centuries—Hippocrates described “Hippocratic fingers” (digital clubbing seen in humans with HO). As a PNS, HO is reported most commonly with primary lung tumors^{2,204}; however, in clinical veterinary practice, HO secondary to pulmonary metastatic disease (especially

• **FIGURE 5-3** Hypertrophic osteopathy (HO) in the front limb of a dog with a primary lung tumor. This paraneoplastic syndrome (PNS) is a bony disease that results in periosteal proliferation and subsequent lameness. This syndrome is seen in a wide variety of malignant and nonmalignant diseases.

osteosarcoma) is common. It has also been reported with urinary bladder rhabdomyosarcoma, esophageal tumors, malignant Sertoli cell tumor, renal TCC, and nephroblastoma and in cats with renal adenoma, papillary carcinoma, and adrenocortical carcinoma.^{102,205-213} Nonmalignant conditions such as heartworms, heart disease, focal lung atelectasis, pregnancy, abscesses, granulomas, foreign bodies, and pneumonia have also been associated with HO.

The clinical signs of dogs or cats afflicted with HO typically include a history of shifting-leg lameness and/or reluctance to move with all four limbs affected. The limbs are typically warm to the touch and swollen with occasional cases having involvement of the ribs and/or pelvis. The diagnosis of HO is made by radiography of the affected bones (starts distally and moves proximally) and finding the unique 90-degree periosteal reaction seen in Figure 5-3. The search for the inciting tumor begins with radiographs of the thorax, and if negative, radiographs and/or ultrasound of the abdomen with blood work and urinalysis should be pursued.

The etiology of HO is still unknown; however, based on measurable increase in blood flow to extremities and resultant connective tissue and periosteal proliferation, it has been well accepted that HO likely develops in part as a result of afferent neurologic stimulation.²¹⁴ This is further supported by the resolution of HO after vagotomy; however, this therapy is not routinely used in veterinary patients.²¹⁵ Recent work suggests that excess production of GHRH

and/or vascular endothelial growth factor (VEGF) by the tumor may also contribute to HO.^{12,216} The treatment for HO is removal of the inciting tumor when possible, and reports have been published documenting resolution of HO in dogs treated for their primary tumor.^{217,218} Prednisone (1 to 2 mg/kg PO daily) or non-steroidal antiinflammatory drugs (NSAIDs) may be a useful adjunct therapy for HO when the inciting tumor cannot be removed (i.e., diffuse metastasis). Other treatments for HO such as intercostal nerve resection, unilateral vagotomy, bilateral cervical vagotomy, analgesics, and subperiosteal rib resection have been suggested; however, these therapies have not been evaluated extensively in veterinary patients.^{204,219} The use of bisphosphonates has become more common for human patients with HO²²⁰ and likely represents an exciting new therapeutic modality in veterinary medicine for a variety of indications.^{53,54} Furthermore, the use of agents such as toceranib phosphate (Palladia),²²¹ in light of its antiangiogenic mechanisms of action, may warrant investigation for patients with resistant HO.

Fever

Although the most common causes of fever are infection, inflammation, autoimmune disease, or drug/blood product reactions, cancer can cause fever as a PNS and should remain an important differential diagnosis. Paraneoplastic fever can accompany a wide variety of tumors in human and veterinary patients. The incidence of fever as a PNS in veterinary medicine is unknown; however, in human patients presenting with fever of unknown origin, cancer is the cause in over one-third of the cases, with the most commonly diagnosed cancers being lymphoma, hepatoma, and renal cell carcinoma.² Approximately 10% of human cancer patients develop noninfectious/inflammation-related fever at some point during the course of their disease.²²² The pathogenesis of PNS fever is predominately due to excess production of cytokines (IL-1, IL-6, TNF- α , and interferons) and febrile-promoting prostaglandins.^{1,222,223}

The most important point in managing fever in veterinary patients with cancer is the evaluation for the presence of concurrent infection. Cancer patients with neutropenia and fever represent a medical emergency. Cancer patients with fever in the absence of neutropenia are not generally medical emergencies but should still be worked up to determine the presence or absence of an infectious and/or inflammatory nidus. If one is not found, then PNS fever is more likely the cause. If the fever is severe and threatens quality of life, the use of an NSAID such as indomethacin or naproxen is commonly utilized in humans with PNS fever. The best therapy for PNS fever is removal of the inciting tumor; however, if this cannot be accomplished, NSAIDs may be useful.

Imaging in Oncology

LISA J. FORREST AND SUSAN L. KRAFT

Diagnostic imaging plays an essential role in the management of the cancer patient. The initial diagnosis, staging, surgical and radiation treatment planning and response to therapy all involve imaging to a varying extent. Routine radiographs, ultrasound, nuclear medicine, and cross-sectional imaging in the form of computed tomography (CT) and magnetic resonance imaging (MRI) are routinely used in veterinary oncology. The choice of imaging modality depends on many factors, including the desired outcome. The biologic behavior of the tumor directs the imaging choice in cancer staging, and imaging may play an important role in guiding serial tumor biopsy during the course of therapy. The sophistication of imaging modalities continues to increase exponentially. Each modality has advantages and disadvantages with regard to cost, availability, sensitivity, specificity, and qualities of anatomic versus functional imaging (Table 6-1). Advanced molecular imaging techniques, which measure biologic processes at the cellular level,¹⁻³ are quickly becoming commonplace in physician-based oncology and have the potential to play an important role in the tailoring of cancer therapy in veterinary patients.

Imaging Modalities

Radiography

Conventional radiography has been the mainstay of cancer imaging for many years because of its accessibility and low cost. However, it usually is relegated to a screening test and is often followed by other imaging modalities to better differentiate and define tumor extent (Figure 6-1).^{4,5} Radiographic images are produced by the differential absorption of x-rays as the primary beam passes through the patient. Some x-ray photons are absorbed by the body and some pass through. Absorption depends on the thickness, physical density, and effective atomic number of the tissues of the patient's body. The x-rays that are not absorbed reach the radiographic film and determine the blackness and gray scale of the image.

Two of the strengths of radiography are the global information it provides and its excellent utility for bone imaging, especially the appendicular skeleton.⁶ Thoracic and abdominal radiographs are excellent screening tools for feline and canine lymphoma patients to determine thoracic lymph node and pulmonary involvement, as well as liver, spleen, and abdominal lymph node neoplastic spread.^{7,8} Radiography's greatest weaknesses are the superimposition of overlying structures and that only a few radiographic opacities are depicted. CT and MRI have replaced radiography for imaging of the head and, in some circumstances, the axial skeleton.⁹⁻¹²

Computed Tomography

As does radiography, CT relies on the physical density differences between tissues to form the image. Unlike radiography, CT portrays

slices of the patient without superimposition of structures because the images are computer generated and the gray scale display is superior. Although thoracic radiographs are routinely used as a screening method for evaluation of primary and metastatic tumors of the lung, mediastinum, and ribs, CT provides superior information for characterizing and anatomically localizing thoracic lesions for their diagnosis and treatment (see Figure 6-1). Compared with radiography, CT is more sensitive for identifying pulmonary nodules (Figure 6-2), mediastinal lymphadenopathy, and pleural and other masses.^{5,13-17} CT should be used to ascertain the full extent of pulmonary nodules from metastatic disease and when a primary lung tumor has been identified to evaluate for intrathoracic metastases and tracheobronchial lymphadenopathy.

CT is more sensitive than radiography to osteolysis and osteoproduction associated with neoplasia, and its three-dimensional (3D) information is especially useful for skeletal structures such as the sinonasal region, orbit (Figure 6-3), ear canals, and skeleton (Figure 6-4).⁹ CT is also useful to determine the origin and extent of abdominal mass lesions, and compared to ultrasonography, CT can better document the relationship of a mass with surrounding anatomic structures (Figure 6-5).^{18,19} Infiltrative muscular lesions such as infiltrative lipomas and soft tissue sarcomas are routinely imaged with CT for both surgical and radiotherapy planning.^{12,20} A contrast-enhanced scan is essential during CT to improve visualization of tumor margins, especially for infiltrative tumors such as feline vaccine-associated sarcomas.²¹

CT is exceedingly useful for both surgical and radiotherapy planning. Although MRI has better tissue differentiation, CT is used most often for radiotherapy treatment planning because there is no image distortion and the physical tissue density is available for input into treatment planning computers.^{22,23} It is extremely important to position the radiotherapy patient for the CT scan done for radiation treatment planning in a manner that can reliably be repeated during therapy. This will ensure the treatment is delivered as planned. CT is also amenable to obtaining image-guided biopsy of masses that are not readily obtained with ultrasound guidance, and is particularly helpful for thoracic, brain, spinal, and skeletal lesion biopsy (Figure 6-6).²⁴⁻²⁸ Contrast-enhanced CT angiography (CTA) is now also becoming more routine due to the increasing availability of multidetector CT scanners in veterinary medicine. CTA allows detection of tumor vascular invasion and can also depict tumor vascular supply for interventional therapies (Figure 6-7). Dynamic multiphase CT can also improve detection of metastases and small tumors such as insulinomas and may distinguish benign from malignant hypervascular primary hepatic tumors.²⁹⁻³²

Tumor perfusion, vascular permeability, and tumor blood volume can predict tumor aggressiveness through the use of

• **TABLE 6-1** Comparison of Imaging Modalities Used in Veterinary Medicine

MODALITY	COST	SENSITIVITY	SPECIFICITY	AVAILABILITY
Radiography*	Low	Moderate-high for bone lesions only	High for bone lesions only	High

*Anatomic imaging.

†Functional/physiologic imaging.

• **FIGURE 6-1** Lateral and ventral dorsal thoracic radiographs (**A** and **B**) and corresponding CT images (**C**, transverse image and **D**, dorsal reconstruction) of a dog with a thoracic wall osteosarcoma. Note that the mass is only faintly visible on lateral and ventral dorsal radiographic images, whereas CT provides complete information about tumor margins and extent of rib involvement (*white arrows*).

• **FIGURE 6-2** This large pulmonary mass is barely visible on the right lateral thoracic radiograph due to its superimposition over the esophagus (**A**) but is clearly visible on CT (*black arrow*, **B**) along with additional metastatic nodules that were too small to see on radiographs (**C**).

• **FIGURE 6-3** CT transverse image of a dog with a multilobular osteochondrosarcoma; note the nodular bone formations arising from the zygoma and palate that are encroaching on the orbit and displacing the eye.

dynamic contrast-enhanced CT, which estimates tumor wash-in and wash-out contrast kinetics.^{33,34}

Ultrasonography

Ultrasound imaging's ability to evaluate the internal structure of organs and to image body cavities when effusion is present has made it an essential diagnostic tool that has replaced abdominal radiography as the first-line choice in evaluation of the abdomen. The information provided by ultrasound is based on differences in acoustic impedance. The acoustic impedance of a material is a product of its physical density and the velocity of sound in the material. As sound waves pass from tissue to tissue, the amount of sound reflected (echoes) is determined by the impedance difference between tissues. The reflected echoes are detected by the transducer and processed into an image.

Ultrasound is superior to radiographs in instances of pleural or peritoneal effusion due to the loss of visceral detail that occurs on radiographs as the fluid will efface the margins of organs.³⁵ Ultrasound is also useful in guidance for biopsy or fine-needle aspiration of an observed abnormality. It is more sensitive than survey radiographs for detecting abdominal lymphadenopathy³⁶⁻³⁸ and size, shape, margins, heterogeneity, perinodal fat appearance, and vascular pattern of lymph nodes are useful in determining malignancy.³⁸⁻⁴² However, radiographs are superior for detection of bony invasion that may be associated with malignant medial iliac lymph node enlargement, often seen with tumors of the urinary bladder, prostate,⁴³ and anal glands. Ultrasound is sensitive in the detection of adrenal abnormalities, including vessel invasion, which is usually associated with malignancy (Figure 6-8).^{19,44} Ultrasound is routinely used to stage and monitor cats and dogs with mast cell disease, which has a varied appearance.^{45,46} It is used extensively in

• **FIGURE 6-4** **A**, CT transverse image (*white arrow*). **B**, Three-dimensional reconstructed image of a dog with scapular osteosarcoma, which provides an excellent visual assessment for surgical planning.

• **FIGURE 6-5** CT images of the urethra of a dog with transitional cell carcinoma (TCC). Note the thickened urethra with multifocal calcifications on the transverse image (**A**) and sagittal reconstructed image (**B**).

patients with gastrointestinal disease for initial diagnosis and monitoring of therapy.⁴⁷⁻⁵²

Ultrasonography is sensitive for lesion detection, but it is not specific for disease etiology. Many studies have attempted unsuccessfully to differentiate benign from malignant lesions based on sonographic appearance.^{44,46,50,53-55} Therefore biopsy or fine-needle aspirates of lesions are necessary. Ultrasound-guided sampling of tissue can be performed quickly, accurately, and safely.⁵⁶⁻⁶⁰ A caveat is the potential seeding of tumor cells from ultrasound-guided percutaneous sampling of transitional cell carcinoma.⁶¹

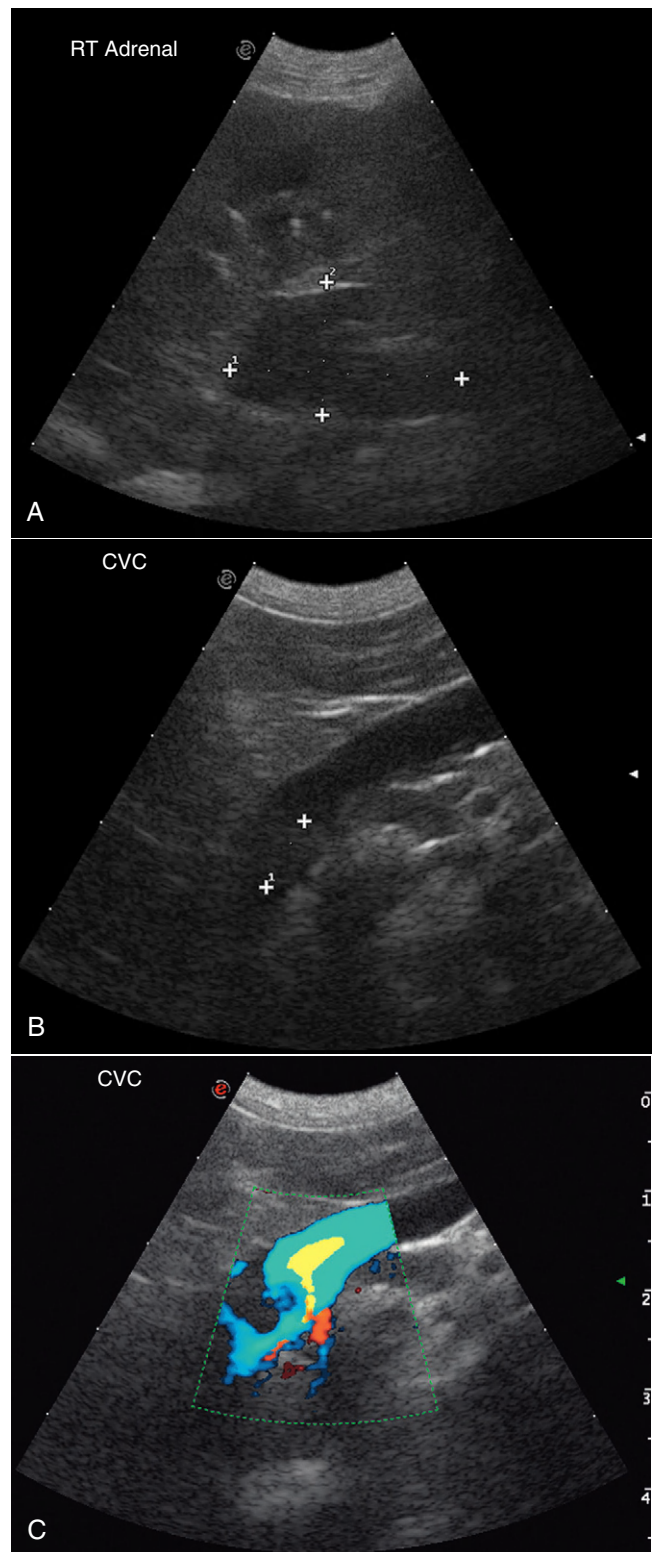

Advances in ultrasound equipment and the development of sonographic contrast agents are increasing the specificity of ultrasound.⁶² Doppler techniques are used to assess tumor vasculature, which is found generally to be tortuous with high velocity as compared to normal tissues.^{40,42,63,64} Tissue harmonic imaging transmits at one frequency and receives at twice that frequency. This technique has advantages over fundamental imaging.^{62,65} Harmonic imaging and/or ultrasound contrast agents have been used to differentiate benign from malignant lesions⁶⁴⁻⁷⁶ and continued exploration of this imaging modality is warranted.

• **FIGURE 6-6** CT transverse image of a biopsy needle being directed into an aggressive osteolytic bone tumor within the ilial wing of the pelvis. The metallic biopsy needle creates a metal streak artifact (*black lines above and below the visible portion of the needle*) on this image.

• **FIGURE 6-7** Lateral view of a 3D-reconstructed CT angiogram of a highly vascular thyroid carcinoma (*white arrow*). This technique can be useful for identifying the larger vascular territory supplying a tumor.

• **FIGURE 6-8** Ultrasound images of a right adrenal gland tumor with invasion into the caudal vena cava and probable tumor thrombus. **A**, Note the large heterogeneous mass (2.93×1.68 cm). **B**, A tumor thrombus or tumor extension is present. **C**, Note the turbulent Doppler flow in the caudal vena cava, indicating invasion of the right adrenal tumor into the vessel.

Magnetic Resonance Imaging

MRI is an advanced imaging technique that provides superb soft tissue images and sensitive detection of pathology based on properties of hydrogen atoms when placed in magnetic and radiofrequency fields. Images can be acquired directly in any plane with MRI, compared to CT in which sagittal and dorsal images are made by reconstructing transverse image data. MRI is the imaging modality of choice for the evaluation of the central nervous system, and the characteristics of the common canine and feline neurologic tumors are now well described (Figure 6-9).⁷⁷⁻⁸² MRI provides better anatomic detail and more sensitive detection of neuropathology than CT but is less useful for assessing cortical bone because of the number and characteristics of hydrogen protons in bone. Bone landmarks, areas of mineralization, and periosteal bone production are not as obvious with MRI as with CT. Nevertheless, MRI provides excellent anatomic detail and sensitive detection of infiltrative diseases affecting the musculoskeletal soft tissues, including joints, ligaments and tendons, and bone marrow, and is most accurate in determining the extent of canine appendicular osteosarcoma for limb-sparing procedures (Figure 6-10).⁸³

As advanced MR equipment becomes more common in veterinary medicine, MRI's use in cancer diagnosis and staging will increase because of its value in determining tumor morphology, margins, characteristics, and composition.^{32,84} MRI is excellent for tumors of the head, neck, and torso, although special measures are sometimes needed to minimize respiratory motion in certain anatomic sites.^{85,86} Whole-body MR is under evaluation as a sensitive method for cancer staging that is superior to CT and scintigraphy, and in human clinical trials it can rival the results of positron-emission tomography-CT (PET-CT) without the use of ionizing radiation.⁸⁷ Whole-body MRI does require ultrafast imaging methods, so it would be limited to veterinary sites having newer and high-field MR instruments.^{84,87} Although CT scans are most often used for radiation therapy planning, MRI provides advantages in select situations, including the ability to anatomically define

small at-risk structures such as the optic chiasm and to contour margins of lesions where beam-hardening artifact is problematic with CT.⁸⁴ MRI is also quite useful for detecting residual or recurring tumors due to its sensitivity to early disease. New MRI techniques are being developed that allow the study of tumor physiology and metabolism and valuable information about treatment response. Dynamic contrast-enhanced MRI provides information about tumor vascularity, perfusion, and angiogenesis that has been shown to have predictive value for treatment response and outcome (Figure 6-11).^{88,89} Diffusion MRI evaluates the mobility of tumor water molecules as a function of cell density and tissue architecture, with an increase in tumor diffusion indicating a positive treatment response and cell death.^{32,88,90,91} In vivo MR spectroscopy for measuring malignant metabolic biomarkers such as choline relative to normal surrounding tissue is moving from the research realm into human clinical use for brain and prostatic cancer and also has future potential for veterinary diagnosis.^{84,92}

Nuclear Medicine

Diagnostic nuclear medicine, or scintigraphy, involves the administration of radiopharmaceuticals that localize to an area of interest in the body by physiologic processes. Images obtained from nuclear medicine studies do not provide the anatomic detail attainable with other imaging techniques; however, the functional dependence on physiologic processes adds important information. Technetium-99m (^{99m}Tc) is the most commonly used radionuclide because it has excellent imaging qualities and a short half-life (6 hours) and is easily bound to localizing pharmaceuticals. Bone scintigraphy using ^{99m}Tc methylene diphosphonate (^{99m}Tc-MDP) is frequently used in veterinary medicine because it is a simple, sensitive, and noninvasive method of evaluating the entire skeleton.⁹³ Other commonly used nuclear imaging studies include renal, thyroid, lung,

• **FIGURE 6-9** Postcontrast T1-weighted transverse MR image of a canine oligodendroglioma (*black arrowheads*). Note its intraaxial location and ring enhancement around a hypointense less enhancing center.

• **FIGURE 6-10** Fat-saturated postcontrast T1-weighted coronal MR image of a canine femur showing contrast-enhancing infiltrative tumor within the bone marrow and extramedullary extension from osteosarcoma.

• **FIGURE 6-11** **A**, Transverse MR images of a soft tissue sarcoma of a canine forelimb. **B**, A color map of maximum slope of increase indicating the most rapidly contrast-enhancing tumor regions and also showing poor uptake in the necrotic core (*). Compare to the normal musculature and cross-sectional views of the radius and ulna in the left of the image.

• **FIGURE 6-12** Ventral, dorsal, and left and right lateral scintigraphic images of a cat with ectopic thyroid carcinoma (black arrows). Images were obtained 20 minutes after intravenous administration of technetium-99m (^{99m}Tc).

and liver scintigraphy (Figure 6-12). Parathyroid scintigraphy has been performed using dual-phase imaging⁹⁴ but due to lack of sensitivity was not recommended for identification of abnormal parathyroid glands in hypercalcemic dogs. At this author's (LJF) institution, ultrasound is used primarily to locate parathyroid masses in hypercalcemic dogs and cats.^{95,96}

In general, nuclear medicine studies are sensitive for lesion detection but are nonspecific for disease etiology. Benign and malignant lesions can have similar scintigraphic appearances. Bone metastases can be detected earlier with scintigraphy, before clinical and radiographic recognition, and scintigraphy can aid in the selection of the best site for biopsy (Figure 6-13).^{93,97} Once a lesion is identified, additional imaging (radiography, ultrasonography, CT, MRI) may be necessary.

Single-Photon Emission Computed Tomography and Positron Emission Tomography

Two advanced radionuclide imaging techniques used extensively in human medicine are single-photon emission computed tomography (SPECT) and positron emission tomography (PET). SPECT utilizes traditional gamma ray-emitting radionuclides, often with a rotating gamma camera or stationary ring, which reconstructs the images in cross-sections. SPECT provides better lesion localization as compared to planar scintigraphy, and hybrid instruments coupling functional SPECT information with CT for anatomy are now in use for oncology.⁹⁸ PET detectors also register gamma rays in a cross-section to reconstruct a 3D image, but these gamma rays are produced during annihilation of another emitted particle, the positron.⁹⁹ Positron-emitting radionuclides are closer in identity to

physiologic atoms than gamma ray-emitting radionuclides, allowing synthesis of compounds of more biologic relevance. Dual-modality hybrid PET/CT and, most recently, PET/MRI scanners are now commercially available with widespread use in oncology. The systems are housed in the same instrument allowing for almost simultaneous acquisition of both images and their fusion, providing both anatomic and physiologic information. The complementary data provided by the two imaging procedures provide the most accurate cancer staging for oncology patients.¹⁰⁰

Compared with normal cells, tumor cells have increased glucose utilization through glycolysis; this makes glucose an appropriate molecule for modification and labeling with a positron-emitting radionuclide. The increased energy demand of tumors is met through upregulation of the hexose monophosphate pathway, cell membrane glucose transporter proteins, and hexokinase. A glucose analog, ¹⁸F-fluorodeoxyglucose (FDG) acts as a glucose molecule and is transported by membrane proteins and becomes phosphorylated by hexokinase in the cell. However, phosphorylated FDG is not used in the glycolytic pathway and remains trapped intracellularly, as tumor cells are deficient in glucose-6-phosphatase. The differential uptake of FDG by tumor cells forms the basis for contrast in images.

Whole-body FDG PET/CT imaging has been utilized extensively for human cancer imaging for cancer staging and detecting metastases and is also proving useful for target definition for radiation therapy.^{3,99,101} Its use has been demonstrated not only for staging and follow-up of human lymphoma but also for prognostication and response evaluation.^{102,103} FDG PET/CT is now also available and being actively studied for use in veterinary cancer patients (Figure 6-14).¹⁰⁴⁻¹⁰⁷ Its utility for cancer staging of canine mast cell tumor and lymphoma has already been demonstrated.¹⁰⁸ However, there are limitations to the interpretation of FDG PET images. The uptake of FDG in normal tissues must be understood relative to veterinary species to avoid false-positive diagnoses because some normal tissues are also highly metabolic.¹⁰⁹⁻¹¹² Normal gray matter of the brain can confound interpretation of intracranial tumor images because of its high glucose utilization normally. Inflammatory processes also have increased FDG uptake, and post-radiation tissue reaction can be difficult to distinguish from tumor recurrence during the early posttherapy time period.¹¹³ Also, certain low-grade or poorly differentiated tumors do not show sufficient FDG uptake to be distinguished from background. Although FDG is still the most commonly used commercial PET agent for cancer imaging, limitations of FDG PET have led to exploration of other novel PET probes.¹⁰¹

Thymidine, the only nucleoside used solely in construction of DNA and not in RNA, provides an accurate measurement of increased cellular proliferation in a tumor both before and after treatment.^{105,114,115} Two fluorinated compounds that have been proved stable to degradation and useful in tumor imaging are 2'-fluoro-5-methyldeoxyuracil (FMAU) and 3'-deoxy-3'-fluorothymidine (FLT). Both compounds are phosphorylated by thymidine kinase (TK) intracellularly and incorporated into DNA to variable degrees. Although FLT acts as a chain terminator in DNA synthesis and has limited incorporation into DNA, for imaging purposes it remains trapped intracellularly by TK and indirectly reflects cellular proliferation. Early studies show normal FLT distribution within the bone marrow, liver, and urinary system as a result of excretion. Research using dogs with spontaneous tumors continues to look at the utility of FLT as a marker of tumor proliferation.¹¹⁴ Figure 6-15 is a sagittal reconstruction PET

FIGURE 6-13 Bone scan images of a dog with primary osteosarcoma of the left proximal humerus (A) with subcutaneous and rib metastases (B and C). Images were obtained 2 hours after intravenous administration of technetium-99m methylene diphosphonate (^{99m}Tc MDP). Note the large mass with associated radiopharmaceutical uptake in the left proximal humerus (A) and the focal increased uptake in multiple ribs and in subcutaneous tissue overlying the thoracic spine and dorsal to the scapula (B and C).

• **FIGURE 6-14** Transverse CT (A), PET (B), and fused PET/CT image (C) of a thymoma in the cranial mediastinum of a dog (arrows). D, A small hypermetabolic pulmonary adenocarcinoma (white arrow), which was not visible radiographically, was found incidentally on fused PET/CT image and also surgically removed.

• **FIGURE 6-15** 3'-Deoxy-3'-fluorothymidine (FLT) sagittal reconstruction of dog with nasal adenocarcinoma.

FLT scan of a dog with a nasal adenocarcinoma. PET radiotracers for noninvasive imaging of tumor hypoxia have been found in human cancer trials to have value in prognostication, predicting response, and better defining hypoxic tumor volumes for boost radiation therapy.^{99,116} Hypoxic radiotracers include several in the nitroimidazole class, including ^{18}F -misonidazole, the more hydrophilic ^{18}F -fluoroazomycin (FAZA), and the more lipophilic version 2-(2-nitro-1H-imidazol-1-yl)-N-(2,2,3,3,3-pentafluoropropyl)-acetamide (^{18}F -EF5). ^{60}Cu -labeled diacetyl-bis(N⁴-methylthiosemicarbazone) (^{60}Cu -ATSM) is a non-nitroimidazole tracer that is also being evaluated as a hypoxic tracer.

^{18}F -sodium fluoride (^{18}F -NaF) is a PET tracer that is now commercially available for bone scans. ^{18}F -NaF localizes to areas of high bone turnover similar to $^{99\text{m}}\text{Tc}$ -MDP that is used for bone scintigraphy. PET imaging with this tracer provides 3D, highly detailed whole-body skeletal images that are superior to bone scintigraphy and SPECT imaging for bone metastases.¹¹⁷⁻¹¹⁹ Its use is being evaluated in veterinary patients for detection of skeletal metastases and other bone disease processes (Figure 6-16).

Advances

The state of the art in human radiotherapy is represented by conformal radiotherapy and intensity-modulated radiotherapy (IMRT). In the former technique, the treatment beam is conformed to the tumor volume. In the latter technique, in addition to shaping the treatment beam to the tumor, beam intensity is modulated to maximize the tumor dose and minimize the dose to normal tissue.^{120,121} These advanced treatment modalities require imaging periodically through the radiation course.

In particular, IMRT requires precise and accurate tumor and normal tissue localization due to its high-dose gradients and maximal sparing of surrounding normal structures. This is accomplished through image-guided radiation therapy (IGRT) via a range of on-board imaging incorporated with IMRT linear accelerators.¹²² In addition to traditional portal image options, IGRT also includes the ability to use kV x-ray and cone-beam CT (CBCT) systems to image the patient at the time of setup so that slight movements can be made with the therapy table to perfectly match bone and soft tissue landmarks on the digitally reconstructed radiographic images and 3D-planning CT scan. These advances in technology make it possible to perform adaptive radiotherapy by taking into consideration changes in size and shape of the target volumes during a treatment course. Tumor motion can be a problem for many sites, especially as oncologists attempt to balance increased tumor dose with reduced normal tissue complications while attempting to improve overall survival. To this end, 4-dimensional (4D) CT imaging, in which respiratory motion is taken into account in the treatment planning process and delivery, is being implemented in human radiation oncology centers.^{120,123-125}

Another advance is helical tomotherapy, which integrates a linear accelerator with a helical CT scanner, allowing IGRT.¹²⁶ Each day before treatment, a CT scan is obtained with the linear accelerator; this scan is fused with the planning CT image, and the patient is moved accordingly to ensure precise treatment delivery.¹²⁷ CT imaging is an integral part of radiotherapy planning and delivery.

Advances are also being made in the area of molecular imaging.^{1-3,101,104,106} These techniques can be used to characterize and measure biologic processes, assess molecular targets, and monitor treatment at the cellular level.^{1,128} Molecular imaging can be used to assess gene delivery and identify marker proteins for apoptosis, angiogenesis, hypoxia, and other growth factors.^{1,3,101,116,129} Moreover, treatment of cancer using molecular targets holds great promise for individualized cancer therapy.^{116,130-132}

• **FIGURE 6-16** **A**, ^{18}F -sodium fluoride (^{18}F -NaF) PET bone scan 3D maximum intensity projection (MIP) image of a dog with a proximal humeral osteosarcoma (black arrow) 6-months poststereotactic radiation therapy. Note the excellent skeletal image with multifocal uptake at the costochondral junctions, the injection catheter, the opposite shoulder joint, and the urinary bladder due to excretion. **B**, The irradiated tumor (black arrow) on the dorsal plane PET image exhibits a photopenic center consistent with inactive bone remodeling and/or necrosis.

Diagnostic Cytopathology in Clinical Oncology

KRISTEN R. FRIEDRICH AND KAREN M. YOUNG

7

Cytologic evaluation plays several important roles in veterinary oncology that aid in clinical decision making, including making a preliminary or definitive diagnosis, planning diagnostic and treatment strategies, determining prognosis through staging, detecting recurrence, and monitoring response to therapy. An understanding of the advantages and limitations of cytologic evaluation is necessary to utilize this diagnostic modality effectively in clinical oncology.

Advantages of cytologic evaluation include the ability to evaluate the morphologic appearance of individual cells, the relatively low risk of procedures to the animal patient, the lower cost compared with biopsy, and the speed with which results can be obtained. Cytologic evaluation also has several limitations. The amount of tissue sampled is small compared with that obtained from a biopsy; therefore cytologic specimens may not be fully representative of the lesion. Sample quality may be poor because of factors intrinsic to the lesion or poor collection technique. Importantly, the inability to evaluate architectural relationships among cells in cytologic specimens may prevent distinction between reactive and neoplastic processes. Examination of histologic samples, in which tissue architecture is preserved, may be required to make a definitive diagnosis of neoplasia, determine tumor type, and assess the extent of the lesion, including metastasis. Even then, ancillary tests like immunohistochemical staining or tests for clonality may be required. Often cytologic evaluation precedes a biopsy and provides information that assists in formulating subsequent diagnostic and treatment procedures.

Some tumors, such as lymphoma, may be diagnosed and staged using cytologic evaluation exclusively, and treatment can be initiated without the need to collect histologic specimens. For other tumors, such as well-differentiated hepatocellular carcinoma, cytologic examination permits formulation of a list of differential diagnoses, and histologic evaluation must be performed for definitive diagnosis. At a minimum, categorization of a tumor as an epithelial, mesenchymal, or discrete round cell tumor often can be determined cytologically; this may be sufficient for initial discussions with the owner about diagnosis and prognosis. Staging the malignancy, monitoring therapy, and detecting recurrence using cytologic evaluation is more easily accomplished once a definitive diagnosis has been made and cytomorphologic features of the tumor described.

Sample Collection

Proper collection and preparation techniques are prerequisites to obtaining diagnostic samples of high quality. Supplies necessary for collecting cytologic samples from a variety of tissues, body cavities, and mucosal surfaces are available in most clinics. These include hypodermic needles and syringes, scalpel blades and handles,

propylene urinary catheters, bone marrow aspiration needles, cotton swabs, clean glass slides, marking pencils, and collection vials and tubes (tubes with ethylenediaminetetraacetic acid [EDTA] and plain sterile tubes). For aspiration of internal lesions, obtained by guidance with ultrasonography or computed tomography (CT), longer spinal needles and butterfly catheters (used to connect the spinal needle to the aspirating syringe) are useful. Cytologic specimens also can be made from tissues collected during biopsy (see Chapter 9). All supplies should be assembled in one location for ready access. Although life-threatening situations are rarely encountered when collecting cytologic specimens, supplies and medications should be available to control bleeding and to treat anaphylaxis. The latter occurs rarely when aspirating mast cell tumors because of release of histamine.

For external or easily accessible lesions, such as cutaneous and subcutaneous masses or enlarged lymph nodes, aspiration simply requires stabilization of the mass and consideration of underlying structures, such as large vessels and nerves. Some large abdominal masses can be aspirated blindly if they can be stabilized and if they are unlikely to be highly vascular or an abscess, aspiration of which may result in hemorrhage or dissemination of infection, respectively. Aspiration of intrathoracic and intraabdominal lesions is typically accomplished with guidance by imaging, either by ultrasonography or by CT, to aid in targeting the lesion and avoiding large vessels and other sensitive areas. Defects in cortical bone also can be identified with imaging, which can facilitate needle placement for aspiration of bone lesions. Cavity effusions are collected easily without imaging if fluid volume is significant; however, imaging can target smaller accumulations of fluid and provide a measure of safety. If there is particular concern for hemorrhage following aspiration, imaging can be repeated to look for evidence of bleeding at the aspiration site. Collection of cytologic specimens from the eye, brain, and lung requires special consideration and expertise.

Collection Techniques

Fine-needle aspiration (FNA) is by far the most common method for collecting cytologic specimens. Small-gauge needles (22 to 25 g) are sufficient for smaller lesions and result in less hemorrhage. Large-gauge needles (18 to 20 g) may be required to collect sufficient material from masses containing abundant matrix (i.e., firm masses and sarcomas), but specimens may contain more blood. Medium-sized syringes (12 to 15 cc) yield more vacuum for aspiration than smaller syringes (3 to 6 cc). The intent of aspiration is to draw cells into the needle shaft, not to fill the syringe with material unless the lesion is fluid-filled. After the needle is inserted into the lesion, vacuum is maintained in the syringe while the needle

is redirected into the tissue several times to collect a broad representation of cells. This is especially important when aspirating lymph nodes to search for metastasis. Following aspiration, vacuum is released prior to removing the needle from the tissue, the needle is removed from the tissue and then from the syringe, the syringe is filled with air and reattached to the needle, and the cells are expelled onto a glass slide. An alternative technique is to obtain cells without aspiration by holding the needle by the hub between the thumb and middle finger while covering the hub opening with the forefinger (to prevent blood or other fluids from escaping) and rapidly and repeatedly inserting the needle into the lesion with redirection until cells are packed into the needle shaft.¹ This method often yields as much cellular material as the aspiration technique and produces less hemorrhage and patient discomfort. Similar to the aspiration technique, a syringe is used to expel the material in the needle onto a glass slide. A second clean slide is then placed on top of the sample and the two slides are pulled apart in parallel, taking care not to exert pressure on the sample. The aim is to obtain a monolayer of intact cells. Failure to spread the specimen immediately leads to a sample that is too thick to interpret; conversely, aggressive pressure on the sample may rupture many if not all cells, also leading to a nondiagnostic specimen.

Cytologic material may be collected from mucosal surfaces such as the respiratory, gastrointestinal, and genital tracts by saline washes or with a brush or biopsy forceps inserted through an endoscope. Cytologic materials collected using an endoscopic brush are gently rolled onto a glass slide and often result in highly cellular smears. In contrast, rolling a cotton swab over the surface of a lesion is only moderately successful at collecting sufficient material for cytologic evaluation of tumors. Traumatic catheterization is the best method for collecting material from bladder masses because of the risk of seeding tumor cells when transitional cell carcinomas (TCCs) are aspirated transabdominally. Traumatic catheterization is accomplished with an open-ended polypropylene urinary catheter attached to a large (50 to 60 cc) syringe. The catheter is inserted into the urethra and bounced off the bladder wall in the region of the lesion (typically using ultrasound guidance), taking care not to perforate the bladder wall. Saline can be flushed into the bladder to facilitate collection of cells and cellular particles, some of which may be large enough to process for histologic evaluation.

Imprinting and scraping are excellent means of preparing cytologic specimens from biopsied tissues. When making imprints, a fresh surface should be exposed on the piece of tissue using a scalpel blade and then gently blotted on absorbent paper until little blood or tissue fluid appears on the paper. The tissue is held with forceps, and the fresh surface is gently pressed repeatedly onto the glass slide, using slightly different pressure with each imprint. The final specimen will contain a row of imprints of varying thickness, one or more of which should be suitable for evaluation. Common mistakes when preparing imprints include insufficient blotting and application of too much pressure, resulting in excessive blood or cellular disruption, respectively. Sometimes mucosal or connective tissue is obtained instead of tumor cells if the incorrect surface is imprinted onto the slide. When tumors such as sarcomas contain abundant matrix, imprinting will often not yield sufficient numbers of cells for evaluation. The surface of these lesions should be cross-hatched with a scalpel blade and imprinted without blotting; this may liberate cells embedded in matrix. Alternatively, the surface of firm lesions can be scraped several times in one direction with a scalpel blade held at 45 degrees to the tissue. The material on the edge of the blade is then gently spread on a glass slide. When using biopsy tissue to prepare cytologic specimens, care must be taken

not to disrupt surfaces or margins important for histologic evaluation, especially for excisional biopsies in which assessment of tumor margins is fundamental to the evaluation.

Tissue particles or mucus collected by saline washes or by traumatic catheterization can be retrieved with a pipette and gently pressed between two glass slides. If washes or cavity fluids are cell-poor, the cells in the fluid must be concentrated to prepare slides of sufficient cellularity. Collection fluid can be centrifuged, the supernatant decanted, and the cell pellet or sediment resuspended in a small amount of remaining fluid and then spread on a glass slide. Similar to preparation of blood smears, the feathered edge of the fluid should be included on the slide because nucleated cells will accumulate there and may be best evaluated at the edge. Alternatively, when spreading the suspended cell pellet fluid on a glass slide, the spreader slide can be abruptly lifted off the slide, leaving a line of fluid—and concentrated cells—on the slide instead of a feathered edge. The best method to concentrate cells in cell-poor fluid samples is to use a cytocentrifuge, but most practices lack this equipment.

Cytologic Stains

A variety of quick stains are available for immediate examination of cytologic specimens and include quick Romanowsky stains, such as Diff-Quik. A specific set of staining jars should be kept exclusively for cytologic specimens and not used concurrently for dermatologic specimens. The jars containing the stain components should be capped between uses to prevent evaporation and contamination of the fixative and stains. Maintenance, including scheduled replacement of stain components, is important to avoid artifacts such as stain precipitate and contamination with organisms or debris that might be misinterpreted. Slides should be completely air-dried prior to fixation in the methanol fixative. Stains must thoroughly penetrate the smear, and in well-stained smears nuclei should be purple (Figure 7-1, A). A thick sample requires more contact time with the stains; understained slides (Figure 7-1, B) can be restained for a longer period of time, and overstained slides can be destained with methanol and restained for a shorter period of time. If the slides will be sent to an outside diagnostic laboratory, clinicians are encouraged to stain a slide to ensure that sufficient material was collected and that cells are intact prior to submitting additional unstained slides for evaluation. Additional specimens should be collected if only noncellular material is present or if all the cells are lysed. For some lesions, the first slide prepared may be the only slide that contains cellular material. It is best to send this slide unstained to the diagnostic laboratory, but, if it is stained, be sure to include it with the other slides.

Quick Romanowsky stains provide good nuclear detail and usually sufficient cytoplasmic detail for cytologic interpretation. Mast cell granules occasionally fail to stain with aqueous quick stains (Figure 7-2, A). Wright-Giemsa and modified Wright stains provide a broader palette of colors and excellent staining of cytoplasmic granules (Figure 7-2, B) but require more steps and longer staining times or use of an automated stainer. Fixation of wet smears is required for Papanicolaou staining, which is not frequently used in veterinary cytology. Heat fixation is not required or recommended for cytologic specimens.

Cytochemical and immunocytochemical staining may be necessary to determine the specific tumor type. A complete list of available special stains and antibodies is beyond the scope of this chapter; consultation with a veterinary cytopathologist is recommended when considering the necessity and use of these stains.

• **FIGURE 7-1** Fine-needle aspirate of a lymph node from a dog with lymphoma. **A**, Well-stained specimen. Lymphocytes are three times the diameter of an erythrocyte and larger than a neutrophil and have multiple prominent nucleoli. Cytoplasmic fragments are visible in the background. **B**, Poorly stained specimen. Cytoplasmic fragments are visible, but cellular detail is poor.

• **FIGURE 7-2** Fine-needle aspirate of a mast cell tumor. **A**, Granules in mast cells (*large arrows*) fail to stain when the specimen is stained with an aqueous quick stain. Small lymphocytes (*small arrow*) are also present. **B**, Granules are prominent in a Wright-stained specimen from the same tumor.

Cytochemical stains identify specific chemical compounds or structures within the cytoplasm or nucleus and include stains such as Prussian blue for iron, periodic acid-Schiff (PAS) for carbohydrates, alkaline phosphatase for identifying osteoblasts,² and a wide variety of leukocyte markers, including Sudan black B, peroxidase, chloracetate esterase, and nonspecific esterases.

Immunocytochemical staining procedures utilize antibodies to identify specific proteins or peptides within or on the surface of the cells. Common antibodies used in veterinary oncology include those directed against CD3 (T-cells), CD79a and CD20 (B-cells), cytokeratin (epithelial cells), vimentin (mesenchymal cells), and Melan A (melanocytes). Use of a single stain or antibody

is discouraged, as cell lineage is rarely identified and aberrant expression by neoplastic cells may lead to an erroneous diagnosis if a single marker is evaluated; a panel of stains or antibodies usually is necessary for complete identification.

Examination and Description of Cytologic Specimens

A good microscope, ideally equipped with a digital camera to document cytologic findings for the medical record or for consultation, should be used for examining cytologic specimens. The 4×, 10×, and 20× objectives are useful for scanning the slide and assessing cellular arrangements and general cell shape, whereas the 40× (“high dry”) and 50× or 100× (oil-immersion) objectives are required for examining cellular detail. To improve clarity the 40× objective requires an additional optical interface, which can be provided by applying a drop of immersion oil or permanent mounting medium to the slide followed by a coverslip. As a note of warning, the 40× objective lens is easily coated with oil applied to the slide for viewing the specimen with oil-immersion objectives; if this occurs, the lens should be cleaned immediately with glass cleaner and lens paper to prevent accumulation of oil inside the objective lens. Proper use, including correct placement of the condenser for viewing stained and unstained specimens, and maintenance of the microscope are essential to adequate examination of cytologic specimens.

Consider the following when examining the slide preparation:

- (1) Is the specimen of sufficient quality to permit a clinically useful interpretation? Clinical decisions should not be made from specimens that are poorly cellular or have too many ruptured cells.
- (2) Based on the tissue sampled, do the cells represent the expected population, an abnormal population, or both? It is important to become familiar with the cytologic appearance of “normal” cells in frequently aspirated tissues, such as lymph node and liver.
- (3) Does the abnormal population represent inflammation or a neoplasm? Whenever inflammation is found in a lesion suspected to be a tumor, caution is advised in making a definitive diagnosis of neoplasia. Although some tumors are accompanied by neutrophilic inflammation, experienced cytopathologists recognize that primary inflammatory lesions can convincingly mimic neoplastic lesions.
- (4) If neoplasia is likely, what is the tissue of origin and is the tumor benign or malignant? These questions can sometimes be answered by cytologic evaluation of the tumor but often require confirmation with histologic examination.

Specimens of Diagnostic Quality

What constitutes adequate cellularity depends on the type of tumor. Aspirates of mesenchymal tumors, which often contain extracellular matrix, tend to be less cellular than those of epithelial and discrete round cell tumors. The degree of cellularity also has an impact on the level of confidence expressed in the interpretation, and diagnostic opinions are often qualified with “possible” or “probable” for poorly cellular specimens compared with “diagnostic for” or “consistent with” for highly cellular specimens. All cytologic specimens contain some ruptured cells, but to render a meaningful interpretation the majority of cells should be intact. Material from ruptured cells is recognized as stringy strands of chromatin or swollen magenta nuclei, often with obvious nucleoli, and free cytoplasmic fragments (see Figure 7-1, A). Large lymphocytes and cells from endocrine tumors are highly susceptible to lysis, and extra

care should be taken not to exert pressure on the cells when preparing cytologic specimens from these lesions.

Nonneoplastic Cells and Noncellular Material Found in Cytologic Specimens

The submandibular salivary gland occasionally is aspirated instead of the mandibular lymph node and is recognized by clusters of foamy cells in a background of mucin and blood. When tissue containing a metastatic tumor is aspirated, the specimen may contain only neoplastic cells or may contain normal cells from the tissue (e.g., lymphoid populations in a lymph node), which helps confirm location of the tumor. Necrosis can be found in tumors that have outgrown their blood supply. Necrotic cells lack detail and consist of gray-pink, indistinct cytoplasm and amorphous nuclei (Figure 7-3); they should not be confused with apoptotic or pyknotic cells, which retain distinct cytoplasmic borders that surround condensed nuclear fragments.

Aspiration usually results in some degree of sampling hemorrhage leading to the presence of few or many erythrocytes admixed with nucleated cells. Aspiration of splenic lesions and thyroid and vascular tumors may result in pronounced hemorrhage and abundant blood in the cytologic specimen. Preexisting intralesional hemorrhage is indicated by the presence of macrophages containing erythrocytes or hemosiderin. Small numbers of peripheral leukocytes, primarily neutrophils, will accompany hemorrhage, but the presence of neutrophils in numbers greater than their proportion in blood is supportive of inflammation. Neutrophilic inflammation may accompany tumors, most notably squamous cell carcinoma and large tumors with necrotic centers; however, inflammation can induce criteria of malignancy in nonneoplastic populations, especially fibroblasts and squamous cells, and biopsy may be required to confirm suspected neoplasia when inflammation is prominent. Some tumors are associated with infiltration of specific inflammatory cells (e.g., eosinophils in mast cell tumors).

• **FIGURE 7-3** Cells from a mass in the bladder obtained by traumatic catheterization. The cells are gray and have indistinct morphologic features, typical of necrotic cells.

• **FIGURE 7-4** Cells from a pulmonary carcinoma (**A**) and a transitional cell carcinoma (TCC) (**B**). Note that in both specimens, cells comprise a homogeneous population of epithelial cells. However, cells from the pulmonary carcinoma are monomorphic, whereas those from the TCC are pleomorphic.

For tumors that produce ground substance(s), such as sarcomas, or that elicit a scirrhous response, such as some carcinomas, extracellular matrix may be observed in cytologic specimens. Collagen and osteoid consist of collections of smooth or fibrillar magenta material, whereas chondroid matrix typically forms larger lakes of bright pink-to-purple material. Mucin may be secreted by a variety of tumors, including salivary, biliary, and intestinal carcinomas and synovial and myxomatous sarcomas. Mucin is pale blue to pink, and cells surrounded by mucin are often aligned in rows. Ultrasound gel may be a contaminant of slides prepared from ultrasound-guided aspirates if the needle is not cleaned prior to expelling cells onto the slide. Ultrasound gel appears as granular, bright magenta material when stained with cytologic stains and, if abundant, may impair cytologic examination.

Description of Neoplastic Populations

Determination of the number of cells exfoliated and the shape and arrangement of cells early in the cytologic evaluation aids in formulating an initial list of differential diagnoses, permitting placement of tumors in three broad categories: epithelial, mesenchymal, and discrete round cell tumors. Briefly, cells from epithelial tumors exfoliate well and are round, cuboidal, columnar, or polygonal cells arranged in cohesive sheets or clusters; cells from mesenchymal tumors exfoliate poorly and are spindle-shaped, stellate, or oval cells arranged individually or in noncohesive aggregates; and cells from discrete round cell tumors exfoliate well and are individualized round cells that are arranged in a monolayer. Cellular arrangements observed in cytologic specimens and their associated histologic correlates and tissue types have been described.³

Proper terminology should be used to succinctly describe cell populations and convey important information. The terms

• **FIGURE 7-5** Fine-needle aspirate of a mast cell tumor. Note the heterogeneous populations of cells, including mast cells, eosinophils (*thick arrow*), fibroblasts (*white arrow*), and lymphocytes. Extracellular matrix (*thin arrows*), likely collagen, is also present and stringy chromatin (*asterisks*) from broken nuclei is noted.

homogeneous and *heterogeneous* describe cell populations (Figures 7-4 and 7-5). Homogeneous denotes a population of one cell type (excluding erythrocytes and associated leukocytes), which is typical of most tumors. Heterogeneous refers to mixed populations of cells, which are commonly found in aspirates of inflammatory lesions; however, some neoplasms will contain heterogeneous populations of cells (e.g., mast cell tumors accompanied by eosinophils and fibroblasts [see Figure 7-5] and squamous cell carcinomas with associated neutrophilic inflammation [see later]). The terms

monomorphic and *pleomorphic* describe the morphologic appearance of cells within a single population. Monomorphic describes cells of a single lineage in which the cells have a uniform morphologic appearance (see Figure 7-4, A). Monomorphic features typically are associated with benign tumors, but a number of malignant tumors are cytologically monomorphic. In contrast, *pleomorphic* is used to describe cells of a single lineage that have variable morphologic features (see Figure 7-4, B). Pleomorphic features comprise a set of criteria of malignancy and suggest malignant behavior, but can be observed in nonneoplastic cells found in primary inflammatory lesions.

Criteria of malignancy are cellular features within a single population that suggest malignant behavior, with greater emphasis placed on nuclear criteria. The more criteria observed, the more likely the tumor is malignant. Cellular and cytoplasmic criteria of malignancy include variation in cell size (*anisocytosis*), abnormal cellular arrangement (3-dimensional [3D] clusters instead of a monolayer), cells that are smaller or larger than their normal counterpart, variable nuclear-to-cytoplasmic (N:C) ratios or N:C ratios that differ from what is expected for the cell type, intensely basophilic cytoplasm (*hyperchromasia*), abnormal vacuolation or granulation, and aberrant phagocytic activity. The nucleus is the most important component of the cell when determining the biologic behavior of a neoplasm. Nuclear criteria of malignancy include variation in nuclear size (*anisokaryosis*), unusual nuclear shape, multinuclearity, variation in nuclear size within the same multinucleated cell, nuclear fragments, multiple nucleoli that vary in size and shape within the same nucleus or among cells, increased mitoses, and nonsymmetric mitoses (Figure 7-6). When Papanicolaou stain is used, additional nuclear features such as irregular thickening of the nuclear membrane can be evaluated. Cellular gigantism (cell >10 times the diameter of an erythrocyte) and the presence of macronuclei (>5 times the diameter of an erythrocyte) or macronucleoli (larger than an erythrocyte) are particularly disturbing criteria of malignancy. In nonneoplastic cells the chromatin pattern is finely stippled in replicating or metabolically active cells and condensed in mature quiescent cells. Finely stippled chromatin is also common in rapidly proliferating neoplastic cells, and chromatin that is irregularly clumped or ropy is unusual and suggestive of a neoplastic process. Some nonneoplastic cells, including

mesothelial cells, fibroblasts, and squamous epithelial cells, may have criteria of malignancy when they are highly proliferative in the presence of inflammation. Conversely, some malignant tumors such as apocrine gland tumors of the anal sac have few criteria of malignancy.

Sending Cytologic Samples to a Diagnostic Laboratory

When using a referral diagnostic laboratory, two to four unstained smears should be sent. If a highly cellular smear has been stained and examined by the oncologist for confirmation of sample quality and the cellularity of the remaining unstained smears is in question, send the stained smear in addition to the unstained smears. Pack all slides in rigid slide containers to prevent breakage during shipment. For shipment by commercial mail services, place slide holders in a cardboard box with sufficient padding; padded envelopes are not recommended because these may not provide sufficient protection. Slides should not be refrigerated prior to or during shipment. Exposure to formalin or formalin fumes should be avoided during the preparation and shipment of cytologic specimens because this will permanently alter staining characteristics and render the sample nondiagnostic; biopsy specimens preserved in formalin should be sent separately from cytologic specimens, or each type of sample should be sealed in separate plastic bags. If cavity fluids or mucosal washes are submitted, include two freshly made unstained smears along with the fluid (in EDTA) or wash (sealed container). Plain tubes (red top) or sterile vials are required for specimens that may be cultured. For all submitted glass slides, indicate how the slides were prepared and whether a concentration method was used for cavity effusions.

Interpretation of Cytologic Specimens

The final interpretation of a cytologic specimen should be based not only on the cytologic findings but also on signalment, history, clinicopathologic findings, and imaging results. This information should be provided in a concise but complete summary to the individual evaluating the sample. When submitting samples to a cytopathologist, the exact location of the lesion should be clearly described because “thoracic mass” could indicate a mass located in the skin, subcutis, body wall, mediastinum, thoracic cavity, or pulmonary parenchyma; the differential diagnoses will be different for different locations. For clinicians who perform an initial evaluation of the cytologic specimen, observational and interpretative skills can be developed by comparing your findings with those described in the cytopathologist’s complete report and by considering the information obtained from other diagnostic tests.

Confidence in cytologic interpretation is based on the quality of the specimen, the completeness of the clinical information provided, and the experience of the cytopathologist. Terms that express the degree of certainty, such as “consistent with,” “diagnostic for,” “cannot rule out,” “probable,” and “possible,” may be used and interpreted differently by cytopathologists and clinicians, respectively.⁴ If the certainty of an interpretation or diagnosis is unclear, the clinician should consult the cytopathologist. Correlations between cytologic and histologic interpretations or diagnoses are highly variable, depending on tissue types, disease processes, and methods of collection and preparation.

• **FIGURE 7-6** Fine-needle aspirate of hemangiosarcoma with multiple criteria of malignancy. *Inset*, An atypical mitotic figure from a liposarcoma.

Epithelial, Mesenchymal, and Discrete Round Cell Tumors

The ability to identify specific tumor types by cytologic evaluation can aid in treatment planning and prognostication. Even if a specific diagnosis cannot be made, classification of the tumor as an epithelial, mesenchymal, or discrete round cell neoplasm can provide sufficient information to formulate a differential diagnosis and plan additional diagnostic procedures.

Tumors of Epithelial Tissues

Tumors derived from epithelial tissue comprise the largest category of neoplasms and include tumors of epithelial surfaces, such as the skin and respiratory, gastrointestinal, and urogenital tracts, as well as tumors of glands and organs. Given their diverse origin, the cytomorphologic appearance of these neoplasms can be highly variable; however, some features are shared by most epithelial tumors. Epithelial cells have intercellular junctions that connect the cells to each other and do not elaborate extracellular matrix. Therefore the cells exfoliate well, resulting in highly cellular specimens, and are arranged in cohesive sheets or clusters in cytologic smears (Figure 7-7). The cytoplasmic borders of individual cells typically are distinct, but this can vary in certain types of tumors. Poorly differentiated epithelial tumors have few or no identifying features and tend to be round cells with moderate-to-high N:C ratios and basophilic cytoplasm. In some cases, the cells no longer have intercellular junctions and appear as discrete round cells (Figure 7-8). Determining the tissue of origin in these cases is difficult, and histologic evaluation, with or without immunohistochemical analysis, is necessary to define the specific tumor type.

Tumors of Hair Follicles and Sebaceous Glands

Differentiating among adnexal tumors of skin by cytologic evaluation may be difficult when identifying features are absent or when multiple cell types are present. Many adnexal tumors have a large component of basilar cells that are small cuboidal or round cells with high N:C ratios and are arranged in tightly cohesive sheets or in palisading rows (see Figure 7-7). Nuclei are uniformly round with condensed to reticular chromatin, and nucleoli are indistinct

• **FIGURE 7-7** Fine-needle aspirate of a basal cell tumor (epithelioma). Note the monomorphic population of cohesive cells aligned in rows.

or appear as a small single nucleolus. The cytoplasm is lightly basophilic and may contain black melanin granules (Figure 7-9). Tumors of hair follicle origin and matrical cysts often have a central cystic space filled with mature squamous cells, keratin flakes, or keratin debris, and this material may be aspirated when the mass is sampled. Tumors with sebaceous differentiation contain clusters of large round cells filled with oily-appearing vacuoles that partially obscure the small central nucleus (Figure 7-10). Tumors of basal cell origin (cutaneous basilar epithelial neoplasms) include trichoblastoma, pilomatricoma, basal cell epithelioma, sebaceous epithelioma, and others, and histologic examination is usually required to identify the specific type. Fortunately, the majority of adnexal tumors are benign; malignant types can occur and typically have pleomorphic features that predict their biologic behavior.

Tumors of the Epidermis

Squamous cell carcinoma (SCC) is the most common malignancy of the epidermis; the tumor has varying degrees of differentiation, even within a single tumor, and the cytologic specimen may consist primarily of basilar cells, more mature keratinized cells, or both

• **FIGURE 7-8** Fine-needle aspirate of an anaplastic colonic carcinoma. The tumor cells have high N:C ratios and are sometimes individualized.

• **FIGURE 7-9** Fine-needle aspirate of a basal cell tumor in which the cells are heavily pigmented.

• **FIGURE 7-10** Fine-needle aspirate of a sebaceous adenoma.

• **FIGURE 7-11** Fine-needle aspirate of a squamous cell carcinoma (SCC). Note the marked anisocytosis and anisokaryosis, variable N:C ratios, perinuclear vacuolation, and angular cytoplasmic borders in some cells. *Inset*, A neutrophilic infiltrate often accompanies SCC.

(Figure 7-11). Pleomorphism can be marked, including moderate-to-marked anisocytosis and anisokaryosis, hyperchromasia, and marked nuclear atypia. Keratin does not stain with Romanowsky stains, and cytologic features suggestive of keratinization include individualization of cells, sharp angular cytoplasmic margins, and smooth and glassy turquoise cytoplasm. Cells that appear keratinized may have small condensed nuclei or absent nuclei, representing a normal maturational process, but may have a large intact nucleus with fine-to-reticular chromatin and multiple visible nuclei. An immature nucleus concurrent with mature cytoplasm signifies “asynchronous maturation.” Perinuclear vacuolation or magenta cytoplasmic inclusions (keratohyaline granules) may be observed in the more mature squamous cells. Keratinization within a tumor typically is accompanied by neutrophilic inflammation (Figure 7-11, *inset*). Differentiating between SCC and a primary inflammatory lesion with dysplastic squamous epithelium is a cytologic dilemma: in both cases the cells may have criteria of malignancy and asynchronous maturation. Location, appearance of the lesion,

• **FIGURE 7-12** Fine-needle aspirate of a mammary adenocarcinoma. *Inset*, Signet-ring cell.

and ultimately histologic examination aid in differentiating inflammatory and neoplastic lesions.

Tumors of Glands

Salivary Gland Tumors Salivary gland tumors may be neoplasms of ductular cells, secretory cells, or both. In ductular tumors, the cells resemble basilar epithelial cells. Pleomorphism typically is minimal even when these tumors are malignant, although mild-to-moderate anisokaryosis may be present and nucleoli may be prominent. Tumors of secretory origin often are more pleomorphic. The neoplastic cells are arranged in 3D clusters, sometimes resembling acini seen histologically, and have moderate and variable N:C ratios. The cytoplasm contains few-to-many secretory vacuoles of varying sizes. Cells with a single large vacuole that displaces the nucleus to an eccentric location may be noted and are referred to as *signet-ring cells*. Anisokaryosis and the presence of visible nucleoli of varying number, shape, and size are typical. Tumors may produce mucin, which appears as pale pink or blue material that aligns surrounding erythrocytes into streaming rows.

Mammary Gland Tumors Mammary gland tumors are classified histologically into benign and malignant tumors based on the type, arrangement, and invasiveness of neoplastic epithelium and on the presence or absence of neoplastic and nonneoplastic mesenchymal components. This classification system cannot be applied to cytologic specimens, nor can biologic behavior reliably be ascertained by cytology. Cytologic specimens from mammary masses may contain ductular cells, secretory cells, mesenchymal cells, or a combination of these. Cells from ductular or tubular mammary tumors resemble basilar epithelial cells with low-to-moderate N:C ratios and occasionally contain basophilic granular cytoplasmic inclusions. Pleomorphic features are mild-to-moderate, even when these tumors are malignant. Tumors of secretory origin have few-to-many criteria of malignancy, including moderate-to-marked anisocytosis and anisokaryosis, variably sized secretory vacuoles within the cytoplasm with some signet-ring formation, and nuclear criteria of malignancy (Figure 7-12). If present, the mesenchymal component may consist of mildly to moderately pleomorphic spindle-shaped cells with or without fibrillar magenta extracellular matrix. The spindle cells represent myoepithelial cells or fibroblasts and may be neoplastic or nonneoplastic. The background of many

mammary tumors contains lakes of blue secretory material, vacuolated macrophages containing a similar material, and low numbers of neutrophils. Although biologic behavior is difficult to determine cytologically, the greater the number of malignant criteria present within any of the cell types, the more likely the tumor is malignant. However, even tumors with mild pleomorphism may be malignant. Features that define inflammatory mammary carcinomas histologically, such as the presence of tumor emboli in lymphatic vessels, cannot be appreciated cytologically, and this diagnosis is suspected when epithelial cells have cytologic criteria of malignancy and when typical clinical signs such as erythema, swelling, and warmth are identified. Mammary hyperplasia cannot be differentiated cytologically from neoplastic proliferation of tubular cells in the absence of pleomorphic features, and knowing the stage of the reproductive cycle in intact females can be helpful.

Perianal Gland Tumors Perianal gland tumors, also called *circumanal* or *hepatoid tumors*, have a characteristic appearance and with experience can be differentiated from tumors of the apocrine gland of the anal sac. Cells are arranged in cohesive clusters and resemble hepatocytes, having uniformly low N:C ratios and abundant amphophilic granular cytoplasm with distinct margins (Figure 7-13). Nuclei are uniformly round and centrally located, with reticular chromatin and a single nucleolus. A population of reserve cells with high N:C ratios may be found at the periphery of the clusters. Occasionally, a perianal gland tumor may consist exclusively of reserve cells and is termed a *hepatoid gland epithelioma*. Although the majority of these tumors are benign, pleomorphic features are not prominent even in the malignant tumors.

Tumors of the Apocrine Gland of the Anal Sac Tumors of the apocrine gland of the anal sac and perianal gland tumors are the most common tumors in the perianal region and with experience can be reliably differentiated cytologically. Although not of neuroendocrine origin, apocrine adenocarcinomas resemble other tumors with a neuroendocrine appearance (see later). Even though pleomorphism is minimal, these tumors usually are malignant and frequently metastasize to the medial iliac lymph nodes.

Tumors of the Prostate Gland Tumors of the prostate gland have features similar to other glandular tumors. Sometimes the cells

contain circular granular eosinophilic inclusions (see section on transitional cell carcinomas). Primary prostatic carcinomas cannot be easily differentiated cytologically from transitional cell carcinomas that arise within the prostate.

Tumors of the Urogenital System

Transitional Cell Carcinoma TCC may be located in the bladder, urethra, ureter, prostate, or vagina. Needle aspiration of tumor tissue is avoided to prevent seeding of tumor cells along the needle tract. Traumatic catheterization of the bladder and prostatic washes are the preferred means of obtaining cytologic specimens. Cells from a TCC are individualized round cells with some cells forming cohesive sheets and clusters. Criteria of malignancy typically are prominent and include marked anisocytosis and anisokaryosis, variation in N:C ratios, marked basophilia, coarse chromatin patterns, and variation in nucleolar size, shape, and number (see Figure 7-4, B). Multinuclearity is common. Large circular eosinophilic or magenta granular inclusions, representing accumulations of glycosaminoglycans, occasionally are found in the cytoplasm, but this feature is not pathognomonic for TCC (Figure 7-14). Moderately pleomorphic TCC must be differentiated from hyperplastic transitional epithelium that occurs secondary to inflammatory processes in the bladder; this can be challenging because inflammation sometimes is present in TCCs. Transitional cell polyps are sampled infrequently and typically consist of sheets of epithelial cells with a uniform or mildly pleomorphic appearance.

Tumors of Organs

Hepatocellular Tumors In the liver, primary tumors may arise from hepatocytes or from biliary epithelium. Hepatic carcinoids may be considered as primarily hepatic in origin (see neuroendocrine tumors below). Hepatocellular tumors include benign adenomas, or hepatomas, and carcinomas. Unfortunately, hepatic nodules and masses, whether areas of hyperplasia, benign tumors, or malignant tumors, may be indistinguishable cytologically because all of these entities may consist of well-differentiated hepatocytes with some atypia. Histologic examination is recommended for a definitive diagnosis. Features of hepatocellular atypia that should raise concern for a neoplastic process include anisocytosis and

• **FIGURE 7-13** Fine-needle aspirate of a perianal adenoma with characteristic hepatoid cells (*left*) and reserve cells (*right*).

• **FIGURE 7-14** Cells from a transitional cell carcinoma (TCC) of the prostate. The arrow indicates a cytoplasmic eosinophilic inclusion that represents an accumulation of glycosaminoglycans.

anisokaryosis, variations in N:C ratios, decreased volume and increased basophilia of the cytoplasm, and the presence of more than two nuclei per cell and multiple visible nucleoli. In addition, the cells may appear disorganized and form 3D clusters rather than appearing in a uniform monolayer. The presence of capillaries coursing through the hepatocellular sheets is suggestive of hepatocellular carcinoma.⁵ In our experience, the absence of cytoplasmic lipofuscin granules suggests formation of new cells and thus a benign or malignant neoplasm. However, all these features may be observed in hyperplastic or regenerative hepatic nodules. Undifferentiated hepatocellular carcinomas may have few cytologic features that identify them as hepatocellular in origin and may resemble other undifferentiated carcinomas that have metastasized to the liver.

Biliary Tumors Biliary tumors include both benign biliary cystadenomas and carcinomas. Biliary cystic tumors consist of cystic spaces lined by attenuated biliary epithelium that is indistinguishable from normal biliary epithelium. Cytologic specimens consist of small-to-large sheets of monomorphic cuboidal epithelial cells, arranged in a monolayer, with moderately high N:C ratios, basophilic cytoplasm, and uniform central round nuclei. The cytoplasm may contain secretory vacuoles. Biliary carcinomas also may have a monomorphic appearance or may be pleomorphic with polygonal cells arranged in sheets and 3D clusters; in this case, the cells may have variable N:C ratios, deeply basophilic cytoplasm, and central-to-eccentric oval nuclei. Secretory vacuoles may be numerous, single, or absent. Nuclear and nucleolar pleomorphism is prominent. A mucinous background that aligns erythrocytes in streaming rows may be associated with the tumor cells and is suggestive that the cells are of biliary origin.

Tumors of the Exocrine Pancreas Tumors of the exocrine pancreas may arise from ductular or acinar epithelium. Cells from ductular carcinomas resemble biliary carcinomas and consist of monomorphic sheets of cuboidal cells with high N:C ratios, basophilic cytoplasm, and central round nuclei. Nuclear pleomorphism is typically mild, but criteria of malignancy may be present. Exocrine pancreatic adenocarcinoma typically has markedly pleomorphic features. The distinctive cytoplasm of exocrine pancreas, consisting of intensely basophilic cytoplasm with numerous small eosinophilic globules, may be observed in a proportion of cells supporting pancreatic origin.

Renal Carcinomas Renal carcinomas have few defining cytologic characteristics. Variably pleomorphic cuboidal epithelial cells may be arranged in loose sheets, clusters, tubules, and acini. The cells have moderate-to-high N:C ratios and may contain a few discrete cytoplasmic vacuoles. Nuclei are generally round and centrally or basally located, with variably distinct nucleoli. Cytologically, renal carcinomas may be mistaken for neuroendocrine tumors.

Pulmonary Carcinomas or Adenocarcinomas Pulmonary carcinomas or adenocarcinomas may occur in animals with respiratory signs or may be found incidentally when thoracic radiographs are taken for another reason. Cats with primary pulmonary tumors may be presented for lameness resulting from metastasis to the digits. Primary lung tumors are often minimally pleomorphic (see Figure 7-4, A), although moderately to markedly pleomorphic features may be observed. Cells are cuboidal to polygonal, are arranged in cohesive sheets and clusters, and have

• **FIGURE 7-15** Fine-needle aspirate of a pulmonary carcinoma. Note the monomorphic population with numerous small cytoplasmic vacuoles.

moderate-to-high N:C ratios. Within a single tumor, some cells may contain many discrete vacuoles (Figure 7-15). Apical cilia typically are lacking. If the tumor is large and has outgrown its blood supply, there may be large amounts of necrotic cellular debris accompanied by neutrophilic inflammation. Aspirates from the center of necrotic lesions may not contain intact epithelial cells, and repeat aspiration from the periphery of the lesion is recommended. When numerous large sheets and clusters of epithelial cells are aspirated from a pulmonary mass, a diagnosis of neoplasia is straightforward. However, when only a few small sheets of deeply basophilic epithelium are found, it is difficult to differentiate a pulmonary neoplasm from consolidated hyperplastic respiratory epithelium resulting from a primary inflammatory process.

Thymoma and Thymic Carcinoma Thymoma and thymic carcinoma result from neoplastic transformation of the supporting epithelium in the thymus. However, neoplastic epithelial cells often comprise only a small proportion of cells aspirated from a thymoma. The majority of cells are small lymphocytes, and in dogs, well-differentiated mast cells often are present (Figure 7-16). Epithelial cells, when observed, are polyhedral cells with abundant cytoplasm and central oval nuclei and are arranged individually or in small sheets. Criteria of malignancy among the epithelial cells are minimal in thymomas. In thymic carcinomas, the epithelial component is much more prominent as are criteria of malignancy.

Nasal Carcinomas and Adenocarcinomas Nasal carcinomas and adenocarcinomas, like primary lung tumors, typically are only mildly to moderately pleomorphic. Cytoplasmic vacuolation also may vary, with the majority of cells having few-to-no secretory vacuoles. Apical cilia are typically lacking. Small numbers of highly pleomorphic epithelial cells arranged in sheets or clusters accompanied by marked neutrophilic inflammation likely represent hyperplastic respiratory epithelium and not a tumor. Biopsy is often required to make a diagnosis of neoplasia, especially when cytoplasmic features are not definitive and when inflammation is concurrently present.

Gastrointestinal Tumors Gastrointestinal tumors include adenocarcinomas of the stomach, small intestine, and large

• **FIGURE 7-16** Fine-needle aspirate of a thymoma in a dog. The majority of cells are small lymphocytes. A mast cell and an eosinophil also are present.

• **FIGURE 7-17** Fine-needle aspirate of a thyroid carcinoma in a dog. Note the loosely cohesive sheets of cells in a background of abundant blood. *Inset*, Some of the tumor cells contain blue-black granules thought to be tyrosine granules.

intestine, and these tumors have similar cytologic features. Aspirates of these tumors typically consist of highly pleomorphic epithelial cells arranged in sheets and clusters. The cells typically contain few-to-many secretory vacuoles. The background may contain abundant mucus produced by the tumor cells or pink fibrillar collagen representing a scirrhous response secondary to the tumor.

Endocrine and Neuroendocrine Tumors Endocrine and neuroendocrine tumors comprise a diverse collection of tumor types. If the primary location of the tumor is not known, specific tumor type may be impossible to determine owing to the cytologic similarity among these tumors. In general, aspirates of endocrine and neuroendocrine tumors are highly cellular and consist of loosely cohesive sheets and clusters of epithelial cells with ill-defined intercellular junctions and cytoplasmic margins (Figure 7-17). The cells are fragile, and numerous free nuclei from ruptured cells are scattered in the background. Nuclei of intact cells may be

• **FIGURE 7-18** Fine-needle aspirate of an anal sac apocrine adenocarcinoma. Note the rosette of tumor cells (*right*).

arranged in a rosette (Figure 7-18), suggestive of acinar formation. Within intact cells, nuclei are round and centrally located with reticular chromatin. Nucleoli are often indistinct, but one to two nucleoli may be observed. The cytoplasm may contain a few clear, distinct vacuoles. There are usually few criteria of malignancy, even in carcinomas, and anisocytosis and anisokaryosis are mild to moderate with large nuclei observed occasionally. Mitotic figures may be present. Some tumors of endocrine origin are biologically active, and tumor type may be identified based on clinical presentation and laboratory findings.

Thyroid Carcinomas Thyroid carcinomas in dogs are highly vascularized, and aspirates may yield abundant blood as well as some hemosiderophages. In addition to displaying general features of endocrine tissue, cells from thyroid tumors may contain blue-black cytoplasmic granules (see Figure 7-17, *inset*), believed to represent tyrosine granules, and amorphous pink material that may represent colloid. In the absence of these features, thyroid tumors cannot be differentiated cytologically from C-cell tumors and parathyroid tumors that occur in the same location. Most thyroid tumors in dogs are nonfunctional carcinomas, whereas in cats thyroidal masses or nodules are functional adenomas or adenomatous hyperplasia. Ectopic thyroid tissue may undergo transformation and be found in unexpected locations, such as the thoracic inlet and mediastinum.

Parathyroid Tumors Parathyroid tumors are typically adenomas but are often functional and result in hypercalcemia through the systemic actions of parathyroid hormone. Parathyroid tumors have the typical features of endocrine tissue. Occasionally, eosinophilic spiculate inclusions are found in the cytoplasm.⁶

Chemodectomas Chemodectomas are neuroendocrine tumors of chemoreceptor cells found in the carotid or aortic bodies located in the submandibular region and at the base of the heart, respectively. They do not have cytologic features that distinguish them from other endocrine tumors, such as ectopic thyroid tumors.

Adrenal Cortical and Medullary Tumors Adrenal cortical and medullary tumors are cytologically similar and have a typical neuroendocrine appearance. Adrenal cortical tumors of the zona

glomerulosa and fasciculata often contain few-to-many discrete clear vacuoles. Pleomorphism is minimal and differentiation between adrenal adenoma and adenocarcinoma is not always possible cytologically. Pheochromocytomas of the adrenal medulla lack distinct cytoplasmic vacuoles and will stain positively with silver stains and express synaptophysin and chromogranin A.⁷

Insulinomas Insulinomas or beta-cell tumors have typical neuroendocrine features without additional defining characteristics except for the clinical presentation of hypoglycemia. Insulinomas may metastasize to liver, regional lymph nodes, mesentery, and omentum.

Carcinoids of Lung, Liver, Intestine, and Colon Carcinoids of lung, liver, intestine, and colon are rare neuroendocrine tumors. They must be distinguished from other neuroendocrine tumors that have metastasized based on history, clinical presentation, presence of other primary tumors, and histologic examination.

Tumors of Mesenchymal Tissues

Tumors derived from mesenchymal or connective tissues can be diverse in their cytologic appearances, but they have some common features. Cells are often embedded in extracellular matrix produced by tumor cells and exfoliate poorly. Thus cytologic samples tend to have low cellularity, although exceptions occur. Cells do not have intercellular junctions and are individually arranged (Figure 7-19); however, in cases in which cellularity is high or when scraping and imprint methods are used to prepare slides, cells may be found in dense noncohesive aggregates that are disorganized. Cell shape is typically oval, spindle-shaped, or stellate, and the tumors are often grouped according to the most common shape. Cytoplasmic margins are characteristically indistinct, and nuclei are generally round, oval, or elongate. Some mesenchymal tumors lack further distinguishing features, and knowledge of the location and other clinical information is necessary to formulate a list of differential diagnoses in anticipation of the definitive diagnosis based on histologic and immunochemical staining.

Reactive or hyperplastic mesenchymal cells that accompany inflammatory and neoplastic lesions present a diagnostic dilemma

because these cells may have criteria of malignancy (Figure 7-20). When a mass is composed of heterogeneous cell populations, caution is advised in making a definitive cytologic diagnosis of a mesenchymal tumor; this is especially true when concurrent neutrophilic inflammation is present. Additional diagnostic measures should be taken to confirm the presence of a neoplasm prior to making major treatment decisions.

Mesenchymal Tumors Composed of Spindle-Shaped and Stellate Cells

Tumors of Fibroblasts Tumors of fibroblasts may have morphologic features of well-differentiated fibroblasts, including monomorphic elongate spindle-shaped or fusiform cells with moderate N:C ratios, basophilic cytoplasm, and central oval nuclei with one to several small nucleoli. However, a population of well-differentiated fibroblasts may represent reactive fibroplasia, as is found in scars or granulation tissue (see Figure 7-20), a fibroma, or a well-differentiated fibrosarcoma. Unfortunately, there are no clear cytomorphologic characteristics that can reliably differentiate among these entities. The presence of accompanying inflammation warrants an interpretation of reactive fibroblasts even when pleomorphic features are present. Epithelioid macrophages found in pyogranulomatous lesions are frequently mistaken for neoplastic fibroblasts by inexperienced clinicians. High cellularity, marked pleomorphism, especially with respect to the nucleus, and absence of inflammation along with a supportive clinical picture lend credible evidence for a cytologic diagnosis of fibrosarcoma. Malignant fibroblasts may vary in shape and N:C ratio and may have numerous nuclear criteria of malignancy. Anisocytosis and anisokaryosis may be moderate to marked (Figure 7-21). Neoplastic fibroblasts may contain pink cytoplasmic granules. Accompanying collagen, consisting of fibrillar bands of pink extracellular material, may support the origin of the cells as fibroblasts; however, similar matrix can be seen with a variety of other mesenchymal neoplasms. Cells from myxosarcoma resemble cells of fibrosarcoma, but are embedded in a lightly eosinophilic matrix that aligns the cells in streaming rows (Figure 7-22; see Figure 7-19). Feline vaccine-associated sarcomas (VAS) are highly pleomorphic mesenchymal tumors, primarily of fibroblastic origin, that occur at sites of previous injections, most often of vaccines containing adjuvant. In

• **FIGURE 7-19** Fine-needle aspirate of a myxosarcoma in a dog. Note the individualized spindle-shaped cells.

• **FIGURE 7-20** Imprint of granulation tissue composed of pleomorphic fibroblasts.

• **FIGURE 7-21** Fine-needle aspirate of a fibrosarcoma in a dog. Note the cellular pleomorphism and pink background, possibly glycosaminoglycans.

• **FIGURE 7-23** Fine-needle aspirate of a vaccine-associated fibrosarcoma in a cat. Note the extreme atypia in the multinucleated tumor cell.

• **FIGURE 7-22** Fine-needle aspirate of a myxosarcoma (same tumor as Figure 7-19). Note the myxomatous background in which tumor cells and erythrocytes are streaming.

• **FIGURE 7-24** Fine-needle aspirate of a perivascular wall tumor (hemangiopericytoma). Note how well the cells exfoliated. *Upper left inset*, Vessels are often associated with the tumor cells. *Lower right inset*, Cells are spindle-shaped, stellate, or oval.

addition to containing pleomorphic mesenchymal cells, aspirates of feline VAS may contain large multinucleated tumor cells (Figure 7-23) and moderate numbers of small lymphocytes.

Tumors of the Perivascular Wall or Nerve Sheath Tumors of the perivascular wall or nerve sheath, such as hemangiopericytoma, peripheral nerve sheath tumor (PNST), and schwannoma, often exfoliate well; samples are highly cellular with cells arranged both individually and in dense aggregates (Figure 7-24). Cells are usually spindle-shaped and plump with wispy cytoplasmic extensions; oval-to-stellate forms also are found. The lightly basophilic cytoplasm frequently contains a few small clear round vacuoles. Nuclei are oval and centrally located with finely stippled chromatin and often one to three small nucleoli. Binuclearity is observed in a small proportion of cells. Anisocytosis and anisokaryosis are mild to moderate. Linear capillaries may be embedded within aggregates of tumor cells in aspirates of hemangiopericytomas.

Tumors of Vascular Endothelium Tumors of vascular endothelium include hemangioma and hemangiosarcoma. Aspirates of hemangioma may contain a uniform population of long thin spindle-shaped cells in a background of abundant blood; however, cellularity is rarely sufficient for a definitive diagnosis of this benign vascular tumor. Aspiration of suspected hemangiosarcoma is approached cautiously because of the potential consequence of hemorrhage, but cellular yields may be sufficient to reach a tentative diagnosis. The neoplastic cells are often markedly pleomorphic and consist of spindle-shaped, stellate, and oval cells that have deeply basophilic cytoplasm containing punctate vacuoles (see Figure 7-6).⁸ Large, irregular, or indented oval nuclei typically have coarse chromatin and multiple prominent nucleoli that vary in shape and size. Multinucleated cells are found occasionally. Anisocytosis and anisokaryosis are often marked. A small amount of pink extracellular matrix may be associated with the neoplastic cells. Erythroid precursors and macrophages containing erythrocytes or

hemosiderin may accompany hemangiosarcoma, especially within the spleen. Important markers of vascular differentiation are CD31 and von Willebrand factor. Hemangiosarcomas primarily occur in the spleen and right atrium with metastasis to liver and lung, but also occur in the dermis and subcutis. Tumor cells rarely exfoliate into hemorrhagic effusions.

Tumors of Adipose Tissue Tumors of adipose tissue comprise lipomas and liposarcomas. Lipomas are common tumors of dogs, and although the gross appearance and texture of these tumors is characteristic, they often are aspirated in order to rule out other types of tumors that require more immediate attention. Aspirates of lipomas consist of abundant lipid that often dissolves during fixation in methanol-based fixatives, leaving an acellular smear. Adipose tissue that adheres throughout the staining procedure consists of clusters of large round cells with a small nucleus peripheralized by a single clear lipid vacuole (Figure 7-25). Supporting stromal strands and capillary vessels are sometimes visible within the cluster of adipocytes, and free fat may be present. Normal subcutaneous adipose tissue cannot be differentiated from a lipoma or infiltrating lipoma cytologically; therefore caution is recommended when making a conclusive cytologic diagnosis of lipoma if the gross appearance or texture of the mass is not typical. Liposarcomas are uncommon and can adopt a variety of cytologic appearances. Cells may be spindle-shaped, stellate, or round with variable N:C ratios. Clear lipid vacuoles of varying sizes are present within a basophilic or amphophilic cytoplasm (Figure 7-26). Nuclei are round to oval and often display criteria of malignancy. Confirming the presence of lipid using Oil Red O stain is best accomplished on unfixed smears. With inflammation of adipose tissue (panniculitis or stetititis), the sample often contains moderately pleomorphic fibroblasts and histiocytes that contain lipid or lipid-like vacuoles; these cells are easily mistaken for a neoplastic population. The presence of even low numbers of neutrophils within these lesions favors a conservative interpretation, and biopsy should be pursued for definitive diagnosis.

Mesenchymal Tumors Composed of Thin Elongate Cells

Tumors of Smooth Muscle and Stroma Tumors of smooth muscle and stroma, such as leiomyoma, leiomyosarcoma, and gastrointestinal stromal tumor (GIST), have a similar cytologic appearance. Aspirates of these tumors, whether benign or malignant, often

• **FIGURE 7-25** Fine-needle aspirate of well-differentiated adipocytes from a lipoma.

are highly cellular and consist of long thin mesenchymal cells arranged in aggregates and linear bundles. Nuclei are often elongate or “cigar-shaped” (Figure 7-27). Pleomorphism is typically mild. The most common sites for these tumors are the gastrointestinal tract and female reproductive tract, especially the uterus and vagina. Immunohistochemical detection of smooth muscle actin or c-kit expression in smooth muscle tumors and GIST, respectively, is required to distinguish these tumors.

Tumors of Striated Muscle Tumors of striated muscle, rhabdomyoma and rhabdomyosarcoma, are uncommon and can have a variety of cytomorphologic appearances. Rhabdomyomas occurring in the tongue and pharynx may present cytologically as a “granular cell tumor” composed of individual round or polygonal cells containing numerous fine pink cytoplasmic granules and a central round nucleus. Electron microscopic examination reveals the pink granules to be numerous mitochondria. Rhabdomyosarcomas typically comprise individualized pleomorphic

• **FIGURE 7-26** Fine-needle aspirate of a liposarcoma in a dog. Note that the polygonal cells contain lipid vacuoles. *Inset*, A large lipid vacuole in a tumor cell.

• **FIGURE 7-27** Fine-needle aspirate of a gastrointestinal stromal tumor (GIST). Many cells are disrupted, but elongated (cigar-shaped) nuclei are visible.

spindle-shaped cells with low numbers of elongate strap cells that may or may not demonstrate cross-striations within the cytoplasm. Strap cells characteristically have several round-to-oval nuclei arranged in a linear row. Normal muscle fibers are bright blue, with prominent cross-striations when viewed at high magnification, and have randomly distributed pale oval nuclei.

Mesenchymal Tumors Composed of Round or Oval Cells

Tumors of Bone Origin Tumors of bone origin include osteosarcoma, osteoma, multilobular tumor of bone, and giant cell tumor of bone. Osteosarcoma is the most common tumor of bone in dogs and results in a mixed osteolytic and osteoproliferative lesion radiographically. Aspirates of osteosarcoma may be highly or poorly cellular, depending on the collection technique and the nature of the lesion. Cytologic features that support osteoblasts as the cells of origin include oval cells with indistinct margins, basophilic cytoplasm containing a distinct paranuclear clearing, and eccentric nuclei with criteria of malignancy (Figure 7-28). The cytoplasm occasionally contains fine-to-coarse magenta granules. N:C ratios are moderate to high, and anisocytosis is moderate to occasionally marked. Often, bright magenta extracellular matrix or osteoid is found. Large multinucleated osteoclasts are typically scattered among the neoplastic osteoblasts. Multilobular tumor of bone and giant cell tumor of bone are tumors of osteoblasts and osteoclasts, respectively, that have characteristic locations or radiographic appearances. The cytologic appearance of plasma cell tumor and osteosarcoma may overlap because both contain cells with eccentric nuclei and paranuclear clearing; for inexperienced clinicians, this may constitute a diagnostic dilemma in dogs, and less frequently in cats, that have osteolytic lesions. Clinical presentation and laboratory abnormalities may be useful in distinguishing these malignancies. Caution is recommended when making a cytologic diagnosis of osteosarcoma at the site of a pathologic fracture as hyperplastic and reactive osteoblasts may have a degree of pleomorphism that can be mistaken for a well-differentiated neoplasm.

• **FIGURE 7-28** Fine-needle aspirate of a proliferative and lytic lesion in bone. The diagnosis was osteosarcoma. The pleomorphic cells tend to be round or oval with eccentric nuclei and sometimes paranuclear clear zones. *Inset*, A multinucleated tumor cell contains prominent pink granules.

Tumors of Chondrocytes Tumors of chondrocytes are less common than osteosarcoma and may arise in any location where cartilage occurs, including epiphyseal bone, nasal cavity, and trachea. Although the amount of matrix present in any given tumor can vary, the most characteristic cytologic finding in aspirates of chondrosarcoma is the large amount of purple extracellular matrix that envelops and often obscures the neoplastic chondroblasts (Figure 7-29). Neoplastic chondroblasts are round with moderate-to-high N:C ratios but may be spindle-shaped or stellate. A few cytoplasmic vacuoles or magenta granules are common, and nuclei are round with finely stippled chromatin and variably prominent nucleoli.

Tumors of Synovial Cells Tumors of synovial cells or synovial cell sarcomas are periarticular tumors. The cells are arranged individually or in noncohesive aggregates and are round to spindle-shaped with moderate N:C ratios. Pleomorphism can vary from mild to marked, including marked anisocytosis and anisokaryosis and nuclear criteria of malignancy. For highly pleomorphic synovial cell sarcomas, immunohistochemical staining may be necessary to distinguish them from periarticular histiocytic sarcomas.

Tumors of Melanocytes

In malignant melanoma, the cells can adopt the appearance of epithelial (sheets of cohesive cells), mesenchymal (individualized oval or spindle-shaped cells), or discrete round cell tumors. Individual melanoblasts are round, oval, or spindle-shaped cells with moderately high N:C ratios, lightly basophilic cytoplasm, and round or oval nuclei with fine chromatin and distinct nucleoli. Criteria of malignancy consist primarily of anisokaryosis and nucleolar pleomorphism. Melanized tumors do not present a diagnostic challenge, and fine black melanin granules may be so numerous that they obscure all cellular detail. Cells with varying degrees of melanization are typically found within the same tumor, and melanin granules may be sparse in some cells (Figure 7-30). Amelanotic tumors present a greater diagnostic challenge. Usually, a faint scattering of fine gray-black melanin granules are found in a few cells to support a diagnosis, but cells may be completely devoid of pigmentation (Figure 7-31). In these circumstances, moderately

• **FIGURE 7-29** Fine-needle aspirate of a chondrosarcoma with pleomorphic tumor cells and abundant magenta matrix that sometimes surrounds the tumor cells (*inset*).

• **FIGURE 7-30** Fine-needle aspirate of a melanoma in a dog. Note the fine melanin granules in the tumor cells and in the background.

• **FIGURE 7-31** Fine-needle aspirate of a melanoma in which melanin granules are not visible (amelanotic melanoma).

pleomorphic tumor cells aspirated from masses on the digits or in the oral cavity should alert the clinician to the possibility of this highly malignant tumor. Because melanocytes are of neuroectodermal origin, the cells may express certain neural markers, such as S-100 and neuron-specific enolase, in addition to vimentin and often Melan A.

An additional cytologic challenge is the identification of metastatic lesions within lymph nodes. Most lymph nodes draining pigmented melanomas contain melanophages, which are macrophages containing abundant melanin; in the authors' experience, this is especially true following surgical removal or biopsy of the primary mass. These melanophages may be mistaken for metastatic cells, but they differ from neoplastic melanoblasts as melanophages typically contain coarse collections of melanin within phagolysosomes rather than the fine granulation typically found within melanoblasts.

Most dermal tumors of melanocytic origin are benign and are termed *melanocytomas*. They consist of polygonal or spindle-shaped cells containing black cytoplasmic granules. Other dermal tumors containing melanin pigment, such as basal cell tumor

(epithelioma), must be differentiated from melanocytomas. These typically are of epithelial origin and should be distinguished by their cellular arrangement in cohesive sheets (see [Figure 7-9](#)).

Mesenchymal Tumors Composed of Cells Arranged in Dense Aggregates

Cells aspirated from some mesenchymal tumors, including rhabdomyosarcoma, perivascular wall tumor, PNST, amelanotic melanoma, and the epithelioid form of hemangiosarcoma, form dense aggregates and clusters that are more characteristic of epithelial cells. Careful examination typically reveals some spindle-shaped cells with indistinct margins and spaces between the closely packed cells indicating the lack of intercellular junctions. Slide preparation by imprinting and scraping also may yield clusters and sheets of mesenchymal cells that mimic epithelial populations.

Mesenchymal Tumors with Frequent Multinucleated Cells

Although any neoplasm can have a few multinucleated cells, multinuclearity is especially common in certain sarcomas. These include histiocytic sarcoma, feline VAS, malignant fibrous histiocytosis, and rhabdomyosarcoma, in which the multinucleated cells are part of the tumor population. In osteosarcoma, multinucleated osteoclasts are often present and are not part of the neoplastic population of cells.

Discrete Round Cell Tumors

The majority of discrete round cell tumors are of hematopoietic (and mesenchymal) origin, including neoplasms of mast cells, plasma cells, lymphocytes, and histiocytes. Transmissible venereal tumors (TVTs) are also included in this category, and there are a variety of epithelial and mesenchymal tumors that sometimes appear as round cell tumors. These tumors share certain cytomorphic features. Cells exfoliate easily leading to highly cellular specimens in which the cells are individualized in noncohesive monolayers. As the moniker indicates, the cells are round and have distinct cytoplasmic margins and round nuclei, although nuclear shape may vary in pleomorphic forms of these tumors.

Mast Cell Tumors

Mast cell tumors consist of cells with numerous purple cytoplasmic granules that fill the cytoplasm and often obscure the nucleus (see [Figures 7-2 and 7-5](#)). In cats, granules are finer than they are in canine mast cells. Even in poorly granulated mast cell tumors, there often are enough granules in some cells to suggest that they are mast cells. One notable exception is when the granules fail to take up stain when one of the aqueous quick stains is used, so clinicians using these stains should be alert to this artifact (see [Figure 7-2](#)). The nucleus is generally centrally located, but may be eccentric. Criteria of malignancy are observed infrequently and may include anisocytosis, anisokaryosis, binuclearity, multinuclearity, multiple visible nucleoli, and frequent mitotic figures. Marked pleomorphism is uncommon and when present suggests a higher grade tumor; however, at present grading is based on histologic findings. Markedly pleomorphic mast cells may have sparse or absent granulation, marked variation in cell and nuclear size, and lobulated or ameboid nuclei. In dogs, aspirates of mast cell tumors often contain numerous eosinophils along with a small proportion of reactive fibroblasts and thick bands of collagen (see [Figure 7-5](#)).

Determining the presence of metastasis in tissues, including lymph node, liver, and spleen, that have resident mast cells may be difficult. Additional features that support metastatic disease include

the presence of large numbers of mast cells suggestive of tissue effacement, mast cells with pleomorphic features, and mast cells arranged in groups instead of singly. If cytologic evaluation cannot distinguish between resident mast cells and metastasis, a biopsy should be evaluated.

Other neoplasms in which the cells contain cytoplasmic granules may be mistaken for mast cell tumors and include granulated T-cell lymphoma, natural killer (NK) cell lymphoma, and granular cell tumors. When cells from mast cell tumors are agranular or when the granules fail to stain with aqueous stains, the tumor may be mistaken for plasmacytoma, histiocytoma, or atypical lymphoma. Reactive nonneoplastic mast cells may be found in increased numbers at sites of fibrosis because of the role mast cells play in wound healing.

Plasma Cell Tumors

Plasma cell tumors composed of well-differentiated plasma cells are easily recognized owing to the characteristic features of plasma cells—abundant royal blue cytoplasm, paranuclear clear zone (Golgi apparatus), eccentric round nucleus, and clumped chromatin. Multinuclearity is common in plasmacytomas, and in more pleomorphic forms of this tumor the nuclei may be multilobulated (Figure 7-32). Neoplastic plasma cells may appear immature and resemble large lymphocytes with higher N:C ratios and finer chromatin. Sometimes the cells contain Russell bodies, collections of immunoglobulin within the endoplasmic reticulum, and are termed *Mott cells*. Plasma cell tumors may occur in the skin, oral mucosa, bone marrow, liver, and spleen, and the specific diagnostic criteria for plasma cell myeloma, extramedullary plasma cell myeloma, and plasmacytoma are presented in Chapter 32, Section D. Reactive plasma cell proliferations consist of a mixture of inflammatory cells and are rarely mistaken for a neoplastic process in a cutaneous mass; however, when plasmacytosis is identified in bone marrow, reactive and neoplastic conditions must be distinguished.

Lymphoma

Lymphoma comprises many variants, and entire chapters are written on their cytologic features. Definitive diagnosis of lymphoma based on examination of cytologic specimens is often possible; however, some types of lymphoma or lymphoma in certain

tissues may be difficult to diagnose cytologically. As with many discrete round cell neoplasms, it is the homogeneity of the population, rather than the morphologic features, that suggest a neoplastic process. In lymphoid organs or other tissues in which there is a reactive or polyclonal infiltrate of lymphocytes, small lymphocytes should predominate and comprise more than 50% of the lymphoid cells, even as the proportion of large and intermediate lymphocytes increases. Plasma cells and other inflammatory cells also may be found in these reactive lesions. As the proportion of intermediate and large lymphocytes approaches or exceeds 50%, it becomes more difficult to differentiate between a reactive and neoplastic process; this is especially true for the spleen and certain lymph nodes, such as mandibular and mesenteric nodes, that are continuously exposed to antigen. Because of this, sampling of other nodes or tissues is preferred. In addition, cats can mount strong lymphocytic responses that can cytologically resemble lymphoma. In contrast, there are certain types of lymphoma, such as T-cell rich B-cell lymphoma and Hodgkin's-like lymphoma, that contain a mixture of clonal (neoplastic) and polyclonal (nonneoplastic) populations of lymphocytes. When a diagnosis of lymphoma is not obvious from the cytologic specimen, additional procedures should be performed, including biopsy with histologic evaluation, immunophenotyping, assessment of clonality, or a combination of these (see Chapter 32, Sections A and B).

Lymphoma can be diagnosed cytologically when large or intermediate lymphocytes comprise the majority of the nodal population. Large and intermediate lymphocytes are defined as those larger than or the same size as a neutrophil, respectively, or that are greater than two times or one-and-a-half to two times the diameter of an erythrocyte, respectively. Cytologic types include immunoblastic or centroblastic types, composed of large cells with visible nucleoli and deeply basophilic cytoplasm (see Figure 7-1, A), and types composed of medium-sized cells often having indistinct nucleoli (Figure 7-33). Mitotic figures and tingible-body macrophages, which are macrophages containing nuclear debris from tumor cells, may be increased, but this is not a defining characteristic. Cytologic diagnosis of small cell lymphoma is more challenging, especially in tissues such as lymph node and spleen with a resident population of small lymphocytes or in tissues such as

• **FIGURE 7-32** Fine-needle aspirate of a plasmacytoma. Many cells have the characteristic appearance of plasma cells. Multinuclearity is a common feature of this tumor.

• **FIGURE 7-33** Fine-needle aspirate of a lymph node from a dog with T-cell lymphoma. Note that most of the cells are about two times the diameter of an erythrocyte and that nucleoli are indistinct in many cells.

liver and small intestine in which lymphocytic inflammation is common. In these cases, additional diagnostic testing is required for confirmation and may include one or more of the following: histologic examination, preferably of a whole node or full-thickness piece of intestine; immunophenotyping by immunocytochemical/histochemical staining or flow cytometry; and polymerase chain reaction (PCR) for antigen receptor rearrangement to detect clonality. Because lymphocytes are fragile, free nuclei and cytoplasmic fragments frequently are observed in aspirates of lymphoma (see Figure 7-1, A); however, these features can be found in samples from reactive lymphocytic populations and are not criteria for neoplasia.

Infrequently, neoplastic lymphocytes are highly pleomorphic and exhibit moderate to marked anisocytosis, indented or deeply clefted nuclei, ameboid nuclei, multinuclearity, cytoplasmic vacuoles, and aberrant phagocytic behavior. When present, a few, some, or most of the neoplastic lymphocytes in a given tumor may have these features and may be mistaken for neoplastic histiocytes.⁹ Sometimes neoplastic lymphocytes contain fine or coarse pink cytoplasmic granules, suggestive of a T- or NK-cell phenotype. In large granular lymphoma, the lymphocytes contain large, coarse, pink granules and are thought to be cytotoxic T- or NK-cells (Figure 7-34).

Tumors of Histiocytic Origin

Cutaneous Histiocytoma Cutaneous histiocytoma originates from epidermal dendritic or Langerhans cells and is typically found on the head or limbs of young dogs. The cells are round and have pale blue to colorless cytoplasm and a round, sometimes indented, central nucleus with fine to reticular chromatin and indistinct nucleoli (Figure 7-35). Occasionally, the cytoplasm is more basophilic, and the nucleus more eccentrically located; in these cases, the cells may be mistaken for immature plasma cells and the mass called a plasmacytoma. Finding a few mitotic figures is common, but binuclearity is infrequent. Often the tumor cells are highlighted by a pale purple proteinaceous background. In mature lesions, there may be an infiltrate of small lymphocytes representing the T-cell-mediated immune response that leads to the spontaneous

resolution of these tumors. Presumed histiocytomas that do not resolve or that increase in size should be biopsied to rule out cutaneous lymphoma.

Histiocytic Sarcomas of Dendritic and Macrophage Lineage Histiocytic sarcomas of dendritic and macrophage lineage are malignant tumors and are variably called *histiocytic sarcoma* (HS), *malignant histiocytosis* (MH), and *hemophagocytic histiocytic sarcoma* (HHS), depending on clinical presentation, cytomorphologic appearance, and specific cell lineage (see Chapter 33, Section F). These tumors have at least three cytologic appearances. First, the tumor may be composed of a highly pleomorphic population of discrete round cells with extreme variations in N:C ratios, cell size, and nuclear size (Figure 7-36).¹⁰ The cytoplasm is basophilic and may contain numerous vacuoles, thought to be lysosomes, or phagocytosed erythrocytes, leukocytes, other tumor cells,

• **FIGURE 7-35** Fine-needle aspirate of a histiocytoma. Note the discrete round cells with a variable appearance. A few small lymphocytes are also present.

• **FIGURE 7-34** Fine-needle aspirate of a mesenteric lymph node from a cat with large granular lymphoma. Note the prominent coarse eosinophilic granules in the tumor cells.

• **FIGURE 7-36** Fine-needle aspirate of a histiocytic sarcoma. Note extreme pleomorphism, phagocytosis, and bizarre multinucleated cell (inset).

or cellular debris. Nuclei are typically round but may vary in shape and have indented or irregular margins. Chromatin is coarse to clumped, and nucleoli are prominent and vary in number, size, and shape. Multinuclearity and bizarre mitotic figures are common. Many of these tumors are infiltrated by small lymphocytes, plasma cells, and neutrophils. The second form comprises round, oval, and spindle-shaped cells with a more sarcoma-like appearance. Pleomorphism is less striking, but criteria of malignancy are present and warrant a cytologic interpretation of malignancy. Cytoplasmic vacuolation and phagocytic behavior also are less frequent. Nuclear shape is typically round to oval or elongate. These two forms are consistent with a tumor of dendritic cell origin.

The third form is hemophagocytic histiocytic sarcoma in which neoplastic macrophages constitute a “wolf in sheep’s clothing” because the cells resemble phagocytic macrophages found in inflammatory lesions and seldom exhibit criteria of malignancy.¹¹ The cells have moderate N:C ratios; vacuolated cytoplasm that frequently contains hemosiderin or phagocytosed erythrocytes, neutrophils, or platelets; and round central nuclei with reticular chromatin and one to two variably prominent nucleoli. More prominent pleomorphic features may be seen in a few cells. The neoplastic macrophages may form dense sheets in spleen, liver, or bone marrow, which may be the sole warning of their malignant nature. Rarely is a definitive diagnosis of HHS made cytologically and biopsy is required; a clinical presentation of hemolytic anemia non-responsive to immunosuppressive therapy, with or without other peripheral blood cytopenias, warrants consideration of HHS. In the absence of defined masses, a histologic diagnosis may also be difficult.

Differential diagnoses for these tumors depend on cytologic appearance. Few tumors are as pleomorphic as the round cell variant of HS; however, differential diagnoses may include anaplastic carcinoma and synovial cell sarcoma, depending on location. Differential diagnoses for the spindle-cell variant include a variety of other sarcomas. Differentials for HHS are not tumors at all, but include reactive macrophage proliferations secondary to other tumors or other inflammatory processes (hemophagocytic syndrome).

Transmissible Venereal Tumor TVT is a unique transmissible tumor thought to be of histiocytic origin. Its morphologic appearance is distinctive, and cytologic evaluation can provide a definitive diagnosis, especially when the tumor is located in typical locations, such as mucous membranes of external genitalia and nasal cavity. The N:C ratio is moderate to high. The nucleus is centrally or eccentrically located and has coarse chromatin and one or more prominent nucleoli (Figure 7-37). The cytoplasm is lightly basophilic and contains characteristic clear vacuoles. Mitotic figures are frequent. Mature lesions may contain infiltrating small lymphocytes. When found in atypical locations, such as the torso, limbs, and lymph nodes, TVT may be mistaken for lymphoma, histiocytic sarcoma, or amelanotic melanoma.

Mesenchymal and Epithelial Tumors That May Appear as Discrete Round Cell Tumors

Mesenchymal and epithelial tumors that may appear as discrete round cell tumors include amelanotic melanoma, granular cell tumor, anaplastic carcinoma, osteosarcoma, chondrosarcoma, rhabdomyosarcoma, and liposarcoma. Histologic examination of the tumor and immunohistochemical evaluation may be required to ascertain the lineage of these round cell imposters.

Tumor Metastases and Tumors Exfoliating into Cavity Effusions

Specific tumor types preferentially metastasize to certain organs or sites, depending on location of the primary tumor, vascular or lymphatic dissemination, and many other factors. Regional lymph nodes, lung, liver, and spleen are common metastatic sites, but any tissue or organ can be involved, including skin, bone, bone marrow, and the central nervous system. Cytologic identification of tumor metastases begins with recognizing an abnormal population of cells in the metastatic site followed by determining the tissue of origin, if possible, based on cytomorphologic features.

Both primary and metastatic tumors may exfoliate into cavities, including the thoracic, abdominal, and pericardial cavities, or into cerebrospinal or synovial fluid. Although neoplastic cells in these abnormal locations may be categorized as epithelial, mesenchymal,

• **FIGURE 7-37** Fine-needle aspirate of a transmissible venereal tumor (TVT). Note the coarse chromatin and small discrete vacuoles in the cytoplasm that are often referred to as a “string of pearls.” (Courtesy Dr. Robert Hall.)

• **FIGURE 7-38** Reactive mesothelial cells in pleural fluid from a cat with chylothorax. These cells may be highly pleomorphic and have criteria of malignancy, but represented hyperplastic mesothelium in this cat.

or discrete round cell tumors, the specific origin of the primary tumor is only rarely determined by examining cells in the effusion. A major cytologic challenge when examining cells in cavity effusions is distinguishing reactive mesothelium, mesothelioma, and carcinoma. Mesothelium undergoes hyperplasia and exfoliation whenever an effusion forms in the thoracic, abdominal, or pericardial cavities, and reactive mesothelial cells can adopt all the criteria of malignancy described for tumor cells, including marked anisocytosis and anisokaryosis, macrocytosis and macrokaryosis, multinuclearity, variation of nuclear size within the same cell, nucleolar pleomorphism, and abnormal mitotic figures (Figure 7-38). Identification of a mass and histologic examination often are required for a definitive diagnosis.

Molecular Diagnostics

ANNE C. AVERY, CHRISTINE OLVER, CHAND KHANNA,
AND MELISSA C. PAOLONI

Goals of Molecular Diagnostic Testing in Oncology

Since the mid-1980s, advances in the fields of molecular biology and genetics have changed our understanding of the biology of cancer. Technologic advances now provide the opportunity for applying this advanced understanding to the clinical arena in the form of novel diagnostic tests and management strategies. Molecular approaches for cancer diagnosis are now part of the standard of care for most human patients.¹ Technologic advances have reduced the unit cost for many of these approaches, and their use and commercialization is increasingly taking hold within the veterinary field. It is now feasible to assess proteins, RNA, DNA, or their metabolites in tumors, effusions, blood, saliva, and urine to more accurately classify and detect various forms of neoplasia.

Recently, the National Comprehensive Cancer Network (NCCN) defined molecular testing in oncology as “procedures designed to detect somatic or germline mutations in DNA and changes in gene or protein expression that could impact the diagnosis, prognosis, prediction and evaluation of therapy for patients with cancer.”¹ Molecular assays are used for a variety of reasons in the diagnostic evaluation of malignancy. For example, the presence or absence of individual oncogene mutations or chromosomal abnormalities has significant prognostic implications in many types of malignancies. In people, finding a mutation in the nucleophosmin gene in cases of acute myelogenous leukemia (AML) predicts a significantly better prognosis, independent of other factors.² In canine mast cell disease, the presence of a mutation in the *c-kit* gene suggests a worse prognosis than for patients without such a mutation.³ In lymphoma, the phenotype (B- versus T-cell) plays a large role in determining prognosis in both veterinary and human patients. A variety of molecular diagnostic tests, including DNA-based and various methods of protein detection, can establish the phenotype of lymphoma.

The presence of a particular mutation or chromosomal abnormality can help to subclassify a tumor. For example, chronic lymphocytic leukemia/small cell lymphoma (CLL/SCL) and mantle cell lymphoma in humans are both neoplasms of mature B-cells, with a similar (but not identical) immunophenotype. Mantle cell lymphoma, however, almost always has a rearrangement between the immunoglobulin heavy chain locus (IgH) and the *CCND1* (encoding cyclinD1) gene, whereas this rearrangement is very rare in CLL/SCL.⁴ The prognosis and treatment of these two diseases is quite different, so the distinction is important to make.

Molecular diagnostic testing also helps guide therapy. This may be best illustrated by the development of tyrosine kinase inhibitors (TKIs). These drugs inhibit signaling through tyrosine kinase

receptors, such as *c-kit*, platelet-derived growth factor (PDGF) receptor, and epidermal growth factor (EGF) receptor. Tumors with mutations in these receptors that result in their constitutive activation respond well to TKIs, whereas those without may require different kinds of chemotherapy. Thus testing for mutations in these genes has become commonplace in human medicine—EGF receptor in small cell lung carcinoma and stem cell factor (SCF) receptor (*c-kit*) in gastrointestinal stromal cell tumors. Similarly, mast cell tumors in dogs that harbor a *c-kit* mutation respond better to TKIs than those without the mutation.³

Finally, oncogenes and chromosomal translocations uniquely distinguish neoplastic from normal tissue. As such, sensitive detection of mutations can be used to quantify residual disease in patients that have been treated. The best example of this is detection of the *bcr-abl* fusion gene, which can allow oncologists to detect as few as $1:10^6$ neoplastic cells in peripheral blood.⁵ Tumor-specific primers that recognize the unique immunoglobulin genes found in both canine and human B-cell lymphomas have been used to quantify tumor burden and monitor disease in both dogs and people with lymphoma.

The goal of this chapter is to review several molecular techniques useful in the diagnosis and classification of cancer. It is likely that advanced molecular methodologies and diagnostics will continue to improve, become increasingly inexpensive and simpler to use, and be more broadly available to veterinarians over the next few years.

Methods for Analyzing Genes

DNA represents the genetic code of all species. This code consists of a series of continuous nucleic acid sugar strands linked through hydrogen bonds. This series of nucleic acids takes on a tertiary folded structure through modification by binding proteins called *histones*. The folded and wrapped DNA strand is packaged within the chromosomes of the cell. The earliest techniques used to assess the genetic changes of cancer were those that defined gains, losses, or structural changes in chromosomes, referred to as *cytogenetics*. Subsequently, polymerase chain reaction (PCR)-based methods and high-throughput sequencing have allowed us to detect smaller discrete mutations in DNA that do not involve changes in large portions of the chromosome. Small deletions and insertions in genes, as well as single nucleotide changes, are now routinely detected.

Detection of Chromosomal Abnormalities

Historically, these techniques involved the examination of metaphase preparations made from chromosomes. Metaphase preparations were then stained (banded) to help in the identification of

distinct chromosome morphologies. Using these techniques, detection of gross abnormalities in chromosome number (ploidy) and of the presence of chromosomal translocations was possible and led to the identification of genes associated with tumor development and progression. Cytogenetic analysis has been most useful in the clinical assessment of leukemias, in which metaphase preparations are relatively easy to develop from whole blood samples.⁶ For most human leukemias, cytogenetic descriptors are used to define distinct subgroups into prognostic groups and to guide treatment decisions. The use of cytogenetic approaches in the management of companion animals has been limited due to the difficulty in using conventional chromosomal banding to identify canine chromosomes. The development of chromosome-specific “paints” that allow the identification of specific canine chromosomes has improved the opportunity to apply cytogenetic descriptors to canine cancers. Using these techniques, Breen and colleagues have identified a chromosomal translocation in canine chronic myelogenous leukemia (CML) and chronic monocytic leukemia that is the equivalent of the *bcr-abl* Philadelphia chromosome found in human CML.^{7,8}

For the most part, traditional cytogenetic techniques, including the use of chromosome-specific paints, are labor intensive and have been replaced by alternative modalities. Comparative genomic hybridization (CGH) arrays can define gains and losses in chromosome number within tumor specimens rapidly and with highly reproducible results. In CGH analysis, the investigator labels genomic DNA from a normal individual and from tumor cells of the patient with two different color fluorescent probes. The labeled DNA is then hybridized to an array of DNA probes that span the majority of the genome. These probes are printed onto a chip or slide, such that the location of each individual probe is identified. The degree of hybridization to each probe is then determined by the level of fluorescence detected by laser excitation. Equal hybridization of the DNA from both sources to an individual probe indicates normal copy number, whereas increased binding by the tumor DNA indicates the presence of chromosomal duplication in the area of the genome covered by that probe (Figure 8-1). Similarly, higher binding by the DNA from the normal individual indicates chromosomal loss in the area.

CGH arrays are useful for localizing chromosomal regions where investigators should focus their search for genes important to that cancer. A canine CGH array with 2 megabase resolution has been reported.⁹ Using this array, Breen and colleagues have shown that a subset of T-cell lymphomas (histologically defined as peripheral T-cell lymphoma, unspecified) exhibits copy number gain in regions common to most examples of this histologic type but not present in other T-cell lymphoma subtypes.¹⁰ This finding will help to identify genes within the duplicated areas that might be useful for diagnostics and therapy and for understanding the genesis of the neoplasm. A similar study in canine malignant histiocytosis (MH) demonstrated that MH frequently exhibits loss of chromosomal regions that contain tumor suppressor genes.¹¹ Such genetic characterization of a diverse group of cancers, with distinct biologic behaviors but similar histologic descriptions, will significantly improve opportunities to target specific therapies and management strategies to distinct biologic subgroups of these diseases.

Polymerase Chain Reaction–Based Techniques: Detection of Mutations, Novel Genes, and Assessment of Clonality

PCR is the process of amplifying a small specific segment of DNA for the purpose of further analysis. Two small segments of DNA

• **FIGURE 8-1** The principle of array analysis. A chip or slide is printed so that each position on the chip (there are thousands) has a single probe, which can range in size, depending on the type of array. DNA from a tumor tested is labeled with one dye (green) and DNA from the reference sample with another (red). Both samples are hybridized to the same chip. The separate red and green panels indicate that the tumor DNA exhibits both chromosomal gain (increased green fluorescence) and loss (decreased green fluorescence). When the two DNA preparations are co-hybridized, a yellow signal indicates equal degrees of red and green fluorescence. When there is a gain in copy number in a region of DNA, the signal will be green. When there is a loss in copy number, the signal will be red.

(commonly about 20 bases long), which are complementary to the DNA sequence surrounding the area to be amplified, are synthesized. These primers are then used to amplify the DNA, which lies between them (typically less than 1000 bases). This amplified DNA product can then be analyzed in a number of ways for mutations to quantify the product for measurement of gene expression, or in the case of lymphoid malignancy the DNA can be separated by size in order to look for clonal populations of B- and T-cells. The same methods can be applied to the analysis of RNA, once the RNA has been transcribed into DNA.

Primer synthesis typically requires that the sequence of the target gene is known. The publication of the canine genome in 2005¹² has been invaluable in this regard, since it is now possible to simply use the known canine sequences rather than hope for sequence similarities with mice and humans.

Detection of Genetic Insertions and Deletions

PCR-based assays are commonly used in human oncology to detect insertions or deletions in genes relevant to the prognosis or treatment of a neoplasm. In veterinary medicine, detection of internal tandem duplications (ITD) in the *c-kit* gene in canine mast cell tumors is now a routine part of the diagnosis for the purpose of determining the most effective treatment. *C-kit* is a TK receptor for the growth factor SCF and is mutated in some cases of canine mast

cell tumors.¹³ The primary mutations described are internal ITD in two different exons, exon 8 and 11.¹⁴ The mutations involve the duplication of a small segment of DNA so that it is repeated, resulting in a larger gene (Figure 8-2). Approximately 14% to 20% of canine mast cell tumors have a duplication in either exon 8 or 11.¹⁴ Since mast cell tumors containing the ITD respond better to TK inhibitors than tumors with wild-type *c-kit*,¹⁵ testing for *c-kit* mutations has become a routine part of the diagnostic work-up for mast cell tumors.

Detection of this type is fairly simple, since the presence of a larger (or smaller, in the case of deletions) PCR product is determined by size separation. It is likely that as more genes are identified as being targets of therapy, such assays will become more frequent. Recently, Suter et al identified an internal duplication in the *FLT3* gene¹⁶ in acute lymphocytic leukemia (ALL) using the same methods and provided preliminary evidence that response to a small molecule inhibitor is predicted by the presence of the mutation in lymphoid cell lines. We are likely to see routine use of mutation detection grow in the near future and continue to guide treatment decisions.

Detection of Single-Base Mutations

Single-base mutations are more difficult to detect, since the base-pair change does not confer a size difference to the PCR product. Several strategies are used in human medicine for detecting these kinds of mutations. First, mutations can be detected by synthesizing primers that are complementary to the mutation, rather than to the wild-type version of the gene. In theory, a PCR product would only be seen if the mutation is present. This approach has to be tested empirically for each individual mutation, since such primers may also anneal to the wild-type gene, although with less affinity. There are a variety of ways to produce primers that are more discriminating, and different methods will be more or less effective for individual mutations.

Another approach employs direct sequencing of the PCR product. Sequencing is now inexpensive and widely available. The limitation of direct sequencing is that the sample must contain a significant percentage of tumor cells for the mutation to be detected—most estimates suggest 10% or more. This is because at best only one-half of the DNA sequenced will have the individual mutation (assuming the tumor also has a wild-type copy of the gene), and the presence of nonneoplastic tissue in most clinically derived samples will serve to further dilute the amount of mutated DNA. Thus, unless the PCR products are cloned and sequenced individually, a significant portion of the DNA must be tumor derived.

Detection of Fusion Gene Products by PCR

One mechanism by which chromosomal translocation causes malignant transformation of cells is to create novel proteins with altered function. The best studied of these fusion genes, the Philadelphia chromosome, is the breakpoint cluster region-Abelson (*bcr-abl*) fusion gene found in greater than 90% of all human CMLs and occasionally ALL and AML.¹⁷ *abl* is a tyrosine kinase that has myriad activities involved in cell growth and differentiation. It is encoded on human chromosome 9, and in CML, it is translocated to chromosome 22. The site of the translocation varies within the *bcr* gene, so that a new fusion gene, *bcr-abl*, is formed. The new fusion protein allows for the constitutive activation of the *abl* tyrosine kinase, which in turn promotes the development of CML (Figure 8-3).

This fusion protein is the product of a novel RNA transcript, which can be readily detected by PCR. To accomplish this, RNA is

extracted from blood containing potentially neoplastic cells and reverse transcribed to cDNA. The cDNA is then amplified with two primers, one which anneals to the *bcr* gene, and the other to the *abl* gene. Since these two genes are normally on different chromosomes, no product will be seen in the absence of a translocation, but will be detected if the genes have been brought together to form a single messenger RNA (mRNA). This assay can detect as few as 1:10⁶ tumor cells⁵ and can therefore be used for both diagnosis of CML and quantifying residual disease after treatment.

Assays for a large number of translocations have been developed over the past 10 years.¹⁸ These assays are now routinely available for characterization of human tumors, particularly leukemia. The finding that canine leukemia and lymphoma can exhibit the same translocations as their human counterparts⁸ suggests that detection of this novel fusion gene would aid in the diagnosis of canine chronic myelogenous leukemia.

Assessment of Clonality in Lymphoma and Leukemia

A clonality assay demonstrates that a group of cells is derived from a single clone. The term is usually used to refer to detection of the unique genes found in each individual B- or T-cell—immunoglobulin genes in B-cells and T-cell receptor (TCR) genes in T-cells. The portion of these genes that encodes the antigen-binding region is the portion that varies between cells, both in size and sequence. When B- or T-cells divide, the immunoglobulin and TCR genes are passed on to the daughter cells.^{19,20}

In the course of a normal immune response to a pathogen, B- and T-cells are activated, expand, and eventually die, leaving behind a small number of residual memory cells. On the other hand, when a cell becomes neoplastic, it no longer responds to growth controls and undergoes unlimited expansion. Therefore, if one can establish that the majority of cells in a particular collection of lymphocytes have the same immunoglobulin or TCR gene, it is most likely that these cells are neoplastic rather than reactive.²¹

When immunoglobulin and TCR genes rearrange during the course of B-cell and T-cell development, respectively, the length and sequence of the resultant gene differs from cell to cell. There are many reasons for this, including the fact that nucleotides are added between V, D, and J segments as they rearrange into a contiguous formation. The clonality assay takes advantage of this fact. In a sample consisting of many different lymphocytes, as in a reactive process (the lymph nodes of a dog with chronic pyoderma or poor dental hygiene, for example), there will be multiple different-sized TCR and immunoglobulin genes. On the other hand, in a sample consisting of neoplastic lymphocytes, the immunoglobulin gene or the TCR gene (depending on whether it is a B-cell or a T-cell lymphoma) will be a single size (Figure 8-4).

Clonality assays are accomplished by isolating DNA from cells suspected to be neoplastic and then using PCR primers directed at the conserved regions of TCR or immunoglobulin genes. The primers amplifying the variable regions and the PCR products are separated by size using a variety of possible methods. The presence of a single-sized PCR product is indicative of clonality, whereas the presence of multiple PCR products supports a reactive process. This assay has now been reported by a number of laboratories²²⁻²⁵ and used to answer a variety of clinical questions.²⁶⁻²⁸ This assay is termed the *PCR for antigen receptor rearrangement* (PARR) assay in order to distinguish it from other types of clonality assays.²³ It should be noted, however, that the term *PARR* is not used in the human literature, where the assay instead is referred to as a *clonality assay*.

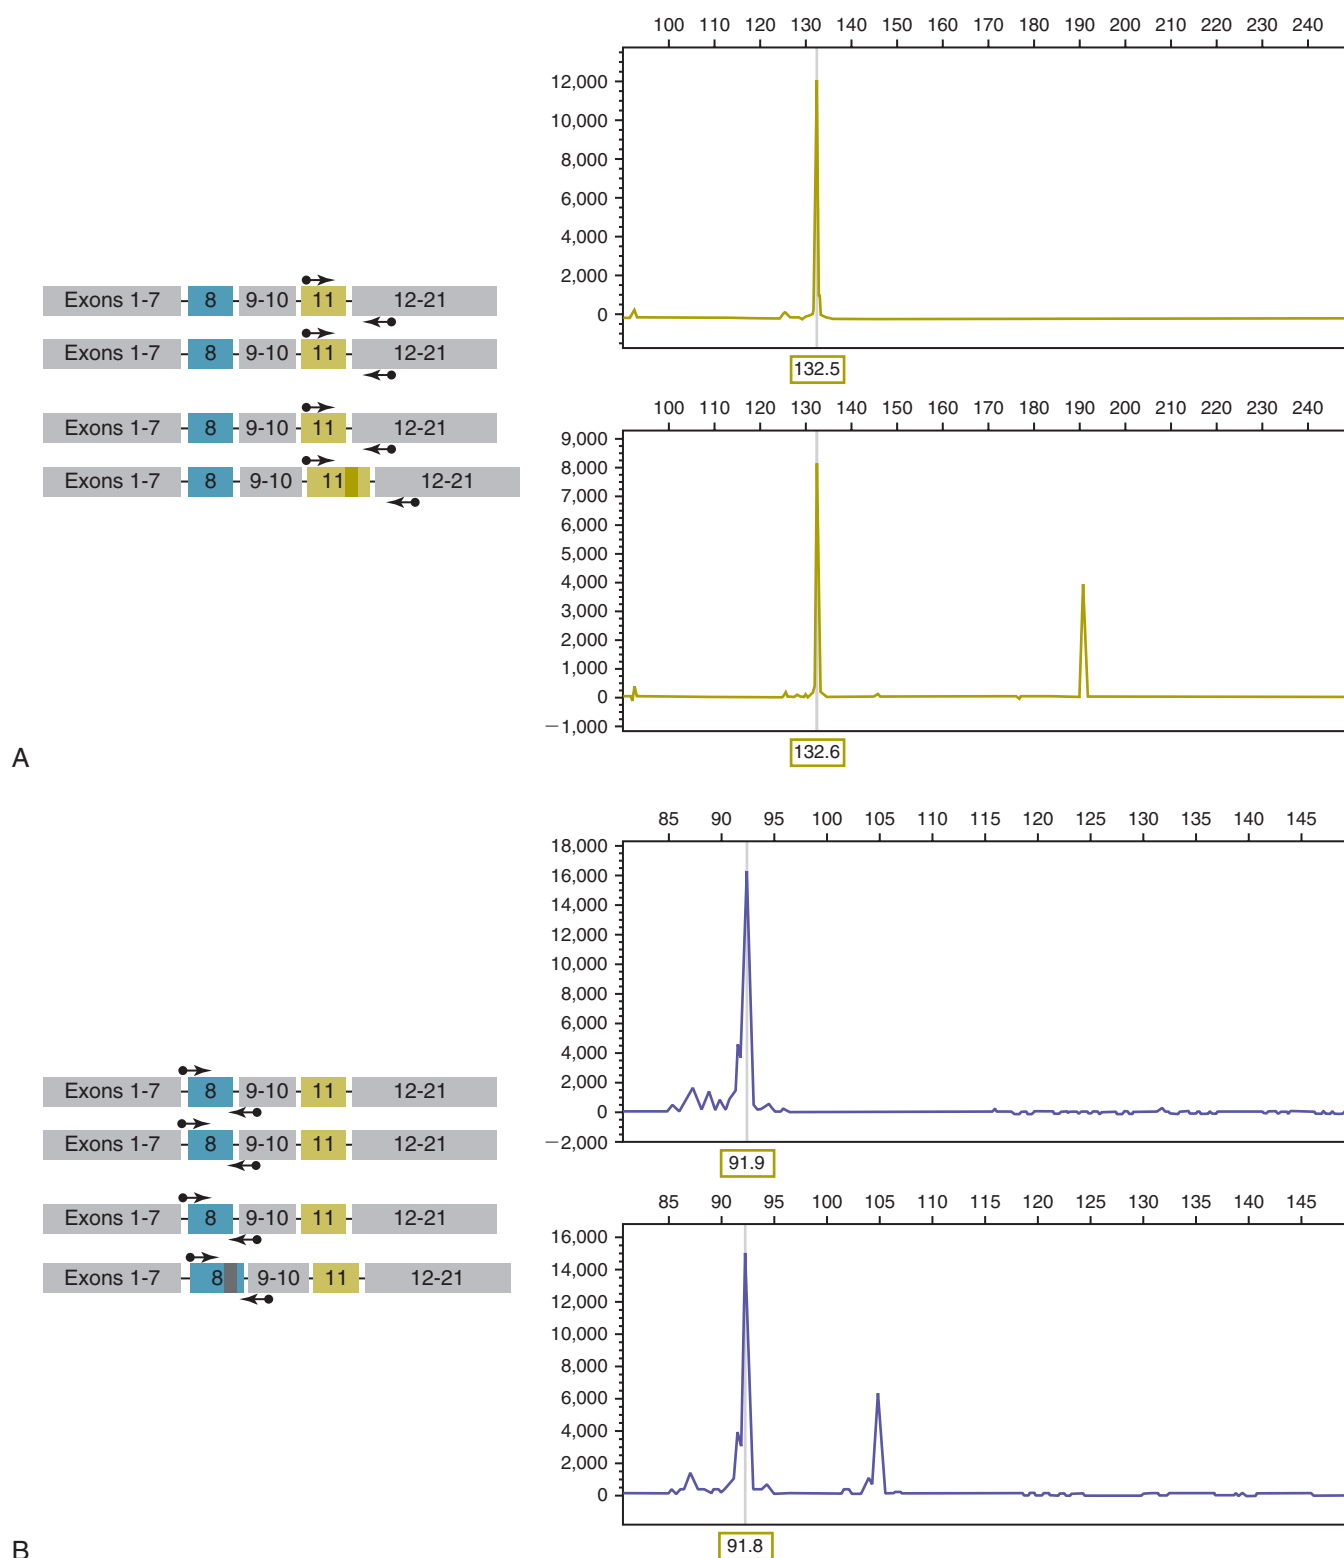

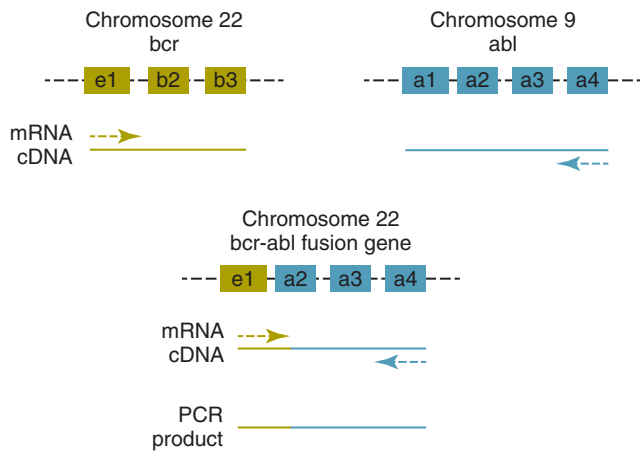

FIGURE 8-2 Detection of *c-kit* mutations by PCR. **A**, Two different tumor types are depicted—one has two copies of a wild type *c-kit* gene, and the second has one copy of a *c-kit* gene containing an internal tandem mutation in exon 11. The PCR products detected after amplification with primers surrounding the duplication (arrows) for each tumor are shown on the right. **B**, Same as in **A**, but in this case, the second tumor has an internal duplication in exon 8, and the PCR products are amplified with primers flanking the region of the duplication.

• **FIGURE 8-3** Translocation of the *abl* gene to the *bcr* gene creates a fusion gene that can be detected by PCR. In nonleukemic cells, primers located as indicated (arrows) will not amplify any product, because they anneal to two distinct cDNAs. When *bcr* and *abl* are brought together, the primers are both annealing to the same cDNA and will amplify this product. e1, b2, and so forth refer to exon numbers.

The PARR assay is able to detect approximately 1 : 100 neoplastic cells. The sensitivity and specificity of the assay will differ between laboratories because the results are highly sensitive to the conditions under which the assay is run and to the technique used to separate the PCR products. Capillary gel electrophoresis has the highest resolution, but high percentage polyacrylamide gels may also be used. Agarose gels, even high-resolution agarose gels, provide insufficient resolution for this assay and should not be used.

The main application of the PARR assay is to establish clonality in a sample that is cytologically or histologically ambiguous—cases in which there are rare cytologically suspicious cells within the context of a reactive node, for example, or a lymph node that was interpreted as “atypical lymphoid hyperplasia” on histology. Clonality assays can sometimes be useful for establishing the lineage (B-versus T-cell) in cytologically unambiguous lymphomas if additional case material is not obtainable from the patient, but in general flow cytometry, immunohistochemistry, or immunocytochemistry are preferable for this purpose. This is because aberrant rearrangements can occasionally be seen in nonlymphoid tumors such as myelogenous leukemias and also in a neoplasm of the opposite phenotype (TCR rearrangement in a B-cell lymphoma, for example). The rate at which this occurs also probably differs from laboratory to laboratory and depends on the subtype of lymphoma being examined.

The principle of the clonality assay can also be used to quantify tumor cells in blood or node and to monitor minimum residual disease. For this type of analysis, PCR primers specific for the immunoglobulin or TCR gene that is carried by the tumor are used, instead of the broadly reactive primers used to screen samples. In this way the investigator is certain that only tumor DNA is being amplified and not nonneoplastic lymphocytes. The specificity of this reaction permits determination of the number of tumor cells in a sample of blood, even when those cells are as rare as 1 : 10,000 cells. Yamazaki et al²⁸ demonstrated that with current chemotherapy protocols, all seven dogs they examined had at least 1 : 10,000 cells in their peripheral blood, even though the dogs achieved clinical remission. Although this kind of analysis may not be practical for routine diagnostics, it is a powerful research tool to compare the efficacy of novel chemotherapy regimens.

Single Nucleotide Polymorphism Analysis

A great deal of interpatient variability in the biology of cancers is based on the presence or absence of mutations in a cancer. However, small differences in host genes—referred to as single nucleotide polymorphisms (SNPs)—have been shown to be important in defining these interindividual differences in disease progression and response to treatment. SNPs can result in a change in the structure or function of a gene. SNPs are considered to be distinct from mutations since they are present in a subset of the population and do not cause disease themselves. A number of SNPs in genes that function in hepatic metabolism in the human population have been identified and can predict increased risk for toxicity to some drugs. Similarly, SNPs in other genes have been shown to predict an increased risk for a more aggressive course of metastatic progression once a patient develops a cancer.²⁹ The release of the canine genome sequence has made possible the high-throughput detection of SNPs—using an array platform³⁰—within a population of dogs. It is likely that SNP-based diagnostics will emerge from these discovery efforts and will contribute to the individualization of therapy of dogs and cats with otherwise similar diseases. SNP-based diagnostics are also helpful in providing an opportunity to attempt to predict or define individual differences seen between patients treated in the same way for the same disease. These differences may include toxicities experienced after receiving a treatment, beneficial response to a therapy, or progression rates for patients with a similar disease stage. These forms of individualized therapy are on the horizon for both human and veterinary cancer patients.

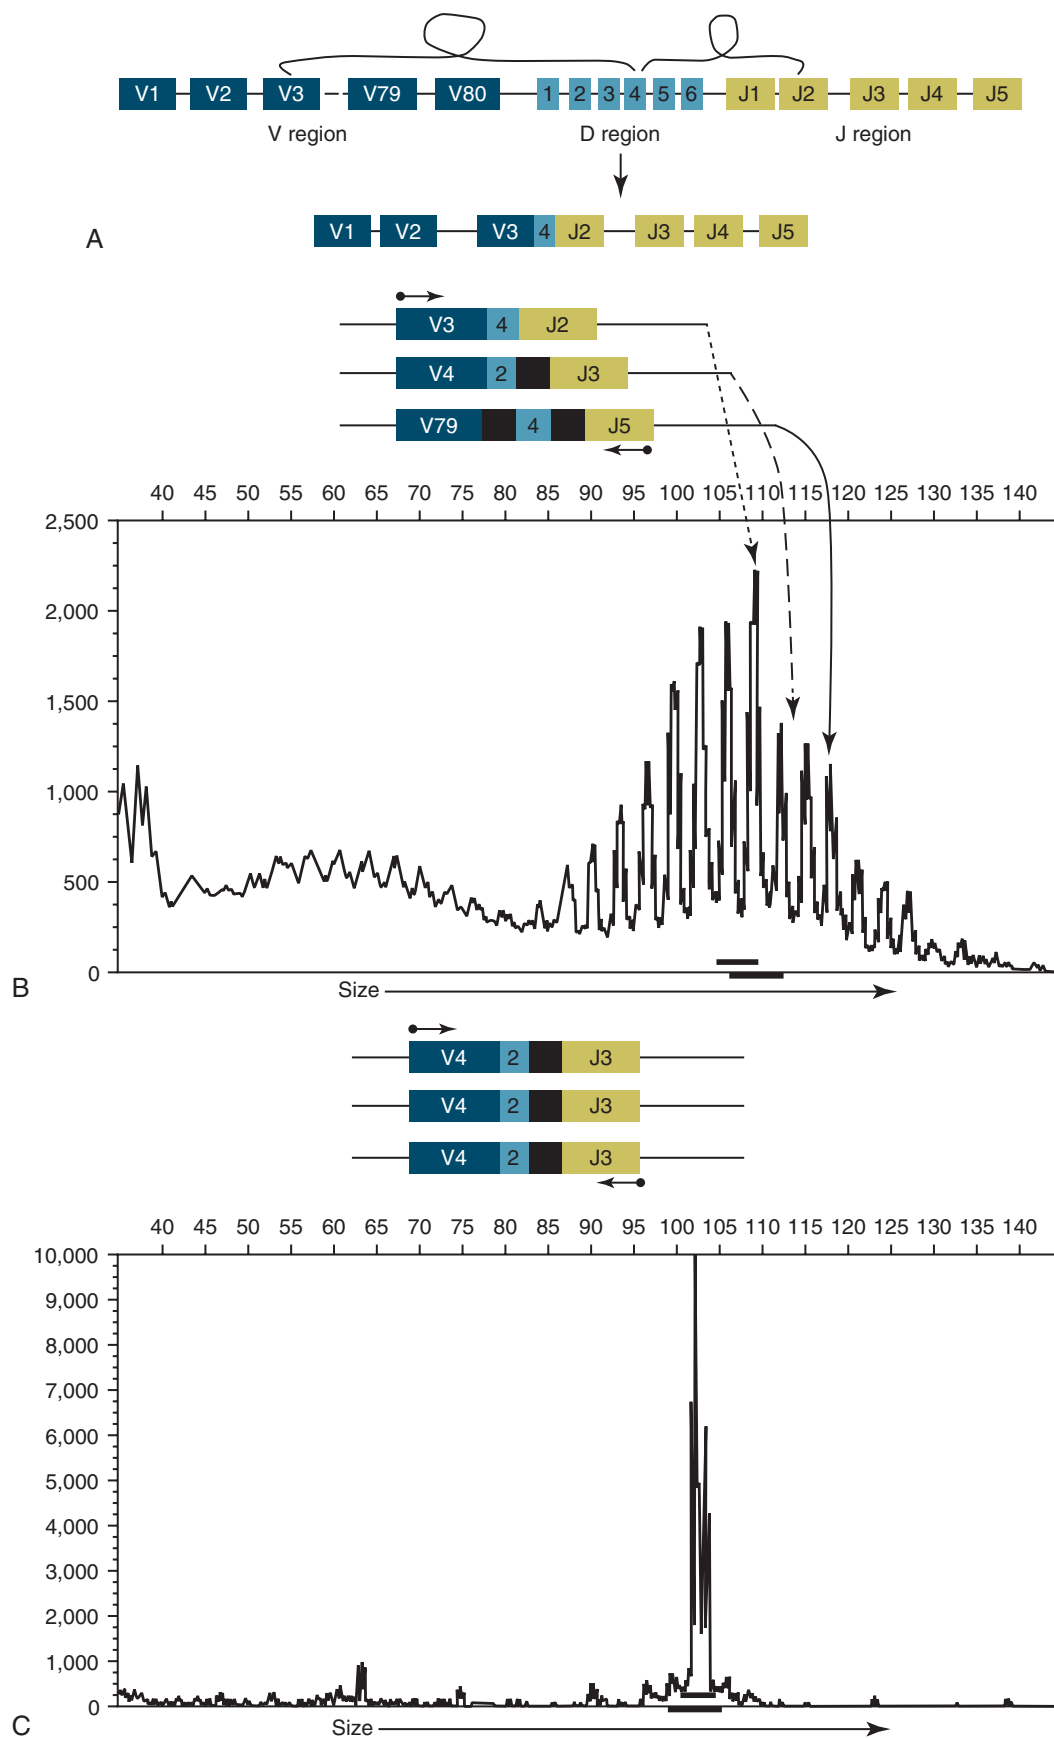

Quantifying Genes and Gene Expression

The complete genetic code, or DNA sequence, is present within every cell in the body. The effective genetic information that uniquely defines each cell type within the body is defined by the genes expressed (transcribed) as mRNA. The expression of mRNA is more responsible for the phenotype of a cancer than the individual genes and mutations harbored by the tumor. When assessing the level of expression of one or a few genes, real time PCR is most commonly used. Assessment of the global level of gene expression is carried out with microarrays and is called *gene expression profiling*. Both methods measure relative expression of message when compared to a control gene whose expression is thought to be more or less constant in all cells and universal. These methods are both likely to be replaced over the next 10 years with new technologies, which allow investigators to count the absolute number of genes or transcripts in a sample.

Real-Time Polymerase Chain Reaction

Real-time PCR (also called *Q-PCR*) refers to the quantitative measurement of DNA—either genes, or more commonly, RNA that has been reverse transcribed to cDNA. The principle of real-time PCR is that DNA is amplified using primers, just as in a routine PCR reaction, but at each round of amplification, fluorescence relative to the amount of PCR product is quantified. Unlike endpoint PCR, in which the reaction runs to completion and the product is separated by size, real-time PCR is highly quantitative.

The two main methods for quantifying DNA in real-time PCR have different advantages and disadvantages. The simplest and least expensive method is the use of the DNA-binding dyes, such as *SYBR green* (pronounced cyber). This dye fluoresces when it

intercollates into DNA. Therefore, at each round of amplification, more dye is intercollated and the degree of fluorescence increases. Eventually, the fluorescence reaches saturation, but the endpoint is less important than the log phase of DNA increase. The amount of starting material is compared between samples by determining at which amplification cycle the degree of fluorescence crosses a given threshold. SYBR green will intercollate into any DNA product, so this method is only accurate when the primers are highly specific and amplify only one gene product.

An alternative method uses fluorescently labeled DNA probes. These are short segments of DNA complementary to the target sequence between the two primer sites. A fluorescent molecule attached to the probe is quenched until the 5' to 3' exonuclease activity of the Taq polymerase releases the fluorescent molecule. As the amount of PCR product increases proportional to the starting material, the amount of fluorescence increases. The advantage of the probe method is that instead of two primers providing specificity to the reaction, there are three. In order to detect a product, these three different segments of DNA need to bind to the target sequence in three separate places. The assay may be less robust at low target numbers and is slightly more expensive but also significantly more specific. This assay with its increased specificity was used by Yamazaki et al²⁸ to quantify individual neoplastic lymphocytes in a background of heterogeneous lymphocytes and thus quantify minimal residual disease.

Real-time PCR can quickly allow for precise quantification of mRNA levels within samples and has a number of defined clinical applications. It is commonly used in the quantification of aberrant oncogenic fusion products. Promyelocytic leukemia gene–retinoic acid receptor (PML-RAR) fusion transcripts in acute promyelocytic leukemia (APL) are identified by this method³¹ and can be used to define molecular remission in patients with APL. Molecular remissions are defined by the absence of not only clinically detectable disease but by the absence of any tumor-associated transcript in blood, bone marrow, or lymph node. Achieving a molecular remission in patients with leukemias and lymphoma is a superior measure of prognosis over clinical assessments of remission that are based on clinical examination, imaging techniques, or histologic or cytologic assessments of at-risk tissues.

Gene Expression Profiling

Gene expression profiling refers to the quantification of thousands of mRNAs simultaneously to create a picture of global gene expression in the cell population. The pattern of gene expression is called a *gene expression profile*. A variety of different software tools are available for identifying patterns of expression involved in a common pathway or function. The companies that produce these tools mine the literature for information about the function(s) of different genes, and then place these genes into pathways. A

collection of genes involved in a particular pathway are frequently referred to as *signatures*. For example, if the gene expression profile shows a proliferation signature, then the genes involved in the regulation of cell division are upregulated. If the cells show a nuclear factor kappa B (NFκB) signature, expression of genes regulated by the transcription factor NFκB are increased.

Gene expression profiling is performed using similar tools as CGH arrays. Oligonucleotides complementary to thousands of different genes are printed on a slide or chip, usually more than one oligo for each gene. mRNA from the sample in question is isolated, reverse transcribed to DNA, and labeled with a fluorescent probe. This fluorescent cDNA is then hybridized to the chip, and the degree of fluorescence is proportional to the amount of mRNA present in the original sample. A variety of controls are built into the chip and are used during the analysis to look at gene expression relative to standard housekeeping genes, such as *GAPDH*.

Gene expression profiling is comparative. Investigators can compare expression profiles of tumor cells to the normal cellular counterpart, to similar tumors with different clinical outcomes, and to tumor cells from the same patient before chemotherapy; can compare primary lesions to metastatic lesions; and can make other comparisons to ask how different pathways have changed. Such information has proved invaluable in a variety of settings. For example, in a study of cervical cancer in humans, investigators analyzed gene expression profiles of tumors that responded to chemotherapy and radiation and compared those with tumors that did not respond. Their study revealed that activation of the PI3K/Akt signaling pathway was associated with a poor response, suggesting one potential therapeutic target.³² Another example of how gene expression profiling has advanced oncology are the studies of B-cell lymphoma by Staudt and colleagues. Noting that diffuse large B-cell lymphoma (DLBCL) has a heterogeneous outcome in people, this group compared the gene expression profiles of 96 DLBCL with B-cells derived from different stages of normal B-cell development.³³ They found that the gene expression profile of DLBCL could either be categorized as similar to germinal center B-cells or similar to activated B-cells. Importantly, these two categories had prognostic significance: germinal center-like DLBCL cases had a better prognosis. The distinction between germinal center DLBCL and activated B-cell DLBCL is now well established as a prognostic indicator.

This same group made another important discovery about B-cell lymphoma using gene expression profiling, which provided insights into immunity to cancer. Expression profiles of lymph nodes from patients with follicular B-cell lymphoma demonstrated that the type of immune response signature was prognostic in this disease. Patients whose lymph node gene expression patterns exhibited evidence of T-cell activation had a better overall survival than patients whose gene expression patterns resembled activated

• **FIGURE 8-4** Rearrangement of immunoglobulin genes. **A**, There are approximately 80 V-region genes, 6 D-region genes, and 5 J-region genes. A single V, D, and J are brought together at random to create a single VDJ gene segment that encodes the antigen-binding portion of an antibody, and the intervening sequence is removed. **B**, In the process of bringing together V, D, and J genes, a variable number of nucleotides (black) are added between V and D and D and J. As a result, each individual B-cell will have a VDJ gene segment with a unique length. When DNA from a heterogeneous population of B-cells is isolated and amplified with primers bracketing the VDJ gene segment (small arrows), the PCR products will be different lengths. The lower panel shows the PCR products separated by size using capillary gel electrophoresis and illustrates multiple different-sized PCR products. **C**, When a population of B-cells is comprised of cells derived from a single clone, all the VDJ gene segments will be identically sized. PCR amplification of the VDJ gene segment will yield a single-sized product as shown in the lower panel. All the principles illustrated here also apply to T-cell receptor (TCR) genes. For the clonality assay, the TCR γ-chain is amplified, although in theory TCR β-chain could also be used.

macrophages.³⁴ The expression profile of the tumor cells themselves was not predictive. This finding suggests that the immune response contributes to survival in patients with follicular B-cell lymphoma, a result which was corroborated in other types of B-cell lymphoma.^{35,36}

Gene expression profiling is now a readily accessible tool in canine oncology because of the availability of the Affymetrix Canine Genome 2.0 and Agilent (V2) Gene Expression microarrays, and investigators have begun to examine gene expression profiles in a variety of canine neoplasms, including hemangiosarcoma,³⁷⁻³⁹ lymphoma,^{40,41} and osteosarcoma.

On the Horizon—Counting Genes

The next generation of genetic analysis uses a new paradigm for evaluating individual genes, gene expression (cDNA analysis), and whole genomes. The old paradigm has been to use fluorescent or other types of DNA labels to quantify copies of DNA—more fluorescence means more copies. For example, if we want to quantify *bcr-abl* fusion messenger RNA for determining the number of circulating cells present before and after treatment, a fluorescent based real time PCR method would be used. Fluorescently labeled probes, corresponding to a portion of the *bcr-abl* fusion gene, would be added to a PCR reaction where that gene is specifically amplified. The amount of fluorescence is directly proportional to the amount of product, which is proportional to the amount of starting cDNA. This is usually compared with the amount of message from a housekeeping gene to give a relative quantity of *bcr-abl* message.

In the new paradigm, the number of cDNAs corresponding to *bcr-abl* in a blood sample would be counted in absolute numbers. One name given to this idea is “digital PCR.” There are many methods to accomplish this kind of quantification, but they all share the idea that millions of isolated PCR reactions are being carried out on single DNA molecules. In the *bcr-abl* example, millions of individual cDNAs from a blood sample, together with *bcr-abl* primers and polymerase, would be isolated on a solid matrix or in individual droplets in an emulsion; the result of that amplification would be positive (if the *bcr-abl* cDNA is present) or negative (if the *bcr-abl* DNA is absent). Presence or absence of a product can still be a fluorescent readout, but the message is quantified by the percentage of individual reactions that are positive. The advantage of this method is the elimination of the need for standard curves and reference samples. In addition, these methods are likely to be significantly more sensitive since thousands to millions of DNA molecules are analyzed at one time. Thus one has the possibility of measuring as few as 1 in 10^6 copies of a gene or message. The first generation of instruments that can carry out this kind of analysis are now commercially available, and it is likely that these will eventually become commonplace.

Next generation whole genome sequencing works on a similar principle. A variety of instruments are now available with the capability of sequencing an entire mammalian genome within days (including setup and DNA isolation) at a cost of about \$10,000 to \$20,000. This is accomplished by carrying out millions of sequencing PCR reactions simultaneously. Whole genomic DNA is sheared into small fragments, and individual sequencing PCR reactions are carried out on each fragment. The result is that the investigator obtains millions of short sequences, which must then be interpreted by extensive software analysis. It is certain that the cost of this type of analysis and its complexity will both decrease in the near future. Current efforts are underway to sequence both whole genome and exons of a number of canine cancers that will continue to identify and characterize important targets and pathways in their

pathogenesis. The day when a patient's entire tumor genome is sequenced as a routine part of diagnostics is imaginable and not that far in the future.

Methods for Protein Analysis

Protein expression represents the accumulation or end product of genetic information. DNA is transcribed into RNA, which is then translated into proteins. Therefore the detection of proteins and their active forms (most often phosphorylated) represents an important step in the global understanding of cancer biology. Protein measurements can be both qualitative and quantitative and can include a variety of candidate approaches, including Western blotting, immunohistochemistry, and various novel noncandidate proteomic platforms, collectively referred to as *proteomic approaches*.

Western Blots

Western blots allow for the detection of a protein within a sample through the use of an antibody that is specific to that protein. Western blots are used widely as a diagnostic modality that has recently seen expanded clinical use in the field of oncology through the availability of antibodies that are specific for phosphorylated forms of proteins and for mutated proteins. As treatment modalities for cancer have become more target-dependent, the need has increased to define the presence of the target protein in a clinical sample. Documentation of HER2/neu oncogene expression in human breast cancer patients has the dual utility of contributing to prognosis (expression of this protein carries a negative prognostic value) and guiding the rational use of trastuzumab (Herceptin), a therapeutic monoclonal antibody that has been shown to improve time to progression and overall survival in metastatic breast cancer patients when combined with chemotherapy.⁴²

In the veterinary field, Western blots have been part of the diagnosis and management of animals with tick-borne infectious disease and feline immunodeficiency virus. The use of in-house “snap” test technology is based on a similar technique of antibody-based detection, including enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay (RIA). In these assays, rather than using gel electrophoresis, the probing antibody is affixed to a substrate for detection of antigen in material passed over or through this substrate. As such, the specificity and sensitivity of antigen-antibody interactions needed for these tests are greater than what are needed for a Western blot. In the field of oncology, these snap tests have been limited by a lack of tumor-specific antibodies (with high sensitivity and specificity) that could aid in the diagnosis of cancer.

Immunohistochemistry and Flow Cytometry

As in the case of Western blots, advances in antibody development have similarly improved the opportunity to define patient groups and direct therapy through the use of immunohistochemistry (IHC; the assessment of protein expression in fixed tissue sections) or by flow cytometry.

Immunohistochemical staining is carried out on formalin-fixed, paraffin-embedded tissue or, less commonly, on frozen sections. Immunocytochemistry (ICC) uses the same methods and reagents but on fine-needle aspirates. Antibodies to specific proteins are applied to the tissue, generally followed by a secondary antibody of a different species than the patient or the primary antibody. The secondary antibodies are conjugated to enzymes that catalyze

a color change when substrate is added. This method allows pathologists to identify individual cells that do or do not express the protein of interest and to put these cells in the context of tissue architecture.

In veterinary oncology, IHC is most commonly used to distinguish sarcomas from carcinomas and to phenotype lymphomas. The first application involves staining tumor sections with antibodies to the cytoskeletal proteins vimentin and cytokeratin. Vimentin is found in mesenchymal origin tumors (e.g., osteosarcomas, fibrosarcomas). Cytokeratin is expressed by epithelial origin cancers (carcinomas). Although the distinction between these two types of tumors is generally straightforward, when there is doubt, it is common to request vimentin/cytokeratin staining (see Chapter 3).

IHC is particularly important in subclassifying lymphoma. The 2008 World Health Organization (WHO) classification of lymphomas describes greater than 40 lymphoproliferative disorders (lymphoma and leukemia) in humans.⁴³ All subclassifications begin with phenotype (B- versus T-cell). The origin and biologic behavior of different subclassifications of lymphoma are different enough that it is not scientifically justified to consider lymphoma a single disease. Therefore, when conducting therapeutic trials, epidemiologic studies, and any other types of analyses on canine lymphoma, it will be necessary to examine individual subtypes separately (Figure 8-5).

The antibodies used to determine the B- or T-cell origin of lymphoma in formalin-fixed sections are anti-CD3 (which identifies T-cells) and one of several anti-B-cell antibodies, including CD79a, Pax5, and CD20. All of these antibodies recognize the cytoplasmic portions of the target antigen—the process of fixation permeabilizes cells to allow antibodies access to these epitopes. The antibodies also recognize conserved regions of the proteins and are therefore useful in a variety of different species. Further subclassification of lymphoma is possible based on the distribution of neoplastic cells within the lymph node. For example, there are a number of neoplasms of mature B-cells with very different outcomes: SCL, mantle cell lymphoma, and follicular lymphoma (FL). These can be differentiated by examining architecture of a lymph node stained with B-cell antibodies. In human patients, they can also be differentiated by flow cytometry (see later) or cytogenetic studies. The human classification has been applied to canine lymphoma by a consortium of pathologists who reached broad but not perfect agreement about histologic subtypes.⁴⁴ There is still a paucity of data, however, on the biologic behavior of these subtypes in dogs.

An alternative method of immunophenotyping lymphomas is flow cytometry. Flow cytometry analyzes cells in single-cell suspension. The flow cytometer uses lasers to identify characteristics of the cells, including their size, their complexity, and the proteins they express on their cell surface. The latter requires that the cells are stained with antibodies, which are conjugated to various fluorescent proteins. Flow cytometry is an extremely powerful tool because for each individual cell in the suspension, the expression of up to 10 different proteins can be analyzed routinely, and even higher numbers are possible. The value of this kind of analysis is highlighted in human medicine by the approach to a patient with circulating neoplastic mature B-cells. The differential diagnosis includes CLL, leukemic mantle cell lymphoma, marginal zone lymphoma, and FL. In all four entities, the cells will express the B-cell antigen CD20, but only mantle cell lymphoma and CLL express CD5. The latter two can then be distinguished from one another by expression of a series of additional surface proteins, which can be examined simultaneously by flow cytometry.⁴⁵

Flow cytometric phenotyping has advantages and disadvantages compared with IHC. As noted above, the advantages are that multiple parameters can be analyzed at once and objective data obtained about each parameter. Information about cell size and granularity and the levels of expression of different antigens have prognostic significance.⁴⁶⁻⁴⁸ Because formalin fixation damages proteins, most of the cell surface proteins examined by flow cytometry cannot be identified in tissue sections, so less information about protein expression is available by IHC. Flow cytometry can be carried out on lymph node aspirates, precluding the requirement of sedation and a biopsy.

IHC, however, allows the pathologist to view the architecture of the node. Veterinary pathologists recognize many of the WHO categories of lymphoma, including diffuse large B-cell lymphoma, FL, and mantle cell lymphoma. One study systematically evaluated outcome using contemporary classifications and found that small cell T-zone lymphoma had the most favorable outcome, whereas Burkitt-like B-cell lymphoma had the worst.⁴⁹ This study was small but revealed the value of classifying and subclassifying lymphomas using contemporary standards. More recently, an investigation of canine indolent T-cell lymphoma, which is a diagnosis that can only be made by histology coupled with IHC, revealed that treatment of this form of lymphoma with a CHOP-based protocol resulted in the same outcome as treatment with chlorambucil and prednisone. This is the first study clearly demonstrating the utility of histology and IHC in guiding treatment decisions.⁵⁰ When additional outcome-based investigations are performed and veterinary pathologists are more widely knowledgeable about the WHO classification scheme, the added expense and invasiveness of a biopsy over flow cytometry will be justified.

Proteomics

Proteomics is the large-scale and high-throughput study of proteins, including their identification, structure (e.g., posttranslational modifications), and function.⁵¹ Proteomics, like gene expression profiling, is often comparative, and differences in protein expression in cell lysates or tissues in various conditions (e.g., neoplastic versus normal) are measured. The proteome is a dynamic entity that is much less stable and more complicated than the genome. Protein expression is influenced by translation, protein activation (most often by phosphorylation) or other posttranslational modifications, and also protein turnover and degradation. Thus the protein complement in a disease state is not solely defined by its genetic expression pattern and can change quickly over time. Because proteins are the molecules that execute cell or tissue processes, their identification globally is thought to be a more accurate “snapshot” of cell status than either the genomic sequence or gene expression at the RNA level. Thus far, proteomics has led to better understanding of cancer and identification of potential markers for diagnosis and prognosis. However, routine clinical application of proteomics is still developing.

A recent review describes proteomics and proteomics techniques in detail.⁵² A typical proteomics experiment, the aim of which is to identify a large number of proteins in a complex mixture, requires multiple steps. These steps can include protein solubilization, separation into less complex fractions, mass spectrometric measurement of peptide masses, and finally protein identification via database searching. Separation of a mixture of proteins can be performed using one-dimensional polyacrylamide gel electrophoresis (1D-PAGE) (separation by size), two-dimensional PAGE (separation by isoelectric point, then size), liquid chromatography (separation of soluble proteins or peptides based on their physical

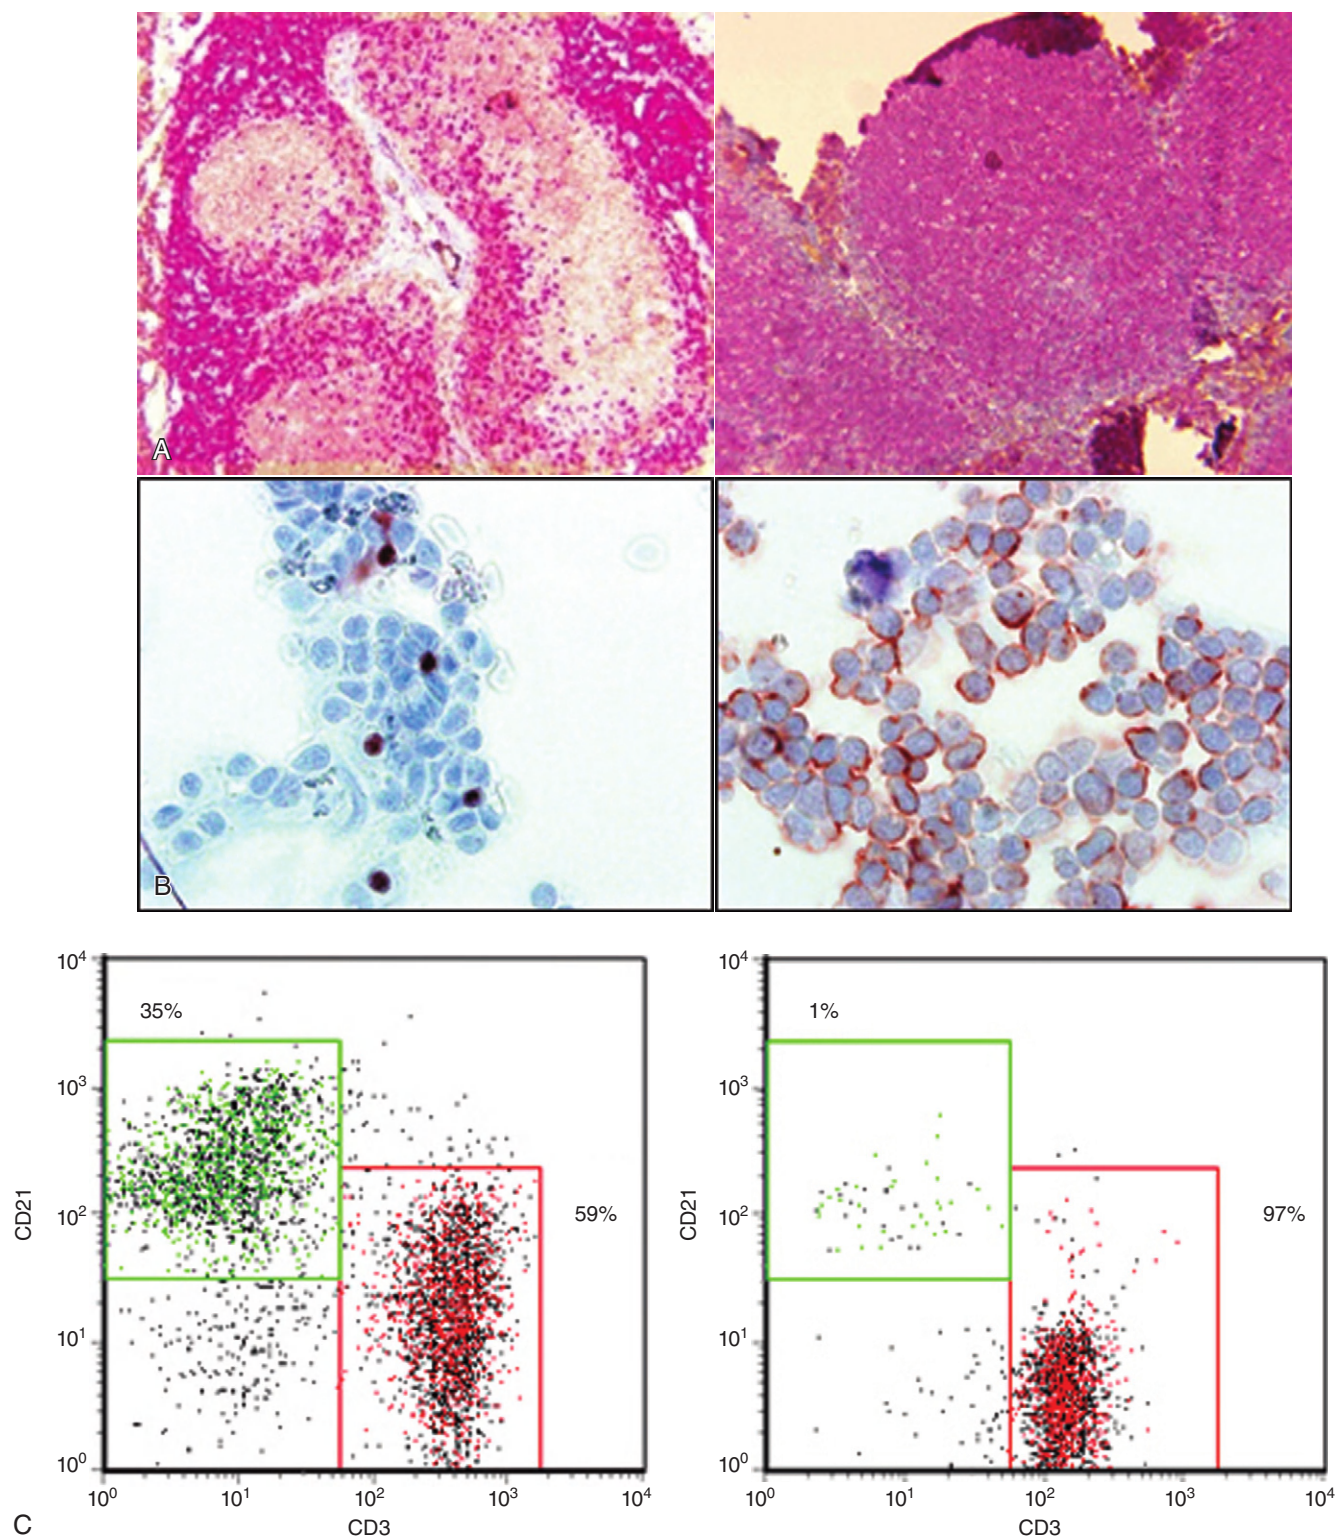

FIGURE 8-5 Two methods for determining immunophenotype in a T-cell lymphoma. **A**, Immunohistochemical staining of a normal lymph node (*left*) and a T-cell lymphoma (*right*). The brown stain in the left panel is the result of binding by anti-CD79a, and indicates the B-cell regions of the lymph node. The red staining indicates binding by anti-CD3 and highlights the T-cell regions of the lymph node. The panel on the right reveals a node effaced by T-cells (T-cell lymphoma). **B**, Immunocytochemical staining of a T-cell lymphoma, showing staining with anti-Pax5 on the left (a B-cell specific antibody) and anti-CD3 on the right. **C**, Flow cytometry staining of a T-cell lymphoma (*right panel*) and a normal lymph node (*left panel*). Each dot represents a cell, which is plotted on the histogram based on the amount of CD3 staining (*x axis, red box*) and CD21 staining (*y axis, green box*) for identifying T-cells and B-cells, respectively. The percentage of total cells in the node is indicated in each box. The lymph node from the dog with T-cell lymphoma contains T-cells almost exclusively, which, in a separate staining reaction, were shown to be CD4+.

properties), or a combination. Once proteins are separated, they are digested with an enzyme into a mixture of peptides. These peptides are applied to a mass spectrometer and their mass-to-charge ratio is measured. A list of measured masses is searched against theoretical peptide masses generated from “in silico” digestion of proteins translated from genomic databases.

There are several types of spectrometers, which vary by their ionization technique and method of mass-to-charge measurement. Briefly, electrospray ionization introduction and ionization of the sample occur in the liquid phase. For matrix-assisted laser desorption ionization (MALDI), the sample is mixed with a matrix (organic acid) and allowed to co-crystallize on a target (metal plate). Biomarker discovery has been performed using a specific application of MALDI-mass spectrometry called *surface-enhanced laser desorption/ionization* (SELDI) mass spectrometry. The separation of proteins for SELDI is performed directly on the plate, which contains specific materials designed to retain certain proteins. SELDI produces a profile of mass spectrometric masses (protein profiling), rather than actual protein identification. This technique was originally described as being highly sensitive and specific for identifying individuals with ovarian cancer,⁵³ although the interpretation of the spectral data has been difficult to reproduce.⁵⁴ This underscores the fact that, regardless of the initial promise of a diagnostic method, it is still necessary to use appropriate study design and statistical analysis (as with any other test).

A recent study demonstrates the utility of proteomic analysis in the study of cancer. Klose et al⁵⁵ asked if progression from hyperplastic mammary tissue to neoplastic and then metastatic disease was associated with changes in protein expression in humans. They compared normal mammary tissue, mammary adenomas, mammary carcinomas (nonmetastatic), and carcinomas that had metastasized. Among their most significant findings was that, while the histologic appearance of nonmetastatic and metastatic tumors was not different, the proteins they express were significantly different. This kind of study can lead directly to the development of prognostic markers, which can be used in routine IHC, and also serves to identify good and poor prognosis patients.

Summary

Molecular diagnostics is becoming more integrated into veterinary medicine and at the same time becoming more affordable. One important feature of such advanced diagnostics is that many of them save money for owners and preclude invasive procedures for their pets. Sensitive methods for detecting lymphoma through a combination of cytology, flow cytometry, and PARR assays, for example, can mean that a diagnosis of splenic lymphoma can be made without splenectomy. Detection of the *c-kit* mutation can guide therapy so that the most efficacious (and therefore cost-effective) drugs are used. More expensive exploratory techniques such as whole genome sequencing and proteomic analysis of tumors will almost certainly lead to discovery of new testing that can further simplify diagnoses. Veterinarians are encouraged to participate in these developmental studies when they can, by providing biologic materials and clinical data to researchers, because ultimately patients and their owners will derive great benefit from current research.

Biopsy Principles

9

NICOLE P. EHRHART AND STEPHEN J. WITHROW

A biopsy refers to a procedure that obtains a tissue specimen for microscopic (i.e., histopathologic) analysis to establish a precise diagnosis. Histopathologic interpretation of tissue removed from a tumor is not infallible and is highly dependent on the quality of the biopsy sample submitted. Therefore it is important to understand basic principles of biopsy procurement and submission in order to obtain an accurate diagnosis. If the tissue diagnosis is incorrect, all subsequent steps in the treatment of the patient will also be incorrect.

Fine-needle aspiration cytology (FNAC) is a simple and rapid way to obtain information about a tumor and is often the first step in the diagnostic work-up (see Chapter 7). Results of FNAC help guide the diagnostic tests for staging. Studies have shown that FNAC is a reliable and useful method to guide further work-up when neoplasia is suspected or, in many cases, to help rule out neoplasia altogether.^{1,2} Nonetheless, FNAC gives only limited information and may be nondiagnostic or equivocal. Inflammation, necrosis, and hemorrhage may result in cytopathologic changes that do not accurately represent the underlying disease process. Histologic confirmation is therefore required for definitive diagnosis of neoplasia.

Many techniques are available for obtaining tissue specimens—ranging from needle-core techniques to complete excision. The choice of technique depends on the anatomic location of the tumor, the patient's overall health, the suspected tumor type, and the clinician's preference. Biopsy techniques can be grouped under one of two major categories: pretreatment biopsy (e.g., needle core biopsy, punch biopsy, wedge biopsy) or excisional biopsy. Pretreatment biopsy is performed in order to obtain additional information about the tumor prior to definitive treatment. Posttreatment (i.e., excisional) biopsy refers to the process of obtaining histopathologic information following surgical removal of the tumor. Excisional biopsy is best used to obtain a more complete picture of the disease process (e.g., histologic subtype, tumor grade, degree of invasion into regional vasculature and lymphatics) and provides an opportunity to evaluate completeness of excision. It is rarely the best first step in obtaining a tissue diagnosis. Although excisional biopsy is attractive to many clinicians because it allows for definitive treatment and diagnosis in one step, it is often used inappropriately in the management of a cancer patient, resulting in incomplete surgical margins. Incomplete surgical margins may result in local recurrence, the need for radiation therapy, or a wider, more extensive surgery. All of these sequelae represent compromise of the optimum treatment pathway for the patient and will involve more morbidity and expense than a properly performed first excision. The issue to be determined before surgery is: how aggressive should the surgery to remove the tumor be? It is intuitive that wide, ablative surgery (e.g., body wall resection) would be inappropriate for a simple

lipoma. It also follows that marginal excision (“shell out”) is inappropriate for definitive treatment of an aggressive tumor, such as a soft tissue sarcoma. Thus thorough knowledge of the tumor type is imperative prior to attempting surgical excision. The best way to obtain this information is often via pretreatment biopsy.

Specific indications for pretreatment biopsy are as follows:

1. When fine-needle aspirate cytology is nondiagnostic or equivocal.
2. When the *type* of recommended treatment (radiation versus chemotherapy versus surgery) would be altered by knowledge of the tumor type or grade.
3. When the *extent* of recommended treatment (ablative surgery versus wide excision versus marginal excision) would be altered by knowledge of the tumor type or grade.
4. When the tumor is in a *difficult area to reconstruct* (maxillectomy, locations requiring extensive flaps, head and neck) and planning is needed to prepare the patient and client appropriately.
5. When knowledge of the tumor type or grade would *change the owner's willingness to go forward* with curative-intent treatment.

If any one of the listed criteria is met, a pretreatment biopsy should be pursued.

There are occasions when pretreatment biopsy would be contraindicated. These include cases when the type of treatment or extent of surgery would not be changed by knowing the tumor type (e.g., testicular mass, solitary splenic mass) or when the surgical procedure to obtain the biopsy is as risky as definitive removal (e.g., spinal cord biopsy). In these cases, the patient would best be served by excisional biopsy of the tumor if staging results support this choice.

Biopsy Methods

The more commonly used methods of tissue procurement are needle core biopsy, punch biopsy, incisional (wedge) biopsy, and excisional biopsy.

Needle Core Biopsy

Needle core biopsy utilizes various types of needle core instruments (e.g., Tru-Cut [Baxter General Healthcare, Deerfield, IL] or ABC needle [Kendall Sherwood-Davis & Geck, St. Louis, MO]) to obtain soft tissue (Figure 9-1). Most of these needles are manually operated, although spring and pneumatically powered needles are available as well. Specialized core instruments are used for bone biopsies and will be covered in Chapter 24. These instruments are generally 14-g in diameter and procure a piece of tissue that is about 1 mm wide and 1.0 to 1.5 cm long. In spite of this small sample size, the

• **FIGURE 9-1** Mechanism of action of needle core biopsy for typical nodular tumor. **A**, A small skin incision is made with a Number 11 blade to allow insertion of the instrument. With the instrument closed, the outer capsule is penetrated. **B**, The outer cannula is fixed in place, and the inner cannula with the specimen notch is thrust into the tumor. The tissue then protrudes into the notch. **C**, The inner cannula is now held steady while the outer cannula is moved forward to cut off the biopsy specimen. **D**, The entire instrument is removed closed with the tissue contained within it. **E**, The inner cannula is pushed ahead to expose the tissue in the specimen notch.

structural relationship of the tissue and tumor cells can usually be visualized by the pathologist. Virtually any accessible mass can be sampled by this method. It may be used for externally located lesions or for deeply seated lesions (e.g., in the kidney, liver, or prostate) with image-guidance via closed methods or at the time of open surgery.

The most common usage of the needle core biopsy is for externally palpable masses. Except for highly inflamed and necrotic cancers (especially in the oral cavity), in which incisional biopsy is preferred, most biopsies can be done on an outpatient basis with local anesthesia and sedation. The area to be biopsied should be clipped of hair and sterilely prepared. The skin or overlying tissue is prepared as for minor surgery. If the overlying tissue (usually skin and muscle) is intact, it is anesthetized using local anesthetic in the region that the biopsy needle will penetrate. Tumor tissue itself is very poorly innervated and generally does not require local anesthesia. The mass is then fixed in place with one hand or by an assistant. A small 1- to 2-mm stab incision is made in the overlying skin with a scalpel blade to allow insertion of the biopsy instrument. The stab incision is necessary to prevent dulling of the needle tip and allow better penetration into the underlying tissue. Through the same skin hole, several needle cores are removed from different sites to get a “cross-section” of tissue types within the mass. The stab incision can be sutured with a single interrupted suture. The tissue is gently removed from the instrument with a scalpel blade or hypodermic needle and placed in formalin. For smaller-gauge biopsy needle instruments, the tissue may be flushed off the needle with saline. Samples may be gently rolled on a glass slide for cytologic preparations before fixation. With experience, the operator

can generally tell from the appearance of the core sample whether diagnostic material has been attained. Small, discontinuous bits of tissue and fluid within the trough will only rarely be diagnostic and usually imply the need for incisional biopsy. Soft tissue sarcomas in particular may not yield good tissue cores because of necrosis and fibrous septa that often permeate the mass. Cystic masses are also problematic.

Needle biopsy tracts are of minimal risk for local tumor seeding but should be removed en bloc with the tumor at subsequent resection. Therefore it is important to plan where the stab incision and needle biopsy tract are placed in order to make the subsequent excision simpler. Avoid excessive tunneling through uninvolved tissues by choosing the most direct path from the skin to the tumor to obtain a representative sample.

Many of these needles are “disposable” with plastic casings and therefore cannot be steam sterilized. It is not uncommon, however, for veterinary practices to resterilize these instruments (using ethylene oxide or hydrogen peroxide gas) and use them repeatedly until they become dull.

Needle core biopsy instruments are inexpensive and easy to use, and needle core biopsy procedures can be performed as outpatient procedures. They are generally more accurate than cytology but likely have lower accuracy than larger incisional or excisional biopsy, especially when a tumor is heterogeneous, inflamed, or cystic or contains a large amount of necrosis. It is important to understand that for a 5-cm diameter mass, one needle core biopsy sample represents less than 1% of the tumor tissue. The smaller the biopsy specimen obtained, the less representative it may be for the entire tumor.

Needle core biopsy can be performed with the aid of image-guidance (discussed in greater detail later). Utilization of image-guidance for needle core biopsy is helpful for obtaining tissue from deeply seated lesions. Ultrasound-, fluoroscopic-, and computed tomographic-assistance may be used to obtain samples from tumors located in areas where percutaneous biopsy would be risky or unlikely to yield a representative sample. In situations in which the lesion is located within a body cavity, the risk of tumor seeding from uncontrolled hemorrhage or fluid leakage as a result of image-guided biopsy must be taken into account when determining if image-guided needle core biopsy techniques hold an advantage over more direct access in a given circumstance.

Punch Biopsy

Punch biopsy tools were originally designed for biopsy of the skin (Figure 9-2). They deliver a shorter and wider (2 to 8 mm) biopsy than does the needle core technique. They can be used on any external tumor (skin, oral, perianal) or tumors where there is direct access (e.g., liver biopsy during laparotomy). Preparation of the site is the same as for needle core biopsy. If the lesion is cutaneous, the punch biopsy instrument is placed on the surface of the area of interest and rotated back and forth using pressure to penetrate the involved tissue. If the skin is intact over the tumor, the skin is first incised using a scalpel. The punch is then introduced through the skin incision to the surface of the tumor. Once the punch has cut into the tumor, the core is gently lifted and the base of the core is cut off with scissors. One or two sutures may be placed to close the skin incision.

Incisional Biopsy

Incisional biopsy is utilized when fine-needle cytology or needle core biopsy has not yielded or is unlikely to yield diagnostic material (Figure 9-3). Additionally, it is preferred for ulcerated and

• **FIGURE 9-2** Mechanism of punch biopsy. **A**, Punch is rotated back and forth over suspect lesion until sufficient depth has been attained. **B**, Punch is removed or angled across base to sever deep attachments. **C**, Specimen may be “gently” grasped with thumb forceps and cut off deeply.

necrotic lesions because larger samples can be obtained, making it more likely to sample representative areas. Most tumors are poorly innervated and may be biopsied without the need for local anesthesia or sedation as long as the overlying normal skin and tissue has been anesthetized. Preparation involves clipping the hair over the incision site. After performing a sterile surgical preparation, surgical drapes are used to protect the field from the surrounding environment. Under sterile conditions, the skin over the tumor, if intact, is incised and a wedge of tumor tissue is removed from the mass. It is not necessary to remove a wedge of intact skin overlying the tumor if it appears to be normal and not fixed to the underlying tumor. The surgeon should confirm at the time of the biopsy that they have not simply removed a small section of the reactive tissue surrounding the tumor. This can be difficult in some cases, however, because most tumors have coloration and texture that is distinct from the surrounding normal and reactive tissue. If needed, “touch-prep” cytology slides can be made using the resected tissue prior to fixation to confirm that neoplastic cells are present in the removed tissue.

Many authors have recommended that the surgeon acquire a composite biopsy of normal and abnormal tissue to ensure accuracy in diagnosis on histopathologic examination. Although this may be helpful to the pathologist in benign skin disease and subtle lesions, it is not recommended in cases where neoplasia is suspected because this may compromise the surgical margin needed to remove the mass entirely at the time of definitive surgery and exposes previously uninvolved tissues to freshly incised tumor. Instead, a representative sample of the tumor itself should be submitted. This may require obtaining multiple samples via the same incision to ensure that a representative sample has been achieved.

Care must be taken to ensure that any biopsy tract (incisional or other) will not compromise subsequent curative resection or contaminate uninvolved tissue needed for reconstruction. The surgeon should avoid wide exposure of uninvolved tissue planes that could become contaminated with released tumor cells. Small incisions, even through expendable muscle bellies, are preferred to contaminating the entire intramuscular compartment. The incisional biopsy tract is always removed in continuity with the tumor at the time of curative-intent resection.

Specialized Biopsy Techniques

Specialized biopsy techniques will generally be covered under the specific individual tumors. However, some general comments follow.

Endoscopic Biopsies

Endoscopic biopsy techniques use flexible or occasionally rigid scopes that allow visualized or blind biopsy of hollow lumens, especially gastrointestinal, respiratory, and urogenital systems. Although these techniques are convenient, cost effective, and generally safe, they may suffer from inadequate visualization and limited biopsy sample size when compared with other techniques. For example, an endoscopic biopsy result of ulcerative gastritis in a dog with a firm, infiltrative mass of the lesser curvature of the stomach does not rule out gastric adenocarcinoma.

Laparoscopy and Thoracoscopy

Evaluation of the abdomen and thorax via minimally invasive techniques, when performed by an experienced operator, can procure tissue for biopsy and yield important information regarding the

• **FIGURE 9-3** Excisional (*top*) contrasted with incisional (*bottom*) biopsy. The top tumor may be as easy to remove as to biopsy, and removal may not negatively influence other possible treatments (e.g., more surgery, radiation). The bottom tumor, however, requires knowledge of the tumor type prior to excision because inappropriate removal could compromise a subsequent aggressive excision (short of amputation). Note that the biopsy incision is in a plane that would be included in a subsequent resection.

locoregional stage of disease. Additionally, laparoscopic- and thoracoscopic-assisted removal results in smaller incisions and rapid recovery times when compared with open procedures. The option to convert to an open procedure is available if problems are encountered that cannot be adequately addressed using minimally invasive methods. As operators become more proficient at these techniques, more options become available for tumor removal.

Image-Guided Biopsy

Diagnostic imaging has greatly expanded the ability to stage various neoplasias. The use of positron emission tomography-computed tomography (PET-CT) in veterinary medicine has also led to significant advances in sentinel node mapping, novel staging methods, and the ability to assess response to treatment. In addition, the use of radiographic, fluoroscopic, ultrasonographic, computed tomographic, and magnetic resonance image-guided needle aspirates or core biopsies can obviate the need for more invasive diagnostic procedures. Common sites for image-guided biopsy include lung, kidney, liver, spleen, prostate, and, more recently, brain.

Excisional Biopsy

Excisional biopsy is utilized when definitive treatment would not be altered by knowledge of tumor type (e.g., “benign” skin tumor, solitary splenic mass, testicular tumor). It is more frequently performed than indicated, but, when used on properly selected cases, it can be both diagnostic and therapeutic, as well as cost effective.

General Guidelines for Tissue Procurement and Fixation

- When properly performed, a pretreatment biopsy will *not* negatively influence survival.³ The metastatic cascade involves a series

of complex events that are not altered by the number of neoplastic cells in circulation. On the other hand, neoplastic cells can contaminate the *local* tissues surrounding the mass and in some cases, successfully attach and grow within these normal tissues. Careful hemostasis, obliteration of dead space, and avoidance of seromas or hematomas will minimize local contamination of the incisional biopsy site. Definitive surgery to remove the tumor along with the associated biopsy tract should take place as soon as possible following the biopsy procedure. If possible, surgical drains should not be placed in biopsy sites because the drain tract can become contaminated with tumor cells and seed them through uninvolved tissue planes. In particular, care should be taken not to “spill” cancer cells within the thoracic or abdominal cavities during biopsy where they may seed pleural or peritoneal surfaces.

- When biopsies are performed on the legs or the tail, the incision should be longitudinal and not transverse. Transverse incisions are much harder to completely resect. If a biopsy is near midline, the incision should be oriented parallel to midline.
- Avoid taking the junction of normal and abnormal tissue for pretreatment biopsy unless a margin is likely necessary for differentiating benign or malignant tumors (e.g., perianal adenoma or adenocarcinoma often can only be differentiated histologically by observing local tissue infiltration). Care should be taken not to incise normal tissue that cannot be resected or would be used in reconstructing the surgical defect. Avoid biopsies that contain only ulcerated or inflamed tissues.
- The larger the sample, the more likely it is to be diagnostic. Tumors are not homogeneous and usually contain areas of necrosis, inflammation, and reactive tissue. Several samples from one mass are more likely to yield an accurate diagnosis than a single sample.
- Biopsies should not be obtained with electrocautery because it tends to deform (autolysis or polarization) the cellular

architecture. Electrocautery is better utilized for hemostasis after blade removal of a diagnostic specimen.

- Care should be taken not to unduly deform the specimen with forceps, suction, or other handling methods prior to fixation.
- Intraoperative diagnosis of disease by frozen sections, although not routinely available in veterinary medicine, has enjoyed widespread use in human oncology. Special equipment and training are required for this technique to be fully utilized. One study in veterinary medicine revealed an accurate and specific diagnosis rate of 83%.⁴
- If evaluation of excisional margins is desired, the surgeon should indicate the surgical margin on the specimen using tissue ink. Several commercial inking systems are available for this use. The resected tissue should be blotted with a paper towel because dyes will adhere better to the tissue when it is slightly tacky. The tissue ink is “painted” on the surgical margins using a cotton swab. The dye is allowed to dry for up to 20 minutes before the tissue is placed in formalin. Tissue already fixed in formalin can be marked; however, dye adherence is lessened and drying time is extended. When the pathologist sees tumor cells at the inked edge, it is a certainty that tumor cells have been left in the patient. Different-colored inks can also be used to denote different sites on the tumor, such as proximal margin or deep margin near nerve. Even with inking, proper fixation, and processing, the clinician must realize the entire margin will not be examined by the pathologist. Rather, representative sections will be obtained from the inked margin. Therefore any guidance that the clinician can give to the pathologist as to the most important sections to look for tumor cells will help the pathologist pay closer attention to such areas. It is vital that the pathologist and the clinician communicate if the pathology report is confusing or does not match the clinical picture. Of course, margin evaluation is only necessary for excisional biopsy or curative-intent surgery and does not apply to needle core biopsies or incisional biopsies, which by definition will have inadequate margins. Incomplete surgical resection of malignant disease is best detected early so that further surgery or other adjuvant therapies can be instituted immediately, as opposed to waiting for local recurrence or metastasis.
- Stainless steel vascular clips in the resected specimen will damage the microtomes used by the pathology laboratory. Remove them before the tissue is submitted.
- Proper fixation is vital. Tissue is generally fixed in 10% buffered neutral formalin with 1 part tissue to 10 parts fixative. If more than one lesion has been biopsied, they should each be placed in a separate container. Certain tissues such as eye, nerve, and muscle may require special fixation techniques. The clinician may want to consult with the pathologist on how to submit tissue for special circumstances.
- Tissue should not be thicker than 1 cm or it will not fix properly. Masses greater than 1 cm in diameter can be sliced like a loaf of bread, leaving the deep-inked margin intact, to allow fixation. Extremely large masses can be incompletely sliced as described above, fixed in a large bucket of formalin for 2 to 3 days and then shipped in a container with 1 part tissue to 1 part formalin. A less ideal but alternative approach is to have the surgeon take representative smaller samples from the mass (e.g., soft and hard pieces, red and pale pieces, deep and superficial pieces) in the hope that one of them is diagnostic. The rest of the mass can be saved in the clinic in formalin in case more tissue needs to be evaluated. This extra tissue should never be frozen. Freezing causes severe tissue artifact.

- A *detailed* history should accompany all biopsy requests. Interpretation of surgical biopsies is a combination of art and science. Without vital diagnostic information (e.g., signalment, history of recurrences, invasion into bone, rate of growth), the pathologist will be significantly compromised in his or her ability to deliver accurate and clinically useful information.
- A veterinary-trained pathologist is preferred over a pathologist trained in human diseases. Although many cancers are histologically similar across species lines, enough differences exist to result in interpretive errors.

In 2011, the American College of Veterinary Pathologists, along with several medical and surgical oncologists, published a comprehensive set of recommendations and guidelines for submission, trimming, margin evaluation, and reporting of tumor biopsy specimens.⁵ This seminal paper was the first collaborative attempt to standardize pathology reporting in veterinary oncology and has been endorsed by a large international group of veterinary pathologists and oncology specialists. It is recommended that clinicians utilize diagnostic laboratories that adhere to these guidelines so that results are standardized and easier to interpret.

Interpretation of Results

The pathologist's task is to determine (1) tumor versus no tumor, (2) benign versus malignant, (3) histologic type, (4) grade (if applicable), and (5) margins (if excisional). Making an accurate diagnosis is not as simple as putting a piece of tissue in formalin and waiting for results. Many pitfalls can occur that render the end result inaccurate. Potential errors can take place at any level of the process, and it is up to the clinician to interpret the full meaning of the biopsy result. In cases in which the biopsy result does not correlate with the clinical scenario, a second opinion should be pursued. A study published in 2009 reviewed first and second opinion histopathology reports.⁶ In 70% of cases, there was diagnostic agreement between first and second opinion results. In 20% of cases, there was partial agreement where the diagnosis did not change, but information such as grade or presence of lymphatic or vascular invasion was disparate. In 10% of cases reviewed, there was complete diagnostic disagreement. Of these, 7% were a disagreement between malignant versus nonmalignant and 3% were disagreements about cell origin. If the biopsy result does not correlate with the clinical scenario, the following several options are possible:

1. Call the pathologist and express your concern over the biopsy result. This exchange of information should be helpful for both parties and not looked on as an affront to the pathologist's authority or expertise. It may lead to the following:
 - a. Resectioning of available tissue or paraffin blocks.
 - b. Special stains for further discrimination of tumor types (e.g., toluidine blue for mast cells).
 - c. A second opinion by another pathologist.
2. If the tumor is still present in the patient and particularly if widely varied options exist for therapy, a second (or third) biopsy should be performed.

A carefully performed, submitted, and interpreted biopsy is the most important step in management and subsequent prognosis of the patient with cancer. The biopsy report is key in decisions regarding prognosis, therapeutic options, and overall case management. All too often tumors are not submitted for histologic evaluation after removal because “the owner didn't want to pay for it.” Histopathologic interpretation should not be an elective owner decision. Instead, it should be as automatic as closing the skin after

surgery. The charge for submission and interpretation of the biopsy should be included in the surgery fee if need be, but histopathology interpretation is not optional. Because of increasing medicolegal concerns, it is not medical curiosity alone that mandates knowledge of tumor type. Understanding how and when to perform a biopsy, how to submit a biopsy specimen, and how to interpret the report is of paramount importance in the treatment of veterinary cancer patients.

Surgical Oncology

10

JAMES P. FARESE AND STEPHEN J. WITHROW

Complete surgical removal of localized cancer cures more cancer patients than any other form of treatment,¹ in part because this modality is generally applied as sole treatment for local disease, early stage disease, or tumors with limited potential to metastasize. In humans, 60% of patients who are cured of cancer are cured by surgery alone.² Before this hope for cure can be realized in veterinary medicine, surgeons must have a thorough understanding of anatomy, physiology, resection, and reconstruction options for all organs; expected tumor behavior; and the various alternatives or adjuvants to surgery. Surgical oncologists should not only be good technical surgeons, but also dedicated tumor biologists. Surgery will likely play a role at one point or another in the management of most cancer patients. Surgical procedures may include any of the following: diagnosis (biopsy), resection for cure, palliation of symptoms, debulking (tumor cell cytoreduction), and a wide variety of ancillary procedures to enhance and complement other forms of treatment.

Surgical resection of cancer was introduced in the sixteenth century BCE and remained relatively underutilized until general anesthesia (1840s), antiseptics (1860s), and pain management made aggressive resection safe and tolerable for the patient. Dr. William Halstead developed the basic principles of surgical oncology in the 1890s. The radical resection of the twentieth century has increasingly been customized to meet the needs of the patient and has frequently been reduced in magnitude. Further refinements in surgery have been made possible with newer equipment (e.g., staples, endoscopy), advanced imaging, pain management, use of blood products, and critical care services.

Most patients with cancer are “old.” However, “old” is a relative term, and a geriatric dog or cat with normal organ function should not be denied treatment simply on the basis of age. Age has not been shown to impact tumor-related prognosis. In fact, dogs with osteosarcoma that are less than 2 years of age do worse than dogs that are more than 2 years of age after amputation alone.³ “Old” animals, in most instances, will tolerate aggressive surgical intervention as well or as poorly as “young” patients.

Surgery for Diagnosis

Although biopsy principles are covered in Chapter 9, it bears emphasizing that properly timed, performed, and interpreted biopsies are one of the most crucial steps in the management of the cancer patient. Not only does the surgeon need to procure adequate and representative tissue to establish a diagnosis, but also the biopsy must not compromise subsequent curative surgical resection or radiation field planning.

Surgery for Cure

Before a surgeon can be in a position to provide the optimal operation for the patient with cancer, the following questions need to be considered:

1. What is the histologic type, stage, and grade of cancer to be treated?
2. What are the expected local and systemic effects of this tumor type, grade, and stage?
3. Is a cure possible and at what price in terms of cosmetics and function?
4. Is an operation indicated at all?
5. What are the options for alternative or planned combination treatment?

A recurring theme in surgical management of cancer is that the first surgery has the best chance of cure. Several mechanisms for this improvement in survival have been advanced. Untreated tumors have had less chronologic time to metastasize than recurrent primary cancer. Untreated tumors and proximate normal tissues have near normal anatomy, which will facilitate operative orientation and maneuvers. Recurrent tumors may have had seeding of previously noninvolved tissue planes, requiring wider resection than would have been required on the initial tumor. If one thinks about a given cancer as resembling a crab, incomplete surgery removes the body of the crab and leaves the legs behind. The “body” of most tumors is often quiescent and hypoxic, whereas the leading edge of the tumor (legs) is the most invasive and well vascularized. Subtotal removal may actually selectively leave behind the most aggressive components of the tumor. Patients with recurrent cancer will often have less normal tissue for closure. An ill-defined negative aspect of recurrent cancer is reported to be related to changes in vascularity and local immune responses. Regardless of the mechanism, curative-intent surgery is best performed at the first operation and the surgeon should have all the necessary diagnostic information in hand when constructing a treatment plan. Radiography and ultrasonography have been routine for many years, and the increased availability of computed tomography (CT) has added greatly to our ability to determine the extent of a solid tumor and optimize the surgical approach. CT allows good visualization of muscle bellies/fascial planes, intraabdominal/intrathoracic organs, lymph nodes, and bone detail. Three-dimensional (3D) CT reconstructions are particularly useful for planning procedures for skull-based tumors.

Advanced imaging has greatly enhanced the surgeon's ability to assess the anatomic location and extent of various cancers; however, we must remember that imaging of any kind needs to be paired

with clinical palpation, assessment of mobility, and expected biologic behavior. Some cancers deemed inoperable by imaging are in fact mobile and operable. Leading edges of some cancers are compressed against adjacent tissue and appear more invasive. Surgeons should always take the opportunity to palpate the local tumor before or after imaging, explore the history of the tumor's growth pattern, and in many cases obtain a tissue sample (i.e., histopathology or cytology when appropriate) before declaring a mass inoperable. Positive prognostic factors typically include slow growth rate, mobility within proximate tissues, first attempt at surgery, discrete tumor borders, small tumor size, and low grade nature. Conversely, surgery may be less effective for the same tumor type and grade if the mass is ill-defined, is recurrent, or has a recent history of rapid growth. Palpation under heavy sedation or anesthesia may suggest that resection is possible in spite of imaging findings (e.g., unilateral thyroid masses, some soft tissue sarcomas). Deeper masses from locations such as ribs and liver may appear inoperable due to inflammation or compression of adjacent organs and structures; however, there actually may be no invasion present.

The surgical oncologist must be able to assimilate all of the information and make an informed decision. We must also remind ourselves and our clients that there is much we do not know (e.g., incomplete margins do not necessarily ensure later local recurrence⁴) and that surgical judgment regarding expected local behavior and likely resection is often qualitative and is an imperfect "science."

The actual surgical technique will vary with the site, size, and stage of the tumor, as well as the skill and experience of the surgeon. The same tumor type in dogs and cats may vary in surgical approach, technique, and prognosis. Some general statements that need to be emphasized with surgical oncology are as follows:

1. All incisional biopsy tracts should be excised in continuity with the primary tumor because tumor cells are capable of growth in these wounds. Fine-needle aspiration (FNA) cytology tracts are of minor, but not zero, concern, whereas punch biopsy tracts are of intermediate concern.⁵ With this in mind, all biopsies should be positioned in such a manner that they can be removed at surgery.
2. Early vascular ligation (especially venous) should be attempted to diminish release of large tumor emboli into the systemic circulation. This is probably only clinically meaningful for those tumors with a well-defined venous supply, such as splenic tumors, retained testicles, and lung tumors. Small numbers of cancer cells are constantly being released into the venous (and lymphatic) circulation by most tumors. Larger, macroscopic cell aggregates may be more dangerous, however, and these may be prevented from vascular escape with early venous ligation.
3. Local control of malignant cancer requires that a margin of normal tissue be removed around the tumor. Resection of the "bad from the good" can and should be classified in more detail than radical versus conservative (Table 10-1).⁶ Tumors with high probability of local recurrence (e.g., high-grade soft tissue sarcoma, high-grade mast cell tumors, feline mammary adenocarcinoma) should have 2- to 3-cm margins removed in three dimensions. Tumors are not flat, and wide removal in one plane does not ensure complete excision. Fixation of cancer to adjacent structures mandates removal of the adherent area in continuity with the tumor. This is commonly seen with oral cancer that is firmly adherent to the underlying mandible or maxilla. Invasive cancer should not be peeled out, shelled out, enucleated, or curetted if a cure is expected. Many cancers are surrounded by a pseudocapsule. This capsule is almost invariably composed of

• **TABLE 10-1** Classification and Resection of Wound Margins

TYPE	PLANE OF DISSECTION	RESULT
Intracapsular	Tumor removed in pieces or curetted, "debulking"	Macroscopic disease left behind
Marginal	Removal just outside or on pseudocapsule or reactive capsule, "shelled out"	Usually leaves microscopic disease
Wide	Tumor and capsule never entered, normal tissue surrounds specimen	Possible skip lesions
Radical	Entire compartment or structure removed (e.g., amputation)	No local residual cancer

compressed and viable tumor cells, not healthy reactive host cells. If a malignant tumor is entered at the time of resection, or if the margins are incomplete, that procedure is often no better therapeutically than a large incisional biopsy. When possible, resection of the previous scar and the entire wound bed with "new" margins (never entering the old wound cavity) is indicated. One should strive for a level of dissection that is one tissue plane away from the mass (Figure 10-1). For example, invasion of cancer into the medullary cavity of a bone requires subtotal or total bone resection and not curettage.

The width of surgical margins necessary for a complete excision for a given tumor type is an ongoing debate, and our current practices are based on little objective data. As a community, we have answered most of the questions about how much tissue we can safely remove, but it will serve our patients well to determine how little extra tissue is necessary to excise and consistently achieve the same success. We must challenge recommendations that are reported in the literature if based solely on a surgeon's personal experience or opinion in the absence of objective findings.

4. Tumors should be handled gently to avoid risk of breaking off tumor cells into the operative wound, where they may thrive.⁷ Copious lavage of all cancer wound beds will help mechanically remove small numbers of exfoliated tumor cells but should not replace gentle tissue handling and avoidance of entering the tumor bed.
5. If more than one malignant mass is being removed, separate surgical packs should be used for each site to avoid iatrogenic tumor cell implantation from site to site.

The aggressiveness of resection should only rarely be tempered by fears of wound closure. It is better to leave a wound partially or even in some cases completely open with no cancer than closed with residual cancer. Numerous innovative reconstructive techniques are available for closure of cancer wounds, and the surgeon is only limited by his or her ingenuity.⁸ Reliable microvascular-free composite transfers of muscle and skin are somewhat hampered due to unique canine skin/muscle anatomy but are being developed.⁹

• **FIGURE 10-1** Typical soft tissue cancer is in proximity to skin and underlying fascia. Inappropriate removal is to “peel it off” the deeper fascia, where microscopic extension is probable. Correct removal entails wide three-dimensional (3D) margins, including underlying skin and underlying fascia.

Lymph Node Removal

Controversy surrounds the surgical management of regional lymph nodes draining the primary tumor site.^{10,11} As a general rule, epithelial cancers are more likely to metastasize to lymph nodes than are mesenchymal cancers. However, any enlarged regional lymph node requires investigation for complete staging. Lymphadenopathy may be from metastasis of cancer (firm, irregular, and sometimes fixed to surrounding tissue) or from hyperplasia and reactivity to various tumor factors, infection, or inflammation.¹² The former cause is a poor prognostic sign, and the latter may be a beneficial host response. Enlarged lymph nodes as a result of cancer metastasis and invasion are generally effaced by tumor cells and can often be diagnosed by FNA. Histologically, positive lymph nodes at diagnosis usually are a sign of impending emergence of systemic metastasis. Removal of lymph nodes should be considered under the following circumstances:

1. If the lymph node is positive for cancer and not fixed to surrounding normal tissues, it may be possible to remove the node with some therapeutic intent. Frequently, however, many lymph nodes drain a primary tumor site (e.g., oral cavity) and lymphadenectomy is incomplete. Lymph node metastasis at the time of initial diagnosis is a poor prognostic sign. However, patients that develop metastasis in a delayed fashion (1 to 2 years) after local tumor control may benefit from lymphadenectomy. Although it is usually not practical, removal of the primary tumor, intervening lymphatic ducts, and draining lymph node has been recommended (en bloc resection). En bloc resection may be possible for a malignant toe tumor with metastasis to the popliteal lymph node but is usually only accomplished with amputation. A mastectomy that includes the regional lymph node (e.g., glands four and five with the inguinal lymph node) is another example of en bloc resection. Few other anatomic sites are routinely amenable to this therapy. A specific instance where local lymphadenectomy may be beneficial is in removal of iliac/sublumbar lymph nodes in patients with metastatic apocrine or sebaceous gland adenocarcinomas of the perineum. Although removal of these lymph nodes is rarely curative, it may help increase the benefit of adjuvant radiation or chemotherapy and

should help alleviate, at least in the short term, the paraneoplastic syndrome of hypercalcemia by reducing levels of parathormone-like substances. Regional lymphadenectomy may also prevent or improve obstruction of the large bowel and urinary tract and can be repeated as necessary in the absence of overt systemic metastasis (e.g., metastasis to lungs, liver).

2. It is well established that normal-sized lymph nodes may contain micrometastasis, and this point should always be explained clearly to a client. Normal-appearing lymph nodes that are known to drain a primary tumor site may be randomly sampled (biopsy or cytology) to gain further staging information. This is particularly important if adjuvant therapy decisions (irradiation or chemotherapy) would be predicated on confirmation of residual or metastatic cancer. Intrathoracic or intraabdominal lymph nodes are perhaps most crucial because they are not readily accessible to histologic or cytologic follow-up examination. However, in some instances, lymph nodes that are not enlarged cannot be sampled safely due to proximity to vital structures (e.g., sublumbar lymph nodes at the aortic bifurcation), even under ultrasound guidance. In such cases, the surgeon must educate the client about the situation and either remove the primary tumor without further knowledge of regional lymph node involvement or recommend removal of the normal-sized nodes concurrently for staging (and possibly therapeutic) purposes. For dogs with malignant anal sac tumors, this approach involves an exploratory surgery of the sublumbar nodal bed and dissection/removal of all nodal tissue encountered.

In human medicine, the concept of the sentinel lymph node (first node to receive lymphatic flow from a primary tumor) has become important in the management of select malignancies, most notably breast cancer.¹² Basically, the area of the primary tumor is injected with blue dye or a low dose of a radionuclide or both. The first draining node is detected visually or with a handheld gamma camera probe and removed for frozen section analysis. If the first node is negative for metastasis, subsequent nodal dissection often is avoided. If the sentinel node is positive, further nodal dissection is performed. Targeting the sentinel node is most valuable in an anatomic location in which there is an extensive nodal bed¹² and hence numerous potential paths for regional

metastasis. The benefits of such an approach in humans are readily apparent because many patients have been spared extensive nodal resections if the sentinel lymph node has been determined to be free of cancer cells. The topic of the sentinel lymph node has only recently emerged in veterinary medicine but is gathering some momentum.¹³ Several techniques have been described, including microbubble detection via ultrasound,¹⁴ fluorescein, and blue dye.¹⁵ Although sentinel lymph node staging may not yet have the relevance and importance that have been demonstrated in humans due to less complex nodal networks, there are several potential indications (e.g., tumors of the head and neck) that should be investigated in clinical studies. Histologically positive lymph nodes will alter prognosis and stage and will also be informative for decisions related to postoperative chemotherapy and radiation.

Lymph node removal is generally *not* performed under the following circumstances:

1. Lymph nodes in critical areas (retropharyngeal, hilar, mesenteric) that have eroded through the capsule and become adherent (fixed) to surrounding tissues. In this scenario, lymph nodes may not be removeable without leaving residual disease in the wound bed (necessitating adjuvant therapy to achieve local control) or an attempt at removal may cause serious harm to the patient by injuring important adjacent structures. In such instances, it is usually prudent to aspirate or biopsy the node to confirm involvement in the disease process and leave the node in situ or treat with other modalities. One example of an exception to this scenario is metastasis of limb and paw tumors to prescapular and popliteal lymph nodes that can be removed with amputation (radical en bloc resection).
2. Prophylactic removal of “normal” draining lymph nodes or chains of lymph nodes (as opposed to sampling for stage) is not beneficial and may be harmful.⁹ Regional lymph nodes may in fact be the initiator of favorable local and systemic immune responses, and elective removal has been associated with poor survival in certain human cancers.^{10,16,17}

Surgery for Distant Disease

Metastasectomy for pulmonary metastasis of sarcoma in *some instances* has been accepted therapy in humans and dogs. Resection of liver metastasis for carcinomas (especially gastrointestinal cancers) is increasing in human oncology. As more effective adjuvant therapies evolve and minimally invasive techniques are further developed, the need for cytoreductive metastasectomy will increase.

Palliative Surgery

Palliative surgery is an attempt to improve the quality of the patient's life (pain relief or improved function) but not necessarily the length of the patient's life.¹⁸ This type of surgery requires careful consideration of the expected morbidity of the procedure versus the expected gain to the patient and the client. In essence, it comes down to a decision of when to discontinue therapy. One of the most difficult decisions in surgical oncology is the decision not to operate. Treatment of any kind should never be worse than no treatment.

Certain situations do exist, however, in which palliative surgery may be beneficial. If an infected and draining mammary tumor in a patient with asymptomatic lung metastasis is the limiting factor in the patient's life, mastectomy may still be a logical procedure. Splenectomy for ruptured hemangiosarcoma is commonly performed but probably has little impact on long-term survival and

can be considered palliative because it will stop the immediate threat of hemorrhage.

Cytoreductive Surgery

Incomplete removal of a tumor (planned or unplanned) is referred to as debulking or cytoreductive surgery. It is commonly performed but rarely indicated.¹⁹ Its theoretical indication is to enhance the efficacy of other treatment modalities. Debulking is a practical consideration prior to cryosurgery to decrease the amount of tissue to freeze and the time it will take. It may also help the treatment planning and dosimetry with certain forms of irradiation, but the improved cancer control achieved is more a result of geometric and dosimetry considerations than intentional and incomplete removal of tumor cells. Removing 99.9% of a 1-cm tumor (1×10^9 cells, one billion) still leaves a million cancer cells behind. Immunotherapy and chemotherapy could theoretically be helped by tumor volume reduction (such as lymph node removal for oral melanoma with the use of a melanoma vaccine),^{20,21} but few well-controlled clinical trials have shown a benefit to date in veterinary medicine. A variety of soft tissue sarcomas in dogs and cats will have better local control when radiation is given adjuvantly rather than for bulky measurable disease. Amputation or limb sparing of dogs with osteosarcoma is essentially an extreme cytoreductive procedure and clearly requires postoperative chemotherapy for prolongation of life. If tumors are debulked with the anticipation of postoperative radiation therapy, the margins of known tumor or the operative field should be marked with radiopaque metal clips to allow proper treatment planning from radiographs or CT. The orientation of the incision should be considered carefully if radiation therapy is possible postoperatively.

Nonsurgical Locally Ablative Procedures

Ablative techniques to eradicate local (or metastatic) disease have a place in oncology but often suffer from “sales before science” and are only rarely based on evidence of outcomes.²² Several of these techniques will be mentioned later, and the reader is referred to accompanying references for details. Indications for the use of local ablative therapy vary but are generally limited to “small” (less than 2 cm diameter) discrete lesions. A limitation of all of the techniques is that completeness of cell kill and margin analysis cannot be determined after treatment. If the operator picked the correct tumor, site, and “dose” delivery, then local control may be achieved; however, monitoring for regrowth is the only way to ensure this. As a general rule, recurrent disease tends to be more invasive and difficult to control than the primary intervention, so the first ablative maneuver is hopefully well planned and executed. All of the local ablative treatments require special equipment and training to properly perform. Selective tumor cell kill while sparing all normal tissue is often claimed for these techniques but is unlikely to be true.

Radiofrequency Ablation

The most common nonsurgical locally ablative procedures in human medicine include radiofrequency (RF), microwave, and cryoablation. RF ablation involves delivery of a high frequency (300 to 500 KHz) alternating current via a needle-like probe. The procedure is typically performed via image guidance (e.g., ultrasound or CT) and is commonly used to treat both primary and secondary

hepatic tumors. The minimally invasive nature of the technique makes it ideal for the latter application. With hepatic metastatic colorectal cancer, RF rivals surgery for increasing 5-year survival. Microwave ablation is similar to RF, but higher frequency current (900 to 2459 MHz) is delivered through the probe. It is a newer technology with less evidence supporting its use but is often used for the same indications as RF ablation. Neither the RF nor microwave procedures have been evaluated for clinical applications in veterinary patients^{23,24}; however, some of the work done to evaluate the safety of these procedures in humans was performed experimentally in dogs.

Cryoablation

Cryosurgery, or cryoablation, is a much older form of local therapy that impacts tumors via direct cell kill and vascular collapse. It has been used extensively in veterinary medicine, most commonly for skin, nasal planum, eyelid, perianal, and oral cavity neoplasms.²⁵⁻²⁷ It continues to be an attractive treatment option for clients not interested in invasive procedures and for palliation of advanced (i.e., nonresectable or metastatic) oral disease and can be used as an adjunct to debulking surgery. There is a recent report of image-guided cryoablation of a nasal mass in a dog that recurred following intensity-modulated radiation therapy (IMRT).²⁸ In humans, laparoscopic and percutaneous cryoablation of select neoplasms (e.g., breast and renal tumors) has become an attractive, minimally invasive treatment option.^{29,30}

Hyperthermia

Hyperthermia is the elevation of tissue temperature above normal physiologic levels. Thus the term *hyperthermia* encompasses a wide range of temperatures and modalities. A variety of methods and devices are used clinically to induce hyperthermia in tissues. Non-invasive methods using RF currents, microwaves, or ultrasound are the most common. Heating of solid tumors is typically nonuniform, due in part to the heating devices available and in part to nonuniform distribution of blood flow in the tumor and heat-dissipating activity of surrounding normal tissue. A number of studies demonstrate improved outcome when hyperthermia is added to radiation therapy of solid tumors in dogs.³¹⁻³⁴ The ideal strategy for clinical hyperthermia treatment, including thermal dose, fractionation, and time and temperature goals, has yet to be identified.

Photodynamic Therapy

The practice of using sunlight to treat disease is ancient, but modern refinements have allowed the interactions between light and drugs to evolve into a highly effective cancer treatment called *photodynamic therapy* (PDT). PDT relies on light of an appropriate activating wavelength, oxygen, and a photosensitizer (PS) that accumulates within a tumor. The excited PS interacts with molecular oxygen, creating reactive oxygen species that are responsible for causing vascular stasis and necrosis, membrane damage, and apoptosis and for initiating a signaling cascade resulting in an influx of inflammatory cells. Although initially studied as a single modality, PDT may also be useful when combined with other cancer treatments. Early studies show that a combination of PDT and low-dose cisplatin increases efficacy in both in vitro and murine models, and similar synergy has been observed when doxorubicin is combined with PDT.^{35,36} In veterinary medicine, PDT has been most commonly used in the treatment of squamous cell carcinoma (SCC). Most SCCs are superficial, localized, and do not metastasize until late in the course of the disease, making them well suited for treatment with PDT. An early description of

chloro-aluminum sulfonated phthalocyanine-based PDT in 10 cats with superficial SCC or carcinoma in situ reported a 70% complete response rate, demonstrating the potential for PDT as a skin cancer treatment.³⁷ With a number of recent technologic improvements, PDT has the potential to become integrated into the mainstream of cancer treatment.³⁸

Surgery and Chemotherapy

The combined use of chemotherapy and surgery is becoming more commonplace in veterinary oncology, and the knowledge an oncologic surgeon must possess to master the use of combination therapy is ever expanding.^{39,40} Many chemotherapy agents will impede wound healing to some extent. In spite of this risk, few clinically relevant problems occur when surgery is performed on a patient receiving chemotherapy.^{41,42} General recommendations are to wait 7 to 10 days after surgery to begin chemotherapy, especially for high-risk procedures such as intestinal anastomosis.⁴³ The use of intraoperative⁴⁴ or perioperative chemotherapy is receiving increased attention^{45,46} and could have greater implications for wound healing. Neoadjuvant chemotherapy is also becoming more popular and in some instances may greatly facilitate excision of a solid tumor. Such an approach is commonly used with some canine mast cell tumors, but there remain unanswered questions, such as what characteristics identify the indications for such an approach? Also, if a tumor reduction occurs, should the location of the original tumor border be used to make measurements for margins or the new outer edge?

Surgery and Radiation

Theoretical advantages can be advanced for both preoperative and postoperative radiation.^{40,47} Either way, some impairment of wound-healing potential will exist and need to be considered.⁴⁸ Radiation damage to normal tissues (stem cells, blood vessels, lymphatics) may be progressive and potentially permanent as total radiation dose, dose per fraction, and field size increase. Therefore close collaboration between the radiation oncologist and surgeon is critical when designing the most effective regimen. If radiation therapy is given preoperatively, surgery can be performed after acute radiation reactions have resolved (generally 3 to 4 weeks). Postoperative radiation is recommended after a 7- to 14-day delay to allow for adequate wound healing. In spite of the theoretical problems, surgery can often be safely performed on irradiated tissues and complications are not prohibitive.

The benefit of surgery and radiation is clear for some tumor types; however, in some instances the improvement in outcome over single modality therapy is controversial. One such debate is that of canine nasal tumors.^{49,50} Early reports did not show benefit of postoperative radiation over radiation alone. A recent report demonstrated preoperative radiation as beneficial when followed by exenteration of the nasal cavity 6 to 10 weeks later.⁵⁰ With the advent of stereotactic radiation therapy (SRT) and IMRT (see Chapter 12), such approaches are even more attractive because the overlying skin or underlying mucosa in the case of nasal tumors can be spared from the full effects of the radiation, thereby diminishing concerns about incisional healing. In the past, surgeons would be reluctant to operate in a radiation field; thus these more focused forms of radiation therapy will hopefully allow the surgeon to operate with fewer wound healing complications and create novel treatment plans that combine radiation and surgery for select tumors. Radiation side effects are greatly diminished with a more

conformal approach, and this in turn makes clients more willing to have their pets undergo radiotherapy.

Access to more sophisticated radiation techniques such as SRT and IMRT is rapidly increasing throughout the world, and with this development, a new paradigm is emerging in veterinary radiation oncology. For example, bone sarcomas in locations not amenable to limb-sparing surgery can now be treated with curative intent therapy⁵¹ and treatment protocols for large solid tumors previously deemed nonresectable are currently being investigated. Combinations of SRT and surgery are also being explored. However, while these new treatment options represent great advances, familiar challenges remain. In the case of dogs with appendicular osteosarcoma, fracture may occur after SRT and while some of these cases are amenable to surgical stabilization, healing of the fracture does not occur normally due to the effects of radiation on bone healing. Thus the role of the surgeon continues to evolve in the management of cases treated with radiation.

Prevention of Cancer

Certain common cancers in dogs and cats can be prevented. The recent elucidation of the canine genome as it relates to genetic susceptibility will likely increase the surgical indications for prevention. It is well known that early (<1 year) oophorectomy will reduce the risk of mammary cancer in the dog by 200-fold compared to intact bitches (and to a lesser degree the cat). Castration of the male dog will help prevent perianal adenomas and obviously testicular cancer. Removal of in situ SCC (precancerous) from the skin of white cats or removal of in situ adenomatous polyps from the rectum of dogs may also prevent subsequent development of cancer. Elective removal of cryptorchid testes, which are at high risk for tumor development, is another example of preventive surgery.

Miscellaneous Oncologic Surgery

Veterinary surgeons are being called on increasingly to facilitate the medical management of cancer patients. The placement of long-term vascular access catheters for delivery of fluids, chemotherapy, or anesthesia and pain relief agents has become commonplace, and ports are routinely placed to aid in the evacuation of malignant thoracic effusions (e.g., mesothelioma). Operative placement of various enteral and parenteral feeding tubes is also commonly performed.

Surgeons and radiotherapists may work together for the operative exposure of nonresectable cancer so that large doses of irradiation may be delivered to the tumor or tumor bed after exclusion of radiosensitive tissues. Surgical intervention for oncologic emergencies such as intractable pain, bleeding, pathologic fracture, infection, and bowel perforation or obstruction may also arise.

The comprehensive veterinary oncology team also now includes the discipline of interventional radiology to help manage/palliate certain malignancies. Examples include the use of self-expanding nitinol stents to treat dogs with malignant urethral obstruction⁵² and double pigtail stents for the treatment of malignant ureteral obstructions resulting from trigonal transitional cell carcinoma (TCC) of the urinary bladder.⁵³

Equipment advances are facilitating tumor excisions (e.g., harmonic scalpel⁵⁴ and LigaSure for splenectomy and liver masses), and laparoscopic and thoracoscopic evaluation of body cavities for staging is increasingly being performed on animals. Cancer resections with this technique are also on the rise and given the potential

for decreased morbidity, veterinary surgeons may feel more comfortable performing surgery in the face of advanced disease for certain solid cancers (e.g., thoracoscopic removal of a solitary metastatic lung nodule at the time of amputation for an appendicular osteosarcoma). A few other examples of minimally invasive surgery performed in companion animals for cancerous diseases include prostatic biopsy,⁵⁵ thoracoscopic pericardiectomy for heart-based tumors, laparoscopy-assisted intestinal biopsy, liver biopsy, pancreatic biopsy, splenectomy,⁵⁶ and adrenalectomy.⁵⁷ Further definition of appropriate case selection and increased access to equipment and training will ultimately expand these techniques because the rising popularity of minimally invasive surgery in the pet-owning public is driving this technology.

Discussion

It is clear that surgery will be the mainstay of local or regionally confined cancer treatment in veterinary medicine for many years to come. It is also clear that just because a surgical procedure is possible, this is not the best reason to do it. It was not long ago that surgical resection of the external genitalia was routine treatment for dogs with transmissible venereal tumors. It is now recognized that chemotherapy alone is curative in over 90% of dogs, and surgery is needed for biopsy only. Simple versus radical mastectomy in the dog and humans does not influence survival for most mammary gland tumors, but more aggressive surgery may indeed be beneficial in the cat.⁵⁸⁻⁶⁰ More surgery is not always better surgery. Long-term follow-up of well-staged and graded tumors with defined surgical technique and margins is necessary to demonstrate the true value of any operation. A great deal of progress in surgical technique and surgical thinking needs to take place before the use of surgery can be optimized.

It is hoped that a better understanding of expected tumor biology and more precise staging methods (e.g., molecular diagnostics, angiograms, ultrasound, CT scans, magnetic resonance imaging [MRI], positron emission tomography [PET]/CT) will facilitate more precise surgical operations to be performed. Surgical techniques will continue to improve and undergo refinements,^{54,61-63} but until surgeons become biologists, the big breakthroughs will be slow in coming. Surgeons should be investigating the influence of anesthesia, infection, immune function, blood transfusions, growth factors, oncogenes, and cytokines, to name a few, on the outcome of our patients.⁶⁴⁻⁷⁰ In spite of these anticipated advances in technology and biology, the most difficult aspect to learn is surgical judgment. "Biology is king; selection of cases is queen, and the technical details of surgical procedures are the princes and princesses of the realm who frequently try to overthrow the powerful forces of the king or queen, usually to no long-term avail, although with some temporary apparent victories."⁷¹

Cancer Chemotherapy

11

DANIEL L. GUSTAFSON AND RODNEY L. PAGE

General Principles of Cancer Chemotherapy

Mechanism of Cancer Therapy

The use of chemical elixirs for the treatment of cancer can be traced through the medicinal customs and practices of a number of cultures.¹ The modern use of pharmacologic agents to treat cancer began in the mid-1940s when Alfred Gilman and Louis Goodman showed the efficacy of nitrogen mustard in tumor-bearing mice, and these results were quickly translated and verified in human patients. These results and the efforts of others such as Sydney Farber with antifolates and George Hitchings and Gertrude Elion with purine analogs rapidly advanced the growing interest of treating cancer with drugs. The beginning of a systematic screening program for anticancer drugs at the National Cancer Institute (NCI) in 1955 set the framework for cancer chemotherapy development in both the public and private sectors and led to the characterization of many of the agents still in clinical use today.^{2,3}

The basis of anticancer drug activity is the targeting of dividing cells through interference with processes involved in progression through the cell cycle. As shown in Figure 11-1, the major classes of drugs used to treat cancer work at various steps in the processes of DNA replication (S phase) and subsequent cell division (M phase). Another set of therapeutic agents, the signal transduction inhibitors, work by interfering with the signaling processes that trigger entry into the cell cycle and continuing cellular proliferation. This newer class of agents is discussed in Chapter 14, Section B, of this text. DNA synthesis is a complicated process involving anabolic processes to create the purine and pyrimidine nucleotide triphosphates required for replication, unwinding of the template DNA to provide access to the replication machinery, and the high fidelity process of creating complementary strands. Anticancer drugs work at all of these levels of DNA synthesis, including the antimetabolites that inhibit anabolic processes required for providing the nucleotide building blocks, topoisomerase inhibitors that interfere with the enzymatic process of DNA unwinding, cross-linking agents that through either interstrand or intrastrand interactions block the processes of strand separation and template processing, and the alkylating agents that interfere with the replication machinery through multiple mechanisms of altered binding and base recognition. The resulting effects of interacting at these levels of DNA replication can include the generation of DNA strand breaks, incomplete replication, and triggering of apoptotic signaling such that cell death is the ultimate result.

Processes in cell division not involving DNA replication are also targets for anticancer agents. The most prominent of these targets is tubulin with several classes of drugs having antitubulin activity. The mechanism of action of these agents involves either inhibiting

the polymerization of tubulin or stabilizing the polymerized form so that depolymerization is blocked. The result of blocking either of these processes is the inhibition of microtubule function in the dividing cell. Microtubule function is critical to progression through mitosis via the spindle fiber formation and the separation of chromosome pairs into daughter cells. Blockade of this process by antitubulin agents has proved to be a very effective strategy of antiproliferation because cells blocked in this part of the cell cycle (M phase) can trigger apoptosis or undergo other mechanisms of cell death and loss of viability.

Terminology and Concepts

Terms that are related to the efficacy and toxicity of cancer chemotherapy are important concepts for understanding their pharmacologic activity. The *therapeutic index* for a given chemotherapeutic agent is the ratio between the toxic dose and the therapeutic dose for that drug. For most cytotoxic chemotherapy used to treat cancer, the therapeutic index is an abstract parameter because the administered dose is based on the *maximum tolerated dose* (MTD) rather than dose response. The MTD is an empirically derived value that represents the highest dose of a given drug that can be administered in the absence of unacceptable or irreversible side effects to a limited population sample. This is an important concept in cancer drug administration in that drug doses are generally based on this value rather than assessments of efficacy. A newer concept for drugs used to treat cancer is the *biologically effective dose* (BED), based on a measured response at a putative target or surrogate that is related to the mechanism of action of the agent. Determination of the BED is currently more related to the use of signal transduction inhibitors and molecularly targeted agents; however, the concept is not exclusive to these agents and this approach may be useful when applied to cytotoxic chemotherapy using dosing protocols not based on the MTD. *Dose intensity* (DI) is a measure of dose per unit of time and thus allows comparisons between protracted and compacted dosing schedules. Comparisons of DI between, for example, every 3 weeks and every week dosing allows for determining whether the total dose of the drug or the DI relates to toxicity or therapeutic outcome and the impact that altering dosing schedules can have on outcome. *Therapeutic gain* is often evaluated when combining two drugs or drug-radiation therapy combinations and quantitatively describes any improved tumor response relative to increased normal tissue toxicity when agents are used in a planned schedule. The basis for a positive therapeutic gain is the additive or synergistic tumor effects that exceed any summative toxicity patterns in normal tissues accomplished with combination therapy.

Indications and Goals of Therapy

The therapeutic intent and goals of a given chemotherapeutic regimen are important contributors to how a given drug is selected

• **FIGURE 11-1** Cell cycle specificity of the major classes of drugs used in cancer chemotherapy. Although agents may have effects throughout the cell cycle, the phase where the major impact is realized is highlighted.

or assessed. *Adjuvant therapy* is the treatment with chemotherapeutic drugs following the surgical removal or radiation control of the primary tumor. The purpose is to treat occult disease and usually involves systemic drug exposure. *Primary or neoadjuvant therapy* is the utilization of chemotherapeutic drugs prior to treatment with other modalities, primarily surgical removal of the primary tumor, with the intent of decreasing tumor size for increased control and preventing possible postoperative growth of micrometastasis. *Induction therapy* is a similar concept to neoadjuvant therapy; however, this refers to the initial drug treatment phase with the intent of inducing remission in lymphoid or hematopoietic cancers. *Maintenance therapy* involves the use of chemotherapy in an ongoing basis to maintain remission. *Consolidation therapy* is intended to sustain an achieved remission. *Rescue or salvage therapy* is the use of chemotherapy after a tumor fails to respond to a previous therapy or after tumor recurrence. *Palliative chemotherapy* is delivered to decrease clinical signs in the case of unresectable or disseminated disease that is associated with functional disturbances or pain. The outcome of this therapy is based more on quality of life issues as opposed to other metrics of tumor response. The more subjective nature of assessing the effect of palliative chemotherapy, especially in terms of pain control, makes systematic testing of protocols difficult and treatment recommendations more at the discretion of the clinician and client. In the cases where organ function is impacted by tumor growth, more objective endpoints may exist in terms of functional improvements following treatment. Doses and scheduling of palliative intent therapies may also differ as strict adherence to schedules originating from trials where objective responses were measured may not be relevant and more patient-based endpoints employed. *Radiosensitization* is the enhancement of cytotoxicity when irradiation and chemotherapeutic agents are combined such that a therapeutic gain is obtained. The basis for chemotherapeutic exposure leading to enhanced radiosensitivity can be multifaceted and involve: (1) the enrichment

of the tumor cell population in a more sensitive phase of the cell cycle, (2) increased tumor oxygenation through cyto-reduction or alterations in tumor vascularization, and (3) selective killing of inherently radioresistant hypoxic cell fractions.

As a preliminary metric, the clinical measurements of the tumor response to cancer chemotherapy are useful for predicting the impact of treatment on the extent of disease or time interval of tumor control. Table 11-1 describes conventional measures of treatment response.

Tumor Susceptibility and Resistance

Tumor Cell Sensitivity

Individual cell sensitivity to anticancer agents has been addressed empirically through the screening of tumor cell panels associated with a given histotype. The NCI60 human tumor cell line panel is the most well characterized and studied compilation with more than 100,000 compounds and 50,000 extracts from natural products screened to date.⁴ Further, rich gene expression and other characterizations of these cell lines exist in public databases so that drug sensitivity and genotypic characteristics can be considered.⁵ The use of canine tumor cell line panels to screen drug sensitivity is becoming established⁶ as a viable way to identify potential drug combinations for further testing as well.

Chemosensitivity depends on a number of factors, including drug uptake into the cell, interaction with a cellular target, generation of lethal damage to important cellular macromolecules, repair of potentially lethal damage, and the cell's response to generated damage as depicted in Figure 11-2. Uptake of some cancer chemotherapeutic agents occurs via passive diffusion due to their lipid-soluble properties; other compounds are actively transported into tumor cells. Melphalan is actively transported into cells by two amino acid transporters,⁷ and blocking transport with amino acid substrates or analogs can significantly reduce cytotoxicity.⁸ Other examples include nucleoside transporters used by Ara-C⁹

• **TABLE 11-1** Measures of Response in Cancer Therapy and Treatment

RESPONSE TERM	ABBREVIATION	DESCRIPTION
Complete remission/response	CR	Complete disappearance of tumor(s) and symptoms of disease.
Partial remission/response	PR	Decrease in tumor volume of $\geq 50\%$ or decrease in tumor maximum diameter of $>30\%$.
Stable disease	SD	Neither an increase nor a decrease in tumor size or disease symptoms (e.g., $\pm 20\%$ diameter changes).
Progressive disease	PD	Increase in tumor volume of $>25\%$ or increase of tumor maximum diameter of $>20\%$; appearance of new lesions.
Median duration of response/ median duration of survival	MDR/MDS	The median value for a group of individuals treated with a given therapy in terms of the length of time they achieved a complete or partial remission (MDR) or length of survival following implementation of therapy (MDS).
Progression-free interval/ progression-free survival	PFI/PFS	The amount of time elapsed without evidence of progressive tumor growth (PFI) or survival without progressive growth of the tumor from treatment start (PFS).
Disease-free interval/disease-free survival	DFI/DFS	The amount of time that elapses without disease recurrence (DFI) or survival (DFS) of the patient following therapy.

• **FIGURE 11-2** Processes involved in the pharmacologic activity and associated chemosensitivity of chemotherapeutic agents in tumor cells. Associated processes include drug uptake, interaction with drug target, impact on DNA and associated DNA repair, and the cellular response to these effects.

and gemcitabine¹⁰ and the reduced folate carrier system involved in methotrexate uptake.¹¹ The intracellular target(s) for specific chemotherapeutic agents can play a role in determining sensitivity based on their levels and the nature of the interaction. For example, topoisomerase II α levels can play a role in the sensitivity of tumor cells to doxorubicin^{12,13} as altered levels via decreased gene copy or transcriptional downregulation leads to a decrease in sensitivity (resistance). The opposite is true for thymidylate synthetase levels and 5-fluorouracil (5-FU) toxicity where increased levels of enzyme correlate to a decrease in sensitivity to 5-FU.¹⁴ Although the nature of the interaction with the target is different for doxorubicin and 5-FU, the fact that altered target levels can modulate response shows how quantitative interactions with the target can alter drug sensitivity.

The extent of cellular damage, potential repair of that damage, and the cellular response occur in a tightly knit continuum that determines cellular fate. The generation of cellular damage is a

consequence of interaction with a cellular target and can be either a primary or secondary event. In general for DNA-damaging agents, the resulting DNA lesions are caused by the interplay of DNA binding and DNA repair. For example, DNA strand breaks that result from O-6-methyl guanine lesions are due to aberrant mismatch repair processes and subsequent replication.¹⁵ DNA damage also triggers response pathways that can result in cell cycle arrest to allow for repair and subsequent survival or the triggering of apoptotic machinery that ultimately results in cell death. The definition of cellular response, whether mitotic catastrophe, apoptosis, necrosis, autophagy, or cellular stasis, depends on an intricate interplay of survival and death signaling and is often specific to the agent, dose at the critical target, and the cell lineage.¹⁶ Alterations in proapoptotic and antiapoptotic signaling clearly play a role in tumorigenesis and response to therapy,¹⁷ and the impact of anti-apoptotic signaling in lymphoma by the mediators, bcl-2 and survivin, seem the most clear in regards to both chemosensitivity¹⁸⁻²⁰ and response to therapy in humans and dogs.²¹⁻²³ However, a clear understanding of the role of damage response and active cell death pathways in chemotherapeutic sensitivity and response in solid tumors is still lacking.

Tumor Cell Resistance

Acquired resistance, or selection of resistant cells, during the treatment process is thought to be one of the major mechanisms of therapeutic failure during cancer drug therapy. Resistance of tumor cells to chemotherapeutic agents can depend on the drug and its mechanism or be through a multidrug mechanism. In general, the development of acquired resistance to a specific agent can come via a variety of mechanisms associated with drug uptake, drug metabolism/detoxification, target modification, damage repair, or damage recognition and response. Changes in cellular drug levels can come about due to either a decrease in drug uptake or through increased efflux. Decreased expression of transporters known to play a role in drug uptake have been observed in response to treatment with melphalan in human breast cancer cells²⁴ and acquired resistance to methotrexate in KB cells,²⁵ with the resulting cells showing drug resistance that correlated with the lower intracellular drug levels. The induction of drug efflux pumps in response to drug

treatment is a primary mechanism for multidrug resistance and will be discussed later in this section.

Alterations in metabolic or detoxification pathways within tumor cells are another mechanism by which acquired resistance occurs. Due to the fact that many chemotherapeutic agents are electrophilic based on their DNA-binding properties, enhancement of conjugation reactions with nucleophiles such as glutathione is a plausible mechanism of resistance.²⁶ Induction of glutathione S-transferases has been shown to be a mechanism by which tumor cells can acquire resistance to nitrogen mustards.^{27,28} Although tumor cells themselves generally have limited drug metabolism capabilities, some metabolic pathways can play a role in the resistance phenotype. For example, the sensitivity of tumor cells to 5-FU is inversely correlated with the expression of dihydropyrimidine dehydrogenase,²⁹⁻³¹ the enzyme predominantly responsible for the metabolism of 5-FU to the inactive 5-FUH₂ metabolite.³² For prodrugs such as gemcitabine, which must be phosphorylated to the di- and tri-phosphate forms prior to eliciting an inhibitory effect on DNA synthesis,^{33,34} the enzyme responsible for this metabolic activation, deoxycytidine kinase,^{35,36} has been shown to be decreased in pancreatic tumor cells made resistant to this drug.^{37,38} This interplay between metabolic detoxification and activation, predominantly with drugs that are nucleotide analogs, leads to complex scenarios involving the upregulation of catabolic processes and the downregulation of anabolic processes regarding the cellular pharmacology of these cytotoxic agents.

Modifications in the cellular target of a given drug usually pertain to mutations in the target protein leading to a decrease in affinity or absence of drug interaction. These modifications can include a decrease in the levels of a specific target responsible for the generation of a toxic product, increases in target levels to ameliorate the effect of target inhibition, or target mutations such that the drug can no longer interact in a manner detrimental to the tumor cell. Decreased topoisomerase II gene expression and activity has been observed in human lung and colon cells with acquired resistance to the epipodophyllotoxins,³⁹ etoposide, and teniposide, whose antitumor activity involves topoisomerase II-dependent DNA strand break formation.^{40,41} Target amplification as a mechanism of acquired resistance has been observed in methotrexate resistance where gene amplification and increased dihydrofolate reductase (DHFR) levels allow for cells to overcome DHFR inhibition by this agent.⁴² Mutations in targets such as β -tubulin in the case of paclitaxel⁴³ and topoisomerase I for camptothecin⁴⁴ affect binding of drug and interaction with the target, thus generating tumor cells resistant to the toxic mechanism of these agents. These examples of altered target levels and structures show that drug resistance can come about via either quantitative or qualitative change in the nature of the interaction of drug and target and will depend on the impact of these changes on tumor cell growth both in the absence and presence of the selective agent.

Damage repair in cancer cells treated with chemotherapy commonly refers to DNA repair processes since a majority of chemotherapy agents work at the level of the DNA. Resistance conferred through alteration in DNA repair include not only the induction of specific processes to repair discrete lesions but also more global DNA repair processes, such as postreplication and mismatch repair.⁴⁵ Multiple studies have shown that enhanced removal of platinum adducts from tumor cell DNA correlate with acquired resistance⁴⁶⁻⁴⁸ to cisplatin, although the exact mechanism(s) and protein(s) responsible for repair of these lesions are unknown. The bulky DNA adducts generated by many cancer chemotherapeutic agents can cause replicative gaps in DNA that require

postreplication surveillance and repair. The ability of cells to bypass these bulky lesions and interstrand cross-links during DNA replication has been found to be an important process in tolerance to agents causing these types of DNA damage (cisplatin, mitomycin C, melphalan); multiple DNA repair pathways can account for this release from DNA replication block.⁴⁹ The fact that DNA repair pathways and processes are redundant and nondiscrete and that both lesion specific and global processes seem to play a role in determining drug resistance highlights the problems associated with attributing specific proteins or pathways to specific resistance phenotypes.

Some mechanisms of acquired resistance result in a phenotype in which the tumor is resistant to multiple chemotherapeutic agents or multidrug resistant (MDR). Some of the mechanisms discussed previously, including DNA repair, enhanced metabolism, or detoxification, and resistance to apoptosis can result in resistance to multiple agents; however, the MDR phenotype generally refers to tumor cells expressing individual or multiple members of the adenosine triphosphate (ATP)-binding cassette (ABC) transporter family who play a primary role in active efflux of drugs from cells. Forty-eight ABC genes have been identified in the human genome,⁵⁰ and currently, fifteen members of the ABC transporter family have been recognized that include a cancer chemotherapeutic as a substrate for transport.⁵¹ These include the well-studied and characterized PGP/MDR1 (*ABCB1*), MXR/BCRP (*ABCG2*), MRP1 (*ABCC1*), and MRP2 (*ABCC2*). The basic function of the ABC transporters is conserved across the family and involves the ATP-dependent transport of xenobiotics and endogenous substrates from the inside of the cell to the extracellular space. The role of ABC transporters in multidrug resistance of canine and feline cancers is poorly explored; however, *ABCB1* is expressed in canine lymphoma,⁵² canine mammary tumors,⁵³ and canine and feline primary pulmonary carcinomas.⁵⁴ *ABCC1*, *ABCC2*, *ABCC5*, *ABCC10*, and *ABCG2* have all been shown to be expressed in canine mammary tumors as well.^{53,55} The normal tissue distribution of the ABC transporters is also beginning to be investigated in dogs, with initial studies showing similar tissue distributions and presumed function, although there appears to be some partial differences in relative expression in various tissues.^{56,57} A recent study has shown that feline *ABCG2* has specific amino acid changes that lead to transporter dysfunction with regard to a number of substrates, suggesting that cats may have altered pharmacokinetic disposition for drugs that are *ABCG2* substrates.⁵⁸

Combination Therapies

The success of combination chemotherapy as compared to single-agent treatment is attributed to the overcoming of both natural and acquired resistance of tumor cells, as well as use of agents that differ in dose-limiting side effects. A premise of cancer chemotherapy is to kill the largest fraction of tumor cells possible with each dose, with the dose and timing of each therapy based on the normal tissue tolerance. Therefore a strategy that allows for more intensive cycles of fractional cell killing without exacerbating the recovery of normal tissue damage is preferred. Combination chemotherapy has been shown to be curative in humans with acute lymphocytic leukemia (ALL), Hodgkin's disease, histiocytic lymphoma, and testicular carcinoma, whereas single-agent therapy was not.⁵⁹ The success of combination therapies as opposed to single-agent therapy is best illustrated in veterinary oncology by treatment protocols for canine lymphoma. Doxorubicin is the most active single-agent therapy tested against canine lymphoma; other combination protocols that generally consist of cyclophosphamide, vincristine, and prednisone

• **TABLE 11-2** Response of Canine Lymphoma to Single-Agent Doxorubicin, Combination Protocols, and Combination Protocols Including Doxorubicin*

TREATMENT	DOGS†	REMISSION RATE (%)	MEDIAN REMISSION (MO)	MEDIAN SURVIVAL (MO)
Doxorubicin alone‡	243 (5)	74.2 ± 9.5	5.3 ± 1.1	7.3 ± 1.3
Combination§	324 (5)	76.6 ± 8.0	4.7 ± 1.0	8.0 ± 1.1
Combination + doxorubicin	618 (9)	80.0 ± 9.5	8.8 ± 2.3	11.9 ± 3.9

*Values represent the mean ± standard deviation (SD) from the cited studies. The combination protocols used included cyclophosphamide, vincristine, and prednisone, with methotrexate and actinomycin D included in some.

†Number represents the total number of dogs, with the number of individual studies in parentheses.

‡Data for doxorubicin alone studies were from references 60–64.

§Data for combination studies were from references 61, 65–68.

||Data for combination studies, including doxorubicin, were from references 68–76.

result in similar outcomes (Table 11-2). However, these same combination protocols with doxorubicin included empirically seem to increase both the median remission and median survival times over either doxorubicin alone or a combination protocol that excludes doxorubicin. It should be noted that the populations represented in Table 11-2 may not be homogeneous, and this data does not represent a formal reanalysis of these data sets.

Toxicities Associated with Drug Therapy of Cancer

Chemotherapy may fail to produce a positive clinical benefit for the reasons described previously but may also fail due to unacceptable toxicity. Anticipating and managing adverse events requires a thorough understanding of drug activity profiles and clinical experience modifying chemotherapeutic administration. The first step in the process of successfully managing cancer in companion animals is always a clear and frank discussion with the owner regarding the potential for benefit, toxicity, cost, and time commitment. A common understanding of the goals of therapy and committing to a continuing dialog as needs may change throughout treatment cannot be underestimated.

Dosing conventions have been developed from formal phase I studies for an increasing number of agents investigated specifically in companion animals. Nonetheless, suggested starting doses represent an estimate of the MTD from a small population of animals and safe individual patient dosing may vary substantially. There are numerous reasons for pharmacokinetic variability in cancer chemotherapy among a population of patients.⁷⁷ Concurrent illness or organ dysfunction, extreme tumor burden, specific breed sensitivities (e.g., Collie with *ABCB1* *mut/mut*) or idiosyncratic considerations (anticipated drug-drug interactions or drug allergies) will mandate modification of the protocol and dosing. Concurrent illness and organ dysfunction can also have profound effects on selection of anticancer agents and dosing. In general, predictable dose adjustments for pets with renal or hepatic disease have not been developed and treatment should be approached conservatively. Interestingly, in cats, the glomerular filtration rate (GFR) can be used to define an individual dose for carboplatin that will permit some patients with renal disease to be safely dosed that would not have been safe if dosed by conventional methods.⁷⁸ Dose adjustments of 30% to 40% have been recommended for drugs that are *ABCB1* substrates in Collie-type breeds in which an *ABCB1* (*mut/mut*) phenotype is confirmed, and even in dogs with an *ABCB1* (*wt/mut*) phenotype, dose adjustments may need to be made.⁷⁹ Chemotherapeutic dosing in obese patients often raises questions

about drug partitioning in lipid storage sites around the body. Distribution of many pharmaceutical agents may be affected in obese patients; however, there is no accepted scale for empiric dose adjustments in humans. Individual factors such as the specific drug, degree of obesity, and other comorbidities may convince a clinician to dose reduce or cap the dose of a chemotherapeutic agent.⁸⁰ Some reviews suggest that dose reductions based on body mass may ultimately be detrimental to outcomes in obese patients.⁸¹ It is the initial chemotherapeutic intervention that is expected to result in the greatest opportunity to benefit the patient; therefore taking the time to assess the patient's specific medical limitations and then proceeding with thoughtfully designing, administering, and completing a therapeutically robust protocol are highly desirable.

As individual patient tolerance and response to each compound in a multiagent protocol is observed, future modifications may be anticipated more accurately. The greatest benefit achievable with anticancer cytotoxic therapy requires a commitment to dose intensity. Optimal dose intensity demands therapeutic monitoring in order to either reduce or increase the dose based on the patient's capacity to maintain a high quality lifestyle during effective therapy. The decision to increase the dose of an agent is conceptually challenging but important. In order to make a recommendation to increase dosing of a cytotoxic compound, owner understanding and monitoring of the patient's white blood cell values and clinical events during the first treatment cycle are critical. A dose of a cytotoxic agent that does not result in any change in the target normal tissue (e.g., blood neutrophil count) is likely ineffective and could be increased 10% at the next infusion with continued follow-up to determine adequacy of dose adjustments (Figure 11-3). Dose reductions are deleterious to the optimum delivery of chemotherapy but are to be anticipated. Specific guidelines for dose adjustments of antineoplastic agents are not standardized. In general, a 20% to 25% reduction is recommended for the subsequent dose for patients experiencing a moderate or severe dose-limiting toxicity, such as neutropenia or emesis. Close monitoring and preemptive handling of signs may permit successful management of some potential future clinical signs, and clinical decisions are based on the extent and severity of the resulting signs as described in Table 11-3.

The toxicity profile for anticancer agents may be categorized into immediately evident toxicities (at the time or within 24 to 48 hours after treatment), acute delayed effects (2 to 14 days), or cumulative/chronic toxicity (weeks, months, or years). Immediate toxicity may include infusion hypersensitivities due to histamine release associated with allergic reactions (L-asparaginase) or vehicle-induced mast cell degranulation (e.g., paclitaxel, etoposide). Routine

• **FIGURE 11-3** Blood neutrophil patterns following chemotherapy treatments (arrows). The appropriate dose (circles) results in noticeable nadirs with return to normal prior to the next dose. Doses that are too high or too low should prompt dose adjustments, including potential dose increases (dashed line).

management of these events with antihistamines and steroids may significantly reduce or eliminate this problem. Acute nausea and vomiting may occur with specific agents (e.g., cisplatin) or when the infusion is too rapid (e.g., doxorubicin). Preemptive antiemetic management is able to manage these situations well. Chemotherapeutics with vesicant properties can cause moderate-severe tissue necrosis if not administered safely through a suitable catheter. Vinca alkaloid and doxorubicin extravasations can be a very severe situation that should be avoided even if sedation is required or rescheduling must be recommended for safe catheter placement. Owners may need to be informed about this possibility prior to treatment and a management plan for this situation should be developed. Management recommendations for extravasations are included in the individual drug descriptions later.

Delayed acute effects from chemotherapy often include bone marrow suppression and nausea, vomiting, and diarrhea. In the majority of instances, these effects are self limiting and the incidence of hospitalization for such problems is low. Table 11-3 reviews the general therapeutic strategies for management of the most common types of adverse events experienced in companion animals following chemotherapy.⁸²

Examples of potential cumulative and/or chronic toxicity include hepatic dysfunction after multiple doses of

cyclohexylchloroethylnitrosourea (CCNU), cardiac abnormalities after exceeding a safe cumulative dose of doxorubicin, and renal disease after cisplatin use in dogs or doxorubicin use in cats. Screening recommendations and strategies to reduce the risks of such chronic effects have been developed and are incorporated into standard protocol procedures. It is critical to the success of treatment that owners be thoroughly informed about monitoring guidelines for the general signs and symptoms of chemotherapy-induced toxicity. Online educational resources for owners are readily available at www.csuanimalcancercenter.org. It is advisable to instruct the owner regarding monitoring and early responses when their pet experiences nausea and vomiting, diarrhea, or hematuria and it is important to inform the owner about how to obtain an accurate body temperature. These “at home” aids will allow the clinician to assess the management options should a concern arise.

Safety Concerns of Cancer Drug Therapy

In general, safety concerns for cancer therapy are only applied to the patient with regard to the impact of drug treatment. An issue with cytotoxic chemotherapy, however, is the preparation and distribution of the drugs, as well as active drug eliminated in the urine and feces of the patient and the potential exposure of health professionals, caregivers, and others in the home. The preparation of these drugs should be done under strict regulations and involves the use of protective clothing, gloves, masks, and chemical hoods. Studies have characterized the potential impact of secondary exposure to these agents on oncology health workers in human medicine with regard to cancer prevalence, reproductive risks, and acute toxicities, and the results show little risk.⁸³ However, these results are a reflection of exposure in trained cohorts of individuals working in human medicine where fecal and urinary exposures are more limited. Clients with animals undergoing cancer therapy need to be informed of potential risks and safety precautions that need to be adhered to when dealing with oral medications and pet excrement. Simple precautions such as wearing gloves when handling oral medications and not opening capsules or splitting tablets are essential. Oral suspensions of these agents should be avoided. Urinary levels of some active drugs may remain high for days after treatment⁸⁴ and fecal excretion may also be expected. Therefore careful avoidance, collection, and disposal of urine and feces must be recommended, as well as having pregnant women, small children, and immunosuppressed individuals in particular avoid any contact with pet wastes for a defined time period following treatments. Preparation of guidelines for minimizing exposure to individuals and the environment should be prepared and distributed to clients for general, as well as drug-specific, instructions.

Pharmacologic Principles in Cancer Therapy

Pharmacokinetics

Pharmacokinetic (PK) considerations in cancer drug therapy are important due to the relationship between drug exposure and pharmacodynamic (PD) response, whether efficacy or toxicity, that is more exact than the relationship between drug dose and PD response.⁸⁵ PK considerations are also important with regard to interactions with other drugs,⁸⁶ herbal products,^{87,88} and genetic differences among breeds and individuals⁸⁹ that can cause changes in drug exposure at a given dose. Cytotoxic chemotherapy is usually dosed on an MTD-based schedule reflecting only acceptable toxicity and thus limits any informative role of drug half-life and

• **FIGURE 11-4** Illustration of pharmacokinetic parameters C_{max} and AUC in a theoretical drug plasma concentration versus time plot.

effective therapeutic concentrations from initial dosing considerations. The most important PK parameters are those that have a relationship with either a response to therapy (efficacy) or toxicity, which is most often either the area under the plasma/serum concentration versus time curve (AUC) or the maximum drug concentration (C_{max}) achieved, illustrated in Figure 11-4. The relationships of AUC and C_{max} in the clinical pharmacology of doxorubicin illustrate the complex associations with PK considerations. The C_{max} during doxorubicin infusion in humans is related to the incidence of cardiotoxicity both in adult⁹⁰ and pediatric⁹¹ patients but is also associated with longer remissions in leukemia patients.⁹² A relationship between AUC values and decreased white blood cells has also been established with doxorubicin.⁹³ However, no clear relationships between AUC and efficacy exist.⁹⁴ These data have allowed for adjustments in doxorubicin dosing protocols so that intermediate infusion times (10 to 30 minutes) are utilized to decrease the C_{max} and thus cardiotoxicity while still maintaining peak levels associated with effective therapy.

PK studies that relate drug exposure to responses are an important first step in establishing relationships that may be exploited for dose modification based on patient characteristics or therapeutic drug monitoring. These data are generally lacking for drugs used to treat cancer in companion animals with a few exceptions. Studies on the PK and myelotoxicity of carboplatin in cats have shown a clear relationship between drug exposure and the neutrophil nadir as well as drug clearance and GFR (Figure 11-5). The fact that PK parameters can be correlated both with a toxic endpoint and a physiologic function allows for the calculation of a dosing metric relating the GFR of an individual cat to a dose that produces a drug exposure (AUC) that results in acceptable toxicity.⁷⁸ It remains to be determined whether such individualized dosing results in improved outcome in a heterogeneous population. Current drug-dosing convention for cancer chemotherapeutic agents is the use of body surface area (BSA) for dose normalization (mg/m^2). Exceptions to this paradigm are the use of body weight (mg/kg) for dogs that weigh less than 15 kg and for cats with doxorubicin dosing based on empiric evidence showing a better toxicity

profile for smaller dogs when mg/kg dosing is used.⁹⁵ The approximate calculation for BSA in dogs and cats based on weight is as follows:

$$m^2 = \frac{A \times (\text{weight in grams})^{2/3}}{10,000}$$

where A is equal to 10.1 for dogs and 10.0 for cats. The implementation of this equation relating body weight in kilograms to BSA in meters squared is shown for dogs and cats in Table 11-4.

Pharmacodynamics

PD considerations for cytotoxic chemotherapy are generally related to standard measures of response (i.e., complete remission [CR], partial remission [PR], stable disease [SD]) and toxicity.⁹⁶ A majority of the literature in veterinary oncology relates PD responses to specific drugs or combinations, doses, or schedules. Figure 11-6 shows the relationships between vinblastine doses and the incidence of grade III or IV neutropenia observed in a phase I cohort of dogs.⁹⁷ These results relate a dose to a PD response with the absence of exposure PK data. PD endpoints can also be used as indicators of efficacy and potentially as targets of therapy. The proportion of dogs in remission following treatment for lymphoma is increased in the subgroup experiencing grade III or IV neutropenia compared to the group that did not show that level of observed toxicity (Figure 11-7).⁹⁸ In this example, the therapeutic response was related to overall drug effects on normal tissues as indicated by

the degree of neutropenia (PD response), whereas DI did not show a significant difference. Again, these data did not include exposure PK assessment and in this case only relate the therapeutic outcome to an observed drug response. A lack of complete PK/PD data relationships in veterinary medicine reduces the opportunities for therapeutic drug monitoring and the potential for optimizing efficacy.

Pharmaceutics

Pharmaceutics is the science associated with dosage form design with regard to formulation and optimizing drug delivery via a

• **FIGURE 11-6** Relationship of prevalence of grade III/IV neutropenia with vinblastine dose in dogs being treated for cancer. (Data from Bailey DB, Rassnick KM, Kristal O, et al: Phase I dose escalation of single-agent vinblastine in dogs, J Vet Intern Med 22:1397, 2008.)

• **FIGURE 11-7** Proportion of dogs in remission following chemotherapy treatment for lymphoma. The dashed line represents those animals experiencing grade III/IV neutropenia, whereas the solid line represents those animals that did not show that level of toxicity. (From Ghan A, Johnson JL, Williams LE: Impact of chemotherapeutic dose intensity and hematologic toxicity on first remission duration in dogs with lymphoma treated with a chemoradiotherapy protocol, J Vet Intern Med 21:1332, 2007.)

specific route. For example, improved formulations of clinical agents such as paclitaxel have made these compounds available for use in veterinary patients. The excipient (drug carrier) used in the original clinical formulation of paclitaxel (Taxol) was Cremophor EL, which causes histamine release and unacceptable toxicity when used in dogs and cats.^{99,100} A new water-soluble formulation of paclitaxel (Paccal Vet) has been tested and shown to be effective without associated hypersensitivity reactions in dogs with mast cell

tumors. The ability of new formulations and delivery methods to alter the efficacy and toxicity profile of agents is a rapidly expanding field. It is expected that new technologies in drug formulation and targeting will be incorporated into veterinary medicine to alter drug delivery and distribution in a more favorable manner.

Specific Chemotherapeutic Agents

Alkylating Agents

The alkylating agents are comprised of antitumor drugs whose mechanism of action involves the covalent binding of alkyl groups to cellular macromolecules. The cellular target of these agents is DNA in which they form monofunctional or bifunctional adducts that generate interstrand or intrastrand cross-links.

Nitrogen Mustards

Mechlorethamine

Basic Pharmacology Mechlorethamine is frequently referred to as “nitrogen mustard” and was the first cytotoxic agent to show antineoplastic activity.¹⁰¹⁻¹⁰³ Mechlorethamine undergoes spontaneous hydrolysis to 2-hydroxyethyl-2-chloroethylmethylamine and bis-2-hydroxyethylmethylamine, yielding nucleophilic reactive centers capable of forming DNA cross-links.¹⁰⁴

Clinical Pharmacology Mechlorethamine rapidly disappears from the plasma following intravenous (IV) administration primarily through spontaneous degradation, although some percentage of the drug is enzymatically metabolized.¹⁰⁵ Mechlorethamine uptake into cells seems to be carrier mediated with decreased uptake as a mechanism for resistance.¹⁰⁶

Clinical Use Mechlorethamine is used predominantly in multiagent protocols for lymphoma in dogs.¹⁰⁷⁻¹⁰⁹ Experience with mechlorethamine as a single agent is not reported, although gastrointestinal (GI) and bone marrow toxicity are dose-limiting toxicities of conventional mustargen, vincristine, prednisone, and procarbazine (MOPP) protocols. Dosing of mechlorethamine in these protocols is reported as 3 mg/m² IV on days 0 and 7 of a 21-day cycle.

Melphalan

Basic Pharmacology Melphalan (L-phenylalanine mustard) is a nitrogen mustard containing DNA cross-linking agent with a similar structure and pharmacology to chlorambucil. The major difference is that melphalan is actively transported into tumor cells by amino acid transporters⁷ and its uptake can be blocked by the amino acid leucine. Melphalan has direct alkylating activity and does not require metabolic activation.

Clinical Pharmacology Melphalan can be given orally with an oral bioavailability of approximately 30%. A relatively high percentage of melphalan (20% to 35%) is excreted unchanged in the urine with a majority of the remainder of the dose undergoing spontaneous chemical decomposition to inert products.¹¹⁰ The primary toxicity is myelosuppression.

Clinical Use The primary indication for melphalan in companion animals is for management of myeloma. The initial dose of 0.1 mg/kg PO daily for 10 to 14 days should be reduced to 0.05 mg/kg PO daily based on control of the paraproteinemia and hematologic screening for both dogs and cats. Alternate dosing

regimens have also been used for dogs: 7 mg/m² PO daily for 5 days every 3 weeks or 2 mg/m² PO daily for 10 days with a 10-days-off cycle and repeated as needed.

Cyclophosphamide

Basic Pharmacology Cyclophosphamide (CP) is a nitrogen mustard-containing prodrug that is inactive in the absence of metabolic activation that occurs via microsomal mixed function oxidases predominantly in the liver.¹¹¹ The activation of CP involves ring oxidation to 4-hydroxycyclophosphamide (4-OHCP), spontaneous and reversible ring opening to the amino aldehyde aldophosphamide, and the subsequent irreversible breakdown of aldophosphamide to phosphoramidate mustard and acrolein. Phosphoramidate mustard is considered the most active CP metabolite and is capable of bifunctional alkylation and cross-link production.¹¹²

Clinical Pharmacology Recent studies have characterized the PK of CP and the 4-OHCP metabolite following both IV and oral dosing in dogs.¹¹³ The results of this study show that although exposure to CP is decreased following oral dosing, the overall exposure of 4-OHCP is similar when CP is dosed either intravenously or orally. The major dose-limiting side effects of CP are neutropenia and thrombocytopenia. GI toxicity (nausea and vomiting) is not common in dogs but has been observed in cats.¹¹⁴ Other common toxicities include alopecia in dog breeds with continually growing hair and hemorrhagic cystitis. Although hemorrhagic cystitis is uncommon at conventional doses, furosemide is often administered (1 mg/kg subcutaneous [SQ] or IV) prior to IV injection and precautions are taken at home to encourage vigorous hydration and frequent urination. CP should be discontinued permanently if hemorrhagic cystitis occurs and chlorambucil may be substituted in a multiagent protocol. Urine culture, antiinflammatory drugs, and antispasmodics should be initiated at the onset of clinical signs of cystitis. Aggressive intravesical therapy or even surgery may be necessary in severe instances.

Clinical Use CP is commonly included in multiagent protocols for lymphoma in both dogs and cats. It is effectively administered as a bolus dose (250 mg/m²) by either an oral (PO) or IV route in the dog.¹¹³ A fractionated dosing schedule is also used in some protocols (50 mg/m² for 3 to 4 consecutive days after doxorubicin).¹¹⁵ Metronomic therapy, the use of very low dosing for prolonged periods, has also been developed for CP. The rationale and application of metronomic therapy is covered extensively in Chapter 14, Section C, of this text. CP is administered IV (200 to 250 mg/m²) in many multiagent protocols for lymphoma in cats. The efficacy of oral dosing of CP has not been as carefully investigated in cats compared to dogs although it may be safely administered at doses of 300 mg/m² PO every 3 weeks in multiagent protocols.¹¹⁶

Ifosfamide

Basic Pharmacology Ifosfamide (IP) is a nitrogen mustard-containing prodrug that like CP requires metabolic activation by microsomal mixed function oxidases prior to generating the isofosforamide mustard metabolite capable of bifunctional alkylation.¹¹⁷

Clinical Pharmacology The major difference between the clinical use of IP and CP is due to differences in the relative metabolism of the parent drugs, with dechloroethylation accounting for up to 25% of the metabolism of IP,¹¹⁸ whereas this number is much smaller for CP. This difference in metabolism accounts for an increase in the formation of the neurotoxic metabolite

chloroacetaldehyde following IP dosing and potentially for the less favorable metabolism profile observed with IP following oral dosing.¹¹⁹ The primary toxicity associated with IP treatment is a dose-related myelosuppression, but nephrotoxicity and damage to the bladder epithelium are not uncommon. Vigorous hydration is required with IP administration; in addition, mesna, a urinary epithelial protectant, must be administered to avoid severe cystitis.

Clinical Use Ifosfamide has been evaluated in dogs and cats with cancer and is primarily recommended for management of sarcomas. The recommended dose for dogs is 300 to 350 mg/m² IV slow infusion with diuresis every 3 weeks, and for cats, the recommended dose is 900 mg/m² IV slow infusion with diuresis every 3 weeks.^{120,121} The basis for such discrepancies in the MTD between species is not understood but reflects profound and interesting differences in metabolism pathways and most likely reduced generation of bioactive metabolites. A phase II study in feline vaccine sarcomas reported moderate objective response rates.¹²²

Chlorambucil

Basic Pharmacology Chlorambucil (*p*-bis[chloro-2-ethyl]amino-phenyl-4-butanolic acid) is a nitrogen mustard derivative that enters cells via passive diffusion¹²³ and has direct bifunctional alkylating ability¹²⁴ that is responsible for the cytotoxic activity.

Clinical Pharmacology Chlorambucil is orally bioavailable with rapid absorption. Hepatic metabolism is extensive with the pharmacologically active phenylacetic acid being the primary metabolite and is presumably responsible for much of the clinical activity.^{125,126} The major dose-limiting toxicity is myelosuppression, including neutropenia and thrombocytopenia.

Clinical Use Chlorambucil is used primarily for control of chronic lymphocytic leukemia (CLL) in dogs and for low-grade GI lymphoma in cats. Chronic oral dosing in dogs should begin with 3 to 6 mg/m² PO every day for 1 to 2 weeks with a decrease to 3 to 6 mg/m² PO every other day as determined by routine hematologic screening and control of the cancer. A convenient oral bolus dose of 20 mg/m² PO every 2 weeks has been reported with excellent response in feline GI lymphoma.¹²⁷

Nitrosoureas

Lomustine (Cyclohexylchloroethylnitrosourea)

Basic Pharmacology Lomustine (CCNU, CeeNU) is a nitrosourea-based agent that is highly lipid soluble and enters cells by passive diffusion.¹²⁸ Under aqueous conditions and at physiologic pH, lomustine will spontaneously decompose to a reactive center capable of DNA alkylation^{129,130} and DNA-DNA and DNA-protein cross-links.¹³¹

Clinical Pharmacology The highly lipophilic properties of lomustine allows for rapid crossing of biologic membranes, including the blood-brain barrier. Lomustine undergoes extensive hepatic metabolism,¹³² predominantly by hydroxylation of the cyclohexyl ring, to metabolites with at least equivalent alkylating activity¹³³ that presumably play an important role in the cytotoxic activity. This extensive hepatic metabolism is presumably responsible for the lack of oral bioavailability of the parent compound but rapid appearance of metabolites following oral dosing.¹³⁴ The major dose-limiting toxicity is myelosuppression with acute neutropenia followed by a thrombocytopenia.¹³⁵ Chronic administration may result in hepatic dysfunction requiring discontinuation of the drug temporarily or

permanently.¹³⁶ A recent report investigating coadministration of Denamarin, a product that increases glutathione levels and provides antioxidant properties, with CCNU reported reduced frequency of grade 4 hepatic toxicity.¹³⁷ Further evaluation of whether this strategy should be routinely employed to reduce chronic hepatic toxicity is needed.

Clinical Use CCNU (70 to 80 mg/m² PO every 3 weeks) is most often used alone or in multiagent protocols for canine multicentric lymphoma, epitheliotropic lymphoma, mast cell tumors, and histiocytic sarcoma. In cats, CCNU (50 to 60 mg/m² PO every 4 to 6 weeks) is used primarily for mast cell tumors and lymphoproliferative disorders.

Streptozotocin

Basic Pharmacology Streptozotocin is a naturally occurring nitrosourea capable of DNA alkylation and inhibition of DNA synthesis in both bacteria and mammalian cells.^{138,139} Cellular uptake of streptozotocin depends on the glucose transporter 2 (GLUT2) transporter and expression of this transporter determines sensitivity of both insulinoma¹⁴⁰ and pancreatic beta cells.¹⁴¹

Clinical Pharmacology Streptozotocin is rapidly cleared from the blood following IV administration with reported half-life of 15 to 40 minutes in humans.¹⁴² Streptozotocin has unique activities for nitrosoureas, including inducing diabetes in animals^{143,144} and a lack of any significant bone marrow toxicity.^{145,146}

Clinical Use Streptozotocin is used to manage malignant insulinoma. Limited reports of efficacy have appeared in the literature, although transient normoglycemia occurred in the experience of these authors.¹⁴⁷ The drug is dosed at 500 mg/m² as an IV infusion with diuresis to avoid renal toxicity, similar to the protocol for cisplatin.

Other Alkylating Agents

Dacarbazine

Basic Pharmacology Dacarbazine, or DTIC, is a prodrug that requires metabolic activation by the hepatic cytochrome P450 system^{148,149} to the resulting 5-aminoimidazole carboxamide and the active methylating intermediate methyldiazonium ion.¹⁵⁰ Resulting DNA methylation products are 3-methyl adenine, 7-methyl guanine, and O-6-methyl guanine,¹⁵¹ which are presumably responsible for the cytotoxic activity.

Clinical Pharmacology Dacarbazine has poor oral bioavailability and is administered intravenously. Use in cats is not recommended due to a lack of information regarding their ability to convert the parent drug to the active form. Dacarbazine is extensively metabolized in the liver and excreted in the urine. The major dose-limiting toxicity is GI toxicity, although occasional severe myelosuppression can be observed.

Clinical Use In dogs, dacarbazine is used as a component of protocols for lymphoproliferative diseases in a relapse setting and historically for melanoma. As a single agent, an IV infusion dose of 800 to 1000 mg/m² every 3 weeks has been used.¹⁵² When combined with other cytotoxics, the dose of 600 mg/m² IV has been reported.¹⁵³

Procarbazine

Basic Pharmacology Procarbazine (PCB), like dacarbazine, is a prodrug requiring chemical or metabolic alteration for the

generation of active, toxic metabolites.^{154,155} The mechanism of action of PCB could involve multiple interactions, including inhibition of DNA and RNA synthesis, but a predominant role for DNA methylation to form O-6-methyl guanine seems likely.¹⁵⁶

Clinical Pharmacology PCB is rapidly and completely absorbed after oral administration followed by rapid disappearance of the parent compound and subsequent appearance of metabolites.¹⁵⁷ PCB and/or metabolites equilibrate rapidly between the blood and cerebrospinal fluid.¹⁵⁸ IV delivery has been tested in humans with the appearance of neurotoxicity not seen with oral delivery, suggesting that first-pass metabolism associated with oral dosing significantly alters the spectrum of exposure to parent drug versus metabolites.¹⁵⁹

Clinical Use PCB is used in multiagent protocols for lymphoma.¹⁰⁷⁻¹⁰⁹ It is dosed at 50 mg/m² PO for 14 days of a 28-day cycle. Every-other-day dosing is required for some dogs due to the limitations of available tablet sizes, and reformulation of the available product is required for small dogs.

Antitumor Antibiotics

The antitumor antibiotics consist of natural products from microbial fermentation including the anthracyclines, mitomycins, and actinomycins that have yielded clinically useful compounds with diverse mechanisms of action. Included in the discussion here are the anthracycline doxorubicin and a synthetic analog of the anthracenediones (mitoxantrone) and actinomycin D.

Doxorubicin

Basic Pharmacology The cellular pharmacology of doxorubicin (DOX) is dominated by its ability to react with a number of cellular components and a multimodal mechanism of cellular toxicity. Its activities include DNA intercalation and inhibition of RNA and DNA polymerases¹⁶⁰ and topoisomerase II,¹⁶¹ alkylation of DNA,¹⁶² reactive oxygen generation,^{163,164} perturbation of cellular Ca²⁺ homeostasis,^{165,166} inhibition of thioredoxin reductase,¹⁶⁷ and interaction with plasma membrane components.¹⁶⁸ These processes are involved in both the antitumor and dose-limiting side effects of DOX, with their relative contributions still open to some debate.

Clinical Pharmacology Following intravenous dosing, DOX is extensively distributed to tissues, with binding to cellular DNA¹⁶⁹ and anionic lipids^{170,171} determining the magnitude of tissue uptake.¹⁷² The elimination of DOX occurs through renal and biliary elimination of parent drug, as well as metabolism to doxorubicinol and the 7-hydroxy aglycone. Metabolism to doxorubicinol is via side chain reduction mediated by aldo-keto reductases¹⁷³ and 7-hydroxy aglycone by reductive cleavage of the sugar moiety both by the liver and extrahepatic tissues.¹⁷⁴ The dose-limiting toxicities associated with DOX treatment are infusion-rate-dependent hypersensitivity, myelosuppression, GI toxicity, and a well-established cumulative dose-related cardiotoxicity.¹⁷⁵ In addition, cats may develop renal tubular damage following repeated dosing.¹⁷⁶

Clinical Use DOX is the most active single agent available for a wide variety of cancers in companion animals. The drug may be used alone or in combination protocols for lymphoma, osteosarcoma (OSA), and most mesenchymal and epithelial neoplasms. Conventional dosing regimens are 30 mg/m² slow IV bolus or infusion (10 to 30 minutes) every 3 weeks in dogs larger than 15 kg, 1 mg/kg for dogs smaller than 15 kg, and for all cats. This nonuniform dosing

formula reflects the cumulative experience of specialists realizing that small dogs and cats are often overdosed with DOX using the BSA prescription base. Unfortunately, a uniform prescription model has not been developed, and thus dose adjustments should be anticipated following the initial DOX administration. The drug is diluted in saline and administered as a slow bolus or infusion over 10 to 30 minutes. Vigilant observation during the infusion is required to ensure proper IV delivery. Any concern about catheter placement should result in replacement using an alternate vein before beginning the infusion. Sedation may be required. If it is suspected that the drug has been delivered external to the vein, stop the infusion, aspirate remaining product out of the catheter, and remove it. Dexrazoxane (Zinecard) is used to reduce cardiac toxicity in humans, and infusion within a 3-hour period at 10 times the prescribed DOX dose may be useful for DOX extravasation.¹⁷⁷ Additional infusions at 24 and 48 hours may be useful as well. If DOX is being administered, a source for dexrazoxane should be identified through a local hospital pharmacy because it is expensive and sometimes difficult to obtain rapidly. Despite active management, DOX extravasations may progress to extensive tissue necrosis requiring surgical intervention, including potential amputation.

Cardiac performance should be carefully evaluated prior to each DOX infusion to detect any new murmurs, arrhythmias, or pulse deficits. Routine electrocardiography or echocardiography is not necessary due to limited sensitivity and specificity of these monitoring procedures for DOX cardiotoxicity in dogs and cats. However, any abnormalities that develop during treatment should be pursued with full diagnostic evaluation. Most protocols ostensibly limit the DOX cumulative dose to 120 to 150 mg/m² (4 to 5 doses) in order to limit potential toxicity in the general population and particularly in certain at-risk breeds, such as the Boxer and Doberman Pinscher. The cumulative dose of DOX may be increased as dictated by the need for additional treatment, such as in relapsed lymphoma following a formal cardiac evaluation. A complete blood count (CBC) is recommended prior to each DOX infusion, and in cats, a serum creatinine and urine specific gravity are recommended to identify any changes in renal function.¹⁷⁶

Mitoxantrone

Basic Pharmacology Mitoxantrone is a synthetic DOX analog and maintains similar activity as DOX in terms of DNA intercalation and the inhibition of RNA and DNA polymerases and topoisomerase II.^{178,179} However, mitoxantrone does not cause oxidative damage to cells¹⁸⁰ and has a reduced potential to undergo one-electron reduction and generate reactive oxygen species.¹⁸¹

Clinical Pharmacology Following IV administration, mitoxantrone is extensively distributed to tissues with residual levels being long lasting. Mitoxantrone is not extensively metabolized and a fraction of the drug (<30%) is excreted unchanged in the urine and feces.¹⁸²⁻¹⁸⁴ Dose-limiting toxicities include GI disturbances and myelosuppression. Cardiotoxicity has not been reported in dogs and only rarely in humans.

Clinical Use Mitoxantrone (5 to 6 mg/m² IV slow bolus every 3 weeks) is used as a cardiac-sparing anthracycline in dogs that have reached the cumulative level of DOX or with evidence of cardiomyopathy and is at risk of further damage with doxorubicin administration. The clinical indications for mitoxantrone include lymphoproliferative disorders and, most recently, transitional cell carcinoma (TCC) of the bladder and urethra.¹⁸⁵

Actinomycin D (Dactinomycin)

Basic Pharmacology Actinomycin D, or dactinomycin (DACT), consists of two symmetric polypeptide chains attached to a central phenoxazone ring. DACT has been shown to interact with double-stranded DNA in multiple ways in a sequence-dependent manner,¹⁸⁶⁻¹⁸⁸ and also bind to single-stranded DNA.¹⁸⁹ The resulting interactions of DACT with both double- and single-stranded DNA results in a potent inhibition of transcription, thus inhibiting RNA and protein synthesis.^{190,191} DACT is taken up into cells by passive diffusion,¹⁹² and the sensitivity of cells may depend on uptake and retention¹⁹³ with *ABCB1* playing a role in DACT efflux.¹⁹⁴

Clinical Pharmacology Following IV administration, DACT is rapidly distributed to tissues and then slowly eliminated from tissues. Metabolism is minimal with 20% of DACT excreted unchanged in the urine and 14% in the feces.¹⁹⁵ The major dose-limiting toxicities of DACT are myelosuppression and GI toxicity.¹⁹⁵

Clinical Use Actinomycin D is used in multi-agent protocols for dogs with lymphoproliferative diseases in the relapse setting or as a doxorubicin substitute in dogs with cardiac abnormalities. It is administered IV at 0.5 to 0.75 mg/m² every 3 weeks. There is risk of perivascular damage following extravasation.

Antimetabolites

The antimetabolites are comprised of agents that inhibit the use of cellular metabolites in the course of cell growth and division. Therefore these agents are generally analogs of compounds used in the normal course of metabolism and in the case of cancer chemotherapeutics, specifically anabolic processes associated with DNA replication.

Cytosine Arabinoside (Cytarabine)

Basic Pharmacology Cytosine arabinoside (Ara-C), or cytarabine, acts as an analog to deoxycytidine and is phosphorylated in cells to generate arabinosylcytosine triphosphate (ara-CTP), which acts as a competitive inhibitor of DNA polymerase α .¹⁹⁶ Ara-CTP is also incorporated into DNA, which correlates with cytotoxicity¹⁹⁷ and thus presumably is the primary mechanism of action. Once incorporated into DNA, it cannot be excised¹⁹⁸ and inhibits both the function of the DNA template and subsequent synthesis.¹⁹⁹ Ara-C has also been reported to have a differentiating function in leukemic cells through decreased *c-myc* expression.²⁰⁰ Ara-C is actively transported into tumor cells via nucleoside transporters²⁰¹ and is phosphorylated sequentially by deoxycytidine kinase, deoxycytidine monophosphate (dCMP) kinase, and nucleoside diphosphate kinase.²⁰²

Clinical Pharmacology Ara-C is water-soluble and dosed by IV infusion or SQ bolus injection. It distributes rapidly in total body water and crosses into the central nervous system (CNS), reaching levels 20% to 40% of those observed in the plasma.²⁰³ The primary mode of metabolism is deamination by the liver and extrahepatic tissues. Observed dose-limiting toxicities are myelosuppression and occasionally GI disturbances.

Clinical Use Ara-C is an infrequent component of combination protocols for leukemias and lymphomas in dogs and cats. It is more often incorporated into treatment protocols for patients with a potential for CNS involvement. Ara-C is ideally administered as a

constant rate infusion over a 4 to 5 day period. However, a more convenient method of administration in dogs and cats is SQ injection twice daily for 2 consecutive days at 150 mg/m² (total dose = 600 mg/m²). Low-dose SQ Ara-C (50 mg/m² twice daily for 2 days or 100 mg/m² as a constant rate infusion for 1 day) has been reported to improve clinical signs in dogs with meningoencephalitis of undetermined origin when combined with prednisone.^{204,205} The collective reported data regarding efficacy of Ara-C for this condition are not sufficient to make a treatment recommendation at this time to use Ara-C in addition to prednisone. Results of a recent small study suggest improved responses in dogs with naïve stage V multicentric lymphoma when Ara-C (150 mg/m²/day as a continuous rate infusion) was infused over 5 days following the first and second cycle of a conventional cyclophosphamide, hydroxydaunorubicin (DOX), vincristine (Oncovin), prednisone (CHOP)-based protocol compared to the CHOP protocol alone.²⁰⁶ Bone marrow support with human granulocyte colony-stimulating factor (G-CSF) and erythropoietin were co-administered with Ara-C, and patients in this treatment group did not experience increased adverse events. Further investigation of this protocol is certainly of interest.

Methotrexate

Basic Pharmacology Methotrexate (MTX) is a folate analog that inhibits the enzyme dihydrofolate reductase, thus depleting reduced folate pools required for purine and thymidylate biosynthesis.²⁰⁷ MTX is also converted to polyglutamates that act as direct inhibitors of folate-dependent enzymes that play a role in de novo purine and thymidylate synthesis.^{208,209} MTX enters cells via active transport through the reduced folate carrier.¹¹

Clinical Pharmacology The oral bioavailability of MTX is high at lower doses but becomes variable as doses increase²¹⁰; thus it is usually dosed orally at lower doses and intravenously at higher doses. The PK of MTX is well understood across species²¹¹ and is dominated by enterohepatic recycling that accounts for the observed GI side effects at doses that do not cause hematopoietic toxicities. At higher doses, both GI toxicity and myelosuppression are observed. MTX does not undergo substantial hepatic metabolism except when administered at high doses and is primarily excreted unchanged in the urine.²¹¹

Clinical Use MTX was used in original multiagent protocols for treatment of lymphoproliferative disorders in dogs and cats. With the development of other less toxic and more potent agents, MTX has been eliminated from conventional treatment regimens and is rarely used in veterinary oncology.

Gemcitabine

Basic Pharmacology Gemcitabine, or 2,2-difluorodeoxycytidine (dFdC), is actively transported into cells by nucleoside transporters²¹² and metabolized by phosphorylation to dFdC monophosphorylated (dFdCMP), dFdC diphosphorylated (dFdCDP), and dFdC triphosphorylated (dFdCTP) species.²⁰² The effect of dFdC treatment on cells is the inhibition of DNA synthesis through dFdCTP inhibition of DNA polymerase,²¹³ dFdCDP inhibition of ribonucleotide reductase and subsequent depletion of deoxyribonucleotide pools,³³ and dFdCTP incorporation into DNA leading to strand termination.³⁴ The dFdCTP incorporated into newly synthesized DNA appears resistant to normal DNA repair,²¹⁴ and its presence is critical for triggering apoptosis by this agent.²¹⁵

Recent studies suggest that the primary deamination metabolite of dFdC, difluorodeoxyuridine (dFdU), may also play a role in cytotoxicity.²¹⁶

Clinical Pharmacology Gemcitabine is dosed intravenously because oral dosing leads to low systemic exposure²¹⁷ presumably due to extensive first-pass metabolism in the liver through deamination to the dFdU metabolite.²¹⁸ The length of the infusion also seems to be a potentially important variable as longer, constant rate infusions have been shown to lead to increased intracellular dFdCTP levels and enhanced response as opposed to shorter infusions.²¹⁹ The dose-limiting toxicity of dFdC is hematologic in both humans and dogs.^{202,220}

Clinical Use Gemcitabine use has been reported infrequently in clinical studies in dogs and cats. Recent reports have used gemcitabine as a single agent or in combination with other antineoplastic agents or combined with radiation therapy. Dosing regimens employed in dogs involve either high dose (800 mg/m² IV over 20 to 30 minutes every week for 4 weeks) or low dose (25 to 50 mg/m² IV once or twice a week per protocol) options, depending on the use of other cytotoxics in the protocol. Cats have been treated with low-dose regimens (20 to 25 mg/m² or 2 mg/kg weekly to biweekly) in combination with full-dose carboplatin or radiation therapy.²²¹⁻²²³ All reports indicate that bone marrow and GI toxicity is moderate to significant with high-dose gemcitabine but manageable with routine prophylaxis. Results to date with current administration schedules support only limited, if any, gemcitabine-specific antitumor activity.^{220,221,224-227}

5-Fluorouracil

Basic Pharmacology 5-Fluorouracil (5-FU) is a halogenated analog of uracil that enters cells using a facilitated-transport system shared by adenine, uracil, and hypoxanthine.²²⁸ 5-FU is converted to active nucleotide forms intracellularly by a series of phosphorylase and kinase reactions to yield monophosphate, diphosphate, and triphosphate forms of both fluorouridine and fluorodeoxyuridine,^{229,230} which are incorporated into RNA and DNA interfering²³¹ with synthesis and function.²³²⁻²³⁴ The 5-FU metabolite, FdUMP, is an inhibitor of thymidylate synthetase leading to depletion of thymidine 5' monophosphate and thymidine 5' triphosphate.²³⁵ The alterations in thymidine and deoxyuridine phosphate pools caused by thymidylate synthetase inhibition, effects on DNA synthesis and integrity, as well as effects on RNA synthesis and processing, are all thought to play a role in cytotoxicity induced by 5-FU.

Clinical Pharmacology 5-FU is dosed intravenously and is extensively metabolized in many tissues by dihydropyrimidine dehydrogenase to dihydrofluorouracil, which is further catabolized to α -fluoro- β -alanine, ammonia, and carbon dioxide (CO₂).^{236,237} Approximately 90% of an administered dose is metabolized, and both 5-FU and its catabolites undergo biliary excretion with less than 5% of the parent drug renally excreted. 5-FU causes a dose-dependent myelosuppression, GI toxicity, and neurotoxicity in dogs. Inadvertent ingestion of a topical 5-FU cream is toxic and/or fatal.²³¹ 5-FU is *contraindicated* in cats due to severe CNS toxicity.

Clinical Use 5-FU is infrequently used for management of epithelial tumors (e.g., hepatic, pancreatic, renal, mammary). The reported dose is 150 mg/m² IV weekly. It also may be administered

topically and intralesionally to dogs, although convincing reports of efficacy are not available.

Antimicrotubule Agents

The antimicrotubule agents currently used in veterinary medicine are structurally complex agents belonging to the taxane or vinca alkaloid classes of compounds. These agents have a mechanism of action involving interference with the polymerization or depolymerization of the microtubules that play critical roles in cell function and division.

Taxanes (Paclitaxel and Docetaxel)

Basic Pharmacology The clinically used taxanes (paclitaxel and docetaxel) both act by stabilizing microtubules against depolymerization and thus inhibit reorganization dynamics required for carrying out cellular functions.²³⁸⁻²⁴⁰ This alteration in microtubule function causes an abnormal organization of spindle microtubules involved in chromosome segregation during mitosis, leading to mitotic arrest.²⁴¹ Paclitaxel and docetaxel share identical mechanisms of action, with the increased potency of docetaxel²⁴² attributable to an approximately twofold higher affinity for tubulin binding as compared to paclitaxel.²⁴³

Clinical Pharmacology The clinical use of the taxanes is complicated by their poor solubility and the use of excipients, including Cremophor EL (paclitaxel) and polysorbate 80 (docetaxel) to allow for IV administration. Both paclitaxel and docetaxel are rapidly distributed throughout the body and eliminated slowly primarily by hepatic metabolism and biliary excretion. Renal elimination is 10% or less for both compounds. Toxicities associated with taxanes include hypersensitivity reactions that are attributable to the Cremophor EL and polysorbate 80 utilized in formulation. Diarrhea and neutropenia are the major dose-limiting, taxane-specific toxicities observed.

Clinical Use The use of paclitaxel has not been frequently described in either dogs or cats. This is likely due to the requirement for significant pretreatment with antihistamines and steroids followed by a prolonged infusion with continued monitoring for acute hypersensitivity. One report documented several responses in dogs treated with paclitaxel at a dose of 165 mg/m² slow IV infusion every 3 weeks.¹⁰⁰ Hypersensitivity was frequent despite pretreatment, and significant bone marrow toxicity was observed, leading to the conclusion that the recommended dose for further evaluation is 132 mg/m² as a slow IV infusion every 3 weeks in dogs. Paclitaxel in cats has been anecdotally used at 80 mg/m² slow IV infusion every 3 weeks in anecdotal reports with similar need for pretreatment. As discussed earlier in the section on pharmaceuticals, a water-soluble formulation of paclitaxel (Paccal Vet) is currently under development for veterinary use, with dose regimens and safety profiles still to be determined.

Docetaxel has been investigated in dogs and cats. In order to overcome hypersensitivity reactions, a strategy was developed to administer oral docetaxel with cyclosporine as an absorption aid. Docetaxel and cyclosporine compete with *ABCB1*-mediated excretion mechanisms on the enterocytes, and both are substrates for CYP3A—the phase I enzymes found in enterocytes and the liver. This was initially studied in normal beagle dogs, confirming acceptable docetaxel bioavailability.²⁴⁴ This strategy was subsequently investigated in phase I studies in dogs and cats with cancer in which the MTD of docetaxel is 1.63 mg/kg and 1.75 mg/kg PO (by gavage) every 2 to 3 weeks, respectively, when combined with cyclosporine

(5 mg/kg PO).^{245,246} Although no hypersensitivities were reported, diarrhea was the dose-limiting adverse event. A recent report of IV docetaxel in cats indicates that hypersensitivity in cats is less difficult to manage compared to hypersensitivity in dogs.²⁴⁷ The MTD for docetaxel in cats is 2.25 mg/kg IV infused over 1 hour with routine pretreatment (antihistamine, steroids, famotidine). Tumor response data following oral or IV docetaxel have not been reported to date.

Vinca Alkaloids (Vinblastine and Vincristine)

The vinca alkaloids as a class of antitumor agents consist of the naturally occurring vincristine (VCR) and vinblastine (VBL), as well as a semisynthetic derivative and metabolite of VBL, vindesine (VDS), and the semisynthetic derivative of VBL, vinorelbine (VRL). These agents all share a similar mechanism of action; however, focus will be on VCR and VBL in this section due to their use in veterinary medicine.

Basic Pharmacology The vinca alkaloids bind to a distinct site on tubulin²⁴⁸ and inhibit microtubule assembly.²⁴⁹ This inhibition of microtubule function leads to a disruption in the mitotic spindle apparatus resulting in metaphase arrest and cytotoxicity.^{250,251} The vinca alkaloids enter cells by a simple diffusion process. Exposure time and concentration seem to be important variables in determining cytotoxicity.

Clinical Pharmacology The vinca alkaloids are administered by IV infusion, rapidly distribute to tissues, and are slowly eliminated primarily by hepatic metabolism and biliary excretion of parent drug and metabolites. Urinary excretion of parent drug and metabolites is relatively low: 10% to 20%. One of the metabolites of VBL is desacetylvinblastine (vindesine), which is active and has been identified in dogs.²⁵² VBL and VCR differ in their respective toxicities with VCR being less myelosuppressive than VBL but causing more peripheral neurotoxic and GI effects, including significant ileus.

Clinical Use Vincristine is used predominantly as a component in multiagent protocols for dogs and cats with lymphoma. It is also used as a single agent for dogs with transmissible venereal tumor. The dose for vincristine is 0.5 to 0.75 mg/m² IV bolus weekly in both dogs and cats or as defined in the protocol. All vinca alkaloids are tissue vesicants if delivered extravascularly, although not as serious as doxorubicin. Extreme care should be taken with the injection.

Vinblastine is most often used to manage canine mast cell tumors, either as a single agent or in combination with other agents. Several dose-schedule variations have been developed in the last 5 years. Vinblastine as a single agent or when appropriately combined with other cytotoxic agents may be administered at 2.5 mg/m² IV every 1 to 2 weeks²⁵³ or 3.0 to 3.5 mg/m² IV every 2 to 3 weeks.⁹⁷

Vinorelbine is a synthetic vinca alkaloid and has been used in dogs with a variety of tumors at a starting dose of 15 mg/m² IV over 5 minutes once weekly. There are insufficient numbers of dogs evaluated to accurately quantify tumor response at this time.^{254,255}

Topoisomerase Inhibitors

The topoisomerase inhibitors represent classes of drugs that inhibit either the type I or type II topoisomerase enzymes that are involved in the unlinking and unwinding of the DNA strand for replication and transcription. The major classes of topoisomerase II inhibitors used in veterinary oncology are the anthracyclines, which have

already been discussed, and the epipodophyllotoxins, of which etoposide and teniposide are the clinically relevant members. The major class of topoisomerase I inhibitors used in human oncology are the camptothecins, which have found little use so far in veterinary medicine and will not be discussed here.

Epipodophyllotoxins (Etoposide and Teniposide)

Basic Pharmacology Etoposide (VP-16) and teniposide (VM-26) both inhibit the catalytic activity of topoisomerase II²⁵⁶ by stabilizing a protein-DNA cleavage complex²⁵⁷ that ultimately results in the generation of single- and double-strand DNA breaks.²⁵⁸ These compounds enter tumor cells by simple diffusion across the cell membrane, and increased levels of topoisomerase II in proliferating tumor cells increases selectivity.²⁵⁹

Clinical Pharmacology Etoposide has been evaluated in dogs both intravenously and orally. Etoposide administered IV is associated with severe histamine release in dogs associated with the polysorbate 80 vehicle as described previously with the use of IV docetaxel. Oral dosing has shown low and highly variable bioavailability in dogs, making this route of delivery difficult to use.²⁶⁰ Etoposide is eliminated following dosing by hepatic metabolism and renal elimination of both parent drugs (30% to 40% of the dose) and glucuronide metabolites. The major dose-limiting toxicity of IV etoposide in the dog is hypersensitivity.²⁶¹

Clinical Use Based on the hypersensitivity reactions experienced in dogs following IV etoposide and the low bioavailability of orally administered etoposide, it is not recommended for use. Strategies to overcome the vehicle-induced hypersensitivity by reformulation or to improve bioavailability are required to continue evaluating etoposide. No studies have been reported in cats.

Steroids

Prednisone

Basic Pharmacology Prednisone, or prednisolone, is a corticosteroid that presumably induces killing of hematopoietic cancer cells through interaction with the glucocorticoid receptor²⁶² and the induction of apoptosis.²⁶³ Mechanisms of apoptosis induction by corticosteroids in hematologic cancers is still not completely understood, and multiple mechanisms exist whereby tumor cells of hematopoietic origin resist steroid-induced killing.²⁶⁴

Clinical Pharmacology Prednisone is generally well tolerated in dogs over short time periods (weeks) when administered on a tapering schedule to a tolerable baseline dose dependent on the response of the patient and the cancer. The adrenal-pituitary axis can become suppressed, with signs of iatrogenic hyperadrenocorticism occurring if prednisone is continued at immunosuppressive doses.

Clinical Use Prednisone is widely used for management of lymphoid malignancies, mast cell tumors, and brain tumors in dogs and cats. Dogs are often dosed at 2 mg/kg (or 40 mg/m²) PO daily at the beginning of multiagent protocols for lymphoma and are weaned off the drug over 3 to 4 weeks. Cats are tolerant of prednisone or prednisolone and are maintained at 5 mg PO every 24 hours or twice a day as needed. Prednisone is also used to manage signs and side effects of chemotherapy-induced toxicity, such as hypersensitivities or hemorrhagic cystitis. Antiinflammatory doses are used in dogs (0.5 to 1.0 mg/kg PO once daily and reduced as indicated by signs).

Others

Platinum (Carboplatin and Cisplatin)

Basic Pharmacology The activity of platinum-containing anti-tumor agents is through covalent binding to DNA through displacement reactions resulting in bifunctional lesions and interstrand or intrastrand cross-links.²⁶⁵ The formation of interstrand cross-links has been shown to correlate to cytotoxicity,²⁶⁶ presumably by blocking strand separation required for replication and transcription. Reactions with water are an important component of the pharmacology of cisplatin due to some of the aquatic species potentially crossing cell membranes more rapidly.²⁶⁷

Clinical Pharmacology Both cisplatin and carboplatin are administered intravenously. Metabolism of both cisplatin and carboplatin occurs primarily through reactions with water and elimination by binding to plasma and tissue proteins. Urinary elimination of unbound and bound forms accounts for nearly 50% of the cisplatin dose 5 days after administration. Carboplatin is predominantly excreted in the urine with approximately 65% of the dose recovered in the urine 24 hours after administration.²⁶⁷ Strong correlations exist between carboplatin exposure and renal function such that simple formulas have been derived in both humans²⁶⁸ and cats²⁶⁹ for dosing calculations based on renal function. The most common toxicities associated with platinum therapies are vomiting and myelosuppression. Nephrotoxicity can occur with cisplatin therapy, and vigorous diuresis is required to avoid or decrease renal toxicity.

Clinical Use Cisplatin (50 to 70 mg/m² IV infusion administered with diuresis and antiemetics every 3 weeks) is indicated primarily for canine OSA. A variety of other tumor types have been reported to be marginally sensitive to cisplatin. Cisplatin is *contraindicated* in cats.

Carboplatin (300 mg/m² IV over 10 to 15 minutes every 3 weeks) is preferred to cisplatin because of the reduced incidence of nausea/vomiting, the absence of nephrotoxicity, and ease of administration. Myelosuppression is the dose-limiting toxicity. It is used for management of OSA in dogs, as well as a variety of sarcomas and carcinomas. The traditional dose of carboplatin in cats is 240 mg/m² IV over 10 minutes every 3 weeks.²⁷⁰ It has a reported indication for sarcomas and carcinomas. As in humans, an individualized dose of carboplatin may be calculated based on GFR.⁷⁸ This provides a uniform systemic dose exposure in cats that may have impaired but subclinical renal disease, as well as makes treatment potentially feasible in cats with overt renal disease. Measurement of GFR requires some extra time and expense but increases the dose intensity and may thus improve response, although no response data using this dosing strategy have been reported to date.

Hydroxyurea

Basic Pharmacology Hydroxyurea enters cells via passive diffusion²⁷¹ and is an inhibitor of ribonucleotide reductase²⁷² resulting in depletion of deoxyribonucleotide pools.²⁷³ This interaction with ribonucleotide reductase can also lead to the allosteric inhibition of other enzymes in the DNA precursor synthesis pathway that make up the replisome complex.²⁷⁴ The magnitude of decrease in cellular deoxyribonucleotide pools induced by hydroxyurea treatment correlates with inhibition of DNA synthesis observed.²⁷⁵

Clinical Pharmacology Hydroxyurea is dosed orally and distributes rapidly to all tissues. Elimination is through hepatic

metabolism, as well as urinary elimination of the parent compound. Toxicities associated with hydroxyurea treatment include GI effects, myelosuppression, onycholysis, and pulmonary fibrosis; cats are more susceptible to myelosuppressive effects and potentially methemoglobinemia at higher doses.

Clinical Use Hydroxyurea is used primarily for management of bone marrow disorders such as polycythemia vera and granulocytic leukemias. Hydroxyurea is safe to use at 50 to 60 mg/kg orally once daily initially for several weeks followed by a decreasing dose adjustment as needed to maintain a low red blood cell count in the case of polycythemia vera. It has been recently evaluated as an alternative agent for advanced mast cell tumors in dogs.²⁷⁶

L-Asparaginase

Basic Pharmacology The enzymatic function of L-asparaginase is the hydrolysis of L-asparagine to L-aspartic acid. This depletion of circulating L-asparagine leads to inhibition of protein synthesis in tumor cells lacking L-asparagine synthetase, causing induction of apoptosis.²⁷⁷

Clinical Pharmacology L-Asparaginase can be dosed subcutaneously, intramuscularly, or intraperitoneally, and blood levels of the protein remain for weeks. Hypersensitivity reactions can lead to a shorter half-life through enhanced clearance. The toxicities associated with L-asparaginase treatment are due to either hypersensitivity reactions, which may be accentuated following repeated exposures, or to decreased protein synthesis from depleted L-asparagine pools.²⁷⁸ Hypersensitivity may be managed through pretreatment with antihistamines and dexamethasone, although owners should be advised to observe the dog for 1 to 4 hours after treatment for signs of hypersensitivity.

Clinical Use L-Asparaginase (400 IU/kg IM or SQ or 10,000 IU/m² IM or SQ) is used exclusively for lymphoproliferative disorders. In order to avoid development of resistance to L-asparaginase it is often used only for patients with relapsed lymphoma.

Future Directions in Drug Therapies for Cancer

Individualized Dosing Population Pharmacokinetics

The convention for drug dosing is to normalize the dose to the weight or surface area of the patient. This is done even though there is often no data to support a relationship between a given drug's exposure in the patient and either of these parameters. These conventions are based on the idea that body weight or BSA is related to drug distribution and/or elimination in a manner that allows for consistent drug exposure in treated individuals. Dosing in mg/kg or mg/m² is a crude attempt at individualized dosing, and for some drugs, substantial variability is expected. Studies specifically aimed at determining what demographic characteristics in the patient population determine variability in drug exposure are termed *population pharmacokinetic studies*.

Molecular Profiling Tumor Sensitivity

Tumors have traditionally been classified by descriptive characteristics, such as tissue or organ of origin, histology, aggressiveness, and extent of spread. That empiric rubric is being challenged, as

molecular classifications made possible by microarrays and other profiling technologies become increasingly common and persuasive.^{279,280} The reductionist program would suggest that eventually all differences among traditional tumor types will be reduced to statements about molecules in the tumors and about the interactions among those molecules. Hence it might then be possible to study physiologic processes in one type of cancer and extrapolate the results in a predictive manner to another type through commonalities in their molecular constitutions. But what if we want to do the same thing at the pharmacologic level—to extrapolate and predict drug sensitivity based on molecular characteristics of the tumor? These types of decisions are already being used in human medicine at a discrete level for the use of antiestrogens in estrogen receptor-positive breast cancers,²⁸¹ and the use of select molecularly targeted agents based on the mutation status of target molecules.^{282,283} However, responses to traditional chemotherapy agents, which still make up the backbone of available therapies both in human and veterinary medicine, are more complex and do not generally sort as responders and nonresponders based on single, or even a few, molecular characteristics. Examples do exist in which this is the case such as overexpression of *ABCB1* and the multidrug resistance phenotype,²⁸⁴ but generally, a multitude of genes involved in drug activation, detoxification, DNA repair, stress responses, and a myriad of other known and unknown pathways play a role in determining tumor cell chemosensitivity. Therefore a mechanism that can evaluate multiple factors in a tumor indiscriminately and determine whether it is sensitive or insensitive to a given chemotherapeutic agent would be an invaluable adjunct in determining which drugs to utilize for which individual tumor.

Prognostic Evaluation

Current clinical practice in both human and veterinary oncology bases the choice of cytotoxic chemotherapy on descriptive histopathology characteristics. For example, a diagnosis of OSA in a veterinary patient would lead to the use of adjuvant DOX and/or a platinum-based drug (carboplatin or cisplatin) following surgical resection of the tumor. Why are these drugs used? The easy answer is that studies have shown that dogs receiving either of these drugs following surgery live significantly longer than dogs receiving surgery alone.²⁸⁵ Studies in human patients have shown in a variety of tumor types that in vitro chemosensitivity testing of tumor biopsies and tailoring therapy can lead to increases in anti-tumor response.²⁸⁶⁻²⁸⁹ Therefore basing therapy on an empiric assessment of drug sensitivity rather than on tumor type alone is a strategy that can lead to preferred outcomes. Issues with the use of chemosensitivity assessment in clinical practice are the technical difficulties associated with tissue procurement and culturing and measures of drug response. Another approach to predicting the chemosensitivity of tumors has evolved around gene expression profiling and informatics.^{290,291} Although much attention has been focused on recent evidence of research impropriety and improper validation of predictors used for clinical trials in human lung and breast cancers^{292,293} and this has dampened some enthusiasm for using genomic predictors in chemosensitivity profiling, it should be noted that extensive review of these data by statisticians²⁹⁴ and NCI review panels has found that the errors made were in data handling and consistency in analysis. Thus these unfortunate events should not be an indictment of “omics” approaches in making clinical decisions but rather a stark reminder that correct and careful research approaches and data analysis must be adhered to.

Novel Combinations

The approval of the first targeted agent for veterinary applications in the United States (Palladia) has provided access to a multitargeted tyrosine kinase inhibitor. Biologic agents, including species-specific cytokines, peptides, monoclonal antibodies, chimeric molecules, and targeted toxins will also invariably become more prevalent as experimental therapies in veterinary medicine. The use of these novel agents in combination with traditional cytotoxic chemotherapy will likely follow the development pathway seen in human oncology, which includes adding these agents to standard protocols in a disease-specific manner. Thus changes to current standards of practice and care should be expected as these newer agents are incorporated and tested.

Radiation Therapy

SUSAN M. LARUE AND IRA K. GORDON

Radiation therapy has been used in veterinary medicine since shortly after the discovery of x-rays by Roentgen in 1895. Alois Pommer, an Austrian veterinarian, published extensively on the irradiation of benign and malignant diseases and established a radiation therapy protocol widely used for many years.¹ Technologic advances improving our understanding of the radiation biology of normal and tumor tissues have enabled development of contemporary radiation therapy techniques and protocols.

Over half of human patients with serious cancers undergo radiation therapy at some point during treatment.² Radiation therapy is an effective treatment modality for animal cancer patients with solid tumors; however, early use of the modality was limited due to the sparse availability of veterinary treatment centers. The last decade has been marked by the opening of numerous veterinary radiation therapy centers and the commissioning of more advanced radiation therapy technologies. More than 60 facilities in North America are actively treating animals with radiation therapy and the American College of Veterinary Radiology (Specialty in Radiation Oncology) has residency training programs at 17 treatment centers.³

The management of cancer patients is complex, and determining the best treatment modality or combination of modalities can be challenging. In most instances, when local control of a solid tumor cannot be obtained surgically without excessively compromising an animal's function, appearance, or quality of life, a consultation with a radiation oncologist should be considered. In many such instances, combining surgery with radiation therapy will allow a more conservative surgery and yield comparable or better tumor control and/or functional outcome than either surgery or radiation alone. In other cases, radiation alone may be a preferred alternative to surgery (i.e., intranasal tumors).

In addition to treating serious cancers with what is referred to as "curative intent," radiation therapy also plays an important role in the palliative treatment of advanced cancers, the treatment of endocrinopathies associated with endocrine adenomas, and as an adjuvant treatment for lymphoma patients.

New modalities such as stereotactic radiation therapy (SRT), image-guided radiation therapy (IGRT), and intensity-modulated radiation therapy (IMRT) are also changing the treatment paradigm by providing improved radiation options for tumors in a variety of locations. Keeping abreast of ongoing clinical evaluation of these modalities is important for optimal patient management.

Biologic Principles of Radiation Oncology

Radiation dose is described by the amount of energy absorbed by the tissue. The unit of absorbed dose is the Gray (Gy); one Gy equals

one joule absorbed per kilogram of tissue. Ionizing radiation kills cells by damaging critical molecules in the cell, primarily DNA, which eventually leads to cell death. Megavoltage photons, the predominant form of radiation used in veterinary medicine, interact with tissue primarily by the Compton effect, producing high energy electrons that cause ionization events either to critical molecules (direct effect) or from water molecules located within nanometers of critical molecules (indirect effect). These events produce highly reactive free radicals that result in biologic damage that may kill the cell or render it incapable of reproducing. In most cells, death from exposure to ionizing radiation results from chromosomal aberrations.

Repair of Radiation Damage

A critical determinant of a cell population's sensitivity to radiation is the ability of cells to repair DNA damage caused by radiation. One Gy of radiation from photons causes approximately 2500 base damages, 1000 single-strand breaks, and 40 double-strand breaks in DNA in each cell.⁴ Most of this damage is repaired by cells within 6 to 24 hours; the double-strand breaks are the most lethal because they may lead to severe chromosomal aberrations. A given dose of radiation is preferentially cytotoxic to proliferating cells, including tumor cells and renewing cell populations (e.g., epithelial stem cells), although slowly dividing and nondividing cells (e.g., bone and cells of the nervous system) are also affected by radiation.

Cell Cycle Effects

The period of the cell cycle in which DNA undergoes synthesis is known as *S-phase*. Before and after *S-phase* are periods without overt activity by the DNA; these periods are called *G₁ phase* and *G₂ phase*. *G₂ phase* is followed by mitosis. Cells are distributed throughout the cell cycle in a tumor or tissue at a given time. The individual cell sensitivity to irradiation varies, depending on the phase of the cell cycle at the time of irradiation. Cells in late *S-phase* are most resistant to irradiation, and cells in late *G₂* or mitosis are most sensitive.

Oxygen Effects

Because of their rapid growth and abnormal vasculature, tumors often become partially hypoxic. This results in upregulation of hypoxia-inducible proteins that may prepare the tumor cells to handle stresses. Oxygen is also a critical factor in the response to irradiation because reactive oxygen species (ROS) generate much of the damage from radiation. As a result, normoxic cells are up to threefold more sensitive to radiation than hypoxic cells.

Relative Biologic Effectiveness

Although this chapter primarily discusses the effects of photons (x-rays and gamma rays) and electrons, there are many other forms

of radiation that can be used in oncology, including protons and neutrons. The biologic effects of 1 Gy of electrons are the same as 1 Gy of photons, but 1 Gy of protons or neutrons may cause substantially more damage than 1 Gy of photons or electrons. This difference is known as the relative biologic effectiveness (RBE) of the type of radiation.

Time, Dose, and Fractionation

Early radiation oncologists found that higher total doses could be given if the doses were divided into smaller fractions. They observed that tumor response was improved, and less injury of normal tissue occurred. In veterinary medicine, standard fractionation denotes a regimen delivering 2.7 to 4 Gy per fraction, 3 to 5 times per week to a total dose of 42 to 57 Gy, although several other regimens are currently being used or investigated. Hyperfractionation refers to schedules in which the dose per fraction is reduced and the total dose is increased. Accelerated fractionation describes a treatment regimen in which the overall time of treatment is reduced, but the dose per fraction and total dose are unchanged. Hypofractionation describes the administration of high doses per fraction given in a small number of fractions to a lower total dose. The response of tumor and normal tissues between fractions throughout the course of radiation therapy has been described by Withers⁵ as the “four Rs” of radiation therapy: repair of DNA damage, redistribution of cells in the cell cycle, reoxygenation of tumor cells, and repopulation of tumor and normal tissues.

Division of the total radiation dose into fractions is important for a number of reasons. The first reason is to exploit potential differences in repair capabilities between tumors and normal tissues. Slowly dividing cells are somewhat less sensitive to small doses of radiation than more rapidly dividing cells; however, they appear to become relatively more sensitive if radiation is delivered in larger doses per fraction. If smaller doses per fraction are used, normal tissues with slowly dividing cells can be spared relative to tumor tissues with rapidly dividing cells.

Other events that occur between radiation fractions are cell cycle redistribution and reoxygenation. When a fraction of radiation therapy is administered, many of the cells in the sensitive portions of the cell cycle are killed. During the interval between fractions, cells from the late S-phase, which are more likely to be alive than other cells, progress to more sensitive parts of the cell cycle. This is known as *redistribution*. Reoxygenation also occurs during the interval between radiation fractions when many of the hypoxic tumor cells become aerobic and thus more sensitive to irradiation.

The length of time over which radiation therapy is administered is important, primarily because of tumor repopulation but also because of rapidly proliferating normal tissues, such as mucosa and skin. Tumor cells that have not been destroyed by irradiation continue to replicate during the course of therapy. This process is exacerbated by a phenomenon known as *accelerated repopulation*. Some have suggested that after approximately 4 weeks of therapy, tumors repopulate more rapidly than initially.⁶ The reason for this is not clear, but the phenomenon could be related to (1) a reduction in the cell cycle time, (2) an increase in the number of tumor cells that are actively dividing, or (3) a reduction in the number of tumor cells that normally die (cell loss factor). Regardless of the cause, when treatment lasts longer than 4 weeks, repopulation may affect the outcome unless total dose is increased to account for this phenomenon. Repopulation may have a greater impact on rapidly dividing tumors than on slowly dividing tumors.

• **FIGURE 12-1** Radiotherapy delivered in small fractions (*solid lines*) can produce a higher probability of tumor control with the same level of late effects as radiotherapy delivered in large fractions (*broken lines*).

Repopulation of proliferating (also known as acutely responding) normal tissues is also affected by time. The same total dose of radiation administered over a short period results in somewhat more severe acute effects than if administered over a longer course. Nonproliferating (late-responding) normal tissues are not significantly affected by the length of time over which therapy is administered. Fraction size and the interval between treatment fractions are more important in late-responding tissues. Fractions should be separated by at least 6 hours to allow repair of DNA damage to normal tissues. Cells of the brain and spinal cord may require additional time for complete repair, and the impact of multiple fractions per day on these late-responding tissues is not clearly understood.

The total dose administered to a patient should have a low probability for causing significant late normal tissue reactions in the region of therapy. However, the response of tissues also depends on the fraction size. For example, 48 Gy administered in 4 Gy fractions has a higher probability of causing late effects than 48 Gy administered in 3 Gy fractions (Figure 12-1). The probability of tumor control is not as affected because rapidly proliferating tissues, including tumors, are not as sensitive to the change in dose per fraction. The benefits of protocols that use small doses per fraction are clear: they allow a higher total dose to be administered without increasing the probability of damage to late-responding normal tissues.

The total dose tolerated depends on the specific normal tissues present in the irradiated field. For example, brain and spinal cord are less tolerant to the effects of irradiation than muscle or bone. Another factor that must be considered when selecting the appropriate dose is the volume of tissue in the field. Large volumes of normal tissues are more susceptible to damage from irradiation than smaller volumes.

Although time, dose and fractionation are still the underpinnings of SRT, the paradigm is different than for fractionated radiation therapy. SRT involves the use of high doses per fraction but overcomes the radiobiologic limitations with stereotactically verified positioning and treatment delivery techniques that leave a minimal volume of normal tissue in the high dose area. Stereotactic radiation therapy, by definition, requires (1) a tumor for targeting (not microscopic disease), (2) treatment planning and

administration that will provide a dramatic dose drop-off between the tumor and the surrounding normal tissue structures, and (3) a method of stereotactically verifying patient positioning. The result is that normal late-responding tissue structures are spared through dose avoidance rather than by administering small doses per fraction. The normal tissue structures still receive dose, and the dose per fraction is higher than for traditional radiation therapy. However, the total dose to the normal structures is lower than what is typical for fractionated radiation therapy. Normal tissue tolerance data are just evolving for SRT, as is long-term follow-up. Estimates of tolerance have been based on limited clinical data, toxicity observation, and educated guessing.⁷ It is inappropriate to extrapolate dose constraints from fractionated protocols. An additional difference between SRT and fractionated radiation therapy is that with SRT, acutely responding normal tissues in the surrounding region such as skin, esophagus, and colon may be susceptible to consequential late effects. A consequential late effect is a late effect that develops from severe acute effects that may be associated with stem cell depletion. Dose constraints therefore must also be applied to these tissues. SRT treatment is generally delivered in 1 to 5 fractions over a period of 1 week or less for most tumors; therefore accelerated repopulation is unlikely to impact tumor control. Although historically stereotactic treatment was delivered in a single fraction (referred to as stereotactic radiosurgery), current technology allowing precise repositioning makes limited fractionation feasible. Even this minimal fractionation should allow higher total doses to be administered safely to late-responding tissues in the region and presumably take advantage of tumor reoxygenation and redistribution. However, biologic response following SRT has not been comprehensively evaluated. From a practical standpoint, SRT minimizes the number of anesthesia episodes to these older and sometimes debilitated patients and is also generally more convenient for the owner. Acute effects are minimal and tumor-associated signs such as discomfort or dysfunction often improve rapidly. Long-term tumor control and late effects need to be quantitated.

No perfect radiation therapy protocol exists, and all protocols commonly used in veterinary and human medicine have advantages and disadvantages. It is not within the scope of this chapter to prescribe specific radiation doses or fractionation schedules because many factors must be considered. Rather, referring veterinarians must know what to expect when sending patients to a radiation oncology center, and they should be able to explain some of the fundamental principles to clients. The radiation oncologist should inform the referring veterinarian and owner of the probabilities of late effects and tumor control and estimate the degree of acute effects expected with a specific protocol. The goal of radiation therapy is to destroy the reproductive capacity of the tumor without excessive damage to surrounding normal tissues. This goal is best achieved by dividing the total dose into a number of smaller fractions (fractionation) that are administered over a period of time or by applying stereotactic technology. Regardless of the approach, the relationship of these three parameters (time-dose-fractionation) must be carefully considered in the development of radiation treatment plans for successful therapy.

Acute and Late Effects

Reactions from radiation therapy are classified as acute (also called early) or late. Acute effects occur during or shortly after radiation therapy. Acute effects involve rapidly proliferating tissues, such as the oral mucosa, intestinal epithelium, and epithelial structures of the eyes and skin. Concurrent chemotherapy can exacerbate acute effects from radiation. These effects generally are self-limiting, and

recovery is rapid. However, acute effects can be unpleasant for the patient and distressing to the owner, and in rare instances they can be life-threatening if the proper care is not given. The referring veterinarian often is called on to treat recently irradiated patients. Acute effects will heal without medical intervention in the vast majority of cases over the course of weeks or occasionally months. In veterinary patients, the most important provision to allow healing during this time is prevention of self-trauma of the radiation site by the patient. Therefore pain management plays an important role and should be addressed. Pain management for cancer patients is discussed in Chapter 15, Section A, of this text, and specific protocols have been published.⁸ Additional treatment is based on common sense, supportive care, and the knowledge that the signs will resolve with time.

Late effects involve more slowly proliferating tissues, such as bone, lung, heart, kidneys, and nervous system. The dose of radiation administered is limited by the tolerance of these normal tissue structures in the field. Late reactions can be difficult to treat; it is the radiation oncologist's obligation to minimize the incidence of late effects with appropriate dose prescriptions and careful radiation planning and treatment. When late effects occur, they may be quite severe, resulting in fibrosis, necrosis, loss of function, or even death.⁹ Late effects occur from the loss of normal tissue stem cells with concurrent radiation-induced vascular changes and inflammation. These changes are multifactorial, but the cytokine transforming growth factor- β (TGF- β) is believed to play a critical role in radiation fibrosis. Strategies attempted in human radiation oncology to mitigate late radiation effects include the use of antioxidants and free radical scavengers (superoxide dismutase, vitamin E, thiol radioprotectors), vascular-directed therapies (clopidogrel, statins, pentoxifylline), antiinflammatory agents (corticosteroids), inhibitors of the renin-angiotensin system (angiotensin-converting enzyme [ACE] inhibitors), and stem cell therapies.⁹ In veterinary patients, severe late reactions such as fibrosis and tissue necrosis should be managed under the guidance of or referred to a surgeon and/or radiation oncologist experienced in dealing with radiation injury.

Radiation-Induced Neoplasia

Ionizing radiation is a complete carcinogen, capable of initiating, promoting, and progressing cellular changes that lead to cancer. Therefore it is possible to see radiation-induced neoplasia develop in a radiation treatment field. It appears that orthovoltage radiation and radiation with high linear energy transfer (high-LET) such as neutrons result in carcinogenesis at a higher frequency than the megavoltage photons typically used in veterinary radiation therapy.¹⁰ Other factors that influence the risk of radiation carcinogenesis include the age of the patient (young patients are more likely to develop subsequent tumors) and the tissues irradiated. Certain tissues are also more prone to development of radiation-induced tumors, such as the thyroid gland. For a tumor to be considered radiation induced, the following criteria must be met^{10,11}:

1. The malignancy must arise within the irradiated field.
2. Sufficient latency must have elapsed between the time of irradiation and development of the tumor (typically at least 1 year).
3. The original tumor and the new tumor must have different histologic diagnoses.
4. The tissue in which the new tumor forms must have been normal prior to radiation exposure.

The overall incidence of radiation-induced tumors in patients treated with radiotherapy is thought to be extremely low (<1% to 2% of patients treated).¹¹

• **FIGURE 12-2** Illustration of the alpha/beta (α/β) model in which cell killing occurs by either a single-even process or a double-even process so that the overall killing by either process is the product of the two, and the (α/β) ratio is the dose at which both processes contribute equally to the total killing. Note that the upper curve is survival for the α component only, the middle curve is for the β component only, and the lower curve is for both components. (Redrawn from Wilson PF, Bedford JS. In Hoppe RT, Phillips TL, Roach M III, editors: Leibel and Phillips textbook of radiation oncology, ed 3, St. Louis, 2010, Elsevier.)

Cell Survival After Irradiation

After a tissue or population of cells is exposed to any dose of radiation, a fraction of the cells will be killed. The proportion of remaining cells is known as the *surviving fraction* (S). The sensitivity of a tumor or tissue to radiation can be shown as a graph of the radiation dose (D) versus the surviving fraction (Figure 12-2).¹² The relationship between a dose of radiation and the surviving fraction of cells is commonly described by the linear quadratic equation:

$$S(D) = e^{-(\alpha D + \beta D^2)}$$

where S is the surviving fraction at a dose (D).¹³ Alpha (α) and beta (β) are constants that vary according to the tissue with α corresponding to the cell death that increases linearly with dose and β corresponding to cell death that increases in proportion to the square of the dose (also known as the *quadratic component*). The α/β ratio is a useful number that is the dose in Gy when cell kill from the linear and quadratic components of the cell survival curve is equal. Cells with a higher α/β ratio have a more linear appearance when plotted on a log scale, and cells with a low α/β ratio have a parabolic shape. The α/β ratio is also an important description of the radiosensitivity of a cell. At low-dose fractions, tissues or cells with low α/β ratio are relatively radiation resistant compared to tissues or cells with high α/β ratio. It has been suggested that tissues and cells with low α/β ratios have a greater capacity for repair of sublethal radiation damage. Sublethal radiation damage is defined as damage that can become lethal if it interacts with additional damage. Sublethal damage repair is the reason that cell survival increases when a radiation dose is split into two fractions separated by a time interval.

Most early responding tissues and tumors have a high α/β ratio, whereas late-responding tissues have a low α/β ratio.¹³ There are some tumors that may have a low α/β ratio, which can influence the optimal radiation prescription in terms of total dose, time, and fractionation. Tumors that may have lower α/β ratios include melanoma, prostatic tumors, soft tissue sarcomas, transitional cell carcinoma, and osteosarcomas.¹⁴⁻¹⁶

The concept of biologic effective dose (BED) is used to predict how changes in dose prescription may preferentially affect different cells or tissues based on their α/β ratio in the linear quadratic model of survival. The formula for BED is as follows:

$$\text{BED} = nd[1 + d/(\alpha/\beta)]$$

where n is the number of fractions and d is the dose per fraction. If the α/β ratio of a tissue is known or can be estimated, one can calculate the BED for any dose prescription. It is possible to use this formula to assess how dosimetry changes or errors alter the effective dose of a protocol. It is important to note that there are several limitations to the use of this equation, including that it does not account for differences in the overall length of time of the radiation protocol or accelerated repopulation. There are other formulas that can be used to account for time. Also, the true α/β ratio of any cell or tissue is rarely known; therefore calculations made with this model involve making assumptions or predictions that may be incorrect. Nevertheless, this formula is a useful tool when considering hyperfractionating or hypofractionating a standard radiation protocol in order to create a new protocol that will have expected outcomes related to either tumor control or tissue complications. However, the validity of BED for SRT is unclear.

Alternative Mechanisms of Radiation Injury

In addition to direct radiation cytotoxicity, the extracellular matrix and local microenvironment also appear to play an important role in radiation response. Some evidence suggests that apoptosis of endothelial cells may precede damage to proliferating cells and cause some of the effects observed after radiation. Apoptosis of endothelium primarily occurs when high-dose fractions are administered and may play a more important role when hypofractionated and radiosurgical doses of radiation are delivered.

Chemical Modifiers of Radiation

Although rarely used clinically in veterinary medicine, many drugs can modify the cellular and tissue response to radiation. Radioprotectors (e.g., amifostine/WR-2721) are compounds that decrease the amount of radiation damage to targeted normal cells without providing similar protection to tumor cells. Radiosensitizers are chemicals that achieve greater tumor inactivation than would be expected from the additive effect of treatment with either radiation or the chemical alone. Mechanisms of action of radiation sensitizers include hypoxic cell sensitizers or cytotoxins and agents that damage or incorporate into DNA.

Palliative Radiation Therapy

Palliative radiation therapy is commonly used in human medicine, and its use in veterinary medicine has increased in recent years. Palliative radiation is generally hypofractionated compared to curative intent protocols, often administered in larger doses per fraction (6 to 10 Gy per fraction) in 1 to 4 total fractions once or twice weekly. Conversely, palliative therapy can be delivered in

conventional doses or modestly hypofractionated daily or twice daily for a short but intense treatment regimen. The goal of palliative radiation therapy is not to provide long-term or definitive tumor control; rather, it is intended to relieve pain or improve function or quality of life in patients in which other factors (e.g., advanced metastatic disease) are likely to lead to early demise. Palliative radiation therapy has been used most often for metastatic or primary bone tumors, principally canine osteosarcoma (see Chapter 24). Palliative therapy is more convenient for the owner, and the cost is modest compared with curative radiation therapy because fewer fractions are administered. It is, however, important to remember that palliative radiation is not a substitute for curative-intent protocols despite the convenience. Some palliative therapy protocols may have an increased probability of causing late radiation effects but because they are prescribed to patients that have a poor long-term prognosis, these late effects may not have time to manifest. Curative-intent radiation protocols require strict adherence to radiation biologic principles; palliative radiation protocols, on the other hand, are far more flexible. As in human hospital settings, the protocols may vary dramatically from radiation center to radiation center.

Radiation Therapy Equipment

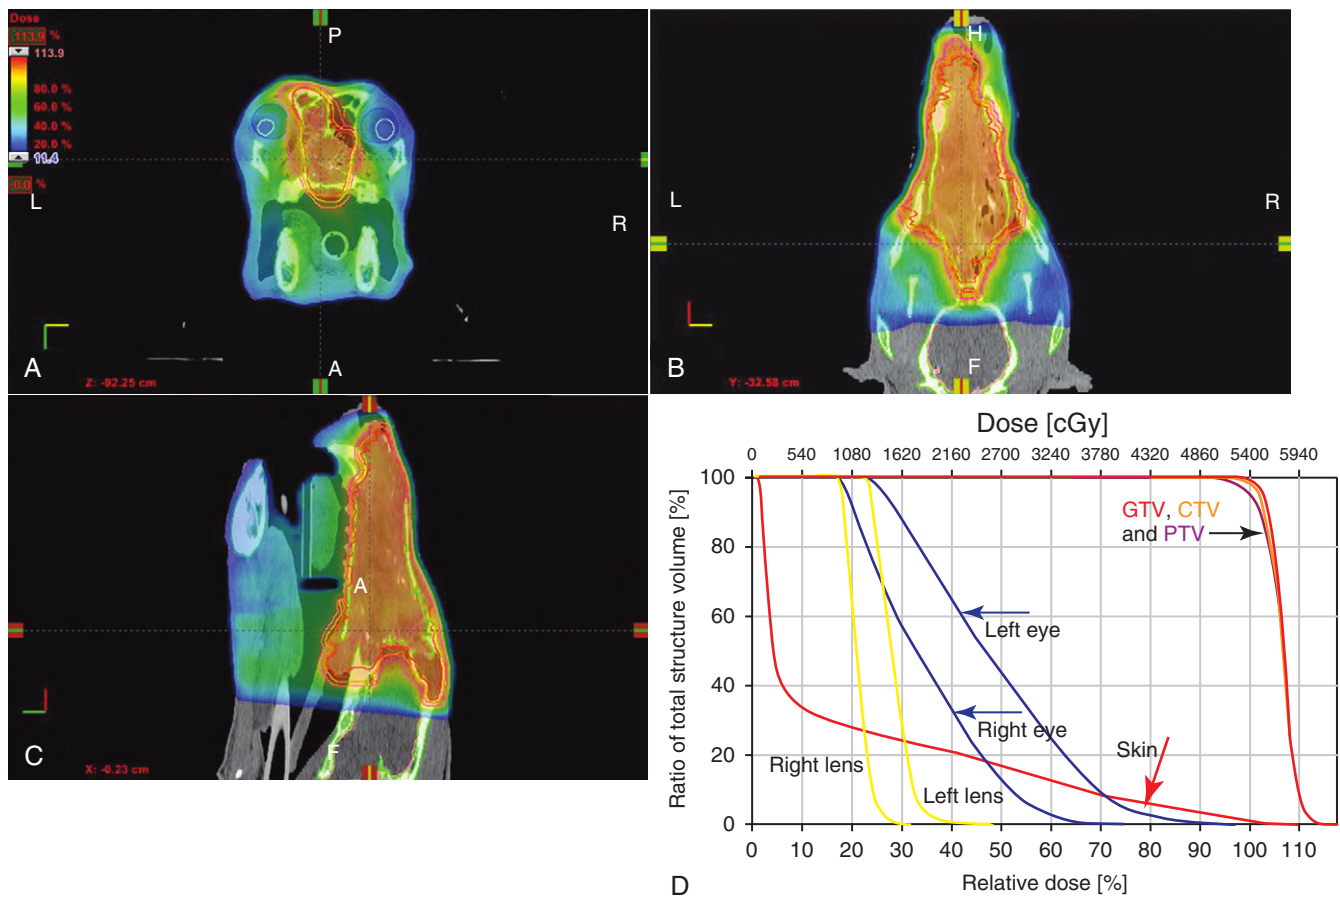

Ionizing radiation can be administered by an external source (teletherapy), through placement of radioactive isotopes interstitially (brachytherapy), or by systemic or cavitory injection of radioisotopes, such as iodine-131 (^{131}I). Teletherapy, also referred to as *external-beam radiation therapy*, is the most commonly used method of radiation therapy in veterinary medicine. External-beam radiation therapy usually is classified as orthovoltage or megavoltage radiotherapy, based on the energy of the photon. Orthovoltage machines produce x-rays with an energy of 150 to 500 kVp; megavoltage radiation emits photons with an average energy greater than 1 million electron volts (1 MeV). Although some veterinary radiation oncology centers continue to treat with orthovoltage machines, megavoltage radiation is primarily used. Megavoltage radiation for therapy can be obtained from cobalt machines or linear accelerators. Because megavoltage radiation has excellent tissue-penetrating capabilities, radiation therapy can be performed on deeply seated tumors for which orthovoltage therapy would not be an option.

Orthovoltage x-rays, which have low energy, distribute maximum doses to the skin surface. Acute effects to the skin can be quite severe, causing discomfort to the patient, and late effects to the skin and subcutaneous tissues can be dose limiting. Megavoltage radiation has a higher energy than orthovoltage, and the photons must interact with tissues, allowing the dose to build up, before the maximum dose can be achieved. The skin therefore can receive a significantly weaker dose than the underlying tumor. This skin-sparing effect of megavoltage radiation allows the optimal dose to be administered to a more deeply seated tumor without causing severe reactions to the skin. When the tumor involves the skin or is in proximity of skin, megavoltage radiation can be used successfully by placing a sheet of tissue-equivalent material, called a *bolus*, over the tumor. This allows the dose build up to occur before reaching the skin, so that the skin and associated tumor can receive the maximum dose of radiation.

The absorption of megavoltage radiation, unlike that of orthovoltage radiation, is minimally dependent on the composition of the tissue. This characteristic permits even distribution of the dose throughout the tissues in the field. Orthovoltage radiation is preferentially absorbed by bone. If a tumor adjacent to or overlying

bone is administered a meaningful dose of orthovoltage radiation, the probability that late effects to the bone (bone necrosis) will develop is quite high. Treatment with orthovoltage should be limited to small, superficial tumors such as nasal planum tumors or to superficial tumor beds after surgical excision. The interaction of megavoltage radiation with tissues is quite predictable, which has allowed the development of computerized treatment planning systems. These planning systems allow treatment of the tumor with multiple beams administered from different angles. Beam modifiers, such as wedges and blocks, can be incorporated into the treatment plan. Wedges are triangular-shaped pieces of lead that can be placed between the beam and the patient. Less radiation penetrates the thick side of the wedge, which modifies the dose distribution. The goal of computerized treatment planning is to ensure a desired minimum tumor dose to a region specified by the radiation oncologist and to spare normal tissue structures when possible. Conventional radiation therapy uses a limited number of computed tomography (CT) or magnetic resonance imaging (MRI) images, which are imported or contoured using a tablet. The summation of multiple beams coming from different directions provides a higher dose to the tumor than surrounding tissues.

Advances in treatment planning and imaging over the past decade have led to the development of image-based, three-dimensional (3D) conformal radiation therapy (3DCRT), which permits better conformity between the irradiated high-dose volume and the geometric shape of the tumor (Figure 12-3). 3DCRT requires importation of CT, MRI, or positron emission tomography (PET) imaging into the treatment planning system. The animal must be positioned for the imaging in a fashion that can be replicated precisely on a day-to-day basis for treatment. Alpha cradles, acrylic face masks, bite plates, and/or Vac-Lok Cushions (Figure 12-4) often are used as positional aids. The radiation oncologist identifies important normal tissue structures, as well as the gross tumor volume (GTV), clinical target volume (CTV), and planning target volume (PTV) on these images. By definition, the GTV only includes gross tumor, and the CTV includes the GTV plus an expansion based on the known clinical behavior of the specific tumor to account for regional microscopic disease. For example, the CTV expansion for a sarcoma is generally larger than for a carcinoma. If the patient has had cytoreductive surgery and only microscopic tumor remains, there is no GTV, and the CTV is based on the scar, regions of surgical disruption, and an expansion for microscopic disease beyond the surgical site. In addition to the GTV and CTV, the PTV includes expansion for an internal margin (IM) that accounts for variations in size and shape relative to anatomic landmarks (filling of bladder, respiratory movements) and set-up margin (SM). The SM accounts for uncertainties in patient positioning and alignment during planning imaging and subsequent treatments. The better the immobilization device, the smaller the SM expansion can be. SM expansions will vary based on the location of the tumor because some sites such as the head are more amenable to rigid immobilization devices such as bite blocks, which provide better replicability. The IM expansion is impacted more by the radiation therapy device. Machines with on-board-imaging devices such as kV x-ray or cone-beam CT (CBCT) can have more confidence in smaller IM expansions. Decreasing the PTV expansion by using good immobilization and available imaging impacts the volume of normal tissue treated and is a key component to successful 3DCRT and is critical to other advanced treatment modalities. More sophisticated beam shaping is performed by taking advantage of fixed multileaf collimators or custom-made blocks. A major advantage of 3DCRT is that dose-volume

• **FIGURE 12-3** A to C, The axial, dorsal, and sagittal sections through a canine nasal tumor. Dose is in color wash, with the prescribed dose in orange. D, The dose-volume histogram. Note the high dose to the tumor compared to regional normal tissue structures.

• **FIGURE 12-4** A, Teeth being placed in preformed acrylic bite block that is inserted into a carbon fiber-indexed frame. Neck is resting on a vacuum lock bag. B, Acrylic face mask being placed.

histograms can be obtained for the tumor and normal tissue structures. This provides a quantitative method of evaluating treatment plans and enhances quality assurance. Defined dosimetric parameters may be useful predictors of outcome.

IMRT and related modalities such as tomotherapy allow even greater sculpting of the radiation dose. These modalities require strategies for patient positioning and immobilization. IMRT requires a specific treatment planning system that uses *inverse planning*. Inverse planning requires that the various tumor structures (GTV, CTV, and PTV), as well as critical normal tissue structures, be identified and contoured into the planning system. Optimization objectives for each structure are entered, and a sophisticated algorithm attempts to meet all objectives. This is the standard of care for treatment of prostate tumors, head and neck cancers, vertebral cancers, some brain cancers, and pelvic cancers in humans. A major benefit associated with IMRT is that the dose to adjacent normal tissue structures can be minimized, dramatically reducing acute effects. Patients are more comfortable and require less pain medication.¹⁷ In addition, the tumor dose can be increased without exceeding normal tissue tolerance, presumably leading to improved tumor control. Fractionation schedules similar to those for conventional radiation therapy are used. Tomotherapy, a form of IMRT that uses a helical delivery system to sculpt the beam, is also being used in veterinary medicine.^{18,19} IMRT is proving useful for the treatment of tumors or tumor beds with complex geometry located near important normal tissues, such as nasal tumors, oral tumors, urogenital tumors, and in cats, vaccine-associated sarcomas.¹⁷

SRT describes an emerging field in radiation oncology that uses advanced technology to achieve a different biologic approach. It was originally coined *stereotactic radiosurgery* (SRS) when the gamma knife was first developed for treatment of inoperable brain tumors in the 1950s by Lars Leksell.²⁰ The gamma knife uses hundreds of small cobalt sources that can converge in 3 dimensions to focus precisely on a small volume of tumor. The gamma knife initially required a rigid frame-based positioning device that was bolted into the patient's skull prior to imaging and treatment planning. Therefore it was primarily used as a single fraction treatment. CyberKnife is a robotic radiosurgery system incorporating a small linear accelerator on a movable robotic arm, integrating advances in robotic technology and real-time computer-tracking technology.²¹ The small linear accelerator is moved around the patient and tumor by the robotic device, while the tracking system verifies position by tracking fiducial markers placed in the tumor prior to treatment planning. This frameless tracking system makes repeat fractions feasible, allowing the benefits of modest fractionation. It also makes treating tumors in other parts of the body possible. SRT can also be delivered by specially designed linear accelerators that have designated beams with attributes conducive to small fields and on-board imaging (OBI) capability. Patients are placed in positioning devices such as bite blocks, face masks, and Vac-Lok cushions prior to imaging. For tumors associated with bony structures such as nasal or brain tumors, orthogonal kV images are obtained and the operating software allows the patient's treatment position to be "matched" to the original imaging positioning. The couch will then make an automatic adjustment. For tumors that may move relative to adjacent bone, CBCT is used and a 3D match is used to verify tumor position.²² The benefits of accelerator-based SRT are that treatment times are generally short, almost any tumor location is accessible, and tumors with larger volumes can be treated.

A number of acronyms are used to describe hypofractionated stereotactic radiation treatment. SRS refers primarily to treatment of brain tumors and generally, but not always, refers to a single

fraction treatment. *Stereotactic body radiation therapy* (SBRT), SRT, and *stereotactic ablative radiation therapy* (SABR) are interchangeable terms used to describe 1 to 5 fraction treatment regimens, regardless of method of administration. Of key importance is the recognition that these stereotactic procedures require gross tumor as a target, must have dramatic dose drop-off between tumor and normal tissues, and must have a method of stereotactic verification.

Radiosurgery has been used on a limited basis in veterinary medicine for brain and bone tumors²³⁻²⁵ and more recently for nasal tumors, multilobular osteochondromas, pituitary tumors, thyroid tumors, heart-based tumors, sarcomas, and tumors in the pelvic canal (personal communications, James Custis, Susan LaRue).²⁶ Technologic advances such as those described previously are likely to become available on a limited basis over the next decade. An important consideration is identifying which tumor types will benefit most from such approaches.

Tumors Commonly Treated with Radiation Therapy

Oral Tumors

Many oral tumors (see Chapter 22, Section A) are responsive to radiation therapy. The region is anatomically complex, and aggressive surgery often can leave functional and cosmetic abnormalities. For many oral tumors, combining surgery and radiation will provide the best outcomes; however, the optimal time to begin irradiation after surgery (or surgery after irradiation) has not been determined. If difficulty in obtaining primary wound healing appears likely, radiation can be delayed. However, the therapeutic gain from combining modalities will be lost if the tumor recurs in the interim. Initiating radiation therapy immediately after surgery does not appear to be a problem if the suture line is tension free and well vascularized. Mucosal flaps can be used successfully to close surgical defects in the oral cavity of patients that will receive postoperative radiotherapy, but complications are common.²⁷

Efficacy of Treatment

Acanthomatous ameloblastomas, previously called adamantinomas or acanthomatous epulides, are very radiation responsive. Tumor control with radiation therapy can be close to 90%.²⁸ A relationship has been demonstrated between tumor (T) stage and local control.²⁹ The reported 3-year, progression-free survival (PFS) for T1 tumors (less than 2 cm) and T2 tumors (2 to 4 cm) is 86%; it is only about 30% for T3 tumors (over 4 cm).²⁹ In 2004 a retrospective study of 57 dogs with epulides that were treated with irradiation reported that the overall median time to first event and overall survival were 1210 and 1441 days, respectively.³⁰ Dogs younger than 8.3 years old (the median age in the study) had a significantly longer median survival time (2322 days) than dogs older than 8.3 years (1106 days). Dogs that received doses higher than 40 Gy had significantly longer survival times than dogs that received 40 Gy or less (2994 days versus 143 days).

Canine oral squamous cell carcinomas (SCCs) are responsive to radiation, although the prognosis is site dependent with tumors located more rostrally having better probability of control.³¹ Tumors of the base of the tongue and tonsil are highly metastatic and are likely to recur locally or regionally. In these locations, radiation therapy has an advantage over surgery because it includes associated lymphatic structures in the treatment field. A 1987 study of oral SCC treated with a coarse fractionation protocol of 10 4.5-Gy

fractions resulted in tumor control at 1 year of about 75%.³² Another study of oral tumors reported a PFS at 1 and 3 years of 72% and 40% for SCC of all T stages.³³ A 1996 study of fractionated radiotherapy (48 to 57 Gy in 3 to 4 Gy fractions) in 14 dogs with SCC reported a median disease-free interval and survival of 365 and 450 days, respectively.³⁴

In cats, oral SCC has a very poor prognosis.³⁵ Although many cats show an initial response and may even show dramatic reductions in tumor size, rapid tumor recurrence is common. Combining curative-intent radiation with etanidazole or mitoxantrone therapy has resulted in median survival times of 116 to 170 days.^{36,37} In one study, seven cats with mandibular SCCs that were treated with hemimandibulectomy and mandibular node excision followed by radiation therapy had a median survival time of 420 days.³⁸ Although the numbers are limited, mandibular SCCs may have a better prognosis than sublingual SCC. Recent studies have indicated that palliative (coarsely fractionated) radiation therapy, with or without chemotherapy, for cats with oral SCC is of dubious value.^{39,40} Another approach investigated in nine cats with oral SCC was accelerated radiotherapy (14 fractions of 3.5 Gy in 9 days), which resulted in a median survival of 86 days although three cats had a complete response with a median survival of 298 days.⁴¹ Although radiation is likely to play a role in the treatment of this disease, new approaches are indicated.

Oral fibrosarcomas are unlikely to metastasize but can be difficult to control locally. The histologic appearance can be deceptive; tumors diagnosed as fibromas or low-grade fibrosarcomas can be extremely aggressive locally.⁴² If clinical evidence of rapid growth, invasion into bone, or tumor recurrence exists, the tumor should be treated aggressively in spite of more benign pathologic features. En bloc surgical resection often is curative but difficult to accomplish because of the invasive nature of the tumor. Oral fibrosarcomas are less radiosensitive than epulides and SCC, although tumor control probabilities ranging from 33% to 67% at 1 year have been reported.^{43,44} One study of oral fibrosarcomas reported a PFS at 1 year and 3 years of 76% and 55%, respectively.³³ Surgical cytoreduction improves the probability of tumor control by radiation therapy, and this should be taken into consideration during surgical planning with a focus on removing clinical disease (avoiding extensive local dissection, which increases the radiation field size) and obtaining a tension-free closure provided that all macroscopic tumor is removed. Forrest and colleagues⁴⁵ reported a median survival time of 540 days in eight dogs with oral sarcomas treated with surgery followed by irradiation. In tumors too large to be surgically resected to a subclinical level, radiation therapy alone is indicated; the probability of long-term tumor control is low with conventional radiation therapy, but new strategies using IMRT or SRT are currently being evaluated.

Malignant melanoma is the most common oral tumor in dogs and is associated with a high rate of regional and distant metastasis.⁴⁶ Higher doses of radiation per fraction (4 Gy and above) are believed to improve response rates for melanoma. In one study, 38 dogs with oral melanoma without evidence of metastasis were treated with 48 Gy delivered in 4 Gy fractions on a Monday-Wednesday-Friday schedule.³³ The median PFS was 17.8 months for all dogs and was stage dependent; for T1 tumors, it was 38 months; for T2 tumors, 11.7 months, and for T3 tumors, 12 months. A retrospective study of 140 dogs evaluated a population of dogs, most of which had regional or distant metastasis at presentation.⁴⁷ Coarsely fractionated (9 to 10 Gy weekly fractions to a total dose of 30 to 36 Gy) and conventionally fractionated (2 to 4 Gy fractions to as high as 45 Gy or more) protocols were used with or without

surgery or chemotherapy. The median times to first event and survival were 5 and 7 months, respectively. Tumor recurrence was the first event in only 27% of the dogs, with new metastases or death accounting for the other 63%. In a retrospective study of 39 dogs with incompletely resected oral melanoma treated with coarsely fractionated radiation therapy plus platinum-based chemotherapy, the median survival time was 363 days.⁴⁸ The dogs received 6 weekly fractions of 6 Gy, with cisplatin (10 to 30 mg/m²) or carboplatin (90 mg/m²) administered 1 hour before irradiation. Fifteen percent of the dogs failed locally, and the median time to metastasis was 311 days.

Melanoma is frequently treated with immunotherapy to potentially prevent or delay the onset of metastasis. Immunotherapy is unlikely to be successful if the primary tumor is not controlled locally with radiation therapy and/or surgery. It is not currently known whether concurrent administration of a melanoma vaccine with radiation therapy may enhance or diminish the effectiveness or toxicities associated with each treatment.

Five cats with oral malignant melanoma were treated with 8 Gy delivered on days 0, 7, and 21. All died from progressive disease, and median survival was 146 days.⁴⁹

Radiation Considerations

Reproducibility of treatment fields for oral tumors can be aided by positioning and immobilization devices. Depending on the size and location of the target, IMRT allows better sparing of surrounding normal structures, such as the eyes and salivary glands. Melanoma may have a low α/β ratio, making them more responsive to coarsely fractionation protocols.⁵⁰

Treatment-Related Toxicities

Treatment toxicity depends on the time-dose-fractionation of the protocol and the specific normal structures in the treatment field. For oral tumors, this can include the skin, nasal cavity, and eyes, which are discussed in subsequent sections. The major acute complication associated with radiation treatment of the oral cavity is mucositis. Mucositis always occurs to some degree in patients that have received irradiation to the oral cavity, pharynx, and/or esophagus. Mucositis typically begins during the second week of therapy and reaches a maximum severity during or shortly after the last week of therapy. Clinical signs include thickened saliva and tenderness of the mouth. These patients occasionally become reluctant to eat or drink and require supportive care. Low-salt foods are more palatable and less irritating to the oral mucosa than regular commercial diets. Rarely, placement of a gastrostomy or esophagostomy tube may be necessary to facilitate feeding. Oral mucositis should subside 1 to 2 weeks after therapy. Rarely, animals treated with chemotherapy subsequent to a course of radiotherapy can develop a return of radiation side effects such as mucositis, which is a phenomenon known as *radiation recall*.

Late complications of radiation specific to the oral cavity include osteoradionecrosis, xerostomia, and oronasal fistula development. Xerostomia (dryness of the mouth due to salivary dysfunction) is a common complication in human patients undergoing radiation therapy of the head and neck region; however, clinically significant xerostomia is not commonly recognized in animals. IMRT technology should provide improved sparing of salivary glands and may decrease the volume of tissue with mucositis. Osteoradionecrosis or development of nonvital bone susceptible to pathologic fracture after radiotherapy is an uncommon complication that can occur in any bone in a radiation field, typically years after treatment. The mandible is the most susceptible bone to osteoradionecrosis but as

with most late effects, the risk can be minimized by administering radiation in lower dose per fraction. Oronasal fistula development after radiation is rare unless the hard or soft palate has been disrupted by an aggressive tumor or oral surgery. At one time, it was suggested that radiation therapy could result in transformation of epulides into malignant epithelial tumors, but this possibility has since been refuted.^{28,30}

Nasal Tumors

Nasal tumors (see Chapter 23, Section B) in dogs are difficult to control. Surgery, chemotherapy, cryosurgery, or immunotherapy alone does not appear to improve survival over no treatment.⁵¹⁻⁵⁶ Radiation therapy provides the best reported tumor control for canine nasal tumors and likely needs to be part of any curative-intent treatment regimen.

Efficacy of Treatment

Radiation therapy has long been the standard of care for nasal and sinonasal tumors. The location is not generally amenable to complete surgical resection, and most reports combining radiation therapy and surgery have not demonstrated therapeutic gain compared to radiation alone. Interestingly, over the last 20 years, advancement in treatment planning technology from point calculations to 2-dimensional (2D), 2.5-dimensional, and 3DCRT technologies has not been associated with improved tumor control or survival. Megavoltage radiation therapy alone has been reported to provide a median survival of about 1 year.⁵⁷⁻⁵⁹ Histologic subpopulations may be prognostically significant; however, most publications are hampered by inadequate patient numbers. Nasal SCCs, undifferentiated carcinomas, and anaplastic carcinomas have been reported to have survival times of 4 to 6 months, and chondrosarcomas have been reported to have survival times up to 15 months. Cribiform erosion has been associated with a poor prognosis.⁶⁰ Adams and colleagues⁶¹ reported a median survival time of 47.7 months in a small group of dogs that underwent surgery in cases in which a nasal tumor did not regress at least 80% 6 weeks after radiation. Late effects were significant; 9 of 13 dogs developed rhinitis, and 4 progressed to osteonecrosis. Surgery and coarse fractionation reduce normal tissue tolerance to radiation, which likely contributed to the high percentage of patients with late effects in this study. The role of chemotherapy combined with radiation therapy for nasal tumors is still unclear. Studies using conventional or low-dose chemotherapy have not improved the outcome over radiation alone.^{52,58} Radiation therapy combined with slow-release cisplatin implanted intramuscularly in a small group of dogs significantly improved survival compared with a group of historic controls with sarcomas and carcinomas treated with radiation therapy alone.⁶² The median survival time for 14 dogs in the combined radiation-cisplatin protocol was 580 days, compared to 325 days for the 13 dogs in the radiation-only group. In a follow-up study of 51 dogs treated with the same radiation-cisplatin regimen, the median survival time was 474 days.⁶³

Two recent publications evaluated outcome in dogs with nasal tumors treated with IMRT.^{17,64} Thirty-one dogs treated with IMRT were compared to 36 historic controls treated with the same prescription using 2D treatment planning. Duration of survival was 420 days and 410 days, respectively.⁶⁴ In another report, twelve dogs treated with IMRT to a dose commonly used for 2D or 3DCRT planning had a median survival of 446 days.¹⁷ Patient numbers in both studies were low, and there was no stratification for prognostic factors. Although conclusions cannot be made regarding tumor control, the decrease in acute effects to the region in both studies

was profound. Although it seems intuitively obvious that improved tumor control would require dose escalation, reducing acute effects and keeping patients more comfortable during treatment may allow more patients to complete treatment as prescribed.

SRT, delivered in 3 daily fractions of 9 to 10 Gy, has been used to treat over 40 dogs with nasal tumors. Treatment was well tolerated with few acute effects, and early improvement in clinical signs was noted. Median survival time was 411 days.⁶⁵ Lymphoproliferative nasal tumors in cats respond well and durably to radiation therapy (these are addressed later in the chapter in the section on lymphoma; also see Chapter 32).⁶⁶ Carcinomas and sarcomas in cats respond comparably to nasal tumors in dogs: 48 Gy administered in 4 Gy fractions over 4 weeks had a 1-year survival rate of 44.3% and a 2-year survival rate of 16.6%.⁶⁷ The histologic type and clinical stage of the tumor did not affect the prognosis.

Nine dogs with recurrent nasal tumors previously treated with 3DCRT (median 50 Gy), were reirradiated.⁶⁸ Overall median survival from initial treatment was 31 months with an increased incidence of late effects. Retreatment becomes a more viable option with new modalities that spare local normal tissues.

The response to planum nasale SCC is affected by the tumor type and stage.⁶⁹ Cats with T1 tumors had a 1-year survival rate of 85% and a 5-year survival rate of 56%, and the mean was 53 months (the median was not calculable). However, larger, more invasive tumors showed a less favorable response when treated with 40 Gy in 4 Gy fractions over 3.5 weeks. Tumor control should be improved by reducing the dose per fraction and increasing the total dose. For small, superficial SCC lesions of the planum nasale in cats, strontium (Sr)-90 plesiotherapy is a viable option. Because Sr-90 emits a low-energy β particle, very high doses can be administered to the surface of a lesion without unacceptable complications or damage to underlying tissue. In one study, 49 cats with SCC of the planum nasale were administered a median of 128 Gy in a single fraction, with a complete response rate of 88% and median progression-free interval of 1710 days. Larger, invasive SCC lesions are usually not amenable to treatment with Sr-90.⁷⁰

Radiation Considerations

Canine and feline sinonasal tumors are challenging to treat with radiation because they are anatomically complex; they frequently involve the nasal sinuses, the cribiform plate, and the nasal pharynx. The geometry of the nasal cavity is problematic because the target is larger caudally than rostrally, making it difficult to achieve even dose distribution. The dose-sculpting benefits of IMRT and SRT decrease acute effects. Optimizing protocols, including modest dose escalation, may lead to improved tumor control. Evidence-based studies need to thoroughly evaluate the impact of IMRT and SRT on acute responding tissues, tumor control, and late effects.

Treatment-Related Toxicities

Because nasal tumors are immediately adjacent to the oral cavity, radiation toxicities of nasal treatment are similar to those described previously for the oral cavity. Radiation side effects in the nasal cavity may mimic signs of the tumor, such as nasal discharge, sneezing, and epistaxis. In most dogs, these clinical signs actually improve rather than worsen during treatment despite acute radiation effects because of the response of the tumor. Recurrence of clinical signs of an intranasal tumor (nasal discharge, sneezing, epistaxis) may indicate chronic radiation effects or tumor recurrence. Ocular radiation complications are extremely common because of the proximity of the nasal cavity and frontal sinus to the orbit. Effects

to the eyes are dose related and vary in severity.⁷¹ Acute effects include blepharitis, blepharospasm, conjunctivitis, and the development of keratoconjunctivitis sicca (KCS). KCS is treated with artificial tears and steroids to prevent corneal ulceration. If corneal ulceration is present, healing may be delayed as a result of radiation damage to the corneal stem cells. KCS may be temporary or permanent, depending on the dose administered and the sensitivity of the patient. Late effects include vascular changes, which may have subtle effects on vision but in most cases do not result in blindness. Radiation-induced cataracts may occur, and the latent period is related to dose. These cataracts can be removed with phacoemulsification. Eyes that are in the field of irradiation may receive the full treatment dose. At doses above 40 Gy, degenerative angiopathy of retinal vessels can progress over 2 years and result in retinal degeneration. Optic nerve axonal degeneration has occurred secondary to the retinal changes.⁷² IMRT decreases dose to the ocular region, resulting in limited acute and late toxicities.⁶⁴

Brain Tumors and Pituitary Tumors

Brain tumors can be treated successfully with radiation therapy (see Chapter 30). In the treatment of brain tumors, surgery may be indicated to relieve life-threatening clinical signs. Although appropriate studies are still needed, for animals with less severe clinical signs, reported survival times after radiation for brain tumors in dogs are frequently comparable to surgery alone. Adjuvant radiation is indicated in patients with incomplete surgical resection; combined surgery and radiation may provide the best long-term control. Radiation therapy alone should be performed in dogs with cancer at surgically inaccessible sites or in locations in which surgical morbidity is high. SRT is being evaluated for treatment of a wide variety of brain tumors in dogs and cats.

Efficacy of Treatment

Published survival times of canine brain tumors treated with radiotherapy compare favorably to surgery, although directly comparable data is lacking, and combined surgical and radiation treatment may be superior. In one study, 46 dogs with brain tumors that initially had shown neurologic signs were treated with radiation alone.⁶⁹ The median overall survival time was 23.3 months; 69% of the dogs survived 1 year, and 47% survived 2 years. The outcome in this study was superior to those from previous reports, in which the median survival time was about 1 year. No prognostic clinical factors (e.g., tumor size or location or clinical signs) were identified.⁷³⁻⁷⁵ Differences may be due to improved treatment planning capabilities. In another study by Axlund et al of 31 dogs with meningioma, postoperative radiation improved the median survival time from 7 months with surgery alone to 16.5 months with surgery followed by radiation therapy. Stereotactic radiation therapy has been used to treat brain tumors.²³ In a recent preliminary summary of 20 dogs with presumed meningiomas treated with 3 fractions of SRT, median survival was 594 days, and treatment was well tolerated (personal communication, Lynn Griffin, CSU).

Radiation therapy should be used in dogs and cats with pituitary macroadenomas because pituitary tumors generally are responsive to radiation, and surgical access is limited. Dogs with pituitary tumors have been reported to have median survival times varying between 1 and 2 years.^{76,77} A study comparing 19 dogs with pituitary tumors receiving radiation therapy (48 Gy in 16 daily fractions of 3 Gy) to untreated dogs found 1-, 2-, and 3-year survival rates of 93%, 87%, and 55% in the irradiated group and 45%, 32%, and 25% in the unirradiated group. Tumor size as assessed by relative tumor area to brain area was prognostic in the irradiated patients.

Fractionated pituitary irradiation in dogs is more effective at delaying tumor growth than in controlling adrenocorticotrophic hormone (ACTH) secretion. Eucortisolism is seen in some patients after irradiation; however, pre-ACTH and post-ACTH cortisol levels should be monitored at regular intervals so that medications can be modified, if indicated.

Cats seem to have marked clinical improvement of associated endocrinopathies. In one study, eight cats with pituitary tumors were treated with radiation therapy, and neurologic signs improved within 2 months in all cats.⁷⁸ Endocrinopathies, including hyperadrenocorticism, acromegaly, and insulin-resistant diabetes, were dramatically improved. The median survival time, regardless of cause of death, was 17.4 months. A study evaluating conformal radiation-focused treatment of 11 cats (single dose of 15 to 20 Gy) found improved regulation of diabetes mellitus in 5/9 cats and improved neurologic function in 2/2 cats, with a median survival time of 25 months. SRT was administered in 3 to 4 fractions to 19 acromegalic cats with macroscopic or microscopic pituitary tumors. Median survival has not been reached, with 90% of cats alive at 1 and 2 years. Insulin-resistant diabetes and other associated endocrinopathies improved. The treatment was well tolerated acutely²⁶ (see Chapter 25).

Radiation Considerations

The integration of 3D imaging, patient-positioning devices, and advanced treatment planning techniques have the potential to improve tumor targeting and sparing of normal brain tissue. For many brain tumors, IMRT will not provide an improved dose distribution compared to 3DCRT; however, dose sculpting may be beneficial for cranial nerve tumors. An additional consideration in patients undergoing radiation therapy for a brain tumor is anesthetic risk related to increased intracranial pressure or brainstem disease; an appropriate anesthetic regimen should be selected to minimize the risk of complications. Specifically, patients should be ventilated while under anesthesia to decrease partial pressure of carbon dioxide ($p\text{CO}_2$) in the blood, and anesthetic agents that decrease (or at least do not increase) intracranial pressure should be selected. SRT limits the number of anesthetic episodes, which may be beneficial in unstable patients. SRT can be used with curative intent or in a single fraction for palliative purposes.

Treatment-Related Toxicities

For most brain tumors, acute effects to the skin can be avoided with megavoltage treatments. Occasionally, ocular and auricular side effects or mucositis to the caudal oral cavity may be seen if in or adjacent to the treatment field. The radiation tolerance is lower when the entire brain is treated; this limits prescription of a dose that is adequate for tumor control but still has an acceptable probability of late effects. The radiation tolerance of brain and spinal tissues is generally considered to be less than that of other commonly treated tissues, and volume may be an important factor for brain and spinal lesions. Early delayed effects can occur 1 to 3 months after treatment and may be due to transient demyelination. Animals with early delayed effects may have signs similar to those of the initial presentation, or they may be generally stuporous. Early delayed effects occur in up to 40% of humans undergoing brain irradiation; symptoms include headache, lethargy, and exacerbation of focal neurologic signs.⁷⁹ In animals, clinical signs often are transient, but response time can be slow. Sometimes administration of systemic cortisone and aggressive supportive care are required. CT and MRI may show an apparent increase in tumor size and tumor enhancement during this time. Focal enhancement in

normal brain associated with edema and demyelination may also be present.⁸⁰

Late effects probably occur in veterinary patients more often than identified and should be considered as a differential diagnosis for signs that occur during that interval. Late delayed effects (more commonly referred to simply as late effects) generally occur at least 6 months after treatment but can also occur years later. Late effects are associated with brain necrosis. The probability of late brain effects depends on the total dose, the fraction size, and the volume of brain irradiated. In a study of 83 dogs with brain masses treated with a hypofractionated protocol (38 Gy administered in 5 weekly fractions), brain necrosis was confirmed or suspected in 14% of dogs (32.7 months).⁸¹ The signs are similar to those associated with early delayed effects, although the response to steroids is limited. Clinically, distinguishing between late effects and tumor recurrence can often be difficult. CT or MRI evaluation can be misleading. Not all brain tumors completely recede after treatment; therefore the presence of a mass does not always indicate a recurring tumor. A prudent course is to obtain a CT or MRI evaluation 6 months after treatment to serve as a reference if clinical signs develop in the future.

Superficial Tumors of the Trunk and Extremities

Many tumors involving the trunk or extremities are amenable to treatment by radiation therapy. Combining radiation therapy with surgery enhances tumor control and improves the functional outcome better than surgery or radiation alone. For tumors in nonresectable locations, radiation alone may provide a good outcome depending on tumor type and volume. The surgeon and radiation oncologist should consult before therapeutic intervention is started to develop an overall treatment approach.

Hemangiopericytomas, fibrosarcomas, neurofibrosarcomas, myxosarcomas, and nerve sheath tumors are classified together as soft tissue sarcomas because of their similar biologic behavior (see Chapter 21). Metastases are uncommon with grade 1 and grade 2 sarcomas; therefore local tumor control is the primary concern. Soft tissue sarcomas are locally invasive, and tumor cells may extend far beyond the bulk of the tumor. Surgery alone is curative if the tumor can be removed completely.⁸² If surgical resection is attempted, the margins should be closely examined by a pathologist for evidence of tumor infiltration. If tumor cells extend out to the margin, radiation therapy should be recommended if further resection is not possible. If it is apparent that a tumor cannot be excised completely, treatment combining radiation and surgery can be beneficial. Radiation therapy can be administered first with the hope of converting an inoperable tumor into an operable one. This approach has the benefit of reducing the volume of normal tissues irradiated. As an alternative, surgical excision can be performed first as a cytoreductive procedure and then followed by radiation therapy to kill the residual subclinical disease. In one study, 48 dogs with soft tissue sarcomas were treated with surgical cytoreduction followed by radiation therapy; only 8 dogs (16%) developed tumor recurrence, and the 5-year survival rate was 78%.⁸³ In a different study, which involved 38 dogs with soft tissue sarcomas of the body and extremities, treatment with surgery followed by irradiation provided a median survival time of 2270 days.⁴⁵ In comparison, soft tissue sarcomas treated by narrow surgical excision alone have recurrence rates of 17% to 40%.⁸⁴⁻⁸⁹

Soft tissue sarcomas can be treated with radiation therapy alone; however, tumor control is not as durable as with a combination of

radiation therapy and surgery.⁴³ Radiation therapy alone is useful for tumors near the pads, where surgical options are limited. Pads in the irradiation field initially may slough; however, if appropriate fractionation schemes are used, the pads regrow and can function normally. Local hyperthermia has been used effectively with radiation therapy to improve local tumor control in canine soft tissue sarcomas.⁹⁰ Currently, no facilities are able to administer hyperthermia. Adjuvant chemotherapy has been considered for grade 3 soft tissue sarcomas because of the higher metastatic potential of these tumors; however, definitive evidence of improvement in local tumor control or survival is lacking.

Cutaneous mast cell tumors (grades 1 and 2) can be treated successfully with radiation therapy (see Chapter 20). The obvious advantage is that greater margins can be obtained with radiation than with surgery. The probability of control may be improved if surgical cytoreduction is performed first. In a study involving 37 dogs with grade 2 tumors treated with cytoreduction and radiation therapy, tumor control at 1 and 2 years exceeded 90%.⁹¹ In 56 dogs with incompletely resected mast cell tumors, the median disease-free interval was 32.7 months.⁹² Radiotherapy also is indicated for cutaneous mast cell tumors with regional lymph node metastasis. In one study, 19 dogs with mast cell tumors and regional node involvement were treated with surgical cytoreduction of the primary site, radiation to the primary tumor and regional node, and prednisone.⁹³ The median disease-free survival time was 1240 days. Palliative radiation therapy is commonly used to treat locoregional mast cell tumors in dogs when systemic spread has occurred.

Vaccine-associated soft tissue sarcomas are a significant problem in cats (see Chapter 21). These tumors are challenging to control locally and seem unresponsive to aggressive radiation therapy or conservative surgery alone. In one study, 33 cats with histologically confirmed fibrosarcomas were treated with radiation therapy followed by surgery.⁹⁴ The median disease-free interval and the overall survival time were 398 and 600 days, respectively. In another study, 25 cats with subclinical disease after surgery were treated with radiation therapy alone (57 Gy delivered in 3 Gy fractions) and in some cases with adjuvant chemotherapy.⁹⁵ The overall median survival time was 701 days. Recurrence was seen in 7 cases (5 of 18 [27.8%] in the group treated with doxorubicin and 2 of 7 [28.6%] in the group not treated with doxorubicin). In the recurrence cases, one tumor developed outside the treatment field and the others arose in the area treated with radiation. Metastases to the lung or other sites were not seen in this group of cats. Similar findings were evident in 78 cats treated with surgical cytoreduction followed by radiation.⁹⁶ In this study, cats that underwent only one surgery before radiation had a lower recurrence rate than cats that had more than one surgery. The survival time and the disease-free interval shortened as the time between surgery and the start of radiation therapy lengthened. In a study of 79 cats treated with either preoperative or postoperative radiation therapy, packed cell volume (PCV) higher than 25 was associated with better outcome (median survival 760 days) than cats with PCV lower than 25 (306 days).⁹⁷

Cats with surgically nonresectable disease present a greater challenge. Escalation of the radiation dose by delivering the dose in smaller fractions probably is necessary for these patients. IMRT or SRT may be beneficial for obtaining adequate dose to the tumor because appropriate sparing of the lungs, viscera, and spinal cord is critical in these patients.

Radiation Considerations

Many tumors of the limbs and trunk extend very close to the skin surface. Application of an appropriate thickness of a bolus material

over the skin is frequently needed when treating with megavoltage photons in order to avoid underdosing the superficial region. When treating a sloped surface such as around a limb, side-scatter equilibrium is lost, resulting in heterogeneous dose distribution that can lead to significant underdosing of tumor and/or overdosing of the skin. The use of tapered bolus can reduce such dose inhomogeneity. Whenever possible, when an extremity is in a radiation field, a 1 to 2 cm strip of tissue should be shielded to avoid the risk of lymphedema, which can present as painful swelling of the distal limb.

Treatment-Related Toxicities

When treating superficial tumors, early effects to the skin are expected and are restricted to the radiation field. The severity of effect is dose related, and the patient may have a variety of lesions. Epilation is common and in some cases may be permanent. The hair may not return for several months, and the amount of regrowth varies in relation to the dose administered to the skin and the individual patient's sensitivity. Damage to the melanocytes may result in hypopigmentation or hyperpigmentation of the skin and/or alteration of the coat color when regrowth occurs, often resulting in whitish-gray fur (leukotrichia). Dry desquamation may accompany epilation; this generally does not cause any problem or discomfort for the patient and usually is not treated. Moist desquamation, which usually appears 3 to 5 weeks after the start of therapy, is associated with pruritus, which can vary in severity. Self-inflicted mutilation exacerbates the problem and may lead to ulceration or necrosis. Severe late effects to the skin are rare in fractionated therapy but include fibrosis and necrosis.

Bone Tumors

Although osteosarcomas are not considered highly radiation-responsive tumors, radiation may be considered as part of a multimodality therapy when surgical excision is not an option. (Radiation therapy for osteosarcoma is discussed at length in Chapter 24.) Radiation therapy can be combined with chemotherapy and surgery for limb-sparing protocols.^{98,99} In a retrospective study of multimodality therapy for axial skeletal osteosarcoma, dogs that underwent curative-intent radiation protocols had a longer duration of tumor control (265 days) than those treated with a palliative regimen (79 days).¹⁰⁰ SRT is currently being evaluated as a limb-sparing alternative. In one study, stereotactic radiosurgery was performed on 11 dogs with appendicular osteosarcomas,²⁴ and although radiation dose varied and not all dogs received adjuvant chemotherapy, good limb function and tumor control were observed in some of the patients. Fifty dogs with appendicular osteosarcoma underwent treatment with SRT followed by chemotherapy. Sites included distal radius and proximal and distal humerus, femur, and tibia. All dogs had improved limb function with no clinical recurrences.²⁵ Fracture was observed in dogs with severely lytic lesions at or before 90 days.¹⁰¹ Criteria were established for patient selection, including evaluation of radiographs and CT scans, reducing fracture rate to less than 20% (personal communication, James Custis). Prophylactic stabilization is indicated in dogs with severely lytic lesions. The mechanism of the amelioration of pain caused by bony neoplasia is not completely understood. Relief of pain may occur almost immediately or may be delayed, sometimes as long as 2 weeks. Human studies have indicated that single, coarsely fractionated radiation may be comparable or superior to multifraction protocols using more conventional doses per fraction.¹⁰² In a recent study of 58 dogs, 8 Gy was administered on 2 consecutive days, providing onset of pain relief within 2 days in 91% of patients.¹⁰³ Commonly in veterinary medicine, 7 to 10 Gy fractions have been administered

on days 0, 7, and 21.^{104,105} In one study, 12 of 15 dogs with appendicular bone tumors treated with palliative radiation therapy had improved limb function, and the median survival time was 130 days.¹⁰⁵ In another study, dogs with appendicular osteosarcoma were given either 3 fractions of 10 Gy or 2 fractions of 8 Gy.¹⁰⁶ Seventy of the 95 dogs experienced pain relief, with a median duration of 73 days. No difference in response was found between the two treatment groups. Sometimes, localized pain recurs before metastatic disease becomes life limiting. Palliative radiation can be readministered as long as the owners understand that continued administration of large doses per fraction eventually leads to late effects.

Radiation Considerations

Radiation is unlikely to have a substantial palliative effect if a pathologic fracture from a bone tumor is already present. Additional padding and support during anesthetic recovery is important to prevent a recovering patient from trying to stand prematurely and injuring the affected limb.

Treatment-Related Toxicities

The most common and concerning bone tumor treatment-related toxicity is pathologic fracture. Most likely, the bone tumor itself rather than any effects of radiation makes the bone susceptible to fracture; however, the pain-relieving effects of radiation and/or other treatments may make animals more likely to put significant weight on the affected limb, resulting in fracture.

Other Tumors

Radiation therapy is used for a variety of tumors in the thoracic and abdominal cavities (Table 12-1). The principles of patient selection for radiation therapy with tumors in these regions are the same as for any other region. Radiation therapy should be considered for any tumor that cannot be excised completely. In one study, dogs with thyroid carcinomas treated with 48 Gy delivered in 4 Gy fractions had PFS rates of 80% at 1 year and 72% at 3 years.¹¹⁹ Thymomas are radiation responsive in human patients.¹²⁰ In a study of seven cats with thymoma that were treated with radiation therapy, the median survival time was close to 2 years (see Chapter 33, Section B).

Palliative radiation therapy can be useful for tumors that may be causing airway, bowel, or urinary tract obstruction or neurologic dysfunction. Mediastinal lymphoma often responds rapidly to irradiation. Relief from respiratory distress can be achieved within hours of a single dose of radiation.

Eighteen dogs with primary disease of the urinary bladder (7), urethra (1), or prostate (10) were treated with IMRT assisted by image guidance to verify tumor position (personal communication, Michael Nolan). The majority of patients were treated with adjuvant chemotherapy and nonsteroidal antiinflammatory drugs (NSAIDs). In all dogs, the radiation dose ranged from 54 to 58 Gy, delivered in 20 daily fractions. Acute and late tissue toxicity was limited, and treatment was well tolerated. Overall median survival time was 654 days. Location of primary tumor had no demonstrable effect on either local tumor control or survival.

Perianal adenocarcinomas and anal sac adenocarcinomas (see Chapter 22, Section H) can be difficult to control locally with surgery alone and are likely to spread to regional lymph nodes. One hundred and thirteen dogs with carcinomas of the apocrine gland were treated with surgery, radiation therapy, chemotherapy, or multimodal treatment. Overall median survival was 544 days. Dogs treated with chemotherapy alone had significantly shorter survival

• **TABLE 12-1** Tumors Commonly Treated with Radiation Therapy

TUMOR LOCATION/TYPE	TREATMENT MODALITY	CONTROL OR SURVIVAL DATA	COMMENTS	REFERENCES
Brain Tumors				
Brain tumors, various types and locations—dogs	Radiation	Median survival: 23.3 months.		69
Pituitary macroadenomas and carcinomas—dogs	Radiation only	1 year: 93%, 2 years: 87%, and 3 years: 55% survival.		107
Pituitary macroadenomas and carcinomas—cats	Radiation only	Overall median survival: 17.4 months, but tumor-related median not reached.	May produce profound improvement in endocrinopathies.	78
	Conformal single fraction	Median survival: 25 months.	55% improved insulin response.	108
	SRT	1 and 2 year: 85% survival.	Decreased insulin requirements in all patients.	26
Tumors of the Extremities and Body—Dogs				
Soft tissue sarcomas	Radiation only	1-year control: 67%. 2-year control: 33%.		43
	Surgery plus radiation	Median control: 86%. Median survival: 5-6 years.	Conservative surgery followed by radiation.	45, 83
Mast cell tumors	Radiation only	1-year control: 44%-78%.		109, 110
	Surgery plus radiation	1-year control: About 90%. Median disease-free interval: 33 months.	For grade 2 tumors.	91
	Surgery plus radiation	Disease-free survival: 3.4 years.	Primary tumor with regional node involvement.	93
Ceruminous gland tumors—dogs and cats	Surgery plus radiation	1-year control: 56%. Mean control: 39.5 months.		111
Tumors of the Extremities and Body—Cats				
Vaccine-associated sarcomas	Radiation followed by surgery	Median disease-free interval: 13-20 months. Median survival: 20 months.	PCV >25, good prognostic indicator.	92, 94, 97, 112
	Surgery followed by radiation	Median survival: 23-43 months.		95, 113
Lymphoma (localized)	Radiation ± chemotherapy	Median survival: 28 months.	Nonnodal, localized forms.	114
Nasal Tumors—Dogs				
Carcinomas (all)	Megavoltage radiation therapy	Median control: 8-12.8 months.	The role of adjuvant chemotherapy has not been determined. Preoperative surgery does not appear to improve tumor control.	52, 57, 58, 60
	IMRT	Median control: 14-15 months.	Dramatically reduced acute effects.	17, 64
Adenocarcinomas	Megavoltage radiation therapy	Median control: 10-12.8 months.		52, 57, 58, 60
Squamous cell tumors	Megavoltage radiotherapy	Median control: 5-8 months.		
Sarcomas (all)	Megavoltage radiotherapy	Median control: 8-12.8 months.		
Chondrosarcomas	Megavoltage radiotherapy	Median control: 12-15 months.		
Carcinomas and sarcomas (all)	Megavoltage radiotherapy	Median control: 16-19 months.	Slow-release cisplatin-impregnated polymer used for sensitization.	62, 63

• TABLE 12-1 Tumors Commonly Treated with Radiation Therapy continued

TUMOR LOCATION/TYPE	TREATMENT MODALITY	CONTROL OR SURVIVAL DATA	COMMENTS	REFERENCES
Nasal Tumors—Cats				
Lymphoma	Orthovoltage or megavoltage radiotherapy	Median survival: 20.8 months.		115
Sarcomas and carcinomas	Megavoltage radiotherapy	Median survival: 11.5 months.		66
Oral Tumors—Dogs				
Acanthomatous ameloblastoma	Radiation only	1-year survival: 85% Median: 48 months.	No evidence of malignant transformation.	29, 30
Squamous cell carcinoma	Radiation only	1-year survival: 65%.		31, 33, 116
Fibrosarcoma	Radiation only	Median control: 4 months.	Surgical cytoreduction followed by radiation therapy improves tumor control.	43, 44
Melanoma	Radiation ± surgery and chemotherapy	Median survival: 8-10 months.	A variety of fractionation schedules. Metastatic disease is a major obstacle to survival.	33, 47, 117, 118
Osteosarcoma—Dogs				
Extremities	SRT limb sparing Radiation (palliative)	10-12 months. Median survival: 4 months.	Multiple sites feasible. Provides pain relief.	24, 106
Axial skeleton	Radiation ± surgery and chemotherapy	Median survival: 4.5 months.	Surgery is performed for cytoreduction if paralysis and/or severe pain are present; cisplatin is used as a radiosensitizer.	100, 104

SRT, Stereotactic radiation therapy; IMRT, intensity-modulated radiation therapy; PCV, packed cell volume.

than those receiving other treatments, whereas the addition of surgery was beneficial.¹²¹ Late effects from radiation therapy to the pelvic region can occur and be clinically significant.¹²² This can be addressed by administering the radiation in smaller doses per fraction. Perianal gland tumors are generally slow to disseminate systemically, so full-course treatment of involved regional nodes may be warranted. Intraoperative therapy as a boost to external-beam radiation therapy may also be useful in the treatment of the regional nodes or associated tumor bed following excision.

Mucositis also can occur whenever any portion of the alimentary system receives radiation therapy. Colitis is a common acute effect during radiation therapy for bladder or colorectal tumors. Severe large bowel diarrhea may be seen. Anusitis from irradiation is worsened by the diarrhea, making the patient quite uncomfortable. High-bulk diets are recommended, along with good hygiene in the region. Steroid enemas seem beneficial in some patients with colitis.¹²³

Lymphoma

Radiation therapy can be important in the treatment of localized lymphoma, and it has an emerging role as an adjuvant therapy in the treatment of systemic lymphoma. Lymphocytes are exquisitely radiation sensitive¹²⁴ and may undergo apoptosis in addition to classic mitotic death after exposure to radiation.¹²⁵ Human patients with non-Hodgkin's lymphoma commonly receive combined

modality treatment with radiation therapy and chemotherapy, primarily for stage I or stage II disease,¹²⁶ although this treatment may have a role in more advanced stages as well.¹²⁷ Combined modality treatment or radiotherapy alone also is beneficial in humans for primary lymphomas of bone, cutaneous B-cell lymphoma, and mycosis fungoides.¹²⁸⁻¹³¹

In one study, a series of feline extranodal lymphomas (nasal cavity, retrobulbar area, mediastinum, subcutaneous tissue, maxilla, and mandible) were treated with megavoltage radiotherapy with or without concurrent chemotherapy.¹¹⁴ Eight of 10 cats attained a complete local remission; one cat with retrobulbar involvement and one with mandibular involvement attained a partial remission. The median remission time for the cats that attained complete remission was 114 weeks, and three cats were alive and disease free at 131 weeks. Three cats developed disease outside the radiation field, which suggests that adjuvant chemotherapy or extending the field for part of the treatment to include additional nodes may improve locoregional control.

Radiation has also been used to treat cutaneous lymphoma in dogs. Radiotherapy of localized lymphoma has been reported to result in prolonged remission times.¹³² Humans with cutaneous B-cell lymphoma commonly undergo radiation therapy, which generally results in long-term control of disease. The extent of skin involvement and the presence of extracutaneous disease are prognostic.¹³¹

Mycosis fungoides is sometimes treated with total skin electron irradiation in humans. As with cutaneous B-cell lymphoma, the stage of disease is prognostic, but human patients with disease confined to the skin may have prolonged remission times.

Interest has developed in the use of half-body radiotherapy to treat canine lymphoma. A dosage of 8 Gy to lymphoma cells reduces the surviving fraction to 0.005, which is much greater than the estimated cell kill from one cycle of chemotherapy.¹²⁴ The rationale for adding radiation to a chemotherapy protocol is that the projected improvement in cell kill would improve the duration of remission and perhaps result in a cure. However, because of the impact of radiation on normal bone marrow cells, the radiation can be administered only to one-half of the body at a time. (8 Gy delivered to the entire body is lethal.) In one study, induction chemotherapy (11 weeks) was administered to 94 dogs, 52 of which received subsequent half-body irradiation.¹³³ Half-body irradiation was administered in 2 daily fractions of 4 Gy to the cranial half of the body; 1 month later, the same protocol was used for the caudal half of the body. No additional chemotherapy was administered because the main purpose of the study was to see whether the half-body irradiation could serve as a substitute for long-term chemotherapy. The median survival of 311 days was comparable to but no better than many chemotherapy-only protocols.

In another study, half-body irradiation was interposed within a 25-week protocol based on cyclophosphamide, doxorubicin, Oncovin, and prednisone (CHOP). The radiation was well tolerated, and the median remission and survival times were 455 and 560 days, respectively. Although these results are very encouraging, the study involved only eight dogs, and the role of radiation in the treatment of systemic lymphoma requires further evaluation. Nevertheless, the addition of irradiation represents a new approach to a disease for which the duration of remission with chemotherapy alone has not improved over the past 10 years. Interestingly, the two half-body studies described previously differed from earlier reports in which each half-body treatment was delivered in a single 7 to 8 Gy fraction (personal communication, A. Abrams-Ogg). Dividing the dose into 4 Gy fractions delivered on consecutive days reduced the number and severity of acute effects. Diarrhea, the most common effect, was seen in about two-thirds of the dogs after the caudal half of the body was treated.¹³⁴

An emerging approach in the management of dogs with lymphoma is total body irradiation (TBI) with autologous transplantation of hematopoietic peripheral blood progenitor cells. In one protocol, following treatment with a standard chemotherapy regimen, dogs are given 500 to 650 mg/m² of cyclophosphamide intravenously. They are then treated with recombinant human granulocyte colony-stimulating factor (rhG-CSF) and undergo apheresis to separate CD34+ progenitor cells followed by two 5 Gy fractions of TBI, 3 hours apart. Immediately after TBI, the cell harvest from apheresis is infused intravenously. In a toxicity study of 10 dogs, all dogs experienced grade 4 neutropenia, lymphopenia, and thrombocytopenia. Neutrophils recovered to at least 500 neutrophils/ μ L by day 12, but thrombocytopenia often persisted for weeks. Collection of long-term outcome data is still ongoing, as are attempts to escalate TBI dose.¹³⁵

Cancer Immunotherapy

AMANDA M. GUTH AND STEVEN DOW

The main role of the immune system is recognition of “foreign” proteins, including mutated or altered forms of self-proteins that arise during tumorigenesis, which are commonly referred to as *tumor antigens* (TAs). However, it is now apparent that powerful regulatory cells whose main function is to prevent rampant, uncontrolled immune responses also serve to block natural development of potent antitumor immune response. Therefore the role of immunotherapy in treatment of various cancers must take into account the ability to overcome these regulators in order to be successful.

It has long been known that the immune system is capable of controlling cancer. For example, it is well established that cancer incidence is increased in immunosuppressed individuals. Moreover, in some cases, spontaneous remission of tumors is observed without any therapeutic intervention, most likely attributed to a successful immune response. Biologically, tumor-specific T-cells are observed in the tumor tissue and tumor-draining lymph nodes, providing evidence that these cells have encountered and recognized the tumor cells as foreign. Finally, in some cases, there is the development of paraneoplastic autoimmunity, suggesting that the antitumor immune response has somehow gone unchecked by the regulator cells.

With the advancement and sophistication of techniques used to study the immune system comes the increased ability to precisely target the malignant cells while leaving normal tissues intact. One of the major goals of immunotherapy is to develop a potent, long-lasting antitumor immune response without producing untoward side effects. However, it is difficult to develop an immunotherapy that is not affected by tumor-induced immune tolerance or even the immune system itself. For example, therapy with the T-cell growth factor cytokine, interleukin-2 (IL-2), leads to expansion of regulatory T-cells, known for their powerful immunosuppressive abilities.¹ In addition, when considering monoclonal antibody (MAb) immunotherapy in companion animals, one must account for the fact that the Fc region of the MAb, the part not involved in antigen recognition, is typically derived from mice or human protein sequences and thus is considered foreign by the immune system. Hence, repeated treatment with a non-canine-based antibody leads to a robust inactivation of the MAb, as well as systemic toxicity, thus eliminating its effectiveness over time.

Knowing more about the immune system and the way it is regulated will increase our ability to design better immunotherapies. In addition, immunotherapy has the potential to work in conjunction with and perhaps enhance the effectiveness of chemotherapies, radiation therapy, surgery, and other adjunct therapies. In this chapter, we will first discuss the role of the immune system in tumor development, then the various classes of immunotherapies both currently in use and those under investigation as part of clinical trials. We will discuss the biologic basis for the therapies, their use in human and companion animals, and their limitations.

Immune System Control of Tumor Development and Growth

Immune Surveillance of Cancer

Forty years ago, Thomas and Burnet, while studying how lymphocytes could respond to newly formed antigens on transformed cells, put forth the concept that the immune system could actively respond to and eliminate cancerous cells, an idea known as *immune surveillance*.² In contrast, later studies^{3,4} showed that genetically manipulated immunodeficient (athymic) mice did not demonstrate an increased incidence of cancer—either spontaneously or carcinogen induced. Such observations were proposed to be due to residual immunity, leading to the immune surveillance concept falling out of favor.

Since the development of more sensitive and sophisticated technologies, many of the ideas behind the concept of the immune surveillance hypothesis are now more accepted, and currently, this modification of the original hypothesis is referred to as the *immunoediting hypothesis*.⁵ Pivotal studies by Robert Schreiber’s group showed that lymphocytes (T-cells) could directly or indirectly through production of a cytokine, interferon γ (IFN- γ), protect mice against the development of methylcholanthrene (MCA)-induced sarcomas.^{6,7} Moreover, they demonstrated that tumors from immunodeficient mice were more immunogenic than tumors from immunocompetent mice, thus leading to the immunoediting hypothesis.^{7,8} This hypothesis consists of three phases: (1) *elimination*: removal of the immunogenic tumor cells by the immune system; however, weakly immunogenic cells can survive; (2) *equilibrium*: tumor growth and immune destruction are equal; and (3) *escape*: tumor growth ensues as the result of decreased immunogenicity, immune suppression, and rapid tumor cell growth.⁵ However, despite recent data, there is still a controversy that remains around the immune surveillance hypothesis, discussed in a review by Schreiber et al.⁵

Mechanisms of Immune Evasion by Tumors

Given the fact that cancer can develop in immunocompetent individuals, some tumor cells are able to avoid recognition by the immune system.⁹ This is accomplished by various mechanisms (discussed later) that involve both changes in the tumor cells themselves and ways in which the tumor and the tumor stromal environment can manipulate the immune system and prevent antitumor immunity. These mechanisms of immune evasion pose a significant challenge to the development of effective immunotherapies. Figure 13-1 demonstrates some of these key mechanisms.

FIGURE 13-1 Mechanisms of tumor cell evasion via hijacking the immune system. DC, Dendritic cell; iDC, immature dendritic cell; MDSC, myeloid-derived suppressor cell; TAM, tumor-associated macrophage; Treg, regulatory T-cell.

Active Immune Suppression by Myeloid-Derived Suppressor Cells

One population of immune cells that play a major role in tumor immunosuppression are myeloid-derived suppressor cells (MDSCs). These cells consist of immature monocytes and granulocytes released from the bone marrow into the blood during pathologic conditions, including cancer. Sometimes included in the functional description of this group of cells are tumor-associated macrophages (TAMs), which have the same ability and use similar mechanisms as MDSCs to induce potent tumor immunosuppression.^{10,11} Numerous studies demonstrate increased numbers of MDSCs in humans with cancer¹²⁻¹⁴ and in mouse models of cancer.^{15,16} Furthermore, it has been shown that the presence of these cells correlates with clinical disease stage and metastatic tumor burden in humans with solid tumors.¹³ MDSCs are recruited to the tumor microenvironment through various chemoattractants,¹⁰ many of which are induced by the tumor during times of hypoxia and are directly released by the effects of hypoxia-inducible factor-1 α (HIF-1 α) production.¹⁷⁻²⁰ Once at the tumor, MDSCs intercalate into the microenvironment and actively suppress the local antitumor immune response and promote tumor invasion and metastasis via the production of matrix metalloproteinases (MMPs) and various chemoattractants.^{21,22} Moreover, these cells, including the TAMs, contribute to increased tumor vessel growth, a process referred to as *angiogenesis*.¹⁰ Of note, although cell surface markers are used to identify these cells in mice and humans, similar markers have yet to be discovered for dogs, thus the role that MDSCs play in canine cancer is currently unknown.

The ability of MDSCs to suppress the antitumor response is the subject of many recent studies.²³⁻²⁵ Numerous mechanisms of suppression have been reported, and MDSCs have the ability to suppress not only T-cells, but also natural killer (NK) cells and dendritic cells (DCs) and they also are able to potentiate T-regulatory cells (Tregs), which are discussed later, and TAMs in the tumor (see

Figure 13-1). Currently known mechanisms of immune suppression by MDSCs include suppression of T-cells through production of inducible nitric oxide (NO) species (iNOS), reactive oxygen species (ROS) and arginase, as well as cysteine deprivation.²³ MDSCs can produce transforming growth factor- β (TGF- β) and IL-10, which stimulate Tregs and TAMs, and MDSCs can cause downregulation of the IL-12 production by TAMs, a cytokine involved in T-cell activation.²⁴ MDSCs cause NK cell anergy (lack of function) also by this decreased IL-12 production and through membrane-bound TGF- β .^{24,25} Thus, given the ability of these cells to use multiple pathways to induce tumor immunosuppression, the development of effective immunotherapies that can target these cells and either eliminate them or lead to their maturation, rather than ones that target specific pathways of suppression, is critical for that therapy's success.

Induction of Regulatory T-Cells by Tumors

Another population of cells that are significantly increased in tumor-bearing humans and animals are Tregs. These cells are phenotypically defined by surface expression of CD4 and CD25 but are most specifically identified by the intracellular transcription factor, forkhead box P3 (foxp3).^{26,27} Other surface markers used to characterize these cells have been described, including cytotoxic T-lymphocyte antigen-4 (CTLA-4), glucocorticoid-induced tumor necrosis factor (TNF) receptor family-regulated gene (GITR), lymphocyte-activation gene 3 (Lag3), and folate receptor-4 (FR-4).²⁸⁻³¹ This distinct subset of CD4+ T-cells is capable of directly suppressing tumor-specific CD4+ and CD8+ T-cells and NK cells and are enriched in the tumor microenvironment by conversion of CD4 T-cells to Tregs by DCs or TGF- β ,³²⁻³⁵ proliferation of tumor-specific Tregs following antigen recognition, or recruitment of these cells via chemokine signaling (i.e., CCR5).³⁶ Recent work has also suggested a role for the chemokine CCL-1 in specifically converting T-cells to Tregs and inducing their suppressive nature.³⁷

Many studies demonstrate that increased numbers of Treg cells are correlated with a poor prognosis.³⁸⁻⁴¹ Additionally, Tregs present in metastatic lymph nodes inhibit the ability of tumor-infiltrating lymphocytes to mount an effective antitumor response.⁴² Work in our laboratory demonstrated that canine Treg cells can also be identified via the expression of CD4 and foxp3.⁴³ Moreover, we saw that cancer-bearing dogs had increased numbers of Tregs compared to healthy dogs and that this difference was greater in certain types of canine cancers.^{43,44} Therefore current therapies aimed at depleting Treg cells in humans could be applied to veterinary medicine. In particular, many studies have shown that the use of cyclophosphamide or anti-Treg-specific antibodies decreases the numbers of Tregs present in tumors and in circulation of tumor-bearing patients.⁴⁵⁻⁴⁹

Impaired Dendritic Cell Activation and Function

Another important mechanism of tumor suppression is through impairment of the potent antigen-presenting cells, dendritic cells (DCs). Numerous studies have denoted that overall numbers of DCs are decreased in various human cancers studied, including head and neck squamous cell carcinomas (HNSCCs),⁵⁰ breast and prostate cancers, and malignant gliomas.⁵¹ A recent study showed that indoleamine 2,3-dioxygenase 1 (IDO1) expression in the tumor microenvironment led to increased DC apoptosis.⁵² Some tumor studies also demonstrated fewer circulating myeloid DCs and a concurrent increase in immature DCs (iDCs) that reduce presentation of antigens and stimulation of T-cells; thus they induce T-cell tolerance rather than activate T-cells.^{51,53,54} Thus the

DCs present in the tumor tend to be immature and dysfunctional. Studies of DCs in numerous human cancers demonstrate minimal activation, decreased ability to stimulate in an alloreactive fashion, and decreased expression of co-stimulatory molecules.^{50,51,55-60} A similar study done in dogs with canine transmissible venereal tumors (CTVT) showed that the tumor environment caused downregulation of DC surface markers of activation and major histocompatibility (MHC), as well as decreased endocytic capabilities and decreased allogenic mixed lymphocyte reaction (MLR) responses.⁶¹ Possible mechanisms causing the DC dysfunction include the overexpression of the protein S100A9,⁶² accumulation of triglycerides in the DCs that leads to decreased capacity to present antigen,⁶³ and downregulation of toll-like receptor 9 (TLR9).⁶⁴ Moreover, factors such as IL-10 and vascular endothelial growth factor (VEGF) can negatively affect DC function and maturation.^{65,66} Finally, some DCs in the tumor are considered to be regulatory based on low expression of surface markers MHC II, CD86, and CD11c with high expression of co-stimulatory molecules CD80, CD40, CD106, and CD11b. These cells secrete regulatory factors such as IL-10 and NO and inhibit proliferation of naïve CD4+ T cells to antigen presented by mature, functional DCs.⁶⁷ Overall, the microenvironment of the tumor leads to attraction of immature and regulatory DCs that due to their decreased activation and function can potentially inhibit the development of antitumor T-cell responses even when copious amounts of antigen are present.

Production of Immunosuppressive Cytokines

In addition to the suppressive milieu established by tumor-infiltrating cells, the tumor cells themselves are capable of producing immunosuppressive cytokines.⁶⁸ A few key cytokines produced by tumor cells are IL-10, TGF-β, and tumor necrosis factor-α (TNF-α).^{68,69} These cytokines act to suppress antitumor T-cell responses and inhibit DC function. IL-10 promotes Treg production and function⁷⁰ and, in an autocrine and/or paracrine fashion, may potentially affect tumor cell proliferation and survival.⁷¹ In human cancer patients, increased levels of serum IL-10 is observed in patients with pancreatic carcinoma and non-Hodgkin's lymphoma (NHL).^{72,73} In addition, elevated levels of IL-10 in diffuse large B-cell lymphoma in humans correlate with a poor prognosis.⁷⁴ TGF-β acts similarly to IL-10 in that it is a potent

immunosuppressive cytokine that can potentiate Treg proliferation and function.^{33,75-77} It can also enhance tumor progression; carcinomas can produce excess TGF-β, which in turn increases epithelial-to-mesenchymal transition, tumor invasion, and metastasis, and inhibit tumor-specific CD8+ T-cells.⁷⁷ Moreover, tumor-produced TNF-α leads to promotion of tumor cell survival via induction of antiapoptotic proteins.⁷⁸ Finally, TNF-α has been shown to promote tumor angiogenesis and metastasis and hamper cytotoxic T-cell and macrophage responses.⁷⁹

One study in veterinary medicine examined a lymph node of a dog with metastatic melanoma. This study revealed an overexpression of IL-10 and TGF-β concurrent with a lack of expression of IL-2, IL-4, or IFN-γ—cytokines typically associated with antitumor immunity—thus demonstrating that tumor immunosuppression occurs in veterinary patients as well.⁸⁰ For a review of cytokines relevant to tumor immunotherapy, see Table 13-1.

Failure of Tumor Cells to Activate Immune System

Tumor cells are also capable of avoiding immune elimination by failing to be recognized by the immune system in the first place. For example, some tumor cells can downmodulate MHC surface expression to escape recognition by T-cells. MHC class I expression can be lost on tumor cells due to changes in protein synthesis, structure, or allelic loss.^{81,82} Moreover, defects in antigen processing and presentation can occur that can also lead to decreased MHC expression.^{81,82} A decrease in class II expression is also observed in certain human hematopoietic cancers, although it should be noted that most tumors are normally MHC class II negative.^{83,84} Reduced expression of MHC class II has been recently correlated with poor outcome in dogs with B-cell lymphoma.⁸⁵

In addition, tumor cells can express co-inhibitory surface molecules, such as CD73 and/or PD-L1. CD73 is an ecto-5'-nucleotidase that catalyzes the breakdown of adenosine monophosphate (AMP) to adenosine. When expressed on tumors, this creates a local microenvironment rich in adenosine, which is immunosuppressive.⁵² The programmed death-1/programmed death ligand-1 (PD-1/PD-L1) axis also plays an immunosuppressive role in cancer. PD-L1 expression on tumors downmodulates antitumor T-cell function⁸⁶⁻⁸⁸ and NK cell⁸⁹ activity via interaction through the PD-L1 expressed on these immune cells. Thus tumor cells themselves can actively and directly suppress antitumor T-cell responses

• **TABLE 13-1** Biologic Activities of Key Cytokines Relevant to Tumor Immunotherapy

CYTOKINE	MAJOR ACTIVITY
IL-2	<ul style="list-style-type: none">■ Growth factor for T-cells, including regulatory T-cells.■ Induces proliferation and differentiation of T-cells to effector T-cells.■ Enhances CTL and NK cell cytotoxicity, production of LAK cells.■ Induces B-cell proliferation.■ Approved for use clinically by the FDA.
IL-3	<ul style="list-style-type: none">■ Multicolony-stimulating factor.■ Promotes production/differentiation and proliferation of macrophages, monocytes, granulocytes, and DCs.■ Secreted by activated T-cells and supports growth and differentiation of T-cells.
IL-4	<ul style="list-style-type: none">■ Key Th2 cytokine.■ Induces differentiation of naïve CD4 T-cells toward Th2 phenotype.■ Inhibits macrophage activation.■ Induces B-cell growth and differentiation.■ Stimulates isotype switching and IgG and IgE production.■ Upregulates MHC class II production.

• **TABLE 13-1** Biologic Activities of Key Cytokines Relevant to Tumor Immunotherapy continued

CYTOKINE	MAJOR ACTIVITY
IL-6	<ul style="list-style-type: none"> Supports B-cell proliferation and differentiation to plasma cells. Proinflammatory, antiapoptotic cytokine that may contribute to tumor development associated with chronic inflammation. Causes upregulation of PD-1 on monocytes that are triggered to produce IL-10 following ligation of this receptor.
IL-8	<ul style="list-style-type: none"> Chemotactic/activation factor for neutrophils and T-cells. Induces MMP2 activity; plays a role in inflammation and tumor metastasis.
IL-10	<ul style="list-style-type: none"> Immunosuppressive cytokine produced by activated DCs, macrophages, and T-cells. Induces regulatory T-cell function. Also overexpressed by some tumors and tumor-associated leukocytes.
IL-11	<ul style="list-style-type: none"> Stimulates proliferation of hematopoietic stem cells. Induces megakaryocyte maturation, resulting in increased platelet production.
IL-12	<ul style="list-style-type: none"> Key Th1 cytokine produced by DCs, macrophages. Stimulates synthesis of IFN-γ and TNF-α by T-cells and NKs, thus decreasing angiogenesis. Enhances cytotoxicity of CTLs and NK cells. Stimulates differentiation of naïve CD4⁺ T-cells to T-cells with the Th1 phenotype.
IL-13	<ul style="list-style-type: none"> Th2-promoting cytokine, produced by NKT cells. Inhibits inflammatory cytokine production by macrophages. Possible inhibitory role in tumor immunosurveillance.
IL-15	<ul style="list-style-type: none"> T-cell growth factor. Supports survival of memory CD8⁺ T-cells. Promotes NK cell activation and survival and triggers cytotoxic activity.
IL-17	<ul style="list-style-type: none"> Induces proinflammatory response. Role in cancer is currently controversial, depending on context, may either promote or inhibit tumor growth.
IL-19	<ul style="list-style-type: none"> Promotes T-cell differentiation toward the Th2 phenotype.
IL-21	<ul style="list-style-type: none"> Member of IL-2 cytokine family. Enhances cytotoxicity and proliferation of CTLs and NK cells.
IL-23	<ul style="list-style-type: none"> Member of IL-12 cytokine family. Upregulates the production of MMP9 in tumors. Increases angiogenesis, while reducing CD8 TILs. Stimulates CD4⁺ T-cells to become Th17 cells.
GM-CSF	<ul style="list-style-type: none"> Promotes growth and differentiation of pluripotent progenitor cells. Stimulates growth of cells of the granulocyte, macrophage, and eosinophil lineage.
CSF-1	<ul style="list-style-type: none"> Promotes differentiation of stem cells into monocytes and macrophages.
G-CSF	<ul style="list-style-type: none"> Stimulates bone marrow to produce granulocytes and stem cells. Stimulates neutrophil survival, function, and maturation.
IFN- α , IFN- β	<ul style="list-style-type: none"> Induces apoptosis of tumor cells. Enhances CTL effector function. Activates NK cells. Modulates MHC class I/II expression. Inhibits tumor angiogenesis.
IFN- γ	<ul style="list-style-type: none"> Key Th1 cytokine produced by activated T-cells and NK cells. Promotes the differentiation of naïve CD4⁺ T cells to Th1 phenotype. Activates macrophages. Increases MHC class I/II expression.
TNF- α	<ul style="list-style-type: none"> Produced by Th1 cells, CTLs, activated DCs, and macrophages. Induces NO production by macrophages. Induces tumor apoptosis. Important proinflammatory cytokine.
TGF- β	<ul style="list-style-type: none"> Immunosuppressive cytokine. Inhibits macrophage activation and B-cell growth. Overexpressed by some tumors.

CTL, Cytotoxic T-lymphocyte; CSF-1, colony-stimulating factor-1; DCs, dendritic cells; FDA, Food and Drug Administration; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IgE, immunoglobulin E; IgG, immunoglobulin G; IL, interleukin; LAK, lymphokine-activated killer; MHC, major histocompatibility; MMP, matrix metalloproteinase; NK, natural killer; NKT, natural killer T-cell; NO, nitric oxide; PD-1, programmed death-1; Th1, T-helper 1; Th2, T-helper 2; TGF, transforming growth factor; TILs, tumor-infiltrating lymphocytes; TNF, tumor necrosis factor.

through such mechanisms as decreased expression of MHC molecules and increased expression of inhibitory molecules.

Strategies to Control Tumor Growth through Immune Activation

Depletion of Immunosuppressive Myeloid-Derived Suppressor Cells to Allow for Effective Immunotherapy

In light of many recent studies, it has become clear that in order to develop an effective immunotherapy, it must be able to overcome, or be combined with other treatments that can overcome, the immunosuppression present in the tumor microenvironment. As mentioned previously, MDSCs are a key component of such immunosuppression. Box 13-1 lists the various potential ways in which MDSCs can be manipulated in order to enhance the effectiveness of immunotherapy.

Nonspecific Immune Activation to Generate Antitumor Activity Using Biologic-Response Modifiers

In the 1900s, William Coley observed that cancer patients who developed bacterial infections survived longer than those that did not (reviewed in Richardson and colleagues¹¹⁰). Building on these observations, Coley developed “Coley’s toxins,” which consisted of killed cultures of *Streptococcus pyogenes* and *Serratia marcescens* that he gave to patients with inoperable sarcomas. Although with this “vaccine,” Coley saw cure rates of approximately 15%, his therapy was discontinued because of its significant failure rate and intolerable side effects. However, this seminal work laid the foundation for further studies aimed at nonspecific, pan-immune activation to treat cancer through the use of biologic-response modifiers (BRMs).

Bacillus Calmette-Guérin and Corynebacterium parvum

One of the most well-known and clinically utilized BRMs is bacillus Calmette-Guérin (BCG), a live, attenuated strain of *Mycobacterium bovis*. Currently, in human medicine, BCG is intravesically instilled into the bladder where it is considered to be effective as a means to treat and prevent relapse of noninvasive transitional cell carcinoma (TCC).^{111,112} One proposed mechanism for its antitumor effects relates to the recruitment of neutrophils and their ability to promote urothelial cell turnover.¹¹³ This recruitment most likely relates to the ability of BCG to elicit T-helper 1 (Th1) inflammatory cytokines.^{114,115}

The use of BCG in veterinary medicine is rather limited. Although its efficacy has been tested on numerous forms of canine cancer,¹¹⁶ its use as an immunotherapy in dogs is limited. BCG can be safely instilled into canine bladders,¹¹⁷ but the rate of true superficial bladder cancers is extremely low in dogs as compared to humans.¹¹⁸ Recent uses of BCG in canines include treatment of CTVT in conjunction with vincristine¹¹⁹ or, in combination with human chorionic gonadotropin (hCG; LDI-100), treatment of mast cell tumors (MCTs).¹²⁰ In this study, response rates for grade I and II MCTs were comparable to single-agent vinblastine but without the myelosuppression.

Another BRM that has been studied in human and veterinary medicine is *Corynebacterium parvum*. In human and dog melanoma studies, *C. parvum* displayed antitumor activity as an adjunct to surgery.^{121,122} However, efficacy of *C. parvum* as an immunotherapy in other canine cancers has been disappointing.¹²³

Salmonella

As a tumor grows, the core may become necrotic as the initial tumor cells are deprived of nutrients. Layered on this necrotic core are tumor cells that exist in an area of hypoxia, which puts them out of reach of blood vessels that can supply them with oxygen. These cells are able to remain viable and pose a challenge to most immunotherapies, chemotherapies, and even small molecule drugs due to their restricted location. Recently, researchers have begun to

genetically modify facultative anaerobic bacteria that can penetrate and survive in these regions. In fact, it has been shown that several strains of *Salmonella*, including *S. typhimurium* and *S. choleraesuis*, target tumors following systemic administration. These bacteria penetrate the necrotic core and feed on the dead cells while also emitting natural toxins that will destroy surrounding, viable cells. Using a mouse melanoma model, treatment with VNP20009, an attenuated *S. typhimurium*, was able to slow tumor growth and specifically target primary tumor and metastatic lesions.¹²⁴ Although this study showed that the effects were independent of B- and T-cells, possible indirect effects of the *Salmonella* include production of inflammatory cytokines, such as TNF- α .¹²⁵ Recently, another proposed mechanism involves the ability of *Salmonella* to induce melanoma cells to express gap junctions that can interact with DCs and cause bits of tumor cell proteins to be loaded and expressed on the surface of these DCs for presentation to T cells.¹²⁶ Unfortunately, in human trials, the bacteria failed to colonize some patients and did not provide any antitumor activity.¹²⁷

Administration of VNP20009 in dogs resulted in a more positive outcome than in humans. In a phase I clinical trial, VNP20009 was administered to dogs with a variety of malignant tumors.¹²⁸ In this study, 41 dogs received intravenous infusions of VNP20009 either weekly or biweekly at escalating doses. Fever and vomiting were reported as dose-limiting toxicities. Bacterial colonization was seen in approximately 40% of dogs, and significant clinical responses were observed in 15% of patients, with an overall rate of 37% of dogs experiencing either a transient response or stable disease. Thus the use of VNP20009 in specific dog tumors should be further investigated, perhaps in combination with modified *Salmonella* engineered to deliver tumor cytotoxic agents.

Superantigens

Bacteria, such as *Staphylococcus aureus*, produce enterotoxins known as *superantigens* (SAGs). Two of these *S. aureus* enterotoxins, referred to as *SEA* or *SEB*, stimulate T-cell proliferation and Th1 cytokine production (IL-2, TNF- α , and IFN- γ) via their ability to cross-link the T-cell receptor and MHC class II molecules. These activated T-cells are highly cytolytic and antitumorogenic in mouse models of cancer.^{129,130} Moreover, the potency of SAGs is increased when delivered with stimulatory cytokines.^{131,132} However, when these SAGs were injected into humans, toxic shock syndrome was elicited.¹³³ Therefore genetically modified versions of the SAGs that maintain their immune potency have been evaluated in humans. In a study of patients with non-small-cell lung carcinoma using a modified SAG, stable disease occurred in 42% of patients with decreased tumor burdens of up to 50%. The dose-limiting side effect noted in this study was hypotension.¹³⁴ SAGs and modified versions are still currently being evaluated for potential use as a human cancer therapeutic.^{135,136}

In veterinary medicine, SAGs were evaluated for efficacy and safety in dogs with oral melanoma and soft tissue sarcoma (STS). Dow et al assessed the efficacy of intratumoral injection of lipid-complexed plasmid DNA that encoded for SEB and either granulocyte-macrophage colony-stimulating factor (GM-CSF) or IL-2.¹³¹ Complete or partial remission was seen in 46% of dogs and increased survival time for stage III diseased dogs was observed. There were no toxicities noted, and analysis of tissue sections revealed increased infiltration of tumors with T-cells and macrophages. Thamm et al assessed the efficacy of a lipid-DNA-SEA/IL-2 therapy in dogs with STS.¹³⁷ In this study, dogs received once weekly intratumoral injections and surgery was done after the 12-week treatment. In the 25% of dogs that responded to the therapy (3

complete responders, 1 partial), a diffuse lymphoplasmacytic infiltrate was observed on histologic evaluation of the tumors. Thus SAGs show some promise for use in veterinary medicine.

Liposome-Encapsulated Muramyl Tripeptide

Similar to SAGs, bacterial cell components such as peptides derived from mycobacterial cell walls were evaluated for potential immunogenicity. One such product is muramyl tripeptide (MTP), which, when encapsulated in a phosphatidylethanolamine-based liposome (L-MTP-PE), can efficiently activate monocytes and macrophages to produce proinflammatory cytokines, such as IL-1 α and β , IL-6, IL-7, IL-8, IL-12, and TNF- α .¹³⁸ The use of L-MTP-PE as a therapeutic was assessed in phase I and II trials of people with osteosarcoma (OSA), renal carcinoma, and metastatic melanoma.¹³⁸⁻¹⁴⁰ Moreover, this drug has been approved for use in treating pediatric osteosarcoma in Europe under the name Mifamurtide.¹⁴¹

L-MTP-PE has been evaluated in veterinary medicine in a variety of studies.¹⁴²⁻¹⁴⁶ The survival benefit of L-MTP-PE therapy has been most clearly demonstrated in dogs with appendicular OSA.¹⁴⁷ In this study, dogs receiving L-MTP-PE following limb amputation had a median survival time (MST) of 222 days, whereas dogs that received placebo had an MST of 77 days. However, since most of the dogs in both groups developed metastatic disease, further studies evaluated the efficacy of L-MTP-PE in conjunction with chemotherapy.¹⁴² In one study, dogs receiving L-MTP-PE after treatment with cisplatin had an MST of 14.4 months versus 9.8 months in dogs that received cisplatin only. Interestingly, only 73% of dogs receiving L-MTP-PE developed metastatic disease compared to 93% in the cisplatin only group. However, in a second trial, these investigators saw no significant survival advantage in dogs with OSA that received L-MTP-PE concurrently with cisplatin. The authors postulated that cisplatin obviated antimetastatic potential of L-MTP-PE due to impaired immune effectors. L-MTP-PE was also evaluated for efficacy in canine hemangiosarcoma (HSA).¹⁴⁴ Dogs that received L-MTP-PE with chemotherapy following splenectomy had an MST of 9 months versus the 5.7 months seen with dogs receiving chemotherapy alone. In another study, only dogs with stage I oral melanoma that received L-MTP-PE had an increased survival over placebo-treated dogs.¹⁴⁵ No differences were seen within the dogs with more advanced disease.

Liposome-DNA Complexes

Bacterial DNA can also stimulate the innate immune system via its CpG-oligonucleotides (CpG-ODNs), particularly when complexed with cationic liposomes, in a form known as cationic lipid-DNA complexes (CLDC).¹⁴⁸ Complexing bacterial plasmid DNA to liposomes allows for more efficient delivery of the CpG DNA to the endosomal compartment of antigen-presenting cells such as DCs, in which it is released from the liposomes and binds to its receptor, TLR9.^{149,150} In mouse studies, CLDC stimulates the immune system largely through induction of NK cell activity and release of IFN- γ .¹⁴⁸ Moreover, CLDC was also shown to stimulate the production of type I IFN¹⁵¹ and thus is a potent nonspecific immunostimulant.

The use of CLDC in dogs has been evaluated in metastatic OSA and in dogs with STS.^{152,153} Intravenous administration of a modified CLDC that encodes for IL-2 was performed in dogs with stage IV OSA.¹⁵² Dogs that received CLDC developed fevers and showed changes in their leukogram profile indicative of immune stimulation. Moreover, NK cell activity was observed, as assessed by target cell lysis, and monocytes showed increased expression of B7.2 on their surface, indicating activation. Treatment was associated with a significant increase in survival times compared to historic

controls. Another study examined the use of CLDC in canine STS. Administration of CLDC intravenously once weekly for 6 weeks resulted in an objective response in 15% of the dogs and a decrease in tumor mean vessel density in half of the dogs receiving treatment.¹⁵³ Thus CLDC has potential to be used as a stand-alone immunotherapeutic in veterinary medicine for a variety of cancer types.

Oncolytic Viruses

Oncolytic viruses are defined as viruses capable of replicating in and lysing tumor cells, thus making them a likely candidate for drug or gene delivery to tumors. A beneficial side effect of these viruses is that they can kill the tumor cell, thus providing release of TAs for processing by the immune system. Adenoviruses that have undergone genetic modification of their early genes, 1A (E1A) and 1B (E1B), preferentially target rapidly dividing tumor cells and have been used to target canine OSA cells.¹⁵⁴⁻¹⁵⁶ Canine distemper virus (CDV) has also been investigated as a treatment for B- and T-cell lymphoma in dogs.¹⁵⁷ In vitro studies using fluorescently labeled, attenuated CDV and canine lymphoma cells demonstrated that CDV infected lymphoid cells via binding of the cell membrane protein CD150, which is overexpressed on malignant B cells, and induced cellular apoptosis.¹⁵⁷

Nonspecific Tumor Immunotherapy Using Recombinant Cytokine Therapy

Interleukin-2

IL-2 is a cytokine that is released by T-cells following their activation via interactions of antigen-loaded MHC and co-stimulatory molecules expressed on the surface of antigen-presenting cells. Its function is to induce clonal expansion of T-cells in an antigen-specific fashion and activate DCs, macrophages, and B-cells, which in turn release proinflammatory cytokines. Moreover, IL-2 stimulates NK cells, thus playing an important role in inducing both the innate and adaptive arms of the immune system.

The therapeutic use of IL-2 in humans is fraught with toxicity.¹⁵⁸⁻¹⁶⁰ However, the use of IL-2 therapy in veterinary medicine holds some promise as a therapeutic. First, Helfand et al demonstrated that intravenously injected recombinant human IL-2 (rhIL-2) activates canine lymphocytes, causing only mild gastrointestinal toxicity, even at high doses for 4 consecutive days.¹⁶¹ Another study demonstrated the ability of rhIL-2 to induce canine lymphokine-activated killer (LAK) cells and incidentally showed that LAK cells from tumor-bearing dogs did not kill tumor cells as efficiently as compared to normal dogs.¹⁶² Further evaluation of toxicity and efficacy of rhIL-2 was done using dogs with primary lung cancer and with lung metastases in an aerosol formulation.¹⁶³ In this study, complete regression was seen in two of the four dogs with pulmonary metastases, and these dogs remained disease free for at least 12 months after treatment. One of the two dogs with a primary lung tumor had disease stabilization for more than 8 months, whereas the other dog had progressive disease. Assessment of the lymphocytes obtained from bronchoalveolar lavage showed increased cytolytic activity following 15 days of IL-2 treatment. In addition, minimal toxicity was noted in this study. Finally, IL-2 gene therapy using viral vectors has been examined for treatment of feline fibrosarcomas and canine melanoma and was shown to be safe and effective.¹⁶⁴⁻¹⁶⁶ Therefore, given its low toxicity and promising effectiveness, rhIL-2 therapy is a plausible treatment for canine cancer.

Interleukin-12

IL-12, produced by antigen-stimulated DCs, macrophages, and B-cells, plays a role in stimulating the growth and function of T-cells and enhances the cytolytic activity of both T-cells and NK cells. Similar to IL-2, IL-12 therapy in humans leads to serious side effects; currently, it is not used clinically. Current investigation into the use of IL-12 in veterinary medicine revolves around recombinant gene therapy for treatment of canine head and neck tumors,¹⁶⁷ with some in vitro work looking at its use in feline hyperthermia-induced gene therapy.¹⁶⁸

Interleukin-15

IL-15 is structurally similar to and uses similar signaling molecules as IL-2. IL-15 plays a role in stimulation of NK cells and promoting proliferation of T-cells. However, from an immunotherapy standpoint, IL-15 holds more promise than IL-2 in that (1) it does not cause activation-induced cell death of CD4+ T-cells following prolonged periods of exposure; rather it sustains T cell proliferation,¹⁶⁹ (2) IL-15 plays a critical role in CD8+ T-cell memory formation and maintenance,¹⁷⁰ and (3) unlike IL-2, IL-15 does not appear to play a role in the development of Tregs.¹

Clinical investigation of IL-15 will begin soon. An initial safety study in nonhuman primates was recently conducted.¹⁷¹ Twelve daily doses of clinical grade rhIL-15 revealed that neutropenia was the dose-limiting toxicity and documented an increase in circulating NK cells and memory CD8+ T-cells.

In veterinary medicine, one study used plasmid IL-15 in combination with plasmid IL-6 in beagles with CTVT.¹⁷² A threefold increase in the proportion of CD8+ T-cells that infiltrated the tumors and an enhancement of IFN- γ -producing cells and increased cytolytic activity against the tumor were observed. Thus IL-15 therapy shows promise as an effective immunotherapy in both human and veterinary medicine.

Interferons

IFNs are proteins produced by lymphocytes that play an important role in immune responses to pathogens and cancer. Broadly, they can influence cell proliferation, play a role in the induction of apoptosis, upregulate antigen presentation to T-cells, and enhance the ability of the adaptive immune system to mount a cytolytic immune response. Moreover, IFNs have antiangiogenic properties. The IFNs are typically classified as either type I (IFN- α , - β , and - ω) or type II (IFN- γ).

Interferon- α , Interferon- β , and Interferon- ω Type I IFNs can affect cellular proliferation through various mechanisms, including interactions with cell cycle proteins (i.e., c-myc and retinoblastoma) and induction of apoptosis via Bcl-2/Bax and TNF/Fas interactions. Their antiangiogenic properties of downregulating VEGF and basic fibroblast growth factor (bFGF)¹⁷³ make them attractive as immunotherapies, and they have been used successfully to treat pediatric hemangiomas.¹⁷⁴

Clinical trials using type I IFNs have met limited success due to the high occurrence of severe toxicity in light of overall limited response rates. Nonetheless, their effectiveness was assessed in melanoma, multiple myeloma, renal cell carcinoma, leukemia, and other cancers, as well as in conjunction with chemotherapies. The best response, in terms of disease-free survival, was seen in renal cell carcinoma and melanoma when used as single agents.^{175,176}

The use of type I IFNs in veterinary medicine is limited and mostly used for feline viral therapies.¹⁷⁷ One study showed that

recombinant feline IFN- ω was safe and easy to use for treating feline fibrosarcomas. As this was a safety study, the therapeutic effects of this treatment were not evaluated. Another recently published study also used recombinant feline IFN- ω with or without chemotherapy to study its effects in treating mammary tumors in vitro.¹⁷⁸ This study reported that the antitumor cell effects of recombinant IFN and chemotherapy were additive and suggested further investigation into its clinical use as an adjuvant therapy.

Interferon- γ IFN- γ plays an important role in stimulating the immune system. It is secreted mostly by NK cells, DCs, and antigen-activated T-cells and counteracts the effects of many of the immunosuppressive cytokines. It is a physiologic activator of macrophages, leading to increased antigen presentation and increased lysosomal function and NO production by macrophages. NO production by macrophages is an efficient mechanism of tumor cytotoxicity. IFN- γ can also cause increased MHC class I and II expression on a variety of cells, including tumors. Increased MHC expression has been confirmed to occur on in vitro IFN- γ -treated canine tumor cell lines¹⁷⁹ and in vivo following treatment with IFN- γ .¹⁸⁰ Thus its role in antitumor immunity is characterized by increased tumor cell lysis and increased tumor antigen presentation to the adaptive immune response.

The use of IFN- γ in veterinary medicine is currently being investigated. A recently published study examined the use of IFN- γ in combination with a single injection of autologous, ex vivo activated DCs in dogs with various malignant or benign tumors.¹⁸¹ In the seven dogs enrolled in the study, the investigators noted four complete responses and two partial responses against malignant tumors and saw moderate partial responses against fast-growing benign tumors. Another study looked at the use of adenoviral IFN- γ gene transfer as an adjuvant therapy to treat a dog with astrocytoma.¹⁸² Following therapy and surgery, the dog was tumor free for greater than 450 days. Finally, a safety study was done in cats with fibrosarcomas using a triple-gene therapy that included IFN- γ along with IL-2 and GM-CSF.¹⁶⁶ In this study, cats tolerated the therapy, although six of the eight cats developed local recurrence of disease within 1 year of treatment.

Specific Immunotherapy for Cancer: Tumor Vaccines

The development of a tumor vaccine that is safe, effective, and long-lasting is an ultimate goal of immunotherapy. Whereas the effects of traditional cancer treatments such as chemotherapy, surgery, and radiation therapy typically result in noticeable clinical responses within hours to days following treatment, cancer vaccine therapeutic responses typically take weeks to months to lead to an appreciable clinical response. This difference in response time, coupled with the lack of congruent and objective ways to measure efficacy, make it difficult to develop tumor vaccines.

In an attempt to alleviate the lack of objectivity in assessing responses to cancer therapy, the National Cancer Institute (NCI) created an objective way to measure clinical responses, termed *response evaluation criteria in solid tumors* (RECIST). Under RECIST criteria, a clinical response is defined as a 30% reduction in the total sum of the maximum diameter of all lesions concurrent with the lack of appearance of new lesions or progression of current lesions.¹⁸³ The RECIST criteria were modified in 2009 to include changes to the number of lesions assessed, evaluation of pathologic

lymph nodes, confirmation of response to treatments, clarification of disease progression, and incorporation of imaging modalities into the RECIST criteria.¹⁸⁴

Nonetheless, despite the challenges to tumor vaccine development, there are many different varieties of tumor vaccines currently in use either clinically or as part of phase I, II, and III clinical trials. In fact, in April of 2010, the first therapeutic cancer vaccine for human prostate cancer was approved by the Food and Drug Administration (FDA). In this section, we will discuss only those vaccines showing success in human trials and those relevant to veterinary medicine.

Tumor Antigen Targets for Immunization

Mutations or differential expression of tumor-derived proteins are referred to as *tumor antigens* (TAs). These proteins include the broad categories of oncogenes, oncofetal proteins, and cancer testis antigens. Although TAs offer potential targets for vaccine development, their downside is that some of them tend to be individual or tumor type specific. Nonetheless, much work has been accomplished characterizing TAs for various forms of cancer, and a table of currently studied TAs can be found in a 2009 publication by a panel of experts organized by the NCI.¹⁸⁵ Whereas numerous TAs exist, the use of these TAs in tumor vaccines is not trivial. As mentioned previously, the tumor is highly capable of inducing a potent, immunosuppressive microenvironment by various mechanisms, thus standard vaccine procedures using TAs can be rendered useless in this powerful environment. In fact, there are little data available showing a clear correlation between in vitro TA responses and prognosis. Success of most tumor vaccines has been limited to animal models of induced disease.^{186,187} However, through the use of better vaccine strategies and by combining therapies that can ultimately overcome tumor immunosuppression, more promising specific immunotherapies are being developed. Next, we will discuss the various platforms used to develop tumor vaccines.

Tumor Vaccine Approaches

Whole Tumor Cell and Tumor Cell Lysate Vaccines

One of the more simple approaches to tumor vaccine development is through the use of whole tumor cell or tumor cell lysate vaccines. These can either be made directly from the patient in the form of an autologous vaccine or from cell lines of similar tumor types from the same species as an allogeneic vaccine. Whole cell preparations are made by rendering tumor cells and/or tissues nonfunctional, typically via gamma irradiation. Tumor lysate vaccines, including membrane protein fraction vaccines, are made by mechanically disrupting the tumor cells and/or tissues. Both whole cell and tumor lysate vaccines are typically administered with some form of adjuvant to enhance the immune response. These polyvalent vaccines are superior to specific peptide or protein (subunit) vaccines in that they contain a heterogeneous population of TAs.

One study out of our laboratory assessed the use of an allogeneic HSA tumor lysate vaccine in combination with chemotherapy.¹⁸⁸ In this phase I/II study, 28 dogs were evaluated and received eight immunizations of tumor lysate plus liposome-DNA adjuvant (see Liposome-DNA Complexes) over a 22-week period while concurrently receiving doxorubicin. The vaccine was well tolerated; side effects were limited to moderate diarrhea and anorexia. Tumor-specific antibody responses were detected in four to five of the six dogs tested, depending on which HSA cell-line they were screened against. Moreover, overall survival times of dogs receiving the

combination treatment were significantly better than historic controls treated with only chemotherapy.

Whole cell and tumor lysate vaccines can also be modified to enhance their immunogenicity. Aside from different adjuvant strategies, combination of these vaccines with modifiers such as immunostimulatory cytokines has been examined. One clinical trial of 16 dogs with STS or melanoma assessed the use of an autologous, whole cell vaccine transfected with human GM-CSF.¹⁸⁹ Three dogs in the study demonstrated objective tumor responses that included regression of primary and metastatic lesions. On histologic examination of tumor tissue in the dogs that received the vaccine, an impressive inflammatory response was noted. Another recent study using a similar human GM-CSF vaccine looked at its efficacy in treating dogs with B-cell lymphoma.¹⁹⁰ Dogs in remission following a 19-week standard CHOP protocol (cyclophosphamide, hydroxydaunorubicin [doxorubicin], vincristine [Oncovin], prednisone) were randomized into placebo or vaccine treatment groups. Although no changes in median length of remission were seen, dogs receiving the vaccine demonstrated a significant increase in overall survival. Lastly, a recent study investigated the use of an allogeneic melanoma vaccine in combination with a xenogenic melanoma protein, human glycoprotein 100 (hgp100).¹⁹¹ In this phase II trial, the vaccine was well tolerated, and the researchers observed an overall response rate of 17% and a tumor control rate (including complete and partial responses as well as stable disease greater than 6 weeks duration) of 35%.

Immunization Against Defined Tumor Antigens Using Plasmid DNA

Vaccines that use specific gene sequences of TAs encoded in plasmid DNA have shown some clinical promise with their ability to invoke both cellular and humoral immunity. The ease of working with bacterial DNA and the ability to quickly produce large quantities of plasmid DNA make this an attractive vaccine platform. Moreover, the DNA sequences of a majority of TAs are known and can be easily inserted into the plasmid DNA and expressed under the control of a constitutively active bacterial promoter. Typically given intradermally or intramuscularly, the proteins expressed by transcription and translation of the plasmid are readily picked up by DCs, processed, and presented in the context of MHC class I and II, thus providing a more “natural” stimulation of the immune system. Moreover, the unmethylated dinucleotide-CpG residues, or CpG motifs, present in high frequency in the bacterial DNA, provide additional stimulation of DCs, triggering them to induce a Th1-type immune response.¹⁹²

No DNA vaccines have been licensed for human use yet. However, many DNA vaccines have been tested in clinical trials, and results have thus far been disappointing for various reasons (see review in Liu¹⁹³). Nonetheless, the first conditionally licensed (by the U.S. Department of Agriculture [USDA]) veterinary cancer vaccine is based off of the DNA plasmid technology.¹⁹⁴ The ONCEPT vaccine (Merial, Duluth, GA) for canine malignant melanoma (CMM) uses xenogeneic DNA plasmids that contain the gene-encoding human tyrosinase (huTyr). Initial studies showed the development of an antibody-mediated immune response against the huTyr protein that cross-reacted to canine tyrosinase.¹⁹⁵ Improved survival of dogs treated with this vaccine compared to historical control animals has been reported with no severe side effects noted.^{194,196} Further studies of this plasmid DNA technology demonstrated that the vaccine could induce antigen-specific IFN- γ + T-cells in normal beagle dogs.¹⁹⁷ Finally, the same group that developed the CMM vaccine has reportedly completed phase I

trials of murine CD20 for treatment of canine B-cell lymphoma and is initiating a phase II trial soon.¹⁹⁸

Tumor Vaccination Using Viral Vector Vaccines

As discussed previously, viruses have been used to target tumor cells, particularly those with innate oncolytic properties. However, viruses can also be used as vectors for expression of particular TAs. Typically, attenuated or replication-defective forms of the virus are used to allow for effective stimulation of the innate and adaptive immune responses without the risk of spreading and rapidly dividing within the host. The most commonly used viral platform for both human and veterinary studies is the Poxviridae family. The poxviruses are easy to work with, amenable to large amounts of foreign DNA, and highly immunogenic, allowing for strong immune responses against weak TAs, such as carcinoembryonic antigen (CEA).¹⁹⁹ In humans, one of the most commonly used viral vaccine platforms is the canarypox virus ALVAC. Recent published human clinical trials using ALVAC include combining CEA-expressing ALVAC with chemotherapy for metastatic colorectal cancer,²⁰⁰ ALVAC-expressing human GM-CSF or IL-2 for treatment of melanoma or leiomyosarcoma,²⁰¹ and intranodal injection of ALVAC-expressing gp100 in high-risk melanoma patients.²⁰² Interestingly, although all of these studies reported that the vaccine was safe to use and that immunologic responses were observed, efficacy of these therapies is limited.²⁰³

Vaccination Against Tumor Antigens Using Dendritic Cells

Dendritic cells (DCs) possess very potent antigen-presenting abilities and are an attractive target for cancer vaccine strategies. Besides their role in vivo in processing and presenting TAs derived either naturally or from tumor vaccines, there are many clinical trials published that examine the use of ex vivo activated and expanded DCs injected back into the donor as a way of activating tumor-specific T-cells in vivo. The drawback to this method is that the ex vivo processing of DCs typically takes about 7 to 10 days, requires growth in a combination of cytokines, and can only be used autologously. Nonetheless, ex vivo prepared DCs have shown clinical efficacy, particularly in human patients with metastatic disease.^{204,205} Recently, it has been determined that the potency of the DCs produced ex vivo depends on the combination of cytokines used.²⁰⁶ DCs generated with GM-CSF and IFN- α or GM-CSF and IL-15 display potent priming of T-cell-mediated and CD8+ T-cell-mediated immune responses in vitro. Moreover, the use of mature DCs is better than immature DCs, since immature DCs actually induce immune tolerance via expansion of IL-10-secreting T-cells.²⁰⁷ However, the methods of maturation matter as well, with studies showing DCs activated with a mixture of IFN- α , polyinosinic-polycytidylic acid, IL-1 β , TNF, and IFN- γ elicit many more anti-melanoma cytotoxic T-lymphocytes (CTLs) in vitro than the standard IL-1 β , TNF, IL-6, and prostaglandin E₂ (PGE₂) cocktail.²⁰⁸ Finally, new methods of targeting antigens to DCs through anti-DC receptor (i.e., lectin receptors such as DEC-205, DC-SIGN, or DNGR-1) antibody-TA fusions, appropriate selection of adjuvants to deliver antigens to DCs, and combination therapies using chemotherapy and DC activation are being investigated.^{204,206}

Of note, the first FDA-approved therapeutic cancer vaccine, Provenge (sipuleucel-T, Dendreon, Seattle) is derived from peripheral blood mononuclear cells (PBMCs) removed from patients with castration-refractory prostate cancer that are cultured and activated ex vivo with a fusion protein of human recombinant prostatic acid phosphatase (PAP) and human GM-CSF prior to transfusion back

into the donor.²⁰⁹ This vaccine has demonstrated an increase in survival time that was a little over 4 months compared to the placebo group in a multicenter clinical trial of over 500 patients. Besides consisting of activated DCs, this vaccine also contains autologous lymphocytes that may be playing a role in its efficacy.²¹⁰

DC vaccination in veterinary medicine has been and is still currently being explored. An initial study of three dogs with oral melanoma showed that bone marrow–derived DCs transduced with an adenovirus expressing human gp100 could safely be used. In this study, dogs received three subcutaneous vaccines over 4 months.²¹¹ One of the dogs that had a complete response with no evidence of disease 4 years later developed a robust CTL response against the gp100. Another dog that relapsed after 22 months had no evidence of anti-gp100 CTLs. A similar study performed in normal dogs was done to assess the immune response of DCs pulsed with canine melanoma cell (CMM2) lysates, in which a good delayed-type hypersensitivity response was seen against CMM2 following vaccination.²¹²

Another study described previously saw success using ex vivo activated DCs and IFN- γ for treating canine solid tumors. Finally, a very recent study looked at the safety of using a DC-mammary tumor cell fusion hybrid vaccine.²¹³ In this case, normal dog PBMCs were used to generate DCs that were subsequently fused to canine mammary tumor cells. Injection of normal Beagle dogs with this fusion plus CpG adjuvant resulted in a robust antibody response against the fusion partner tumor cell line, as well as three unrelated canine mammary tumor cells. However, no CTL responses were noted. Hence development of DC vaccines for use in veterinary medicine is currently being explored in various tumor models and by using various strategies to optimize the induced antitumor immune response.

Antibody Therapy for Cancer

Monoclonal Antibodies

The use of monoclonal antibody (MAb) therapy for cancer has been studied for over a quarter century, following the development of hybridoma technology by Kohler and Milstein in 1975.²¹⁴ This technique consisted of antibody-producing cells fused with mouse myeloma cells, thus becoming immortalized and capable of continuously producing antibody that can be purified out of the culture media. Initially, the use of MAbs clinically was limited due to the responses mounted by the host against the foreign mouse proteins. However, recent technology allowed for “humanizing” these antibodies by genetically grafting the mouse hypervariable region of interest onto the human immunoglobulin, thus resulting in an antibody that is 95% human. Moreover, mice genetically rendered to express human immunoglobulins can successfully generate 100% human antibodies in response to various antigens.²¹⁵ Using humanized antibodies improves antibody-dependent cell-mediated cytotoxicity (ADCC), improves antibody stability, and decreases immunogenicity of the antibody itself. The use of MAbs in human medicine has increased over the years. Several MAbs are approved by the FDA for use as human cancer treatments, and many are in active development and currently undergoing testing in human clinical trials.²¹⁶ As a general guide, MAb names ending in -omab are murine based, -ximab and -zumab are chimeric, and -umab are humanized versions of the antibodies.

Unfortunately, the generation of canine versions of antibodies for use in veterinary medicine has yet to occur. Nonetheless, one recent study looked at the use of a murine (L243) and humanized

form (IMMU-114) of an anti-HLA-DR MAb in normal dogs and dogs with B-cell lymphoma.²¹⁷ In vitro studies demonstrated that both of these antibodies bound normal and malignant canine lymphocytes, inducing apoptosis in some. In vivo administration to normal dogs provided safety and pharmacokinetic data. A pilot study was then performed on seven dogs with either lymphoma or plasmacytomas; these dogs received 1 to 4 treatments with L243 MAb every 2 weeks. Myelosuppression was a cumulative-dose adverse effect, but some dogs displayed a transient response to the treatments. Thus future investigation of the use of this MAb in canine lymphoma is warranted.

Conjugated Monoclonal Antibodies

Another use of MAbs is linking them to potential toxins or radioisotopes. Initial studies involved linking chemical toxins to immunoglobulins to generate molecules called *immunotoxins*. Such chemicals tested were ricin and diphtheria toxins, but these conjugates were immunogenically and chemically unstable. Development of recombinant immunotoxins helped address this issue, although the current concern with immunotoxins is their ability to nonspecifically kill any cell expressing the antibody-specific receptor.

MAbs can also be linked to radionuclides. The concept behind these antibodies is that the antibody targets tumor tissue and the energy released by the radioisotope attached to the antibody can penetrate bulky solid tumors and may also kill surrounding tumor and stromal cells. Examples of radiolabeled MAbs in clinical therapeutic use in humans currently exist. The current use of radiolabeled MAbs in dogs is limited to imaging modalities rather than treatment of cancer.

Cancer Immunotherapy Using Adoptive Transfer of T-Cells

Adoptive T-cell transfer (ACT) is a technique in which cells are collected from a cancer patient, expanded and activated in culture, and then transferred back into the patient. Although this technique allows for the enhancement of tumor-specific T-cells, it is labor intensive and time consuming, thus its use is limited in both human and veterinary patients. Below, we will discuss a couple of historic methods used to generate these cells, as well as new techniques currently being investigated to improve this form of immunotherapy.

Transfer of Lymphokine-Activated Killer Cells

Initial T-cell transfer studies involved the generation of LAK cells. This was done by culturing PBMCs in high concentrations of IL-2, thus selecting for a population of cells with potent tumor cell-lysis ability. Clinical trials using this technique in humans were disappointing and unfeasible, despite promising mouse studies.²¹⁸ Use of LAK cells in veterinary medicine is limited to studies of cats with feline leukemia virus (FeLV) or feline immunodeficiency virus (FIV).²¹⁹

Transfer of Tumor-Infiltrating Lymphocytes

One source of potent antitumor T-cells is in the tumor itself. These cells, called *tumor-infiltrating lymphocytes* (TILs), when expanded

using IL-2, exhibit potent cytolytic activity that is many times higher than LAK cells against tumors in both a specific and non-specific way.²²⁰ Although they are considered the best source of T-cells for ACT,^{221,222} their use in human medicine is limited because of a few variables such as time of isolation, the tumor they were isolated from, and the functional state of the cells when isolated.²¹⁸ Nonetheless, limited success has been observed in cases of treating human melanoma with TILs, particularly when combined with nonmyeloablative chemotherapy such as fludarabine and cyclophosphamide, which deplete lymphocytes but spare bone marrow stem cells.²²³ In one study, six of thirteen melanoma patients had significant tumor regression and four had a mixed response including regression of some lesions and growth of others.²²³ In a follow-up study involving a larger number of patients (34 in total), tumor regression was seen in 51% of the patients that received chemotherapy prior to the TIL transfer and IL-2 treatment.²²⁴ In addition to the use of nonmyeloablative treatments, recent studies have investigated the use of other forms of Th1 stimulation along with ACT. One group has investigated the use of adding CpG-ODNs to their TILs to increase their efficacy.²²⁵ In a study using ex vivo isolated human TILs, instillation of the activated TILs with CpG-ODN into athymic nude, tumor-bearing mice resulted in decreased tumor burden and prolonged survival. Regardless of the human clinical trials' results, TILs have not been used in veterinary medicine, perhaps due to the lack of reliable efficacy across multiple tumor types.

New Approaches to Adoptive T-Cell Transfers

As mentioned at the beginning of this chapter, one limitation to most immunotherapies is the fact that tumors can orchestrate an immunosuppressive environment. Thus, even if one instilled thousands of activated, tumor-specific T-cells into a cancer patient, the majority of these cells will become inactivated on reaching the tumor, particularly when dealing with solid tumors.²²⁶ It is currently being recognized that strategies to overcome immunosuppression must be implemented in order to enhance the efficiency of tumor-specific T-cells in ACT studies. One technique to address this suppression is performing lymphodepletion prior to ACT.²²⁷⁻²²⁹ Recent studies have also suggested the isolation of CD4+ T-cells for ACT, rather than cytotoxic CD8+ T-cells because CD4+ T-cells are capable of activating both innate immune cells and CD8+ T-cells.^{230,231} However, CD4+ T-cells contain Treg cells, thus strategies to block the development of Treg cells during CD4+ T-cell ACT have also been investigated.²³⁰ In addition, the availability of TAs also appears to play a role in the strength of CD4+ ACT therapy.²³² Similarly, the addition of cytokines and/or blocking antibodies against suppressor cells, along with ACTs, has been shown to enhance the effectiveness of this therapy.^{230,233-235}

The Future of Cancer Immunotherapy

The use of immunotherapy for the treatment of cancer is an exciting and ever-evolving field of research and application. With the advancement of techniques used to assess immune responses to tumors; better ways of predicting responses, including development of RECIST; and an understanding that tumor responses to immunotherapies may be delayed as compared to conventional chemotherapy, radiation therapy, and surgery, one can more reliably assess

the clinical efficacy and safety of novel immunotherapies. Moreover, a better understanding of the disease pathology in our veterinary patients has led to a movement toward using spontaneous canine and feline cancers as models for human disease, thus allowing for testing of novel immunotherapies in our small animal patients that will not only benefit them, but benefit human cancer patients as well.^{236,237}

However, the development of a successful immunotherapy protocol is not without limitations. One of the main reasons for failure of many immunotherapies is due to the immunosuppressive micro-environment established by the tumor. Thus immunotherapies that are best able to overcome this suppression will prove the most successful.²³⁸ In addition, certain drugs and/or proteins that can deplete or inactivate the key players in immune suppression (i.e., MDSCs and Tregs) may be best used in concert with novel vaccines or other immunotherapies in order to optimize their effectiveness. Along those lines, the use of newer and more potent adjuvants such as various preparations of CpG motifs to stimulate the immune system will be a critical component of newer vaccines. It has now become clear that the most successful adjuvants are those that not only stimulate a strong primary response against the tumor, but also lead to the development of a robust central memory response.

One of the more successful categories of immunotherapies currently used in human medicine is MABs. Advances in technology led to the development of humanized, nonimmunogenic forms of antibodies against key cellular receptors, either to activate key anti-tumor immune cells or lead to cytolytic activity against tumor cells. However, similar advances in treating dogs with MABs are lacking, although some promising preliminary results have been seen using human or mouse antibodies to treat canine lymphoma.²¹⁷

It should be understood that many, if not all, immunotherapies developed should work in concert and synergize with current cancer treatment modalities. Given the ability of tumor cells to become resistant to chemotherapy and radiation therapy and their ability to suppress the immune system, one would be naïve to think that a single-modality treatment is the most effective means of tumor control. While the immune system can be manipulated to mount an effective antitumor immune response, it is best utilized in cases of minimal residual and metastatic disease, in which radiation therapy, chemotherapy, and/or surgery are used to cytorreduce large tumors. Moreover, it is becoming very clear that the immune system is a key player involved in the tumor response to radiation and chemotherapy; thus finding ways to incorporate immunotherapy into current standards of care may actually enhance the effectiveness of these modalities. For example, we have observed that the use of liposomal clodronate therapy to eliminate MDSCs can enhance the tumor response to lomustine (CCNU) in dogs with malignant histiocytosis (unpublished observation). We hypothesize that the immunosuppressive cells present in the tumor microenvironment are capable of protecting tumor cells from the effects of chemotherapy, thus by removing these tumor cells we can enhance the effectiveness of the chemotherapy. We predict that the use of immunotherapy as part of a protocol to treat canine and feline diseases should soon become routine. By understanding the role of the immune system in cancer in our small animal patients, we can develop not only better immunotherapies that will benefit these patients, but also therapies that will be applicable to human medicine.

Molecular/Targeted Therapy of Cancer

14

■ SECTION A Gene Therapy for Cancer

DAVID J. ARGYLE

Since its development, recombinant DNA technology has been vigorously applied to the advancement of medicine. New molecular techniques have been used to study the role of specific genes and their products in disease, to improve diagnosis, and to produce novel therapeutics. Gene therapy, in its simplest definition, is the introduction of genes into cells *in vivo* to treat a disease.¹ Although one may recognize this as one of the newest areas of medicine, the actual concept of gene therapy is not a new idea. In the late 1960s, the idea of gene therapy was hypothesized by many working in the field of molecular biology, in particular the use of gene therapy to deliver a normal copy of a gene into a patient with a single gene defect, such as hemophilia. However, the technology to manipulate genes and be able to deliver them safely to patients was not available until very recently. Even now and despite improvements in technologies involving gene manipulation and delivery, there are still many technical hurdles to overcome before gene therapy can become accepted clinical practice.^{1,2}

Efficient Gene Delivery: The Major Hurdle to Clinical Benefits

In simple terms, gene therapy is the introduction of nucleic acid into a cell to ameliorate a disease process. For this to be effective, the gene has to be delivered to sufficient numbers of target cells in the body, and this requires a vehicle or vector for delivery. In addition, the gene has to be expressed at a sufficient level and for a length of time appropriate for the disease.²

Early studies on how viruses were able to cause tumors by delivery of their own DNA to foreign cells made them ideal candidates for vectors for gene therapy (i.e., the vehicles by which we could transfer therapeutic genes to patients). However, it was not until the 1980s when work on the retroviral life cycle started to revolutionize the development of gene therapy. In these early studies, it was demonstrated that retroviruses could transfer DNA to cells and this DNA could be stably integrated into the host cell's genome. Since these early experiments, a number of viruses have been manipulated to act as vehicles for gene delivery. In addition, because of concerns over safety of viral vectors for gene delivery, a number of workers have also explored the possibility of using naked DNA (a therapeutic gene delivered in a bacterial plasmid

or lipid/DNA complexes) with some success. The vehicles used for gene delivery and their associated problems are shown in Table 14-1.

The ideal vector would efficiently deliver the gene of interest (transgene) specifically to the cancer cell. It would be easy and cheap to manufacture and would be nonimmunogenic. Obviously the ideal vector does not exist, but there have been great advances in both viral and nonviral delivery systems.²

Viral Vectors

The great advantage to viral vectors for gene delivery is their ability to infect cells and our ability to exploit their replicative machinery. The majority of systems utilize replicative-defective viruses to overcome concerns that recombination within the host may lead to the production of wild-type virus with pathogenic potential. The common systems rely on oncogenic retroviruses (e.g., murine leukemia virus [MuLV]) or adenoviruses (e.g., human adenovirus type 5 [AD5]), but great strides are also being made with lentiviral vectors (particularly human immunodeficiency virus-1 [HIV-1]).³⁻⁸ Most of the systems described involve the local delivery of virus to tumor deposits (e.g., by intratumoral injection). Systemic delivery is hindered by rapid clearance of viruses from the body by the immune and complement systems. To overcome this, work is in progress to explore cellular delivery of viruses by the systemic route. In this delivery system, viral producer cells are delivered to the patient, and virus production is triggered when the cells reach the tumor. Endothelial cell cultures lend themselves well to this technology because they specifically home in to areas of neoangiogenesis. However, T-cells, macrophages, and dendritic cells are also being explored as potential cell delivery systems. The advantage of this system is that virus could potentially be delivered to metastatic disease, as well as primary tumors.⁹⁻¹³ Recent evidence suggests that mesenchymal stem cells also have homing ability to tumors and could be used to deliver "suicide" genes (see later).

Nonviral Gene Delivery

Concerns relating to virus safety and an inability to produce high enough viral titers have led to the development of nonviral delivery systems for gene therapy.¹⁴ Liposomes have been used to safely and efficiently deliver genes to tumor cells through direct injection.^{15,16} Further, naked DNA delivery (the delivery of plasmid DNA alone containing the gene of interest) has been shown to be taken up by tumor cells and antigen-presenting cells after simple direct injection. A modification of this is particle-mediated gene delivery using a "gene gun." In this approach, DNA is adsorbed on to gold particles and fired into tissues under high pressure (using helium as the

• **TABLE 14-1** Gene Therapy Vector Systems

VECTORS	COMMENTS
Viral Vectors	
Retroviruses (oncoviruses)	Originally the gold-standard vector, the gene is packaged into replication-defective viral particles using a packaging cell line. The therapeutic gene is integrated into the host cell genome when the virus is delivered to the target cell. Limited by their inability to infect postmitotic cells.
Retroviruses (lentivirus)	Many based on HIV-1. These vectors have become significantly safer in recent years and have many of the benefits of the oncoviruses and also will infect postmitotic cells. Construction of the vector takes place in a packaging cell line, and the therapeutic gene is integrated into the host cell genome.
Adenoviruses	Have become the most popular viral delivery mechanism. Gene is packaged into a replication-incompetent adenovirus (usually E1 deleted). Gene expression remains episomal when delivered to the host cell. Concerns have been raised about the safety of adenoviral vectors, particularly potential toxic side effects at high doses. Adenoviruses can infect a wide range of premitotic and postmitotic cells. Conditionally replicating adenoviruses are being explored as oncolytic vectors.
Adeno-associated viruses (AAV)	Gaining popularity as a vector because they are potentially safer than adenoviruses. They infect a wide variety of mammalian cell types but are limited by the amount of DNA they can deliver. Gene expression in the host cell is episomal. However, in the natural host, integration is possible.
Nonviral Vectors	
Naked DNA	Simple form of gene delivery in which “naked” plasmid DNA is directly injected into the tumor. Vectors are derived from bacterial plasmids and are engineered to express the therapeutic gene under the control of a strong promoter. Naked DNA can be taken up by many tissues, but typically the efficiency for delivery is lower than that for viral gene delivery.
Particle bombardment (gene gun)	A more sophisticated approach to the delivery of naked DNA. In this system, plasmid DNA is typically adsorbed onto gold particles. Helium is then used as a motive force to fire the gold particles into cells or tissues via a handheld “gene gun.”
Liposome/DNA conjugates	In this system, naked DNA is coated with liposome to improve uptake by endocytosis. This enhances the efficiency of gene delivery.
Ligand/DNA conjugates	Ligands are used to specifically target DNA to tumor tissue.

HIV-1, Human immunodeficiency virus-1.

motive force).^{17,18} However, the majority of these techniques are still inefficient vehicles for delivery and are not able to be given systemically (Figure 14-1; see Table 14-1).

Targeted Gene Delivery

One of the major barriers to gene therapy becoming accepted in clinical practice is the ability to give vectors systemically and to ensure that therapeutic transgenes are not expressed in normal cells. Numerous strategies have been attempted to provide levels of targeting to spare normal tissue. In a later section, we describe the use of conditionally replicating viruses, which is one method of targeting. Surface modification of viruses (transductional targeting) is also being explored. An example of this is the use of modified fibers on the surface of adenoviruses that only allow the virus to enter cells with specific receptors (Figure 14-2).

A further targeting strategy is transcriptional targeting once the vector has entered the cell.¹⁹⁻²⁶ Although every gene is represented in every cell of the body, expression of any one gene requires specific transcription factors that may be unique to a particular cell or tissue type. Certain genes have been identified that are expressed in cancer cells but are not expressed in normal cells (e.g., telomerase) or are only expressed in a specific tissue type (e.g. prostate-specific antigen [PSA]). By using the promoter sequences for these

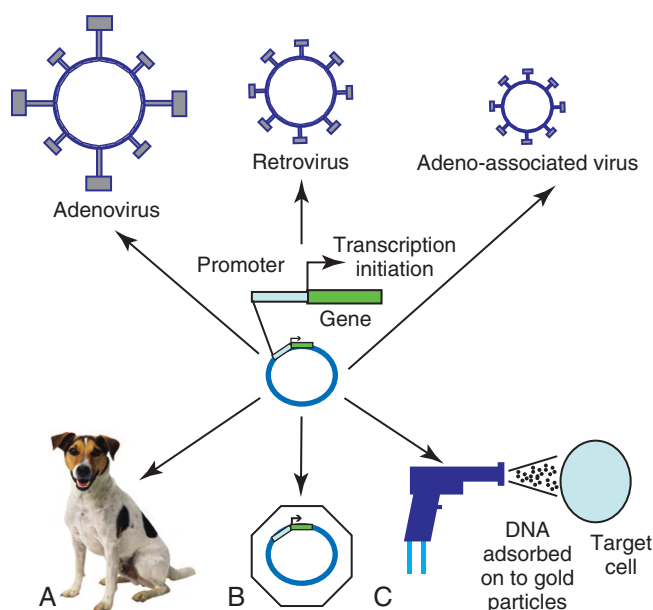

genes to drive transgene expression, targeted expression in cancer cells only (e.g., using the promoter for telomerase) or to a specific tissue type (e.g., to the prostate using the promoter for PSA) can be achieved (see Figure 14-2).

Gene Therapy Strategies for Cancer

Despite advances in surgical techniques and the use of radiotherapy and chemotherapy, cancer still remains a disease of high mortality in both human and veterinary medicine, warranting the investigation of alternative treatments. Gene therapy has the potential to play a major role in the development of new cancer therapeutic agents, and there are four broad approaches that can be applied, as follows.

Rescue of the Cancer Cell Through Gene Replacement Technologies

The increased understanding of the molecular events in cancer has made possible the identification of defective genes involved in the cancer phenotype. One of the most studied genes in cancer development has been the tumor suppressor gene *p53*. *p53* acts as a genomic guardian for the cell; it is switched on when a cell's DNA is damaged. The product of this gene causes the cell to either stop

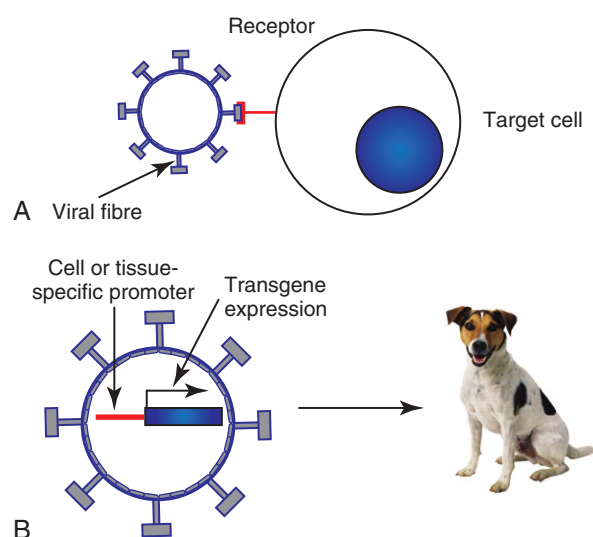

• **FIGURE 14-1** Viral and nonviral gene delivery. Adenoviral vectors are produced in “producer cell lines.” They enter the cell by transduction, and their genetic material is transported to the nucleus. In contrast to retroviruses, the DNA is not integrated into the host genome—gene expression is achieved episomally. Retroviral vectors are also produced in specialized producer cell lines. They enter the cell by transduction, but their RNA genome is reverse transcribed into proviral DNA. This integrates into the host genome in which expression of the transgene takes place. DNA plasmid vectors contain a gene cassette that incorporates the therapeutic transgene under the control of a promoter. The plasmid can be delivered by direct injection as naked or liposome-encapsulated DNA (**A**), by direct injection or systemically wrapped in nanomedicine particles (**B**), or by direct injection utilizing a helium-driven “biolistic” gene gun (**C**).

dividing or become apoptotic (programmed cell death), depending on the degree of damage. In many cancers, this gene is defective; thus damaged cells fail to stop dividing and can accumulate further damaging events, which can allow selection for a malignant phenotype. A number of studies have addressed this by attempting to replace the defective *p53* gene with its normal counterpart.²⁷ However, problems associated with this approach include the following:

- The inability of our current technology to be able to efficiently deliver a normal *p53* gene to every cancer cell in a tumor mass.
- Cancer is a multigenetic abnormality, and the delivery of one correct gene to a tumor cell may still not have the desired phenotypic effect.

A more promising approach has been to use the lack of a normal functioning *p53* gene to target viruses to kill cells. The use of E1b-deleted adenoviruses to specifically cause oncolysis in *p53* null cells is described later and has proved successful in some human clinical models.²⁸ *p53* mutations in domestic species such as the dog and cat have also been well characterized, and these may provide targets for therapy, particularly for diseases such as canine osteosarcoma (OSA) and feline vaccine-associated sarcomas (FVAS).

• **FIGURE 14-2** Vector targeting. The specificity of viral vectors can be improved utilizing either transductional targeting (**A**) where the viral surface proteins are modified so they will only enter the cell of interest or transcriptional targeting (**B**) where the expression of the therapeutic transgene is under the control of a tissue or cell-specific promoter. Transcriptional targeting can also be employed in nonviral vectors and directly delivered to the patient.

Destruction of Cancer Cells Through Delivery of “Suicide Genes”

Typically, the “suicide gene” approach involves the delivery of a gene (usually an enzyme) to cancer cells that has the ability to convert a relatively nontoxic prodrug to an active compound within the cancer cell (gene-directed enzyme prodrug therapy [GDEPT]) (Figure 14-3). At the clinical level, the gene would be delivered to the patient’s tumor and the enzyme activity would be confined to the cancer cells.²⁹ The patient would then be given a prodrug systemically. In the cancer cells, this novel enzyme can convert the prodrug to a more active compound that has the ability to kill the cancer cell (see Figure 14-3). A number of successful approaches have been developed based on this system. For example, the *Escherichia coli* nitroreductase gene has been used in preclinical models to cause reduction of an inactive prodrug (CB1954, a weak alkylating agent) to promote cell killing in cancer cells.²⁹ However, due to the low efficiency of existing vectors, the success of this therapy will largely depend on the extent of the bystander effect. In this, the activation of the prodrug in the cell causes cell death and also leakage of toxic metabolites to neighboring cells. Consequently, it is estimated that only a small fraction of the cells need receive the gene for there to be a dramatic effect on tumor volume. Further, in mouse models, a distant bystander effect on tumor metastases has been demonstrated that is mediated through the patient’s immune system.²² The in-situ destruction of tumor cells is mediated through necrosis rather than apoptosis, creating an ideal inflammatory environment for the exposure and presentation of tumor antigens to the immune system. This allows the patient’s immune system to recognize tumor metastases and has caused regression in a number of preclinical model systems. These systems have been combined with

• **FIGURE 14-3** In gene-directed enzyme prodrug therapy (GDEPT), an activating gene is delivered to the cancer cells. A relatively inactive prodrug is then given to the patient systemically. In cells processing the activating gene, the prodrug is converted to a highly toxic drug, which can kill the cancer cell. The advantage of this system is evidence of the bystander effect. In this, only a small proportion of cancer cells need to receive the activating gene, as toxic metabolites leak across gap junctions and kill surrounding cancer cells.

transcriptionally targeted vectors (described previously) to improve the eventual therapeutic index.

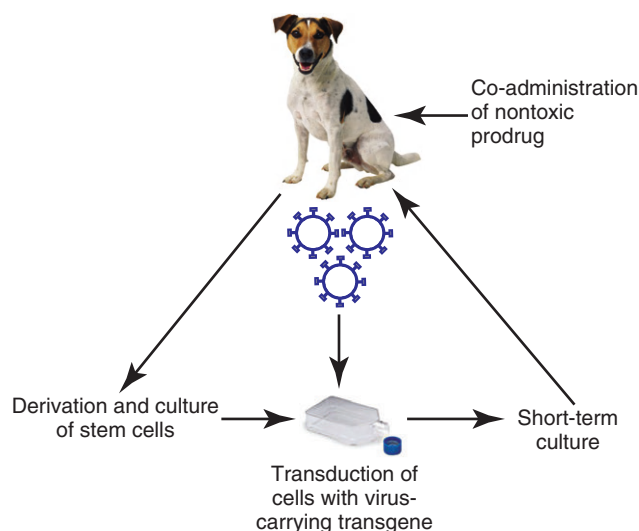

Utilizing Stem Cells to Deliver “Suicide Genes”

The attractiveness of prodrug cancer gene therapy has been described earlier, but it does rely on the ability to specifically target prodrugs to tumors. This can be achieved using transcriptional targeting of vectors (i.e., the use of cell-specific promoters to drive prodrug gene expression). However, this targeting needs an effective and efficient delivery vehicle, and viruses demonstrate some severe deficiencies in this role. The use of stem cells to target tumors can avoid systemic toxicity. Tumor stroma is composed of a variety of cells, including proliferating tumor cells, cancer stem cells (CSCs), tumor fibroblasts, endothelial cells, lymphocytes, and other cells. Many therapeutic strategies are now geared toward killing both tumor cells and CSCs. Prodrug cancer gene therapy driven by mesenchymal stem cells (MSCs) has been suggested as a treatment modality that could achieve this.³⁰ It represents an attractive tool for activating the prodrug directly within the tumor mass, thus avoiding systemic toxicity. In addition, MSCs lack major histocompatibility complex (MHC)-II and show only minimal MHC-I expression.³¹⁻³³ Thanks to their immunosuppressive properties, allogeneic MSCs can substitute for autologous stem cells in delivering the therapeutic agent in targeted tumor therapy. Stem cell-driven cancer gene therapy is based on the tumor-trophic property of MSCs. Tumor-homing ability of MSCs holds therapeutic advantages compared to vehicles such as proteins, antibodies, nanoparticles, and to some extent viruses. The success of an enzyme-prodrug gene therapy depends on several factors. The catalytic activity of the enzyme encoded by a suicide gene, a suitable prodrug-enzyme

combination, ability of the vector to target tumor cells, sufficient transgene expression, and, importantly, the extent of the bystander effect are the main indicators of effective and successful suicide gene therapy. Various combinations of suicide genes, prodrugs, and gene transfer technologies have been investigated in order to find the most suitable and effective system in combating the otherwise incurable tumors. The failures of the present suicide gene therapies were mainly caused by the inability of vectors carrying the suicide gene to reach invasive tumor cells distant from the tumor bulk, as well as inefficient spread of the vectors within the tumor. Therefore the stem cell-based suicide gene therapy based on the inherent and privileged tumor-trophic nature of MSCs holds great potential for moving suicide gene therapy closer to translation (Figure 14-4).

Gene-Directed Immunotherapy

The search for an effective cancer vaccine over the past 150 years has led to extensive studies of the immune response of cancer patients. These studies have suggested that cell-mediated immune responses are important components of the antitumor immune response. Cytokines are small glycoprotein molecules that orchestrate the immune response, tissue repair, and hemopoiesis, and it has been demonstrated that the relative amounts of individual cytokines can direct the immune system toward either a mainly humoral or a mainly cell-mediated response. In particular, cytokines such as interleukin-2 (IL-2), interferon- γ (IFN- γ), IL-12, and IL-18 have the ability to promote cell-mediated responses. Further, evidence derived from animal models suggested that local production of cytokines around a tumor mass can lead to production of an anti-tumor immune response and a reversal of T-cell anergy (nonresponsiveness).^{34,35} Thus there appears a rationale for using cytokine molecules in cancer patients to improve the antitumor immune response to tumors that present weakly antigenic epitopes or

• **FIGURE 14-4** Mesenchymal stem cell (MSC)-targeted cancer gene therapy. MSCs are isolated from patients. Bone marrow-MSCs (BM-MSCs) are isolated from mononuclear fraction of bone marrow obtained by Percoll density gradient centrifugation. Obtained cells are plated in a plastic dish and expanded. Stem cells are transduced with virus containing a suicide gene and gene encoding resistance to antibiotic G418. Transduced cells are exposed to selective medium containing antibiotic G418. The population of selected therapeutic stem cells is expanded and used for systemic or intratumoral injections. Therapeutic cells migrate to the tumor site. Subsequently, nontoxic prodrug is administered and converted at the tumor site to toxic drug killing tumor cells and therapeutic cells as well. No adverse systemic toxicities have been observed.

epitopes that evade immune recognition. In the 1980s and 1990s, a number of clinical studies were undertaken using recombinant cytokine proteins to improve the survival of human cancer patients. However, cytokines tend to be autocrine or paracrine in nature and the levels of protein required to demonstrate a biologic effect were often too toxic for the patient to withstand. However, a more promising approach has been to deliver the actual cytokine genes to cancer cells rather than delivery of the protein to the whole patient.³⁶⁻³⁸ This approach has also been adopted in a number of small-scale veterinary studies, including one on canine malignant melanoma, which used cells to deliver IL-2 to tumors.³⁹ These studies have had encouraging results and warrant further larger scale trials.

In the preceding section, we described how the in-situ destruction of tumor cells by enzymes can lead to a distant bystander effect mediated by the immune system. Many trials have now combined this approach with gene-directed immunotherapy. In this approach, cytokine genes, as well as the prodrug-activating gene, are delivered to cancer cells. The conversion of an inactive prodrug by the activating gene leads to destruction of the cancer cells by necrosis. The co-delivery of cytokines that enhance cell-mediated immune responses such as IL-2, IFN- γ , IL-12, and IL-18 enhances the anti-tumor response and may potentially improve the distant bystander effect against micrometastatic disease.^{1,2}

Delivery of Chemoprotective Genes

An alternative approach to gene therapy for cancer involves the delivery of genes to normal cells of the bone marrow to protect

• **FIGURE 14-5** Conditionally replicating adenovirus. The Onyx 015 vector is an E1b-deleted adenovirus that conditionally replicates in cells with a nonfunctional *p53* gene. *p53* protein has the potential to shut down cell cycling when infected with wild-type adenovirus but is prevented from doing so through the actions of the product of viral E1b. E1b-deficient viruses cannot replicate in normal cells with *p53* intact. However, in cells that have no functional *p53* protein, viral replication can proceed and cause cell lysis.

them against the cytotoxic effects of conventional chemotherapeutic drugs. In particular, the multidrug resistance (MDR) gene has been cloned and delivered to normal bone marrow cells. When patients are given high doses of chemotherapy, the normal cells with the MDR gene are able to export the toxic drugs across their membranes and reduce potential side effects.⁴⁰⁻⁴² However, this approach does not protect gastrointestinal cells, which limit this approach. Further, there is also a danger that the MDR gene could transfer to malignant cells, rendering them insensitive to the effects of standard drugs.

The Use of Replication-Competent Viral Vectors

Progress has been made in the development of replication-competent viruses that conditionally replicate in cancer cells.⁴³⁻⁴⁸ As an example, the Onyx 015 vector is an E1b-deleted adenovirus that conditionally replicates in cells with a nonfunctional *p53* gene. *p53* protein has the potential to shut down cell cycling when infected with wild-type adenovirus but is prevented from doing so through the actions of the product of viral E1b. E1b-deficient viruses cannot replicate in normal cells with *p53* intact. However, in cells that have no functional *p53* protein, viral replication can proceed and cause cell lysis (Figure 14-5). Many other conditionally replicating viruses are being developed that rely on specific cancer cell defects (e.g., Reo viruses that conditionally replicate in cells with intact Ras signalling pathways) or are transcriptionally targeted. *p53* mutations in domestic species such as the dog and cat have also been well characterized, and this may provide targets for therapy, particularly for diseases such as canine OSA and feline vaccine-associated sarcomas. In one study, researchers have utilized the osteocalcin promoter for restricting the replication of a canine adenovirus to dog OSA cells.⁴⁷ This has shown promise in preclinical evaluations and has been shown to yield a therapeutic benefit

in vivo. A cautionary note, however, is that the majority of dogs in the United States and Europe are vaccinated against canine adenovirus, and these vectors may not be able to overcome host immunity.

Miscellaneous Approaches to Cancer Gene Therapy

The multigenetic abnormalities of cancer lend themselves to multiple gene therapy approaches. In addition to those approaches described previously, there is vigorous exploration of the following:

- Gene delivery of sodium iodide symporter genes to tumors to allow them to concentrate radioactive iodine.¹
- Delivering proapoptotic genes to cancer cells.¹
- Delivering antiangiogenesis genes to cancers to inhibit growth of their blood supply.¹

It is highly likely that one individual approach to cancer will be insufficient to cure or control particular cancers. However, it is possible that a combination of treatments, with or without conventional therapies, will prove to provide the best therapeutic solution.

Safety Considerations in Gene Therapy

One of the major considerations in gene therapy revolves around issues of safety, in particular the safety of the vectors used for gene delivery. In 1999, gene therapy suffered a major setback with the death of a patient as a direct result of adenovirus gene therapy. Problems associated with vector delivery include inappropriate inflammatory responses caused by vector delivery (e.g., adenoviruses), the generation of replication-competent viruses (although this is unlikely with new generation vectors), and insertional mutagenesis caused by integrating viruses (e.g., retroviruses).

Until recently, many gene therapy trials had utilized retroviral vectors for gene delivery. There are many advantages to using retroviruses as outlined in Table 14-1. However, retroviruses are also associated with serious diseases of domestic animals and the use of these in gene therapy poses a risk of insertional mutagenesis or the production of replication-competent viruses during the manufacturing process. Realistically, insertional mutagenesis leading to a malignant transformation is an unlikely event because cancer is a multistep process. In fact, there may be a greater risk of malignant transformation from external beam radiation than from the use of retroviruses to treat cancer. The production of replication-competent retroviruses during the production process would also be unlikely because of the rigorous testing that is required prior to clinical application. Many of these issues are resolving with the development of new generation vectors.¹ As an example, in the use of retroviruses and to prevent insertional mutagenesis in normal tissues, one group recently described the use of zinc finger nucleases (engineered DNA-editing enzymes) that allows the insertion of DNA to a site of choice within the genome.⁴⁹ This adds a further level of safety in a high-risk procedure.

In recent years, there has been a shift from using retroviruses in gene therapy to using viruses such as adenovirus and the human adeno-associated viruses (AAV). Adenoviruses may also pose some risks, including inappropriate inflammatory responses leading to serious clinical complications. However, a great deal of work is currently underway to improve viral vectors by removing most of

their genetic material to produce “ghost vectors.” These would be potentially less toxic and offer a brighter future for virally mediated gene transfer.

One might imagine that the delivery of naked DNA may offer a safer alternative. However, all of the potential safety issues using this technology are still not fully answered. These include potential risks of autoimmunity and also the actual fate of the DNA when it has been delivered to the patient; in the case of the former, however, there would appear to be no evidence of autoimmunity being a problem in preclinical models.

One of the most exciting developments in cancer gene therapy is the use of conditionally replicating viruses. However, the safety of these vector systems needs special consideration as many of them in their native form could pose a risk to both human and animal health.

New Horizons

Gene therapy promises a completely new approach to the treatment of cancer and represents the newest area of pharmacology. It has suffered over the past 10 years as clinical trials in human medicine have not delivered what they had originally promised. However, one has to put this into context in that many of these studies were conducted in patients with high-grade or end-stage disease and many studies were conducted prematurely without refining the delivery technologies. Clearly, there are a number of technical issues such as safety issues surrounding the delivery and efficiency of the vectors that need to be resolved before gene therapy becomes established clinical practice. Despite gene therapy being very much in its infancy, the field is advancing at a rapid rate. A number of clinical trials have begun in companion animals, and products are in development for clinical application. However, although these treatments would appear to be powerful in preclinical models, it is likely that their greatest benefit will be in the management of patients with minimal disease states. Thus gene therapy will probably have its greatest advantage not as a stand-alone treatment but as an adjunct to more conventional therapies such as surgery, radiation, or chemotherapy.

SECTION B

Signal Transduction and Cancer

CHERYL A. LONDON

In normal cells, signals are generated that begin at the outside of the cell and transmit through the cytoplasm to the nucleus, regulating cell growth, differentiation, survival, and death. Over the past few years, researchers have recognized that many of the components of the signal transduction pathways are dysregulated in cancer cells, leading to uncontrolled cell growth and thereby contributing to tumorigenesis. Because many tumors have similar alterations in signal transduction components, these have become promising targets for therapeutic intervention. This

section primarily focuses on the role of a particular group of signal transducers called *protein kinases*, their role in normal cells, the mechanisms by which they contribute to tumorigenesis, and the use of agents designed to inhibit them when they become dysfunctional.

Protein Kinases and Normal Cells

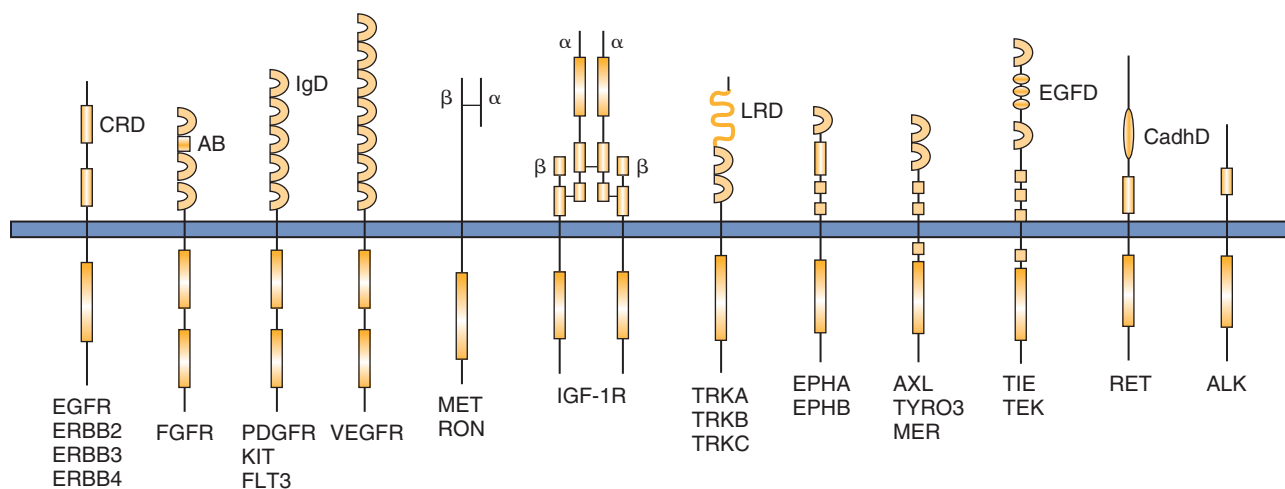

Protein kinases play critical roles in normal cell signal transduction, acting to tightly regulate critical cellular processes such as growth and differentiation. These proteins work through phosphorylation; that is, they bind adenosine triphosphate (ATP) and use it to add phosphate groups to key residues on themselves (a process called *autophosphorylation*) and on other molecules, thereby stimulating a downstream signal inside the cell. This process typically occurs in response to external signals generated by growth factors (GFs) or other stimuli that initiate the cascade. Protein kinases are classified as tyrosine kinases (TKs) if they phosphorylate proteins on tyrosine residues or serine/threonine kinases if they phosphorylate proteins on serine and threonine residues. In some cases the kinases perform both functions (i.e., dual function kinases). These kinases can be expressed on the cell surface, in the cytoplasm, and in the nucleus. The human genome encodes approximately 518 kinases, of which 90 are classified as TKs.¹

TKs on the cell surface that are activated through binding of GFs are called receptor TKs (RTKs). Of the 90 identified TKs, 58 are known to be RTKs. Each RTK contains an extracellular domain that binds the GF, a transmembrane domain, and a cytoplasmic kinase domain that positively and negatively regulates phosphorylation of the RTK (Figure 14-6).²⁻⁴ Most RTKs are monomers on the cell surface and are dimerized through the act of GF binding; this changes the three-dimensional structure of the receptor, permitting ATP to bind and autophosphorylation to occur, resulting in generation of a downstream signal through subsequent binding of adaptor proteins and nonreceptor kinases.² Dysregulation of RTKs resulting in pathway activation/uncontrolled signaling is

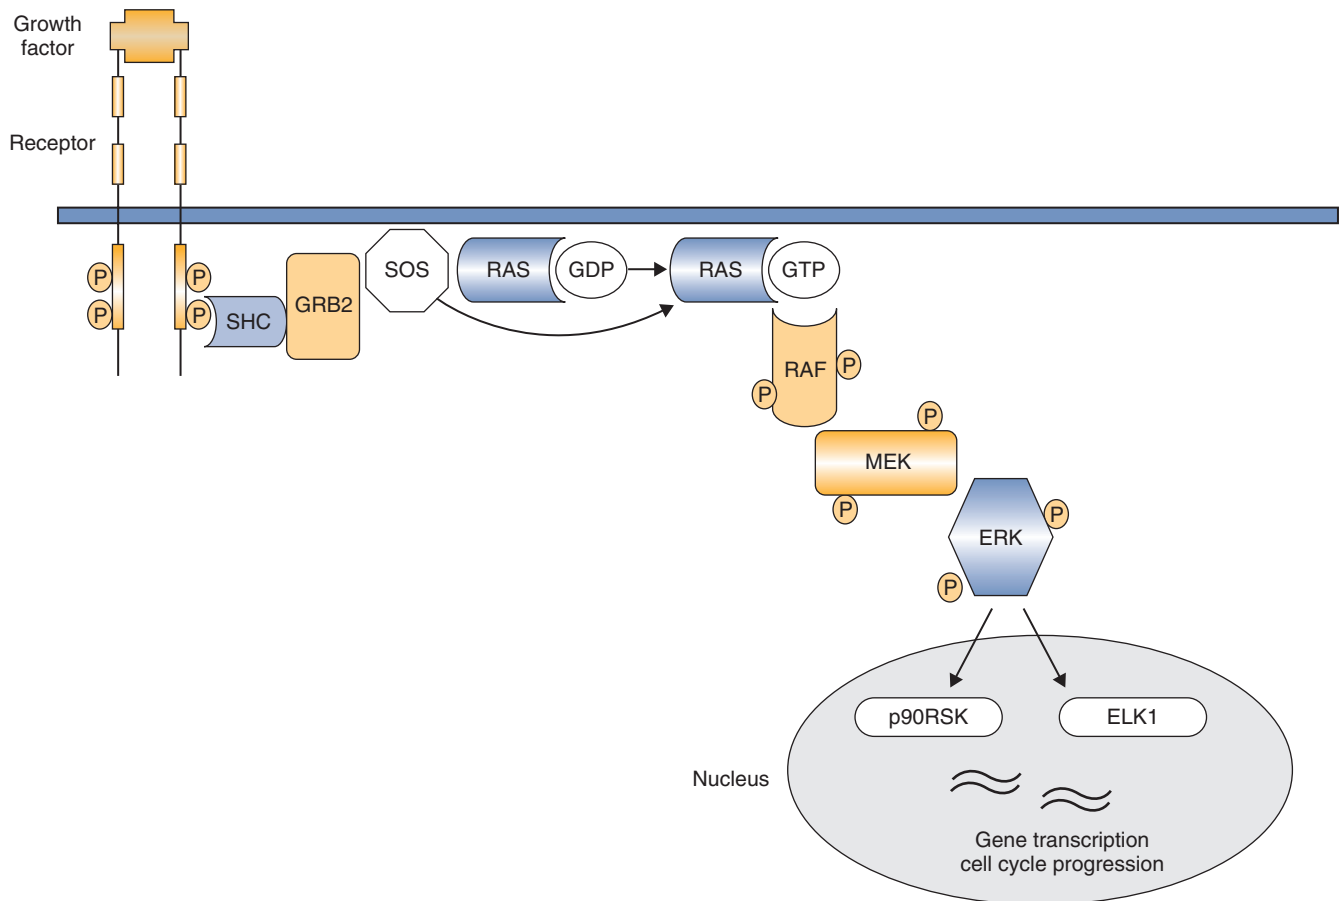

known to contribute to several human cancers, and work is ongoing to characterize such abnormalities in canine and feline cancers. Examples of RTKs known to play prominent roles in specific cancers include KIT, MET, epidermal growth factor receptor (EGFR), and anaplastic lymphoma kinase (ALK), which can be activated by overexpression, mutation, and chromosomal translocation.⁵⁻⁹

RKT signaling is critical for regulating typical cell functions and is also an important regulator of angiogenesis, a process known to be essential for continued tumor cell growth. The RTKs involved in angiogenesis include vascular endothelial growth factor receptor (VEGFR), platelet-derived growth factor receptor (PDGFR), fibroblast growth factor receptor (FGFR), and Tie-1 and Tie-2 (receptors for angiopoietin).¹⁰⁻¹³ VEGFRs are expressed on vascular endothelium, and VEGFR signaling drives endothelial migration and proliferation.¹⁰ PDGFR is expressed on stroma and pericytes that are critical for the maintenance of newly formed blood vessels. It also supports angiogenesis by inducing VEGF transcription and secretion.^{12,13} FGFR is expressed on vascular endothelium and works with VEGFR to promote increased expression of VEGF.¹² Tie-1 and Tie-2 are expressed on blood vessels in tumors and are important in the recruitment of pericytes and smooth muscle cells to the newly forming vascular channels.¹⁴

Kinases in the cytoplasm act as a bridge, conducting signals generated by RTKs to the nucleus through a series of intermediates that become phosphorylated.¹⁵ The cytoplasmic kinases may be directly on the inside of the cell membrane or free in the cytoplasm. With respect to tumor cell biology, two particular cytoplasmic pathways are often dysregulated in a number of cancers. The first includes members of the RAS-RAF-MEK-ERK/p38/JNK families (Figure 14-7).^{16,17} Most of these are serine/threonine kinases, and their activation leads to ERK phosphorylation, translocation into the nucleus, and subsequent alteration of transcription factors and nuclear kinase activity important for controlling the cell cycle. Examples of dysregulation in human cancers include RAS mutations in lung cancer, colon cancer, and several hematologic

• **FIGURE 14-6** The structures of receptor tyrosine kinase (RTK) families implicated in a variety of malignancies are shown. The symbols α and β indicate specific RTK subunits. AB, Acid box; ALK, anaplastic lymphoma kinase; CadhD, cadherin-like domain; CRD, cysteine-rich domain; EGFD, epidermal growth factor-like domain; EGFR, epidermal growth factor receptor; EPH, member of ephrin receptor family; FGFR, fibroblast growth factor receptor; IgD, immunoglobulin-like domain; IGF-1R, insulin-like growth factor receptor 1; LRD, leucine-rich domain; PDGFR, platelet-derived growth factor receptor; Tie, tyrosine kinase receptor on endothelial cells; TRK, member of nerve growth factor receptor family; VEGFR, vascular endothelial growth factor receptor. (From London CA: *Kinase inhibitors in cancer therapy*, Vet Comp Oncol 2:177–193, 2004. Reprinted with permission from Blackwell Publishing.)

• **FIGURE 14-7** RAS signal transduction. Activated receptor tyrosine kinases recruit SOS to the plasma membrane through binding of SHC and GRB2. SOS replaces bound GDP with GTP, thereby activating RAS. The downstream target RAF is then phosphorylated by RAS, leading to subsequent activation of MEK, then ERK. ERK has several substrates both in the nucleus and in the cytoplasm, including ETS transcription factors such as ELK1 and RSK, which regulate cell cycle progression. (From London CA: *Kinase inhibitors in cancer therapy*, Vet Comp Oncol 2:177–193, 2004. Reprinted with permission from Blackwell Publishing.)

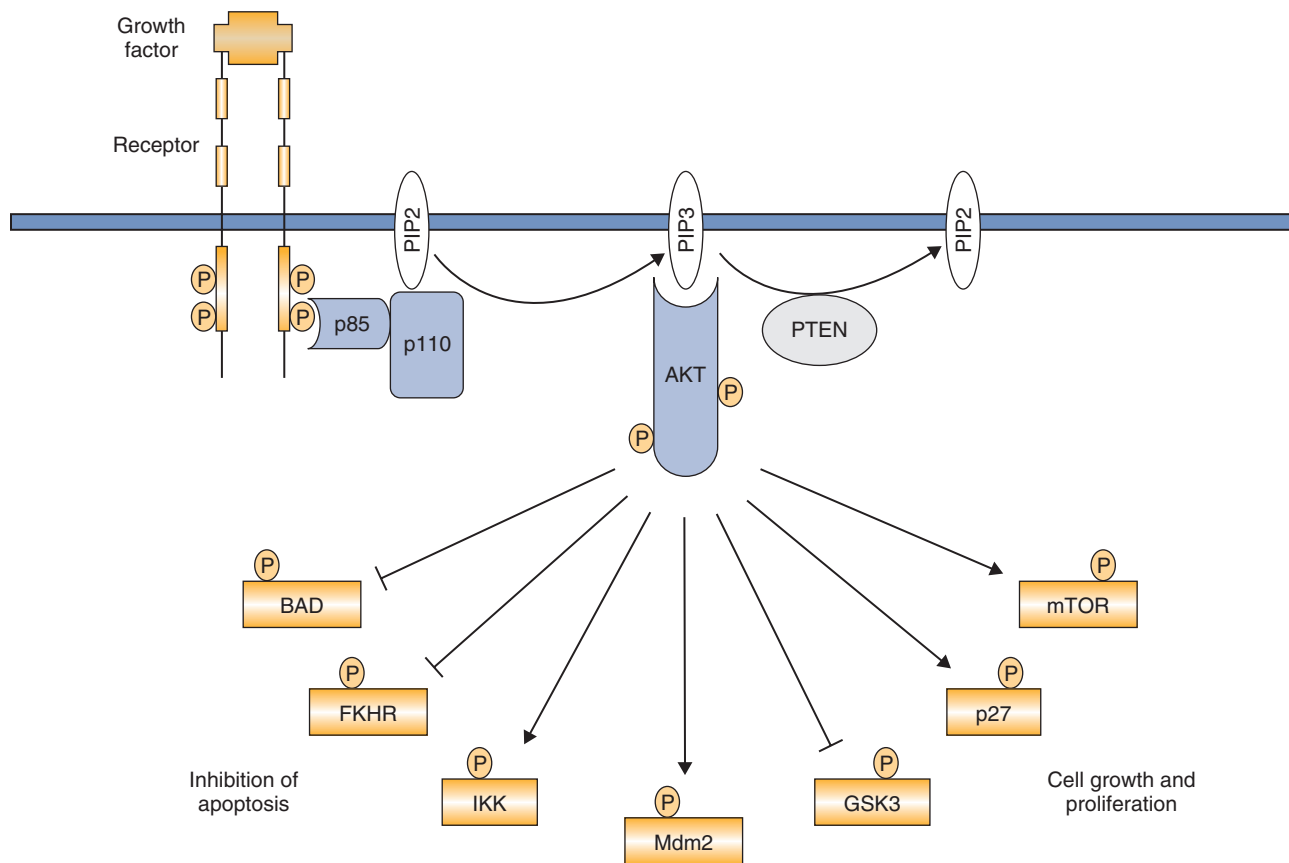

malignancies and BRAF mutations in cutaneous melanomas and papillary thyroid carcinomas.^{18–20}

The second cytoplasmic pathway includes phosphatidylinositol-3 kinase (PI3K) and its associated downstream signal transducers AKT, nuclear factor κ B (NF κ B), and mTOR, among others (Figure 14-8).^{21,22} PI3K is activated by RTKs and in turn activates AKT, which alters several additional proteins involved in the regulation of cell survival, cycling, and growth.²³ AKT phosphorylates targets that promote apoptosis (BAD, procaspase-9, and Forkhead transcription factors) and activates NF κ B, a transcription factor that has antiapoptotic activity.^{21–23} AKT also phosphorylates other proteins such as mTOR, p21, p27, and glycogen synthase kinase 3 (GSK3). This leads to redistribution of these proteins either in or out of the nucleus, ultimately inhibiting apoptosis while promoting cell cycling.^{21–23} Abnormalities of PI3K resulting in pathway activation are commonly found in human cancers, including mutations (breast and colorectal cancers and glioblastoma) and gene amplification (gastric, lung, ovarian cancers).²⁴ This pathway may also become dysregulated through loss of activity of PTEN, a phosphatase that normally acts to dephosphorylate AKT and terminate signaling.^{21,25,26} PTEN mutations and/or decreased PTEN expression are found in several human cancers (e.g., glioblastoma and prostate cancer)^{24,25} and have been documented in canine cancers (OSA, melanoma).^{27–29}

RTK-induced signaling ultimately influences cellular events by affecting transcription and the proteins that control cell cycling. The cyclins and their kinase partners (cyclin-dependent kinases [CDKs]) act to regulate the progression of cells through various phases of the cell cycle (Figure 14-9).^{30–32} The cyclins comprise several families. Cyclins D and E control restriction point passage by activating their respective CDKs (CDK4 and CDK6 for cyclin D and CDK2 for cyclin E). Coordinated function of cyclins D and E is required for cells to progress from G₁ into S phase (see Figure 14-9). In many cases, RTK-generated signals induce expression of cyclin D, which complexes with CDK4 and CDK6, resulting in phosphorylation of the tumor suppressor Rb, partially repressing its function.^{31,32} Functional cyclin D/CDK complexes induce transcription of cyclin E, and active cyclin E/CDK complexes further reduce Rb activity through phosphorylation. This in turn initiates the process of DNA replication important for cell cycling. Dysregulation of the cyclins and CDKs is common in human cancers; for example, overexpression of cyclins D and E is often present in breast, pancreas, and head and neck carcinomas.³²

Protein Kinases and Cancer Cells

Dysfunction of protein kinases is now recognized to be a common event in tumors. Although this has been best characterized in

• **FIGURE 14-8** Phosphatidylinositol-3 kinase (PI3K) signal transduction. Following receptor tyrosine kinase (RTK) activation, PI3K is recruited to the phosphorylated receptor through binding of the p85 adaptor subunit, leading to activation of the catalytic subunit (p110). This activation results in the generation of the second messenger phosphatidylinositol-3,4,5-triphosphate (PIP3). PIP3 recruits AKT to the membrane and following its phosphorylation, several downstream targets are subsequently phosphorylated, leading to either their activation or inhibition. The cumulative effect results in cell survival, growth, and proliferation. (From London CA: *Kinase inhibitors in cancer therapy*, Vet Comp Oncol 2:177–193, 2004. Reprinted with permission from Blackwell Publishing.)

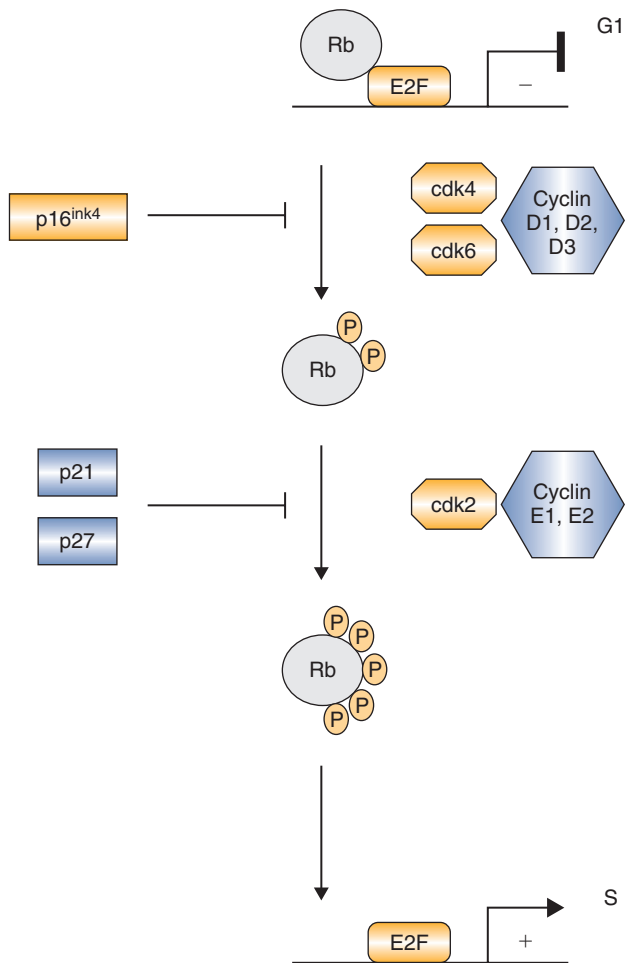

humans, recent data indicate that dog and cat cancers experience similar dysregulation (Table 14-2). Kinases may be dysregulated through a variety of mechanisms, including mutation, overexpression, fusion proteins, or autocrine loops. In the case of mutations, these may result in phosphorylation of the kinase in the absence of an appropriate signal. Such mutations can consist of a single amino acid change through a point mutation, deletion of amino acids, or insertion of amino acids, usually in the form of an internal tandem duplication (ITD). For example, a point mutation occurs in the BRAF gene (V600E, exon 15) in approximately 60% of human cutaneous melanomas.^{18,33,34} This amino acid change causes a conformation change in BRAF that mimics its activated form, thereby inducing constitutive downstream ERK signaling and abnormal promotion of cell growth and survival.^{35,36} RAS is another kinase that is dysregulated through point mutation in several hematopoietic neoplasms (multiple myeloma, juvenile chronic myelogenous leukemia [CML], acute myelogenous leukemia [AML], and chronic myelomonocytic leukemia [CMML]) and in lung cancer, colon cancer, and many others.^{17,37,38}

Another example of a mutation involves KIT, an RTK that normally is expressed on hematopoietic stem cells, on melanocytes, in the central nervous system, and on mast cells.³⁹ In approximately 25% to 30% of canine grade 2 and grade 3 mast cell tumors (MCTs), mutations consisting of ITDs are found in the juxtamembrane

domain of KIT, resulting in constitutive activation in the absence of ligand binding. These mutations are associated with a higher risk of local recurrence and metastasis.^{40–42} KIT mutations consisting of deletions in the juxtamembrane domain are also found in approximately 50% of human patients with gastrointestinal stromal tumors (GISTs) and are also found in GISTs in dogs.^{43–45} There are now several well-characterized mutations involving RTKs in human cancers, including FLT3 ITDs in AML,^{46–49} EGFR point mutations in lung carcinomas,^{50,51} and PI3K mutations in several types of carcinomas.²⁴

Overexpression of kinases usually involves the RTKs and may result in enhanced response of the cancer cells to normal levels of growth factor; or, if the levels are high enough, the kinase may become activated through spontaneous dimerization in the absence of signal/growth factor. In humans, the RTK human epidermal growth factor receptor 2 (HER2; also known as ErbB2, a member of the EGFR family) is overexpressed in both breast and ovarian carcinomas and often correlates with a more aggressive phenotype.^{4,52,53} EGFR is also overexpressed in human lung, bladder, cervical, ovarian, renal, and pancreatic cancers, and some tumors have as many as 60 copies of the gene per cell.^{7,54,55} As with HER2, such overexpression is linked to a worse outcome in affected patients.⁷

Fusion proteins are generated when a portion of the kinase becomes attached to another gene through chromosomal

• **FIGURE 14-9** Cyclin and cyclin-dependent kinase (CDK) regulation of G1-S transition. CDK inhibitors such as p16^{ink4} and p21 restrict the activity of cyclin D- and cyclin E-dependent kinases. Progressive Rb phosphorylation by the cyclins results in liberation of E2F and the resultant transcription of S-phase genes. (From London CA: *Kinase inhibitors in cancer therapy*, Vet Comp Oncol 2:177–193, 2004. Reprinted with permission from Blackwell Publishing.)

rearrangement and the normal mechanisms that control protein function are disrupted. One of the best characterized fusion proteins is BCR-ABL, which is found in 90% of patients with CML.^{56–59} ABL is a cytoplasmic tyrosine kinase that, when fused to BCR, results in dysregulation of ABL, inappropriate activity of the protein, and resultant malignant transformation. Other examples include TEL-PDGFR β in CMML, FIP1-PDGFR α in hypereosinophilic syndrome with mastocytosis, and (EML4)-ALK in non-small-cell lung cancer (NSCLC).⁶⁰

Autocrine loops of activation primarily occur when the tumor cell expresses both the RTK and the growth factor; in most cases, one or the other usually is also overexpressed, resulting in constitutive activation of the RTK. Examples include coexpression of transforming growth factor α (TGF α) and EGFR in glioblastoma and squamous cell carcinoma, insulin-like growth factor (IGF) and its ligand, IGF-1R, in breast and colorectal cancer, and VEGF and VEGFR in melanoma.^{4,61–63} In canine cancers, possible autocrine loops have been documented in OSA (co-expression of MET and its ligand, HGF) and hemangiosarcoma (HSA; co-expression of KIT and its ligand, SCF).^{64–66}

• **TABLE 14-2** Receptor Tyrosine Kinases Associated with Cancer

TYROSINE KINASE	CANCER ASSOCIATION
EGFR family	Breast, ovary, lung, stomach, colon, glioblastoma
Insulin receptor family	Sarcomas, cervix, kidney
PDGFR family	Glioblastoma, ovary, CMML, GIST
KIT	AML, GIST, seminoma, MCT, melanoma
Flt3	AML
VEGFR family	Angiogenesis, Kaposi's sarcoma, hemangiosarcoma, melanoma
FGFR family	AML, lymphoma, breast, prostate, multiple myeloma, TCC
NGFR family	Thyroid cancer, neuroblastoma, fibrosarcoma, AML
Met/Ron	Thyroid cancer, osteosarcoma, rhabdomyosarcoma, liver, kidney, colon
EPHR family	Melanoma, stomach, colon, breast, esophagus
AXL	AML
Tie family	Angiogenesis, stomach, hemangioblastoma
RET family	Thyroid cancer, multiple endocrine neoplasia
ALK	Non-Hodgkin's lymphoma, lung

ALK, Anaplastic lymphoma kinase; AML, acute myelogenous leukemia; CMML, chronic myelomonocytic leukemia; EGFR, epidermal growth factor receptor; EPHR, ephrin receptor; FGFR, fibroblast growth factor receptor; GIST, gastrointestinal stromal tumors; MCT, mast cell tumors; NGFR, nerve growth factor receptor; PDGFR, platelet-derived growth factor receptor; TCC, transitional cell carcinoma; Tie, tyrosine kinase receptor on endothelial cells; VEGFR, vascular endothelial growth factor receptor.

Inhibition of Kinases

Given the detailed molecular characterization of signal transducer dysregulation in cancer cells, significant efforts have been directed at developing strategies to inhibit those transducers that participate in tumorigenesis through direct effects on the cancer cell or through modulation of tumor microenvironment (stroma and neovascularity). The two most successful approaches to date have been monoclonal antibodies (MAbs) and small molecule inhibitors.

Several antibodies have been developed to target the extracellular domain of RTKs known to be important in a variety of tumors. These antibodies may prevent the growth factor from binding, may promote internalization of the RTK and subsequent degradation, or may induce an immune response against the cancer cell. One of the most successful examples is a humanized MAb called *trastuzumab* (Herceptin). This antibody targets HER2, which as previously discussed is overexpressed in approximately 30% of breast cancers, as well as other cancers, including prostate cancer, ovarian cancer, and NSCLC.⁶⁷ In initial clinical trials, trastuzumab treatment of HER2-positive breast cancer resulted in a response rate of approximately 25% in patients with metastatic disease.⁶⁸ The response rate approached 50% when trastuzumab was combined with chemotherapy.⁶⁹ When used in the adjuvant setting, multiple studies have demonstrated that trastuzumab markedly improves

survival rates of women with HER2-positive disease; trastuzumab is now part of the routine standard of care for this disease.^{70,71} Other examples of MABs that have demonstrated significant activity in human cancers include rituximab (Rituxan) that targets CD20 expressed in a number of B-cell lymphomas^{72,73} and cetuximab (Erbix) that targets ERBB1/HER1 EGFR known to be overexpressed in several carcinomas.^{7,67,74}

Small molecule inhibitors work primarily by blocking the ATP-binding site of kinases, essentially acting as competitive inhibitors; a smaller number of these inhibitors work by preventing necessary protein-protein interactions (allosteric inhibition).⁷⁵ In the absence of ATP, the kinase is unable to phosphorylate itself or downstream signaling elements, thereby interrupting a survival/growth signal essential to the tumor cell, ultimately resulting in cell death. As the molecular characterization of tumors has improved, the development and application of small molecule inhibitors have rapidly expanded in human oncology and their use is markedly altering how cancers are managed. Such inhibitors often are easy to synthesize in large quantities, frequently orally bioavailable, and can readily enter cells to bind the intended target.

The first small molecule inhibitor to be approved for human use was imatinib (Gleevec), an orally administered drug that binds the ATP pocket of ABL, as well as the RTKs KIT and PDGFR α .⁷⁶ As previously discussed, BCR-ABL fusion proteins are present in 90% of human patients with CML, making ABL a good target for therapeutic intervention. The application of imatinib to CML has been transformative, with significant biologic activity demonstrated in several clinical trials, resulting in the approval of imatinib for up-front care of affected individuals.⁷⁷⁻⁸² In the chronic phase of CML, imatinib induces a remission rate of close to 95%, and most patients remain in remission for longer than 1 year. Unfortunately, the remission rate is much lower for patients in blast crisis (20% to 50%), often lasting less than 10 months. Resistance to imatinib has been well characterized and is primarily due to the development of mutations in ABL that preclude drug binding, although gene amplification has also been documented.^{83,84} Imatinib also has clinical activity against human GIST in which 60% to 80% of the tumors have point mutations or deletions in the juxtamembrane domain of KIT, resulting in constitutive activation.^{85,86} Response rates of 50% to 70% have been reported with imatinib, far better than the 5% response rate seen with standard chemotherapy.^{87,88} A small number of GISTs have activating mutations in PDGFR α instead of KIT mutations; these patients also respond to imatinib.⁸⁹

There are now several small molecule inhibitors approved for the treatment of human cancers that possess specific mutations in kinases known to drive tumor growth and survival. A subset of patients with NSCLC have tumors with activating mutations in EGFR that respond to erlotinib (Tarceva) or gefitinib (Iressa), small molecule inhibitors of EGFR.⁹⁰ Response rates in patients with EGFR mutations can be as high as 80% compared to less than 10% to 20% for those without, demonstrating that efficacy of targeted therapies often depends on the presence of a known activated signaling element. A small number of patients with NSCLC also exhibit activation of the RTK ALK through its fusion to EML4.⁹¹ A small molecule inhibitor of ALK, crizotinib (Xalkori), has demonstrated significant activity against lung cancer patients whose tumors express the EML4-ALK translocation. In a recent phase II study, an objective response rate of 56% was achieved in this subset of patients, with another 31% of patients experiencing stable disease.^{91,92} As expected with a targeted therapeutic that disrupts key cell-signaling events, responses were rapid with most occurring by 8 weeks of treatment.

Vemurafenib (Zelboraf) is a small molecule inhibitor of BRAF that has shown significant activity against cutaneous malignant melanomas that possess activating mutations in BRAF. Most patients treated with vemurafenib experienced tumor shrinkage, with close to 50% meeting the criteria for objective response.⁹³ This compares to an objective response rate of only 5% in patients treated with dacarbazine. Inhibition of mTOR has become of interest in several cancers given the activation of the PI3K pathway and the critical role of mTOR in mediating its effects. Rapamycin, a drug used for many years as an immunosuppressive agent, is the prototypical mTOR inhibitor.^{94,95} Temsirolimus and everolimus, two rapamycin analogs, have already been approved for use in patients with metastatic renal carcinoma and other mTOR inhibitors are currently under investigation for their potential utility in treating soft tissue sarcomas and bone sarcomas.^{94,95}

Flavopiridol, a partly synthetic flavonoid derived from an indigenous plant (rohitukine) found in India, sits in the ATP-binding pocket of CDK2, acting as a competitive inhibitor.^{89,90} This compound has been shown to inhibit most of the CDKs evaluated, although some less potently than others.^{91,92} Although flavopiridol initially failed to demonstrate significant efficacy when used as a single agent,⁸⁹ recent pharmacokinetic data demonstrated activity in some patients, particularly those with chronic lymphocytic leukemia (CLL), when an alternative dosing schedule that enhanced the area under the curve was employed.⁹⁶

The inhibitors discussed previously tend to affect a restricted set of kinases, although other drugs exhibit much more broadly targeted inhibition. Sunitinib (Sutent) is a small molecule inhibitor of several RTKs, including VEGFR1, VEGFR2, PDGFR α/β , KIT, FLT3, receptor of colony-stimulating factor 1 (CSFR1), and rearranged during transfection receptor (RET).⁹⁷ The multitargeted nature of this inhibitor may be responsible for its observed activity in several types of cancer, including GIST, renal cell carcinoma, thyroid carcinoma, and insulinoma, among others.⁹⁷ Although such agents often have significant clinical activity, they are typically associated with a broader range of toxicities that may limit their use.

Kinase Inhibitors in Veterinary Medicine

There are now two small molecule inhibitors approved for use in dogs in veterinary medicine. Toceranib (Palladia) is a multitargeted inhibitor closely related to sunitinib that exhibits a similar target profile, including VEGFR, PDGFR, KIT, FLT3, and CSFR1. Toceranib has demonstrated activity against MCT, as well as sarcomas and carcinomas. In the original phase I study, 28% of dogs experienced objective responses to treatment, with an additional 26% experiencing stable disease for an overall biologic activity of 54%.⁹⁸ A pivotal study of toceranib was subsequently conducted in dogs with recurrent or metastatic intermediate or high grade MCT resulting in an objective response rate of 42.8% (21 complete responses, 42 partial responses), with an additional 16 dogs experiencing stable disease for an overall biologic activity of 60%.⁹⁹ Dogs whose MCT harbored activating mutations in KIT were roughly twice as likely to respond to toceranib than those without mutation (69% versus 37%). Following approval of toceranib in 2009, it has been used to treat a number of different solid tumors.¹⁰⁰ Preliminary observations of biologic activity were reported in dogs with anal sac adenocarcinoma, thyroid carcinoma, head and neck carcinoma, nasal carcinoma, and OSA. Several studies are ongoing to more clearly define the role of toceranib in the treatment of canine and feline cancer.

Masitinib (Kinavet) is a small molecule inhibitor of KIT, PDGFR α/β , and Lyn. In dogs with MCTs, masitinib significantly improved time to progression compared to placebo, and outcome was improved in dogs with MCT harboring KIT mutations.¹⁰¹ Subsequent follow-up of patients treated with long-term masitinib identified an increased number of patients with long-term disease control compared to those treated with placebo (40% versus 15% alive at 2 years).¹⁰² Finally, small studies have evaluated the efficacy of imatinib for the treatment of canine and feline MCT.^{103–105} Imatinib was well tolerated, and objective antitumor responses were observed in dogs with both mutant and wild-type KIT. Responses have also been observed in cats with MCT.^{106,107}

Conclusion

With the advent of molecular techniques, the characterization of signal transduction pathways that are dysfunctional in cancer cells has become commonplace. Advances in computer modeling and small molecule engineering have led to the rapid development of inhibitors capable of blocking specific pathways critical for cancer cell survival. The success of inhibitors such as imatinib and crizotinib indicate that the application of this therapeutic strategy can markedly improve clinical outcome. Perhaps the greatest challenges will be determining how these novel therapeutics can be effectively combined with standard treatment regimens such as chemotherapy and radiation therapy to provide optimal anticancer efficacy without enhancing toxicity and identifying strategies to use these therapeutics in ways that are less likely to result in drug resistance.

■ SECTION C

Antiangiogenic and Metronomic Therapy

ANTHONY J. MUTSAERS

Tumor Angiogenesis

Angiogenesis has emerged as a validated therapeutic target in oncology over the last several years, particularly with the widespread approval of drugs that target the proangiogenic vascular endothelial growth factor (VEGF) signaling pathway.^{1–5} Drugs such as bevacizumab (Avastin), the humanized anti-VEGF monoclonal antibody, and small molecule RTK inhibitors (RTKIs) such as sunitinib (Sutent) and sorafenib (Nexavar) in human oncology and toceranib (Palladia) in veterinary medicine are all considered to be efficacious, at least in part, because of an antiangiogenic mechanism of action.^{6,7} The guiding principle of tumor angiogenesis states that in order for a solid tumor to grow beyond a few millimeters in size, it must recruit its own blood supply to provide adequate nutrients and oxygen to the dividing cell mass, as well as the removal of waste products.^{8,9} Inducing angiogenesis is considered a hallmark of cancer progression,¹⁰ yet angiogenesis is a prominent aspect of normal physiology and transient pathology (e.g., in wound healing) and is tightly regulated. A large number of proangiogenic growth factors and signaling pathways promote the process of blood vessel growth.⁸ Similarly, endogenous inhibitors of angiogenesis are temporally expressed to suppress vessel expansion and maintain angiogenic balance.¹¹ The net effect depends on this relative balance, which is tipped toward promoting angiogenesis during tumor growth. Therapeutic interventions aim to tip the scales back toward inhibition of tumor angiogenesis.¹²

Angiogenesis occurs through the sprouting of new vessels from existing vasculature, whereas the term *vasculogenesis* is generally used to describe the de novo formation of new blood vessels from bone marrow–derived progenitor cell populations that respond to locally produced proangiogenic signals.^{13,14} In addition, although controversial, circulating endothelial progenitor cells (CEPs) from the bone marrow may contribute to tumor angiogenesis by traveling to tumor sites and incorporating into existing vessel walls.^{15–18} Finally, mature endothelial cells originating from the growing vasculature itself may be shed into the bloodstream, and are referred to as circulating endothelial cells (CECs).¹⁹ These CECs may represent a byproduct of local angiogenesis rather than an indicator of bone marrow involvement. At the present time, there is still much to learn regarding the morphology, surface marker expression, and relative contribution circulating cell populations make to tumor blood vessel growth and maintenance.^{20,21}

Despite the principles of angiogenesis finding extensive application in the field of solid tumor growth, blood vessels are also a normal component of the bone marrow microenvironment, and angiogenesis is a prominent feature of malignant bone marrow disorders. Many of the same growth factor and inhibitory pathway components described in solid tumor angiogenesis contribute to the biology of myelodysplasia, leukemias, myeloma, and lymphoma, among other “liquid” tumors.²² As a result, targeting angiogenesis is being investigated for the treatment of blood and bone marrow neoplasia and, indeed, one such agent with demonstrated antiangiogenic effects, thalidomide, has been approved for treatment of human multiple myeloma.²³

In addition to blood vessels, lymphatics are an important component of the tumor microenvironment and a prominent feature of tissue homeostasis, immunosurveillance, and a gateway to metastatic spread.²⁴ The regulation of lymphatic vessel growth is physiologically similar in principle to that of blood vessels, although the contribution of cells from the bone marrow to the formation and maintenance of lymphatic channels may be equally controversial.²⁵ Similar to angiogenesis, targeting lymphangiogenesis is an attractive prospect in clinical oncology that is receiving an increased research focus.²⁶

Antiangiogenic Therapy

There are multiple theories to explain the potential antitumor effects that result from antiangiogenic therapies.³ The first and most intuitive is vascular collapse resulting in impaired oxygen delivery to the tumor, leading to nutrient starvation, hypoxia, and death of cancer cells that cannot survive in this oxygen-deprived environment. Conversely, a second mechanism actually involves more efficient delivery of oxygen, nutrients, and indeed other drugs (such as chemotherapeutics) to tumor cells by a process termed *vessel normalization*.^{27,28} Normalization occurs when smaller, tortuous, inefficient, and leaky tumor vessels are selectively destroyed, resulting in improved blood flow through the tumor as a whole.²⁹ Vascular normalization has been demonstrated clinically using functional magnetic resonance imaging (fMRI) methods in patients undergoing treatment with VEGF pathway inhibitors.^{30,31} The most common clinical approach to targeting tumor angiogenesis has been either inhibition of overexpressed proangiogenic stimuli or supplementation of factors that inhibit angiogenesis. Targeting vasculogenesis through neutralization of CEPs is also a potential treatment strategy.³²

Inhibition of Proangiogenic Factors—Receptor Tyrosine Kinase Inhibitors

Currently, most RTKIs target numerous receptors to a varying degree.^{7,33} Toleranib is an example of an RTKI approved for veterinary use that complements its direct effects on tumor cells (e.g., via mutated *c-kit* inhibition) with angiogenesis inhibition because it directly targets VEGF receptors (VEGFR).³⁴ Binding to VEGFR results in blockade of the most powerful endothelial growth and survival factor. Additionally, through inhibition of platelet-derived growth factor receptors (PDGFR), toceranib and another veterinary approved RTKI, masitinib (Masivet, Kinavet), disrupt signaling pathways for blood vessel support structures, such as the stromal pericyte component of larger vessels.^{35,36} The relative antiangiogenic and direct antitumor effect of these RTKIs is made more complicated by the fact that some angiogenesis receptors such as VEGFR and PDGFR may also be concomitantly expressed by certain cancer cell types, resulting in an autocrine growth factor loop.^{37,38} The end result is that in certain cases targeting angiogenic pathways may have concurrent antitumor cell and antiangiogenic effects.

Significant cross-talk exists between growth signaling pathways, and as a result there is strong interaction between tumor cell-based oncogene or tumor suppressor gene expression and regulation of blood vessel growth *via* factors such as VEGF. Therefore many drugs designed to target oncogenes have demonstrated antiangiogenic “off-target” effects as a byproduct of VEGF inhibition.³⁹⁻⁴¹ For example, the anti-HER2 (*ErbB-2*) human MAb trastuzumab (Herceptin) and anti-EGFR antibodies such as cetuximab (Erbix) are examples of drugs that indirectly suppress angiogenesis because

neutralization of their oncogenic targets leads to a dramatic reduction in tumor cell VEGF production, which increases again at the time of targeted drug resistance.^{42,43} Through reduction in VEGF or other growth factor levels, there is an antiangiogenic component inherent in many forms of cancer treatment, including not only targeted inhibitors but also cytotoxic chemotherapy and radiation therapy. As a result, antiangiogenic mechanisms are not necessarily restricted to treatment modalities that target known angiogenesis pathways directly.

Angiogenic Inhibitor Supplementation

Since the discovery of endogenous proteins and protein fragments that inhibit blood vessel growth such as angiostatin, endostatin, and thrombospondins, there has been clinical interest in using angiogenesis inhibitors as cancer therapeutics.^{11,44} In veterinary medicine, thrombospondin-1 mimetic peptides have been evaluated as an antiangiogenic strategy in dogs with multiple tumor types. Treatment with the mimetic peptides ABT-526 and ABT-510 in a prospective clinical trial of 242 dogs with multiple tumor types showed an objective response or substantially stabilized disease in 42 dogs and a lack of dose-limiting toxicity.⁴⁵ Interestingly, most objective responses were recorded after 60 days of continuous drug treatment. A prospective randomized placebo-controlled clinical trial has also been reported in dogs with multicentric lymphoma treated at first relapse.⁴⁶ Results revealed a significant improvement in time to tumor progression and remission duration, but not remission rate, when ABT-526 was used in combination with lomustine, compared to dogs treated with lomustine alone, with no ABT-526-specific toxicities noted. In addition to thrombospondin-1, preliminary studies documenting detection of the endogenous inhibitors angiostatin and endostatin in normal and tumor-bearing dogs have been reported.^{47,48} In a preliminary study of endostatin as a therapeutic agent, 13 dogs with soft tissue sarcomas were treated with the canine endostatin gene delivered via liposome-DNA complexes.⁴⁹ Although endostatin gene expression was not detected in the tumors following treatment, objective responses were documented in 2 dogs, and 8 dogs experienced stable disease, suggesting potential nonspecific antitumor activity.

Direct Targeting of Tumor Endothelial Cell Surface Markers

Tumor endothelial cells differ from normal endothelia in their genetic and protein composition.⁵⁰ These differences may represent an opportunity for a favorable therapeutic index when drugs are designed to bind differentially expressed targets on tumor-specific endothelium. If not naturally destructive to these cells, drugs can be designed to carry a payload to induce local cytotoxicity, resulting in an antiangiogenic effect. A phage vector delivering tumor necrosis factor (RGD-A-TNF) to αV integrins on tumor endothelium is one example of such a strategy that has undergone evaluation in dogs.⁵¹ Through serial biopsy, this dose escalation trial was able to demonstrate selective targeting of tumor endothelium via αV integrin-targeted expression of TNF, and treatment of a cohort of tumor-bearing dogs with the maximum tolerated dose (MTD) resulting in partial remission in 2/14 and stable disease in 6/14 dogs.

Other Antiangiogenic Agents

A vast array of drugs not necessarily designed as anticancer therapeutics may derive at least a portion of their activity through

inhibition of angiogenesis. Two examples investigated in a veterinary setting include inhibitors of matrix metalloproteinase (MMP) and cyclooxygenase (COX). The MMPs are a family of enzymes that degrade the extracellular matrix and basement membrane, thereby mediating tumor invasion, angiogenesis, and metastasis.⁵² Unfortunately, clinical evaluation of compounds that inhibit these enzymes has to date been largely unrewarding,^{53,54} including results from a large randomized trial of 303 dogs with OSA, in which treatment with the MMP inhibitor Bay12-9566 or placebo after doxorubicin chemotherapy did not improve overall survival.⁵⁵ Inhibition of the proinflammatory COX enzymes has been commonly studied in numerous tumor types in veterinary oncology.⁵⁶⁻⁵⁸ The effects of COX inhibition on reducing angiogenesis specifically have been evaluated with piroxicam treatment of canine transitional cell carcinoma (TCC). In a study of 18 dogs, piroxicam treatment was associated with reduced urinary concentrations of the proangiogenic growth factor basic fibroblast growth factor (bFGF) and induction of apoptosis.⁵⁹ In a subsequent study evaluating these parameters in 12 dogs treated with piroxicam in combination with cisplatin, reductions in urinary bFGF and VEGF were associated with response to the combination regimen.⁶⁰

Metronomic Chemotherapy

Conventional cytotoxic chemotherapy agents that have been in clinical use for many decades also achieve at least a portion of their therapeutic efficacy by inhibition of tumor angiogenesis.^{61,62} The basis for this notion likely originated with the observation that tumor endothelial cell populations are much more proliferative than the quiescent endothelium found elsewhere in the body. These rapidly dividing endothelial cells would be targets of chemotherapy in the same way that other proliferative cells such as intestinal epithelia and bone marrow precursors are damaged. The key to maximizing the antiangiogenic potential of chemotherapeutic drugs was considered to be through reduction or elimination of the break period between doses. It is during this break period that repair and repopulation of endothelial cells were likely to occur, as they do for other cell populations.⁶¹ However, conventional chemotherapeutic protocols are largely based on the principle of MTD, which originated through models of optimized tumor cell kill that require a break period to allow recovery of normal cell populations.^{63,64} Despite the success of MTD chemotherapy protocols for the treatment and outright cure of certain cancers, critics of such models point out that the preclinical experiments were performed in exponential growth phase cell culture models, and the exposure time of the cells to chemotherapy was not an included variable.⁶⁵ More continuous exposure to chemotherapy, with reduction or elimination of the break period between each dose, has come to be known as “metronomic” delivery.⁶⁶ Not surprisingly, dose reduction is required to provide a more continuous treatment schedule. Generally speaking, metronomic chemotherapy protocols are well tolerated. The low toxicity profile, combined with ease of administration when oral drugs are used, and often lower cost make metronomic chemotherapy protocols appealing in veterinary oncology. However, mechanistic and clinical evaluation in veterinary patients is still at an early stage.

Mechanisms of Treatment

When different types of dividing cells in culture are exposed to continuous ultra-low doses of chemotherapy, endothelial cell populations display an exquisite sensitivity compared to other cell types, including tumor cells in many instances.^{67,68} Although the reasons for this selectivity are not entirely clear, the explanation likely goes

beyond mere targeting of rapidly dividing cells. Experimental evidence has suggested that upregulation of the endogenous angiogenesis inhibitor thrombospondin-1 occurs during treatment with metronomic cyclophosphamide and possibly other agents.^{69,70} The resulting angiogenic suppression is likely reinforced by a decrease in tumor cell production of proangiogenic growth factors such as VEGF. Decreased VEGF production may be accomplished through reduced tumor cell mass as a result of direct cancer cell killing by chemotherapy. This explains why the antiangiogenic actions of metronomic chemotherapy may be enhanced when there is concomitant tumor cell kill; however, in theory, antiangiogenic targeting of chemotherapy drugs does not require drug sensitivity from the tumor cell population. Targeting the genetically stable endothelial component of the tumor microenvironment instead of the genetically unstable tumor cell population was promoted early on as a potential advantage of antiangiogenic treatment strategies.⁷¹

Other components of the tumor microenvironment may also be targeted by metronomic delivery of certain cytotoxic chemotherapy drugs. As mentioned earlier, tumor angiogenesis may involve recruitment of CEPs.¹⁷ These cells, if they play a significant role in the growth of tumor blood vessels, may be most influential after the acute damage that would occur in the early break period of MTD chemotherapy schedules.⁷² Preclinical models have demonstrated that CEPs acutely decrease with MTD treatment, only to rapidly rebound during the break period, when they may contribute to endothelial cell repopulation.⁷³ In contrast, metronomic chemotherapy delivery does not appear to be associated with this CEP surge, leading instead to a sustained antiangiogenic effect.⁷³⁻⁷⁵

Other cells also compose a significant component of the tumor microenvironment. Immune effector cells such as lymphocytes and macrophages influence tumor biology and may be affected by chemotherapy treatment. As such, the potential immunomodulatory antitumor mechanisms of metronomic chemotherapy, particularly with the alkylating agent cyclophosphamide, are receiving significant investigation. Low doses of cyclophosphamide influence the T-lymphocyte subset population by decreasing levels of CD4+CD25+ regulatory T-cells.⁷⁶ Regulatory T-cells (Tregs) inhibit the immune response, thereby suppressing tumor immunosurveillance. In dogs with various malignancies, regulatory T-cells have been quantified by flow cytometry^{77,78} and have been shown to decrease in blood samples taken from dogs with soft tissue sarcoma treated with low-dose cyclophosphamide chemotherapy.⁷⁹ Further effects of metronomic cyclophosphamide on tumor immunology remain to be determined, and the nature of potential immunomodulatory mechanisms for other chemotherapeutics delivered metronomically is currently largely unexplored.

Clinical Trial Evaluation

Recent small retrospective and phase II clinical trials have been reported in human and veterinary oncology with a variety of chemotherapy drugs and combinations.⁸⁰⁻⁸⁶ Most clinical trial evaluations to date have paired conventional chemotherapy drugs with noncytotoxic drugs that target angiogenesis directly or indirectly. Preclinical results demonstrated over a decade ago that such combinations resulted in superior outcomes, likely due to more robust neutralization of the pro-survival functions of VEGF in the tumor endothelium.^{87,88} As a result, most clinical trials have evaluated combination approaches without necessarily any clear prior documentation of single-agent clinical activity for each drug. Bevacizumab has been a popular choice to pair with human metronomic chemotherapy schedules and is FDA-approved for multiple indications.^{83,89-92} Other, more readily available “targeted” drugs, shown

• **TABLE 14-3** Reported Veterinary Metronomic Chemotherapy Protocols with Alkylating Agents

TUMOR	CHEMOTHERAPY DRUG	DOSE	OTHER DRUGS	SETTING
Hemangiosarcoma ¹⁰⁰	Cyclophosphamide	12.5-25 mg/m ² daily for 3 weeks, alternating with etoposide	Etoposide 50 mg/m ² daily for 3 weeks Piroxicam daily 0.3 mg/kg	Adjuvant
Soft tissue sarcoma ¹⁰¹	Cyclophosphamide	10 mg/m ² daily or every other day	Piroxicam daily 0.3 mg/kg	Adjuvant
Soft tissue sarcoma ⁷⁸	Cyclophosphamide	12.5 mg/m ² or 15 mg/m ² daily	None	Gross disease
Multiple tumor types ¹⁰²	Cyclophosphamide	25 mg/m ² daily	Celecoxib daily 2 mg/kg	First-line metastatic
Multiple tumor types ¹⁰³	Chlorambucil	4 mg/m ² daily	None	Any
Multiple tumor types ¹⁰⁴	Lomustine	2.84 mg/m ² daily	None	Any

to have at least indirect antiangiogenic effects, are also commonly utilized. Examples include COX inhibitors,^{81,93-97} tetracyclines, thalidomide,^{23,98} and others.⁹⁹ Generally speaking, in contrast to MTD chemotherapy protocols, targeted drugs are often given for longer periods of time at their optimal biologic dose (OBD). As a result, targeted drug combinations with metronomic chemotherapy may be an effective treatment strategy, as each follows a similar dose and scheduling principle. In addition, it is possible that there may be a role for targeted antiangiogenic treatment or metronomic chemotherapy in combination with MTD chemotherapy schedules to neutralize rebound angiogenic responses that occur during the break period. This approach has been demonstrated successfully in preclinical studies.^{72,100} Ultimately, rigorous clinical trials are necessary to identify and optimize successful drug combinations and schedules of antiangiogenic drugs and chemotherapy.

Veterinary Trials with Cyclophosphamide

Cyclophosphamide has been the most common drug by far to be studied in low-dose metronomic treatment protocols in both human and veterinary oncology. At this time, metronomic chemotherapy protocols have only been evaluated in small retrospective studies and phase I and II veterinary clinical trials (Table 14-3).^{78,100-104} A protocol of low-dose cyclophosphamide (12.5 to 25 mg/m² orally daily) alternating with etoposide (50 mg/m² orally daily) and paired with continuous piroxicam treatment has been evaluated for adjuvant treatment of splenic HSA in dogs.¹⁰⁵ The survival time of 9 dogs treated with this regimen was not different from a historic control group of 24 dogs treated with doxorubicin alone. The metronomic protocol was well tolerated over a 6-month period. Pharmacokinetic analysis of etoposide in 3 dogs revealed detectable drug levels. Another report of etoposide administration in dogs demonstrated a low and variable oral bioavailability with this drug.¹⁰¹

Low-dose continuous cyclophosphamide and piroxicam were also studied for the adjuvant treatment of canine incompletely resected soft tissue sarcoma.¹⁰² Unlike the HSA study, in this trial the dose of cyclophosphamide was 10 mg/m² daily or every other day. The disease-free interval was significantly prolonged in the treated group of 30 dogs compared to an age, site, and grade-matched contemporary control group of 55 dogs treated with surgery alone. Again, the protocol was well tolerated, although 40% of dogs experienced mild toxicity at some point of the treatment, and 1 dog experienced grade 4 sterile hemorrhagic cystitis. The every-other-day dosing regimen was better tolerated than daily cyclophosphamide dosing.

Metronomic cyclophosphamide treatment was also recently reported for first-line therapy of metastatic canine tumors of

varying histologies.¹⁰⁶ Fifteen dogs were treated with daily oral cyclophosphamide at 25 mg/m² combined with the COX-2 inhibitor celecoxib at 2 mg/kg. One dog had a complete response, and five dogs had stable disease with a treatment protocol that was devoid of toxicity. All dogs were reported to have improved quality of life scores. Most of the tumors treated were carcinomas, and as with many other trials it is not apparent what the relative contribution of each drug may have been to the overall response rate, as single-agent responses to COX inhibitors have been documented in cancer-bearing dogs.⁵⁸ Interestingly, the authors measured circulating VEGF and IL-6 and observed that pretreatment plasma VEGF levels were significantly lower in responders than nonresponders,¹⁰⁶ as has been observed in other clinical trials of metronomic cyclophosphamide.¹⁰³

Other Alkylating Agents

Chlorambucil has been used in many veterinary treatment protocols, such as first-line treatment of canine chronic lymphocytic leukemia (CLL), low-grade lymphoma, MCTs, and as a cyclophosphamide replacement for cases that develop sterile hemorrhagic cystitis.¹⁰⁷ A recent prospective clinical trial of daily single-agent metronomic chlorambucil therapy at a dose of 4 mg/m² in 36 dogs with tumors of varying histologies and prior therapies revealed a complete response over 35 weeks duration in 3 dogs, a partial response in 1 dog, and stable disease in 17 dogs.¹⁰⁴ The median progression-free interval was 61 days, and there were no grade 3 or 4 toxicities noted.

Lomustine (CCNU) has also been evaluated in a metronomic protocol at a dose of 2.84 mg/m² by mouth, which corresponds to the conversion of a 60 mg/m² every 3 week dose into a daily schedule.¹⁰⁸ A total of 81 dogs with various primary and metastatic tumors were treated with this single-agent regimen for a median of 98 days. Twenty-two dogs had treatment discontinued for adverse events of gastrointestinal, bone marrow, hepatic, or renal origin, although the authors concluded that the treatment was generally well tolerated.

Platinum Compounds

While not designed to be administered in a metronomic fashion per se, the various slow-release and oral formulations of platinum compounds that have been evaluated in veterinary oncology may represent metronomic application of these drugs. Slow-release cisplatin using delivery systems such as the open-cell polylactic acid polymer impregnated with drug (OPLA-Pt) has been studied in a variety of scenarios, including treatment of canine OSA, soft tissue sarcoma, and nasal tumors with desirable efficacy and manageable toxicity.¹⁰⁹⁻¹¹¹ A dose escalation and pharmacokinetic study of

satraplatin, the first orally bioavailable platinum agent, has recently been reported.¹¹² The aim of this study was to determine the MTD; however, the fact that this drug is administered orally makes possible the future investigation of satraplatin in a metronomic-dosing schedule. These studies with platinum compounds raise the general question of whether forms of slow-release chemotherapeutic delivery such as liposome encapsulation represent a form of metronomic drug delivery.

Biomarkers for Antiangiogenic and Metronomic Therapy

The identification and application of biomarkers is becoming increasingly important as the field of oncology moves further into clinical application of targeted therapeutics.¹¹³ The aims of validated biomarkers are to (1) predict patient populations that will or will not respond to treatment, (2) monitor response to therapy on a cellular or molecular level, or (3) determine the proper therapeutic dose for targeted agents that often possess optimal biologic activity at doses well below the traditionally defined MTD. The use of biomarkers for antiangiogenic agents is valid in all three categories.

Tumor tissue expression and/or blood-based circulating growth factor levels have been the most popular approaches to predicting response to angiogenesis inhibitors, with VEGF being the most studied molecule.¹¹⁴⁻¹¹⁶ For example, in the study of metronomic cyclophosphamide and celecoxib by Marchetti and colleagues, low baseline plasma VEGF was predictive of response.¹⁰⁶ In many cases it may be through comparison of pretreatment to posttreatment levels that insight will be gained from this surrogate marker, as was demonstrated with urinary bFGF and VEGF with piroxicam treatment of canine TCC.^{59,60} The most important biomarker in angiogenesis may be one that defines tumor response because inhibition of angiogenesis does not necessarily correspond to a reduction in tumor volume. This static response sits in sharp contrast to MTD chemotherapy approaches that result in measureable tumor shrinkage. Systems for clinical evaluation of tumor response to therapy are often formally based on World Health Organization (WHO) criteria or response evaluation criteria in solid tumors (RECIST), which equate tumor shrinkage with positive outcome. Therefore there may be a need for both recognition of sustained stable disease as a desirable clinical trial endpoint and biomarkers to evaluate angiogenic function during treatment. Imaging modalities that can provide information about vascular function are a potentially valuable tool for monitoring tumor angiogenesis and the effects of antiangiogenic therapy.¹¹⁴ Dynamic contrast-enhanced MRI (DCE-MRI) has been studied for its ability to quantitatively assess vascular parameters.¹¹⁷ A study by MacLeod and colleagues demonstrated blood volume and permeability measurements in canine intracranial masses using this modality.¹¹⁸

The area of dose optimization also represents an unmet need for biomarkers in antiangiogenic and metronomic chemotherapy. Tregs are providing insight in this regard. Recent results from Burton and coworkers demonstrated a dose-dependent reduction in Tregs with metronomic cyclophosphamide treatment, observed at 15 mg/m² but not 12.5 mg/m² doses, leading the investigators to conclude that 15 mg/m² may be a more appropriate dose for future clinical trials.⁷⁹ In addition to Treg levels, temporal evaluation of other markers has been studied. Assessment of CECs and/or CEPs has been applied for biomarker analysis of dosing antiangiogenic and metronomic therapy.^{75,97,119} For example, in the study by Rusk and colleagues, decreasing CEC levels in dogs treated with the

thrombospondin-1 mimetic peptide ABT-526 may have indicated adequate exposure to the antiangiogenic drug, which in this study was utilized at a single dose.⁴⁵

Side Effects (Adverse Events)

Despite the therapeutic index achieved by treating activated versus dormant vasculature, there is still potential risk that drug effects on vessels have unwanted consequences. For bevacizumab, potential side effects of a vascular etiology include hypertension, edema, hemorrhage, thromboembolism, proteinuria, intestinal perforation, and impaired wound healing.¹²⁰ Through further clinical evaluation, we will learn the relative risks for different antiangiogenic drugs applied to a number of tumor settings. Resistance to antiangiogenic therapy has also become evident from early clinical data. Given the genetically stable nature of the blood vessel/endothelial cell target compared to the mutationally prone cancer cell population, antiangiogenic treatment was originally postulated to be less likely to demonstrate drug resistance.⁷¹ Proposed mechanisms of resistance to antiangiogenic therapies involve both tumor and host-mediated pathways that can be intrinsic or induced by treatment.¹²¹ One alarming consequence of antiangiogenic treatment that has emerged from recent preclinical studies is the potential that certain drugs may alter the host microenvironment, leading to metastatic conditioning.^{122,123} This phenomenon of increased invasion and metastasis as a result of antiangiogenic drug treatment, despite successful suppression of primary tumor growth, has been demonstrated in preclinical models with certain antiangiogenic RTKIs. The drugs studied include sunitinib, an RTKI with a similar target spectrum to toceranib.¹²³ Further validation and investigation into potential explanations for these provocative results are ongoing.

Finally, it is worth noting that similar to most other drugs, antiangiogenic agents are not innocuous and may have a unique side-effect profile that is independent of their effects on blood vessels or the tumor microenvironment. Side effects for toceranib include dose-dependent gastrointestinal upset, including bleeding, myelosuppression, azotemia, anemia, lethargy, or lameness.¹²⁴⁻¹²⁶ Masitinib's side effects include gastrointestinal upset, regenerative or nonregenerative anemia, and protein-losing nephropathy.^{35,124} Cyclophosphamide has become a popular drug for metronomic scheduling but is associated with the potential for sterile hemorrhagic cystitis.¹²⁷ It is currently unknown whether cystitis is more frequent in metronomic protocols; however, close urinary monitoring is strongly recommended for these patients. Similarly, chlorambucil has been clinically evaluated for metronomic use¹⁰⁴ and can be used as an alternative to cyclophosphamide, although it is still not known whether drug efficacy will be similar for different drugs applied across multiple tumor types.

■ SECTION D

Novel and Emerging Therapeutic Targets

DOUGLAS H. THAMM AND DAVID J. ARGYLE

The recent explosion in available cancer bioinformatics, rational and combinatorial drug design, and high-throughput drug screening has resulted in a massive increase in potential therapeutic targets and anticancer treatment strategies. An exhaustive survey of all potential novel targets for cancer therapy would be impossible; thus this review is designed to present a brief overview of some of the more promising and well-developed “druggable” targets that have been discovered recently and, when applicable, their potential application to veterinary oncology.

DNA Methylation

In addition to the information encoded within the genome sequence, it has been shown that epigenetic changes are of great importance in the modification and maintenance of gene expression. These changes take place through a number of mechanisms, including polymerase enzyme modulation, chromatin condensation, and DNA methylation. Mammalian DNA is methylated at cytosines within cytosine-guanine (CpG) dinucleotide sequences. During tissue differentiation, the methylation pattern is one governor of tissue-specific gene expression and thus phenotype.^{1–3}

Two different methylation-related phenomena have been identified in cancer. First, tumor cell DNA has been shown in both dogs and other mammals to be globally hypomethylated,^{4,5} specifically in pericentromeric satellite sequences. This may lead to decreased genome stability and an increase in the incidence of oncogenic chromosome defects. Indeed, the purposeful induction of genomic hypomethylation by reduction in germline DNA methyltransferase-1 (DNMT1) levels in genetically engineered mice is associated with a high incidence of T-cell lymphomas displaying trisomy 15.⁶ Second, cancer cells also acquire sequence-specific promoter hypermethylation and transcriptional repression in normally unmethylated regions, several of which have been shown to be associated with known tumor suppressor genes, including *Rb*, *p16*, *p73*, and the von Hippel-Lindau protein (*VHL*),^{1,2,7–9} or other important tumor-associated genes such as *E-cadherin* and estrogen and retinoic acid receptors.¹⁰

The methylation of DNA is controlled by four known DNMTs, of which DNMT1 may be the most important in cancer.^{1–3} A variety of agents can inhibit DNMT function. The two best studied are 5-azacytidine (Vidaza) and 5-aza-deoxycytidine (decitabine, Dacogen), which are nucleoside analogs that incorporate into DNA and inhibit DNMT activity but allow replication to proceed. A large

number of single-agent clinical trials with these agents have been reported, and significant activity has been demonstrated in hematopoietic neoplasia, leading to the Food and Drug Administration (FDA) approval of 5-azacytidine and decitabine for the treatment of myelodysplastic syndrome.^{11,12} Encouraging response rates to the nucleoside analog decitabine have also been seen in human patients with imatinib-refractory CML.^{13,14} Results in advanced solid tumors have been generally disappointing^{15,16}; however, studies in combination with standard antineoplastic therapy and other targeted agents (e.g., histone deacetylase inhibitors) are ongoing.¹⁷ One drawback of these drugs is the requirement of DNA replication for activity. There are various other drugs that have DNMT inhibitory activity in nonreplicating cells, including green tea polyphenols¹ and marine products of the psammaphin class,¹⁸ a synthetic derivative of which concurrently inhibits histone deacetylase (see later) and is in human clinical trials.¹⁹ Interestingly, the commonly used cardiac medications procainamide and hydralazine also possess demethylating activity,^{10,20} and clinical trials have demonstrated alterations in promoter methylation and reactivation of silenced genes following administration of well-tolerated doses of hydralazine to human cervical cancer patients.²¹ Hydralazine-valproic acid combinations have demonstrated activity in myelodysplastic syndrome in early human trials.²² Procainamide and hydralazine have a long track record of use in veterinary medicine and as such could serve as interesting and readily available drugs for the initial evaluation of methylation inhibition in veterinary cancer patients.

Two potential problems exist regarding the wide clinical implementation of DNMT inhibitors for cancer treatment. As discussed previously, induction of long-term genome-wide hypomethylation could decrease chromosome stability leading to potentially tumorigenic chromosome rearrangements.³ Demethylation could also trigger the reactivation of genes promoting a more aggressive or metastatic phenotype.³ In support of this theory, treatment of non-metastatic breast cancer cells with 5-azacytidine was shown to upregulate expression of urokinase-like plasminogen activator, an enzyme important in tumor invasion and metastasis, leading to enhanced metastatic potential.²³

Histone Deacetylase

Another critical determinant of gene expression is the condensation of chromatin in the form of heterochromatin, which results in transcriptional silencing and enhanced genome stability. This is accomplished by a number of pathways, one of which is the acetylation and deacetylation of histones, controlled by histone acetyltransferases and histone deacetylases (HDACs).²⁴ The HDACs specifically maintain chromatin in a condensed form, and can associate with specific transcription factors resulting in transcription repression. The acetylation of histones may be key in regulating the expression of genes associated with cellular proliferation, differentiation, and survival, both in development and carcinogenesis.^{25,26} Studies suggest that histone acetylation reduces electrostatic charge interactions between histones, leading to chromatin decondensation, and more recent work has suggested that HDAC enzymes' effects may also be indirect through modulation of other proteins important in chromatin condensation, including DNMT1.²⁷ Induction of HDAC expression, leading to transcriptional repression, is a common feature in human cancers such as colon cancer²⁸ and negatively regulates the expression of several tumor suppressor genes, including *p53* and *VHL*.²⁹ Differential expression of certain HDAC isoforms has been associated with outcome in a variety of human tumors, with HDAC2 and 6 studied most completely.³⁰

Pharmacologic inhibition of HDAC can affect multiple facets of the malignant phenotype. HDAC inhibition inhibits colon carcinogenesis in the adenomatosis polyposis coli (APC) mouse model.²⁸ Angiogenesis can be inhibited through upregulation of VHL and subsequent inhibition of hypoxia-inducible factor-1 α (HIF-1 α) function and VEGF production^{29,31,32}; decreased expression of other proangiogenic factors such as bFGF, angiopoietin-2, and Tie2^{31,32}; inhibition of endothelial nitric oxide (NO) synthase and endothelial cell proliferation and tube formation^{33,34}; and inhibition of the commitment of endothelial progenitor cells to the endothelial lineage.³⁵ Inhibition of HDAC can enhance apoptosis in tumor and endothelial cells^{32,36-38} and directly inhibit tumor cell proliferation.^{37,39-41} Consistent with its role as a transcription repressor, inhibition of HDAC has been shown to induce differentiation in thyroid and prostate cancers, neuroblastoma, and the leukemias.⁴²⁻⁴⁶ HDAC inhibition dramatically enhances the *in vitro* and *in vivo* efficacy of multiple standard cytotoxic therapies, as well as novel antibodies and small molecules.^{27,32,38,47-54}

Two HDAC inhibitors, vorinostat (suberoylanilide hydroxamic acid [SAHA], Zolinza) and romidepsin (FK228, Istodax), have recently been approved by the FDA for the treatment of cutaneous T-cell lymphoma (CTCL),⁵⁵⁻⁵⁷ and a large number of additional agents are in intermediate to late-stage clinical trials. A number of studies are being conducted evaluating HDAC inhibitors for various other hematologic and solid tumors, and early studies combining these drugs with other targeted and cytotoxic therapies have been reported.⁵⁸⁻⁶¹

A recent *in vitro* study demonstrated potent induction of histone acetylation, growth inhibition, and induction of apoptosis in a variety of canine tumor cell lines treated with either vorinostat or the novel HDAC inhibitor OSU-HDAC42 (AR42).⁶² The commercially available anticonvulsant drug valproic acid (VPA) can function as an HDAC inhibitor and is capable of inhibiting tumor cell invasion, P-glycoprotein expression, proliferation, and angiogenesis and enhancing chemosensitivity.^{24,27,43} VPA was recently shown to enhance the antiproliferative and proapoptotic effects of doxorubicin in canine OSA cell lines *in vitro* and to synergize with doxorubicin in a canine OSA xenograft.⁵³

There is a single case report describing administration of vorinostat to a dog with microscopic HSA.⁶³ Although apparently well tolerated, the dose was empirically chosen, there was no pharmacokinetic analysis or demonstration of target inhibition, and the drug's impact on the course of the disease could not be unequivocally determined. A recent study demonstrated that VPA could be administered prior to a standard dose of doxorubicin in tumor-bearing dogs, at dosages sufficient to enhance histone acetylation in tumor and peripheral blood mononuclear cells, but was not associated with toxicity or apparent potentiation of doxorubicin's adverse effects.⁵⁴

The Proteasome

The abundance of cellular proteins is tightly controlled at the levels of both production and destruction. Protein production can be modified at the transcriptional and posttranscriptional level, and therapies based on these approaches are relatively abundant. Until recently, relatively little attention has been paid to the manipulation of protein degradation as a therapeutic modality. The ubiquitin-proteasome pathway (UPP) is responsible for the degradation of the majority of intracellular proteins and for the regulation of many proteins with key roles in cancer.

The 26S proteasome is a large multiprotein complex containing ubiquitin recognition domains, which bind ubiquitinated proteins tagged for degradation, and proteolytic domains with trypsin-like, chymotrypsin-like, and caspase-like activity, which degrade proteins into short polypeptide sequences.⁶⁴ It is responsible for the degradation of a variety of proteins responsible for cell-cycle regulation, angiogenesis, apoptosis, and chemotherapy and radiation sensitivity (Table 14-4).⁶⁴⁻⁶⁶

Tumor cells are generally more sensitive to the effects of proteasome inhibition than are normal cells. Various studies have demonstrated a threefold to fortyfold increase in susceptibility to proteasome inhibitor-associated apoptosis when comparing tumor cells to corresponding normal tissues.⁶⁶⁻⁷⁰ The mechanisms for this differential sensitivity are unclear, but proliferating cells generally appear more sensitive than do quiescent cells.^{64,66} Additionally, dysregulation of UPP function appears to occur in many cancer cells, thus potentially rendering them more sensitive to inhibition.^{66,71} Recent studies implicate profound upregulation of the proapoptotic factor Noxa as being a key mediator of proteasome inhibitor-induced tumor cell apoptosis.^{72,73}

Although a number of chemicals appear capable of proteasome inhibition *in vitro*, only the boronic acid derivatives appear suitable for clinical use and only one drug, bortezomib (Velcade, PS-341), has received FDA approval for the treatment of multiple myeloma.⁷⁴⁻⁷⁷ Several additional proteasome inhibitors are in clinical development. Meaningful antitumor activity has been observed in patients with other hematopoietic neoplasms,⁷⁸⁻⁸⁰ but less activity has been seen in solid tumors to date.⁸¹⁻⁸⁴ Although toxicology studies with bortezomib have been performed in dogs,⁸⁵ there is no information available to date regarding the safety or biologic effect of proteasome inhibitors in veterinary patients or tumor cells.

Heat Shock Protein 90

Given the complex nature of cancer and the multiple pathways that can be subjugated to contribute to the malignant phenotype, an optimal cancer drug might target a variety of oncogenic pathways simultaneously. One molecular target that has the potential to interrupt a wide variety of pathways important in cancer is heat shock protein 90 (HSP90), a molecular chaperone responsible for the conformational maturation of many proteins involved in diverse oncogenic activities such as cell adhesion/migration/invasion, signal transduction, cell cycle progression, angiogenesis, and survival (Table 14-5).⁸⁶⁻¹¹¹ HSP90 and other chaperones are responsible for ensuring the correct folding and prevention of aggregation of their client proteins.¹¹² Misfolding and aggregation of proteins lead to ubiquitination and proteasomal destruction, resulting in proteins with diminished function and greatly shortened half-lives.¹¹³ Although several classes of compound are capable of inhibiting HSP90 chaperone function,^{97,98,103} the best studied are ansamycin antibiotics of the geldanamycin class.

Many HSP90 inhibitors appear to demonstrate significant preferential activity against malignant versus normal somatic cells. The HSP90 derived from most tumor cells has a binding affinity for 17-allylaminogeldanamycin (17-AAG) approximately 100-fold higher than HSP90 derived from normal cells. This may occur as a result of the overaccumulation of mutated, misfolded, and overexpressed signaling proteins in tumor cells, leading to increased HSP90 chaperone activity and a greater proportion of the molecule in the bound, active, and 17-AAG-sensitive state.¹¹⁴

Tumor cells display considerable variation in sensitivities to HSP90 inhibition. Although the mechanisms underlying this

• **TABLE 14-4** Molecular Targets and Consequences of Proteasome Inhibition

PROCESS	PROTEINS DEGRADED BY PROTEASOME	CELLULAR CONSEQUENCES
Nuclear factor- κ B (NF- κ B) activation	I κ B	Accumulation of I κ B inhibits nuclear translocation and activity of NF- κ B, leading to decreased proliferation, survival, invasion, angiogenesis
Apoptosis	p53, Bax, tBid, Smac, JNK, Noxa	Accumulation of these proteins directly or indirectly promotes apoptosis through various pathways.
Cell cycle regulation	p21, p27, other cyclin-dependent kinase (CDK) inhibitors, cyclins, p53	Accumulation of CDK inhibitors can cause cell-cycle arrest and apoptosis. The dysregulated elevation of multiple cyclins can send contradictory signals to the cell resulting in apoptosis.
Signal transduction	Mitogen-activated protein (MAP) kinase (MKP-1) phosphatase	Accumulation dephosphorylates p44/42 MAP kinase, leading to decreased MAP kinase pathway signaling, proliferation, survival, \pm angiogenesis.
Oncogenic transformation	c-Fos, c-jun, c-myc, N-myc	Unclear how overabundance of these proteins exerts an antitumor effect.
Unfolded protein response	Various damaged/misfolded proteins	Accumulation of damaged proteins leads to endoplasmic reticulum stress and apoptosis.
Chemo/radiation sensitivity	I κ B, P-glycoprotein, topoisomerase II α , DNA damage repair enzyme downregulation	NF- κ B is induced in response to DNA damage; normal proteasome function is required for correct folding of P-glycoprotein; downregulation of topoisomerase II α may reduce sensitivity to doxorubicin.

• **TABLE 14-5** Molecules Targeted by Heat Shock Protein 90 (HSP90) Inhibition

PROCESS	TARGETS	REFERENCES
Invasion and migration	Urokinase-like plasminogen activator,* focal adhesion kinase (FAK) phosphorylation	86-88
Cell cycle progression	Cyclin D3, cyclin-dependent kinase 4 (CDK4)	89
Signal transduction	AKT, KIT, RAF-1, EGFR, <i>HER2</i> , Jun, Lyn, Src, IGF-1R, PDGFR, Met, <i>Bcr-Abl</i> , ILK, androgen receptor, progesterone receptor, glucocorticoid receptor	89-96
Hypoxic response/angiogenesis	HIF-1, VEGF, Glut-1, nitric oxide synthase	90, 97-102
Antiapoptosis	Wild-type and mutant p53, survivin	103-109
Cell senescence	Telomerase	110, 111

EGFR, Epidermal growth factor receptor; HIF-1, hypoxia-inducible factor-1; IGF-1R, insulin-like growth factor receptor 1; ILK, integrin-linked kinase; PDGFR, platelet-derived growth factor receptor; VEGF, vascular endothelial growth factor.

*Urokinase-like plasminogen activator activity appears to be inhibited by geldanamycin class drugs through a mechanism other than heat shock protein 90 (HSP90) inhibition.

differential sensitivity are incompletely characterized, some important characteristics include reliance on certain kinase cascades, expression of apoptotic and cell-cycle regulators, and p-glycoprotein expression.⁹⁰

Many RTKs targeted by the geldanamycins may have an important role in canine and feline tumors. For example, they are capable of inhibiting the function of mutant and wild-type KIT,⁹¹ important in canine mast cell neoplasia¹¹⁵; Met,⁹² expressed in multiple canine tumor types^{116,117}; PDGFR,¹¹⁸ expressed in FVAS and OSA^{119,120}; and IGF-1R,⁹¹ which is expressed and functional in canine OSA and melanoma.¹²¹⁻¹²³ The geldanamycins are likewise able to attenuate the function of the HIF-1 α protein, a key transcription factor

responsible for sensing and responding to hypoxia and activating the angiogenic switch.^{97,99,100} They are additionally able to deplete key antiapoptotic proteins such as mutant p53 and survivin,¹⁰⁴⁻¹⁰⁷ contributing to enhanced in vitro sensitivity to standard cytotoxic therapies such as radiation and chemotherapy when used in combination.^{93,94,101,124-126}

Under certain circumstances, HSP90 inhibitors may have undesirable effects from the standpoint of cancer therapy. For example, 17-AAG has been shown to protect colon carcinoma cells from cisplatin-mediated toxicity,⁹⁵ whereas it has additive or synergistic activity when combined with cisplatin against human neuroblastoma and OSA cells.¹²⁴ Additionally, 17-AAG inhibited primary

tumor formation, although it potentiated bone-specific mammary carcinoma metastasis by enhancing osteoclastogenesis in one murine model.¹²⁷

The impressive preclinical data generated with compounds such as HSP90 inhibitors have led to phase I human clinical trials of multiple agents,¹²⁸⁻¹³² including some early combinatorial studies.¹³⁰⁻¹³² Evidence of biologic effect in the form of upregulation of HSP70 chaperone expression in peripheral blood cells has been observed. There is in vitro evidence of antitumor activity of HSP90 inhibitors in canine OSA and mast cell tumor cell lines^{133,134}; however, no clinical evaluation of these agents has been reported to date.

Poly Adenosine Diphosphate Ribose Polymerase and Poly Adenosine Diphosphate Ribose Glycohydrolase

Poly adenosine diphosphate (ADP)-ribose polymerase (PARP) is a “nick-sensor” that signals the presence of DNA damage and facilitates DNA repair.¹³⁵ The first PARP enzyme was discovered by Chambon et al and is now recognized as a superfamily of 18 members,¹³⁶ although only PARP-1 and PARP-2 are known to act in DNA damage.¹³⁷ The PARP family is also involved in the regulation of several transcription factors such as NFκB in modulating the expression of chemokines, adhesion molecules, inflammatory cytokines, and mediators.¹³⁵ Poly ADP-ribose glycohydrolase (PARG) is the main enzyme in catabolizing poly ADP-ribose to ADP-ribose. To date, only one single PARG gene has been detected in mammals, encoding for three complementary DNAs (cDNA), which generate three isoforms.¹³⁵

PARP has multiple intracellular functions, including signaling DNA damage, and recognizing and binding to DNA strand breaks generated by DNA-damaging agents (cytotoxic drugs and ionizing radiation).¹³⁸ Activation of PARP is one of the earliest DNA damage responses. PARP is also a modulator of DNA base excision repair (BER), which constitutes a major mechanism for genomic stability. There is increasing evidence demonstrating that both PARP and PARG repair DNA.¹³⁶ When PARP binds to DNA strand breaks, it activates an enzyme causing shuttling of PARP and, subsequently, opening of the chromatin. PARG enters the nucleus, it moves to the PARP substrate, and DNA strand breaks are repaired. Due to excessive PARG, poly ADP-ribose decreases and thus chromatin reverts back to its original structure.

PARP inhibition has been suggested as an important approach in sensitizing cancer cells to conventional cancer therapy, leading to early clinical trials with PARP inhibitors.¹³⁸ PARP inhibitors have been shown to be lethal in *BRCA*-deficient cells due to persistence of DNA lesions that would normally be repaired in a *BRCA*-dependent fashion,¹³⁹ suggesting that PARP inhibitors might be an effective monotherapy in these cancers. However, one might expect that their major benefit would be to enhance conventional cytotoxic drug treatment or radiation therapy, and studies have demonstrated that PARP inhibition potentiates the cytotoxicity of anticancer drugs and ionizing radiation through inhibition of DNA repair in cancer cells. PARG inhibition could also be one of the pathways selected for cancer management due to its effects on increased sensitivity to both radiation and chemotherapy.

Although PARG inhibitors have lagged behind PARP inhibitors, a number of molecules have been developed that target these pathways, with varying degrees of specificity. In experimental mouse

models, these have shown promise in breast, colon, lung, and brain tumors and in melanoma, either as monotherapy or combined with conventional drugs or radiation.¹⁴⁰⁻¹⁴⁴ Only PARP inhibitors have been used in early human clinical trials (phase I). It is too early to pass judgment on these early trials, and the next 5 years will demonstrate whether PARP inhibitors will have a place in the drug arsenal for cancer treatment.

Carbonic Anhydrase

Hypoxia in cancer tissues is emerging as a key negative prognostic marker in cancer survival. Carbonic anhydrase functions to interconvert carbon dioxide and bicarbonate to maintain acid-base balance in tissues and may play important roles in hypoxic states. In humans, there are 13 active isoenzymes of carbonic anhydrase (CA), and the transmembrane isoform CA IX has been linked with carcinogenesis.¹⁴⁵ High levels of CA IX expression have been demonstrated in human epithelial tumors such as carcinomas of the cervix, uterus, kidney, lung, esophagus, breast, and colon. Normally, this isoenzyme has restricted expression to the epithelia of the gastrointestinal tract, which is in contrast to studies in cancer where ectopic expression has been demonstrated in hypoxic tumors, participating in tumor cell environment acidosis and contributing to malignant progression and poor treatment outcome.¹⁴⁵ Modulation of extracellular tumor pH via inhibition of CA IX activity has been suggested as a promising approach to novel anticancer therapies. Much attention has recently been paid to the CA IX inhibitors' drug design, and efforts have been made to obtain isozyme IX inhibitors, with putative applications as antitumor drugs or diagnostic agents. A large number of selective CA IX inhibitors have been developed in the past 5 years in the sulfonamide, sulfamide, and sulfamate series.¹⁴⁶ Some of these compounds can constitute interesting leads for further development. Furthermore, new classes of prodrug have emerged in the design of new anticancer compounds, which can be activated under hypoxia. As yet, there is little clinical information regarding the efficacy of any of these compounds, but one may anticipate that these drugs could be beneficial in large hypoxic tumors that have failed conventional treatments or as possible sensitizers to radiation damage.^{145,147}

Management of Chronic Cancer Pain

B. DUNCAN X. LASCELLES

In 1978 Yoxall¹ stated: “It is surprising, for instance, how much a dog’s quality of life, observed by the owner, may be improved by the administration of a simple analgesic if the dog is suffering from a tumor, which although painless on palpation, may be causing considerable chronic pain.” Despite this statement and the fact that obvious pain associated with specific tumors such as osteosarcoma (OSA) has been emphasized for a long time as a diagnostic criterion, there is little literature specifically investigating cancer pain in companion animals.²⁻¹⁴ However, it is very encouraging that since the previous edition of this book, there has been an approximately fourfold increase in published studies (from 4 to 17 using a PubMed search). Encouragingly, we have seen the first studies looking at mechanisms in companion animal cancer pain.^{15,16}

This chapter will deal with the treatment of chronic cancer pain in dogs and cats. Given the relative lack of clinical work in dogs and cats, the information in this chapter cannot be based on peer-reviewed investigations. Rather, it is a combination of the authors’ experience and the experience of others who are heavily involved in the treatment of cancer patients. It is also based on considered extrapolations from human medicine and from veterinary research in other chronically painful conditions, such as osteoarthritis. The control of acute perioperative pain in cancer patients is also very important (see section on relationship between cancer and pain), and readers are referred to appropriate texts for information on perioperative pain control.¹⁷

How Painful Is Cancer in Animals?

Not all tumors are painful, and the amount of pain is likely to vary considerably from one animal to another, even with similar tumor types. The author’s experience and the experience of others would suggest that, using a conservative estimate, 30% of tumors in dogs and cats are associated with significant pain at the time of diagnosis. Tumors most likely to be associated with pain include those at the following sites: oral cavity, bone, urogenital tract, eyes, nose, nerve roots, gastrointestinal tract, and skin (Table 15-1). The 30% estimate is likely conservative since pain is experienced by 20% to 50% of human patients when the lesion is diagnosed, by nearly half undergoing active treatment, and by up to 90% with far advanced or terminal cancer. An overall average of about 70% of human patients with advanced cancer suffer pain.¹⁸

In addition to pain caused by the tumor itself, pain in cancer patients can also be caused by chemotherapy, radiation therapy, or surgery (perioperative pain, postoperative pain, and conditions such as “phantom limb” associated with some amputations) and by concurrent noncancerous disease, most notably osteoarthritis, gingivitis, and dermatologic conditions.

General Approach to Cancer Pain Management

The incidence of pain in animals caused by cancer is very difficult to estimate, as is the effectiveness of analgesic therapy. Recent surveys have found that significant numbers of animals in the perioperative setting were not receiving analgesic drugs,¹⁹⁻²⁶ although an overview of these studies seems to suggest the situation is improving. Analgesics are even less likely to be used for cancer pain. Glucocorticoids do provide some analgesia, and their use may be more widespread,²² but the specific treatment of cancer pain in animals is still likely to be suboptimal.

Suboptimal treatment of cancer pain in animals probably results from a number of factors such as the following:

- Lack of appreciation that many cancers are associated with significant pain.
- Overly focusing on the cancer treatment, rather than patient comfort.
- Inability to assess pain in cancer patients.
- Lack of knowledge of drugs, drug therapy, and other pain-relieving techniques
- Lack of communication with clients and lack of involvement of clients in the assessment and treatment phases.
- Under-use of nursing staff for assessment and reevaluation of pain in cancer patients.

In large part, these factors associated with suboptimal treatment of cancer pain in animals result from a lack of published, scientifically sound information on the subject. Such information also stimulates presentation and discussion of the topic in continuing education forums. In many respects, continuing education in a topic is facilitated by having Food and Drug Administration (FDA)-approved drugs or proven treatments because industry then has a vested interest in improving knowledge of the subject. Unfortunately, there are no analgesics with FDA approval for cancer pain in animals.

Although drug treatment is the mainstay of cancer pain treatment, effective cancer pain treatment often involves a combination of drug therapy, nondrug therapies, and good communication between all parties involved. A basic approach to cancer pain management is summarized in Table 15-2.

• **TABLE 15-1** List of Tumors Most Likely to Be Associated with Pain

TUMOR CATEGORY	NOTES
Tumors involving bone	Primary bone tumors (both of the appendicular and axial skeleton) and metastasis to bone are painful. Just as in humans, sometimes metastasis to bone can be relatively nonpainful; however, this should be considered the exception.
Central nervous system tumors	Extradural tumors that expand and put pressure on neural tissue are often associated with pain. Tumors originating from within the neural tissue are often not associated with pain until later on in the course of the disease. In humans with primary brain tumors or metastases to brain, 60%-90% of them suffer from headaches; it should be presumed that animals also suffer such headaches.
Gastrointestinal	Especially esophagus, stomach, colon, and rectum. Such pain may be very difficult to localize, and it may manifest as vague signs and behavioral changes. Colonic and rectal pain is often manifested as perineal discomfort.
Inflammatory mammary carcinoma	This form of mammary cancer is very painful in humans, and dogs with this form of mammary cancer appear to exhibit obvious signs of pain.
Genitourinary tract tumors	Stretching of the renal capsule appears to produce significant pain. Bladder tumors appear to be predictably associated with pain. Tumors of the distal genitourinary tract are often manifested as perineal pain or pain apparently associated with the lower back.
Prostate	Prostatic tumors appear to be particularly painful, especially if local metastasis to bone is present, and the pain may be manifested as lower back or abdominal pain.
Oral and pharyngeal tumors	Soft tissue tumors that are growing by projecting from the surface (e.g., projecting from the gingival surface) appear to be relatively nonpainful. Tumors involving bone or those growing within the tissues of the maxilla or mandible appear to be significantly more painful. Soft tissue tumors of the pharynx and caudal oral cavity are particularly painful.
Intranasal tumors	Pain probably results both from the destruction of turbinates and from the destruction of bone of the nasal cavity.
Invasive soft tissue sarcomas	The aggressive vaccine-associated sarcomas in cats are particularly painful—the apparent size of the lesion does not correlate with the degree of pain. Other invasive sarcomas in both species are painful. Also, in both cats and dogs, noninvasive soft tissue sarcomas that are pressing on nerves and other sensitive structures will be painful. One form of soft tissue sarcomas, the peripheral nerve sheath tumor (PNST), is sometimes reported to be painful to the touch.
Invasive cutaneous tumors	Especially those that are ulcerative.
Liver and biliary tumors	Especially those that are expansile, stretching the liver capsule. Expansile liver tumors are reported to be painful in humans.
Disseminated intrathoracic and intraabdominal tumors (e.g., mesothelioma, malignant histiocytosis)	The signs associated with such tumors are particularly vague; however, often, intracavitary analgesia (such as intraabdominal local anesthetic) can markedly improve the animal's demeanor, and thus, just as in humans, it appears disseminated neoplasia of these cavities is associated with significant pain.
Lung tumors	Although significant pain is reported in humans with lung cancer, often animals appear to show few signs of pain. However, even in those animals, the provision of an analgesic can often improve demeanor.
Pain following surgical removal of a tumor	Pain well beyond the postoperative period occurs in animals that have undergone surgery and is probably neuropathic in nature. Phantom pain (such as phantom limb pain), a form of neuropathic pain, does appear to exist in animals. If tumor recurrence occurs, significant pain is usually associated with this.

The Importance of Alleviating Pain in the Cancer Patient

The alleviation of pain is important not only from a physiologic and biologic standpoint, but also from an ethical point of view.²⁷ To help in an evaluation of welfare, “five freedoms,” initially proposed by the Brambell Committee in reference to farmed animals,²⁸ have been suggested. They may be applied equally in the context of companion animals²⁷ and are as follows:

- Freedom from hunger and thirst
- Freedom from physical and thermal discomfort
- Freedom from pain, injury, and disease
- Freedom to express normal behavior
- Freedom from fear and distress

For each freedom, there should be a consideration of the severity, incidence, and duration. As an example, consider a dog undergoing a maxillectomy. With such a surgery, it is possible that thirst and hunger may result from interference with the dog's ability to eat and drink. However, the dog could be hand-fed and gradually

• TABLE 15-2 A Basic Approach to Cancer Pain Management

A	Assess the patient	Ask for the owner's perceptions of the pain present or of any compromise of the animal's quality of life. Assess the patient thoroughly, using palpation and observation.
B	Believe the owner	The owner sees the pet every day in its own environment and knows when alterations in behavior occur. They can rarely suggest diagnoses, but they do know when something is wrong and when their pet is in pain, just as a mother knows when something is wrong with her child.
C	Choose appropriate therapy	Anything other than mild pain should be treated with more than one class of analgesic, or an analgesic drug combined with nondrug adjunctive therapy. Be aware of potential drug interactions.
D	Deliver therapy	Deliver the therapy in a logical coordinated manner and explain carefully to the owner about any possible side effects.
E	Empower the client	Empower the clients to participate actively in their pet's treatment; ask for feedback and updates on how the therapy is working.

taught to eat and drink despite the facial alteration. If the dog was never able to eat or drink again on its own, the owners could hand-feed him for the rest of his life or the dog could be fed via a feeding tube. Although this may represent a compromise to his freedom to express normal eating behavior, he would not be hungry or thirsty. Such a surgery may result in a cure for the disease and eliminate pain. However, the surgery may also result in pain and distress. Fear and distress would result because of the unfamiliar surroundings and people during the hospital stay. With appropriate nursing care, the dog should not suffer any physical or thermal discomfort. It can be seen from this example how many factors are interrelated, and all need consideration in the cancer patient, including pain and consideration of the length and severity of pain.

Pain relief may affect survival in cancer patients. Immunosuppression has been shown to depend on the severity of surgery in clinical²⁹⁻³¹ and experimental animal studies.^{32,33} Additionally, the severity of surgery has been shown to influence tumor metastasis.³⁴⁻³⁷ In 2002, a human clinical study suggested that laparoscopic colectomy was associated with increased survival,³⁸ and although subsequent studies found no difference in long-term survival,³⁹ there is interest in the immunologic and oncologic implications of less-invasive surgery.⁴⁰ In 2001, Page and coworkers found that the provision of analgesics significantly reduced the tumor-promoting effects of undergoing and recovering from surgery in a rodent model.⁴¹ The reduction of the tumor-promoting effects of surgery by analgesics may result from maintenance of natural killer (NK) cell function, but it is likely that other unrecognized factors also play a role.^{41,42} More recently, it was found that spinal analgesia attenuated the laparotomy-induced suppression of tumoricidal function of liver mononuclear cells and decreased metastasis compared to rodents undergoing laparotomy without spinal analgesia.⁴³ This was considered to be due to preservation of T helper 1/T helper 2 (Th1/Th2) cytokine balance. Thus the provision of adequate perioperative pain management in oncologic surgery may be protective against metastatic sequelae in clinical patients. It is quite possible that chronic pain experienced by animals with cancer may also affect metastasis.

Assessment of Cancer Pain

Assessment of pain in animals, while often difficult, is extremely important. It is likely that the tolerance of pain by an individual animal varies greatly and is further complicated by the innate ability of dogs and cats to mask significant disease and pain. Physiologic variables such as heart rate, respiratory rate, temperature, and pupil size are not reliable measures of acute perioperative pain in dogs⁴⁴ and are unlikely to be useful in chronic pain states. The mainstay

of pain assessment in cats and dogs suffering from cancer is likely to be changes in behavior. Table 15-3 outlines behaviors that are probably indicative in certain situations of pain. In general, if a tumor is considered to be painful in humans, it is appropriate to give an animal with a similar condition the benefit of the doubt and treat it for pain.

One of the most useful ways of determining if a tumor is painful is to palpate the area and evaluate the animal's response. This may not correlate precisely with the amount of pain the animal spontaneously experiences, but if a tumor is painful on manipulation or palpation, it is highly likely there is spontaneous pain associated with it. As veterinarians, we struggle to measure spontaneous pain. It is perhaps reassuring that there is tremendous debate in the research community on how to measure spontaneous pain in rodent models.

Veterinarians should involve technicians and other staff members in the assessment process because they are usually the ones spending the most time with the patients in the hospital and may have more time to converse in a relaxed and informal way with owners.

The most important people in the assessment process are the owners. The veterinarian must work closely with the owner to capture this information. Often, owners need to be educated as to what signs to look for and that certain behaviors may be indicative of pain. Once very specific changes in behavior can be identified and recorded, these behaviors can be used to monitor the effectiveness of analgesic therapy. Furthermore, these specific activities can be used to create goals and therapy tailored to try to meet these goals. The importance of patient-reported outcomes (PROs) in human medicine is widely recognized.⁴⁵ These PROs may refer to a large variety of different health data reported by patients, such as symptoms, functional status, quality of life (QOL), and health-related quality of life (HRQOL).⁴⁵ In humans, QOL is a complex, abstract, multidimensional concept defining an individual's satisfaction with life in domains he or she considers important. The term *HRQOL* reflects an attempt to restrict this complex concept to those aspects of life specifically related to the individual's health and potentially modifiable by healthcare.⁴⁶ Both QOL and HRQOL have been used in veterinary medicine. Questionnaires have been developed to assess HRQOL in dogs^{47,48} and cats⁴⁹ with cancer. Although pain certainly appears to be assessed in these HRQOL tools, it is not known how specific or sensitive these tools are to changing pain status.

The author's approach to the evaluation of pain at each visit is to evaluate each of the following three aspects:

1. Palpation-induced pain
2. Activity parameters
3. Behavioral parameters

• **TABLE 15-3** Outline of Behaviors that May Be Seen with Cancer-Associated or Cancer Therapy–Associated Pain in Cats and Dogs

BEHAVIOR	NOTES
Activity	Less activity than normal; may be very specific activities that are changed; decreased jumping; less playing; less venturing outside; less willing to go on walks (dogs); stiff gait, altered gait, or lameness can be associated with generalized pain but is more often associated with limb or joint pain; slow to rise and get moving after rest (osteoarthritis is often concurrently present).
Appetite	Often decreased with chronic pain.
Attitude	Any change in behavior can be associated with cancer pain—aggressiveness, dullness, shyness, “clinginess,” increased dependence
Facial expression	Head hung low, squinted eyes in cats. Sad expression in dogs, head carried low.
Grooming	Failure to groom can be due to either a painful oral lesion or generalized pain.
Response to palpation	This is one of the best ways to diagnose and monitor pain. Pain can be elicited by palpation of the affected area, or manipulation of the affected area, which exacerbates the pain present. This is manifested as an aversion response from the animal (i.e., the animal attempts to escape the procedure, or yowls, cries, hisses, or bites). Pain is inferred when this occurs.
Respiration	May be elevated with severe cancer pain.
Self-trauma	Licking at an area (e.g., joint with osteoarthritis, bone with primary bone cancer, the abdomen with intraabdominal cancer) can indicate pain; scratching can indicate pain (e.g., scratching at cutaneous tumors, scratching and biting at the flank with prostatic or colonic neoplasia).
Urinary and bowel elimination	Failure to use litter box (cats); urinating and defecating inside (dogs).
Vocalization	Vocalization is rare in response to chronic pain in dogs and cats; however, owners of dogs will often report frequent odd noises (whining, grunting) associated with cancer pain. Occasionally, cats will hiss, utter spontaneous plaintive meows, or purr in association with cancer pain

Follow-up is important, and the assessment of activity and behavioral parameters can be evaluated over the telephone.

Principles of Alleviation of Cancer Pain

Pharmacologic Therapy

Drugs are the mainstay of cancer pain management, although nondrug adjunctive therapies are becoming recognized as increasingly important. The World Health Organization (WHO) has outlined a general approach to the management of cancer pain based on the use of the following groups of analgesics:

- Nonopioid analgesics (e.g., nonsteroidal antiinflammatory drugs [NSAIDs], acetaminophen)
- Weak opioid drugs (e.g., codeine)
- Strong opioid drugs (e.g., morphine)
- Adjuvant drugs (e.g., corticosteroids, tricyclic antidepressants, anticonvulsants, *N*-methyl *D*-aspartate [NMDA] antagonists).

The general approach of the WHO ladder is a three-step hierarchy. Initially, pain is treated with a nonopioid (usually an NSAID), ± an adjuvant drug. The next two stages add on a “weak” opioid, then a “strong” opioid. There are several problems with this approach. First, it is naïve because our current understanding of pain indicates that drugs are not “strong” and “weak” but rather “appropriate” and “less appropriate.” Furthermore, there is little information from human medicine and virtually none from veterinary medicine on which drugs are most effective for particular types of cancer pain. It may well be that “third-tier” drugs might be most effective for a particular condition and therefore used upfront.

The second problem is that the approach is not well suited to patients that present initially with significant-to-severe pain. Many

veterinary cancer patients present at an advanced stage of disease and thus are already in moderate-to-severe pain. Once pain has been present for a period of time, changes take place in the central nervous system (CNS) that alter the way pain signals are processed. A better understanding of this is helped by understanding the classification of cancer pain.

Classification of Cancer Pain

Pain is a multifactorial experience with sensory (the sensation), affective/emotional (how it makes the subject feel), and functional (can the subject still perform particular functions) components. It can result from obvious causes (e.g., ulcerated skin tumor) and last an expected time. However, in many cases (e.g., postamputation pain) the pain persists after the original painful cancer has been removed or the surgical wound appears to be healed. In the past, pain has often been categorized as acute or chronic based solely on duration—the latter arbitrarily being pain that lasts more than 3 to 6 months. However, it is now accepted that this may not be a helpful classification. It has been suggested that the terms *adaptive* and *maladaptive* be adopted; adaptive infers a normal response to tissue damage and involves an inflammatory component (e.g., a surgical incision) and is reversible over an expected, relatively short time. Maladaptive pain results from changes in the spinal cord and brain that result in abnormal sensory processing and is usually persistent. Maladaptive pain can result from poorly treated adaptive pain, and maladaptive pain can occur quickly in some circumstances. A key feature of maladaptive pain is central sensitization—changes in the CNS (anywhere from the dorsal root ganglion rostrally) that are likely initiated by cellular wind-up and result in amplification and facilitation of nociceptive signal generation and transmission. *Until proved otherwise, cancer pain should be considered maladaptive, with both peripheral and central changes in the pain processing*

system contributing to the pain, in addition to noxious input from the cancer or pathologic area.

Ideally, pain would be classified by the underlying mechanism, for example, inflammatory or neuropathic. However, many diseases are associated with overlapping “forms” of pain. Taken one step further, pain occurring in different diseases or conditions would be further classified by the underlying mechanisms in that particular disease and even patient. This could be referred to as the *neurobiologic signature* of pain in a particular disease or patient. Knowing this would better guide the practitioner in the choice of treatment. For example, a diagnosis of “cancer” pain is not very helpful since the cause could be mechanical compression of a nerve, inflammation from tissue necrosis, mechanical distension of an organ, neuropathic pain, or a combination of these. However, a diagnosis of “transitional cell carcinoma pain of the bladder,” with the associated knowledge of the upregulation of peripheral sodium channel (e.g., NaV1.7) and acid-sensing ion channel (ASIC) receptors and nerve growth factor and central glial cell activity and cyclooxygenase-2 (COX-2) enzyme, is far more informative in terms of guiding clinical treatment. Without this information, treatment is empiric and it may be better termed “hit or miss.”

Early intervention is recommended to limit cellular wind-up and prevent central sensitization. In patients experiencing long-lasting, persistent pain, as is the case with many types of cancer, changes within the peripheral and CNS may occur. These changes (peripheral or central sensitization) may contribute to the further development of pain, separate from the initial inciting cause and should be considered in patients with pain that is unresponsive to first-line or conventional analgesics. Pain syndromes commonly associated with sensitization include prolonged pain or pain experienced outside of the immediate area that is affected, hyperalgesia (increased sensitivity to noxious stimuli), and allodynia (pain after nonnoxious stimuli). The author has found altered sensory processing states to be associated with long-standing osteoarthritis-associated pain, and it is likely many cancers are associated with the same changes.

At the current time, with limited information as to what the “ideal” therapies are for individual cancer pains, the most important aspect to remember in the treatment of cancer pain is that for the majority of situations, *multimodal therapy* (i.e., concurrent use of more than one class of drug) is required for successful alleviation of the pain.

A general outline to approaching cancer pain is given in Figure 15-1. This figure can be used in combination with Tables 15-4 and 15-5. There are many different scenarios that the clinician may face when dealing with cancer pain, and this figure and these tables are only guides. The term *wind-down therapy* refers to admitting refractory pain patients into the hospital and treating them with multiple intravenous (IV) analgesic medications in the hope that the pain can be controlled, making it easier to subsequently manage the pain at home.

Drugs and Strategies Used for Management of Pain in Cancer Patients

The drugs that can be used for chronic cancer pain management are outlined in Tables 15-4 and 15-5. The following notes are not a comprehensive appraisal of each class of drug but are suggestions for their use for cancer pain.

Nonsteroidal Antiinflammatory Drugs

NSAIDs have been the mainstay of therapy for chronic pain, especially in osteoarthritis, and they are an excellent first line of treatment in cancer pain. There are several excellent reviews on NSAID use in small animals, and the reader is referred to these.⁵⁰⁻⁵⁴ The choice of NSAIDs available can be bewildering, but a few key points are as follows:

- On a population basis, all NSAIDs are probably equally efficacious in relieving pain, but for a given patient, one drug is often more effective than another.
- Gastrointestinal side effects associated with NSAID use appear to be more common with drugs that preferentially block COX-1 over COX-2.
- There is no difference in renal toxicity between COX-1 selective drugs and COX-2 selective drugs.
- Liver toxicity can occur with any NSAID.
- There are no completely safe NSAIDs, but the approved NSAIDs are significantly safer than the older nonapproved NSAIDs.
- Longer term or continuous NSAID use appears to be more effective than short-term or reactive use,⁵² but in relatively stable disease states, gradual dose reduction may be possible while maintaining efficacy.⁵⁵

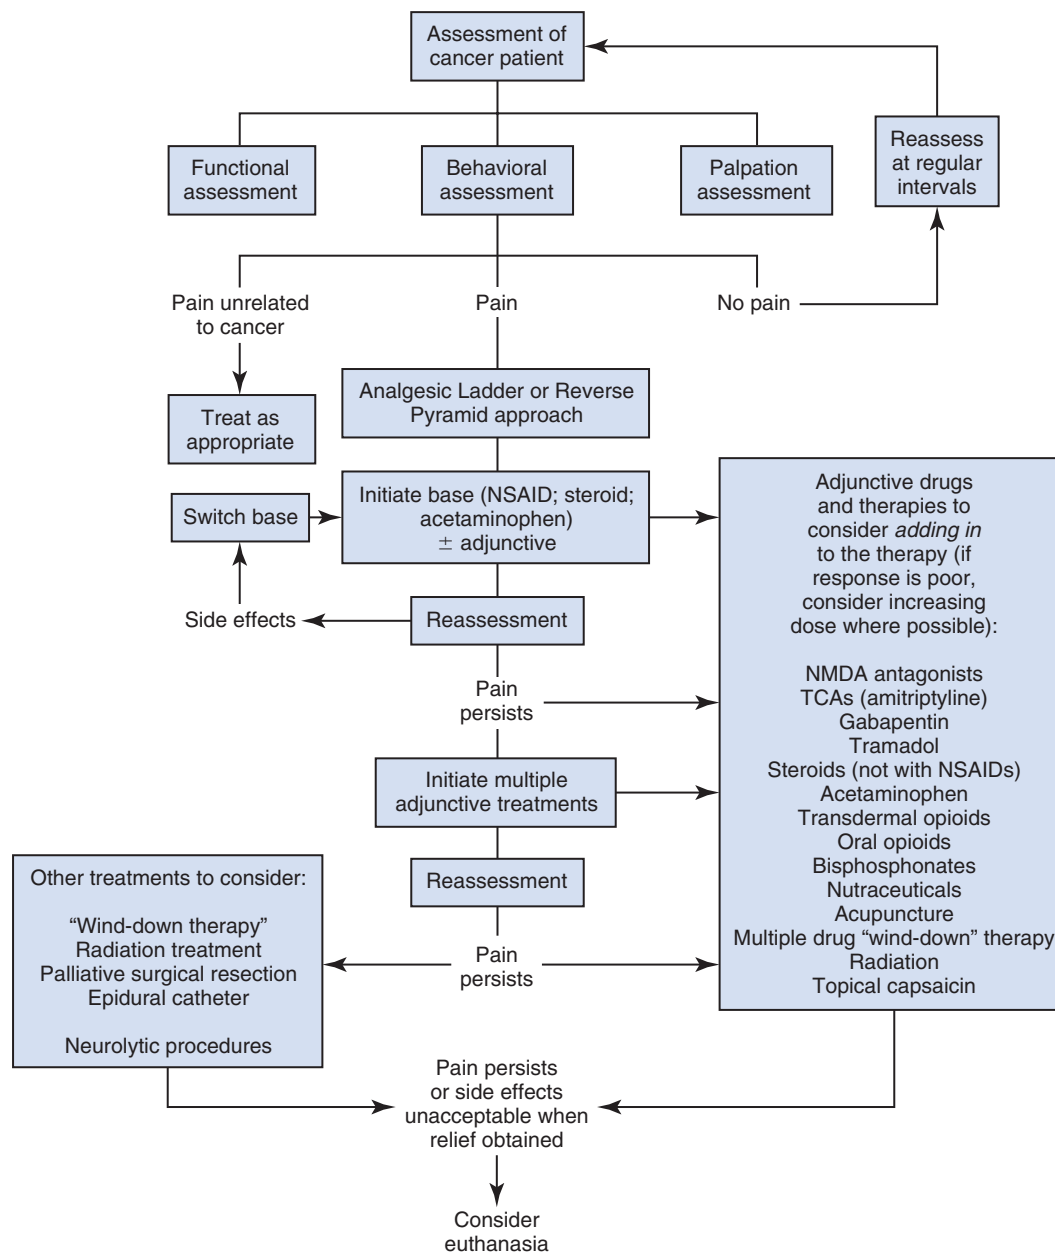

There are no licensed NSAIDs for long-term administration in cats other than meloxicam, which is approved in the European Union for long-term treatment of musculoskeletal pain. However, a number of these compounds can probably be used safely (see Table 15-5). The key to safe chronic NSAID administration in cats is the use of the smallest effective dose and avoiding use or using decreased doses in cats with renal disease. Choosing drugs with short half-lives is also considered important by the author.

The patient on NSAIDs should be monitored for toxicity by informing the owner of potential toxicity and what signs to watch for (lethargy, depression, vomiting, melena, increased water ingestion), as well as through the regular evaluation of blood work (and urinalysis) to evaluate renal and liver function. A baseline should be obtained when therapy is initiated and parameters monitored on a regular basis thereafter. The author repeats evaluations after 2 to 4 weeks and then at 1- to 4-month intervals as dictated by the individual patient and client.

If pain relief with NSAIDs is inadequate, oral opioid medications such as morphine or tramadol can be administered (see later). Acetaminophen or acetaminophen/codeine combinations can often be used in conjunction with NSAIDs. Transdermal fentanyl can also be used. Fentanyl, morphine, or tramadol can be used for dogs that cannot be given NSAIDs. Other agents that are used to treat chronic pain include: amantadine, an NMDA antagonist; anticonvulsants such as gabapentin; and tricyclic antidepressants such as amitriptyline. These can all be combined with NSAIDs, although we do not know the full extent of side effects. Readers are cautioned that they should not assume that combinations of different adjunctive drugs are without side effects—quite the contrary, there is much to be learned about potential adverse interactions, especially in cancer patients that may be on other therapies.

Acetaminophen

Acetaminophen is a nonacidic NSAID; many authorities do not consider it an NSAID as it probably acts by somewhat different mechanisms.⁵⁶ With any chronic pain, there are always CNS changes, so for what seems a “peripheral” problem such as many cancers, centrally acting analgesics can be very effective. *Although highly toxic in the cat, even in small quantities, it can be effectively used in dogs for pain control in the acute setting.*^{57,58} No studies of

• **FIGURE 15-1** Outline to approaching cancer pain.

toxicity in dogs have been done, but if toxicity is seen, it will probably affect the liver; thus the drug, in common with all NSAIDs and opioids, should be used cautiously in dogs with liver dysfunction. It can be used on its own or in a preparation combined with codeine and is initially dosed at about 10 to 15 mg/kg twice a day (bid). The author often uses it as the first-line analgesic therapy in dogs with renal compromise in which NSAIDs cannot be used or in dogs that appear to be otherwise intolerant to NSAIDs (e.g., vomiting or gastrointestinal ulceration).

Opioids

Opioids can be an effective part of the management of cancer pain, particularly when used as part of a multimodal approach (i.e., including NSAIDs or adjunctive analgesics). Side effects of opioids include diarrhea, vomiting, sedation, and constipation with

long-term use. It is often constipation and occasionally the sedation that owners object to most as a side effect in their pet. Oral morphine, transdermal fentanyl, oral butorphanol, sublingual buprenorphine (cats only), and oral codeine are used most often for the alleviation of chronic cancer pain. None of these drugs has been fully evaluated for clinical toxicity when administered long term nor for efficacy against chronic cancer pain. Dosing must be done on an individual basis, and adjustment of the dose to produce effective analgesia without undesirable side effects requires interaction and communication with clients. However, despite these suggestions, recent evidence has indicated that oral opioids may not reach effective plasma concentrations in dogs when dosed at the currently recommended levels.⁵⁹⁻⁶²

There is currently no information on the long-term use of oral opioids for chronic pain in the cat. There appears to be individual

• **TABLE 15-4** Suggested Doses of Analgesics that May Be Used for the Alleviation of Chronic Cancer Pain in the Dog

DRUG	DOSE FOR DOGS	COMMENTS
Paracetamol (acetaminophen)	10-15 mg/kg PO q12 hrs	Associated with fewer GI side effects than regular NSAIDs and has not been noted to be associated with renal toxicity. Toxicity has, however, not been evaluated clinically in dogs. Can be combined with regular NSAIDs in severe cancer pain, but this combination has not been evaluated for toxicity.
Paracetamol (acetaminophen) + codeine (30 or 60 mg)	10-15 mg/kg of acetaminophen	Sedation can be seen as a side effect with doses at or above 2 mg/kg codeine.
Amantadine	4.0-5.0 mg/kg PO q24 hrs	Loose stools and excess GI gas can be seen at higher doses for a few days. Should not be combined with drugs such as selegiline or sertraline until more is known about drug interactions. Should not be used in seizure patients or patients in heart failure.
Amitriptyline	0.5-2.0 mg/kg PO q24 hrs	Has not been evaluated for clinical toxicity in the dog. Should be used cautiously in combination with tramadol.
Butorphanol	0.2-0.5 mg/kg PO up to q8 hrs	May produce sedation at higher doses. Not a very predictable analgesic, especially in the dog, and best when used in combination with other analgesics (e.g., NSAIDs).
Codeine	0.5-2.0 mg/kg PO q8-12 hrs	Sedation can be seen at higher doses. Like all oral opioids, it is subject to significant first-pass effect at the liver, likely limiting its analgesic effect.
Fentanyl, transdermal	2-5 mcg/kg/hr	Can be very useful in the short-term control of cancer pain. For long-term therapy, usefulness is limited due to need to change the patch every 4 to 7 days.
Gabapentin	3-10 mg/kg PO q6-12 hrs	Has not been evaluated in dogs as an analgesic. The most likely side effect is sedation.
Glucosamine and chondroitin sulfate	13-15 mg/kg chondroitin sulfate PO q24 hrs	Can be used in a variety of cancer pains due to its mild antiinflammatory and analgesic effects.
Morphine, liquid	0.2-0.5 mg/kg PO q 6-8 hrs	Can be useful for dosing smaller dogs where the morphine tablets are not suitable. Sedation and particularly constipation are side effects that are seen as the dose is increased. Like all oral opioids, it is subject to significant first-pass effect at the liver, likely limiting its analgesic effect.
Morphine, sustained release	0.5-3.0 mg/kg PO q 8-12 hrs	Doses higher than 0.5-1.0 mg/kg are often associated with unacceptable constipation according to owners, so suggest using 0.5 mg/kg several times a day. Like all oral opioids, it is subject to significant first-pass effect at the liver, likely limiting its analgesic effect.
Pamidronate	1-1.5 mg/kg slowly IV diluted in 4 mL/kg normal saline, administered over 2 hrs; repeat every 4-6 weeks	Inhibits osteoclast activity and thus only provides analgesia in cases suffering from a primary or metastatic bone tumor that is causing osteolysis. Effect may be delayed days-weeks.
Prednisolone	0.25-1 mg/kg PO q12-24 hrs; taper to q48 hrs if possible after 14 days	Do NOT use concurrently with NSAIDs. Can be particularly useful in providing analgesia when there is a significant inflammatory component associated with the tumor and for CNS or nerve tumors.
Tramadol	4-5 mg/kg PO q6-12 hrs	This drug has not been evaluated for efficacy or toxicity in dogs.

PO, By mouth; GI, gastrointestinal; NSAIDs, nonsteroidal antiinflammatories; IV, intravenous.

None of these drugs have been evaluated for efficacy in the treatment of cancer pain.

None of these drugs are approved or licensed for use in chronic cancer pain. The NSAIDs have not been included in this table. NSAIDs should be used as a first line of pain relief if it is clinically appropriate to use them and should be used at their approved dose.

The doses given come from the author's experience and the experience of others working in the area of clinical cancer pain control.

• **TABLE 15-5** Suggested Doses of Analgesics that May Be Used for the Alleviation of Chronic Cancer Pain in the Cat

DRUG	CAT DOSE (MG/KG)	NOTES
Acetaminophen (Paracetamol)	Contraindicated	Small doses rapidly cause death in cats.
Amantadine	3.0-5.0 mg/kg PO q24 hrs	This drug has not been evaluated for toxicity but is well tolerated in dogs and humans, with occasional side effects of agitation and GI irritation. May be a useful addition to NSAIDs in the treatment of chronic cancer pain conditions. Amantadine powder can be purchased and formulated into appropriately sized capsules. The kinetics have recently been evaluated in cats.
Amitriptyline	0.5-2.0 mg/kg PO q24 hrs	This drug appears to be well tolerated for up to 12 months of daily administration. May be a useful addition to NSAIDs for treatment of chronic pain conditions.
Aspirin	10 mg/kg PO q48 hrs	Can cause significant GI ulceration.
Buprenorphine	0.01-0.02 mg/kg SL q8-12 hrs	SL route is not resented by cats and may be a good way to provide postoperative analgesia at home. Feedback from owners indicates that after 2-3 days dosing at this dose, anorexia develops. Smaller doses (5-10 µg/kg) may be more appropriate for "long-term" administration, especially in combination with other drugs.
Butorphanol	0.2-1.0 mg/kg PO q6 hrs	One study suggests using oral form after surgery may be beneficial. Generally considered to be a poor analgesic in cats except for visceral pain; however, the author has found it to be useful as part of a multimodal approach to cancer pain therapy.
Carprofen	Not enough data to enable recommendations for long-term administration.	—
Etodolac	Not recommended.	—
Firocoxib	—	Has not been reported in clinical cases, but it has a half-life of 8-12 hours in the cat, and at 3 mg/kg provided antipyretic effects in a pyrexia model.
Flunixin meglumine	1 mg/kg PO daily for 7 days	Daily dosing for 7 days results in increased rate of metabolism of the drug but a rise in liver enzymes, suggesting liver toxicity <i>may</i> be a problem with prolonged dosing.
Gabapentin	10 mg/kg q12 hrs	Appears to be particularly effective in chronic pain in cats where an increase in sensitivity has occurred, or where the pain appears to be excessive in comparison to the lesion present.
Glucosamine/chondroitin sulphate combinations	Approximately 15 mg/kg chondroitin sulphate PO q12-24 hrs	May be associated with mild analgesic effects.
Glucosamine/chondroitin sulphate combination with avocado/soya extracts	Labelled dose	May be associated with mild analgesic effects.
Ketoprofen	1 mg/kg PO q24 hrs	Probably well tolerated as pulse therapy for chronic pain, with a few days "rest" between treatments of approximately 5 days. Has also been used by some at 1 mg/kg every 3 days long term. Another approach has been to use 0.5 mg/kg daily for 5 days (weekdays) followed by no drug over the weekend and repeated.

• **TABLE 15-5** Suggested Doses of Analgesics that May Be Used for the Alleviation of Chronic Cancer Pain in the Cat (continued)

DRUG	CAT DOSE (MG/KG)	NOTES
Meloxicam	0.01 mg/kg PO on day 1, followed by 0.05 mg/kg PO daily for 4 days, then 0.05 mg/kg every other day thereafter. (Approval in the European Union at 0.05mg/kg daily indefinitely for musculoskeletal pain.)	Well received by cats due to its formulation as a honey syrup. Also, the drop formulation makes it very easy to gradually and accurately decrease the dose. A decreasing regimen has not been evaluated for efficacy in cats but has been found to be successful in dogs. Meloxicam should be dosed accurately using syringes.
Morphine (oral liquid)	0.2-0.5 mg/kg PO tid-qid	Best compounded into a palatable, flavored syrup; however, cats usually resent this medication. Morphine may not be as effective in cats as it is in dogs.
Morphine (oral sustained release)	Tablets too large for dosing cats.	—
Piroxicam	1 mg/cat PO daily for a maximum of 7 days. If longer term medication is considered, suggest every other day dosing.	Daily dosing for 7 days results in a slight increase in the half-life.
Prednisolone	0.5-1.0 mg/kg PO q24 hrs	Can be very effective. NOT to be combined with concurrent NSAID administration.
Polysulfated glycosaminoglycans (PSGAGs; Adequan)	5 mg/kg SQ twice weekly for 4 weeks; then once weekly for 4 weeks; then once monthly (other suggested regimens call for once weekly injections for 4 weeks, then once monthly).	There is no evidence-based medicine that it provides any analgesic effect, but anecdotal information suggests improvement can be seen after a few injections.
Robenacoxib	1-2 mg/kg q24 hrs	Has varying approvals in different parts of the world (approved for up to 11 days administration in Switzerland). First NSAID that is a COX-2 inhibitor, has a short half-life, and demonstrates tissue selectivity.
Tepoxalin	5-10 mg/kg q24 hrs	The author has used this successfully long-term in cats, likely due to its short half-life (5 hours) and true dual inhibition characteristics.
Tolfenamic acid	4 mg/kg PO q24 hrs for 3 days maximum	Has not been evaluated for chronic pain, but recent objective measurements demonstrate analgesia in the cat when administered perioperatively.
Tramadol	1-2 mg/kg once to twice daily	Main problem is dosing cats—the tablets are very bitter and aversive to cats.
Transdermal fentanyl patch	2-5 µg/kg/hrs	The patches may provide 5-7 days of analgesia in some cases and should be left on for longer than 3 days. Following removal, the decay in plasma levels following patch removal is slow.
Vedaprofen	0.5 mg/kg q 24 hrs for 3 days	Has not been evaluated for chronic pain but was evaluated for controlling pyrexia in upper respiratory infection, and for controlling postoperative pain following ovariectomy.

PO, By mouth; GI, gastrointestinal; NSAIDs, nonsteroidal antiinflammatories; SL, sublingual; SQ, subcutaneous; tid, three times a day; qid, four times a day; COX-2, cyclooxygenase-2.

None of the drugs have been evaluated for efficacy in the treatment of cancer pain.

None of these drugs are approved or licensed for use in chronic cancer pain. Some drugs are approved for inflammatory or painful conditions in the cat in certain countries, and doses for the control of cancer pain are extrapolated from these. The doses given come from the author's experience and the experience of others working in the area of clinical cancer pain control.

variation in the level of analgesia obtained with certain opioids, especially morphine and butorphanol, in the acute setting.^{63,64} Buprenorphine appears to produce predictable analgesia when given sublingually⁶⁵ and is well accepted by most cats. The small volume required (max 0.066 mL/kg [20 µg/kg]) makes administration simple. Based on clinical feedback from owners, this is an acceptable technique for home use. Inappetence can occur after several days of treatment and sometimes lower doses (5 to 10 µg/kg) can overcome this problem. When administered concurrently with other drugs, less frequent dosing is often required.⁶⁵

N-Methyl D-Aspartate Antagonists

The NMDA receptor appears to be central to the induction and maintenance of central sensitization,⁶⁶⁻⁶⁸ and the use of NMDA receptor antagonists would appear to offer benefit where central sensitization has become established (i.e., especially chronic pain). Ketamine, tiletamine, dextromethorphan, and amantadine possess NMDA antagonist properties, among other actions.

Ketamine is not obviously useful for the management of chronic pain due to the formulation available and the tendency for dysphoric side effects even at low doses. However, oral ketamine has not been evaluated in dogs or cats for long-term administration. Intraoperative microdose IV ketamine appears to provide beneficial effects for a variety of oncology surgical procedures, including limb amputations,⁶⁹ and this may decrease the incidence of chronic pain later. Other reports suggest a benefit of using ketamine perioperatively in low doses.⁷⁰ When used in this manner, ketamine should be administered as a bolus (0.5 mg/kg IV) followed by an infusion (10 µg/kg/min) prior to and during surgical stimulation. A lower infusion rate (2 µg/kg/min) may be beneficial for the first 24 hours postoperatively and an even lower rate (1 µg/kg/min) for the next 24 hours. In the absence of an infusion pump, ketamine can be mixed in a bag of crystalloid solutions for administration during anesthesia. Using anesthesia fluid administration rates of 10 mL/kg/hr, 60 mg (0.6 mL) of ketamine should be added to a 1-liter bag of crystalloid fluids to deliver ketamine at 10 µg/kg/min.

The active metabolite of dextromethorphan may not be produced in dogs, probably negating its use in the species for chronic pain.⁶¹

Amantadine has been used for the treatment of neuropathic pain in humans,⁷¹ and one report suggests a benefit of adding amantadine to an NSAID in dogs that do not get complete relief from the NSAID alone.⁷² Suggested dosages are given in Tables 15-4 and 15-5. The toxic side effects have been evaluated in the dog (but not the cat), and the dosages suggested are considered safe.⁷³ Amantadine should be avoided in patients with congestive heart failure, history of seizure, or those on selegiline, sertraline, or tricyclic antidepressants.

Combination Analgesics

Tramadol is a synthetic derivative of codeine and is classified as an opioidergic/monoaminergic drug.^{74,75} It has been found to be effective in the alleviation of pain associated with osteoarthritis in humans. Tramadol's analgesic efficacy is a result of complex interactions between opiate, adrenergic, and serotonin receptor systems. Hepatic demethylation of tramadol produces the active metabolite, O-desmethyltramadol (M1). The different metabolites interact with different receptors; thus efficacy in different species is likely to depend on the metabolic characteristics in the particular species. Initial work in dogs suggested that tramadol was absorbed sufficiently, producing levels that would theoretically provide

analgesia.⁷⁶ However, recently there has been some discussion about the actual amounts of the M1 metabolite that are formed in dogs, and the pharmacokinetics of tramadol does not favor an analgesic effect.⁷⁷⁻⁸¹ There is no published evidence of efficacy for canine pain.

Little is known about the side effects of tramadol in dogs, and almost nothing is known about the side effects seen when tramadol is combined with other drugs in human or canine medicine. In human medicine, a recent study found that for patients hospitalized for peptic ulcer treatment, tramadol use prior to admission was associated with just as high a risk of mortality as was NSAID use prior to admission. Additionally, mortality was 2.02- and 1.41-fold higher in these groups of patients, respectively, than in patients who used neither tramadol nor NSAIDs.⁸² A recent study evaluating the analgesic effects of various doses of rofecoxib and tramadol alone and in combination found that the most analgesic combination of tramadol and rofecoxib produced gastric injury in rats that was more severe than with rofecoxib or tramadol alone.⁸³ Tramadol is metabolized differently in the cat^{84,85} and appears to have clinical efficacy when administered intravenously perioperatively⁸⁶ and has shown antinociceptive activity when administered orally in an experimental setting.⁸⁷

The dosages given in Tables 15-4 and 15-5 are for the regular (not prolonged release) form of the drug. It has not been thoroughly evaluated for toxicity in the dog or cat.

Anticonvulsant Drugs

Many anticonvulsants such as carbamazepine, phenytoin, baclofen, and more recently gabapentin have been used to treat chronic pain, including neuropathic pain in humans, as well as chemotherapy-induced peripheral neuropathies. Gabapentin and the more recently introduced pregabalin appear to be among the most effective drugs available for neuropathic pain in humans. While the exact mechanism of action of these drugs is unclear, one potential mode by which they exert their analgesic effect is by binding to the $\alpha_2\delta$ protein subunit of voltage-gated calcium channels, thereby reducing excitatory neurotransmitter release through channel modulation or channel trafficking. Although there is considerable information on gabapentin disposition in dogs^{88,89} and some information on its use as an anticonvulsant in dogs,⁹⁰ there is as yet no information on its use for the control of chronic or long-term pain. However, a recent small study suggested no beneficial effect of perioperative gabapentin.⁹¹ Information on the kinetics of gabapentin in cats has become available,⁹² and one study found a lack of thermal antinociception.⁹³ There are no scientific publications demonstrating its efficacy for long-term pain in this species. While the indications for gabapentin (and pregabalin) are presently unclear in veterinary patients, they do appear to be useful for cancer pain in some patients and are probably particularly effective in cancers that have some neurogenic or nerve destruction component. Suggested dosages are in Tables 15-4 and 15-5.

Tricyclic Antidepressants

Tricyclic antidepressants have been used for many years for the treatment of chronic pain syndromes in people and are becoming widely used for the modulation of behavioral disorders in animals. Within the CNS, there are descending inhibitory serotonergic and noradrenergic pathways that reduce pain transmission in the spinal cord. Tricyclic antidepressants such as amitriptyline, clomipramine, fluoxetine, imipramine, maprotiline, and paroxetine primarily inhibit the reuptake of various monoamines (serotonin for clomipramine, fluoxetine, and paroxetine; noradrenaline for imipramine,

amitriptyline, and maprotiline). Tricyclic antidepressants can also interact directly with 5-hydroxytryptamine (5-HT) and peripheral noradrenergic receptors and may also contribute other actions such as voltage-gated sodium channel blockade and reduction in peripheral prostaglandin E₂ (PGE₂)-like activity or tumor necrosis factor (TNF) production. However, in human medicine, there is a relative lack of controlled, clinical trials specifically evaluating the efficacy of antidepressants in treating cancer pain,⁹⁴ with the exception of two studies demonstrating a lack of efficacy in the treatment of chemotherapy-induced peripheral neuropathy.^{95,96} If there are beneficial effects, it could be from modulation of pain or improvement in mood or feeling.

The tricyclic antidepressant amitriptyline appears to be effective in the cat for pain alleviation in interstitial cystitis,⁹⁷ and many practitioners are reporting efficacy in other chronically painful conditions in the cat, including osteoarthritis. Amitriptyline has been used daily for periods up to 1 year for interstitial cystitis, and few side effects are reported. The author has also used amitriptyline in the cat for cancer pain with some encouraging results. It should probably not be used concurrently with other drugs that modify the serotonergic system such as amantadine or tramadol until more is known about drug interactions.

Sodium Channel Blockade

Alterations in the level of expression, cellular localization, and distribution of sodium channels are seen in many pain states. These aberrantly expressed sodium channels result in hyperexcitability and ectopic activity in peripheral and central nerves that encode nociceptive information. Low doses of lidocaine and other sodium-channel blockers readily block these aberrantly expressed sodium channels, producing pain relief. Low-dose IV lidocaine has proven as effective as other commonly used medications for treatment of neuropathic pain in humans,⁹⁸ and the author uses such an approach to “downregulate” central sensitization in veterinary cancer patients. There is increasing interest in the use of transdermal lidocaine patches for treatment of cancer pain.⁹⁹ Much of this interest revolves around using the patch to administer a low systemic level of lidocaine that blocks the aberrantly expressed sodium channels. Studies have been performed evaluating the kinetics of lidocaine absorbed from patches applied to dogs and cats.¹⁰⁰⁻¹⁰² Peak plasma concentrations of lidocaine were obtained between 10 and 24 hours postapplication in dogs and at 65 hours postapplication in cats. The results of these studies indicate that, similar to humans, systemic absorption of lidocaine from the patch is minimal. Peak plasma concentrations were over 100 times below the level reported to induce neurologic signs and 10 times below the level reported to result in myocardial depression in dogs and 25 times lower than that observed following an IV injection of lidocaine (2 mg/kg) in cats. Potential systemic toxicity associated with lidocaine administration, including bradycardia, hypotension, cardiac arrest, muscle or facial twitching, tremors, seizures, nausea, and vomiting, were not noted in any study. Dosing guidelines have been suggested,¹⁰³ although to date there have been no published reports evaluating the analgesic efficacy of lidocaine patches in veterinary cancer patients, but the technique holds promise.

Steroids

Steroids have a mild analgesic action, can produce a state of euphoria, and are often used for these reasons to palliate cancer and cancer pain in cats and dogs. They should not be used concurrently with NSAIDs because the risk of side effects (especially gastrointestinal) is increased dramatically.

Bisphosphonates

Malignant bone disease creates a unique pain state, with a neurobiologic signature distinct from that of inflammatory and neuropathic pain.¹⁰⁴⁻¹⁰⁶ Bone cancer-related pain is thought to be initiated and perpetuated by dysregulated osteoclast activity and activation of nociceptors by prostaglandins, cytokines, and H⁺ ions. Therapies that block osteoclast activity not only have the potential to markedly reduce bone pain but may also mitigate other skeletal complications associated with neoplastic conditions, including pathologic fractures and hypercalcemia of malignancy. Bisphosphonates are synthetic analogs of pyrophosphate whose primary effect is to inhibit osteoclast activity. Bisphosphonates accumulate in bone, and following osteoclast-mediated bone resorption, bisphosphonates are released and disrupt cellular functions, resulting in osteoclast death. Oral absorption of bisphosphonates tends to be poor, and IV dosing is the preferred route of administration. Adverse effects include nephrotoxicity, electrolyte abnormalities, and acute-phase reactions.^{107,108} In addition to the inhibitory effects of bisphosphonates on osteoclasts, reports suggest that they may also exert direct effects on cancer cells, including canine OSA and fibrosarcoma lines.^{109,110} Studies have found beneficial effects of IV pamidronate for the treatment of malignant osteolysis associated with primary and secondary bone neoplasms.^{10,11,108,111} These studies have also suggested analgesic effects; however, the positive assessments have been based on subjective evaluations. In a placebo-controlled study, there was no difference in the pain relief between placebo and bisphosphonates using either subjective or objective (force plate) evaluations.⁹ Despite these results, it is believed that some patients attain pain relief from bisphosphonate administration, and a better and validated means of assessing cancer pain may help elucidate the degree of pain relief that can be achieved. Pamidronate may be administered at a dose of 1 to 2 mg/kg as a 2 to 4 hour infusion (diluted in saline) and repeated at 3 to 5 week intervals. Other examples of a bisphosphonate that can be used in dogs are clodronate, alendronate, and zoledronate.¹¹¹⁻¹¹³

Neuronal Ablation or Exhaustion Therapy

Several new approaches to pain treatment revolve around the use of mechanisms to destroy or exhaust neurons involved in pain transmission. One approach is to use targeted neurotoxins to cause neuronal death.¹¹⁴ An example of this is the combination of a neurotoxin (saponin) to substance P. Substance P, when administered, binds to the neurokinin receptor (NKR), and the conjugate is internalized (a normal phenomenon of the receptor-ligand interaction), resulting in cell death due to the neurotoxin.^{115,116} Because sensory neurons are rich in NKRs, if the conjugate is targeted appropriately (e.g., given intrathecally), sensory neurons are killed. Basic science studies suggest that in models of chronic pain, general sensory function is left intact, whereas hyperalgesia associated with chronic pain is decreased. Some toxicity work has been performed in dogs,¹¹⁷ and clinical trials in dogs with naturally occurring bone OSA are underway, with these being used as a model of human OSA pain. Another approach uses the transient receptor potential channel, vanilloid subfamily member 1 (TRPV1) to target neurons involved in pain. When drugs such as capsaicin and resiniferatoxin bind to TRPV1, the resulting calcium influx that is initiated results in an inability of the neuron to function. If the activation of TRPV1 occurs for long enough or is intense enough, the resulting calcium influx can cause the neurons to degenerate and undergo apoptosis.

Capsaicin is used in humans for neuropathic pain, and resiniferatoxin has been evaluated in dogs with naturally occurring bone cancer pain in which it provided prolonged pain relief, despite significant hemodynamic effects.⁵

Radiation Therapy

Radiation therapy is considered to palliate pain in canine OSA, although the evidence is largely anecdotal. A 0-7-21 palliative regimen, using 8 or 10 Gy fractions, has been reported to result in pain relief lasting about 70 days.^{4,118} Additionally, two 8 Gy fractions over 2 consecutive days was reported to result in pain relief for a duration of 67 days.¹³ The difficulty in interpreting the value of radiation therapy for pain relief in these studies is the lack of controls or objective measures. Indeed, the natural course of pain and lameness in dogs with appendicular OSA has not been determined. One study evaluating objective measure of limb use in dogs with OSA undergoing radiation therapy found no significant changes in kinetic parameters after one 8-Gy dose of radiation.²

Samarium is a radioisotope that has been evaluated for use in dogs.¹¹⁹ Although the use of samarium Sm153 lexidronam in veterinary medicine is still limited, results of a noncontrolled clinical study with subjective assessments suggested improvement in lameness scores in 63% of dogs, suggesting that this therapy may be useful in the palliation of pain in dogs with bone tumors in which curative-intent treatment is not pursued.³

Acupuncture

Acupuncture can be provided through simple needle placement or by needle placement combined with electrical stimulation (of high or low frequency, although most types of pain respond to low-frequency stimulation). Results of a study in normal experimental dogs demonstrated a weak analgesic effect of electroacupuncture in anesthetized patients as evaluated by a reduction in the minimum alveolar concentration (MAC) of inhaled anesthetic agent.¹²⁰ Recent data utilizing a rodent model suggest that electroacupuncture may have beneficial effects in treatment of pain associated with bone cancer.^{121,122} As yet, there is no evidence that acupuncture provides pain relief in veterinary patients.

The Future: Toward a Mechanistic Understanding of Cancer Pain

Over the last few years, it has become evident that the pain transmission system is plastic (i.e., it alters in response to inputs). This plasticity results in a unique neurobiologic signature within the CNS and peripheral nervous system for each painful disease. Understanding the individual neurobiologic signatures for different disease processes should allow novel, targeted, and more effective treatments to be established.¹²³ This approach should also allow for a more informed choice to be made regarding which of the currently available drugs might be most effective.

The first relevant model of cancer pain has been established in rats—an OSA model.¹²⁴ Prior to this model, evaluation of mechanisms and treatments were undertaken in chronic pain models such as sciatic nerve ligation or injection of chronic irritants—models that did not involve cancer. The introduction of clinically relevant cancer pain models is allowing tremendous progress to be made in the translation to effective human cancer pain treatment.¹⁰⁴ It is likely that spontaneous cancer in veterinary species will play a

significant role in the future in the development of new analgesic approaches for humans, with an obvious benefit to canine and feline patients. Indeed, we are starting to see this with an exciting example being the evaluation of resiniferatoxin in dogs with bone cancer.⁵

■ SECTION B

Nutritional Management of the Cancer Patient

JOSEPH J. WAKSHLAG

Over the past 75 years the examination of nutrients and their relationship to cancer control and cancer prevention has led to a better understanding of how nutrition may play a role in the management of neoplastic disease. The paucity of well-controlled studies in companion animals and the extrapolation of data derived from studies conducted in humans investigating tumor types uncommon to companion animals (colon, prostate, pancreas) are frustrating and make general recommendations for nutritional intervention challenging. However, owners often wish to alter their pet's feeding regimen regardless of proven efficacy. In this context, three areas of

nutrition are often discussed with clients, including modification in tumor metabolism, adjustment of nutritional risk factors that may impact outcomes, and nutritional intervention during therapy, all of which will be addressed in this section.

Metabolism of Cancer: Substrate Utilization

Numerous neoplastic cell lines have been successfully propagated in culture allowing examination of cell biology. A fundamental observation is that the majority of neoplastic cells propagate better in a high glucose media, which is likely the result of limited fatty acid metabolism coupled with increases in metabolic pathways that utilize glucose. This has traditionally been termed the *Warburg effect* after Otto Warburg's seminal work suggesting that glycolysis is the primary pathway for energy production in neoplastic cells.^{1,2} Studies in humans have shown that certain cancer patients liberate excessive lactate from solid tumors,^{3,4} providing evidence that glycolysis and pyruvate production are critical to neoplastic cell metabolism. This has led to the Cori cycle hypothesis of neoplasia, whereby neoplastic tissues, much like skeletal muscle tissue, appear to undergo regeneration of glucose from lactate through hepatic resynthesis of glucose.⁵ Unfortunately, this regeneration of glucose is an energy costly cycle and is thought to contribute to increases in resting energy requirements.

In veterinary medicine, there is a significant body of work examining metabolism and cancer, often through the application of indirect calorimetry assessments to study whole body metabolism. These studies have interrogated oxygen consumption and carbon dioxide liberation and such data provide an estimate of energy consumption (resting energy expenditure [REE]) and substrate utilization (respiratory quotient [RQ]). Healthy dogs display higher REE than dogs with stage III and IV lymphoma.⁶ RQ values between the groups were not different, suggesting that all dogs were using similar substrate, and dogs with lymphoma were not preferentially consuming more glucose than their control counterparts.⁶ In a separate study, dogs with lymphoma fed either a high-fat or high-carbohydrate diet during doxorubicin chemotherapy did not differ in remission times, survival times, or tumor burden, suggesting that dogs with lymphoma under treatment were not sensitive to this basic dietary alteration.⁷ During this study the REE and RQ assessed during treatment did not change significantly when the tumor burden was eliminated with chemotherapy suggesting no significant changes in energy expenditure or metabolism. These data collectively indicate that there is no fundamental difference observed between normal healthy dogs and dogs with lymphoma and that removal of the tumor burden does not alter the resting energy requirement.

Canine nonhematopoietic malignancies were also examined before and 4 to 6 weeks after excision of their primary tumors, including mammary carcinoma, OSA, high-grade mast cell tumors, and lung carcinoma. As in dogs with lymphoma, REE was not different from control dogs nor was there any difference in REE between preexcision and postexcision of the primary tumor, suggesting no futile cycling of energy in these patients.⁸ Interestingly, in this study the RQ values were above 0.8 for all control and tumor-bearing dogs, suggesting that the resting energy was not from lipolysis, which was contradictory to a follow-up study performed in dogs with OSA. In that follow-up study, there was an increase observed in the REE in dogs with OSA compared to control dogs but a RQ of 0.7 in both affected and control dogs.⁹ This increased

REE persisted after excision of the primary lesion, suggesting that the modest increase in REE was due to factors other than the primary neoplasia and may be associated with micrometastasis, inflammation associated with neoplastic disease, or heightened pain response associated with the primary tumor and surgical procedure.⁹ These findings were surprising in light of the previous studies mentioned but were likely more valid considering that the REE calculations in the OSA study were based on lean mass rather than total kilograms of body weight.⁹ It is well known that fat mass is relatively metabolically inert; therefore REE based on lean body mass is more appropriate. The previous studies in nonhematopoietic malignancies and lymphoma did not adjust for body condition or lean body mass in tumor-bearing or normal populations under study,^{7,8} and the inability to document differences in REE noted in these two studies may have been confounded by a lack of body condition assessment.

Specific metabolic changes have been reported in dogs with several types of cancer. Alterations in glucose metabolism (potentially higher glucose turnover), increased protein turnover, and urinary protein losses in dogs with OSA have been observed.⁹ In addition, studies in dogs with lymphoma identified alterations in carbohydrate metabolism such as increased serum lactate and insulin concentrations during glucose tolerance testing that suggest insulin resistance.^{6,10,11} This may be partially explained by aberrant interleukin-6 (IL-6) and other cytokine influences on glucose metabolism resulting in insulin resistance in dogs with lymphoma.¹² Insulin insensitivity and serum lactate did not change once remission was achieved in one of these studies.⁶ Mild alterations in lipid metabolism in dogs with lymphoma were suggested by higher basal triglyceride and cholesterol concentrations compared to control dogs,¹³ and treatment with doxorubicin lowered serum cholesterol, perhaps due to hepatic effects of chemotherapy.¹³ However, the dyslipidemia present was not ameliorated once the primary tumor burden was eliminated, which is logical in light of the insulin resistance observed.

Cancer Anorexia and Cachexia

Anorexia or hyporexia (inadequate food intake) in cancer patients is a common occurrence and can be one of the presenting clinical signs of cancer. Inadequate appetite is often due to an enhanced inflammatory cytokine response (i.e., IL-6 and IL-1) associated with the tumor, resulting in hypothalamic arcuate nucleus suppression of appetite. In the case of gastrointestinal cancer, pain associated with eating, obstruction, or dysfunctional transit mechanisms can lead to anorexia. In patients undergoing treatment, anorexia may be partially explained by adverse events associated with the use of chemotherapy. Chemotherapeutics can cause a variety of alterations in olfactory and taste sensorium. Since dogs and cats rely heavily on olfactory cues, the loss of olfactory bulb stimulus diminishes palatability of foods.^{13,14} Additionally, the loss or alteration of taste (ageusia or dysgeusia) can further complicate anorexia and may last for several months before neuronal regeneration can take place at the olfactory bulb and tongue.^{13,14}

Cachexia, on the other hand, although identified in many human cancer patients, does not appear to be common in dogs with nonhematopoietic malignancies other than a predisposition toward insulin resistance.^{6,10,15,16} Evidence in humans and mouse models suggests that the most prominent influence inciting the cachectic phenomenon may be excessive cytokine stimulation, which leads to insulin resistance, extensive lipolysis, and proteolysis of tissue stores.^{17,18} The three primary cytokines thought to be involved in

promoting enhanced proteolysis are TNF- α , IL-1 β , and IL-6.^{17,18} TNF- α and IL-1 β have both been directly associated with anorexia and upregulation of mitochondrial uncoupling protein, whereas IL-6 and TNF- α have been observed to increase myofibrillar degradation machinery, all of which may play a role in the anorexia/cachexia syndrome associated with neoplasia.^{19,20} IL-6 and c-reactive protein, both markers of inflammation, have been observed to increase in canine lymphoma patients.^{12,21,22} Yet, it does not appear that cachexia is a common occurrence in dogs diagnosed with neoplasia since dogs examined 6 months prior to diagnosis of cancer showed no difference in body weight or body condition than at presentation for various neoplasms.¹⁵ This may be partially explained by differences in common tumor types between species. Cachexia in humans is often associated with epithelial cancers such as pancreatic, colon, mammary, and prostate cancer. Additionally, human patients undergo dramatically different and more aggressive treatment protocols over lengthy time periods, which we typically do not encounter in veterinary medicine due to owner financial constraints and QOL considerations.

Cats on the other hand may show a more typical cachectic response involving excessive lean body mass wasting. Recent evidence suggests that approximately 56% of cats with lymphoma and other solid tumors have body condition scores of less than 5 out of 9.²³ More intriguing is that the survival time for cats with lymphoma with a body condition score of 5 or greater was 16.9 months, compared to those with lower scores (3.3 months).²³ This warrants monitoring of caloric intake and aggressive implementation of nutritional interventions in feline cancer patients.

Epidemiology, Prevention, and Risk Factors

In humans, the two major nutritional factors associated with risk of developing cancer are excess body weight (obesity) and low fruit and vegetable consumption.²⁴⁻²⁷ Although these parameters may be interrelated, both appear to play a direct role in the risk of cancer development. Convincing data suggest that the westernized diet and lack of fruit and vegetable matter are linked to increased relative risk of nearly all types of neoplasia, including prostate, colon, breast, lymphoma, and leukemia.²⁸⁻³⁰ Although the evidence is compelling, the data do not support a causal association, and it may be a combination of factors associated with diet, as well as confounding lifestyle differences in humans consuming higher amounts of fruits and vegetables, that may be important in determining cancer.

In veterinary medicine, there are few studies examining the effects of dietary substrate (protein, fat, carbohydrate) and plant-based dietary intake and cancer incidence. Two epidemiologic studies using validated food frequency questionnaires examined the effect on survival of calories coming from fat, protein, and carbohydrate for 1 year prior to and after diagnosis of mammary carcinoma.^{31,32} These data were contradictory to human findings, showing that dogs with increased protein intake had increased survival times and that fat and carbohydrate intake did not play a role in progression of disease.^{31,32} Another study suggested that risk of neoplasia was increased in dogs receiving nontraditional, poorly balanced diets (i.e., table foods as primary consumption).³³ Further examination of this group showed no association between blood selenium concentration and mammary carcinoma when compared to healthy age-matched and hospitalized control dogs. Serum retinol (vitamin A) values were also decreased in dogs with

mammary carcinoma in this study.³³ Whether the lower serum retinol was a reflection of poor retinol intake or a reflection of the disease manifestation was not determined. A diet high in red meat was also identified as a risk factor in this study. In many cases, a high-protein food may be evaluated as higher quality because protein is an expensive ingredient; however, many variables in addition to ingredients are important. Ingredient quality, digestibility, and socioeconomic factors such as veterinary care should be considered. It does suggest that feeding an incomplete diet is associated with increased cancer risk and provides justification for a complete and balanced diet (Association of American Feed Control Officials [AAFCO]-approved commercial dog food) throughout the life of a dog.

Nutritional risk factors examined in Scottish terriers, who have a genetic predisposition to develop transitional cell carcinoma (TCC), showed that the addition of vegetables to a dog's diet resulted in a lower incidence of the disease.³⁴ However, there are confounding lifestyle factors that cannot be accounted for in this epidemiologic investigation, including better health care, variation in nutrition supplied as commercial food, and other associated environmental exposures. Yet, this study is provocative and suggests further study is warranted.

Specific vitamins and their relationship to cancer development have received significant attention in humans, including retinol, ascorbic acid, vitamin E, selenium, and vitamin D. In veterinary medicine, these nutrients have not been thoroughly studied in relation to cancer risk. Human metaanalyses examining oral supplementation for single nutrients such as ascorbate, selenium, and vitamin E have been inconclusive or negative when examining protective, anticarcinogenic effects.³⁵⁻³⁷ Other nutrients like β -carotene, the precursor to retinol, is currently thought to be ineffective as a chemopreventive agent and in some instances has proved to be harmful in certain populations (i.e., smoking populations).³⁸⁻⁴⁰ Currently, vitamin D (25-hydroxyvitamin [OH] D₃) status and supplementation has been an area of vigorous epidemiologic investigation due to an increased relative risk of various neoplastic diseases associated with low serum vitamin D status.⁴¹⁻⁴³ In dogs and cats, unlike humans, vitamin D status is directly dependent on dietary intake since they cannot convert 7-OH-dehydrocholesterol to pre-vitamin D. One would expect that serum vitamin D concentrations would not fluctuate tremendously in dogs being fed commercial dog food.⁴⁴ A recent investigation suggests that Labrador retrievers with mast cell disease have lower serum vitamin D status than healthy Labrador retrievers, making vitamin D status an interesting area of future investigation.⁴⁵ Whether this is a direct reflection of dietary intake or a reflection of the biochemical disposition in affected dogs with cancer remains to be determined.

In humans, obesity has been associated with an increased risk of many cancers, including breast, prostate, colon, leukemia, lymphoma, and pancreatic neoplasia.²⁴⁻²⁷ In companion species, studies examining this association are limited. The largest retrospective study in dogs showed no association between body condition and neoplastic disease,¹⁵ whereas other epidemiologic studies suggested that obese cats and dogs may have a slightly higher rate of neoplastic disease.^{46,47} Two other investigations revealed a more definitive link between obesity in female dogs and the onset of mammary carcinoma.^{31,33} The risk of mammary carcinoma was greater in obese spayed dogs in one study, although obesity was an increased risk factor but independent of spay status in another.^{31,33} Both studies suggest an increased risk when obesity is present at 1 year of age, and one suggested that obesity at 1 year before diagnosis also increased risk.⁴⁷ The question of whether early onset obesity, much

like early spaying, epigenetically predisposes mammary glands to an altered risk of cancer remains to be addressed.

Implementing a Nutritional Plan for the Oncology Patient: Nutritional Assessment

To fully assess the cancer patient, information regarding body weight, body condition score, and diet history are crucial. Dietary history, before and during treatment, should be obtained to appropriately assess the kilocalorie intake. This information will allow the practitioner to feed the patient appropriately during hospitalization and, more importantly, to recognize hypophagic behaviors, allowing for proactive interventions. A typical diet history should include the forms of food (wet or dry), amounts fed daily, as well as treats, human table foods, and additional supplements provided. A food diary has been helpful for humans attempting to understand energy and nutrient intake and is likely to also be helpful for dogs in particular as a wide variety of food stuffs are offered to dogs.

Serial assessment of body weight is important, particularly where malnutrition is a consideration. Malnutrition is often associated with cachexia and/or anorexia. Anorexic behavior can be deduced from the diet history and can be treated aggressively with nutritional and/or pharmacologic intervention; however, if cachexia is suspected, then alternative treatments can be sought. The difficulty in clinically differentiating cachexia from anorexia is our inability to measure loss of lean versus fat mass. The loss of fat mass is typical during anorexia, and equal loss of lean and fat mass suggests cachexia. Although this cannot be deciphered efficiently in veterinary practice, overall weight loss guidelines have been offered in the human literature whereby body weight loss of 5% in 1 month or 10% in 3 months without conscientious dieting suggests cancer cachexia.⁴⁸ Two body condition scoring (BCS) systems have been adopted as a means of nutritional assessment in companion species; however, the 1 to 9 BCS system (Figure 15-2) has been more thoroughly validated in the literature.^{49,50} Modest differences in BCS between dogs and cats exist due to preferential deposition of body fat along the inguinal and abdominal areas in cats, whereas dogs tend to have no preferential deposition. These differences may justify a muscle condition scoring system in cats (Table 15-6).²³

The final component of nutritional assessment consists of a routine physical examination, complete blood cell count, and serum chemistry evaluation. Physical examination findings consistent with malnutrition include poor hair coat, chronic gastrointestinal disturbance, seborrhea, lethargy, and pallor. The first signs of chronic nutrient deficiency are often manifested in areas of rapid cellular turnover leading to skin, gastrointestinal, and hematologic

• **TABLE 15-6** Description of the Muscle Mass Scoring System (MMS)

SCORE	MUSCLE MASS
0	On palpation over the spine, muscle mass is severely wasted.
1	On palpation over the spine, mass is moderately wasted.
2	On palpation over the spine, muscle mass is mildly wasted.
3	On palpation over the spine, muscle mass is normal.

signs and should be considered in cases of prolonged anorexia. Chronic malnutrition can result in low hemoglobin and red blood cell counts, as well as hypoproteinemia and hypoalbuminemia. Additionally, with the trend toward nontraditional feeding practices, there is the potential for diets that lack sufficient mineral content (e.g., calcium, iron, and copper) resulting in bone and hematologic manifestations. Many homemade diets lacking supplementation with bone meal can lead to secondary hyperparathyroidism and clinical osteopenia.^{51,52} Clients using nontraditional diets should be educated through consultation with a veterinary nutritionist.

In dogs, excess body condition (i.e., obesity) may be more of a concern than malnutrition or deficiency. Treatment of obesity is not a priority in many cancer patients, considering metabolic changes that may occur during chemotherapy and the potential for treatment-related eating pattern changes. One study suggests that body condition does not change from 6 months prior to diagnosis to the day of diagnosis,¹⁵ whereas another study suggests that over 68% of dogs lose weight during treatment⁵³; however, loss was less than 5% of body weight and nearly 30% of dogs were scored as obese prior to treatment. The occurrence of obesity in dogs with neoplasia appears to follow the national trends in canine obesity.

Feeding the Hospitalized Oncology Patient

Hospitalization of debilitated cancer patients undergoing evaluation or therapy has unique nutritional opportunities and challenges. Hospitalization during some fractionated radiation therapy is common, and the provision of more than the resting energy requirement (RER) during this period is often unnecessary unless extreme circumstances exist where extensive tissue repair is ongoing (e.g., postoperatively, epithelial mucositis). This increased energy requirement is known as the illness energy requirement (IER) and is often considered to be between 1.1 to 2 times the RER, particularly when transudates or exudates are involved with the repair process and protein losses are excessive. Energy requirements post-discharge may also be increased above hospitalization RER due to increased activity and neuter status, which is represented as the maintenance energy requirement (MER). Table 15-7 presents starting calculations for MER based on the linear equation used in veterinary patients taking into account the activity status. Exponential equations are preferred in dogs and cats under 2 kg or over 30 kg to derive a more accurate estimate of the RER:

$$\text{RER} = 70(\text{BW in kg})^{0.75}$$

• **TABLE 15-7** Maintenance Energy Requirement Equations for Adult Cats and Dogs

ANIMAL	MER EQUATION
Neutered adult dog	$(70 + 30 [\text{BW}_{\text{kg}}]) \times 1.6$
Intact adult dog	$(70 + 30 [\text{BW}_{\text{kg}}]) \times 1.8$
Obesity-prone adult dog	$(70 + 30 [\text{BW}_{\text{kg}}]) \times 1.2 \text{ to } 1.4$
Neutered adult cat	$(70 + 30 [\text{BW}_{\text{kg}}]) \times 1.2 \text{ to } 1.4$
Intact adult cat	$(70 + 30 [\text{BW}_{\text{kg}}]) \times 1.4 \text{ to } 1.6$
Inactive obesity-prone adult cat	$(70 + 30 [\text{BW}_{\text{kg}}]) \times 1.0$

BW, Body weight; MER, maintenance energy requirement.

Evidence suggests that the exponent of the equation may be different for cats (e.g., 0.67).⁵⁴ Once a patient returns home, its RER typically increases slightly due to increased activity. Therefore clinicians should adjust the energy intake on discharge.

Coax Feeding and Pharmacologic Appetite Stimulation

Ensuring full energy requirement intake enterally may be difficult due to a diminished appetite in canine and feline cancer patients. There are many considerations when trying to promote adequate intake, and these may be different in dogs and cats. Hand-feeding in dogs and cats that enjoy this approach should be considered rather than putting a bowl in the cage and leaving it there. Hand-feeding may be best achieved during owner visits when the animal is most comfortable and often away from the busy atmosphere of most intensive care units or oncology wards.⁵⁵ For cats, having a quiet place away from distractions that create a fearful environment may be helpful to achieve adequate intake. Making one cage an eating cage that is covered and away from the litter box is ideal as some cats will not eat near the litter box during hospitalization.⁵⁵

Addition of flavorings may also be helpful. Dogs have salt and sweet receptors, and the addition of sugar, syrups, or other sweeteners can sometimes improve appetite.⁵⁵ Cats do not have the lingual receptors to appreciate sweet flavors. Therefore salt can be used to entice cats to eat; however, they tend to be more averse to oversalted foods.⁵⁵ Additional protein added to the diet of both dogs and cats can improve appetite and enhance intake since dogs appear to prefer higher protein diets and cats have increased density of lingual amino acid receptors, making high protein choices logical.⁵⁵ The supplementation of animal-based or vegetable-based fat may increase palatability but must be monitored as additional fat can dilute the nutrient content of the feed. In the presence of nausea, introducing multiple foods can create long-term aversions limiting choices of form and texture once the nausea has resolved.⁵⁵ Using one or two foods to coax feed is ideal, rather than an entire array of products from the kitchen.

Pharmacologic approaches to improve enteral support may be attempted; however, many of the purported effects are anecdotal with little evidence of their true utility in veterinary medicine. Human studies suggest several approaches, including pharmacologic alterations in serotonergic stimulation in the brain, decreased cytokine stimulation, and the promotion of hypothalamic satiety center signaling.^{56,57} Approaches in veterinary medicine have focused on the use of the antiserotonergics (e.g., cyproheptadine and mirtazapine). Unfortunately, no definitive clinical studies documenting the efficacy of these drugs in dogs and cats with cancer exist.⁵⁵ Of some interest is the use of valium to stimulate appetite in cats and the recommended dosing of 1 mg by mouth (PO) daily has proved useful.⁵⁸ However, the use of valium does not come without the potential for severe side effects (e.g., hepatic necrosis), making long-term use of valium ill advised.⁵⁹ In dogs, low-dose propofol is used to briefly stimulate eating behavior to test the integrity of the bowel (i.e., vomiting) when unsure about enteral functional status, although more prolonged use of propofol is not attempted.⁶⁰

Assisted Enteral Support

In many instances, the use of assisted enteral nutrition should be considered, particularly if the animal is not consuming appropriate

kilocalorie requirements. In the hypophagic cancer patient, it may be essential to provide assisted feeding through various techniques, including syringe, nasogastric, esophagostomy, or gastrostomy feeding. Syringe feeding is the easiest and requires the least attention to detail by owners and clinicians. In the nauseous and anosmic patient, this can be difficult to implement due to patient resistance. Nasogastric tubes can be easily placed without anesthesia and can be useful in hospitalized animals but are often problematic to manage at home and are limited to the use of liquid enteral products due to tube diameter. The two most widely accepted means of implementing long-term enteral support is the placement of an esophagostomy or gastrostomy tube. The esophagostomy tube is typically placed under anesthesia; techniques for placement have been described elsewhere.⁶¹ Once secured, the tube site is typically wrapped, and the insertion site should be examined every 24 to 48 hours for signs of cellulitis and discharge. These tubes are typically recommended for intermediate to long-term feeding for a period of 2 to 3 weeks up to 2 to 3 months.

Gastrostomy tube placement should be considered when tube placement is required for longer than 6 to 8 weeks.^{61,62} Advantages include direct gastric delivery of nutrients and prevention of tube eversion if emesis is encountered. Anesthesia is required for either surgical or percutaneous endoscopic placement approaches. The endoscopic approach is generally safe and effective, although associated with a higher risk of complications.⁶² The author prefers surgical placement in large breed dogs because they may be predisposed to separation of the stomach from the body wall after endoscopic placement. Peritonitis is the most serious complication following tube placement since the peritoneum is disturbed with this approach and leads to a permanent stoma from the stomach to the outside of the body.^{61,62} After successful gastrostomy tube placement, the tube can be used within 24 hours of placement but should not be removed before 2 weeks, allowing for adhesion and fibrosis of the gastric wall to the abdominal wall. Once a stoma has formed, the original surgically placed tube may be replaced with a low profile or “button” feeding device. Owners should be aware that these low profile devices need replacing every 6 to 8 months and will require mild sedation for replacement.⁶³

Esophagostomy and gastrostomy tubes allow for a diverse number of products to be used for feeding beyond the liquid veterinary diets. Many over-the-counter and veterinary therapeutic diets can be blended for feeding; however, when some products are blended with water, they result in less than 1 kcal/mL. Diets that provide higher caloric density that can be passed through a 7 French or greater diameter catheter are listed in Table 15-8. These

products tend to be higher in protein and fat and can be fed at reduced volumes and rates when nausea or food volume is an issue. A typical dog or cat receiving a slurry of food at 1 kcal/mL will also be meeting their fluid requirements.⁶⁴ Similarly, providing 1 kcal/mL for dogs and cats that are not actively consuming water at home is also advised.

Parenteral Support

If enteral support is not an option, then parenteral nutrition (PN) should be considered. Parenteral support can be either partial PN (PPN) or total PN (TPN). PPN has also been termed *peripheral parenteral nutrition* considering it is typically delivered through peripheral veins. Prospective studies examining outcome following parenteral support have not been performed in clinical veterinary medicine and only a handful of retrospective investigations characterize complication rates.⁶⁵⁻⁷⁰ In veterinary patients, particularly cats, the metabolic complication most often encountered is hyperglycemia. Mechanical complications are also prevalent (i.e., feeding line problems, inadvertent patient removal). A common misconception is that sepsis is a common complication, but in fact it is quite rare.⁶⁵⁻⁷⁰ Parenteral support should only be considered when enteral support is not an option due to medical complications; enteral support is considered superior as it prevents transmigration of bacteria to the portal blood and improves the immunologic status of patients.⁷¹

Parenteral support is not well studied in veterinary medicine, and the relative use and utility of the three main substrates (glucose, amino acid, and lipid) differ, depending on the source of information.⁷²⁻⁷⁴ Some advocate using glucose and lipid to meet the energy requirements and then add in amino acids to the formulation based on the protein needs per kilogram of body weight. Others advocate adding just above the minimal protein requirement as amino acids making up part of the REE. The protein requirements for ill cats and dogs are currently unknown, and we can only assume the requirements are similar to those of healthy normal animals. Extrapolation from human data suggests that protein turnover may be higher during catabolic illness, and we often add slightly more protein than required. In an elegantly designed study, it was found that approximately 2.3 g protein/kg body weight is sufficient for IV amino acid solution in normal dogs.⁷⁵ This suggests that adding 2.5 to 3 g/kg amino acid solution for a dog appears sufficient and 4 g/kg is often used as a starting point for cats. Amino acids come in several different formulations and strengths (e.g., 5.5%, 8.5%, and 10%). Additionally, amino acid

solutions come with and without electrolytes. Amino acids with electrolytes typically provide basal sodium, chloride, magnesium, phosphorus, and potassium when used at 1.5 to 2.5 g/kg body weight of protein; however, these are used less often in veterinary species, particularly in cats whose protein requirements are higher. When using amino acids with electrolytes, the electrolytes provided should be considered before supplementing additional electrolytes in fluids. [Figure 15-3](#) describes a typical TPN feeding program for a cat or dog using a 10% amino acid solution without electrolytes. During the first day of TPN, it is recommended to provide only half of the calorie requirement, particularly if there has been a history of anorexia. This recommendation is due to the potential for refeeding syndrome, whereby rapid glucose metabolism can lead to hypophosphatemia, hypokalemia, and hypomagnesemia. This also illustrates the need to assess electrolyte status every 12 to 24 hours for the first 48 to 72 hours when implementing TPN.

PN formulation should be done in a laminar flow hood with appropriate aseptic procedures to prevent contamination of solutions. A sterile catheter should be used, and PN should be administered through its own port in a multilumen catheter with the most distal port reserved for PN. Avoid the addition of other medications or treatments because some medications are not compatible with PN. The typical osmolality and pH of a TPN solution will be far different than plasma osmolality (around 1000 to 1300 mOsmol and pH less than 7). This may be irritating to the vascular endothelium and requires a large vessel for administration.⁷⁴ Such high osmolar solutions cannot be used in a peripheral vein as they may

induce thrombophlebitis, and this is the reason that 5% glucose is used to dilute PPN rather than the 50% glucose solution used in TPN solutions.^{66,72} Using 5% dextrose creates an osmolality of less than 700 mOsmol, which is a guideline from human medicine that has been adopted by many veterinary nutritionists and internists.⁷⁶ [Figure 15-4](#) describes guidelines for PPN formulation for dogs and cats.^{66,72} Addition of B-complex vitamins should also be considered when using TPN and PPN. Most preparations do not include folate, and cobalamin may be insufficient or absent and should be considered separately if long-term support is required. Furthermore, if chronic use of TPN is required, the addition of calcium to separate fluids and the use of amino acids with electrolytes and trace mineral additions to the TPN should be considered.

The proportions of glucose and lipids in parenteral solutions is a subject of much debate, particularly in the cancer patient, because of suggestions that neoplastic tissues utilize glucose more readily and the possibility of mild insulin resistance.^{10,11} However, increasing lipid content to meet energy requirements has also been met with some trepidation due to lipid's potential to mildly suppress the immune system.⁷⁷ Lipid has also been incriminated as the cause of microemboli,⁷⁸ and some suggest placing a 1.5 to 2 μm filter in the line to remove lipid particles and microbes; however, recent evidence suggests that in a typical veterinary-formulated TPN solution the lipid particles remain well emulsified—no bacterial growth was evident for 3 days following formulation when kept refrigerated.⁷⁹ PPN, with its lower osmolality, is at an increased risk of sequestering microbial growth.

Nutritional Support in the Cancer-Bearing Patient

Substrate

Based on our present understanding, the use of specific dietary regimens in cancer patients is premature. It has been hypothesized that due to the glycolytic nature of neoplastic cell growth, altering the substrates to hypothetically “starve the tumor” by eliminating some carbohydrates may be indicated.^{1,2,10,11} This argument falls short for a number of reasons. If carbohydrates are limited, energy sources are replaced with additional fat and/or protein. Added

protein will lead to increased transaminase and deaminase activity causing conversion of the protein to glucose and carbon precursors for glucose or fatty acid synthesis, and serum glucose and delivery of glucose to the tumor tissue may still remain constant. If appetite is diminished, choosing a higher protein and higher fat food may enhance palatability and caloric density, making these foods appropriate for long-term management during treatment.⁵⁵ Previous sections have discussed the discordance of results of studies investigating low-carbohydrate, high-fat, and modified-fat diets.⁷ One study documented slight increases in remission and survival times when a high polyunsaturated fat diet (high ω -3 fatty acids) and arginine diet was used, suggesting that the type of fats and amino

acids may influence remission and survival (see subsequent discussion).¹²

Cats appear more prone to weight loss during hospitalization. Many cats receive inadequate caloric intake, particularly during radiation treatment when food availability is limited each day due to repeated anesthesia. Many cats will eat 12 to 20 small meals throughout the day and night based on observed feeding patterns.⁸⁰ The use of higher protein may be worthwhile because recent rodent data show that a high-protein and low-carbohydrate diet decreases tumor growth in a variety of different xenografted tumors.⁸¹ In this diet study, calories were met with approximately 50% protein, implying that high protein may be the benefit, rather than low carbohydrate.⁸¹ The use of high-protein diets may also have benefits in cats with lean body mass wasting issues.^{82,83} Although these were small studies, it suggests that in cats, skeletal muscle may respond to higher protein by increasing lean mass to a small extent. With this in mind we often recommend feeding cats higher protein (>35% dry matter) and fat (>20% dry matter). Dogs can be fed similarly, even though many commercial dog foods will have lower protein (typically >30% dry matter is achievable) than cat food.

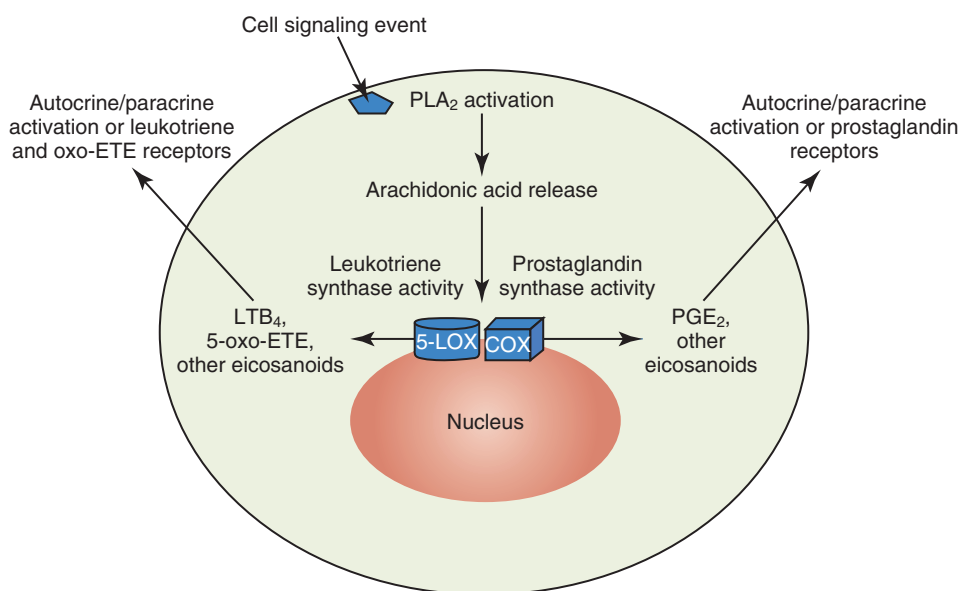

Amino Acids

The benefits of additional protein to the diet of cancer patients may result from increased circulating amino acids as inhibitory molecules in neoplastic cell proliferation.⁸¹ Arginine has received considerable attention since low-millimolar concentrations of arginine can inhibit various neoplastic cell lines by altering cell cycle progression.⁸⁴⁻⁸⁷ Additional xenograft data using human and mouse cell lines show diminished tumor growth when mice are provided foods with high dietary arginine, and a single study in dogs with lymphoma, using an arginine-enhanced diet in combination with enhanced ω -3 fatty acids, documented improved remission and survival times.¹² However, the practicality of using an amino acid supplement like arginine leaves much to be desired since the required dose is in excess of 100 mg/kg body weight. Additionally,

the bitter taste of arginine and potential for creating amino acid imbalance also prevents its use in long-term feeding regimens. The benefits of glutamine have also been touted due to lean body mass preservation properties and its ability to enhance mucosal barrier function.^{88,89} However, enterocytes' ability to utilize glutamine and first-pass hepatic metabolism do not allow glutamine to have any pronounced effects on lean mass. The use of high-protein mixed meals to support enterocyte health and mucosal barrier function is often recommended for general health.

Polyunsaturated Fats

Using fat in diets is helpful in increasing palatability and energy density, but in many instances the fatty acid constituents can influence neoplastic cell growth. Human and rodent studies suggest that consumption of high concentrations of ω -3 fatty acids, namely eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), in the form of marine oils may perturb loss of lean body mass and possibly decrease tumor growth rate.⁹⁰⁻⁹⁷ These fatty acids may transform into inert eicosanoids (PGE₃, leukotriene B₅ [LTB₅], 12-hydroxyeicosapentaenoic acid [12-HEPE], 5-HEPE) rather than proinflammatory eicosanoids (PGE₂, LTB₄, 12-hydroxyeicosatetraenoic acid [12-HETE], and 5-HETE). The pathways and eicosanoids liberated are highly dependent on the enzymatic machinery present in the cells. Although the addition of fatty acids into the cell membrane may affect intracellular signaling events, the intracellular enzymatic machinery that modifies the primary fatty acid into promitogenic or inert eicosanoids may be more important.⁹⁶⁻⁹⁹ Cell signaling events that lead to liberation of arachidonic acid from the cell membrane can be converted to eicosanoids, which when released from the cell can have local or paracrine effects on cell growth through interactions with eicosanoid receptors (Figure 15-5). The two enzymes that have received the most attention are COX and 5-lipoxygenase (5-LOX) due to the promitogenic mechanisms of action observed by their respective eicosanoids, PGE₂ (COX) and 5-oxo-EET/LTB₄ (5-LOX).⁹⁶⁻⁹⁹

• **FIGURE 15-5** The liberation of arachidonic acid (AA) from the cell membrane due to cell signaling events leading to nuclear translocation of AA. Cyclooxygenase and lipoxygenase activity coupled with leukotriene synthase or prostaglandin synthase will allow for formation of bioactive eicosanoids that when released can have autocrine or paracrine cell proliferation signaling activities depending on receptor presence. PLA₂, Phospholipase A₂; LTB₄, leukotriene B₄; PGE₂, prostaglandin E₂; 5-LOX, 5-lipoxygenase; COX, cyclooxygenase.

Although possibly relevant to many types of human cancers, there is a paucity of data in companion animals, with the most intriguing studies documenting the use of COX inhibition in TCC.^{100,101}

A single study in cancer-bearing dogs using a fish-based ω -3 fatty acid–enhanced diet showed a small improvement in survival times; however, there were multiple changes in the dietary trial, including arginine and energy substrate differences that may have played a role.¹² Although the biochemical principle that increased EPA in cells will inhibit promitogenic eicosanoid formation as an autocrine/paracrine signaling molecule is valid,⁹⁹ it is unclear what tumor types this may apply to. Some neoplastic tissues will utilize the proinflammatory cytokine milieu to promote proliferation or upregulate pathways that may promote metastasis.¹⁰² The benefits of fish oils may go beyond mild suppression of tumor cell proliferation because the antiinflammatory effects of fish oil may also quench the inflammatory reactions associated with certain cancers.^{103–105} Thus there is little downside to increasing ω -3 fatty acid consumption in the diet of cancer patients. The lack of clinical studies in this area precludes an optimal dosing regimen, and recent metaanalysis of human trials using fish oils for QOL issues were inconclusive.¹⁰⁶ Additionally, cats seem to be more sensitive to fish oil supplementation than dogs as the result of greater effects on platelet reactivity resulting in alterations of clotting times.¹⁰⁷ A safe and tolerable dose for fatty acids in dogs can be extrapolated from studies in cardiac cachexia in dogs,^{108,109} in which EPA 45 mg and DHA 25 mg/kg body weight (e.g., 1 tsp/20 kg body weight) was used, but higher doses may be needed in dogs with cancer. Furthermore, the type of fish oil can significantly affect the ratio of EPA to DHA. Salmon oils tend to have higher DHA than EPA, and whitefish oils (e.g., herring, menhaden, cod) tend to have higher EPA than DHA; therefore whitefish oils are the preferred source. A safe and potentially effective dose in cats cannot be recommended.

During radiation therapy, the paradigm may be altered because radiation therapy causes irreparable damage to tumor cellular microstructure, resulting in apoptosis of cells and negative effects on surrounding tissues. The use of polyunsaturated fats (the longest, the ω -3 fatty acid DHA, has more double bonds) may be oxidized to a greater extent during radiation treatment, potentially leading to increased membrane compromise and cellular death.¹¹⁰ Surrounding tissues may not exhibit an aggressive inflammatory action due to the hastened eicosanoid response with EPA, and other essential fatty acids quenching this proinflammatory response may lead to less surrounding tissue damage.¹¹¹ This principle has not been studied in veterinary patients but has been proved to diminish radiation-induced tissue damage in pig models.¹¹¹

Vitamins and Minerals

Essential vitamin and mineral supplementation has been an interesting area of investigation in human cancer, with nutrients such as vitamin A, vitamin D, and selenium receiving attention.* Much of the research has centered on cancer prevention rather than cancer treatment, which has been addressed earlier in this section. That being said, certain vitamins and minerals are being used in therapeutic clinical trials in humans due to their ability to diminish tumor cell proliferation in preclinical models. Vitamin A, in the form of retinoic acid and synthetic derivatives, has been used to treat certain cancers; however, discordant effects on nuclear signaling occur with different heterodimers.^{113,114} Some heterodimers drive the proliferative response, whereas others diminish cell

proliferation.¹¹⁵ Their use cannot be globally recommended at this time.

Regarding vitamin D, low concentrations of the precursor to active vitamin D (25, OH D3 calcidiol) in people may promote tumorigenesis and treatment with active vitamin D (1,25, OH D3 calcitriol) may cause tumor regression in some cases.^{41–43,116} Although antiproliferative at high doses, calcitriol can lead to hypercalcemia and its sequelae, including calcification of soft tissues. This is illustrated in a recent trial characterizing dosing in dogs with mast cell tumors in which many patients developed clinical signs of hypercalcemia, inappetence, and vomiting.^{116,117}

Selenium has generated considerable interest in certain human neoplastic diseases, such as lung, squamous cell, and prostatic carcinoma.^{118–121} Low serum concentrations have been associated with an increased risk of prostatic cancer in humans.^{118,120} Interestingly, the selenium requirement in most dog food based on the AAFCO is considerably lower than what the National Research Council deems adequate intake in dogs and cats.¹²² Thus many pet foods may not have optimal concentrations of selenium, and modest supplementation may be considered.^{118–121} However, recent metaanalysis of human intervention studies suggests no definitive benefits from selenium supplementation in treatment or prevention of neoplastic disease.³⁷

B vitamins of interest include folate and vitamin B₁₂ (cobalamin). The interest once again derives from human literature in which their effects on epigenetic alterations may affect tumor suppressor and oncogene expression over time.^{122–124} Considering the consistent intake of folate and cobalamin in the pet population caused by commercial dog food consumption, there is a large gap in applying these paradigms of subclinical deficiency to pet populations. Furthermore, the lack of clinical or even canine or feline in-vitro investigation prevents any postulation as to their effects on cancer cells.

Antioxidants/Supplements

Utilization of supplements, most commonly substances termed *antioxidants*, has grown tremendously in the past 15 years. Studies suggest that approximately 65% of pet owners are using some sort of alternative treatments—over 30% are oral supplements and over 50% say their veterinarian approves of this use.¹²⁵ In oncology referral centers, the general recommendation to clients is to refrain from using antioxidants or herbal supplements due to the lack of clinical data to support their use.¹²⁶

It is clear that antioxidant and oxidative balance is altered in tumor tissue. Canine mammary cancer tissue has been shown to have an increased presence of lipid peroxidation coupled with an increase in upregulated antioxidant mechanisms, including glutathione peroxidase, glutathione, superoxide dismutase, and catalase.¹²⁷ In dogs with lymphoma, reductions in serum antioxidants (tocopherols) and increased lipid peroxidation were observed, whereas total oxygen radical absorption capacity and glutathione peroxidase were increased, suggesting an increase in antioxidant capability.¹²⁸ Therefore the addition of an antioxidant is unlikely to have a dramatic effect on the overall antioxidant capability of tumor cells when compared to normal tissue.

Further complicating this issue, many substances given as “antioxidants” may be considered pro-oxidants in some environments.¹²⁹ Many isothiocyanates, flavonoids, and carotenoids that clients use may actually cause alteration of cell signaling or depletion of specific antioxidant systems.^{129,130} Furthermore, there is increasing evidence that many of these compounds upregulate or downregulate specific or sometimes global cell signaling systems to alter the proliferative cycle from activities such as cell cycle disruption (cyclin-dependent

*References 35, 36, 41–43, 112–114.

kinase [CDKs], p16, p21), prosurvival signals (nuclear factor- κ B [NF- κ B], AKT), mitochondrial-induced apoptosis (bcl and bax family proteins), and proliferative signaling pathways (i.e., mitogen-activated protein [MAP] kinase, tyrosine kinase [TK] activity).¹³¹⁻¹³³ Recent primary cancer cell culture data in lymphoma and OSA support these principles. Astaxanthin and lycopene, two carotenoids, showed limited antioxidant capability in canine OSA cell lines, and when coupled with the chemotherapeutic agent doxorubicin or irradiation, there were no protective effects on cell proliferation indices or cell death,^{134,135} whereas isoflavones appear to induce mitochondrial apoptosis in canine lymphoma cells.¹³⁶

Even if some of these compounds have little to no detrimental effect on current chemotherapy or radiation protocols, the limiting factor to their effective use is absorption, hepatic metabolism, and the attainment of tissue concentrations that recapitulate what has been used *in vitro*.¹³¹ Pharmacokinetic data have been collected on three nutraceuticals: genistein (an isoflavone) in cats, epigallocatechin gallate (EGCG, a flavone from green tea) in dogs, and lycopene in dogs (carotenoids). All of these nutraceuticals required dosing at very high concentrations, which may preclude their use. There is a tremendous disconnect from what is available and what may be required, as well as a lack of clinical investigation to assess efficacy and safety except for the few examples listed above. Furthermore, metabolism of these compounds may be different in cats and dogs; therefore caution is advised. Doses of over 150 mg/kg of EGCG in dogs caused hepatic necrosis, and the use of lipoic acid (an antioxidant thought to help salvage glutathione) has potential for toxicity and hepatic damage in cats, when used at doses thought safe in dogs and humans.^{137,138}

In conclusion, set nutritional requirements for cancer-bearing companion species do not exist. In part, this is due to the variety of neoplastic diseases involved and the danger in trying to extrapolate data generated in human trials. There remain many aspects to address, including nutritional interventions (during treatment and remission) for anorexia/cachexia and nutrition recommendations based on specific disease processes. Therefore there is no one dietary recommendation for cancer patients; rather each case should be evaluated based on the body condition of the patient, the specific neoplastic process, and the treatment protocol initiated by the oncologist. The topics discussed are merely guidelines for interested clients and clinicians, and the most important factor in nutritional intervention is to supply a complete and balanced ration that meets the energy requirements of the patient to prevent weight loss.

■ SECTION C

Relationship-Centered Approach to Cancer Communication

JANE R. SHAW

The increasing recognition of the relationships that people develop with their companion animals^{1,2} brings an awareness of the impact of animal illness on pet caregivers and the veterinary team.³ Rising acknowledgment of pets as family members has also been

associated with increasing expectations of pet owners for the highest quality medical care for their companion animals, as well as compassionate care and respectful communication for themselves.^{1,4,5} The human-animal bond is particularly stressed and fragile when an animal is sick and even more so with a cancer diagnosis. Appreciating the impact of animal companionship on the health and well-being of humans creates a new dimension in public health. The responsibilities of veterinary professionals have expanded to include the mental health and well being of their clients, as well as their clients' pets.⁴

Cancer communication presents challenges for both oncologists and clients. From the veterinarian's perspective, a number of factors^{6,7} may contribute to discomfort, including lack of training, being short of time, practice culture, feeling responsible for the patient's illness, perceptions of failure, unease with death and dying, lack of comfort with uncertainty, impact on the veterinarian-client-patient relationship, worry about the patient's QOL, concerns about the client's emotional response, and their own emotional response to the circumstances. Some of these same reasons may account for client anxiety during difficult conversations. These include self-blame, unease with death and dying, anticipatory grief, effect on the human-animal bond, impact on the veterinarian-client-patient relationship, pet's QOL, and concerns about their emotional response to the situation. Research⁶⁻⁹ in human medicine indicates that end-of-life discussions are often suboptimal due to many of these barriers and a lack of specific training in communication.

The content, duration, and methods of communication training in veterinary curricula are highly diverse and variable. Many practitioners have not received formal communication training and may feel unprepared to engage in difficult conversations.^{10,11} The veterinary profession has identified a skills gap between the content of the veterinary school curriculum and the actual skills required to be a successful veterinarian.¹² Using experiential techniques, defining key skills, and creating opportunities to practice them enhance effective communication.¹³⁻¹⁵ In accreditation standards, the American Veterinary Medical Association Council on Education recognizes communication as a core clinical competency for success.

Several aspects of cancer care make it a unique communication context.¹⁶ The diagnosis is frequently made by the primary care veterinarian who may refer the client and patient to an oncologist. Therefore the first visit with the oncologist often occurs after the patient has been diagnosed and the focus of the conversation is on confirming the diagnosis, treatment information, and decision making. In this setting, tough conversations occur on the back of a newly formed veterinarian-client-patient relationship. Cancer is an emotionally laden diagnosis, and clients often present with high levels of uncertainty, anxiety, fear, frustration, and guilt, which heightens the stakes for both parties. Fortunately, today we can offer clients a menu of sophisticated diagnostic and therapeutic options to treat their companion animal's cancer. The challenge is navigating the complexity of the information and the decision-making process of making the "right choice" for their pet without overwhelming the client. It may require as much listening as talking to hear what is most important to your clients to address these challenges.

There are six functions of relationship-centered communication in cancer care: exchanging information, making decisions, fostering healing relationships, enabling clients to provide patient care, managing uncertainty, and responding to emotions.¹⁷ Cancer communication is a process that occurs over time, starting with

delivering the diagnosis (i.e., often delivering bad news), discussing prognosis, making decisions about treatment options, assessing QOL, transitioning to palliative or supportive care, and ending with preparing families for euthanasia, dying, and death.¹⁸ These difficult conversations are spread throughout multiple visits, as the relationship grows and a partnership develops with the client in caring for the patient.

The purpose of this section is to present best practices for cancer communication. There are limited empiric studies in the veterinary literature concerning veterinarian-client-patient communication, and information pertaining specifically to oncology is based largely on clinical experience. In contrast, the literature on human medical communication contains a large number of empiric studies; however, in relation to cancer communication, what is available is based on expert opinion, case studies, reviews, and predominantly descriptive studies.^{16,18} The objectives of this section are to describe relationship-centered care, define core cancer communication skills, and highlight communication approaches to difficult discussions. The medical cancer communication literature^{7,9,18-20} and clinical experience provide the foundation for communication techniques presented here.

A Paradigm Shift: Paternalism to Partnership

Recent societal changes have caused a paradigm shift in the veterinarian-client-patient relationship. Growing client expectations, the strong attachment between people and their pets, and increasing consumer knowledge demand a shift in communication style from the traditional paternalistic approach to a collaborative partnership.^{5,21,22} Many clients are no longer content with taking a passive role in their animal's healthcare, preferring to take an active role in the decision-making process.⁵

Paternalism is characterized as a relationship in which the oncologist sets the agenda for the appointment, assumes that the client's values are the same as the veterinarian's, and takes on the role of a guardian for the patient.^{23,24} Traditionally, paternalism is the most common approach to medical and veterinary visits. In general practice, the veterinarian used a paternalistic approach in 31% of wellness visits and 85% of problem visits.²¹ The topic of conversation is primarily biomedical in nature, focusing on the medical condition, diagnosis, treatment, and prognosis.²¹

In a paternalistic relationship, the oncologist does most of the talking and the client plays a passive role. This approach is often referred to as the *data dump* and symbolized by a shot-put.²⁵ Throwing a shot-put is unidirectional, the intent is on the delivery, the information to be delivered is large in mass and scale, and it is challenging to receive the message. Intuitively, it seems like this directive approach enhances efficiency and promotes time management. The challenge is that the agenda and subsequent diagnostic or treatment plan may not be shared between the oncologist and client, compromising the ability to reach agreement, move forward, and achieve full compliance. This could result in a roadblock and the need to take steps backward to recover and regain client understanding, commitment, and trust.

In contrast, partnership or relationship-centered care represents a balance of power between veterinarian and client and is based on mutuality.^{23,24,26} In the relationship-centered model, the relationship between oncologist and client is characterized by negotiation between partners, resulting in creation of a joint venture, with the veterinarian taking on the role of advisor for the client. Respect for

the client's perspective and values and recognition of the role the animal plays in the life of the client are incorporated into all aspects of care. In general practice, 69% of wellness visits and 15% of problem visits were characterized as relationship-centered.²¹

The conversation content of relationship-centered visits is broad, including biomedical topics, lifestyle discussion of the pet's daily activities (e.g., exercise regimen, environment, travel, diet, and sleeping habits) and social interactions (e.g., personality or temperament, behavior, human-animal interaction, and animal-animal interactions) that are key indicators of patient quality of life.²¹ In addition, a relationship-centered approach encompasses building rapport, establishing a partnership, and encouraging client participation in the animal's care, all of which have the potential to enhance clinical outcomes.

This collaborative relationship is symbolized by a Frisbee.²⁵ In playing Frisbee, the interaction is reciprocal; the intent is on dialog; the delivery is airy, light, and free; small pieces of information are delivered at a time; and the deliverer and receiver adjust their message to stay on target. The emphasis of the Frisbee analogy is on eliciting client feedback to assess how the client perceives, processes, and understands the information presented.

Relationship-Centered Care

Combining several frameworks, Mead and Bower²⁷ identified the following five distinct dimensions of relationship or patient-centered care in the human medical setting:

1. The biopsychosocial perspective—a perspective on illness that includes the social and psychologic, as well as biomedical factors.
2. The “patient as a person”—understand the personal meaning of the illness for each individual patient.
3. Sharing power and responsibility—sensitivity to patients' preferences for information and shared decision making.
4. The therapeutic alliance—developing common therapeutic goals and enhancing the physician-patient relationship.
5. The “doctor as person”—awareness of the influence of the subjectivity of the doctor on the practice of medicine.

These principles translate readily to the veterinary context.^{21,22} Expanding data gathering to explore the broader lifestyle of the client and pet enhances the understanding of the animal's illness. Discussing unique details such as financial resources, the role of the primary caregiver, feasibility of implementing the plan, and recent life events (i.e., new birth, death, new job, or moving) promotes compliance. With increased recognition of the human-animal bond, it is important to assess the level of attachment and the impact of the animal's illness on the family. Eliciting information on the client's expectations, thoughts, feelings, and fears about the pet's illness fosters client participation and satisfaction and promotes shared decision making.

Based on medical communication studies, the following principles of relationship-centered care are associated with significant clinical outcomes:

1. Broadening the explanatory perspective of disease beyond the biomedical to include lifestyle and social factors is related to expanding the field of inquiry and improved diagnostic reasoning and accuracy.²⁵
2. Building a strong relationship is associated with increased accuracy of data gathering,²⁵ patient satisfaction,²⁸⁻³⁰ and physician satisfaction.^{31,32}
3. Encouraging participation, negotiation, and shared decision making promotes patient satisfaction,²⁸⁻³⁰ adherence,³³ and improved health.³⁴

In veterinary medicine, a study investigating the use of patient-centered communication in euthanasia discussions with undisclosed standardized clients identified that veterinarians did not fully explore client feelings, ideas, and expectations.²² In these visits, veterinarians did not involve clients in defining the problem and identifying treatment goals. Shared decision making is a key component of relationship-centered care, in which there is two-way exchange between the veterinarian and client, identifying preferences and working toward consensus to achieve significant clinical outcomes for the veterinarian, client, and patient.

Core Communication Skills for Cancer Communication

The Calgary-Cambridge Guide²⁵ is an evidence-based communication model that provides structure to the clinical interview, describing the tasks and identifying key communication skills to help veterinarians achieve clinical outcomes. Defining and demonstrating specific skills and behaviors are instrumental first steps to enhancing communication approaches.^{14,15} The communication tools described next were identified as core communication skills¹⁵ in human cancer communication literature^{7,13,18,20} and are highly applicable to veterinary oncologist-client-patient interactions.

Gathering Information

Identify the Client's Full Agenda

Eliciting the client's full agenda through open-ended inquiry promotes early detection of the problem(s) and sets a plan for the rest of the visit.³⁵ An open-ended question is designed to draw out a full response from the client rather than a brief one and usually begins with "how," "what," or "tell me or describe for me."³⁶

"What brings you and Mandy in today?" [open-ended question]

"What other questions do you have about Mandy's cancer?" [open-ended question]

"Anything else you would like to discuss?" [open-ended question]

This process of questioning may seem redundant, but clients often bring a laundry list of concerns, questions, or topics that they would like to discuss with their oncologist. Given the overwhelming nature of cancer conversations, these steps help identify the key questions and information sought by the client. Helping to generate the client's list of concerns and melding it with your agenda will set the structure for the remainder of the appointment and optimizes use of the visit time.

Elicit the Client's Perspective

Invite the clients to share their thoughts, ideas, feelings, and perceptions.²² How the client perceives the patient's illness can have a major impact on the decision-making process and compliance. Many clients have had previous experiences with cancer, and it is helpful to hear these stories to address client concerns, provide reassurance, and identify misconceptions or barriers to patient care. Pick up on client verbal cues (*"I am not sure how she will do with chemotherapy."* or *"I am really concerned about her loss of appetite."* or *"My big fear is that we won't get quality time"*). Knowing the client's expectations enables you to get on the same page and customize the message to the client's concerns and meet their needs.

"What are your goals for treating Mandy's cancer?"

"I am wondering about what experiences you have had with cancer in your life, as it may impact decisions we make for Mandy."

"How are you doing with all of this?"

"What are your greatest hopes in caring for Mandy?"

"What are your greatest fears in treating her cancer?"

Explaining and Planning

Assess the Client's Knowledge Level

Assessing the client's prior knowledge and experiences allows you to evaluate the client's understanding and determine what level to pitch the information.²⁵ An equally important goal is to ascertain the type and kind of information the client desires because not all clients may want the same degree of information. Client preferences for information may change over time; initially, overwhelmed clients may want just the big picture and as they absorb and process the information, they may produce a list of detailed questions for follow-up discussions.

"What have you heard or read about osteosarcoma?"

"I am wondering what your veterinarian told you about Mandy's cancer."

"What other questions would you like me to address today?"

"What additional information will be helpful to you?"

"Some clients prefer the big picture and for others it is important to get into the details. What is your preference?"

Give Information in Manageable Chunks and Checks

Chunks and checks (chunk-n-check) consists of giving information in small pieces (i.e., chunks), followed by checking for understanding before proceeding further (i.e., check)—the Frisbee approach in action.²⁵ Sharing small pieces of information, one to three sentences at a time, allows your client time to absorb the news, and checking-in encourages client participation in the discussion and ensures that the client stays with you to achieve shared understanding. This approach to information giving avoids lecturing to the client and aims to increase recall, understanding, and commitment to plans. In this manner, the information-giving process is responsive to the client's needs and provides an opportunity for the client to participate in the conversation, provide feedback, or ask for clarification. The check can take on various forms such as taking a pause, encouraging the client to contribute to the conversation (*"What questions do you have at this point?"*), picking up on client cues (*"You seem a little hesitant about surgery."*), asking for client suggestions (*"What options have you and your husband discussed?"*), and checking for the client's understanding (*"What part of the plan will be most difficult for you and Mandy?"*).

Building Relationships

Offer Partnership

Partnership is inclusive language (i.e., let's, we, together, our, or us), which reflects that you and the client are working as a team toward mutual goals. Offering partnership informs the client that they are not alone and that they have a working partner in their oncologist, who will guide and advise them at each stage. Often, clients may arrive at their oncology appointment on their own and it may be helpful to assess their support system and offer to include other key decision makers in the conversations.

"What else can I do for you and Mandy today?"

"We'll work together to determine the best treatment plan for Mandy."

"I'm here for you. Take your time. We have a few days to decide how to proceed."

"Who else will take part in making decisions in Mandy's care?"

Ask Permission

Asking permission is a gentle approach to assess the client's readiness to take the next step. This act of respect allows the client to ready their minds, be receptive to what you have to say, and pace the conversation with you. Asking permission is a method of structuring the conversation by proposing a transition to the client and to determine whether they would like to move on.

"Would it be all right if we sit down and I asked you some questions about Mandy?"

"I am wondering if we could talk more about pain management."

"Are you OK with talking about how we might debulk the tumor?"

"Maybe you could write down your specific questions before our next visit."

Express Empathy

The stress of cancer can result in intense emotions: sadness, fear, anxiety, uncertainty, and guilt, and acknowledging these emotions reduces client distress. Empathy is an affective response resulting from perceiving the situation of another, vicariously experiencing what it might be like, and paying deep attention to another person's emotions. As a result, there are three tasks to expressing empathy.³⁷

The first is to appreciate the client's situation, perspective, and feelings and their attached meanings. The second is to communicate that understanding back to the client and check its accuracy. The third is to move forward in the clinical interview and act on that understanding with the client and patient in a helpful way. Simply, empathy is putting yourself in the client's shoes and communicating that you understand where they are coming from. Expressing empathy acknowledges, validates, and normalizes the client's emotional response and is essential to establishing a trusting veterinarian-client-patient relationship.³⁶

"I'm so sorry to tell you this. I know it was not what you were expecting."

"I can only imagine how hard this is to hear. Mandy has been your companion for so long."

"I can see that you are agonizing over the right decision for Mandy."

Demonstrate Appropriate Nonverbal Behavior

Expression of all of the verbal core communication skills is strengthened when accompanied by complementary nonverbal communication.³⁶ As much as 80% of communication is nonverbal in nature, whereas 20% is based on verbal content.²⁵ When verbal and nonverbal communication are incongruent with each other, the nonverbal behaviors reveal the truth. There are two areas of focus for nonverbal communication: the first is to increase your sensitivity to picking up on client cues and the second is enhanced awareness of the nonverbal messages you are sending out. Tune in closely to client nonverbal behaviors such as breaking eye contact, nervous body movements, or tone of voice because client nonverbal behaviors often reflect their true underlying feelings and responses. Out of respect for their relationship with their oncologist, clients often express hesitation indirectly through their nonverbal behaviors and may not feel comfortable with directly verbalizing their concerns. It is important to pick up on these client cues and follow-up on them with the client to explore the concerns (*"I sensed some hesitation when I mentioned chemotherapy as a treatment option."* or *"You seem worried about taking Mandy to surgery, what are you most scared about?"*).

Veterinarian nonverbal cues include attentive body posture, appropriate distance from the client, turning your body toward the

client, sitting at the same level, maintaining good eye contact, and complementary gestures. Display your compassion through nonverbal cues such as sitting close to your client; using a gentle, calm tone and soft volume; slowing your pace of speech; and leaning forward and reaching out through touch. Use silence to create time for the client to examine his/her thoughts and feelings. It can be difficult at times to find the right words to say and simply being a caring presence can provide just as much comfort to the client as any spoken words. Being mindful of the messages sent is important because when veterinarians are triggered or feeling judgmental, these sentiments can be leaked to the client through nonverbal behaviors.

Providing Structure

Summarize

Summarizing is an explicit review of the information that has been discovered and discussed with the client. Therefore there are multiple opportunities to present a summary: reflect back what you heard and learned at several stages during information gathering, then take time to repeat the key aspects of the diagnostic and treatment plan, and finally provide a full and complete summary at the end of the clinical interview. Summarizing helps structure the conversation by reviewing what has been discussed, identifying data that needs further clarification, providing an opportunity for reflection on where the interview should go next, and managing effective use of time during the visit.²⁵ The skill of summary creates a window to inform the client that they have been heard and time for the clinician to gather their thoughts, synthesize and integrate the data, and work through the diagnostic reasoning process.

"So, if I understand it correctly, your referring veterinarian felt the large lymph nodes, took a sample, and diagnosed lymphoma. You were sent here for further testing to determine if the lymphoma has spread to other organs. Is that correct?"

"What we talked about doing today, is requesting a second opinion from our pathologist on the tumor sample and conducting an ultrasound exam to look at the abdominal lymph nodes, liver, and spleen for spread of the tumor."

"I Don't Have Time for This..."

Before moving on to how to use these skills in crucial cancer conversations, one of the most common concerns expressed in communication training is that there is not enough time in the clinical interview. It seems like the facilitative approach (i.e., Frisbee) of relationship-centered care takes more time; however, it was found in veterinary general practice visits that relationship-centered care appointments were shorter in length because the veterinarian and the client achieved common ground.²¹ In human medicine, when patients are left to tell their story uninterrupted, their average talking time was 92 seconds, sharing key clues to the diagnosis.²⁵ Empathy can be expressed as well without prolonging the appointment time; in one study, as little as 40 seconds of empathy decreased the patient's anxiety level.^{38,39} Although counterintuitive, evidence suggests that using the core communication skills actually saves time and allows for a more efficient veterinarian-client-patient interaction. In addition, spending time to build a relationship at the beginning of the evaluation process creates trust, which will pay dividends as the management process progresses through the diagnostic and treatment phases.

Approaches to Cancer Conversations

As presented in the introduction, cancer communication is a series of conversations over time, starting with delivering the diagnosis (i.e., delivering bad news), discussing prognosis, making decisions about treatment options, assessing QOL, transitioning to palliative or supportive care, and ending with preparing families for euthanasia, dying, and death.¹⁸ These difficult conversations are spread throughout multiple visits. This step-by-step approach is guided by the veterinarian's expertise, the client's agenda and perspective, and the patient's condition, response to treatment, and QOL.

Delivering Bad News

Bad news is defined as any news that drastically and negatively alters the person's views of her or his future with their pet such as a cancer diagnosis.⁷ Clients interpret bad news on an individual basis and their response is related to their relationship with their companion animal, severity of the diagnosis, past experiences, other stressors in their lives, and their support system. Grief often accompanies change, and clients may express a wide range of emotions that are largely unpredictable. One useful model for delivering bad news is the SPIKES six-step model developed by Buckman⁷ and employed in many medical school curricula. The SPIKES model⁷ (setting, perception, invitation, knowledge, empathize, and summarize) provides guidelines on how to present information, structure the conversation, and create a supportive environment. Communication techniques for delivering bad news in the veterinary setting were previously published.^{40,41}

Discussing Prognosis

Three different approaches have been described in the medical communication literature for presenting prognostic information—realism, optimism, and avoidance.⁹ The challenge with realism in human medicine is that approximately 20% of patients do not want full information about their prognosis,^{42–45} and unfortunately such studies of client perceptions are lacking in veterinary medicine. The drawback of optimism is that clients may lose opportunities to fulfill last wishes, prepare themselves and their family, and spend quality time with their pet. Finally, the shortcoming of avoidance is appearing evasive or dishonest, risking the trust that has been built between veterinarian and client potentially compromising the care of the pet.

Based on recommendations in human medicine,^{9,18,19} be mindful of making assumptions about what the client wants to know and instead explicitly ask if and how the client wants to talk about prognosis (*"How much would you like to know about the course of Mandy's cancer?"* or *"Some clients would like all the details and others would like the big picture. What works best for you?"*). It is effective to break the information into small pieces (i.e., chunk) and then to check for client understanding and for how the prognostic information is impacting the client (*"This is hard to talk about."* or *"I am wondering if this is the kind of information you need."*). Asking permission is a key skill in this conversation to assess the client's readiness to hear more information (*"What questions do you have at this point?"* or *"Would you like me to continue?"*), along with reading the client's nonverbal cues to assess how they are processing the information (*"I notice that you seem hesitant when I was talking about survival time with chemotherapy. Could you tell me more about this?"*). To balance sustaining hope and maintaining reality, it may

be helpful to frame the prognosis, using both positive and negative language (*"Median survival time means that half of the patients live longer than 2 years and half the patients live less than 2 years."*).

Given the overwhelming nature of this discussion, take time to acknowledge the client's emotional reactions (*"This is a lot of information to take in. How are you doing?"* or *"This is really difficult to talk about and we can take it one step at a time."* or *"I can see how sad this is for you."*). Allowing for silence or offering to take a break creates space for clients to work through their emotions and process the information shared with them. It can be difficult for clients to recall and understand all of the data presented, so you may want them to invite friends or family to take part (*"Who else plays a role in caring for Mandy? I am wondering if they might want to be part of this discussion."*). As this is an emotionally laden conversation loaded with complex information and associated with decision-making, it is helpful to compose and center yourself beforehand, pace yourself with your client, and offer some time for reflection.

Assessing Quality of Life

In human medicine, a spectrum of hopes has been described from the initial cancer diagnosis to preparing for death.⁴⁶ With a cancer diagnosis, a client's initial hopes may center around curing the cancer and the pet living longer and then move toward spending special time with loved ones, finding meaning, and then seeking a peaceful death. This reflects the transition that many veterinary clients go through in caring for their companion animal with cancer. This breakpoint discussion is a crucial conversation that signals the transition from fighting for quantity of time to fighting for QOL.⁴⁷ It can be challenging for clients who have been working so hard to fight the cancer to shift their energy to living the fullest life with their pet right now and preparing to let go (*"It can be difficult to switch gears from fighting the cancer to preserving Mandy's quality of life."* or *"It seems like it may be helpful to focus on what time Mandy has left with you."* or *"Just because we can do something does not mean that we should."*).

Eliciting the client and patient goals may help in moving the conversation forward (*"Can we create a plan together to ensure Mandy's quality of life?"* or *"Let's focus on what we can do to help Mandy now."* or *"What is most important to you in caring for Mandy at the end of life?"*). A supportive way to acknowledge the client's desire to do more is through expressions of *"I hope"* or *"I wish"* statements (*"I wish there were something we could do to cure Mandy's cancer."* or *"I hope that Mandy has many good weeks ahead."*).⁴⁸ At this stage, it is equally important to reflect on the oncologist's conversational emphasis and what influence the presentation of information may have on client decision making⁴⁹ such as how much time is spent talking about anticancer therapy compared to QOL, supportive care, or euthanasia. Inadvertently, the veterinarian can influence the client's decisions because of the prioritization placed on the options for care.⁴⁹

As a source of validation and support, clients may also need to hear from their oncologist that they did everything they could for their pet (*"You have given Mandy every chance possible."*).⁵⁰ Words of reassurance and partnership can be highly supportive such as *"All along you have made your decisions with Mandy's best interests in mind."* or *"We will do this together, just as we have done everything that got us to this point."*⁵⁰ Clients are often overwhelmed and feel alone in the enormity of the decision to euthanize their pet, and it is comforting to know that their veterinarian will guide, advise, and inform them through the process.

Transitioning to Palliative Care

Fortunately, there is much that can be done for patient comfort, despite the inability to effect a cure, including symptom management, supportive care, and pain management to ease suffering. Depending on the resources in your region, it may be appropriate to refer the client and patient to a veterinary hospice service.^{51,52} Veterinary hospice is the patient care provided after a terminal diagnosis of weeks to months has been given and includes providing palliative treatment for the animal and emotional support for the family to prepare for the imminent death of the animal and focus on spending quality time together. At-home patient care entails administering medications, assessing and monitoring pain management, evaluating proper hydration and nutrition, and educating families about euthanasia, the grief process, and death and dying.⁵¹ Today, statements such as “there is nothing more we can do” can be replaced with words of encouragement and offers of partnership to comfort clients (*“There is still much that we can do to make sure that Mandy is content and comfortable.”*).⁴⁹

Client and patient abandonment may be a concern that arises during this stage of care. The value placed on the client’s relationship with the oncologist may increase as the patient’s cancer progresses, as the desire for information lessens and the need for support grows.⁵³ With the change in focus on the care provided from cancer treatment to palliative care, the client may perceive that the oncologist’s relationship with the client and patient has ended. Offering partnership helps create a sense of support for the client (*“We will work through these decisions together.”* or *“I will be here to help you and Mandy whatever your decisions may be.”*) Clients may want to hear explicitly that the oncologist will still be taking care of their pet, even if they decide to discontinue treatment. Depending on the client’s relationship with the oncologist and the primary care clinician, it may be critical to determine the client’s expectations and offer to maintain the relationship to provide end-of-life care. Caring for clients and patients at the end of life can be a source of meaning and fulfillment for the oncologist as well and an opportunity to recognize the special relationships formed during this difficult time.

Preparing Families for Euthanasia

Clients may be waiting for the oncologist to raise the option of euthanasia to give them permission to consider euthanasia as a valid and supported option (*“One of the options that is important to discuss is hospice care and euthanasia.”*). Clients may be worried that the oncologist may perceive them as “giving up” if they bring up the option of euthanasia and therefore clients may need your validation (*“It is a valid and caring decision to consider euthanasia at this time”* or *“Euthanasia is a humane option for Mandy given how the cancer has spread.”*). Client anxiety results from the uncertainty that lies ahead, and a large part of these conversations is helping clients cope.⁴⁷ Previously, clients had a clear plan for how to treat the cancer, and it may be helpful to have a designated path for how to care for their animal at the end of life. Discussing end-of-life wishes for the patient is crucial to preparing the client for euthanasia decision making, and creating a euthanasia plan often eases the client’s discomfort.⁴¹ Once completed, it can be put on the shelf until it is needed and the client can focus their energies on being present with their pet during these final precious days, weeks, or months. Being prepared ensures that the client’s needs are met and minimizes regrets during this difficult time of grief. Communication techniques for euthanasia decision making were previously published and provide guidelines on how to walk a client through making a euthanasia decision, discussing the procedure, and

presenting options for location, body care, memorializing, and family presence.^{41,54}

Providing Support for Grief and Loss

Research indicates that 70% of clients are affected emotionally by the death of their pet and that as many as 30% of clients experience severe grief in anticipation of or following the death of their pet.³ In addition, approximately 50% of clients studied reported feeling guilty about their decision to euthanize their pet. One of the factors contributing to client grief was the perception of the professional support provided by the veterinarian. The manner in which the veterinarian provides care for a client whose pet has died has the potential to alleviate or aggravate grief. A thorough description of client grief responses and techniques for providing emotional support were outlined in the previous edition of this textbook.⁵⁴

Caring for Yourself

Compassion fatigue is deep physical, emotional, and spiritual exhaustion that can result from working day to day in an intense caregiving environment.^{55,56} The natural response to this downward spiral is to work harder until there is nothing left to give, which is counter to the adaptive response of taking a break. The symptoms are the same as those of chronic stress and are a consequence of caring for the needs of others before caring for your own needs.⁵⁴ Compassion fatigue results from a lack of daily self-care practices that create opportunities to reflect, refuel, and rejuvenate. The good news is that feeling compassion fatigue results from being a deeply caring person. When oncologists care for themselves, they can care for others from a place of abundance not scarcity. With development of healthy self-care routines, practitioners can continue to successfully provide compassionate care to others. Recognizing the signs of compassion fatigue is the first step toward positive change, and the second step is making a daily firm commitment to choices that lead to resiliency. A thorough description of caregiver stress and stress management strategies was provided in the previous edition of this textbook.⁵⁴

Conclusion

Given the growing expectations of clients, the strength of the human-animal relationship, and the resultant emotional impact of cancer communication on pet caregivers and the oncology team, relationship-centered care is integral to providing quality cancer care.^{5,21,22} Extrapolating from evidence in human medicine, compassionate cancer communication is related to significant clinical outcomes for the oncologist, client, and the patient, including enhancing client²⁸⁻³⁰ and veterinarian satisfaction,^{31,32} improving adherence to recommendations,³³ working through emotions,^{38,39} and promoting patient health.³⁴ Effective techniques for cancer communication can be taught and are a series of learned skills.^{15,25} Through supportive approaches, cancer communication can be made less distressing to the client, fostering client relationships and optimizing patient care while promoting professional fulfillment for the veterinarian.

Complementary and Alternative Medicine for Cancer: The Good, the Bad, and the Dangerous

NARDA G. ROBINSON

Complementary and alternative medicine (CAM) constitutes a diverse and often controversial group of treatments that exist outside of mainstream medicine. Although CAM has yet to produce a single, proven cancer cure,¹ this does not stop some veterinarians and lay healers from continuing to claim that these products can “stop cancer in its tracks” or eliminate neoplasia. Other claims for CAM cancer treatments are not as extreme, and scientific evidence shows that some methods or products actually do benefit oncology patients.

Clients need their veterinarians’ help in navigating both factual and fictitious CAM options for their animal companions with cancer. As one human oncologist wrote,

It is no longer acceptable to patients for physicians to label all of these alleged treatments as ludicrous and unfounded. Medical professionals must be able to converse intelligently about them with patience and learn not to denigrate out of hand those who utilize alternative and complementary techniques, as long as they are safe. Physicians must also warn patients of danger and hoaxes when that is appropriate.²

One way to assist clients is by indicating which CAM treatments have evidence of both efficacy and safety and which ones are deemed ineffective or unsafe.^{3,4}

The popularity of CAM is undeniable. For human patients with cancer, the usage rate is well over 50%.⁵ A 2006 survey of clients who brought their pet to the Colorado State University Animal Cancer Center found that 76% of surveyed owners used CAM to improve well being. Other reasons they provided included attempting to reduce pain and treatment toxicity, as well as to improve appetite.⁶ However, a majority of those surveyed had not yet spoken to their veterinarian about CAM. If clients seek input and treatment from nonveterinarian practitioners in lieu of science-based veterinary professionals, patient health and safety could be jeopardized. Lay healers’ lack of formal veterinary medical training hinders their capacity to coordinate medically sound recommendations for animals. Nonveterinarians are, for the most part, unable to rapidly identify health problems and intervene effectively in disease progression. For cancer patients, delays in prompt and appropriate medical attention may make an otherwise treatable condition resistant to therapy.⁷

The veterinary medical profession and educational institutions owe their students and graduates scientific, evidence-informed CAM instruction in both undergraduate curricula and continuing education courses. As Memon et al found in their 2011 survey of veterinary college academic deans,

... CAVM [Complementary and alternative veterinary medicine] is an important topic that should be addressed in veterinary medical

education.... The most common comment reflected strong opinions that inclusion of CAVM ... must be evidence-based.... [S]tudents should be aware of CAVM modalities because of strong public interest in CAVM and because practitioners should be able to address client questions from a position of knowledge.⁸

Still, a client’s desperate search for nontoxic alternative or adjunctive therapy can lead some to consider unproven remedies. The penchant of some practitioners to promote products designed to treat cancer is too often based on belief systems rather than strong science and evidence. Even within the veterinary profession, holistic “healers” continue to claim to have found a “powerful” mixture of Chinese herbs, homeopathic remedies, or invisible energy manipulations that will cure, treat, or prevent cancer. This belief-system basis of CAM practice has prevailed entirely too long. It perpetuates learning CAM methods in the absence of critical thinking and sidesteps concerns about best practices and evidence-informed options. This puts clients in the difficult position of all too often opting for CAM approaches based on their faith in a charismatic practitioner rather than evidence-driven outcomes.

Thankfully, research on integrative approaches for humans with cancer is building steadily. As such, elevating CAM cancer care by replacing folklore with facts and metaphors with meaningful mechanisms is becoming a real possibility. The information in this chapter is designed to help veterinary professionals sort between a range of CAM modalities according to their scientific basis (or lack thereof) and evidenced-based insights concerning their potential to impart real benefits to patients with cancer. For each treatment type included here, the discussion will address the good, bad, or dangerous aspects about the therapy.

Acupuncture

What Is Acupuncture?

Acupuncture involves the insertion of thin, sterile needles into certain sites on the body corresponding to influential neurovascular or myofascial zones that, when stimulated, promote analgesia, recovery of normal circulation and immune function, overall physiologic restoration, and homeostasis. In addition to needling, other forms of somatic afferent stimulation include acupressure, laser acupuncture, and electroacupuncture, wherein one clips electrode wires to the needles in order to augment the stimulation and neurologic response.

How Does Acupuncture Work?

Acupuncture counteracts pain and other adverse sequelae of cancer treatment through neuromodulation. It may reduce the levels of medication required.⁹ Nerve fiber stimulation begins at the needle-tissue interface, where local alterations in cytokines and

inflammatory mediators lead to modulation (i.e., normalization) of circulation and immune function in the immediate area surrounding the site around the needle. From there, agitation of the connective tissue and subsequent tugging of the collagen fibers, fibroblasts, and myofascia in the region produce activation of sensory somatic and autonomic nerve fibers. When excited, afferent pathways ferry action potentials along large nerve axons that underlie and often define the trajectory of acupuncture channels. A cascade of simultaneous central nervous system (CNS) and autonomic nervous system (ANS) changes follow soon thereafter, producing somato-somatic, somatoautonomic, and somatovisceral reflexes in spinal cord segments related to the excited nerve(s). In addition to propriospinal signaling, acupuncture incites a barrage of brain stimulation in the limbic system, the cerebellum, the cortex, and the brainstem. Functional brain imaging research illustrates, through changes in neuronal metabolism, which centers process pain, regulate autonomic function, and affect moods in response to acupuncture. This aids in the ever deepening understanding of the neurophysiologic premise underlying acupuncture.

How Might Acupuncture Benefit a Veterinary Patient with Cancer?

Human integrative oncology clinics have found acupuncture to be a safe, inexpensive, and valuable intervention for several problems that cancer patients often encounter, including leukopenia, gastrointestinal upset, and systemic reactions.⁹⁻¹² Acupuncture is often effective in reducing emetic effects of chemotherapy and opioids.¹³⁻¹⁸ For pain, acupuncture provides benefits along several routes, including normalizing muscle tone, deactivating myofascial trigger points, upregulating analgesic gene expression in the spinal cord, promoting segmental analgesia, reducing neuropathic pain, elevating endogenous opioid release, and promoting a sense of well being through pathways that influence the limbic system.¹⁹⁻²⁸ Acupuncture also activates natural killer (NK) cells that aid in anticancer immune mechanisms at least in part through its effects on neural circuitry connected to somatosympathetic reflexes.²⁹⁻³²

Through neurologic and circulatory modulation, acupuncture affects the diameter of arterial, venous, and lymphatic vessels, working to assist in the alleviation of chronic lymphedema, and accelerates wound healing.^{33,34} Patients with head and neck cancer also appear to benefit from acupuncture's effects on glandular function by helping to minimize xerostomia following radiation.³⁵⁻³⁸ Even for human patients with advanced, incurable cancer, acupuncture has been shown to alleviate a wide range of symptoms with no significant or unexpected adverse effects.³⁹ Any acupuncturist treating animals should have a thorough understanding of animal health and disease, as well as acupuncture anatomy and physiology, in order to minimize risk of injury.⁴⁰

Although acupuncture provides repeatable and measurable benefits for patients with advanced cancer, the treatment is underutilized.⁴¹ Whether due to lack of knowledge about the evidential support for acupuncture in cancer, its scientifically based mechanisms of action, or unsubstantiated bias against the technique, oncologists may forget to recommend it or resist requests for it.

The Importance of Approaching Acupuncture Scientifically

Despite accruing facts regarding the mechanisms and clinical benefits of acupuncture, a notable subset of practitioners continue to believe that acupuncture point stimulation moves invisible energy

(qi) through invisible pathways on the body (meridians). Although this misconception may not directly harm a patient, metaphysical misimpressions about how needling works may mislead veterinarians and clients in a number of ways. For example, certain energy-based acupuncture courses teach that veterinarians could successfully and easily treat cancer by selecting and stimulating a single acupuncture point chosen according to abstract ideas and psychic powers. The inventor of this technique alludes to "total disappearance or significant regression" of cancer in 80% of patients.⁴²⁻⁴⁴ This claim has no rational scientific mechanism nor has it been submitted to experimental scrutiny. It risks delaying proper treatment through conventional means and allowing the cancer to progress to an untreatable stage.

Conversely, myths have circulated within the veterinary acupuncture community for decades that acupuncture could raise the risk of metastasis by increasing blood flow to a tumor. This has led to unnecessary underutilization in patients who stood to benefit from this palliative, pain-reducing, and quality-of-life-supporting modality.⁴⁵

Herbs

Herbs for oncology clients typically offer anticancer, antiinflammatory, antioxidant, and/or analgesic benefits. Herbs to support quality of life include those that support wound healing (for example, during or after radiation therapy), anxiolytics to reduce the burden of cancer and conventional treatment on the psyche, and antiemetics. The pros and cons of representatives from each herbal category follow.

Do Herbs Have Anticancer Benefits?

Several phytochemicals influence the activity of cancer (whether in vitro cell cultures or in vivo). Perhaps the most common products include Asian mushrooms for their immune-enhancing benefits, curcumin (a component of the spice turmeric) and *Boswellia* (an oleoresin gum from the frankincense tree) for their antitumor and antiinflammatory activities, and topical bloodroot (sanguinaria) for its tumor-dissolving value. Most plant-based substances confer an antioxidant benefit; some phytotherapeutics such as green tea are strong enough that clinicians should consider the risk of antagonizing the benefits of chemotherapy if the two are co-administered.

How Do Herbs Work to Fight Cancer?

Natural products from both Asian and Western herbs have the capacity to inhibit proliferation, induce apoptosis, reduce angiogenesis, retard metastasis, and even enhance the effects of chemotherapy.⁴⁶⁻⁴⁸ The challenge, however, is to know which herbs to prescribe for each specific cancer type. Another mystery entails how the herbs' biochemistries interact and possibly interfere with conventional medication or chemotherapy.

The pharmacokinetics and pharmacodynamics of herbs are mostly a mystery for nonhuman animals, leading to questions about how the various veterinary species that receive these products metabolize and clear the xenobiotics (herbs). What is more concerning is the multiplicity and undisclosed quantities of herbs, animal residues, and toxic substances such as strychnine and aconite included in traditional Chinese veterinary medicine (TCVM) products.⁴⁹ Many TCVM practitioners have little to no understanding of the biochemical actions of a plant product, instead relying on metaphoric descriptions of the remedies' properties. In addition, TCVM practitioners may utilize unvalidated,

primitive, folkloric diagnostic methods in order to arrive at a quasi-diagnosis. They assemble subjective impressions derived from various physical observations and pulse palpation into a “pattern,” which is then matched to a TCVM compound that is supposed to address that pattern. This method is fraught with problems and pitfalls but is important to note because a large segment of veterinary herbalists adhere to this approach.

Veterinarians treating cancer patients should be conversant with not only the potential value of unconventional cancer approaches⁵⁰⁻⁵² but also their dangers. The likelihood of TCVM herbal toxicity and interactions is in part due to the sheer number of herbal (and animal) ingredients in each mixture. Most have never been tested in typical veterinary species, worsening confusion.

Recommending TCVM herbs based on rigorously derived discoveries in botanical research allows practitioners to discard untestable, abstract mechanisms of action such as claiming that they “resolve stagnation, invigorate Qi, and remove phlegm/damp accumulation.”⁵³ Medical professionals should, in contrast, insist on instruction that describes Chinese herb effects in simple, biologic language, especially when scientific investigations have already shown how they work. For example, astragalus upregulates host immune response and reduces chemotherapy toxicity, and *Oldenlandia diffusa* directly attacks tumor cells through apoptosis. One could then conceive of incorporating these two herbs into a combination with others that work through additive or synergistic means, rather than guessing at their metaphoric effects. An oncologist might choose a third herb that inhibits abnormal gene transcription activity (*Coix lachrymal*) and a fourth that promotes tumor necrosis (*Glycyrrhiza glabra*).⁵⁴

Until more becomes known about how Chinese herbs affect chemotherapy in veterinary cancer patients,

Caution should be taken when anticancer drugs are used in combination with herbal medicines, particularly for cytotoxic anticancer drugs with narrow therapeutic indices. Monitoring plasma concentrations of concurrently administered anticancer drugs and observing for possible signs of clinical toxicity are necessary when herbal remedies are used concurrently.⁵⁵

Computerized databases are further assisting oncologists by enabling determination of relevant, potential interactions between anticancer drugs and Chinese herbs.⁵⁶ Even oncologists in China are encouraging their colleagues to maintain a watchful eye for surprise sequelae. For example, one paper warned:

[P]rofessional complacency about TCM [Traditional Chinese Medicine] use is becoming less acceptable as the knowledge base of TCM-induced toxicities and interactions expands. Being rich sources of bioactive xenobiotics, TCMs are frequent causes of puzzling complications, including hepatotoxicity, nephrotoxicity, and hematologic disorders.⁵⁷

Some traditional Chinese herbal medicines (TCHMs) are chemosensitizing or radiosensitizing and thus may cause conventional treatment to work more robustly, whereas others directly antagonize medication through one or more mechanisms. Toxicity from Chinese herbs co-administered with chemotherapy may lead to diagnostic dilemmas when clinicians misattribute problems to the drug rather than the TCHM product, thereby delaying discontinuation of the appropriate compound.⁵⁷ In fact, Chinese herbalists in Taiwan who work directly with herbs in the raw form are finding themselves at increased risk of liver and bladder cancer, possibly

due to the heavy metal contamination of TCHMs and/or the intrinsic toxicity of some ingredients.⁵⁸ This heightened risk for urologic cancers, chronic and unspecified nephritis, renal failure, and renal sclerosis “highlights the urgent need for safety assessments of Chinese herbs.”⁵⁹

Public perception holds that TCHMs protect cancer patients’ health and well being during chemotherapy.⁵⁷ A double-blind, randomized, placebo-controlled study questioned this assumption, showing that TCHMs did not significantly reduce any of the hematologic toxicities (leukopenia, neutropenia, and thrombocytopenia) associated with adjuvant chemotherapy for breast and colon cancer.⁶⁰ Three licensed, experienced TCHM practitioners from China prescribed herbal formulas to patients on an individualized basis, since many believe this approach yields superior benefits. Even the myth that individualizing TCHMs produces better outcomes could be more folklore than fact.⁶¹ According to some critics, “[A]lmost all individualized herbal medicine is practiced without the support of any rigorous evidence about effectiveness whatsoever.”⁶² They continue,

The lack of standardisation and use of multiple herbs in a single prescription also greatly multiply the safety risks. There are additional risks associated with variability in the diagnostics skills of the practitioner, their awareness or lack of awareness of potential interactions, and their ability or inability to identify red flag symptoms indicating serious diseases requiring immediate mainstream medical treatment. Given the risks and lack of supporting evidence, the use of individualised herbal medicine cannot be recommended in any indication.

Despite these limitations, the potential for Chinese herbs to one day participate legitimately within a methodic, evidence-informed herb and chemotherapy regimen seems imminent. To this end, one group, the nonprofit Consortium for Globalization of Chinese Medicine (<http://www.tcmedicine.org>) has assembled a broad collective of scientists from academia and industry. Researchers are conducting national and international collaborative clinical trials along with experimental animal and in vitro studies. They aim to fulfill four basic regulatory requirements: batch-to-batch consistency in Chinese herbal preparations; evidence-based clinical effectiveness; safety; and rational understanding of mechanisms of actions, sites of biochemical impact, active ingredients, and drug-herb interactions.⁶³

For the most up-to-date information on the mechanisms, safety, and effectiveness of a given herb, veterinarians should consult the scientific medical databases. Literature searches through PubMed and CAB abstracts provide rational, up-to-date information and impartial reviews that are unavailable through herbal practitioners who base their recommendations on centuries-old folkloric practices and metaphoric mechanisms.

Additional Issues with Herbs for Cancer Patients

Herbs may interfere with blood coagulation, upregulate or downregulate drug metabolism systems, or otherwise interact unpredictably with conventional treatments.

Many common herbal products modulate intestinal P-glycoprotein and/or cytochrome P450 (CYP450) enzymes, producing clinically important herb-drug interactions.⁶⁴ Because of this, owners should disclose all dietary supplements and/or herbs they are giving the patient. The veterinarian should then weigh the

potential for interactions between the conventional treatment and the supplement against the proven benefits of the product and determine prior to treatment whether or not the patient should stop the product.

Whether an herb will interact with chemotherapy and/or radiation therapy is often unknown, although research is gradually illuminating when and how this can happen.⁶⁵⁻⁶⁷ Garlic, often recommended by holistic practitioners for cancer, induces the P-glycoprotein drug efflux transport system to aid the body in ridding itself of perceived toxins, such as chemotherapeutics.⁶⁸

Clinicians unaware of herbal antiplatelet effects may find themselves surprised by bleeding during biopsies or surgeries. Because of this, the American Society of Anesthesiologists recommends that human patients discontinue dietary supplements at least 2 weeks prior to surgery.⁶⁹ Botanicals such as angelica root (dong quai), German chamomile, red clover, and ginseng increase the risk of bleeding. Garlic, ginkgo, and saw palmetto also may have significant anticoagulant actions. Cancer patients may already have thrombocytopenia from chemotherapy or myelosuppression from bone marrow invasion that compromises their capacity to clot.

Herbs that have anticancer effects but contain phytoestrogens such as *Angelica sinensis* may adversely affect patients with hormone-sensitive cancer.⁷⁰

The task of assessing complex herb-drug interactions even in one species, the human, reveals the daunting number of considerations involved when designing research strategies. For example, the herb astragalus is a plant commonly employed for cancer treatment that potentiates host immune function. A 2006 metaanalysis of randomized trials concluded that, when combined with platinum-based chemotherapy, Chinese herbal formulations with astragalus improved survival, increased tumor response, and reduced toxicity from the chemotherapy in human patients with non-small-cell lung cancer.⁷¹ Critics of this metaanalysis questioned the findings, citing unevenness in treatment methods.⁷² Only two of the 30 studies utilized astragalus as a single agent; the rest involved combinations of plants. In addition, the species of astragalus studied in each case was unclear; was it *Astragalus membranaceus* (huang qi), whose major constituents include triterpene saponins and polysaccharides in the roots, or was another plant in the astragalus genus substituted in some cases? How did the amount of astragalus in each mixture compare, given that single herb preparations putatively contained 100% astragalus, whereas in others it was only one of up to 17 herbs. Finally, which part of the plant was used and how was it prepared? Decoctions, fluid extracts, and dry matter vary considerably in their concentration of active constituents; thus their biochemical make-up and resultant pharmacologic activity may differ dramatically.

Examples of Herbs for Patients with Cancer

Some of the most common herbs sought for their anticancer properties are presented next in order to illustrate the breadth of their mechanisms of action, as well as clinical considerations regarding toxicity and possible interactions with chemotherapy.

Asian Mushrooms

Mushroom mixtures and mushroom-derived polysaccharide preparations modify tumor response and improve immune function in patients with solid tumors.⁷³ The active agents in Asian mushrooms, polysaccharides, also possess antitumor effects through inhibition

of cellular proliferation and tumor growth, invasion, and angiogenesis.⁷⁴

A proprietary, protein-bound polysaccharide extract of *Coriolis versicolor* reduced serum levels of immunosuppressive acidic protein in stage II and III colorectal cancer patients, increased 5-year disease-free survival, and decreased relative risk of regional metastases.⁷⁵ A metaanalysis of three trials involving over a thousand subjects with colorectal cancer confirmed these results.⁷⁶ A variety of other medicinal mushrooms and extracts have proved beneficial, improving immune parameters such as NK cell activity and cytokines, without significant toxicity.

The still-unanswered question regarding medicinal mushrooms pertains to their risk or value in lymphoma, given their immunostimulatory effects. A study of a standardized extract of Maitake mushroom in dogs with lymphoma reported no objective value, although two dogs did develop hyphema and one developed petechiae.⁷⁷ These agents can inhibit platelet function; whether the bleeding noted in this study related to the Maitake mushroom or the lymphoma remained unknown.

Curcumin

Cancer cells employ various pathways to evade host defenses. This means that a drug or herb works best against cancer when it takes more than one route of action to attack the disease. In its interaction with several cellular proteins, curcumin^{78,79} constituents induce phase II detoxification enzymes, suppress tumor cell proliferation in several cancer cell lines, and downregulate transcription factors (nuclear factor κ B [NF- κ B], activator protein 1 [AP-1], early growth response 1 [EGR-1]). Curcumin downregulates enzymes such as cyclooxygenase-2 (COX-2), lipoxygenase (LOX), nitric oxide synthase (NOS), matrix metalloproteinase 9 (MMP9), urokinase-type plasminogen activator, and more. Curcumin also downregulates other factors and receptors such as tumor necrosis factor, chemokines, cell surface adhesion molecules, and growth factor receptors (e.g., epidermal growth factor receptor [EGFR], human EGFR 2 [HER2]). Curcumin acts antiangiogenically and enhances the cytotoxicity of certain chemotherapy drugs.

Curcumin causes cell death in several human cancer cell lines, including breast, lung, prostate, colon, melanoma, kidney, hepatocellular, ovarian, and leukemia. The effect curcumin has on cell death involves both the usual apoptotic mechanisms such as oligonucleosomal DNA degradation and alternative means. When resistance develops to apoptosis-inducing factors, curcumin can overcome this impediment through alternative cell-signaling pathways, such as mitotic catastrophe.⁸⁰ Mitotic catastrophe involves a morphologically distinct and aberrant mitotic process that distinguishes it from apoptosis, characterized by the formation of giant, multinucleated cells carrying uncondensed chromosomes. Curcumin may also counteract the induction of prosurvival factors in cells generated by radiation therapy and chemotherapy.

Human clinical trials demonstrate no dose-limiting toxicity when given up to 10 g of curcumin in 1 day.⁸¹ The amount of curcumin contained in turmeric averages only about 3% by weight⁸²; concentrated curcumin supplements therefore supposedly provide higher levels of the active constituent, provided that the label and actual contents agree. The hurdles of maintaining adequate blood levels of curcumin pertain to its low bioavailability, although absorption varies between species. One way to overcome delivery challenges could include coupling it with compounds that focus curcumin's activity toward specific target cells.

Curcumin could hypothetically negate some of the effects of chemotherapy because it affects so many pathways. Research

suggests that curcumin can inhibit chemotherapy-induced apoptosis in breast cancer cells, specifically in combination with camptothecin, mechlorethamine, or doxorubicin. The potential benefits of certain herbs should be considered and compared against the risks. For example, a synthetic analog of curcumin helped reduce doxorubicin-induced cardiotoxicity through an anticancer-antioxidant dual function in vitro.⁸³ Additionally, curcumin and catechin (from green tea) may work synergistically against cancer through cytotoxicity, nuclear fragmentation, and antiproliferative and proapoptotic effects.⁸⁴

Boswellia

Boswellic acids exhibit potent antiinflammatory properties in vitro and in vivo. Triterpenes in boswellic acid reduce the synthesis of leukotrienes in intact neutrophils by inhibiting 5-LOX, the key enzyme involved in the biosynthesis of leukotrienes, which mediate inflammation.^{85,86} *Boswellia* extracts exert immunomodulatory benefits by simultaneously inhibiting T-helper 1 (Th1) and promoting Th2 cytokine production.⁸⁷ They regulate vascular responses to inflammation⁸⁶ and stabilize mast cells.⁸⁹ In cases of intestinal inflammation, boswellic acids may modulate the adhesive interactions between leukocytes and endothelial cells by countering the activation of leukocytes and/or downregulating the expression of endothelial cell-adhesion molecules.^{90,91}

Specific to their anticancer properties, boswellic acids induce antiproliferation, differentiation, and apoptosis in leukemia cell lines.⁹²⁻⁹⁵ They exert cytotoxic effects on established human glioblastoma and leukemia cell lines, as well as on primary human meningioma cells.⁹⁶ Boswellic acids may help reduce cerebral edema in patients with brain tumors.⁹⁷

Side effects of boswellic acids include abdominal discomfort, nausea, epigastric pain, hyperacidity,⁹⁸ and diarrhea.⁹⁹

The presence of food in the stomach, as well as the type of food eaten, dramatically alters the bioavailability of boswellic acids, and bile acids significantly affect their absorption.¹⁰⁰ When human subjects ingested boswellic acids along with a high-fat meal, the areas under the plasma concentration-time curves and peak concentrations totaled several times higher than when the herbal preparations are taken in the fasting condition. A human study showed that the elimination half-life for *Boswellia* was approximately 6 hours, suggesting that oral administration would require dosing every 6 to 8 hours.¹⁰¹

Frankincense extracts, as well as boswellic acids themselves, display moderate-to-potent inhibition of human drug-metabolizing CYP450 enzymes,¹⁰² but the clinical significance and comparative effects on nonhuman P450 enzyme systems remain largely unexplored.

Milk Thistle

Most veterinarians are familiar with milk thistle as a liver support supplement, but its value as an adjunct for cancer patients should not be overlooked. The most salient new applications for milk thistle arise in its role as an adjunct for cancer chemoprevention and treatment and to reduce side effects of treatment.^{103,104} Specifically, silymarin has led to reductions in tumor incidence and a number of chemically induced tumors in rat models for colon, tongue, and bladder cancer. It inhibits the growth of human prostate cancer and lung cancer xenografts in mice.¹⁰⁵ Milk thistle derivatives protect the kidneys from radiation injury and cisplatin nephrotoxicity.^{104,106} They may also protect the heart from doxorubicin-induced lipid peroxidation, as well as the liver from CCNU (lomustine) toxicity (see Chapter 11). When combined with

ω-3 fatty acids, milk thistle has reduced the number of radionecrosis sites in cancer patients and prolonged survival.¹⁰⁴ Milk thistle potentiated antitumor effects of drugs like cisplatin in both in vivo and in vitro studies.¹⁰⁴

The risk of herb-drug interactions from milk thistle appears to be low but not nonexistent. Milk thistle may inhibit certain isoforms of the CYP450 family, namely CYP3A4 and CYP2C9. This becomes significant when combined with agents that depend on CYP3A4 for metabolism, raising concerns about adding milk thistle for “liver protection” during chemotherapy, especially at high doses.¹⁰⁷ Silymarin has potentiated chemotherapy toxicity in at least one study.¹⁰⁴ However, a recent investigation testing its effects on the disposition of irinotecan as a model drug indicated that milk thistle poses little risk of interfering with agents of similar metabolic profile.¹⁰⁸ Still, evaluating clinically significant interactions for each target species will likely prove necessary, given the large interspecies differences in CYP450-mediated metabolic activities between humans, horses, dogs, and cats.¹⁰⁹

Milk thistle's ability to promote liver regeneration could conceivably stimulate tumor growth in cases of hepatocellular carcinoma.¹⁰⁴ An in vitro study showed that milk thistle demonstrated strong anticancer (i.e., proapoptotic and growth-inhibiting) activity against human hepatocellular carcinoma cells.¹¹⁰ However, silymarin/silibinin promoted mammary tumor growth in two rodent models. This likely occurred through stimulation of estrogen-receptor signaling by silymarin,¹⁰⁵ which raises caution about its safety in cases of breast cancer. Overall, the majority of patients tolerate even high doses of milk thistle. As with most herbs, adverse effects typically involve gastrointestinal upset, diarrhea, or inappetence, although practitioners should monitor blood chemistries and platelet function on a regular basis (at least every 6 months), if animals are taking herbs for months or years.

Bloodroot

Bloodroot extract is an escharotic that may be topically applied in a salve or injected directly into tumors.^{111,112} The “black salve” version of bloodroot (*Sanguinaria canadensis*) may come admixed with mineral agents such as zinc chloride, chromium chloride, or arsenic trisulfide and possibly other herbs. Bloodroot pastes became popular in the mid-twentieth century and have persisted despite risks of serious injury. It causes strong and rapid apoptotic responses through several modes of cell death, including an early and severe glutathione-depleting effect.

Sanguinarine, the active ingredient in bloodroot, supposedly targets only cancer cells, according to its enthusiastic supporters. Sanguinarine does appear to selectively target cancer cells over normal ones in vitro, and it may sensitize these cells to chemotherapy-mediated growth inhibition and apoptosis.¹¹³ Sanguinarine has also been reported to provide dose-dependent differential antiproliferative and apoptotic effects on cancer and normal cells.¹¹⁴ How tissue levels in vivo would compare to those tested in vitro is unknown, although high concentrations of sanguinarine can cause normal keratinocytes to necrose.¹¹²

Websites selling black salves for veterinary cancer patients generate undeniable excitement. One website lists pages of testimonials claiming quick and complete resolution of tumors deemed untreatable by conventional practitioners. Pictures of these tumors disappearing in a wide variety of animals make the message even more convincing. Even Dr. Andrew Weil, the author of the bestseller *Spontaneous Healing* and director of the Program in Integrative Medicine (PIM) at the University of Arizona in Tucson, claims that

black salve cured a tumor on his dog. Further, he advocates the use of black salve for skin growths on his website.¹¹⁵

However, the toxicity of bloodroot in dogs with cancer was recently reported.¹¹² Childress et al describe the case of two dogs from the same household who were submitted to intratumoral injection of a preparation commonly employed by holistic veterinarians who treat tumors with bloodroot. Both underwent surgical excision of the tumors following bloodroot extract injection. In one dog, histologic evaluation revealed severe necrosis and inflammation; this dog developed postsurgical wound complications and required rehabilitation to treat wound contracture. The other dog had a less severe response and an uncomplicated recovery. The authors

believe that bloodroot and other escharotics constitute potentially harmful herbal products, and that their use in the treatment of cutaneous neoplasia in domestic animals should be discouraged.... [E]scharotics may be manufactured without regard to accepted standards and therefore may contain unknown quantities of pharmacologically active compounds or toxic adulterants. Second, in the absence of biopsy prior to escharotic administration, escharotic treatment precludes accurate histologic identification of tumor type. Third, escharotic treatment prevents accurate in vivo or histologic assessment of tumor margins.... Fourth, escharotic treatment is painful and cosmetically unappealing. Fifth, escharotic treatment has no documented history of success in the human or veterinary medical literature. Sixth, escharotic treatment may be unnecessary [given the percentage of benign tumors that appear in veterinary patients that do not require aggressive treatment]. Finally, and most importantly, escharotic administration may delay or prevent definitive treatment by a more effective means, notably surgical excision, which is curative for many cutaneous tumors.¹¹²

They conclude

Veterinarians should be aware of the potential deleterious consequences of escharotic administration and should likewise discourage clients from using escharotics on their animals until indications for their use, appropriate dosages, and incidences and types of adverse effects are established in well-designed clinical trials.¹¹²

Yunnan Baiyao

Yunnan Baiyao (also known as Yunnan Paiyao) is a Chinese herbal mixture consisting primarily of notoginseng that has become a popular product among veterinary clients, particularly those caring for animals with hemangiosarcoma. This popularity is the result of the claim that Yunnan Baiyao regulates bleeding. Therefore patients with a high risk of hemorrhage might be less likely to bleed if Yunnan Baiyao was indeed effective.

Westerners first learned of the Chinese herbal mixture “Yunnan Baiyao,” meaning “the white medicine of Yunnan,” during the Vietnam War. Members of the U.S. military discovered that prisoners from North Vietnam often carried with them a tiny bottle of this product to take in the event that they were injured and bleeding, either internally or externally.¹¹⁶ Over the ensuing decades, Yunnan Baiyao has grown in popularity among complementary medical practitioners and even in some conventional medicine practices for its hemostatic and thrombolytic properties.

At first glance, the foil packet of Yunnan Baiyao capsules may seem puzzling because an unidentified little red pill lies at one end. Folklore has it that the North Vietnamese soldiers would take this red “hit pill” when seriously wounded, as in receiving a gunshot

wound, and this would check the bleeding. The *Chinese Herbal Patent Formulas* contain an equally curious recommendation for the hit pill: “In cases of serious wounds or bleeding, take the single red pill that comes with each bottle first, with wine.”¹¹⁷ The contents of this “hit pill” remain a mystery.

The Chinese doctor Qu Huangzhang developed Yunnan Baiyao in the Yunnan province of China in the early 1900s. The Yunnan province is known as “the Kingdom of Fauna and Flora” for its vast supply of plants and animals used in Chinese medicinals. Although the capsule’s contents remained a manufacturing secret until fairly recently, suspicion grew that its main active ingredient consisted of pseudoginseng root, now called *Panax notoginseng*, notoginseng, “tien chi,” or “san qi.”¹¹⁷ Notoginseng is a type of ginseng that offers the highest concentration of hemostatic constituents among all seven major ginseng types.¹¹⁸ Its origin in Yunnan makes sense because the notoginseng grown there outperforms that grown elsewhere in terms of crop yield and quality.¹¹⁹ Other substances in Yunnan Baiyao formulations vary between manufacturers and may include myrrh, ox bile, Chinese yam, sweet geranium, lesser galangal root, and possibly other antiseptics or astringent substances in a starch base. No contents of the hit pill specifically appear on the Yunnan Baiyao label, although it may contain a concentrated dose of notoginseng.

Studies done decades ago showed that Yunnan Baiyao activates platelets and decreases bleeding and clotting times. However, much more remains to be known about the effects of this Chinese herb on various species and for those patients with cancer. Limited information is available documenting the value of this product in both human and nonhuman patients. A prospective, randomized, double-blind, placebo-controlled study on Yunnan Baiyao for human patients undergoing bimaxillary orthognathic surgery found significant reduction in intraoperative blood loss when Yunnan Baiyao was administered presurgically for 3 days.¹²⁰ No thrombotic events or other side effects were noted during this short-term administration.

Additional indications in the future may arise for cancer treatment due to the cytotoxic effects of notoginseng,¹²¹ as well as its capacity to specifically sensitize tumor cells to ionizing radiation.¹²²

High doses of notoginseng could be toxic to bone marrow stem cells.¹²² In addition, the usual drawbacks to Chinese herbal products apply—lack of quality control, manufacturing regulations, and standardization.

In summary, as is so often the case for Chinese herbs, although Yunnan Baiyao appears to offer possible value, at this time its anecdotal acclaim outweighs the evidence, and unknowns regarding dosage, purity, and long-term benefits or risks persist.

Massage

What Is Massage and How Can It Help Cancer Patients?

Massage incorporates several methods of hands-on, low-force techniques that target restrictions and pain, mostly in the soft tissues of the body. The benefits that massage may hold for cancer patients encompass quality of life, control of postoperative or postprocedural pain and stress, and support of improved mobility and functional recovery following amputation. Cancer and its treatments can make people and animals physically uncomfortable. A 2011 study of patients with metastatic bone cancer, reported in the journal *Pain*, found that “[T]he reduction in pain with massage was both

statistically and clinically significant, and the massage-related effects on relaxation were sustained for at least 16-18 hours postintervention.¹²³ Massage was also shown to benefit subjects in terms of mood, muscle relaxation, and sleep quality. Research on massage supports its value for treating pain and stress¹²⁴⁻¹³¹; immune dysfunction¹³²; lymphedema¹³³⁻¹³⁷; relief of anxiety, nausea, depression, and fatigue¹³⁸; and chemotherapy-induced peripheral neuropathy.¹³⁹

How Does Massage Work?

Thanks to the rapidly expanding paradigm of autonomic neuromodulation and the desire by medical massage therapists to explain how their treatments work, a unifying theory is beginning to emerge: neurophysiology explains how and why soft tissue therapy improves many bodily processes, including—but not limited to—digestion, emotional states, sleep, weight regulation, pain control, and immune function.^{140,141}

The recognition that moderate pressure massage gave patients slower heart rates, lower blood pressure, and reduced cortisol levels pointed to changes within the ANS.¹⁴⁰ Eventually, investigations led to the vagal nerve network as the final common pathway. This tenth cranial nerve and associated brainstem nuclei affect nearly every bodily function, serving as a neural expressway mediating the tightly orchestrated, restorative parasympathetic nervous system. Some of the most compelling research on massage and the vagus nerve involves term and preterm infants. For example, massage allows preterm infants to better autoregulate their body temperature.¹⁴² Properly massaged infants show less physiologic stress and reactivity,¹⁴³ higher vagal tone, and significantly less fussing, crying, and stress behavior such as hiccups.

Vagal afferent fibers on the body wall innervate pressure-sensitive mechanoreceptors; massage applied to the skin, subcutaneous tissue, and underlying myofascia activates these nerve endings. Signals then travel to brainstem nuclei and cerebral centers that coordinate ANS homeostasis by means of moment-to-moment alterations in parasympathetic and sympathetic output.

Ordinarily, animals suffering from acute and chronic illness exhibit heightened sympathetic tone that can cause maladaptive changes. The complementary, dualistic reciprocity encoded within the ANS dictates that as parasympathetic tone increases, sympathetic (fight-or-flight) activity calms down.¹⁴⁴ Consequently, reducing sympathetic hyperactivity by means of massage can benefit patients by countering peripheral vasoconstriction, inflammation, muscle tension, spinal cord wind-up, and pain.^{145,146} For older veterinary patients suffering from cancer, as well as those recovering from surgery and experiencing postoperative ileus, regulation of digestive function through massage may provide much-needed parasympathetic support.^{147,148}

The relaxing benefits of medical massage would assist veterinary oncology patients in counteracting stress during minimally invasive procedures, although it should never be relied on to replace conventional anesthesia and analgesia for more painful events. Facial massage calms patients at least in part by activating trigeminal-vagal reflexes.¹⁴⁹ Veterinary technicians can include certain techniques while assisting with gentle restraint; slow, up-and-down moderate pressure massage along the midline between the nose and forehead can sometimes induce a quasi-hypnotic state in patients.¹⁵⁰

How Does Massage Benefit Cancer Patients?

Massage offers additional attributes such as improved immune, circulatory, and visceral functions. Veterinary massage, although lacking in research, is growing in popularity.^{151,152} The benefits of

massage may include relief of pain, anxiety, and nausea, as well as alleviation of lymphedema and chemotherapy-related neuropathy. Home-care providers can be instructed in several of these procedures to assist in patient recovery and providing comfort.

What Are the Risks of Massage for Cancer Patients?

Patients with osteosarcoma, skeletal metastasis, spinal instability, low platelet count, or osteopenia should avoid deep massage. Light or moderate pressure, delivered through skilled hands after informed palpation, would not be contraindicated, except over areas of recent surgery, instability, or infection. Massage should be avoided over implantations to deliver chemotherapy or other drugs. Massage to sites containing stents or prostheses may cause displacement. Tissues subjected to prior surgery or radiation therapy may be fragile, and massage to these areas should either be avoided or be done gently. Hypercoagulable patients may experience emboli subsequent to deep pressure over a thrombus; patients who are prone to bleeding may develop hematomas secondary to pressures that in normal patients would not cause problems. Deep abdominal massage has caused internal bleeding even in the absence of bleeding disorders. Although no evidence exists to indicate that massage promotes the likelihood of tumor metastasis, one should avoid massage directly over known tumors or predictable metastasis sites.

Laser Therapy

What Is Laser Therapy?

The acronym “laser” stands for *Light Amplification by Stimulated Emission of Radiation*. Low-level laser therapy (LLLT) and laser therapy (LT) refer to similar applications, but in LLLT, the instrument utilized does not produce heat (i.e., in the Class IIIB category, delivering <500 mW per laser), whereas Class IV units can in fact warm tissue (>500 mW, up to 12 W or higher).

Evidence is accruing that LT can provide safe and cost-effective treatment for wound healing, neurologic recovery, and pain reduction. Investigations into the benefits of LT are taking place in a number of areas, including oncology. Lasers are usually considered contraindicated in cancer patients, although a body of evidence suggests that LT may help to alleviate oral mucositis.^{153,154}

How Does Laser Therapy Work?

In contrast to acupuncture, in which input begins with the micro-traumatic mechanical effects of the needle on local tissue, LT relies on the absorption and scattering of light within tissue. LT imparts a monochromatic, narrow-band, coherent light source. Photons from the laser create a stimulating, biomodulatory effect, which is probably the main reason why LT has typically been avoided for cancer patients.

Physiologic responses from LT’s photobiomodulation include increased phagocytosis, vasodilation, increased rate of regeneration of lymphatic and blood vessels, stimulation of enzyme activity at the wound edges, fibroblast stimulation, keratinocyte and fibroblast proliferation, scar and keloid reduction, increased adenosine triphosphate (ATP) and DNA synthesis, and stimulation of muscle, tendon, and nerve regeneration.¹⁵⁵

How Might Laser Therapy Benefit Cancer Patients?

A 2007 phase III, randomized, double-blind, placebo-controlled clinical trial that evaluated the efficacy of LLLT for the prevention

of oral mucositis (OM) indicated that laser with a 650-nm wavelength reduced the severity of OM as well as pain scores.¹⁵⁶ No adverse effects were noted in this study.

In 2011, a systematic review of studies on this topic concluded that

[T]here is moderate to strong evidence in favour of LLLT applied with doses of 1-6 J per point in the oropharyngeal area in cancer patients receiving chemotherapy or radiation therapy. There are limitations to the material in terms of small sample size in the included trials. However, the material was consistently in favour of LLLT in both the prevention of OM occurrences and reductions of severity, pain, and duration of OM ulcers.¹⁵⁷

How Might Laser Therapy Harm Cancer Patients?

Little *in vivo* research is currently available pertaining to the risk of LT stimulating cancer growth. However, prudent practice warrants avoiding LT in cancer patients or at least, tumor sites. Furthermore, LT's immunostimulatory effects make this therapy contraindicated for lymphoma patients.

Homeopathy

What Is Homeopathy?

Homeopathy is conceptually difficult for scientifically oriented practitioners to grasp due to its irrational philosophic basis that the more dilute a remedy is, the more potent it is. Homeopathic remedies exist in moderate-to-extremely dilute concentrations, wherein the homeopathic solution is nearly pure water.

Homeopathic practitioners claim that they prescribe minute dilutions of natural substances (from plants, minerals, or animals) in order to stimulate that individual's natural healing response. According to homeopathic principles, a natural substance that causes symptoms of illness in a healthy person can cure that same sickness in an unhealthy person suffering from those same symptoms, when it is administered in a highly dilute form. When selecting a remedy for a patient, a homeopath first determines which substance most closely resembles the symptoms of that patient's disease and then selects a specific remedy to match the clinical picture.

Contrary to conventional medical pharmacotherapeutic principles, homeopathic doctrine states that remedies are more powerful as they become more dilute. A matter of confusion among those accustomed to conventional medical approaches is the fact that highly diluted remedies may not even contain one molecule of the original substance.¹⁵⁸ The mechanism of purported action of homeopathy, other than its placebo effects, remains unknown. Proponents speculate that homeopathic remedies may have properties distinct from those of water, although skeptics would argue that there is little, if any, difference between homeopathic remedies and water.

As difficult as homeopathic theory is to understand, the remedies are as easy to administer as sugar pills because for many remedies the pills are just that: lactose tablets impregnated on the outer surface with the diluted homeopathic mixture. Most remedies are available over the counter. Although most states consider the practice of homeopathy on animals as part of veterinary medicine, clients can and do self-prescribe and self-administer the medication to their animals. Several do-it-yourself books on veterinary homeopathy are available.

How Does Homeopathy Work?

First, there is the question of whether homeopathy does, in fact, work. Most systematic reviews and metaanalyses find that the effects of homeopathy resemble the strength of placebos. The benefits seen in humans receiving homeopathy may be due to the lengthy interviewing process itself rather than the homeopathic remedies *per se*.¹⁵⁹ Currently, there is no repeatable, rigorous evidence that homeopathy works for veterinary patients. Similarly, there is no rational mechanism of action.

Despite this lack of scientific substantiation, veterinary homeopaths claim that homeopathy is "powerful medicine." In one popular instructor's words, "In my experience, the potential of homeopathy is to cure at the deepest level, with all symptoms resolving and the animal living a long and healthy life."¹⁶⁰ She continues, "[F]rom day one homeopathy can improve the overall well being and health of the animal in spite of the continuing presence of the original, uncured pathology such as renal disease, Cushing's, cancer, diabetes and more." These are big claims for a small or nonexistent dose of plant, mineral, or animal matter.

How Might Homeopathy Benefit Patients with Cancer?

Evidence for the incorporation of homeopathy for symptom control in cancer patients is weak and burdened with methodologic flaws, uncontrolled trials, and/or small subject numbers. Reports from these types of studies suggest a benefit from homeopathy for symptoms of pain, fatigue, hot flushes, and mood disturbances^{161,162}; control of skin reactions during radiotherapy for breast cancer^{163,164}; chemotherapy-induced stomatitis in children¹⁶⁵; and hot flushes for women receiving Tamoxifen.¹⁶⁶ One study investigating the effects of a homeopathic drug, Chelidonium, reported antitumor and non-genotoxic activity, as well as favorable modulation of certain marker enzymes.^{167,168} Nevertheless, studies such as these are usually unreplicated and positive benefits disappear when the study is repeated with larger numbers and controls.

Thus the most reliable benefit from homeopathy may be its placebo effects on the client (i.e., bolstering a feeling that they are doing something safe and supportive for their animal with cancer). This false sense of assurance could work against the animal's best interests if it delays meaningful diagnosis and effective care, as illustrated in a human study on the effect of antecedent use of CAM in delaying medical advice sought for breast cancer.⁷

One of the strongest studies for what has been called "homeopathy" involves assessment of a mouth rinse containing Traumeel S. The product tested, however, is not homeopathic in the classic sense. Classic homeopathy usually relies on remedies of higher dilutions with only a single substance. It also entails tailoring that substance to the individual's constitution and symptom picture; the highly diluted homeopathic remedies are given one time. In contrast, this small, randomized, double-blind, placebo-controlled clinical trial looked at the effects of a "homotoxicologic" remedy (often confused with homeopathy) containing Traumeel S that was given to children with either lymphoma or acute myelogenous leukemia.¹⁶⁹ These patients received stem cell transplantation and subsequently developed chemotherapy-induced stomatitis. All children underwent standard oral care for the stomatitis along with a 5-times-a-day mouth rinse of either placebo or Traumeel S. Of the 15 patients in the treatment group, 5 (33%) did not develop stomatitis, whereas only 1 (7%) out of the 15 children receiving placebo avoided it. Stomatitis worsened in 47% of the individuals receiving Traumeel S, as compared to 93% worsening in the placebo group. The benefits of Traumeel S were statistically significant.

Traumeel S differs from many homeopathic remedies in terms of the concentration of its ingredients in which it more resembles a weak extract of agents (in this case plants and minerals), rather than a solution of infinitesimal dilution. It also contains 14 components rather than only one. Instead of working through “vibrational frequencies” as many ascribe to homeopathic remedies, homotoxicologic agents likely confer benefits through pharmacologic activities because they are actually weak solutions of plant, mineral, or animal matter.

Thus far, this study has not been replicated.¹⁷⁰

Can Homeopathy Harm Cancer Patients?

Although homeopaths may administer remedies to serve as a complementary treatment to minimize side effects of conventional treatment methods, they have not as often attempted to treat the cancer itself.¹⁷¹ Homeopathy in general is unlikely to harm patients unless it is used as a substitute for proper conventional care.¹⁷²

Edzard Ernst, a well-respected and prolific author from the University of Exeter in the United Kingdom, critic of CAM, and former homeopath summarized the “intangible risks of complementary and alternative medicine” for patients with cancer.¹⁷³ Ernst noted,

[C]omplementary therapies, particularly those popular in palliative and supportive cancer care (e.g., acupressure, homeopathy, reflexology, and spiritual healing), might be judged as entirely free of direct risks; nevertheless they are associated with indirect risks. The most obvious of such risks is the use of complementary therapies as true alternatives to conventional cancer treatments.¹⁷³

Ernst continues, referencing a “nonmedically qualified CAM practitioner” acquaintance who self-medicated with homeopathic remedies for a brown lesion on her arm. When she finally consulted an allopathic physician, she discovered it was advanced malignant melanoma; she died shortly thereafter. Ernst continues, “Complementary therapists assure us that such disasters almost never happen, but I find this hard to believe. Underreporting is probably close to 100%, and very little systematic research exists in this area...”¹⁷³

Words of Caution

Oncology clients today have access to an information overload on CAM for cancer. The Internet provides, literally at clients’ fingertips, abundant opportunities to purchase remedies from companies and even holistic veterinarians who have neither taken a history nor examined the animal with cancer. The lay literature on alternative treatments for cancer recommends well over a hundred approaches for cancer, with little consensus among authors and even less scientific or evidential support.¹⁷⁴

One author provided the following alerts regarding “signs of a hoax” to help human patients and their healthcare providers with detection of fraudulent treatments¹⁷⁵:

- “The treatment is a ‘secret’ that only specific individuals can provide.”
- “Patients are told not to use conventional medical treatment.”
- “The treatment promises a cure for almost all cancers or medical conditions.”
- “The treatment is promoted only in the mass media such as the Internet, television, or radio ‘talk shows,’ and books instead of reputable scientific journals.”

- “The promoters claim that they are persecuted by the medical establishment.”
- “Advertisements for the treatment claim to ‘cleanse the body of poisons and toxins.’”
- “The treatment will help the patient by ‘strengthening the immune system.’”
- “Testimonials and case reports are used to promote a specific treatment or product.”
- “Catch phrases such as ‘nontoxic,’ ‘no side effects,’ and ‘painless’ are used.”
- “The promoters attack the medical community.”

General Considerations When Recommending Integrative Care for Oncology Patients

CAM practitioners are not subject to litigation as often as physicians, but referrals to CAM practitioners are not without risk.¹⁷⁶ A referral to a CAM practitioner that delays, prevents, or minimizes the opportunity for the patient to receive necessary care via conventional means and which subsequently causes the patient suffering may be considered negligent, as can referrals made to incompetent practitioners.

According to the January 1999 issue of the *Journal of the American Veterinary Medical Association*, “More inquiries and complaints are directed to the AVMA (American Veterinary Medical Association) about alternative and complementary therapies than any other issue.”¹⁷⁷ Referring animals for unconventional care can raise issues of CAM provider credibility, especially if the practitioner is not a licensed doctor of veterinary medicine. To quote the AVMA committee studying this matter:

the veterinary profession wants to assure the public that, when alternative and complementary modalities are being used, they are being used by persons rendered capable and responsible through education and regulation, and that, as a result, these practitioners will “do no harm.” Licensed professionals who have not received adequate education or who do not submit themselves to a required standard of practice in these modalities, and unlicensed nonprofessionals who possess minimal acquired or practical experience, both pose a danger to clients and patients. Furthermore, the committee encourages the use of these modalities within the context of a valid veterinarian/client/patient relationship.¹⁷⁸

As more academic institutions provide courses and training programs in CAM techniques, a greater emphasis on scientific exploration will arise, along with substantially more opportunities for methodical and in-depth study. For the treatment of cancer in particular, evidence-based clinical research on the safety and efficacy of CAM modalities in veterinary cancer patients must take place in order to determine where these approaches best partner and synergize with conventional veterinary cancer care. Indeed, as concluded by the American Veterinary Medical Law Association in 2004, veterinarians offering complementary or alternative therapies: “[S]hould remain vigilant to use only what has been demonstrated to be scientifically reliable treatments or therapies. In other words, treatments and therapies that have been subjected to the same critical analysis and assessment as conventional treatments and therapies.”¹⁷⁹

Clinical Trials and Developmental Therapeutics

17

MELISSA C. PAOLONI AND DAVID M. VAIL

Clinical research is essential to improving patient outcome and quality of life (QOL). This is never more important than in the field of oncology in which scientific and technologic advances must translate to novel therapies or approaches that benefit patients. Clinical trials in veterinary oncology have gained interest and focus over the last decade, with both veterinary and comparative oncology drug development leading the effort. There have also been a growing number of consortia and cooperative groups that have functioned successfully by uniting multiinstitutional efforts, advocating for veterinary clinical trials, and emphasizing the synergy between basic science and clinical progress. With support from clients who are motivated to seek advanced care for their pets and to enroll them in investigational trials that offer new therapies, clinical research in veterinary oncology is growing in scope and importance.

Oncology clinical trials attempt to answer questions and find better ways to prevent, diagnose, or treat cancer. Their model is different from trials involving infectious or even chronic diseases because the risks involved have greater morbidity and mortality. Traditional drug development follows a strict, step-wise paradigm that begins with a phase I dose-finding trial, followed by a phase II efficacy/activity trial, and concludes with a phase III “pivotal” trial that pits a novel agent against or with the current standard of care (Table 17-1).^{1,2} Although veterinary oncology trials sometimes combine these concepts, their individual descriptions serve as the framework for new drug development. Clinical designs, pertinent endpoints and analyses, the process for drug approval, and clinical trial ethics will be explored in the following sections.

Phase I Trials (Dose Finding)

Phase I trials are the first step in the evaluation of a new agent or biologic. The primary goal is to determine a tolerable dose to be used in future studies by evaluating safety, tolerance, and dose-limiting toxicity (DLT).²⁻⁴ Typically, safety is determined in increasing dosing cohorts that escalate toward the goal of a maximum tolerated dose (MTD) or, for targeted therapies, biologically optimal dose (BOD). Activity/efficacy is not a primary goal. In fact, response rates in phase I trials are seldom more than 10%.²⁻⁴ Secondary goals of phase I trials may include scheduling issues, response rate, pharmacokinetic (PK) information (absorption, distribution, metabolism, and elimination [ADME]), and effects on molecular targets or pathways (pharmacodynamics [PD]). These later biologic endpoints are increasingly important components of phase I trials as dose determinants are inherently linked to drug exposure and effect, especially as we move away from more indiscriminant cytotoxic agents and toward the study of molecular-focused therapeutics. These biologic questions are also the basis of comparative oncology modeling of drug development and are emphasized in their design.^{5,6}

Human oncology phase I trials are typically small, single-arm trials that include patients who have failed standard therapies. As such, subjects are generally heavily pretreated with advanced disease. In veterinary medicine, the phase I patient may have failed standard of care or have a condition for which no effective standard of care exists, the standard of care is beyond the client's financial wherewithal, or the client is interested in investigational therapy. Additionally, since standard of care is not necessarily requisite, phase I veterinary trials can proceed in patients with naïve disease. Many veterinary oncology trials provide financial support for enrolled patients and/or include the provision of funds for traditional therapies if novel ones fail. Incentivization enhances accrual. Phase I trial designs must take into account patient selection, starting dose, dose escalation method, definition of MTD or BOD, and target toxicity criteria.

Phase I starting dose selection is a critical design question.⁷ Dose is based on data in normal research on Beagle dogs, extrapolation from rodent data, and even human patient data if such exist.^{1,3,4} Different options include starting with one-third of the “no observable adverse event level” (NOAEL), or one-tenth of the severe toxicity dose in the most sensitive species, or if normal dog data are available, one-half of the MTD in Beagles as they seem to be less sensitive to adverse events (i.e., toxicity) than are more age-advanced, tumor-bearing patient dogs. Phase I design is integral to the long-term success or failure of an agent's development. Therefore, if the starting dose is too low, the length of the trials is longer, there is poor use of resources, and the number of patients exposed to suboptimal doses is increased. For targeted therapies, it also makes defining the BOD or therapeutic index more difficult.^{8,9}

As with starting dose, escalation strategies greatly affect the number of patients treated at a potentially ineffective dose, the length of the trial, the use of resources, and the risk of adverse events.⁷ The traditional method of escalation, outlined in Table 17-2, uses a “3 × 3” cohort design, wherein dose escalations are made with three dogs per dose level and the MTD is set based on the number of patients experiencing a DLT. A DLT is defined as grade III or greater toxicity in any category (except hematologic) according to predefined adverse event categories, such as those in the Veterinary Cooperative Oncology Group—Common Terminology Criteria for Adverse Events (VCOG-CTCAE version 1.1).^{2,7,10} Grade IV is the cutoff most preferred for myelosuppression DLTs because these events are usually considered manageable with supportive care, generally transient, and often clinically silent.¹⁻⁴ Additional DLTs are defined on an agent-by-agent basis due to expected toxicities. These can include or exclude some grade III events from being DLTs, again if transient and clinically silent in nature and are prospectively defined in the study protocol. The MTD is defined as the highest dose level in which no more than one of six dogs develops a DLT. Traditionally, a fixed-dose modified

• **TABLE 17-1** Goals of Phase I–III Clinical Trials

CHARACTERISTIC	PHASE OF CLINICAL TRIAL		
	PHASE I (DOSE FINDING)	PHASE II (ACTIVITY/EFFICACY)	PHASE III (PIVOTAL)
Primary goals	<ul style="list-style-type: none"> ■ Determine MTD ■ Define DLT ■ Characterize type and severity of adverse events 	<ul style="list-style-type: none"> ■ Determine activity/efficacy in defined populations ■ Inform the decision to move to a Phase III trial 	<ul style="list-style-type: none"> ■ Compare a new drug or combination to therapy currently regarded as standard of care
Secondary goals	<ul style="list-style-type: none"> ■ PK/PD issues ■ Scheduling issues ■ Target modulation effects ■ Preliminary efficacy data ■ Investigate surrogate biomarkers of response 	<ul style="list-style-type: none"> ■ Estimate therapeutic index ■ Expand adverse event data ■ Evaluate additional dosing groups ■ Expand target modulation and biomarker data ■ Quality of life measures 	<ul style="list-style-type: none"> ■ Quality of life comparisons ■ Comparative costs

MTD, Maximum tolerated dose; DLT, dose-limiting toxicity; PK/PD, pharmacokinetic/pharmacodynamic.

• **TABLE 17-2** Standard Phase I Dose Escalation Scheme

NUMBER OF PATIENTS WITH DLT AT A GIVEN DOSE LEVEL	ESCALATION DECISION RULE
0 out of 3	Enter three patients at the next dose level.
≥2	Dose escalation will be stopped. This dose level will be declared the maximally administered dose (highest dose administered). Three additional patients will be entered at the next lowest dose level if only three patients were treated previously at that dose.
1 out of 3	Enter at least three more patients at this dose level. <ul style="list-style-type: none"> ■ If none of these three patients experiences DLT, proceed to the next dose level. ■ If one or more of this group suffer DLT, then dose escalation is stopped, and this dose is declared the maximally administered dose. Three additional patients will be entered at the next lowest dose level if only three patients were treated previously at that dose.
≤1 out of 6 at highest dose level below the maximally administered dose	This is generally the recommended phase 2 dose (MTD). At least six patients must be entered at the recommended phase 2 dose.

MTD, Maximum tolerated dose; DLT, dose-limiting toxicity.

From National Cancer Institute: Cancer Therapy Evaluation Program: http://ctep.cancer.gov/protocolDevelopment/templates_applications.htm.

Fibonacci method of dose escalation is used, wherein the dose is escalated 100%, 67%, 50%, 40%, and then 33% of the previous dose as the dosing cohorts increase.^{7,11} Similar to starting at too low of a dose, if the escalations are too conservative, more patients receive a suboptimal dose; conversely, if the escalations are too rapid, more patients are at risk for significant toxicity and the accuracy of the MTD is compromised. Additionally, interdosing cohorts can be added during the study period if more refined escalation or de-escalation is found to be necessary.

Although the phase I MTD approach works well for traditional cytotoxic chemotherapeutics, it may be irrelevant for molecularly targeted drugs, and phase I trials designed to determine the BOD may be more relevant for so-called “static” agents.^{8,12,13} Trials evaluating the BOD require validated assays that measure target effect in serial tumor samples and/or a surrogate tissue or fluid that documents activity at the molecular level. One example would be measuring γ -H2AX in tumor or surrogate normal tissues after use of a DNA-damaging agent.^{14,15} This is a marker of double-stranded DNA breaks and has proved effective in both molecularly targeted and traditional agent evaluation. The depiction in Figure 17-1 shows the immunofluorescent measurement of γ -H2AX in canine

lymphoma after treatment with topotecan, illustrating its use as a marker of the drug’s biologic effect and PD readout. Classically, studies of inhibition of c-kit phosphorylation in canine mast cell tumors provided the rationale for approval of tyrosine kinase inhibitors (toceranib phosphate and masitinib).^{16,17} Such pharmacodynamic modulation studies are increasingly important endpoints of phase I and II designs and now more commonly required as proof of mechanism for drug approval.

Phase II Trials (Activity/Efficacy Trials)

Several good reviews have outlined phase II trial design.^{4,18–20} The primary goal of phase II trials is, using the MTD or BOD established in phase I, to identify the clinical or biologic activity in defined patient populations (e.g., tumors with a particular histology, tumors with a particular molecular target) and inform the decision to embark on a larger pivotal phase III trial. The traditional phase II design (phase IIA), the single-arm, open-label phase II trial, is a nonrandomized nonblind activity assessment of a novel

• **FIGURE 17-1** γ -H2AX phosphorylation is evident after treatment with topotecan in a dog with lymphoma. A biopsy was taken of a patient tumor (canine lymphoma) after administration with topotecan and histopathologic and immunofluorescent analysis performed. **A**, Hematoxylin and eosin (H&E) staining at 10 \times . **B**, H&E staining at 40 \times . **C**, Immunofluorescent image in black and white of same patient sample. **D**, Immunofluorescent staining of γ -H2AX phosphorylation with nuclei staining in blue (Dapi) and γ -H2AX in green. γ -H2AX phosphorylation is an intracellular pharmacodynamic (PD) readout of exposure to a DNA damaging agent.

drug or therapeutic modality that lacks a control group or uses historic controls that are prone to bias (selection, population drift, and stage migration bias).^{4,18,19} Simplistically, at least 9 to 14 patients with the same histology or molecular target are treated with the investigational drug to test the null hypothesis of insufficient efficacy.²¹ Assuming the likelihood of spontaneous regression is less than 5% and expecting at least a 25% response rate for the agent to be clinically useful, with a p less than 0.05 (type I [α] error; false positive) and a power of 0.8 (type II [β] error; false negative), if no responses are observed after the initial cases, the study ends. If a response is noted in one of the cases, the accrual is increased to 31 patients to establish a more accurate response rate.

If you expect a less robust response rate (e.g., 5% to 20%), the initial accrual number must be increased.²² Sample-size impact on study power calculations will be outlined in a subsequent section. Some have opined that the leading cause of drug failure in later phase development is our overdependence on these unpredictable single-arm, uncontrolled phase II trials in oncology and that, as such, they should be avoided to ensure phase III trial resources are not wasted because of the results of poorly designed phase II trials.²³ It used to be considered that the consequence of type I error (false

positive) was less deleterious than that of type II error (false negative) because false-positive trials are likely to be repeated, whereas false-negative trials would result in the abandonment of a potentially active treatment.²⁴ The goals of comparative oncology modeling can help minimize type II error by mechanistically defining activity of novel agents through more detailed PK-PD studies. In today's environment, however, with an abundance of novel drugs to be evaluated, false-positive results are just as serious because they tie up patient and financial resources. With this in mind, the ideal phase II design would be randomized (e.g., between more than one new investigational drug in the pipeline), blinded, and controlled; modifications of this type applied to standard phase II design are discussed subsequently (controlled phase II or phase IIB trials).²⁵

Endpoints of Activity/Efficacy

Since the primary goal of phase II trials is assessment of activity/efficacy, endpoints used to evaluate response are critical to the design. With traditional cytotoxic chemotherapeutics, response criteria are fairly straightforward because size or volume is used to assess response according to several published methodologies (e.g., Response Evaluation Criteria in Solid Tumors [RECIST], World

Health Organization [WHO]).²⁶⁻²⁸ These measurements are both repeatable and have criteria that are strictly defining. It is readily evident that such criteria may not be appropriate for newer molecular-targeted agents that are more likely to be cytostatic rather than cytotoxic and result in stabilization of disease rather than in measurable regression.^{29,30} In such cases, temporal measures such as progression-free survival (PFS) or time to progression (TTP) are appropriate endpoints; however, these often take too long to mature for timely phase II trials.³¹ Alternatively, an adequate compromise could be progression-free rate (PFR) at predetermined time points. Again, comparative oncology models may more expediently define TTP or PFR due to compressed progression times in our veterinary patients. These measures can also more accurately define response in the minimal residual disease (MRD) setting such as trials interrogating novel adjuvant therapies for canine osteosarcoma (OSA) in the postamputation setting. This will be expanded on in future sections.

Secondary endpoints that may be evaluated in phase II trials include QOL assessments, comparative cost of therapy, days of hospitalization, and more detailed adverse event evaluations. Importantly, phase II trials serve to expand our knowledge of the cumulative or long-term toxicities associated with new agents that may not be observed in short-term phase I trials designed to elucidate acute toxicity. An example of this in the veterinary literature involved a combined phase I/II trial simultaneously investigating the safety of liposome-encapsulated doxorubicin (LED) while comparing its activity with native doxorubicin in cats with vaccine-associated sarcomas.³² Unexpectedly, the MTD established for LED in the acute phase I component of the trial was found to result in delayed and dose-limiting nephrotoxicity after long-term follow-up in the phase II component of the trial. Such discoveries are key to defining an agent's therapeutic window with repeated administrations.

New clinical trial concepts have entered into use in great part due to a recent initiative of the Food and Drug Administration (FDA) to allow for "preclinical studies to provide evidence necessary to support the safety of administering new compounds to humans."³³ These are known as phase 0 trials, and they precede the traditional trials defined previously.^{34,35} The role of phase 0 in cancer drug development is for biomarker and assay development/validation and evaluation of target modulation.³³ Phase 0 trials allow for the systematic de-prioritization of investigational agents that exhibit excessive toxicity or fail to show expected biologic effects and are used to direct dose selection for future studies.³³ They represent first-in-species trials, usually of a small number of patients, and utilize lower and likely subtherapeutic drug doses. Comparative oncology trials allow the unique opportunity to answer the preclinical questions required within these trials. Phase 0 trials are "proof of concept" studies, and PD effects are measured within target tissues, such as the tumor itself.^{34,35} These trials can also define surrogate markers of target effect, therapeutic response, or metabolites in surrogate tissues or fluids, such as blood or urine. PK data are also a hallmark of phase 0 trial designs. Biologic endpoints such as PK/PD analysis allow for a much broader understanding of new drug mechanism, therefore informing phase I/II trial design.

Phase III Trials (Pivotal/Confirming Trials)

It has been suggested that if phase II trials are "learning" trials, phase III trials are "confirming" trials.^{2,19,36} These larger, randomized, blind, and controlled trials have the goal of comparing a new

drug or combination with standard-of-care therapies. They are often performed by large co-operative groups, which ensures greater case accrual, and FDA pivotal trials require multiinstitutional involvement. True phase III trials have not been common in veterinary medicine because of their size and expense, but this culture is changing with a broader focus on veterinary oncology drug development and approval. An example of a multicenter phase III trial would be the randomized comparison of liposome-encapsulated cisplatin (SPI-77) versus standard-of-care carboplatin in dogs with appendicular OSA.³⁷ No difference was observed between treatment groups, and SPI-77 did not show an activity advantage, despite allowing five times the MTD of native cisplatin to be delivered in a liposome-encapsulated form.³⁷ This helps define the application of phase III efforts in veterinary oncology.

Additionally, there are a number of pivotal veterinary oncology clinical trials that have directly impacted how we treat patients today. Chemotherapy as an adjunct treatment has improved survival in many pets with cancer. This is highlighted in a disease such as canine OSA, in which disease-free survival (DFS) postamputation alone is just 4 months but, with the addition of chemotherapy (cisplatin, carboplatin, or doxorubicin), improves median survival to approximately 1 year.³⁸⁻⁴² Although a number of clinical trials have been performed with various schedules and regimens of delivery, all highlight the importance of treatment with chemotherapy in the micrometastatic minimal residual disease setting. These are treatment trials, wherein most studies compare groups to historic controls, but many are prospective in nature to more accurately detect a difference in treatment protocols if one exists. Another definitive example of clinical trials with high clinical impact were those comparing the inclusion of doxorubicin in multiagent chemotherapy protocols for dogs and cats with lymphoma versus COP (cyclophosphamide, vincristine, and prednisone) or single-agent therapy alone.⁴³⁻⁴⁸ It was evidenced by a number of protocols that doxorubicin administration contributed significantly to improved survival over those protocols without it, therefore securing its place as the single most efficacious agent against lymphoma.^{47,48} More recent pivotal trials have included the registration of the first approved veterinary oncology agents, two tyrosine kinase inhibitors (TKIs; Palladia, Pfizer; Kinavet, AB Sciences) for the treatment of mast cell tumors.^{16,17,49,50} TKIs showed improvement in PFS over placebo controls, and these trials define the process for expanding future efforts in veterinary oncology drug approval.

Sample Size and Power

The overriding function of clinical research is to provide a definitive answer to a clinical question. However, it is rarely that simple. It is possible that once complete, clinical trial conclusions may be incorrect based on chance or design error. Chance error results when an erroneous inference is drawn from a study sample group that is not actually representative of an entire patient population. Accounting for this potential error is essential in prospective clinical trial design, and its first critical step is to articulate the study hypothesis.⁵¹ Type I or α error (false positive) occurs if an investigator rejects the null hypothesis when it is actually true.^{36,52} This is also referred to as the study's level of significance. Type II or β error (false negative) occurs when one fails to reject the null hypothesis when it is actually incorrect.^{36,52} Type I and II errors are due to chance and cannot be avoided completely, although steps can be taken to reduce their potential impact by increasing sample size and augmenting study design or measurements.

Power is the ultimate measure of a clinical trial's results and also must be prospectively controlled. Power is defined as $1 - \beta$, the probability of correctly rejecting the null in the sample if the actual effect

in the population is equal to (or greater than) the effect size.^{36,52} Power is governed by sample size, with the goal being to enroll enough patients to accurately allow for a difference to be seen between groups. Power is irrelevant if the results are statistically significant, but if not, it is important to ensure the study had adequate numbers to detect a difference between groups. If a study to detect the difference between two cancer treatments is designed with an α of 0.05, then the principal investigator (PI) has set 5% as the maximum chance of incorrectly rejecting the null hypothesis if it is true. This is the level of doubt the PI is willing to accept when statistical tests are used to compare the two treatments. If β is set at 0.10, the PI is willing to accept a 10% chance of missing an association of a given effect if it exists. This represents a power of 0.90 ($1-\beta$), or a 90% chance of finding an association of that size or greater. α and β levels are determined prior to trial initiation, and their set points are based on the importance of avoiding either a false-positive or a false-negative result.

Randomization

Bias is introduced error in clinical research. One of the main ways to minimize bias is through the use of randomization. Randomization is the process of assigning research participants to a group within a clinical trial by chance instead of choice.^{2,36,52} Groups include either the investigational group, those to receive the study drug, or the control group, those to receive a placebo (or comparator drug). Each participant enrolling in a trial has an equal chance of receiving the study drug, and the goal is to balance the groups based on participant characteristics (e.g., age, stage of disease, previous treatments) that may influence a response to therapy.^{2,36,52} At the end of the study, if bias is reduced by randomization, then the result (positive or negative) is more likely to be true. Although this is the ideal way to conduct clinical trials, it is still uncommon in veterinary oncology trials. Unfortunately, in veterinary medicine, historic rather than active controls have been used for comparison of new therapies all too often. It is common in oncology trials to also blind participants so that patients, or in our case clients, do not know which treatment group their pet is in. Blinded or true active comparator trials, although rare in veterinary oncology due in part to limited funding, are becoming more frequent as regulatory registration trials ultimately require them.

Reducing bias in clinical trials is an integral concept within trial design. Stratification is a concept used often in human oncology trials and is gaining headway in veterinary oncology trial design as well.^{36,52,53} This allows for grouping of patients based on known prognostic factors. For example, this might include the stratification of dogs with lymphoma by clinical stage or T- versus B-cell immunophenotype with the goal of creating equal numbers of each within a treatment group. One of the main benefits of stratification is that it can prevent potential bias from *known* prognostic factors. For example, a treatment cohort may be doing comparatively poorly because the majority of dogs in that cohort had T-cell lymphoma. However, a difficulty with stratification is that the more prognostic factors are controlled, the less power the study has, and thus the need to increase sample size considerably. Randomization to treatment groups should be performed after stratification.

Phase IV Trials (Postregistration Trials)

Once a drug has been granted a license or registered for a specific label use by the appropriate regulatory body (e.g., the FDA), post-registration phase IV trials may be performed to gain more

information on adverse events, long-term risks, off-label benefits, and the economic impact of the agent in the marketplace.⁵⁴ Essentially, phase IV trials investigate the drug more widely than do the clinical trials used for registration. They may also involve treatment of special populations (e.g., the elderly, pediatric patients, or individuals with renal or hepatic dysfunction).⁴ The body of data on PK generated from postregistration trials is used to inform decisions on dose in special populations. Productivity and economic differences of one treatment over another, mostly due to insurance reimbursement requirements on the human side, are also a consideration in data collection and evaluation in phase IV clinical trials.

Good Manufacturing Practice/ Good Clinical Practice Criteria

When designing clinical trials it is key to define provisions that create uniformity and consistency in clinical research. Their primary intent is to ensure the safety of trial materials and participants and the integrity of clinical data. Such provisions determine good manufacturing practice (GMP) and good clinical practice (GCP). GMP principles ensure the safe manufacture and testing of pharmaceutical drugs, biologics, and medical devices by outlining aspects of production that can impact the quality of a product. GCP guidelines were devised by the International Conference on Harmonization (ICH) to protect the rights and safety of human patients in clinical trials.^{36,55}

GCP includes standards on how clinical trials should be designed and conducted, defines the roles and responsibilities of trial sponsors and clinical research investigators, and monitors the reporting of trial data.⁵⁵ It requires the use of a standardized clinical protocol and strict documentation of procedures and adherence to that protocol. GCP also establishes guidelines for oversight by external bodies, such as the Institutional Review Board (IRB) and the Data Safety and Monitoring Board (DSMB).⁵⁵ The IRB serves as an independent ethics committee that has the power to approve, disapprove, or ask for modifications to planned study protocols. IRBs traditionally were institutional entities involved with in-house clinical trial oversight but now have grown in scope and purpose. IRBs must include at least one nonscientist and a noninstitutional member known as a *community member*. If a clinical trial includes a vulnerable population, then the IRB must include an expert in the needs and specialties of this group. The IRB reviews protocol ethics, informed consent, and possible conflicts of interest and provides scientific review of study protocol and results.^{36,55} IRB review and approval occur both prior to study initiation and periodically within the conduct of a clinical trial to ensure ethical standards are being met throughout the trial process.

The DSMB (sometimes called a Data Monitoring Committee) is a third-party panel of experts consisting of at least one statistician and is populated by clinicians expert in the field of research or drug of study.^{36,56} In long-term and high-impact studies an ethicist and/or a patient advocate representative may also serve on the DSMB. The purpose of the DSMB is to ensure the safety of participants, the validity of data, and the appropriate termination of studies for which significant benefits or risks have been uncovered or if it appears that the trial cannot be concluded successfully. The main role of the DSMB is to oversee serious adverse events (SAE) and their management to ensure patient safety.⁵⁶ However, the DSMB also reviews interim study results to determine if an overwhelming benefit is evident in either the study or the control arm or if it is unlikely the study will answer the proposed study aim. The latter results if interim data reveal continuance is unlikely to produce a statistically significant result, and the study will then be terminated

prematurely. It is important for all safety monitoring to be contemporaneous, including disclosure to the FDA of SAEs in real time. GCP compliance is necessary for FDA registration trials in both veterinary and human oncology drug development. Oversight of GMP and GCP provisions are provided by the FDA (<http://www.fda.gov>), and in the European Union (EU), oversight is provided by the European Medicines Agency (EMA; <http://www.ema.europa.eu>).

Effectiveness versus Efficacy Definitions

A key distinction in phase III or comparativeness trials is that data may be obtained within the context of randomized clinical trials (RCTs) or from effectiveness studies in the “real world.” The differences between the two types of study design have implications for the data that can be obtained and the interpretation of the resultant findings. Because RCTs are designed to assess the safety and efficacy of pharmaceuticals and because the study design of RCTs emphasizes study validity over generalizability, the applicability of data collected from them are limited.³⁶ The data may not be valid in more heterogeneous patients encountered in actual clinical practice and may be inaccurate because of strict protocol requirements or inclusion/exclusion criteria. Effectiveness studies, in which treatments are studied under real-world conditions, remedy some of these limitations.³⁶ Generalizability to actual users is enhanced in effectiveness designs, but data may be biased in other ways. An efficacy study asks the question, “Does the drug work?” Whereas an effectiveness study asks the question “Does the drug help the targeted general population?” Some refer to this efficacy research as type I research (bench to bedside) and effectiveness research as type II (bedside to curbside) research. Generally, a RCT that determines efficacy occurs under ideal conditions while long-term effectiveness studies, which can be prospective or on occasion either metaanalyses or retrospective, define the overall impact of a drug. Another important element of effectiveness studies may be pharmacoconomics or cost analyses. A cost-benefit analysis weighs factors such as actual cost of medication, number or lives saved, minimization or exacerbation of hospital stays or doctor’s visits, and QOL measures and computes their individual and societal expense. Once these outcome measures are studied and calculated, then comparisons between agents, new and old, can be made.⁵⁷⁻⁵⁹ Measures of effectiveness reflect the actual effects of a drug or an intervention on a population or disease state over time.

Regulatory Oversight

The FDA is the regulatory body of the U. S. government that oversees the activities of the drug and pharmaceutical industry.^{36,60,61} The FDA provides oversight for drug development primarily through written guidances, which describe rules and requirements for quality control and conduct. FDA guidances include oversight of drug standards, including chemistry, manufacturing, and control (CMC); preclinical animal toxicology; documentary requirements for investigational new drug (INDs) and new drug applications (NDAs); and ethics of clinical trials. It is responsible for reviewing clinical trial protocol designs and data, namely to evaluate safety and effectiveness of new drugs or biologics. In 1997 the FDA moved beyond its traditional approval paradigm by creating the FDA Modernization Act.⁶¹ It necessitates PK bridging studies for new populations (e.g., pediatric PK studies) and allows for one adequate and well-controlled clinical investigation by “confirmatory evidence” comprising PK or PK/PD data to lead to drug approval. This emphasizes the importance of exposure and mechanism studies to more accurately determine the safety and effectiveness of novel

drugs, especially targeted agents or ones evaluated in special populations.⁶² FDA guidances are increasingly based on clinical pharmacology and the impact of this is felt most pertinently in oncology drug development.

FDA drug development is a multistep process that defines interaction between the FDA, the drug sponsor, and their discovery and clinical teams. The result of this process, if successful, is FDA approval. It involves a preclinical testing phase (IND requirements for CMC, animal testing, design of phase I clinical studies), IND evaluation, and NDA review, and marketing.² On the human side, due to recent concerns about safety and drug withdrawals (e.g., Vioxx in 2004, Avastin for breast cancer in 2011), the FDA is attempting to improve and expedite the process of drug development through a number of initiatives. The most innovative are the Critical Path Initiative (2004), end-of-phase 2a (EOP2a) meeting (2004), and model-based drug development (2005) (physiologically based PK [PBPK], 2009).⁶³ Various aspects of these efforts include biomarker development, bioinformatics focus, decrease of late phase II failures, and development of public/private partnerships or consortia.

Veterinary Registration Trials

Veterinary drug development follows the same critical regulatory steps described above but oversight is provided by the Center for Veterinary Medicine (FDA-CVM), and in the case of biologics, by the U.S. Department of Agriculture (USDA). Prior to 2007 with the conditional approval of ONCEPT (melanoma treatment vaccine, Merial), all cancer drugs used in veterinary medicine were originally developed for humans and not approved for use in animals. Cancer chemotherapeutics are used in an “extra-label” manner as allowed by the Animal Medicinal Drug Use Clarification Act of 1994. The last few years have seen significant gains in veterinary oncology product development with the approval of toceranib phosphate (Palladia, Pfizer), masitinib (Kinavet (US)/Masivet (EU/ROW), AB Science) and ONCEPT (Merial). Palladia and Kinavet are both receptor TKIs and are approved for use in the treatment of recurrent or inoperable grade II or III mast cell tumors with or without regional lymph node involvement.^{16,17,49,64,65} Palladia was developed by SUGEN as SU11654, a sister compound to SU11248 later approved for human patients as Sutent. ONCEPT is a xenogeneic tyrosinase DNA vaccine indicated for dogs with stage II or stage III oral canine melanoma.^{66,67} Registration trials for these agents involved safety and efficacy defining in multicenter clinical trials under GCP conditions. Postmarket analysis (phase IV) for each is still ongoing. However, their approvals have defined the process for future veterinary oncology product development for years to come.

Consortia

One of the most exciting achievements in veterinary oncology over the last decade has been the development of successful and collaborative consortia groups that are purposed to perform multicenter clinical trials and prospective tumor biospecimen repository collections. Consortia infrastructures allow larger scale clinical trials and provide the voice for collective advocacy in veterinary and comparative oncology. Their success is an example of the growing importance of the study of tumor and clinical biology. Some of these efforts are profiled here.

Comparative Oncology Trials Consortium

The Comparative Oncology Trials Consortium (COTC) is an active network of 20 academic comparative oncology centers

(<https://ccrod.cancer.gov/confluence/display/CCRCOPWeb/Comparative+Oncology+Trials+Consortium>), centrally managed by the National Institutes of Health–National Cancer Institute’s Comparative Oncology Program (NCI-COP), that functions to design and execute clinical trials in dogs with cancer to assess novel therapies.^{68,69} The goal of this effort is to answer biologic questions geared to inform the development path of these agents for use in human cancer patients. COTC trials are pharmacokinetically and pharmacodynamically rich with the product of this work directly integrated into the design of current human early and late phase clinical trials. They are focused to answer mechanism of action (MOA) questions and define dose-toxicity and dose-response relationships. They can be designed to compare varying schedules and routes of drug administration, validate target biology, model clinical standard operating procedures (SOPs), and assess biomarkers. The COTC has also led the way for outlining proposed regulatory oversight of comparative oncology trials and established the first DSMB for client-owned animal clinical trials. Additionally, within this effort, the COTC PD Core was created. The COTC PD Core is a virtual laboratory of assays and services, including pathology, immunohistochemistry, immunocytochemistry, flow cytometry, genomics, proteomics, cell culture, PKs, and cell biology designed to support COTC clinical trial biologic endpoints.⁷⁰ As of 2011, the COTC has completed nine clinical trials and has been successful in promoting the utility of comparative oncology modeling within the drug development community.^{69,71}

Animal Clinical Investigation

Animal Clinical Investigation (ACI; www.animalci.com) is a privately organized and run specialty network of veterinary hospitals that designs, conducts, and reports clinical studies for the animal health industry. ACI trials emphasize oncology drug development but have recently expanded to include other medical conditions, including inflammatory and metabolic disease, cardiovascular disease, and arthritis. ACI provides multisite, pivotal, or nonpivotal studies and commercialization support to help define effective novel veterinary therapeutics. It is the first example of a commercial clinical research organization (CRO) in veterinary medicine. Over 30 clinical trials have been conducted through this network over the last 10 years.^{72,73}

Canine Comparative Oncology and Genomics Consortium

The Canine Comparative Oncology and Genomics Consortium (CCOGC; www.ccohc.net) is an informal collaboration of veterinary and medical oncologists, pathologists, surgeons, geneticists, and molecular and cellular biologists with a common interest in the comparative study of canine and human genomics and cancer. The goals of the CCOGC are to facilitate partnerships and collaborations focused on the problem of cancer in dogs. Early priorities included advocacy for the field of comparative oncology, the development of a mechanism to share reagents and resources in the community, and the development of a biospecimen repository. The repository houses tumor tissue, normal tissues, serum, plasma, peripheral blood mononuclear cell preparations, genomic DNA, RNA, and urine samples. Seven leading veterinary schools across the United States are currently acting as collection sites to populate this repository. Histologies were selected for collection due to their importance to the field of veterinary and comparative oncology and include lymphoma, melanoma, OSA, hemangiosarcoma (HSA), mast cell tumors, soft tissue sarcomas, and pulmonary tumors. As

of 2011 the CCOGC has collected 1600 of 3000 anticipated samples. The repository will serve as a seminal resource for the research community to acquire tissues for target biology studies, as well as its mechanism for prospective collections of unique samples. Future efforts will focus on dissemination of these tissues.

Current Challenges and Opportunities in Oncology Drug Development

Oncology drug development is a difficult and costly process. It is estimated that only 5% to 10% of drugs entering phase I oncology clinical trials ultimately are approved by the FDA, with a cost of between 0.8 and 1.7 billion dollars per drug accrued through the development process.⁵⁷ The most prevalent cause of cancer drug failure is toxicity or inactivity. For every 1000 oncology agents in development, only 40% transition from preclinical studies to phase I, 75% from phase I to phase II, 60% from phase II to phase III, and 55% from phase III to approval.⁵⁷ This means that for every 1000 preclinical candidates, only 99 new drugs will reach the clinic. Oncology has one of the poorest records for drug development, with success rates more than three times lower than those for cardiovascular drugs. A recent review of the human literature revealed that the 2003–2010 phase III oncology failure rate was 34%, a real challenge as late-phase failures are extremely costly in time, expense, patient morbidity, and mortality. Although the highest success rate was also surprisingly low, 68% for autoimmune therapies, this highlights the need for new clinical trial approaches and models for oncology (outlined subsequently) and other fields as well.⁵⁹

New Trial Designs

Alternative “accelerated titration” dose escalation strategies for phase I trials have been suggested.^{2–4} These include (1) two-stage designs, wherein single-patient cohorts are used initially and dose is increased by a factor of 2 until a grade II toxicity occurs, and the second stage then involves more traditional three-patient cohorts and acceleration strategies; (2) within-patient escalation, wherein the same patient gets a higher dose on subsequent treatments until a DLT is observed (this may mask cumulative toxicity, however); (3) escalations based on PK parameters; (4) escalations based on target modification (if known); and (5) continuous reassessment methods using Bayesian methods (see subsequent section).⁷ In the end, it is always a tradeoff of risk versus benefit; however, rapid accelerations are less likely to deny efficacious dosing to someone with a fatal disease.³

Adaptive Trial Designs and Stopping Rules

Adaptive trial designs allow investigators to modify trials while they are ongoing based on newly acquired data and, in some cases, taking into account data generated in other trials or past trials.

Stopping Rules

Stopping rules, which are rules that terminate a clinical trial earlier than originally projected or within a predetermined adaptive trial design, can be applied to randomized phase II or phase III trials. Several methods and variations have been extensively reviewed.^{19,36,74–76} Stopping rules are designed to protect treatment subjects from unsafe drugs, to hasten the general availability of superior drugs as soon as sufficient evidence has been collected,

and to help ensure the transfer of resources and patients to alternative trials. Trials are stopped for three reasons: the investigational treatment is clearly better than the control, the investigational treatment is clearly worse than the control (less activity or more toxicity), or the investigation's therapy is not likely to be better (so-called "stopping for futility" or "futility analysis"). The methods by which stopping rules are applied usually involve some type of interim analysis that looks at the data (by a blinded individual or DSMB) generated so far and makes a determination based on predetermined rules. The interim data are often analyzed for conditional power, which is the probability of the final study result demonstrating statistical significance in the primary efficacy endpoint, conditional on the current data observed so far, and a specific assumption about the pattern of the data to be observed in the remainder of the study.^{75,76} If a study is designed up front to involve conditional power calculations of interim data, the rules for early termination are sometimes referred to as *stochastic curtailing*.

Bayesian (Continuous Learning) Adaptive Designs

Adaptive trial designs can be used not only to stop trials early but also to adapt trials with respect to changing the randomization weight to better performing treatment arms, adding new treatment arms, dropping poorly performing arms, or extending accrual beyond the original target when more information is needed. With the availability of advanced computational techniques, a new statistical methodology, the Bayesian approach, was developed that makes statistical inferences that focus on the probability that a hypothesis is true given the available evidence.^{75,76}

Traditionally, a *frequentist* approach to statistics is applied to clinical trials in which parameters are fixed and not subject to future probabilities. In contrast, Bayesian trials use available patient outcome information, including biomarkers that accumulate data related to outcome (if available and validated), and even historic information or results from other relevant trials.⁷⁷⁻⁷⁹ The Bayesian approach uses this information to adapt the current trial design continually based on newly informed probabilities. Bayesian designs are intrinsically adaptive and data driven, which allows inferences to depend less on the original study design.¹⁹ Bayesian approaches can be incorporated into the trial at the beginning or can be used to monitor clinical trials originally designed with frequentist statistical methods. An example that illustrates the utility of the Bayesian approach involves interim analysis applied to a randomized phase II trial of neoadjuvant epidermal growth factor receptor 2 (HER2/neu)-positive breast cancer.⁸⁰ In this trial initially designed to enter 164 patients (based on the frequentist approach to power), a Bayesian approach was used to perform an interim analysis after 34 patients were enrolled; 67% of patients in the investigational treatment arm experienced complete responses compared with 25% in the standard treatment arm. The Bayesian predictive probability of statistical significance if 164 patients were accrued, based on the data available from these 34 patients, was calculated to be 95%, and the trial was stopped and the drug moved to phase III early due to these promising results.

Randomized Discontinuation Trials

This phase II design was proposed for evaluating the efficacy of newer targeted agents that are thought to have disease-stabilizing activity (cytostatic) in contrast to disease-regression activity of more traditional cytotoxic chemotherapeutics. Several reviews of this trial design are recommended.⁸¹⁻⁸³ Trials that evaluated growth-inhibiting agents in tumors with a variable natural history seem ideally suited for randomized discontinuation trials (RDTs) because

• **FIGURE 17-2** Generalized schema for a randomized discontinuation trial (RDT) design. (Adapted from Stadler WM: *The randomized discontinuation trial: A phase II design to assess growth-inhibitory agents*, Mol Cancer Ther 6(4):1180-1185, 2007, with permission.)

the "no treatment effect" is hard to control in these cases. In essence, these trials serve to enrich and homogenize the static agent for those patients likely to benefit from it. RDTs involve a two-stage trial design, wherein the first stage involves a "run-in" phase in which all patients receive the cytostatic agent under investigation (Figure 17-2). At the end of the run-in phase, assessment of disease response is made. If a response is noted, the subject continues on the investigational drug, whereas if progression (or excess toxicity) is noted, the subject is removed from trial and allowed to receive alternative treatment. Those patients who meet stable disease criteria enter the second stage of the RDT and are randomized to continue on the investigational drug or placebo (the discontinuation arm). Then, at predetermined times, follow-up determinations are made. Endpoints in stage 2 of the trial at these follow-up intervals are "stable or better" versus "progression." Time-to-event measures may be applied as well (e.g., PFS, TTP), although this takes more time to complete. If a subject progresses in the second stage, the code can be broken, and if that subject is in the placebo group, the investigational drug can be reinstituted. Therefore there are two ways for RDTs to be stopped: there are a substantial number of objective responses noted in the run-in phase, making a second stage unnecessary, or the number of subjects progressing in the second stage differs statistically between the treatment and placebo groups. It becomes intuitive that the length of the run-in phase is critical to RDTs: if it is too long, some initially responding patients progress during the late stage of the run-in and are missed (therefore increasing subject numbers); if it is too short, insufficient enrichment occurs (not enough time for nonresponders to progress) and the randomization might as well have been done at the outset. Therefore it pays to have some preliminary ideas as to the natural history of the disease. The two major advantages of RDTs are that all subjects receive the drug up front so that every patient is given a chance to respond to the drug (something that is popular with patients [or companion animal owners]) and enrichment of likely responders may increase power and decrease subject numbers. Potential disadvantages of RDTs include the ethics of discontinuation (but the design can allow reinstitution), the potential for a carry-over effect of the drug after discontinuation (unlikely for most targeted agents), and failure to detect short duration activity (but this would likely be a clinically irrelevant duration anyway). RDTs can be improved by combining other modifications of clinical trials, such as interim analysis and Bayesian analysis, and by using active controls. For purposes of illustration, an RDT in veterinary

medicine that the author has considered would be the investigation of a cytostatic agent in dogs with pulmonary metastatic OSA. All dogs would enter the run-in phase, receive the cytostatic drug for 4 weeks, and then be evaluated for response. From what we already know about the natural history of OSA in dogs, most (probably 80%) of dogs that did not receive treatment would progress in that period. Those that were stable at 4 weeks, however, would be randomized to drug continuation or discontinuation (placebo) and followed with monthly reevaluations. This would ensure all dogs had a chance to respond to the drug and enrich the population likely to respond, and a positive result would be clinical response noted in the run-in phase or a statistical difference in PFR between groups in the second stage.

Personalized Medicine

Advancements in genomic, proteomic, and epigenetic profiling have created new opportunities to tailor cancer treatments to individual patient and tumor molecular characteristics; this field is known as personalized or molecular-based medicine. The goals of personalized medicine approaches include improving outcomes by revealing disease drivers, toxicity, susceptibilities, and resistance profiles unique to the individual patient. Molecular profiling approaches have been employed to stratify and prescribe therapies for human oncology patients. The most successful examples to date have been in the identification of oncogenic mutations such as HER2/neu (EGFR2) in breast cancer and *bcr-abl* in chronic myelogenous leukemia and the prescription of monoclonal antibodies (trastuzumab, Herceptin) and TKIs (imatinib, Gleevec) against these key pathways (also the basis for Bayesian approaches previously mentioned).⁸⁴⁻⁸⁶ Veterinary oncology has also benefited from molecular-based approaches, most notably in the targeting of *c-kit* mutations in canine mast cell tumors (toceranib and masitinib).^{87,88} TKIs (toceranib and masitinib) have shown clinical utility against macroscopic disease and have been approved by the FDA for use in this setting. Although both agents are nonselective inhibitors that also have activity against other key pathways (e.g., vascular endothelial growth factor receptor [VEGFR] for toceranib), their approval marks an important step forward in veterinary tumor biology-based therapeutics and sets the stage for future-directed research in other histologies.

The field of personalized medicine expands beyond patient prescription to also include the study of patient pharmacogenomics and pharmacometabolics, the genetic variation of response and metabolism of novel agents or medications. These include the study of individual patient single nucleotide polymorphisms (SNPs) in key metabolic pathways (cytochrome p450) and the measurement of metabolites in blood and urine. An example of this in veterinary oncology is the use of multidrug resistance gene 1 (*MDR1*) mutation analysis in certain herding breeds (e.g., collies and shelties) prior to initiating *MDR1* substrate chemotherapeutic agents (e.g., doxorubicin and vincristine).

Newer personalized medicine approaches based on complex mathematical algorithms have been created that include a broader base of tumor characteristics to define potential treatments. Although exciting, these techniques require prospective tumor biopsies and the extent of clinical benefit (improvement in outcome) from these time-consuming and costly techniques is yet unproved. Publishing the canine genome and the advent of high throughput technologies have enabled the field of veterinary oncology to describe canine cancer biology and characterize potential therapeutic targets more globally.⁸⁹ This creates the opportunity for personalized medicine investigations in the dog to inform novel therapy

development for both veterinary and human oncology patients using these algorithmic approaches. In addition, strong cancer breed predilections support “breed-based” genetic approaches that may uncover oncogenic pathways and targets more easily and inform discovery and application of personalized medicine strategies. Many challenges remain as to the best ways to collect tissues, define applicable targets, prioritize single- or combinational-agent therapies, or measure the effects of predictive algorithms. Personalized medicine modeling in veterinary cancers may help advance the field through the address of these questions over the next 5 to 10 years.

Clinical Trial Ethics

There are key ethical standards employed in clinical trial design, and it is the goal of all clinicians to ensure standards are met when offering a trial to a client or enrolling a patient within a clinical trial. Many clinical trials provide partially or fully funded care for eligible pets with cancer. This is important because traditional veterinary oncology treatments, surgery, chemotherapy, and radiation therapy, are expensive and costs are prohibitive for some clients. Clinical trial enrollment may present an opportunity to help some clients who may not have the financial means to pursue treatment or receive care for their pet. Clinical trials can also provide treatment to those dogs or cats that have progressed in the face of traditional therapies. When all medical options are described to clients as far as care for their pet’s disease, some may choose clinical trials in order to make an impact for future pets or people with cancer. This altruism (by proxy) drives the decision-making process for many caregivers.

Informed consent is required for all patients to enroll in a clinical trial. This consent is a written acknowledgment, created by a trial’s principal investigators and signed by a client, of the possible positive and conversely adverse effects (known or unknown) of an investigational agent.^{36,90} Goals for clinical trials must be clearly outlined so true informed consent (or assent as it is referred to in pediatric clinical trials) can be obtained. Informed consent defines a trial’s purpose and the requirements for the client to return with their pet for future follow-up procedures/appointments. It ensures the relationship of all parties is clear to those involved. Although adverse events outside of those described are always possible, informed consent ensures that clients understand that in many trials the outcome/side effects are as yet unknown. Ethical considerations also require rigorous informed consent of study procedures, especially in biologically intensive trials, because repeated invasive procedures or even serial imaging may result in the false perception of a stronger therapeutic intent.^{34,91} In academic human oncology centers, the goal is for all patients to be enrolled on clinical trials and this is an objective we should strive for in veterinary oncology as well.

Since the treatment of pet animals with cancer is purely a client-driven choice, there are no true “standards of care” in veterinary oncology. Although there are proven active regimes for the care of common cancers in dogs (i.e., cyclophosphamide, hydroxydaunorubicin (doxorubicin), vincristine [Oncovin], and prednisone [CHOP]-based chemotherapy in lymphoma, platinum or anthracyclines in OSA), these therapies are not required. Therefore veterinary and comparative oncology trials can offer investigational therapies in naïve disease. For clients, the main drivers of the decision to seek investigational trials are the costs or toxicities associated with traditional cytotoxic drugs and the lack of significantly effective available treatments. Clinical trials can randomize patients to placebo arms if there is an interest in comparing a novel therapy

Box 17-1 Suggested “Elements of Consent” to Include in Informed Client Consent Documents

1. Purpose of research
2. Expected duration of participation
3. Description of procedures
4. Possible discomforts and risks
5. Possible benefits
6. Alternative treatment (or alternative to participation)
7. Extent of confidentiality of records
8. Compensation or therapy for injuries or adverse events
9. Contact person for the study
10. Voluntary participation and right to withdraw
11. Termination of participation by the principal investigator
12. Unforeseen risks
13. Financial obligations
14. Hospital review committee contact person

Modified with permission from Morris Animal Foundation:
www.morrisanimalfoundation.org.

to no therapy. Although, as in human trials, informed consent must clearly state the inclusion of a placebo arm, the protocol design may include an allowance for crossover to study drug or traditional therapies either at a defined interval or in documented progressive disease. Requirements for early stopping rules can also alleviate some of these ethical concerns when overt drug inactivity or activity is evident.⁹² Box 17-1 defines the suggested elements that should be included in any clinical trial informed consent document.¹

Many regulatory safeguards have been put in place to promote the welfare and interests of animals used in biomedical and clinical research. Protocols to use animal subjects in clinical research must be approved by institutional Animal Care and Use Committees (ACUC), and these bodies are also involved in oversight of research study conduct to ensure ethical standards are maintained. Some veterinary hospitals also have Clinical Review Boards that function similarly to human IRBs as described previously. Although clinical trials do have the potential to provide a therapeutic benefit for patients, early phase trials are used to assess the acute and chronic toxicities of novel drugs. In some cases, pet dogs are receiving “first in dog” drugs and adverse events are expected, with grade 5 events (fatality) possible. Although this would be predicted to reflect what is seen in an aged and ill cancer population, it is an important element to be detailed in informed consent. The grading and reporting of adverse events in VCOG-CTCAE version 1.1 clinical trials include uniform common toxicity criteria for adverse events, and ethical care includes treatment for any such events.¹⁰ Clients also have the option to withdraw their pet from a clinical trial at any time without penalty. All of these provisions are designed to ensure safety for trial participants and the ethical conduct of clinical research. This field will continue to grow and evolve along with the scope of veterinary clinical oncology.

Conclusions

Clinical trials are an important research discipline to improve care and outcome for cancer patients in both human and veterinary oncology. Steps should be made to ensure study aims are achievable within a crafted study design and protocol. Rules governing

design are prospective and involve questions of dose and schedule selection, toxicity, activity, and comparison to known effective therapies. Statistical expertise is also necessary to ensure appropriate clinical trial design. Regulatory oversight of veterinary oncology trials is increasing, and new approval of veterinary oncology agents will emphasize these processes over the next decade. Comparative oncology trials also are key to the inclusion of pet animals in the evaluation of novel anticancer therapeutics, imaging strategies, and medical devices. Consortia groups will continue to advocate and advance the use and utility of veterinary oncology clinical trials. The field of veterinary oncology will continue to grow through the proper use and design of both traditional and novel clinical trials.

Tumors of the Skin and Subcutaneous Tissues

18

MARLENE L. HAUCK

Incidence

The overall incidence of tumors of the skin and subcutaneous tissues of dogs and cats is difficult to determine due to inconsistency of reporting, particularly with tumors of the subcutaneous tissues. If one considers only those tumors determined to be of “skin” origin, the percentage of biopsy specimens in this category has been reported to be 25.5% to 43%.¹⁻⁶ Of these skin tumors, between 20% and 40% are malignant.^{2,3} In a survey of neoplasms in the California counties of Alameda and Contra Costa, performed from 1963 until 1966, the estimated incidence of skin and connective tissue tumors was 150.4/100,000 dogs.⁴ If one considers only nonmelanoma skin tumors, the incidence is calculated at 90.4/100,000 dogs.

This same study places the incidence of skin and connective tissue tumors in cats at 51.7/100,000 cats.⁴ In one report, skin tumors were 9.6% of all feline biopsy or necropsy accessions; however, skin tumors account for 29.6% of all cancer.⁵ Other studies report a similar percentage of tumors arising from the skin, from 19.3%⁶ to 21%.⁷ Disregarding basal cell tumors (BCTs), the percentage of skin tumors that are malignant is much higher in cats than dogs, with studies reporting from 69.7%⁶ to 82%.⁵

The relative prevalence of the most common tumor types in dogs and cats can be determined from multiple studies.^{1,2,7-14} In dogs, the numbers are based on a fairly large number of surveys of skin tumor types from across the globe, totaling almost 9000 skin tumor submissions to various pathology services. The data for the prevalence of the most common tumors of dogs are presented in Table 18-1. The overall prevalence of lipomas and sebaceous adenomas is likely higher than reported as a result of the bias present in samples submitted for histopathologic evaluation. The data on the prevalence of feline tumors are compiled from four studies with a total of 1225 feline skin tumors and are presented in Table 18-2.^{5,6,9,15} In cats, the top four tumor types of the skin and subcutaneous tissues are consistently BCTs, mast cell tumors, squamous cell carcinoma (SCC), and fibrosarcoma. These four tumor types make up on average approximately 70% of all feline skin tumors.

The remainder of this chapter will focus on SCCs, BCTs, glandular skin tumors, and additional assorted primary tumors of the skin, ears, and digits. Mast cell tumors, melanomas, cutaneous lymphomas, and soft tissue sarcomas will be addressed separately in corresponding chapters of this text.

Etiology

Physical Factors

Ionizing radiation and thermal injury have been reported to increase the risk of skin cancer in many species. A recent

epidemiologic study on the incidence of cancer in human burn victims demonstrated no increased risk of the development of skin cancer when compared to the general population, however.¹⁶ Ultra-violet (UV) radiation has long been known to cause neoplastic transformation in the skin and is a major contributor to rising rates of skin cancer of all subtypes in humans.¹⁷ Evidence for the role of UV irradiation in the development of skin tumors in cats and dogs is primarily epidemiologic in nature¹⁸⁻²⁰ and supported by case reports on dogs diagnosed with a spectrum of sunlight-induced lesions.^{21,22}

The association between SCC development and solar exposure of skin in light-colored cats has been established epidemiologically. Dorn and colleagues calculated that a white cat in California had a 13.4-fold increased risk of developing SCC, and 143 of the 149 cases of nonoral SCC in this study occurred on the head or neck.¹⁸ Similar results were found in a case series of nasal planum or pinnal SCC in cats: of the 61 cats, 58 were white or partially white in color and all but three spent time outdoors.²³

Viral Factors

The ability to induce neoplastic transformation in mucosal infections of papillomaviruses of humans is well established. Papillomaviruses are only able to replicate in terminally differentiated cells; therefore infection of the keratinocyte can stimulate increased proliferation and terminal differentiation.²⁴ Neoplastic transformation arises from the viral effects on cell proliferation, integration into the genome, and interaction of papilloma viral proteins with cellular proteins, particularly the destabilization of p53 by viral protein E6 and the inhibition of pRB by viral protein E7.²⁵ This disruption in p53 can result in increased levels of p16 protein, which is detectable with immunohistochemistry (IHC).²⁶ The association between papillomavirus infection and cutaneous SCC in humans is primarily epidemiologic in nature—organ transplant recipients and immunosuppressed individuals have an increased rate of cutaneous papillomavirus infection and increased risk of SCC development.^{27,28}

The association between canine oral papillomavirus and the development of oral papillomas has been studied since the 1950s.²⁹ The association between viral infection and the development of SCC has evolved from a combination of evidence, including the detection of canine papillomavirus in oral and cutaneous SCCs and the induction of cutaneous SCC in 10 beagles—out of 4500 vaccinated—with a live oral papillomavirus vaccine.³⁰⁻³² Canine oral papillomavirus has also been detected in multiple cases of cutaneous SCC.³¹ A novel papillomavirus with malignant potential was cloned from a dog with footpad papillomas.³³ Dogs persistently infected with this novel virus developed invasive and metastatic SCC.³⁴ Several additional novel canine papillomaviruses were detected in SCC from a variety of locations, including four cutaneous tumors.³⁵

• **TABLE 18-1** Skin Tumor Incidence in Dogs*

TUMOR TYPE	OVERALL (No.)	OVERALL (%)
Mast cell tumor	1494	16.8
Lipoma	758	8.5
Histiocytoma	752	8.4
Perianal gland adenoma	692	7.8
Sebaceous gland hyperplasia/adenoma	577	6.5
Squamous cell carcinoma	531	6.0
Melanoma	500	5.6
Fibrosarcoma	478	5.4
Basal cell tumor	445	5.0
Malignant peripheral nerve sheath tumor	381	4.3
Papilloma	251	2.8
Sweat gland adenocarcinoma	101	1.1
Sebaceous adenocarcinoma	42	0.5
Miscellaneous	1899	21.3
TOTAL	8901	100

*Overall incidence of the most common canine skin tumors as determined from the collation of 10 worldwide studies.

• **TABLE 18-2** Skin Tumor Incidence In Cats*

TUMOR TYPE	OVERALL (No.)	OVERALL (%)
Basal cell tumor	282	23.02
Mast cell tumor	202	16.49
Squamous cell carcinoma	127	10.37
Fibrosarcoma	219	17.88
Apocrine adenoma	41	3.35
Lipoma	40	3.27
Hemangiosarcoma	35	2.86
Sebaceous adenoma	34	2.78
Fibroma	33	2.69
Hemangioma	21	1.71
Melanoma	21	1.71
Malignant fibrous histiocytoma	9	0.73
Miscellaneous	124	10.12
TOTAL	1225	100

*Relative incidence of the most common skin tumors in cats collated from three studies.

Case reports support the correlation between papillomavirus infection and the development of invasive SCC, including lesions of mixed histology.^{32,36,37} Similar to the epidemiologic studies in immunosuppressed humans, a case report of a patient on ongoing chemotherapy developing cutaneous papillomavirus infection and multiple papillomas supports the necessity of immunosuppression in allowing persistent infection of papillomavirus.³⁸ Susceptibility to infection may also depend on the breed.^{39,40} Recently, a dog with multiple viral plaques developed more than 20 invasive cutaneous SCC over a 3-year period, with no evidence of underlying immunosuppression.⁴¹ A novel papillomavirus was sequenced from these lesions.

In cats, papillomaviruses are associated with viral plaques and feline fibropapillomas (sometimes referred to as *feline sarcoids*).^{42,43} Papillomavirus can be detected with IHC in the majority of feline viral plaques, and as these plaques progress to SCC, the ability to detect papillomavirus antigens decreases.⁴⁴ However, when polymerase chain reaction (PCR) is used to amplify papillomavirus DNA, up to 76% of “UV-protected” SCCs are positive in comparison with 42% of SCCs in regions exposed to UV irradiation.²⁶ In humans, it has been suggested that UV exposure and papillomavirus infection may act as co-factors in the development of SCC. A large retrospective study tested for the presence of papillomavirus in 126 SCCs, SCCs in situ, or Bowen’s in situ carcinoma (BISC) in 84 cats.⁴⁵ These investigators found no correlation between likelihood of papillomavirus infection and UV exposure. A novel feline papillomavirus has been sequenced from three feline BISC lesions.⁴⁶ A total of 25% of the 73 cutaneous lesions were positive for papillomavirus by PCR. Human papillomaviruses 5, 21, and 38 were identified in approximately half of the virus-positive cats. A second study evaluated the levels of p16 in 60 cats; tissues tested were comprised of 14 viral plaques, 14 BISC, 18 invasive SCCs, and 14 trichoblastomas (controls).²⁶ Eleven of the invasive SCCs were solar-induced, and seven were classified as non-solar-induced tumors. P16 protein levels were compared to the trichoblastomas and solar-induced SCC and were found to be elevated in all viral plaques, Bowenoid tumors, and non-solar invasive SCC, which is consistent with the presence of papillomavirus infection. Taken together, these data support the possibility of feline papillomaviruses’ role in the development of SCC in cats.

Immune Status

Immunosuppressed humans have a greatly increased risk of skin cancer, whereas organ transplant recipients have up to 100-fold increased risk for development of SCC.⁴⁷ Although this may reflect susceptibility to persistent papillomavirus infection in some instances, it is also thought to reflect loss of normal immune surveillance, with resulting lack of an immune response against early neoplasia. A case report of the development of multiple cutaneous hamartomas and SCC in situ in a dog receiving long-term immunosuppressive therapy with prednisone and cyclosporine also demonstrated positive staining for papillomavirus antigens.⁴⁸ Interestingly, the lesions persisted and new lesions developed, even after discontinuation of the drug therapy. The successful use of immune stimulants for early cancer lesions such as imiquimod for carcinoma in situ supports the role of the immune system in controlling skin cancer. The ability of the immune system of dogs to cause regression of histiocytomas and papillomas also illustrates the role of immune surveillance in veterinary patients.⁴⁹

Genetic Abnormalities in Skin Cancer

Cancer is a genetic disease (see Chapter 1, Section A). The accumulation of multiple alterations in critical genes is usually necessary for full neoplastic transformation. An understanding of the genetic abnormalities, including both genetic and epigenetic modifications in a particular cancer type, allows for the formulation of therapeutics to circumvent these critical mutations and their pathways. The accumulation of such genetic data is only beginning in veterinary oncology. The discovery of activating mutations in the stem cell factor receptor, c-KIT, in canine mast cell tumors and the subsequent successful targeting of this mutation with tyrosine

kinase inhibitors (TKIs) is the first step in applying this approach in veterinary oncology. Current understanding of mutations present in the most common forms of skin cancer, and their role in either tumorigenesis or prognosis/response to treatment is presented according to tumor type.

Basal Cell Carcinomas

In humans, basal cell carcinomas (BCCs) are thought to arise from critical mutations in the hedgehog signaling pathway.⁵⁰ Very little genetic evaluation of BCTs has been performed in veterinary medicine. However, one study demonstrated a reciprocal translocation in a canine BCT: t(10;35).⁵¹ In the dog, chromosome 10 contains the gene *GLI1*, which is the effector transcription factor of the hedgehog signaling cascade. Two aberrant karyotypes were found in feline BCTs: trisomy E3 and monosomy E3, although the significance of these findings are unknown.^{52,53} IHC for p53 in five feline BCTs were negative.⁵⁴ Likewise, IHC evaluation for the presence of the apoptotic regulatory proteins Bcl-2 and Bax showed 23 of 24 tumors expressed Bcl-2, only 7 of the BCTs expressed Bax.⁵⁵ Interestingly, Bcl-2 staining is considered specific for human BCC.⁵⁶

Squamous Cell Carcinomas

The genetic abnormalities responsible for the development of cutaneous SCCs are incompletely understood in human oncology. One common finding is mutations in p53. A proposed pathway of sequentially necessary mutations was proposed by Burnworth et al.⁵⁷ In addition, several genetic changes in cutaneous SCCs have been suggested to be of prognostic value in humans with this disease.

There are a number of studies evaluating p53 in canine and feline cutaneous SCCs. When p53 is present in the wild-type form, its short half-life prevents detection of the protein with IHC. The presence of a detectable form of the p53 protein correlates with mutations within the coding sequence. A series of three IHC studies of p53 in canine cutaneous SCCs revealed that 29.5%, or 19 of 65 tumors studied, were positive for p53 overexpression.^{31,54,58} Interestingly, two of six cutaneous papillomas were also positive for p53 expression by IHC.³¹ Detectable expression is even more prevalent in feline cutaneous SCCs, with 19 of 40 cutaneous SCCs (47.5%) positive for p53 expression in three studies.^{53,54,59} In addition, feline actinic keratosis was also found to be highly positive for p53 expression (11 of 14 cases), whereas BISC lesions were less commonly positive (4 of 22 cases).⁶⁰ These studies have raised questions as to the relative roles of papillomavirus infection and UV irradiation in the development of different subtypes of feline SCCs because both mechanisms of tumorigenesis can result in increased identification of p53.

Several studies evaluated changes in selected protein expression with IHC. For example, immunohistochemical staining of p27, a protein thought important in maintaining cells in G0, showed SCCs to have much lower levels than benign cutaneous neoplasms.⁶¹ β -Catenin is a protein responsible for normal skin homeostasis. When dysregulated, β -catenin can be oncogenic. A study of β -catenin expression in normal skin and benign and malignant tumors demonstrated nuclear presence of this protein, representing pathway activation, in 100% of the trichoepithelioma and pilomatricoma; no nuclear expression was found in any of the other malignant tumors or normal skin.⁶² This finding led the authors to suggest a role for aberrantly activated β -catenin in the formation of tumors of the hair follicle. Evaluation for the presence of cyclin D1 and cyclin A, which are proteins important in the regulation of the cell cycle, demonstrated that cyclin A was present in 90% of feline SCCs and 44% of canine SCCs. Cyclin D1 was rarely expressed in

skin tumors of any type.⁵⁴ Staining for these proteins in normal skin and benign tumors showed rare or weak staining. The investigators suggested a role for cyclin A in the regulation of proliferation and neoplastic transformation in cutaneous SCCs.

The syndrome of renal cystadenocarcinoma and nodular dermatofibrosis (RCND) deserves mention because this disease often presents to the veterinarian as the result of the manifestation of multiple firm cutaneous nodules. Although first described as a genetic disease in the mid-1980s, it was not until 2003 that the causative mutation in the *Birt-Hogg-Dubé* (*BHD*) gene was described.^{63,64} The *BHD* gene codes for the tumor suppressor protein folliculin, and mutations in this gene are thought to lead to loss of function.⁶⁵ Although mostly seen in German shepherd dogs, this syndrome has been reported in Alsations as well.⁶⁶

Identification of the driver mutations underlying neoplastic transformation in the skin will be key to optimizing the use of drugs that target these pathways and avoiding unwanted cutaneous side effects. The use of pathway-specific drugs may have unanticipated effects in the skin. Sorafenib, a TKI of Raf and vascular endothelial growth factor/platelet-derived growth factor receptor (VEGF/PDGFR), has been associated with the rapid development of actinic keratosis and invasive SCCs in humans.^{67,68} As better understanding of these pathways and their role in normal skin homeostasis develops, it may be possible to prevent these types of unintended consequences.

Pathologic Classification of Skin Tumors

Skin tumors arise from the epidermis and associated structures. For ease of use, these tumors are divided based on their differentiation into specific subelements of the skin.⁶⁹ Some histologies are divided into benign and malignant forms, based on known clinical and histologic predictors of behavior. In other tumor types, such clear-cut division may not be possible.

The World Health Organization (WHO) classification system of tumor-node-metastasis can be applied to skin tumors in the clinical setting.⁷⁰ Box 18-1 describes the application of this staging system to skin tumors. Location is also prognostic for particular tumor types; for example, melanomas of the oral cavity are often malignant, which differs from the expected behavior of a melanoma of haired skin, so this information should be included in the clinical description of the tumor at presentation.

History and Clinical Signs

Tumors of the skin are often noticed by pet owners and brought to their veterinarian's attention. The biologic history of these masses can be quite variable. Self-trauma or secondary infection may cause a patient to be presented for evaluation by their veterinarian. Ultimately, however, it is critical to remember that physical inspection cannot definitively determine whether a lesion is benign or malignant. Cytology or histopathology is necessary to diagnose any skin tumor.

Diagnostic Techniques and Work-Up

The evaluation of a skin tumor is generally similar to the evaluation for any solid tumor. A complete history can be very informative.

Box 18-1 Clinical Stages (TNM) of Canine or Feline Tumors of Epidermal or Dermal Origin

Primary Tumor

T0	No evidence of tumor
Tis	Carcinoma in situ
T1	Tumor <2 cm maximum diameter, superficial or exophytic
T2	Tumor 2-5 cm maximum diameter or with minimal invasion irrespective of size
T3	Tumor >5 cm maximum diameter or with invasion of the subcutis, irrespective of size
T4	Tumor invading other structures, such as fascia, muscle, bone, or cartilage

Simultaneous tumors are recorded by number, with the highest T category selected and the total number indicated in parentheses, for example, T2 (3). Successive tumors are classified independently.

Regional Lymph Nodes (RLN)

N0	No evidence of RLN involvement
N1	Movable ipsilateral nodes
N1a	Nodes considered non-metastatic
N1b	Nodes considered metastatic
N2	Movable contralateral or bilateral nodes
N2a	Nodes considered nonmetastatic
N2b	Nodes considered metastatic
N3	Fixed nodes

Distant Metastasis

M0	No evidence of distant metastasis
M1	Distant metastasis detected—specify site(s)

Careful elucidation of the length of duration, rate of growth, and any clinical signs associated with the tumor may be helpful in differentiating benign from malignant masses. There are two steps in the clinical evaluation of any patient with a mass: diagnosis and staging. Diagnosis of many cutaneous and subcutaneous masses can be achieved with fine-needle aspiration and cytology or direct impression cytology of a lesion. Cytology is an inexpensive and relatively noninvasive means of diagnosing many common benign skin tumors, such as lipomas or sebaceous adenomas. For lesions that appear malignant or are nondiagnostic on cytology, histopathology is necessary. In addition to confirming a diagnosis, histopathology yields useful information on the grade of some tumors such as mast cell tumors or the malignant behavior of a tumor on the tissue level, such as vascular and lymphatic invasion. Other characteristics such as degree of differentiation, nuclear morphology, and percentage of necrosis may be helpful with certain tumor types.

The type of biopsy performed is usually dictated by the location. Where wide surgical excision is feasible without undue morbidity, the biopsy can be combined with a therapeutic procedure. However, in most instances, the biopsy is a diagnostic test. The author's preference for a biopsy of a skin or subcutaneous mass is multiple punch biopsies or an incisional biopsy. These techniques allow the procurement of a sufficiently large piece of tissue for an accurate

diagnosis and, where applicable, grading of the tumor. In addition, advanced histopathologic techniques such as IHC for evaluation of prognostic markers can also be performed. Molecular tests such as PCR can be carried out on formalin-fixed tissues as well.

Staging involves determination of the extent of disease locally, regionally, and distantly. Assessment of primary tumor size with measurement of the longest diameter is the first step in the staging process. For large, infiltrative, or fixed masses, local assessment may require advanced imaging such as a computed tomography (CT) scan or magnetic resonance imaging (MRI) to accurately determine tumor size and extent. One study demonstrated that the use of advanced local imaging techniques increased the stage of the primary tumor in 69% of patients.⁷¹ Regional staging involves the assessment of the draining lymph node(s). Determination of the draining node can be difficult for some locations, so evaluation of all nodes in the region may be necessary. Metastatic lymph nodes may be a normal size and consistency on palpation. Conversely, large, firm nodes may be reactive in response to an infection or inflammatory process. Aspiration and cytologic examination by an experienced clinical pathologist is critical for the assessment of regional lymph nodes for evidence of metastasis. Despite careful evaluation of a cytology sample, it is possible to miss metastatic disease. In cases of questionable cytologic results, histopathologic evaluation of the lymph node is recommended.

Evaluation of the patient for distant metastatic disease prior to histopathologic confirmation of a neoplastic process is based on the degree of suspicion that the mass is malignant, as well as the desires and financial limitations of the owner. After confirmation of a malignant process, additional staging for detection of distant metastatic disease and evaluation of overall suitability for proposed treatments are indicated. Such staging may include chest radiographs, abdominal ultrasound, and/or additional tests as indicated by the tumor type or clinical findings.

Treatment and Prognosis for Specific Tumor Types

Given their external location, the primary treatment option to achieve local control of most skin and subcutaneous tumors is surgery. For benign masses, marginal excision may be adequate to achieve long-term control. For malignant tumors, adequate surgical excision requires a margin of normal tissue around the neoplasm. In order for a pathologist to determine if excision is complete, all surgical margins must be identified, with surgical ink or sutures, for correct reporting of margins to occur (see Chapter 9).⁷² The surgeon or clinician must properly prepare the sample to allow the pathologist to report all critical information, including margin evaluation. A more complete discussion of this topic is reviewed by Kamstock et al.⁷²

Likewise, in order to accurately report tumor grade in those tumors for which a grading scheme has been validated, a pathologist needs a reasonably sized piece of tissue to evaluate. Needle core or Tru-Cut biopsies often yield limited amounts of tissue and should only be used on those tumors for which they are the sole option.

The most common cutaneous and subcutaneous tumors, melanomas, mast cell tumors, and soft tissue sarcomas, are discussed in Chapters 19, 20, and 21, respectively. The remainder of this chapter will cover the additional skin tumors, focusing on those with malignant behavior.

Epithelial Tumors

Tumors of the Primitive Follicular Epithelium

The term *basal cell tumor* (BCT) was used for many years to include BCCs, basal cell epithelioma, trichoblastoma, and solid-cystic ductular sweat gland adenomas and adenocarcinomas. As pathologists' abilities to differentiate these tumors on the basis of keratin and other membrane markers has progressed, trichoblastomas and solid-cystic ductular sweat gland tumors are no longer considered "basal cell" tumors. As a consequence, older studies that reported high rates of BCT, particularly in cats, may not be reflective of diagnostic patterns today.⁷³ These related tumor types are believed to arise from stem cells in the outer follicular root sheath, displaying variable differentiation, although the origin for all tumors in this category cannot be absolutely identified. Basosquamous cell carcinoma is a tumor with characteristics of both BCCs and SCCs. Immunohistochemically, basosquamous cell carcinomas are more closely related to BCCs and will be discussed in this section. Trichoepitheliomas are a more differentiated form of the trichoblastoma. The most appropriate nomenclature and classification schema for this group of tumors remain controversial. Tumor types will be presented as categorized in the Armed Forces Institute of Pathology publication on the histologic classification of skin tumors.⁶⁹

Basal Cell Carcinomas

The true incidence of BCCs in both dogs and cats is unknown. The different tumors previously categorized as BCTs are difficult to distinguish histologically and cytologically—both the category of tumor and differentiating benign lesions from malignant. On cytology, BCTs can contain inflammatory cells, squamous cells, sebaceous epithelial cells, melanin, and melanophages, and cells can express the criteria of malignancy. Well-differentiated fibroblasts, reactive fibroblasts, and mast cells may also be present on cytologic examination.⁷⁴ The inability to distinguish the subtypes on cytology has led to the suggestion these tumors be called *cutaneous basilar epithelial neoplasms* when evaluated by cytology alone.⁷⁵

Based on histopathologic evaluation, tumors sometimes can be grossly differentiated based on growth pattern.⁷⁶ The epithelial membrane glycoprotein BerEP4 is highly specific for BCCs versus SCCs or cystic-solid ductular tumors in the diagnosis of BCC in humans.⁵⁶ Cytokeratin 8 (CAM 5.2) is used with human tumors to identify tumors with sweat gland epithelial differentiation and has been used to differentiate a BCC from a solid-cystic ductular tumor in a dog.⁷⁵ However, validation of these immunohistochemical markers in a larger veterinary population remains to be performed.

BCCs are thought to be rare in dogs. In two studies reporting BCCs or basal cell epithelioma (the benign variant), the incidence ranged from 5.5% to 8.4% of all skin tumors; however, it is unclear if trichoblastomas were included in these populations.^{10,11} Breeds reported to be at increased risk for BCCs included cocker spaniels and poodles in one study; however, another study reported no breed predispositions. Clinically, these tumors present as plaques or nodules, often darkly pigmented. The overlying skin may be alopecic and intact or ulcerated. In dogs, the median age of patients was reported to be 9 years; however, dogs of all ages may be affected^{10,11} (Figure 18-1). There are three recognized histologic subtypes: solid, keratinizing, and clear cell.⁷⁶

In dogs, BCCs are considered a low-grade malignancy. Although there are reports of local recurrence of this tumor after surgical

• **FIGURE 18-1** Large basal cell carcinoma on the muzzle of a dog.

excision, no reports of metastasis in the dog could be found. The application of morphometric analysis of cell nuclei has been reported to be useful in differentiating BCCs potentially able to recur from those that are not likely to recur.⁷⁷

In cats, BCCs are now thought to be rare, with many of the tumors previously diagnosed as BCTs actually falling into the categories of solid-cystic apocrine ductular adenoma (approximately 60%) and trichoblastoma (approximately 40%).⁷⁸ However, given the preponderance of the literature referring to "basal cell tumors" in cats, this group of tumors will be discussed here, realizing the population is actually mixed. These tumors comprise some of the most common solid tumors in cats, second only to mammary tumors in one large study.⁷⁹ They represent 10% to 26% of feline skin tumors.^{5,9,79,80} These are tumors of middle-aged cats, with a reported mean age of 9.6 to 10.8 years.^{5,6,80} Although one study reported a predisposition to BCT in Siamese cats, other studies did not find breed differences. BCCs can appear anywhere on the body but may have a predilection for the head and neck. BCC can appear pigmented and resemble a melanoma (Figure 18-2).

Clinically, the majority of tumors classified as BCT appear benign in their behavior. Based on the presence of stromal invasion, vascular invasion (five tumors), necrosis, high mitotic index, and lymph node metastasis (one tumor), 10 of 97 feline BCTs were considered malignant in one study.⁷⁹ A case report presented a cat with four concurrent BCTs,⁸¹ and there are two cases in the literature deemed malignant BCCs based on the presence of lymphatic vascular invasion in one cat and the presence of pulmonary metastatic disease in the second.⁸² Nucleomorphometric analysis was able to predict recurrence in one study of 24 cats with BCCs.⁸³ Overall, the likelihood of metastasis with BCCs in cats appears low.

Treatment for BCCs is wide surgical excision, which often results in long-term control. Although the data are limited, radiation therapy has been used to treat this tumor, along with subsequent doxorubicin chemotherapy.⁸² The impact from these treatment options on survival is unknown.

Basosquamous Cell Carcinomas

Histologically, basosquamous cell tumors have characteristics of both SCCs and BCCs. Clinically, these tumors are indistinguishable

• **FIGURE 18-2** Firm, circumscribed, pigmented basal cell tumor (likely an apocrine ductal adenoma or a trichoblastoma) on the face of cat.

from both BCCs and SCCs. The true incidence and clinical behavior of these tumors in dogs and cats are unknown.

Papillomas

Papillomas are benign epidermal proliferative lesions that are often associated with papillomavirus infection.³⁴ They are considered rare in the cat and dog.⁸⁴ Papillomas typically have an exophytic growth pattern. Another benign variant is the inverted papilloma, which grows into the subcutaneous tissue rather than externally. Cutaneous papillomas are typically found in younger dogs, with an average age of 3.2 years³⁷ (see Figures 1-9 to 1-11). Surgical excision can be curative, and some of these lesions will spontaneously regress.⁸⁵ In patients with multiple lesions, azithromycin has been shown to be effective.⁸⁶

In cats, a particular type of papilloma, the fibropapilloma, is seen. These tumors demonstrate a proliferation of mesenchymal cells covered by hyperplastic epithelium.⁴³ Evaluation for papillomavirus demonstrated an apparent nonproductive infection of the mesenchymal cells.⁸⁷ It has been suggested these feline tumors are more similar to equine sarcoids than papillomas.

Squamous Cell Carcinoma in Situ

SCC in situ is defined as a carcinoma that has not penetrated the basement membrane of the epithelium. When it appears in multiple sites, it is also known as Bowen's carcinoma, Bowenoid carcinoma in situ (BISC), and multicentric papillomavirus-induced SCC. This disease is seen primarily in cats, with only a few reports in dogs.^{5,48,88-90} Actinic keratosis is the name typically used for SCC in situ that arises as a consequence of UV exposure.⁷⁶ Differentiation of actinic keratosis from BISC is based on location and histologic appearance.

Clinically, SCC in situ can present as erosions of the epidermis, proliferations, or crusted plaques. They may be painful on palpation. BISC lesions can occur anywhere on the body—both haired and unhaired skin, areas with and without sun exposure (Figure 18-3). Solitary lesions are unusual.^{5,89} Actinic keratosis, on the other hand, occurs in lightly haired skin with UV exposure and can occur as a solitary lesion. It is typically accompanied by solar elastosis and fibrosis of the skin, consistent with the effects of chronic UV exposure.⁷⁶ By definition, carcinoma in situ is not yet invasive, and thus

• **FIGURE 18-3** Plaquelike lesion of Bowen's in situ carcinoma on the head of a cat. Multiple such lesions may be present on the patient. (Courtesy Dr. Rodney Rosychuk.)

metastasis has not occurred. However, left untreated, carcinoma in situ can progress to invasive carcinoma and put the patient at risk for metastasis. Patients with BISC typically will continue to develop new lesions over time, but metastasis appears to be uncommon.^{5,48,88-90}

Many treatment approaches are effective for SCC in situ. Surgical excision is the treatment of choice for most lesions. Median disease-free interval and survival in 39 cats treated with surgical excision were 594 days and 675 days, respectively.²³ Imiquimod cream (5%) has been reported to be effective in treating BISC in 12 cats, with 5 of the cats having at least one lesion undergoing a complete response to treatment.⁸⁹ Most cats were treated with daily application, although some were treated three times per week. The author's institution has found palliative radiation to be effective in controlling these lesions for at least 8 months. Photodynamic therapy is also very effective in the treatment of Bowen's disease in humans and cats, with reported response rates up to 100%.⁹¹⁻⁹³ Clinical stage of the tumor was prognostic for survival. Strontium-90 plesiotherapy in 14 cats with SCC in situ of the nasal planum resulted in 14 complete responses with no recurrences and an overall survival time of more than 3000 days.⁹⁴ As expected, metastasis appears rare in cats with SCC in situ/actinic keratosis—in 61 cats with SCC of the nasal planum and pinnae, only one cat eventually developed metastasis to the regional lymph node, at the same time as recurrence of the primary tumor.²³

One study on the use of 13-cis-retinoic acid for SCC in situ did not demonstrate clinical efficacy in cats with BISC or SCC.⁹⁵ Etretnate showed some promise for the treatment of SCC in situ, as well as invasive SCC, but this drug is no longer available.⁹⁶

Squamous Cell Carcinomas

SCCs are malignant tumors of the epidermis in which the cells demonstrate differentiation to squamous cells (keratinocytes).⁹⁷ These tumors typically occur in cats older than 10 years of age and at a median age of 10 to 11 years in dogs.^{5,37,97} There is a predilection for cats to develop these tumors on their heads, particularly in lightly haired areas of white cats⁵ (Figure 18-4). This predilection reflects the role of UV light in the induction of many of these

FIGURE 18-4 **A**, Squamous cell carcinoma of the lower eyelid of a white cat. This is a fairly advanced lesion characterized by local invasion and ulceration. **B**, Squamous cell carcinoma of the sparsely haired pinna of a cat. **C**, Squamous cell carcinoma of the nasal planum of a cat.

tumors. A decreased risk has been reported in Siamese, Himalayan, and Persian breeds.^{5,84} There may be a predisposition for the development of nasal planum SCCs in Labradors and golden retrievers.⁹⁸ Bloodhounds, Bassett hounds, and standard poodles may be predisposed to develop cutaneous SCCs.⁹⁷

Clinical presentation of cutaneous SCCs can be highly variable. Cutaneous SCCs can appear plaque-like to papillary, from crateriform to fungiform⁷⁶ (Figure 18-5). They may be erythemic, ulcerated, or covered with a crust.⁸⁴ Paraneoplastic hypercalcemia has

been reported in three cats with cutaneous SCCs—two with aural tumors and one with multiple cutaneous tumors.^{99,100} Metastasis at the time of death was present in 6 of 15 cats with invasive SCC of the nasal planum—organs involved included mandibular (6) and retropharyngeal (1) lymph nodes and lungs (1).¹⁰¹ Metastasis in dogs with cutaneous SCCs appears very uncommon, with a literature review only disclosing four cases of distant metastasis: three to lung, liver, and bone in dogs that had received a bone marrow transplant and one to bone in a dog with a cutaneous SCC.^{34,102} Four of 17 dogs with SCCs of the nasal planum had regional metastasis to the mandibular lymph nodes.⁹⁸ Metastasis to distant sites was not reported.

Treatment for cutaneous SCCs is primarily surgical when feasible. Wide surgical excision results in long-term control in both dogs and cats, given the low incidence of metastatic disease. In a series of 61 cats treated with surgery, radiation, and cryosurgery, surgery resulted in the longest median disease-free interval at 594 days, although many of these cats may not have had invasive disease.²³ Complete surgical excision of nasal planum SCCs in dogs resulted in long-term control in four of six dogs—the two dogs that suffered recurrence had incomplete resections.¹⁰³ (Also see Chapter 23, Section A.)

In cats, tumors of the nasal planum can be effectively treated with external-beam radiation therapy, strontium-90 plesiotherapy, and proton therapy.^{94,101,104,105} Definitive radiation therapy (orthovoltage, 10×4 Gy) yielded a 60% 1-year survival in 90 cats treated with this modality.¹⁰¹ This study also found that histologic stage was predictive of progression-free survival (PFS)—stage T1 tumors had an 85% 1-year survival rate, whereas the stage T3 tumor had a 45.5% 1-year survival rate. Proton radiation therapy to 15 cats with a dose equivalent to 40 Gy yielded 9 complete responses and 5 partial responses. One cat did not respond at all.¹⁰⁵ The PFS rate at one year was 64%, with a median survival of 946 days. Plesiotherapy with strontium-90 in 49 cats with invasive SCCs of the nasal planum had an overall response rate of 98%, with 88% (43 cats) having a complete response.⁹⁴ Median dose delivered in the single treatment administered to these cats was 128 Gy. Ten of 35 cats in this study developed a recurrence; median time to recurrence was 308 days. Median PFS was 1710 days, and the median overall survival was 3076 days. In a series of 15 cats treated by fractionated plesiotherapy with strontium-90, the 13 cats that achieved a complete remission had no recurrences at a median follow-up time of 652 days.¹⁰⁴

Unlike in cats, radiation therapy does not appear to be effective for the treatment of nasal planum SCCs in dogs. In a group of four dogs treated with radiation alone to gross disease, only one achieved a durable remission.⁹⁸ In this same study, seven additional dogs were treated with a combination of surgery and radiation—all seven dogs had a recurrence at a median interval of 9 weeks. Eight dogs treated with either orthovoltage (six dogs) or implants of radon-222 (two dogs) experienced local recurrence in another case series.¹⁰⁶

There are few data on the use of chemotherapy to treat cutaneous SCCs in dogs and cats. Intralesional carboplatin/sterile sesame oil injected into nasal planum SCCs in cats did show significant activity, with a complete response rate of 73% and a 55% PFS rate at 1 year.¹⁰⁷ Two dogs with metastatic SCCs were treated with cisplatin. One dog with metastatic cutaneous SCC (axillary lymph node, lung) had a marked reduction in the number and size of the lung nodules, as well as a partial response of the axillary mass following cisplatin chemotherapy. However, the patient progressed approximately 4.5 months after starting treatment. The other dog had a complete and durable response of multiple lesions (>22 months).¹⁰⁸ Bleomycin has demonstrated short-lived clinical

• **FIGURE 18-5** **A**, Wholebody photograph of a white boxer with cutaneous squamous cell carcinoma. **B**, Skin of ventral abdomen illustrating squamous cell carcinoma tracking in unpigmented regions of the skin.

activity in both dogs and cats.¹⁰⁹ Two dogs with SCCs were treated with actinomycin-D: one dog had stable disease after one dose and the second dog had a partial response and received a total of six doses.¹¹⁰ Mitoxantrone treatment resulted in a response in 4 of 9 dogs with SCCs in one study, but only 4 of 32 cats with SCCs responded to treatment with mitoxantrone.^{111,112}

Tumors with Adnexal Differentiation

There are a number of tumors that arise from the hair follicle, and the majority of these are benign. Treatment for these benign tumors is adequate surgical excision. Characteristics unique to these tumors are discussed individually.

Infundibular Keratinizing Acanthomas

Infundibular keratinizing acanthomas (IKAs) are benign tumors considered common in dogs. No reports of these tumors were found in cats. Previous names for this tumor include intracutaneous cornifying epithelioma (ICE), intracutaneous keratinizing epithelioma, keratoacanthoma, and squamous papilloma.⁸⁴ Peak incidence is from 4 to 9 years of age, but IKAs can occur in dogs younger than 4 years of age as well.¹¹³ Nordic breeds (particularly Norwegian elkhounds), Belgian sheepdogs, Lhasa Apso, German shepherd dogs, terriers, and other breeds appear to be at increased risk for the development of these tumors, and a dog may have multiple tumors.¹¹³⁻¹¹⁶ They occur most commonly on the back, neck, sides of thorax, tail, and limbs/shoulders. They may have a central pore communicating with the surface. Rupture of these masses can allow keratinized tissue into the adjacent dermis and incite a marked inflammatory response. When surgical excision is not feasible, isotretinoin therapy at a dose of 1.7 to 3.7 mg/kg/day

had an effect in three of seven dogs treated, with one complete response and two dogs with partial improvement.¹¹⁵

Tricholemmoma

Tricholemmoma is a rare, benign tumor of dogs.^{117,118} Gross appearance is a well-encapsulated mass in dermis or subcutaneous tissue. There may be hair loss in the overlying skin. The most common location appears to be the head.¹¹³ Surgical excision is the treatment of choice.

Trichoblastoma

Trichoblastoma is the new designation for what were previously called *basal cell tumors* (BCTs) in the dog and the *spindle cell variant BCTs* in the cat.⁸⁴ Histologically, this tumor shows differentiation to the hair germ of the developing hair follicle. Breeds apparently at increased risk of developing trichoblastomas include poodles and setters.¹¹³ It is considered a common tumor in the dog and cat. In one large review of follicular tumors and tumorlike lesions presenting to a veterinary teaching hospital, trichoblastomas comprised 25.6% of the samples in the 308 canine follicular lesions (approximately 2% of the skin biopsies overall), and 26% of the samples in the 50 follicular lesions from cats (1.5% of all skin biopsies).¹¹³ Mean age at diagnosis in this population was approximately 7 years for dogs and 10 years for cats. In dogs, the most common sites for trichoblastomas are the head and neck; in cats, these tumors can be found on the head, neck, limbs, and trunk. Although there are at least six subtypes of trichoblastomas—ribbon, medusoid, trabecular, spindle, granular cell, and clear cell—all appear benign in their behavior and adequate surgical excision is the treatment of choice.^{84,119}

Trichoepitheliomas

Trichoepitheliomas are benign tumors and demonstrate differentiation into all segments of the hair follicle.⁶⁹ Trichoepitheliomas appear to be uncommon tumors in both dogs and cats and comprise approximately 4% of the diagnoses in the retrospective study of follicular tumors and tumorlike lesions.¹¹³ In dogs, their most common sites of occurrence were the limbs, neck, and back. Breeds predisposed to this tumor include Bassett hounds, coonhounds, English springer spaniels, and setters.^{113,120} Persian cats may also be predisposed. Basset hounds and English springer spaniels may present with multiple tumors. Trichoepitheliomas are dermal in origin but can extend into the subcutis. Their surface can be ulcerated or alopecic. Surgical excision is the best treatment, except in cases with a multicentric presentation.¹²⁰

Malignant Trichoepithelioma

The malignant version of the trichoepithelioma is differentiated on the basis of invasion into the surrounding tissues and lymphatic involvement. It is also known as *matrical carcinoma* and may be difficult to differentiate from a malignant pilomatricoma.¹²¹ The mitotic index is usually much higher in the malignant trichoepithelioma when compared to the benign counterpart.⁶⁹ The few cases presented in reference texts were highly metastatic to the regional lymph node and lungs.¹²⁰ The locally invasive nature of some trichoepitheliomas may also represent a lower grade malignant trichoepithelioma.¹²¹ No information on response to therapy beyond surgical excision was found in the literature. Wide surgical excision appears necessary to prevent recurrence.¹²⁰

Pilomatricomas

Pilomatricomas are benign follicular tumors that demonstrate only matrical differentiation.⁶⁹ Alternative names for these tumors include the necrotizing and calcifying epitheliomas of Malherbe and pilomatricomas. These tumors are considered uncommon, representing 13% of the follicular lesions in one study and approximately 1% of all skin biopsies.¹¹³ They are rare in the cat, with only one case out of 898 skin biopsies found in a literature review. Breed predispositions reported include the Kerry blue terrier, soft-coated Wheaten terrier, Bouvier des Flandres, standard poodle, Old English sheepdog, Bichon Frise, and Airedale terrier, among others.¹²² The most common locations are the neck, back, and trunk, with an average age of 6.5 years. These tumors present as well-circumscribed masses and may be very firm due to ossification.^{121,122} Treatment of choice is adequate surgical excision.

Malignant Pilomatricomas

Malignant pilomatricomas are thought to be rare, although a recent report suggests they may be more common than previously appreciated: of 13 pilomatricomas diagnosed in a 2-year period, 4 were malignant.¹²³ No reports of malignant pilomatricomas were found in cats. Defining a pilomatricoma as malignant can be difficult because some appear very like their benign counterpart on initial histologic evaluation.¹²⁴ Invasion into underlying tissues, particularly bone, may be a reasonable indicator of potential malignant behavior in the absence of a malignant appearance on histopathology.¹²³⁻¹²⁵ A recent review of several published cases demonstrated their highly metastatic nature, with documented spread to lungs, bone, lymph node, mammary gland, or skin in 11 of the 12 dogs in this series—the last dog had no follow-up information available.¹²³ There is one report of the use of surgery followed by radiation therapy to control a recurrent malignant pilomatricoma, which prevented local recurrence until 14 months later,

when diffuse pulmonary metastasis was documented.¹²⁴ No reports on the activity or efficacy of chemotherapy for the treatment of malignant pilomatricoma in dogs were found.

Tumors of Glandular Origin

Sebaceous Hyperplasia, Sebaceous Adenoma, Sebaceous Ductal Adenoma, and Sebaceous Epithelioma

Sebaceous hyperplasia, sebaceous adenoma, sebaceous ductal adenoma, and sebaceous epithelioma are very common in the dog and rare in the cat, and the division between these tumors may be “arbitrary.”⁸⁴ A review of 172 tumors of the sebaceous gland revealed a preponderance of female representation with sebaceous hyperplasia and an overrepresentation of miniature schnauzers, beagles, poodles, and cocker spaniels.^{126,127} Coonhounds, Nordic breeds, and some terriers may also be predisposed to develop benign sebaceous tumors.¹²⁸ Limbs, trunk, and eyelids were the most common locations. Although these tumors can occur even in young dogs, peak occurrence is from 7 to 13 years of age.

Sebaceous epitheliomas may recur locally, and lymphatic metastasis has been reported anecdotally. Because lymphatic invasion may occasionally be found at the margin of sebaceous epitheliomas, they are sometimes considered a low-grade malignancy rather than benign.⁶⁹ A recent report of distant metastases (lung, central nervous system) from a recurrent sebaceous epithelioma confirms their malignant potential.¹²⁹ In general, adequate surgical excision is the preferred treatment.

Sebaceous Gland Carcinomas

Sebaceous gland carcinomas are uncommon in the dog and cat.⁸⁴ They are more common in the intact male dog.¹²⁸ They most frequently occur on the head, and the Cavalier King Charles spaniel, cocker spaniel, and terrier breeds are at increased risk of developing these tumors. Sebaceous gland carcinomas tend to be low-grade malignancies, with metastasis beyond the lymph node found only in one report.^{130,131} This patient had widespread metastasis, with bone, skin, and lung involvement. They are typically found on the head and neck in dogs and on the head, thorax, and perineum in cats.¹²⁸ The most common finding of malignancy is local infiltration. The only reported treatment for these tumors is wide surgical excision.

Apocrine Gland Adenomas and Solid-Cystic Apocrine Ductal Adenomas

Apocrine gland adenomas are considered fairly common in the dog, although they are not common in the cat. These tumors may be fluid filled. Apocrine ductal adenomas are firm on palpation. Feline apocrine gland adenomas have a high predilection for the head.¹³² Solid-cystic apocrine ductal adenomas were previously designated as BCTs. These benign tumors are appropriately treated with adequate surgical excision.

Apocrine Gland Carcinomas

Apocrine sweat gland tumors are relatively uncommon in dogs (overall 1.1% of all skin tumors) and perhaps a bit more common in cats (overall 3% of all skin tumors). In dogs, the median age for diagnosis of these tumors is 9 years, with the majority of tumors occurring between 6 and 11 years of age.¹³³ The front legs were the most common site for dogs. Golden retrievers and Treeing Walker coonhounds may be predisposed to the development of apocrine gland adenocarcinomas.^{132,134} In a series of apocrine gland tumors, 40 of 44 in dogs were considered malignant on histopathologic

examination and 8 of 10 in cats.¹³⁴ In cats, the tumors occurred from 6 to 17 years of age, and no breed or sex predilections were identified. The most common locations for this tumor in cats are the head, limbs, and abdomen.¹³² In both species, most lesions are solitary. In addition to the nodular tumors, apocrine gland carcinomas may present as erosive and inflammatory skin disease. This presentation is sometimes designated as an “inflammatory carcinoma.”¹³²

Local invasion of apocrine gland carcinomas is common, with 66% of tumors demonstrating invasion of the capsule and/or stroma and 11% invading the vasculature.¹³³ In another series of cases, 22.5% had invasion of the lymphatic system.¹³⁴ Grossly, there were no distinguishing features to differentiate benign from malignant lesions. Despite the high incidence of local invasion, the rate of distant metastasis in these two case series was low, with only two dogs developing local recurrence/continued growth (4%) and one developing distant metastatic disease to the lungs (2%). This is distinctly different from the high metastatic rate seen with apocrine gland carcinomas of the anal sac. In general, optimal treatment consists of wide surgical excision of these tumors, although the author has seen several of these tumors develop distant metastatic disease. No reports on the efficacy of radiation or chemotherapy for the treatment of apocrine gland carcinomas of the skin were found.

Eccrine Adenomas and Carcinomas

Eccrine adenomas and carcinomas are tumors of the sweat glands of the foot pads. They are considered rare in dogs and cats, and no reports on clinical behavior or outcome were found. Treatment is wide surgical excision.⁸⁴

Neuroendocrine Carcinomas

Neuroendocrine carcinomas are also known as Merkel cell carcinomas. Merkel cells are thought to be part of the mechanoreceptor in the skin. Recent studies in human Merkel cell tumors have demonstrated a role for the Merkel cell polyomavirus in the development of these tumors.¹³⁵ Although a highly malignant tumor in humans, most case reports in veterinary medicine suggest a more benign clinical course.^{136,137} There is a single case report in a cat with multiple recurrences and the development of pulmonary metastases, suggesting a more malignant behavior can be seen.¹³⁸ A similar case in a dog reported multiple skin masses with widespread metastasis in the abdomen.¹³⁹ An additional canine case report described a dog with multiple (six) lesions that progressed with carboplatin and doxorubicin chemotherapy, as well as with metronomic chemotherapy treatment.¹⁴⁰ A recent evaluation of two canine neuroendocrine carcinomas demonstrated expression of β -catenin or E-cadherin, which are proteins whose loss predicts a more malignant behavior in humans.¹⁴¹ However, there was expression of chromogranin-A, neurone-specific enolase, S100, and c-KIT (which is also expressed in human neuroendocrine carcinomas). Current treatment recommendations reflect the generally benign behavior of these tumors and consist of wide surgical excision. The efficacy of chemotherapy for treatment of more widespread tumors is unknown, as is the effect of c-KIT-targeted TKI.

Renal Cystadenocarcinoma and Nodular Dermatofibrosis

A syndrome of renal cystadenocarcinoma and nodular dermatofibrosis has been described in German shepherd dogs and Alsatians (see Chapter 29).^{63,66} These dogs have multiple firm, haired masses distributed over their bodies. On histopathologic examination, these nodules are dense, irregular collagen. They typically do not

result in clinical problems unless they cause lameness or otherwise disrupt normal function. Surgical removal is indicated in these instances. Most of these dogs will die from renal failure or progressive renal cystadenocarcinoma, on average 3 years after initial detection of the dermatofibrosis.¹⁴² There are no known effective treatments for the renal cysts or bilateral renal adenocarcinomas. A recent case report of nodular dermatofibrosis in an Australian cattle dog without any evidence at necropsy of renal cysts or adenocarcinomas reveals the possibility of a nonlethal version of this syndrome.¹⁴³

Tumors of the Ear Canal

Ceruminous glands are modified apocrine glands found in the external ear canal. Benign and malignant tumors arising from these glands are the most common tumor types in the ear. Additional tumor types that have been reported include SCCs, undifferentiated carcinomas, BCCs, fibromas, papillomas, hemangiosarcomas (HSAs), mast cell tumors, melanomas, sebaceous gland tumors, ceruminous gland cysts, and histiocytomas.¹⁴⁴⁻¹⁴⁷ Inflammatory polyps are also found in dogs and more commonly in cats.

In the largest published series of tumors of the ear canal, the 33 benign tumors diagnosed in dogs were comprised of polyps (8), papillomas (6), sebaceous gland adenomas (5), BCTs (5), ceruminous gland adenomas (4), and histiocytomas (2) and single cases of plasmacytoma, melanoma, and fibroma. The 8 benign feline tumors were polyps (4), ceruminous gland adenomas (3), and one papilloma.¹⁴⁷

In this same series, the relative frequencies of malignant tumors in 48 dogs consisted of 23 ceruminous gland adenocarcinomas, 9 undifferentiated carcinomas, 8 SCCs, 3 round cell tumors, 2 sarcomas, 2 malignant melanomas, and a single case of HSA. In cats, the most common malignant tumor was also ceruminous gland adenocarcinomas, with 22 cases, followed by SCCs (20), carcinomas of undetermined origin (13), and one case of sebaceous gland adenocarcinoma.

Most tumors of the ear canal are diagnosed due to the mass effect, which may result in clinical signs such as chronic otitis or partial deafness. Occasionally, patients may present for pain on opening of the mouth or neurologic signs, but this is more common with malignant tumors.¹⁴⁷ The role of chronic otitis in the development of these tumors is an area of ongoing discussion.

Ceruminous Gland Adenomas and Cysts

Ceruminous gland adenomas and cysts are benign tumors of the ceruminous gland. On gross appearance, they are typically exophytic and pedunculated, although they can also be ulcerated.¹⁴⁸ Cats with ceruminous gland adenomas are slightly younger than those patients presenting with malignant tumors; in dogs, both lesions present around 9 years of age.^{147,148} Cocker spaniels and poodles appear predisposed to the development of these tumors. Treatment of choice is adequate surgical excision.

Ceruminous gland cysts can be found in cats. These are darkly pigmented, sessile masses that are usually smaller than 5 mm in diameter and can be multiple.¹⁴⁶ If necessary, these can be surgically excised.

Ceruminous Gland Adenocarcinomas

Ceruminous gland adenocarcinomas are the most common malignant tumors of the ear canal in both dogs and cats. In dogs, it has been reported that cocker spaniels and German shepherd dogs are at increased risk.¹⁴⁸ Malignant ceruminous gland tumors are more common than benign tumors in cats; however, there is conflicting

information on whether malignant or benign tumors are more common in the dog.^{148,149}

Ceruminous gland adenocarcinomas have metastatic potential, and full staging is recommended prior to treatment. Local invasion, even through the cartilage of the ear canal, can occur. CT is indicated to better delineate the extent of local invasion prior to surgery. Skull radiographs revealed lysis of the bulla in 13 of 27 dogs with malignant tumors of the ear canal and sclerosis of the bulla in 8. In the cats with malignant tumors, 5 of 27 had lysis of the bulla on skull radiographs and 5 had sclerosis of the bulla.¹⁴⁷ Thirty dogs had regional lymph nodes evaluated cytologically for evidence of metastasis, and only one dog tested positive. In contrast, 5 of 56 cats had cytologic evidence of metastasis to the mandibular (4) or superficial cervical (1) node. Three of 35 dogs radiographed with malignant ear tumors had evidence of pulmonary metastasis at the time of diagnosis, and one had a lytic scapular lesion. Of the 32 cats evaluated for pulmonary metastasis, none had evidence on chest radiographs.¹⁴⁷ However, these tumors have an increased metastatic potential over time—in a series of seven patients (dogs and cats) evaluated for metastasis after radiation therapy, three had spread: one to a lymph node, one to the lungs, and one to abdominal organs.¹⁵⁰ A staging scheme derived from the one used in humans has been proposed for primary tumors of the ear canal (Box 18-2).¹⁵⁰

The primary modality of treatment of tumors of the ear canal is complete surgical excision. This is best accomplished with a total ear canal ablation (TECA) and lateral bulla osteotomy.^{151,152} Recurrence was significantly lower in both dogs and cats treated with this surgical approach, compared to those treated with a lateral ear canal

resection: seven dogs treated with TECA had no recurrences and a median follow-up of 36 months; of four dogs treated with lateral ear canal resection, three recurred with a median follow-up time of 4 months. Of 16 cats treated with TECA/lateral bulla osteotomy, the recurrence rate was 25% with a median disease-free interval of 42 months. The six cats treated with a lateral ear canal resection had a recurrence rate of 66.7% and median disease-free interval of 10 months. A second case series of 18 cats treated with TECA for ceruminous gland adenocarcinomas was equally encouraging. Median survival for cats undergoing TECA for malignant tumors was 50.3 months, statistically equivalent to the median survivals for cats with nonneoplastic diseases (33.7 and 24.3 months).¹⁵³ Five of these cats developed local recurrence. None of the 18 cats had evidence of metastasis at the time of surgery. Radiation therapy also appears effective for the treatment of ceruminous gland adenocarcinomas.¹⁵⁰ Treatment of six cats and five dogs with orthovoltage, 48 Gy in 12 4-Gy fractions, resulted in an estimated mean PFS of 39.5 months. Six of these patients had previous surgery. One year PFS was 56%.

Several prognostic factors that have been determined for ceruminous gland adenocarcinomas are presented in Table 18-3. In cats, a grading scheme failed to be prognostic for survival, but a mitotic index of 2 or less predicted improved survival. A correlation between mitotic index and tumor grade was also noted in a series of patients treated with radiation therapy, although the small sample size precluded further evaluation for prognostic significance.¹⁵⁰ The overriding conclusion from the series of studies regarding treatment for ceruminous gland adenocarcinomas is that long-term survival is possible with appropriate local therapy.

Tumors of the Digit

The most common clinical signs in dogs with digital tumors are the presence of a mass and/or lameness. These dogs tend to be older, with a median age of 10 years.^{156,157} A review of three retrospective studies totaling 362 malignancies on the relative frequency of different malignancies in the digit of the dog revealed that SCC is the most common, with 171 tumors (47.2%), followed by malignant melanoma, with 86 cases (23.8%).¹⁵⁶⁻¹⁵⁸ Interestingly, approximately 3% of dogs with digital SCC demonstrated involvement of multiple digits. These patients are typically large breed dogs with black skin and haircoat¹⁵⁹ (Figure 18-6). Breeds with this syndrome include standard poodles, black Labradors, giant schnauzers, Gordon setters, and Rottweilers. Additional breeds that may be predisposed to digital SCC include the dachshund and flat coat retriever.¹⁵⁸

Box 18-2 Proposed Staging Scheme for Primary Tumors of the Ear Canal

- T1 Tumor confined to the external or horizontal ear canal
- T2 Tumor extending beyond the tympanic membrane
- T3 Tumor extending beyond the middle ear/bone destruction

Data from Theon AP, Barthez PY, Madewell BR, et al: Radiation therapy of ceruminous gland carcinomas in dogs and cats, *J Am Vet Med Assoc* 205:566–569, 1994.

Presence of neurologic signs	No	Feline	15.5	147
	Yes		1.5	
Histology	Ceruminous gland adenocarcinoma	Feline	49	147
	Squamous cell carcinoma		3.8	
	Cancer of unknown origin		5.7	
Extension beyond the ear canal	No	Feline	21.7	147
	Yes		4	

• **FIGURE 18-6** Paw of a dog with multiple, digital squamous cell carcinomas.

Scottish terriers were overrepresented in the dogs with digital malignant melanomas. The remainder of the tumors were comprised of 48 soft tissue sarcomas (13.3%); 28 mast cell tumors (7.7%); 12 osteosarcomas (OSAs; 3.3%); 4 round cell sarcomas; 3 adenocarcinomas; 2 malignant adnexal tumors; 2 HSAs; 2 plasmacytomas and 1 dog each with lymphoma, chondrosarcoma, giant cell tumor of bone, and synovial cell sarcoma. Similar results were found for malignant tumors of feline digits.¹⁶⁰ In a series of 60 digital malignancies, 15 (25%) were SCC, 14 were fibrosarcoma (23.3%), 13 cases of adenocarcinoma (21.6%) were diagnosed, and there were 5 cases each of OSA and HSA. There were also 4 cases of mast cell tumor, 2 cases each of giant cell tumor of bone and malignant fibrous histiocytoma, and 1 sarcoma of unknown origin. There may be a predilection for tumor development in the front feet. Two of the cats with fibrosarcoma and 4 of the cats with adenocarcinoma had involvement of multiple digits. Primary SCC of the digit has also been reported to affect adjacent toes.¹⁶¹ Malignant melanoma has also been diagnosed on feline digits.¹⁶²

A number of nonneoplastic masses can also be found on the digit. In addition to the malignancies listed previously, pyogranulomatous inflammations, epithelial inclusion cysts, intracutaneous cornifying epitheliomas, IKAs, keratoacanthomas, benign adnexal tumors, histiocytomas, hemangiomas, BCTs, intraosseous epidermoid cysts, infiltrating lipomas, fibromas, papillomas, hamartomas, trichoblastomas, keratomas, cysts, and plasmacytomas have been diagnosed on canine digits.^{156,158} It is clinically important that the diagnosis of digital masses is apparently difficult because a review among pathologists demonstrated an approximately 20% rate of disagreement in the diagnosis on amputated digits, with 75% of the changes in diagnosis being clinically significant.¹⁶³ In particular, the differentiation between SCC and IKA is apparently problematic. In cats, the nonneoplastic mass lesions included inflammatory masses, hemangiomas, and a BCT.¹⁶⁰

One key difference in the evaluation of digital masses in cats is the clinical syndrome of digital metastasis with primary pulmonary

carcinomas. In a series of 64 cats with digital carcinomas, 87.5% of the lesions represented metastasis from primary lung tumors, whereas only 8 had primary SCC of the digit.¹⁶¹ These tumors were able to be differentiated based on histopathologic staining characteristics, as well as cell morphology. In this series of cases, median survival of cats with digital metastatic lesions was only 4.9 weeks, whereas cats with primary digital SCC had a median survival of 29.5 weeks.

Digital tumors can metastasize and thus require appropriate staging at initial evaluation.¹⁵⁵⁻¹⁵⁸ In dogs with digital SCC, 8.8% (5/57) had evidence of metastasis at the time of presentation and an additional 23.2% (23/99) went on to develop metastasis. Bone lysis was very common in these patients, with 80.7% (46/57) showing lysis on radiographs. Dogs with malignant melanomas had a higher percentage presenting with metastatic disease, with 12/43 (28%) having either regional or distant metastasis. An additional 25 of 65 dogs (38.5%) developed metastasis at a later time. Nine dogs (21%) had evidence of bone invasion on radiographs, whereas 14/14 dogs in a separate study had histologic evidence of bone invasion.¹⁶⁴ Additional digital tumors that developed metastatic disease include one dog with OSA, one dog diagnosed with a keratoacanthoma (considered likely to be a well-differentiated SCC), and one dog with a malignant adnexal tumor. It is important to note these are minimum estimates of metastatic rates because not all dogs were fully staged or necropsied.

Of eight cats with digital SCC, three of six had evidence of bone invasion and one cat had metastasis to the draining lymph node.¹⁶¹ Only three cats had chest radiographs, none of which demonstrated pulmonary metastasis. Of the five reported feline cases of digital malignant melanoma, four developed metastasis to lymph node, lung, bone, and vertebrae.¹⁶²

Treatment reports for digital tumors are primarily limited to surgery, which is the only treatment modality that has been shown to improve outcome.¹⁵⁷ In the majority of cases, wide surgical excision can be accomplished with a toe amputation. However, a limb amputation may be necessary for larger tumors involving more of the foot. For SCC of the digit, reported 1-year survival rates range from 50% to 83% and reported 2-year survival rates from 18% to 62%.¹⁵⁶⁻¹⁵⁸ When divided by site of origin, dogs with SCC arising from the subungual epithelium had a significantly improved survival in comparison with dogs with SCC from other sites on the digit. Dogs with a subungual SCC had 1- and 2-year survival rates of 95% and 74%, respectively, whereas dogs with SCC at other digital sites had 1- and 2-year survival rates of 60% and 40%, respectively.¹⁵⁶ Median survival times for cats with digital SCC are reported from 73 days to 29.5 weeks.^{160,161}

Dogs with digital malignant melanoma had similar survival times as dogs with digital SCC. One-year survival rates for these patients ranged from 42% to 57%, and 2-year survival rates from 13% to 36%.^{155-158,164} Of five cats diagnosed with digital malignant melanoma, survival times ranged from 0 to 577+ days, with four of the five cats developing metastatic disease.¹⁶²

The possible roles of radiation therapy and chemotherapy remain to be elucidated for the treatment of malignant digital tumors in the dog and cat. The high metastatic rate in dogs with digital malignant melanoma clearly suggests that adjuvant treatment should be considered. A recent paper evaluated the use of a xenogeneic (murine) tyrosinase vaccine in dogs with digital melanoma.¹⁶⁵ Fifty-seven of the 58 dogs had surgical excision of their primary tumor prior to treatment with the vaccination. Three dogs had received adjuvant chemotherapy, and two dogs had received radiation therapy. Sixteen dogs (27%) had regional or distant

metastasis at the time of presentation. The overall median survival time from the time of digit amputation was 476 days, with a 1- and 2-year survival rate of 63% and 32%, respectively. This study did identify the presence of metastatic disease as a negative prognostic factor. Distant metastatic disease carried a worse prognosis than metastasis to regional lymph nodes. This finding was interesting because evaluation of prognostic factors on overall survival in dogs with digital neoplasia, including tumor stage and the presence or absence of metastatic disease, resulted in no useful prognostic factors aside from surgery in an earlier study.¹⁵⁷ The implication of the earlier finding was that surgery is beneficial, even in dogs with metastatic disease. The smaller number of dogs (10) in this earlier study may have contributed to the lack of statistical significance.

In summary, complete resection of malignant digital tumors can result in long-term survival. Additional consideration to adjuvant treatment for possible metastatic disease should be considered in patients with malignant melanomas.

PHILIP J. BERGMAN, MICHAEL S. KENT, AND JAMES P. FARESE

Melanoma is a relatively common cancer of dogs, especially those with significant levels of skin pigmentation. Melanomas in cats are relatively rare. The most common location for canine malignant melanomas (CMMs) is the haired skin, in which they grossly appear to be small brown-to-black masses but can also appear as large, flat, and/or wrinkled masses.^{1,2} Primary melanomas also can occur in the oral cavity, nail bed, footpad, eye, gastrointestinal tract, or mucocutaneous junction.³ Ocular melanomas of dogs and cats represent a distinct clinical syndrome and are discussed in Chapter 31. Metastatic sites can be varied, including local draining lymph nodes, the lungs, liver, meninges, adrenals, and other miscellaneous sites.

Melanoma arises from melanocytes, which are the cells that generate pigment through the melanosome by a number of melanosomal glycoproteins. In humans, cutaneous melanoma can arise due to mutations induced by repeated, intense exposure to ultraviolet (UV) light (e.g., frequent tanning or working outdoors). Melanoma is currently the most rapidly increasing incident human cancer.⁴ Significant recent research into the etiology of human melanoma suggests multiple causes that are independent of the aforementioned UV-associated mutagenesis.⁵ Since most breeds of dogs have a hair coat that likely affords them protection from sunlight, UV-associated melanoma is less likely as a primary causative agent in the dog. However, pigment cells divide every time there is injury to the skin or if there is constant trauma (e.g., areas where dogs scratch or lick). Nevertheless, risk factors for canine melanoma are not well established.

The most common oral malignancy in the dog is melanoma.^{2,3,6,7} Oral melanoma is most commonly diagnosed in Scottish terriers, golden retrievers, poodles, and dachshunds.^{2,8} Oral melanoma is primarily a disease of older dogs without gender predilection but may be seen in younger dogs.⁸⁻¹⁰ Additional oral tumor differentials include squamous cell carcinoma (SCC), fibrosarcoma, epulides/odontogenic tumors, and others.^{2,3,7,11-13} Melanomas in the oral cavities of dogs are found in the following locations by order of decreasing frequency: gingiva, lips, tongue, and hard palate. Feline melanoma is relatively rare but appears to be malignant in most cases.^{3,14-21}

Melanomas in dogs have extremely diverse biologic behaviors, depending on a large variety of factors. A thorough understanding of these factors helps the clinician to delineate in advance the appropriate staging, prognosis, and treatments. The primary factors that determine the biologic behavior of an oral melanoma in a dog are site, size, stage, and histologic parameters.^{8-10,22,23} Unfortunately, even with a comprehensive understanding of all of these factors, there are melanomas that have an unreliable biologic behavior; thus there is a need for additional research into this relatively common, heterogeneous, and frequently extremely malignant tumor.

Pathology and Molecular Biology

Melanomas can be difficult to diagnose pathologically in some situations, especially anaplastic amelanotic melanomas, which can masquerade as soft tissue sarcomas.^{24,25} Numerous investigators have attempted to increase the precision of identification of melanomas predominantly through immunohistochemical means.²⁵⁻²⁹ This identification can be accomplished through the use of multiple immunohistochemical assays on suspected melanoma tissue or through the use of an immunohistochemical cocktail of antibodies. The use of PNL2 and tyrosinase, beyond the typical use of Melan A and S100, appears to hold particular promise.^{30,31}

The molecular characterization of canine and feline melanomas remains comparatively attenuated compared to the more comprehensive evaluation of human melanomas.³² *BRAF* is a member of the mitogen-activated protein kinase (MAPK) signaling pathway, which is commonly mutated in human cutaneous melanoma.³³ However, *BRAF* mutations are uncommon in canine oral malignant melanoma,³⁴ suggesting that certain canine and/or feline malignancies can have similar molecular signatures in addition to their already well-known clinical similarities in the context of resistance to chemotherapy and irradiation and similar variable sites of metastatic propensity. A number of investigators have reported a variety of molecular abnormalities or associations in canine and feline melanoma.³⁵⁻⁵²

Biologic Behavior and Prognostic Factors

The biologic behavior of canine oral melanoma is extremely variable and best characterized based on anatomic site, size, stage, and histologic parameters. On divergent ends of the spectrum would be a low-grade 0.5-cm haired-skin melanoma, which is highly likely to be cured with simple surgical extirpation, in comparison to a 5.0-cm high-grade malignant oral melanoma with a poor-to-grave prognosis. Similar to the development of a rational staging, prognostic, and therapeutic plan for any tumor, two primary questions must be answered: what is the local invasiveness of the tumor and what is the metastatic propensity? The answers to these questions will determine the prognosis and appropriate therapies.

The anatomic site of melanoma is highly, although not completely, predictive of local invasiveness and metastatic propensity. Melanomas involving the haired-skin that are not in proximity to mucosal margins often behave in a benign manner.^{1,3} Surgical extirpation is often curative, but histopathologic examination is imperative for delineation of margins, as well as a description of cytologic features. The use of Ki67 immunohistochemistry (IHC) has been

reported to more reliably predict potential malignant behavior compared to classic histology for cutaneous melanoma.⁵³

Oral and/or mucosal melanoma has been considered an extremely malignant tumor with a high degree of local invasiveness and high metastatic propensity.^{2,8-10,22,54} This biologic behavior is similar to human oral and/or mucosal melanoma.^{3,55} Two recent studies have called this dogma into question and suggest benign oral melanomas can occur more frequently than previously published.^{56,57} Caution is necessary when assessing histopathologic descriptions, suggesting a benign course for oral melanoma. The first author has managed approximately 20 dogs over the last 7 years presenting with florid systemic metastases with an original histopathologic report, suggesting an expectation for a benign clinical course based on a high degree of differentiation. Similar to cutaneous melanoma, Ki67 appears to hold prognostic importance in canine oral melanoma as well.⁵⁸

Anatomic sites of intermediate prognostic significance between the generally benign-acting haired-skin and the often malignant and metastatic oral/mucosal melanomas in dogs include the digit and footpad. Dogs with melanoma of the digits without lymph node or distant metastasis treated with digit amputation are reported to have a median survival time (MST) of approximately 12 months, with 42% to 57% alive at 1 year and 11% to 13% alive at 2 years.^{59,60} Unfortunately, metastasis from digit melanoma at presentation is reported to be 30% to 40%,^{59,61} and the aforementioned outcomes with surgery suggest that subsequent distant metastasis is common even when no overt metastasis is found at presentation or digit amputation. The prognosis for dogs with melanoma of the footpad has not been thoroughly established; the first author (PJB) has found this anatomic site to be anecdotally similar in metastatic propensity and prognosis to digit melanoma. Interestingly, human acral lentiginous melanoma (plantar surface of the foot, palms of the hand and digit) has an increased propensity for metastasis.⁶²

A thorough review of prognostic factors in canine melanocytic neoplasms has been recently published.⁶³ This review took a regimented, systematic approach to analyzing published reports to date in order to identify those factors that appear to be repeatable and statistically defensible, while also identifying areas in which additional work is necessary due to incomplete data. For those veterinary clinicians and/or researchers interested in canine melanoma, this publication cannot be more strongly recommended. Tables 1 and 2 from this report are particularly useful in estimating prognosis for a specific patient and subsequent identification of the most logical treatment options.

Size and Stage

For dogs with oral melanoma, primary tumor size has been found to be prognostic. The World Health Organization (WHO) staging scheme for dogs with oral melanoma is based on size and metastasis and is summarized in Box 19-1. MacEwen and colleagues reported MSTs for dogs with oral melanoma treated with surgery to be approximately 17 to 18 months, 5 to 6 months, and 3 months for stage I, II, and III disease, respectively.⁹ More recent reports suggest stage I oral melanoma treated with conventional therapies, including surgery, radiation, and/or chemotherapy, have MSTs of approximately 12 to 14 months, with most dogs dying of distant metastatic disease rather than local recurrence.^{64,65} Other investigators have found dogs with stage I oral melanoma to have median progression-free survival (PFS) times of 19 months, similar to the original MacEwen et al report.⁶⁶

Box 19-1 Traditional World Health Organization (WHO) TNM-Based Staging Scheme for Dogs with Oral Melanoma

T: Primary Tumor

- T1 Tumor ≤2 cm in diameter
- T2 Tumor 2-4 cm in diameter
- T3 Tumor >4 cm in diameter

N: Regional Lymph Nodes

- N0 No evidence of regional node involvement
- N1 Histologic/cytologic evidence of regional node involvement
- N2 Fixed nodes

M: Distant Metastasis

- M0 No evidence of distant metastasis
- M1 Evidence of distant metastasis

Stage I = T1 N0 M0

Stage II = T2 N0 M0

Stage III = T2 N1 M0 or T3 N0 M0

Stage IV = Any T, any N, and M1

Staging

The staging of dogs with melanoma is relatively straightforward. A minimum database should include a thorough history and physical examination, complete blood and platelet count, biochemical profile, urinalysis, three-view thoracic radiographs, and local lymph node aspiration with cytology, whether lymphadenomegaly is present or not. Williams and Packer reported that approximately 70% of dogs with oral malignant melanoma had local lymph node metastasis when lymphadenomegaly was present, but more importantly, approximately 40% had local lymph node metastasis when no lymphadenomegaly was present.⁶⁷ Additional considerations should be made for abdominal compartment testing (e.g., abdominal ultrasound) in all cases of CMM, especially in cases with moderate-to-high metastatic anatomic sites such as the oral cavity, feet, or mucosal surface of the lips, because melanoma metastasizes to the abdominal lymph nodes, liver, adrenal glands, and other sites.

The use of sentinel lymph node mapping and lymphadenectomy is of diagnostic, prognostic, and clinical benefit in human melanoma.⁶⁸ Relatively few investigations have been reported to date for sentinel lymph node mapping and/or excision for dogs with malignancies,⁶⁹⁻⁷³ and we strongly encourage additional investigation in this area. Furthermore, the use of novel staging modalities such as gallium citrate scintigraphy is also encouraged.⁷⁴

Treatment

Surgical Aspects

Surgery continues to be the most effective local treatment modality for melanoma, and early detection is often necessary for a successful outcome. Tumors in the caudal aspect of the oral cavity are often large by the time they are diagnosed relative to rostral tumors; therefore it is more difficult to obtain complete surgical excision. Gross characteristics of melanomas raise suspicion for the

• **FIGURE 19-1** Excisional biopsy being performed on the popliteal lymph node from the dog in Figure 19-6. Note the effaced node overtaken with pigmented cells and the smaller nodule within the lymphatic vessel slightly distal to the node (toward the right in the photograph).

diagnosis, and pigmented melanomas can be easily confirmed via fine needle aspiration and cytology. In dogs, small (<2 cm), mobile, well-circumscribed, slow-growing cutaneous melanomas tend to be benign and easily excisable, whereas large, poorly defined, ulcerated, and rapidly growing tumors can make surgical excision difficult. In the latter example, incisional biopsy and IHC can be an important part of the diagnostic work-up, particularly if the mass is nonpigmented and the diagnosis of melanoma is in question. In cases for which lymph node cytology results are equivocal (e.g., difficulty distinguishing between melanophages and melanoma cells), lymph nodes should be surgically excised and submitted for histopathologic evaluation (which includes IHC). Enlarged lymph nodes are often associated with metastasis, particularly with advanced tumors or tumors of high grade, and nodal effacement is common (Figure 19-1).

Benign cutaneous tumors are typically completely excised with 1-cm skin margins (and ideally one fascial plane deep). Partial mandibulectomy and maxillectomy are usually required for complete removal of oral melanomas arising from the gingiva or from other oral mucosa in close proximity to bone.⁷⁵ A common error is to “shave off” a gingival mass simply because bone invasion is not observed. Due to the close proximity of the gingiva to the underlying bone, this approach typically leaves residual microscopic disease that leads to local recurrence (Figure 19-2). Advanced imaging (i.e., computed tomography [CT] scans or magnetic resonance imaging [MRI]) is critical for assessment of tumor extent and potential bone involvement. It is also helpful in the detection of enlarged regional lymph nodes (e.g., medial retropharyngeal nodes) that are difficult to palpate.

Some tumors do occur in mucosal areas that are not adjacent to bone (e.g., buccal mucosa) or originate in the lip (Figure 19-3) or tongue (Figure 19-4) and are amenable to excision of the soft tissues only. The location of the tumor dictates the type of partial maxillectomy (i.e., premaxillary, unilateral rostral, central, or caudal) that is required. Complete excision of oral tumors has been shown to significantly impact prognosis.⁷⁶ Dogs with tumor cells extending to the peripheral margin were 3.6 times more likely to die from tumor-related causes compared to dogs for which margins were

• **FIGURE 19-2** Local recurrence following incomplete resection and postoperative radiation of a gingival melanoma above the right carnassial tooth (caudal is to the left and the right canine tooth can be seen in the lower right-hand corner). When first treated, the mass was reportedly less than 1 cm diameter and wide resection (i.e., partial maxillectomy) was not performed.

• **FIGURE 19-3** Amelanotic melanoma involving the rostral aspect of the right lip; 1- to 2-cm margins resulted in complete excision.

considered complete. In that same study, dogs with tumors caudal to premolar number three (PM3) were 4.3 times more likely to die from tumor-related causes compared to dogs with tumors located rostral to PM3.

For small caudal tumors lateral to the dental arcade (Figure 19-5), an oral approach provides enough exposure/access for complete excision; however, large tumors of the caudal maxilla or small tumors that extend medial to the dental arcade are best treated via a combined dorsal and intraoral approach.⁷⁷ The combined approach maximizes the surgeon's ability to obtain wide margins on tumors involving the caudal hard palate and inferior orbit. For small, superficial melanomas associated with the mandible, partial mandibulectomy is typically sufficient⁷⁸; however, for large tumors that show evidence of intramedullary extension, consideration

• **FIGURE 19-4** **A**, Lingual melanoma near the midline of the tongue of a dog. These masses are often superficial and can be easily excised with 1- to 2-cm lingual mucosal margins and a layer of muscle fibers deep to the mass. **B**, Closure results in little disruption of the lingual architecture and postoperative function is excellent.

should be given to a subtotal or complete hemimandibulectomy. Local recurrence rates vary from 22% following mandibulectomy to 48% after maxillectomy^{75,79} and the MST for dogs treated with surgery alone varies from 150 to 318 days, with 1-year survival rates less than 35%.^{28,75,76,78-81}

There are few objective data available to guide decision making for surgical margin width. Given the invasive nature of malignant melanomas, wide margins (2 to 3 cm) are optimal whenever possible; however, for oral lesions, wide margins are often not possible due to the limited amount of surrounding normal tissues. In the author's experience, 1 to 2 cm margins are usually adequate for complete excision of malignant tumors with well-defined borders (Figures 19-5 and 19-6). As with any oral tumor, inspection of the gross tumor borders must be interpreted along with diagnostic imaging to determine resectability and resection lines. Wider margins are usually possible with digital melanomas because digit amputation can often be performed at a level several joints above the proximal extent of the tumor.

With the widespread access to advanced imaging and improvements in surgical techniques (e.g., combined dorsal and intraoral approach for caudal maxillary tumors) and surgical oncologic

• **FIGURE 19-5** **A**, Intraoperative photograph of a melanoma confined to the lateral aspect of the caudal dental arcade. Surgical margin width in this case is approximately 1.5 cm around the cranial, dorsal, and caudal borders of the tumor. The incision along the hard palate was made just medial to the dental arcade. **B**, Surgical margins are inked with a green surgical ink and histopathologic assessment showed complete margins.

• **FIGURE 19-6** Malignant melanoma in the webbing between digits 3 and 4 (same dog as in Figure 19-1). Surgical margins were between 1 and 2 cm beyond the tumor edge. Excision was complete in this case.

training, complete tumor excision is more likely to be achieved. The surgical goals should be driven by the tumor stage, its location, and the surgeon's ability to perform a wide resection in locations where surgery is difficult (e.g., large caudal tumors). Unplanned or limited attempts at excision should not be made because the first chance to operate is the best chance to achieve tumor-free margins. For patients that undergo surgical excision, quality of life is usually very good and most dogs resume eating in the first day or two following surgery. Further, owner satisfaction with functional and cosmetic results following mandibulectomy and maxillectomy is high.⁸² The functional outcome of single digit amputation is excellent and partial foot amputations (requiring excision of more than one digit; see Figure 19-6) are also tolerated very well and result in a good functional outcome.⁸³

For tumors that are not amenable to wide excision or result in incomplete margins via histopathologic assessment, the combination of surgery and radiation or surgery plus adjuvant therapy should be considered. Historically, surgery has not been recommended when metastatic disease has been documented (e.g., a positive lymph node is discovered during tumor staging). However, the role of adjuvant therapy (chemotherapy or immunotherapy) in conjunction with cytoreductive surgery is being investigated for human metastatic melanoma and such approaches are now being explored in dogs (covered elsewhere in this chapter).⁸⁴⁻⁸⁶

Radiation Therapy

Radiation therapy plays an important role in the management and treatment of canine and feline oral melanomas. As with most tumor types, radiation therapy is used for the purpose of achieving local or regional control of the tumor. Radiation therapy has been described as both a primary and adjuvant therapy and both hypofractionated and definitive protocols have been used (Table 19-1).⁸⁷⁻⁹²

Melanoma is thought to be a relatively radioresistant tumor type often necessitating a higher dose in each fraction to achieve local control, although this point is somewhat controversial.⁹³ Most protocols used in dogs and cats have pursued higher dose per fraction protocols accordingly, although the relative radiosensitivity of melanoma in companion animal species has not been determined.

Hypofractionated protocols have the advantage of fewer treatments with fewer anesthetic episodes, lower cost, and less

time commitment for the owner. These protocols in general also result in less severe acute effects. The main disadvantage of hypofractionated protocols is a lower overall and biologic equivalent dose, which results in lower rates of local control and an increased risk for late side effects. For a discussion of side effects, see the section on radiation side effects later in this chapter and in Chapter 12.

When planning a radiation field, most clinicians will choose to treat both the oral component of the disease and the regional lymph nodes, including the mandibular and medial retropharyngeal lymph nodes due to the high rate of metastasis to these sites.

Treatment planning can be done manually or can be planned by computer to allow a more conformal and homogeneous dose distribution with better sparing of normal tissues. Most studies have reported using at least a 2-cm margin around the tumor bed or surgical incision site. The field can be shaped by using manual blocking or, if available at the treating facility, a multileaf collimator (Figure 19-7).

Outcomes of Dogs and Cats Treated with Radiation Therapy for Oral Melanoma

The reported range of partial and complete responses to radiation therapy are 25% to 31% and 51% to 69%, respectively, yielding an overall response rate of 82% to 94%.^{87,90,92} When treating gross disease, responses are generally rapid, and dramatic decreases in tumor volume can be seen within several weeks of starting therapy (Figure 19-8). PFS has been reported to range from 5 to 7.9 months.^{89,90} Reported recurrence rates after radiotherapy vary and are confounded by different radiation protocols and adjuvant therapies used in these studies. Proulx et al reported a local recurrence rate of 26% when treating microscopic disease after incomplete surgical resection and radiotherapy and 45% for dogs treated with radiotherapy for macroscopic disease.⁹⁰

The reported MSTs for dogs treated with radiotherapy range from 5.3 to 11.9 months (see Table 19-1).^{87,90-92} The majority of these studies are retrospective and use a variety of radiotherapy equipment, protocols, and adjuvant therapies, making it difficult to determine an ideal treatment regimen. Reported protocols include 2 to 4 Gy fractions daily for 12 to 19 treatments, 4 Gy per fraction 3

• **FIGURE 19-7** Multileaf collimator plan for a dog with an oral melanoma (A) and a portal image taken of the same dog (B). The outlined red area is the exposed field for the radiotherapy plan. A second wider exposure was taken to be able to view the surrounding anatomy and allow adjustment of the patient to ensure the correct anatomic area was treated. This plan was designed to cover the primary tumor, as well as the submandibular and medial retropharyngeal lymph nodes.

• **TABLE 19-1** Published Studies on the Treatment of Oral Melanoma with Radiation Therapy

STUDY (YEAR PUBLISHED)	SPECIES (No.)	SOURCE AND DOSE OF RADIATION	OUTCOMES	CHEMOTHERAPY
Bateman et al (1994) ⁸⁷	Canine (18)	Cobalt-60: 24 Gy in three 8-Gy fractions once weekly.	One dog died during treatment, 9/18 had a complete response, 5/18 had a partial response, 3 had no response, MST: 7.9 months.	
Blackwood et al (1996) ⁸⁸	Canine (36)	4 MV linear accelerator (n = 29), 250 kVp orthovoltage unit (n = 1), combination of the two machines (n = 4), 36 Gy in four 9 Gy once weekly fractions.	25/36 dogs had a complete response, 9/36 had a partial response, overall MST not reported (range 5 to 213 weeks), MST for dogs that died of tumor-related causes: 21 weeks.	
Theon et al (1997) ⁸⁹	Canine (38)	Cobalt-60: 48 Gy in twelve 4-Gy fractions three times weekly.	PFS: 7.9 months, MST: not reported.	
Proulx et al (2003) ⁹⁰	Canine (140)	Cobalt-60: 36 Gy in four 9-Gy fractions once weekly (n = 54); 30 Gy in three 10-Gy fractions once weekly (n = 69), or 45.6-57 Gy in twelve to nineteen 2-4-Gy fractions (n = 17).	Median time to first event (metastasis, local recurrence, or death): 5.0 months, MST: 7.0 months.	80 dogs received chemotherapy (carboplatin [n = 60], cisplatin [n = 3], melphalan [n = 17]). Chemotherapy did not impact time to first event or survival.
Freeman et al (2003) ⁹¹	Canine (39)	Cobalt-60 and 4 MV linear accelerator: 36 Gy in six 6-Gy fractions once weekly.	MST: 363 days.	Dogs received cisplatin (10-30 mg/m ² IV) or carboplatin (90 mg/m ² IV) chemotherapy 60 minutes before radiation delivery.
Farrelly et al (2004) ¹⁸	Feline (5)	Cobalt-60: 24 Gy in three 8-Gy fractions once weekly.	One complete response, two partial responses, MST: 146 days.	Two cats received chemotherapy, one received carboplatin, one carboplatin and mitoxantrone, and one was treated with a DNA-based vaccine. One cat had additional radiation after initial failure.
Murphy et al (2005) ⁹²	Canine (28)	4 MV linear accelerator: 36 Gy in 4 once weekly fractions.	No chemotherapy group MST: 307 days. Chemotherapy-treated group MST: 286 days.	No chemotherapy given to 13. 15 received carboplatin chemotherapy (300 mg/m ² IV every 21 days).

MST, Median survival time; PFS, progression-free survival; IV, intravenous.

FIGURE 19-8 A dog with an oral melanoma treated with an 8 Gy per fraction once weekly protocol on the first day of therapy (A) and before the fourth and final fraction of radiotherapy (B). This dog went on to have a complete response.

times weekly for 4 weeks, 8 Gy per fraction once weekly for 3 treatments, and 9 Gy per fraction once weekly for 4 fractions.

Farrelly et al reported five cats that were treated with radiotherapy for oral melanoma.¹⁸ There was one complete response and two partial responses with a MST of 146 days. One cat was treated with carboplatin, and one cat was treated with carboplatin and mitoxantrone, in addition to the radiation protocol. Another cat in this study was given a DNA-based vaccine as adjuvant to radiation.

Combining Chemotherapy with Radiation Therapy

There are conflicting data regarding the efficacy of chemotherapy used concurrently or in the adjuvant setting, and there is no clear evidence that chemotherapy decreases the risk of metastasis or local recurrence or that it extends MSTs. Published studies have reported on dogs receiving carboplatin, intralesional cisplatin, intravenous cisplatin, and melphalan.^{90-92,94-97}

Freeman et al reported on 39 dogs with incompletely resected oral melanoma that were treated with either cisplatin (10 to 30 mg/m² IV) or carboplatin (90 mg/m² IV) given once weekly approximately 1 hour before receiving radiation therapy.⁹¹ The radiation protocol consisted of 6 once-weekly 6 Gy fractions. They reported a MST of 11.9 months. Fifteen percent of the dogs had local recurrence, with a reported median time to metastasis of 10.2 months. Although this is among the longest survival times reported, the majority of dogs had stage T1 (56.4%) or stage T2 (35.9%) tumors prior to surgery, which may have biased their findings for longer survival times, making this result less applicable to the general population of dogs presenting with oral melanoma.

Proulx et al retrospectively looked at dogs treated with a variety of radiation protocols in which 60 dogs received no chemotherapy and 80 dogs received a chemotherapy protocol consisting of carboplatin (n = 60), cisplatin (n = 3), or melphalan (n = 17).⁹⁰ They found that chemotherapy treatment had no significant impact on either time to first event or overall survival. The mean dose of carboplatin used in this study was 225 mg/m² IV, which is lower than the dose most often used in this species.⁹⁵ This lower dose may have contributed to the lack of statistical differences in delaying time to metastasis or recurrence and impact on overall survival.

Murphy et al retrospectively evaluated a series of 28 dogs that received once weekly 8 Gy fractions to a total dose of 32 Gy.⁹² Fifteen dogs in this study received 300 mg/m² IV of carboplatin every 21 days for a median of 3 doses, although chemotherapy dose reductions were allowed on subsequent doses if toxicity was found

on the initial dose. Thirteen dogs received no chemotherapy with a MST of 307 days, and the 15 dogs that were treated with chemotherapy had an overall MST of 286 days. These numbers were not significantly different. The use of chemotherapy also did not reduce the proportion of dogs that died from metastasis. The dose of carboplatin in this study was chosen to decrease the risk of toxicity seen in another report that evaluated the use of carboplatin alone in dogs with melanoma in which dogs over 15 kg received 350 mg/m² IV, and several of the dogs experienced significant toxicity requiring hospitalization, although the dose used was higher than the dose used in the Proulx study.^{90,96}

Some concerns have been raised that using radiotherapy and chemotherapy concurrently can increase systemic side effects. Hume et al reported on 65 dogs treated with concurrent carboplatin and a definitive course of radiation therapy; six of these dogs were diagnosed with an oral melanoma.⁹⁷ Carboplatin was administered at 200 to 300 mg/m² IV. Dogs with oral melanoma in this study were prescribed 4 Gy per fraction delivered on Mondays, Wednesdays, and Fridays for a total dose of 48 Gy. They found that 21% developed grade 3 or 4 neutropenia, 20% developed grade 3 or 4 thrombocytopenia, and 10% developed grade 3 to 5 gastrointestinal toxicity according to the Veterinary Cooperative Oncology Group—Common Terminology Criteria for Adverse Events (VCOG-CTAE), version 1.0.⁹⁸ Further, five of the dogs did not complete the radiation course and seven had delays in radiation therapy due to illness.

Radiation-Associated Prognostic Factors

Several possible prognostic factors have been identified that affect radiation treatment outcomes in dogs diagnosed with malignant oral melanoma. These factors must be viewed with caution because some of the data are conflicting and most are derived from retrospective case series without the use of control groups.

Proulx et al reported outcomes from a total of 140 dogs treated with radiation and identified that dogs without radiologic evidence of bone destruction were found to have longer times to first event and longer overall survival times than dogs with radiographically evident bone changes.⁹⁰ Destruction of underlying bone can be evaluated by using survey radiographs or by CT scan with greater sensitivity. Underlying bony involvement has been reported in up to 92% of dogs with melanoma (Figure 19-9).⁹¹

The size of an oral tumor also affects prognosis, but more studies need to be conducted to confirm that size is a prognostic factor for dogs undergoing irradiation. Theon et al analyzed a series of 105 dogs with oral tumors treated with 4 Gy per fraction of radiation on an alternate day basis to a total dose of 48 Gy.⁸⁹ Thirty-eight dogs in this report were diagnosed with oral melanoma. They found a

FIGURE 19-9 **A**, Postcontrast axial computed tomography (CT) image of a dog with a maxillary oral melanoma. Note the heterogeneously contrast enhancing soft tissue mass. **B**, Precontrast axial image at the same level as the image in **A**. Note the bone destruction of the maxillary bone and the invasion of the soft tissue mass into the nasal cavity.

median PFS of 7.9 months. Dogs from this group diagnosed with T1 stage lesions had a median PFS of 11.3 months, whereas dogs with stage T2 and T3 lesions had a median PFS of 6.0 and 6.7 months, respectively. They also found that distant metastasis as opposed to local failure of radiation was the major cause of first failure event. Blackwood et al also found that dogs with smaller oral melanomas treated with a 9 Gy per fraction once weekly protocol delivered over a 4-week period did better than dogs with larger tumors.⁸⁸ Dogs with tumors less than 5 cm³ were more likely to achieve a complete response. Further, the volume of the tumor affected median overall survival with a MST of 86 weeks for dogs with tumors less than 5 cm³ compared to 16 weeks for dogs with tumors between 5 and 15 cm³ and 20.5 weeks for dogs with tumors greater than 15 cm³ in size. Proulx et al found that tumor size affected times to first event, pulmonary metastasis, and death.⁹⁰ These studies contrast the findings of Bateman et al, who did not find an association of stage of the oral melanoma and response to radiation therapy or survival times.⁸⁷

The role of vascular endothelial growth factor (VEGF) in the radiation response of melanoma has been incompletely evaluated.

Several studies have found that dogs with oral melanoma have higher plasma VEGF concentrations than normal control dogs.^{43,99} In a preliminary study looking at plasma VEGF levels in a variety of tumor types treated with hypofractionated radiotherapy, the four dogs diagnosed with melanoma had the highest mean plasma VEGF levels of all tumor types, although no significant changes in VEGF levels were noted over the course of treatment.⁹⁹ This same group also evaluated the effect that VEGF levels had on patient outcome.^{100,101} In a group of 39 dogs, 6 of which were diagnosed with melanoma, it was also found that VEGF levels did not significantly increase over the course of radiotherapy. However, dogs with higher plasma VEGF levels treated with hypofractionated protocols had a shorter time to treatment failure and a shorter median survival.

Side Effects of Radiation Therapy

Side effects of radiation therapy are a major concern of owners and can impact a patient's quality of life. Prolonged side effects are particularly important to take into account when the goal of radiotherapy is palliative in nature (i.e., to improve quality of life). The severity and scope of radiation side effects and the type seen depend on several factors, including the total dose of radiation given, the dose per fraction, and the volume of tissue in the radiation field. Higher total radiation doses delivered in smaller dose per fractions tend to produce worse acute effects, whereas higher dose per fraction will increase the risk of late effects occurring. Newer treatment machines and computerized treatment planning have helped limit the volume of normal tissue that is irradiated, which in turn limits the area where these acute effects are seen. Side effects are generally broken down into acute and late effects. A standardized radiation scoring system for acute and late effects on oral mucosa and bone have been published by the Veterinary Radiation Therapy Oncology Group (VROG).¹⁰² Acute radiation effects on the oral cavity range from injected mucous membranes (grade 1) to patchy mucositis without evidence of pain (grade 2) to confluent fibrinous mucositis requiring the use of analgesics to ulceration, hemorrhage, and necrosis (grade 3). These can be seen on the gingival surfaces, tongue, or buccal mucosa.¹⁰² Although grade 3 toxicity is possible, most studies have not reported high-grade toxicity with either definitive or palliative protocols.⁸⁷⁻⁸⁹ The worst clinical signs associated with acute effects generally occur toward the end or just after the completion of radiotherapy and heal within 1 to 2 weeks given that the oral mucosa tends to heal rapidly.

Skin effects can also be seen with dry and moist desquamation possible. Most studies have reported these side effects to be minimal and to resolve quickly after completion of the radiation course. Other skin side effects reported include permanent alopecia in the radiation field and skin fibrosis.⁸⁹

Bone necrosis is a reported late side effect of radiation therapy and probably is a greater risk in hypofractionated protocols. Blackwood et al reported three cases of bone necrosis in a series of 36 dogs treated with a hypofractionated protocol; two required surgical debridement.⁸⁸ Theon et al also reported 7.6% of dogs developed bone necrosis and fistula formation in a series of oral tumors treated with a curative-intent protocol.⁸⁹

Another possible late effect is a radiation-induced tumor. In order for a tumor to be classified as likely being radiation induced the following criteria are applied: (1) the tumor developed in an area that was previously irradiated, (2) an adequate period of time has passed since initial irradiation to allow for new tumor formation, (3) preirradiation evaluation revealed normal bone in cases in which the second tumor is of bone origin, and (4) histologic

diagnosis of a second, different malignant tumor was confirmed at the site of initial irradiation.¹⁰³

In dogs with oral melanoma treated with radiation therapy, most patients do not survive long enough for radiation-induced tumors to become a significant issue, but as more effective systemic adjuvant therapies become available, this becomes a concern. Sarcomas are thought to be the most common radiation-induced tumor, although Theon et al did report on a gingival SCC forming within a radiation field 36 months after radiation treatment.⁸⁹

Salvage procedures using flaps for the surgical repair of radiation late effects have been described in dogs, although they are more likely to result in complications than the surgical flaps used in the surgical treatment of an area treated with preoperative radiotherapy or in flaps exposed to radiation in the immediate postoperative period.¹⁰⁴

Radiation therapy is an effective modality used to achieve local-regional control for oral melanoma with minimal side effects in dogs and cats. Until more effective treatments to control and treat metastatic disease become available and the effectiveness of lower dose per fraction protocols are better studied, hypofractionated protocols will likely remain the most commonly used radiation protocols in veterinary medicine.

Treatments Other than Surgery and Radiation

Other modalities reported for local tumor control as case reports and/or case series have included intralesional cisplatin implants, intralesional bleomycin with electronic pulsing, and others, but widespread use has not been reported to date.¹⁰⁵⁻¹⁰⁸

In dogs with melanoma in the aforementioned anatomic sites predicted to have a moderate-to-high metastatic propensity or dogs with cutaneous melanoma with a high tumor score and/or increased proliferation index through increased Ki67 expression, the use of systemic therapies is warranted due to the high risk for metastasis. Rassnick and colleagues reported an overall response rate of 28% using carboplatin for dogs with malignant melanoma.⁹⁶ Unfortunately, only one dog had a minimally durable complete response (approximately 150 days), and the rest were nondurable partial responses. Similarly, Boria et al reported an 18% response rate and MST of 119 days with cisplatin and piroxicam in canine oral melanoma.¹⁰⁹ Other reports using single-agent dacarbazine, melphalan, or doxorubicin suggest poor or absent activity.¹¹⁰⁻¹¹³ More recently and importantly, two studies suggest that chemotherapy plays an insignificant role in the adjuvant treatment of canine melanoma.^{65,99} Although it can be argued that the studies performed to date that evaluate the activity of chemotherapy in an adjuvant setting for canine melanoma have been suboptimal due to a variety of reasons, the extensive human literature in this specific setting also suggests melanoma is an extremely chemotherapy-resistant tumor.¹¹⁴ It is clear that new approaches to the systemic treatment of this disease are desperately needed.

One potential therapeutic avenue that has not been reported to date in canine or feline melanoma is the use of cyclooxygenase-2 (COX-2) inhibitors. A number of authors have investigated the expression of COX-2 in canine melanoma and have found positive correlations of COX-2 expression to proliferation and survival.¹¹⁵⁻¹¹⁷ Studies investigating the clinical responsiveness of canine melanoma to COX-2 inhibitors (and potential correlation to COX-2 expression) are encouraged.

Immunotherapy represents one logical systemic therapeutic strategy for melanoma. A variety of immunotherapeutic strategies

for the treatment of human melanoma have been reported previously, with typically poor outcomes due to a lack of breaking tolerance. Immunotherapy targets and strategies to date in canine melanoma have used autologous tumor cell vaccines (with or without transfection with immunostimulatory cytokines and/or melanosomal differentiation antigens), allogeneic tumor cell vaccines transfected with interleukin 2 (IL-2) or granulocyte-macrophage colony-stimulating factor (GM-CSF), liposomal-encapsulated nonspecific immunostimulators (e.g., L-MTP-PE), intralesional Fas ligand DNA, small interfering RNA (siRNA) against the survivin and/or *Bcl-2* genes, bacterial super-antigen approaches with GM-CSF or IL-2 as immune adjuvants, PEGylated tumor-necrosis factor α (TNF- α), suicide gene therapy, adenovector CD40 ligand, and finally, canine dendritic cell vaccines loaded with melanosomal differentiation antigens.^{9,118-132} Although these approaches have produced some clinical antitumor responses, the methodologies for the generation of these products are expensive, time consuming, sometimes dependent on patient tumor samples being established into cell lines, and fraught with the difficulties of consistency, reproducibility, and other quality control issues. Furthermore, we are just beginning to more fully understand the native immune dysregulation potentially induced by the malignancy through increased T regulatory (Treg) cells, which suppress antitumor responses^{133,134} (see also Chapter 13).

The advent of DNA vaccination circumvents many of the previously encountered hurdles in vaccine development. DNA is relatively inexpensive and simple to purify in large quantities. The gene coding for the antigen of interest is cloned into a bacterial expression plasmid with a constitutively active promoter. The plasmid is introduced into the skin or muscle with an intradermal or intramuscular injection. Once in the skin or muscle, professional antigen-presenting cells, particularly dendritic cells, are able to present the transcribed and translated antigen in the proper context of major histocompatibility complex and co-stimulatory molecules. Although DNA vaccines have induced immune responses to viral proteins, vaccinating against tissue-specific self-proteins on cancer cells is clearly a more difficult problem. One way to induce immunity against a tissue-specific differentiation antigen on cancer cells is to vaccinate with xenogeneic (different species) antigen or DNA that is homologous to the cancer antigen. As illustrated in Figure 19-10, vaccination with DNA-encoding cancer differentiation antigens is ineffective when self-DNA is used, but tumor immunity can be induced by orthologous DNA from another species.¹³⁵

Tyrosinase is a melanosomal glycoprotein, essential in melanin synthesis, and routinely found to be overexpressed in a wide variety of melanomas across species.^{31,136-139} Immunization with xenogeneic human DNA-encoding tyrosinase family proteins induced antibodies and cytotoxic T-cells against syngeneic B16 melanoma cells in C57BL/6 mice, but immunization with mouse tyrosinase-related DNA did not induce detectable immunity.¹⁴⁰ In particular, xenogeneic DNA vaccination induced tumor protection from syngeneic melanoma challenge and autoimmune hypopigmentation. Thus xenogeneic DNA vaccination could break tolerance against a self-tumor differentiation antigen, inducing antibody, T-cell, and anti-tumor responses.

Dogs with stage I to III locoregionally controlled CMM inclusive across all xenogeneic vaccine studies to date have a Kaplan-Meier (KM) MST of more than 1075 days (median not yet reached), whereas those dogs with stage I to III CMM without local tumor control have a KM MST of 553 days ($p = 0.0002$). The KM MST for stage II to IV dogs on the phase I trials of human tyrosinase (huTyr), murine GP75 (muGP75), and murine tyrosinase (muTyr) are 389,

• **FIGURE 19-10** Cartoon outlining the xenogeneic DNA vaccination concept.

153, and 224 days, respectively. The KM MST for stage II to IV dogs treated with 50 µg muTyr, 100/400/800 µg human GM-CSF, or combination muTyr/human GM-CSF are 242, 148, and more than 900 days (median not reached), respectively. For dogs that received any melanoma vaccine except for dogs on the muTyr ± GM-CSF trial (i.e., huTyr, muTyr, and muGP75), the KM MST for stages I, II, III, and IV CMM was more than 939 days (median not reached with 92.8% survival), more than 908 days (median not reached, 79% alive at 1 year, 63% alive at 2 years), more than 1646 days (median not reached; 77%, 65%, and 57% alive at 1, 2, and 3 years, respectively), and 239 days (40.5% and 18.8% alive at 1 and 2 years, respectively).^{141,142} The results from dogs vaccinated with huTyr were published in 2003.¹⁴³

We investigated the humoral responses of dogs receiving huTyr as a potential explanation for the long-term survival seen in some of the dogs on this study. Utilizing standard enzyme-linked immunosorbent assay (ELISA) with mammalian expressed purified huTyr protein as the target of interest, we have found three of nine dogs with twofold to fivefold postvaccinal humoral responses compared to preimmune sera. We have confirmed these findings utilizing a flow-cytometric-based assay of prevaccinal and postvaccinal sera in permeabilized human SK-Mel melanoma cells expressing endogenous huTyr. Interestingly, the three dogs with postvaccinal anti-huTyr humoral responses are dogs with unexpected long-term tumor control.¹⁴⁴ Co-investigators have also determined that normal dogs receiving the huTyr-based melanoma vaccine develop Ag-specific interferon-γ (IFN-γ) T-cells.¹⁴⁵

The results of these trials demonstrate that xenogeneic DNA vaccination in CMM (1) is safe, (2) causes dogs to develop specific anti-Tyr immune responses, (3) is potentially therapeutic in stage II/III locoregionally controlled disease, and (4) is an attractive candidate for further evaluation in an adjuvant, minimal residual disease phase II setting for CMM. Based on these preliminary studies, a multiinstitutional safety and efficacy trial for U.S. Drug Administration (USDA) licensure in dogs with locally controlled stage II/III oral melanoma was initiated in 2006 with granting of conditional licensure in 2007. Results of this trial documented a statistically significant improvement in survival for vaccinates compared to historic controls,⁸⁵ and a full licensure for the huTyr-based canine melanoma vaccine from USDA-Centers for Veterinary Biology (CVB) was received in 2009. Subsequently, we have investigated the efficacy of local tumor control and use of muTyr-based DNA vaccination in dogs with digit melanoma. These investigations have found an improvement in survival compared to

historic outcomes with digit amputation only and also documented a decreased prognosis for dogs with advanced stage disease and/or increased time from digit amputation to the start of vaccination.¹⁴⁶

A similar approach has been used in human patients with metastatic melanoma in the minimal residual disease setting. Although no clinical response data are available since these patients did not have measurable disease, several phase I trials of xenogeneic DNA vaccines have been completed. Across studies of tyrosinase and gp100 DNA immunization, approximately 40% of patients develop quantifiable CD8+ T-cell responses to the syngeneic human target antigen.¹⁴⁷⁻¹⁴⁹ Two additional exciting new approaches that appear to confer a survival benefit in human metastatic melanoma include the use of the anti-CTLA-4 antibody, ipilimumab (Yervoy, Bristol-Myers Squibb), and the selective BRAF inhibitors, vemurafenib (Zelboraf, Genentech) and dabrafenib (GSK2118436, GlaxoSmith-Kline), in patients who are BRAF V600 mutation positive.¹⁵⁰⁻¹⁵²

CMM strongly appears to be a more clinically faithful therapeutic model for human melanoma when compared to more traditional mouse systems because both human and canine diseases are chemoresistant, are radioresistant, share similar metastatic phenotypes/site selectivity, and occur spontaneously in an outbred, immunocompetent scenario. It is hoped in the future that this same vaccine also plays a role in the treatment of melanoma in other species (e.g., horses, cats, humans) due to its xenogeneic origins¹³⁹ and in melanoma prevention once the genetic determinants of melanoma risk in dogs are further defined. The xenogeneic DNA vaccine platform holds promise for investigations with other antigen targets. To this end, we have recently completed a phase I study of murine CD20 DNA vaccination in dogs with B-cell non-Hodgkin's lymphoma. We also have phase I and phase II studies initiating shortly, utilizing murine CD20 and rat HER2 DNA vaccination.
