Mast Cell Tumors

20

CHERYL A. LONDON AND DOUGLAS H. THAMM

The neoplastic proliferation of mast cells referred to as a *mast cell tumor* (MCT; histiocytic mastocytoma, mast cell sarcoma) represents the most commonly encountered cutaneous tumor in the dog and the second most common cutaneous tumor in the cat.¹⁻⁵ Systemic forms of the disease are often referred to as *mastocytosis*. Canine and feline forms of the disease will be considered separately in this chapter because many differences exist with regard to histologic type, biologic behavior, therapy, and prognosis.

Canine Mast Cell Tumors

Biology of Canine Mast Cells

Mast cell precursors leave the bone marrow and migrate to various tissues throughout the body where they undergo differentiation into mature mast cells with their characteristic cytoplasmic granules, which stain metachromatically with Giemsa and toluidine blue.⁶ These granules contain a number of bioactive substances, including heparin, histamine, preformed tumor necrosis factor- α (TNF- α), and several proteases.⁶ The nature and composition of mast cell granules are highly influenced by the microenvironment in which the mast cells mature. For example, in dogs, mast cells in the gastrointestinal (GI) tract express primarily chymase, whereas mast cells in the skin express both chymase and tryptase.⁷ When stimulated, mast cells can rapidly produce a variety of proteases (chymase, tryptase), cytokines (TNF- α , interleukin-6 [IL-6]), chemokines (CCL2, CXCL1), growth factors (vascular endothelial growth factor [VEGF], basic fibroblast growth factor [bFGF]), and lipid mediators (prostaglandin D₂ [PGD₂], leukotriene C₄ [LTC₄]).⁶ Through this process, mast cells participate in several biologic activities, including wound healing, induction of innate immune responses, antiparasite activity, and modulation of reaction to insect and spider venoms.^{6,8}

Normal canine mast cells can be generated from bone marrow-derived hematopoietic precursors.^{9,10} These cells, known as *canine bone marrow-derived mast cells* (cBMMCs), have been used to characterize the functional properties of mast cells in this species. As with normal human mast cells, their differentiation requires the presence of the growth factor stem cell factor (SCF) and can be influenced by the presence of other cytokines.^{9,10} When stimulated, these cells rapidly release histamine, monocyte chemotactic protein-1 (MCP-1), TNF- α , and tryptase, and they produce several additional cytokines and chemokines, including IL-3, IL-13, granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage inflammatory protein 1 α (MIP1 α).^{9,10} Interestingly, the cBMMCs are extremely sensitive to chemical degranulation, which may help to explain why dogs exhibit such a high degree of hypersensitivity to several chemical agents, including polysorbate 80, Cremophor EL, and doxorubicin.⁹ The function of cBMMCs

can be modulated by cytokines, steroids, and nonsteroidal antiinflammatory drugs (NSAIDs).⁹⁻¹¹

Incidence and Risk Factors

MCTs represent the most common cutaneous tumor in the dog, accounting for between 16% and 21% of all cutaneous tumors.^{1,3,5,12} Although MCTs are primarily a disease of older dogs (mean age approximately 8 to 9 years), they have also been reported in younger dogs and there is no apparent gender predilection.^{1,3,5,13} Most tumors occur in mixed breeds; however, several breeds are at an increased risk for MCTs, including dogs of bulldog descent (Boxers, Boston terriers, English bulldogs, pugs), Labrador and golden retrievers, cocker spaniels, schnauzers, Staffordshire terriers, beagles, Rhodesian ridgebacks, Weimaraners, and Shar-Peis.^{1,5,14-16} The increased incidence of MCTs in certain breeds suggests the possibility of an underlying genetic cause,¹⁵ and studies are ongoing to identify these putative genetic risk factors. Interestingly, although dogs of bulldog ancestry are at higher risk for MCT development, it is generally accepted that MCTs in these dogs are more likely to behave in a benign fashion.¹ Additionally, it was recently demonstrated that pugs may develop multiple MCTs that behave in a benign fashion.¹⁷ In contrast, anecdotal evidence suggests that Shar-Peis develop MCTs that may be more biologically aggressive. Spontaneously regressing MCTs in young animals have been described in cats, pigs, horses, and humans. Multiple cutaneous MCTs that regressed within 27 weeks were reported in a 3-week-old Jack Russell terrier.¹⁸ This syndrome of spontaneous regression in young animals may indicate a hyperplastic or dysplastic syndrome rather than a true neoplastic lesion.

The etiology of MCTs in the dog is for the most part unknown. Historically, MCTs have been associated with chronic inflammation or the application of skin irritants; however, the epidemiology of disease in dogs does not support the role of a topical carcinogen.¹⁹⁻²¹ Unequivocal evidence is lacking for a viral etiology, although MCTs have been transplanted to very young or immunocompromised laboratory dogs using tumor cell tissues and rarely by cell-free extracts.²²⁻²⁴ No C-type or other identifiable virus particles have been observed, and no epidemiologic evidence exists to suggest horizontal transmission. Chromosomal fragile site expression, a phenomenon thought to genetically predispose humans to develop certain tumors, was shown to be increased in Boxers with MCTs.²⁵ However, the control population for this study was young, non-tumor-bearing Boxers, and the increased expression of chromosomal fragile sites may be due to this age difference.

The genetic changes that predispose dogs to MCTs are incompletely understood. Alterations in the *p53* tumor suppressor pathway have been identified in some canine MCTs,²⁶⁻²⁸ but *p53* sequencing in a limited number of cases has revealed no mutations.²⁹ Perturbations in expression of the proteins p21 and p27,

which are cyclin-dependent kinase inhibitors (CDKIs) that contribute to regulation of the cell cycle, have been identified in many canine MCTs.³⁰ Cytosolic receptors for estrogen and progesterone have also been detected in canine MCTs.³¹ Their role in the etio-pathogenesis of MCT is poorly understood, but evidence exists that estrogen and progesterone may influence mast cell function.³² One European study reported that female dogs with MCTs had a more favorable prognosis with chemotherapy.³³ Although the majority of studies performed in the United States have failed to detect such an association, the relatively higher frequency of intact females present in the European population may have allowed the effect of sex hormones to have a greater statistical impact on biologic behavior.

Perhaps the best-described molecular abnormality in canine MCT involves the receptor tyrosine kinase (RTK), KIT. KIT is expressed normally on a variety of cells, including hematopoietic stem cells, melanocytes, and mast cells, among others.³⁴⁻³⁶ The ligand for KIT, SCF, induces KIT dimerization, subsequent phosphorylation, and generation of intracellular signaling that promotes the proliferation, differentiation, and maturation of normal mast cells.³⁴⁻³⁶ SCF is essential for the differentiation of mature mast cells from CD34+ hematopoietic stem cells in vitro, and inhibition of KIT signaling induces apoptosis of cBMMCs.^{10,35,36} KIT expression has been demonstrated on canine MCTs, and aberrant cytoplasmic localization of KIT in MCTs may be associated with dysregulated KIT function.³⁷⁻⁴⁰ A significant proportion of canine MCTs possess mutations in the *c-kit* gene involving either the juxtamembrane domain (exons 11 and 12) or extracellular domain (exons 8 and 9).⁴¹⁻⁴⁵ These mutations result in SCF-independent activation of KIT and subsequent unregulated KIT signal transduction.^{43,44} In dogs, activating *c-kit* mutations appear to be present in 25% to 30% of intermediate-grade and high-grade MCTs, and evidence suggests that they are linked to increased risk of local recurrence, metastasis, and a worse prognosis.^{41,44,46-48} The reason for the high rate of *c-kit* mutations in dog MCTs is unknown; however, it is clear that these mutations are not germline in nature.

History and Clinical Signs

The vast majority of MCTs in dogs occur in the dermis and subcutaneous tissue,^{5,49} and most are solitary in nature, although 11% to 14% of dogs present with multiple lesions.⁵⁰⁻⁵² Approximately 50% of cutaneous MCTs occur on the trunk and perineal region, 40% on the limbs, and 10% on the head and neck.^{20,53,54} MCTs have also been reported to occur on other sites, including the conjunctiva, salivary gland, nasopharynx, larynx, oral cavity, ureter, and spine.⁵⁵⁻⁵⁹ A visceral form of MCT, often referred to as *disseminated* or *systemic mastocytosis*, has also been documented, although it is usually preceded by an aggressive primary lesion.⁶⁰⁻⁶⁴ Infiltration of abdominal lymph nodes, spleen, liver, and bone marrow is commonly observed in the setting of visceral disease, and pleural/peritoneal effusions containing neoplastic mast cells have been documented. A case series of dogs with primary GI MCTs was recently reported in which most dogs presented with vomiting, diarrhea, and melena. Only 40% of the dogs were alive at 30 days after first admission, and fewer than 10% were alive at 6 months.²⁸

It is important to note that cutaneous MCTs have an extremely varied range of clinical appearances, and they are sometimes inadvertently mistaken for nonneoplastic lesions. Well-differentiated MCTs tend to be solitary, small, slow-growing tumors that may have been present for several months. They are not typically ulcerated, but overlying hair may be lost. Undifferentiated MCTs tend to be rapidly growing, ulcerated lesions that cause considerable irritation and attain a large size. Surrounding tissues may become

FIGURE 20-1 Subcutaneous MCT from the shoulder of a dog. This mass was originally misdiagnosed as a lipoma based on palpation alone. Note tumor extension through fascia and muscle. Wide surgical excision to include deep muscle layer is necessary to achieve complete (“clean”) surgical margins.

inflamed and edematous. Small satellite nodules may develop in surrounding tissues. Tumors of intermediate differentiation fill the spectrum between these two extremes. A subcutaneous form of MCT that is soft and fleshy on palpation is often misdiagnosed clinically as a lipoma (Figure 20-1).

The history and clinical signs of dogs with MCTs may be complicated by signs attributable to the release of histamine, heparin, and other vasoactive amines from mast cell granules. Occasionally, mechanical manipulation during examination of the tumor results in degranulation and subsequent erythema and wheal formation in surrounding tissues. This phenomenon has been referred to as *Darier’s sign* (Figure 20-2)⁵¹ and can also occur spontaneously; dog owners may describe the tumor as increasing and decreasing in size. GI ulceration has been documented in 35% to 83% of dogs with MCTs that underwent necropsy.^{65,66} Histamine released from MCT granules is thought to act on parietal cells via H₂ receptors, resulting in increased hydrochloric acid secretion. Plasma histamine concentrations have been shown to be high in dogs with MCTs, and there is preliminary information that monitoring of plasma histamine concentrations may be useful in assessing disease progression.⁶⁷ These dogs also have decreased concentrations of plasma gastrin, which is normally released by antral G-cells in response to increased gastric hydrochloric acid concentrations, acting as a negative feedback loop. Dogs with substantial MCT burden (i.e., large tumors, metastatic disease, systemic disease) are much more likely to present with clinical signs related to the release of mast cell mediators. These may include vomiting, diarrhea, fever, peripheral edema, and, rarely, collapse.

Perioperative degranulation of MCTs and subsequent release of histamine and other less-characterized vasoactive substances may also result in potentially life-threatening hypotensive events during surgery. It is thought that prostaglandins in the D series secreted by tumor cells may mediate the hypotensive effects observed in humans with mast cell diseases.^{68,69} Coagulation abnormalities, also reported in dogs with MCTs, are likely due to heparin release from mast cell granules.^{63,70} Although clinical evidence of hemorrhage is not typically associated with this phenomenon, localized hemorrhage at the time of surgery as the result of degranulation following

• **FIGURE 20-2** Erythema and wheal formation occurred in surrounding skin following manipulation of this cutaneous MCT. This phenomenon, resulting from the release of vasoactive amines from mast cell granules, is known as *Darier's sign*.

tumor manipulation can be a serious complication, even in the presence of normal presurgical coagulation parameters.

Prognostic Factors

A discussion of prognostic factors associated with canine MCTs will precede sections on diagnosis and treatment because steps followed in those sections are predicated on the presence or absence of these prognostic factors. Table 20-1 lists factors known to be predictive of biologic behavior and clinical outcome in dogs with MCTs. It is important to note that no one factor is entirely predictive of biologic behavior; thus all prognostic indicators should be taken into consideration when evaluating a patient.

Histologic grade is considered the most consistent and reliable prognostic factor available for dogs with MCTs, although it will not predict the behavior of every tumor.^{14,49,71,72} Several investigators have applied histologic grading systems to canine MCTs based on degree of differentiation (Table 20-2). The number grades used in these studies are at odds. Therefore, for the sake of clarity, the three differentiation groups should be simply referred to as undifferentiated (high) grade, intermediate grade, and well-differentiated (low) grade. Table 20-3 lists the relative distribution of MCT grades encountered in larger series. Survival following surgical excision based on grade is presented in Table 20-4. The vast majority of dogs with well-differentiated tumors (80% to 90%) and approximately 75% of dogs with intermediate-grade tumors experience long-term survival following complete surgical excision.^{50,71,74-77} Metastatic rates for undifferentiated tumors range from 55% to 96%, and most dogs with these tumors die of their disease within 1 year.^{49,78} The majority disseminate first to local lymph nodes, then to the spleen

• **TABLE 20-1** Prognostic Factors for Mast Cell Tumors in Dogs

FACTOR	COMMENT
Histologic grade	Strongly predictive of outcome. Dogs with undifferentiated tumors typically die of their disease following local therapy alone, whereas those with well-differentiated tumors are usually cured with appropriate local therapy.
Clinical stage	Stages 0 and I, confined to the skin without local lymph node or distant metastasis, have a better prognosis than higher-stage disease.
Location	Subungual, oral, and other mucous membrane sites are associated with more high-grade tumors and worse prognosis. Preputial and scrotal tumors are also associated with a worse prognosis. Subcutaneous tumors may have a better prognosis. Visceral or bone marrow disease usually carries a grave prognosis.
Cell proliferation rate	MI, relative frequency of AgNORs, percentage of PCNA, or Ki67 immunopositivity are predictive of postsurgical outcome.
Growth rate	MCTs that remain localized and are present for prolonged periods of time (months or years) without significant change are usually benign.
DNA ploidy	There is a trend toward shorter survival times and higher-stage disease in dogs with aneuploid tumors.
Microvessel density	Increased microvessel density is associated with higher grade, a higher degree of invasiveness, and a worse prognosis.
Recurrence	Local recurrence following surgical excision may carry a more guarded prognosis.
Systemic signs	The presence of systemic illness (e.g., anorexia, vomiting, melena, GI ulceration) may be associated with higher-stage disease.
Age	Older dogs may have shorter median DFIs when treated with RT than younger dogs.
Breed	MCTs in Boxers (and potentially other brachycephalic breeds) tend to be low or intermediate grade and are thus associated with a better prognosis.
Sex	Male dogs had a shorter survival time than female dogs when treated with chemotherapy.
Tumor size	Large tumors may be associated with a worse prognosis following surgical removal and/or RT.
<i>c-kit</i> mutation	The presence of an activating mutation in the <i>c-kit</i> gene is associated with a worse prognosis.

MI, Mitotic index; AgNORs, argyrophilic nucleolar organizer regions; PCNA, proliferating cell nuclear antigen; MCTs, mast cell tumors; GI, gastrointestinal; DFIs, disease-free intervals; RT, radiation therapy.

• **TABLE 20-2** Histologic Classification of Mast Cell Tumors in Dogs

GRADE	BOSTOCK GRADING	PATNAIK GRADING	MICROSCOPIC DESCRIPTION
Anaplastic, undifferentiated (high grade)	1	3	Highly cellular, undifferentiated cytoplasmic boundaries, irregular size and shape of nuclei, frequent mitoses, sparse cytoplasmic granules.
Intermediate grade	2	2	Cells closely packed with indistinct cytoplasmic boundaries, nucleus-to-cytoplasmic ratio lower than anaplastic, infrequent mitoses, more granules than anaplastic.
Well differentiated (low grade)	3	1	Clearly defined cytoplasmic boundaries with regular, spheric, or ovoid nuclei; mitoses rare or absent; cytoplasmic granules large, deep staining, and abundant.

and liver. Other visceral organs may be involved; however, lung involvement is infrequent. Neoplastic mast cells may be observed in the bone marrow and peripheral blood in cases of widespread systemic dissemination.⁶³

The current histopathologic grading system does not detect a small percentage (15% to 30%) of those well-differentiated or intermediately differentiated MCTs that result in the death of affected dogs; this is complicated by the fact that there is disagreement in tumor grading among pathologists. In one study, there was significant variation among pathologists in grading a specific set of MCTs ($p < 0.001$), although this was found to be less so if all pathologists strictly employed the system described by Patnaik.^{14,79,80} Recently, an attempt was made to develop a new grading system that would separate tumors into high or low grade based on one of four features identified on histopathologic evaluation.⁸¹ In this setting, tumors would be classified as high grade if they possessed (1) at least seven mitotic figures/10 HPF, (2) at least three multinucleated cells/10 HPF, (3) at least three bizarre nuclei/10 HPF, or (4) karyomegaly. In a series of 95 dogs evaluated by both the Patnaik system and this alternative system, the alternative system was somewhat better at predicting which dogs would be more likely to die of disease⁸¹; however, further validation of this new two-tiered system will be necessary to determine whether it is truly better than the more commonly used Patnaik three-tiered system for predicting the biologic behavior of MCTs.

Several markers of proliferation have been evaluated to assist in determining whether an MCT is likely to behave in a more aggressive manner.^{47,72,82-90} Ki67 is a protein found in the nucleus, the levels of which appear to correlate with cell proliferation. In one study, the mean number of Ki67-positive nuclei was significantly higher for dogs that died of MCTs than for those that survived.⁸³ In another study, the Ki67 score was used to divide intermediate-grade MCTs into two groups with markedly different expected survival times.⁸⁴ Silver colloid staining of paraffin-embedded sections can be used to determine the relative presence of argyrophilic nucleolar organizer regions (AgNORs), another surrogate marker of proliferation. These have been correlated with histologic grade and postsurgical outcome.^{72,73} In a study of 50 dogs with cutaneous MCTs, the AgNOR frequency was as predictive or more predictive of biologic behavior than histologic grade.⁷³ Finally, proliferating cell nuclear antigen (PCNA), another indicator of cell proliferation, has been used to determine the biologic behavior of MCTs, although this is probably not as reliable as the other markers.^{72,73,91} The previously discussed markers of proliferation all require the use of special stains. In contrast, the mitotic index (MI), or number of mitoses/10 HPF in hematoxylin and eosin (H&E) sections, has been used to assess the biologic behavior of canine MCTs.⁹² In one study, those dogs with tumors possessing an MI of 5 or lower had a median survival time (MST) of 80 months, compared to 3 months for those possessing an MI of more than 5, suggesting that the MI is a strong predictor of overall survival for dogs with MCTs. Additional studies have also found a role for MI in MCT prognosis.^{81,90,92-95}

Other cellular assessments have been employed to evaluate the biologic behavior of MCT. A study of DNA ploidy determined by flow cytometric analysis suggested a trend toward shorter survival and higher clinical stage of disease in aneuploid tumors compared to diploid tumors.⁹⁶ Recent studies have found a correlation between intratumor microvessel density and invasiveness, mitotic rate, and prognosis^{82,97} and a correlation between nuclear characteristics (assessed by computerized morphometry) and outcome and grade.^{98,99} The potential role of KIT dysregulation in MCT prognosis was investigated by assessing KIT immunohistochemical

staining patterns on histopathologic specimens.¹⁰⁰ Three distinct patterns were identified: membrane, focal/stippled, and diffuse cytoplasmic staining. Although there was some evidence that dogs with diffuse cytoplasmic KIT staining patterns did not live as long as those with other patterns, no group reached an MST and most dogs in each of the KIT staining groups evaluated experienced extremely long survival times postsurgery.¹⁰⁰ In contrast, the presence of *c-kit*-activating mutations has been associated with a higher rate of local recurrence, metastasis, and death from disease, suggesting that KIT dysregulation confers a more aggressive phenotype to MCTs.^{41,46,47} Finally, investigators have attempted to correlate histologic grading of MCTs with a combined Ki67/PCNA/AgNOR/KIT immunohistochemical scoring.¹⁰¹ No significant correlation was found for KIT staining and MCT grade, but high Ki67/PCNA/AgNOR scores all did correlate positively with tumor grade (i.e., higher scores for higher grade). This suggests that proliferation indices increase with increasing grade and are ultimately reflected in the eventual biologic behavior of the tumor.

Tumor location has been investigated as a potential prognostic indicator.^{50,102-108} Tumors in the preputial/inguinal area, subungual (nailbed) region (Figure 20-3), and other mucocutaneous sites, including the oral cavity and perineum, have been associated historically with aggressive behavior. Two reports did not show a negative prognosis for tumors occurring in the inguinal and perineal

• **FIGURE 20-3** Subungual undifferentiated MCT in an English bulldog. As with some MCTs in this location, early lymph node metastasis has occurred.

region; however, when preputial and scrotal regions were specifically evaluated, they were indeed associated with a poorer prognosis.^{106,107} Approximately 50% to 60% of dogs with MCTs located in the muzzle present with regional lymph node metastasis.^{108,109} Interestingly, this does not necessarily indicate a worse long-term prognosis because the MST for dogs with metastatic disease was 14 months.¹⁰⁸ MCTs that originate in the viscera (GI tract, liver, spleen) or bone marrow carry a grave prognosis.^{62,63} Recent data indicate that MCTs arising in the subcutaneous tissues have a favorable prognosis, with extended survival time and low rates of recurrence and metastasis. In one study of 306 dogs with subcutaneous MCTs, metastasis occurred in 4% of dogs and 8% experienced local recurrence.⁹⁵ The estimated 2- and 5-year survival probabilities were 92% and 86%, respectively. Decreased survival was linked to MI higher than 4, infiltrative growth pattern, and presence of multinucleation. Finally, conjunctival MCTs were found to have a good prognosis, with 15/32 dogs disease free at a mean of 21.4 months postsurgery; no dogs in this study died of MCT-related disease.¹¹⁰

Clinical stage, represented in Table 20-5, is also predictive of outcome.^{33,49,96,105,111} There is controversy regarding the effect of multiple MCTs on prognosis, and as such, this part of the staging scheme may not accurately correlate with outcome. Several studies indicate that there is no difference in outcome between patients with a single cutaneous MCT and those with multiple MCTs,^{50,112-114} whereas others have suggested an inferior outcome in dogs with multiple tumors.^{94,115} It is uncertain at this time whether this phenomenon represents an atypical form of metastasis or multiple, unrelated tumors arising independently, although one study demonstrated a clonal origin for two distant cutaneous tumors arising over years.¹¹⁶ The effect of lymph node metastasis on prognosis is also somewhat controversial. In two studies, the presence of mast cells in the regional lymph node was a negative prognostic factor for survival and disease-free interval (DFI)^{113,117}; however, an

additional study revealed that dogs with intermediately differentiated MCTs and lymph node metastasis treated with radiation therapy (RT) postsurgery achieved long-term survival.¹¹⁸ Other studies have shown that dogs with intermediately differentiated MCT with lymph node metastasis may have a good prognosis if the affected lymph node is removed and adjuvant chemotherapy is administered.^{113,114,119} For poorly differentiated tumors, the presence of metastatic disease resulted in an MST of 194 days compared to 503 days for dogs with no metastasis.⁷⁸ For these dogs, treatment of the lymph node improved survival time (240 days) compared to those dogs whose lymph nodes were not treated (42 days).⁷⁸ As with all cases, clinical judgment regarding lymph node metastasis is probably important. A dog with an effaced enlarged lymph node will be more likely to fail therapy when compared to a dog with a lymph node that is not clinically enlarged but has cytologic evidence of metastasis.

Several miscellaneous factors have been linked to prognosis in dogs with MCTs. Certain breeds of dogs such as Boxers, pugs, and dogs of bulldog descent appear to develop MCTs that often behave in a more benign fashion.^{1,17,49} Recent rapid growth has been associated with a worse outcome. For example, in one study, 83% of dogs with tumors present for longer than 28 weeks prior to surgery survived for at least 30 weeks, compared to only 25% of dogs with tumors present for less than 28 weeks.⁴⁹ Systemic signs of anorexia, vomiting, melena, widespread erythema, and edema associated with vasoactive substances from mast cell degranulation are more commonly associated with visceral forms of MCT and carry a more guarded prognosis.^{50,63,64} In 16 cases of visceral MCTs, an MST of 90 days was reported and all dogs with follow-up died of their disease.¹⁰³ Local tumor ulceration, erythema, or pruritus has been associated with a worse prognosis in some studies.^{50,113} Finally, recurrence of MCT following surgical excision has also been associated with a more guarded prognosis.¹¹³ Thus appropriate aggressive therapy at the time of first presentation, rather than at the time of recurrence, may improve the long-term prognosis in patients with MCTs.

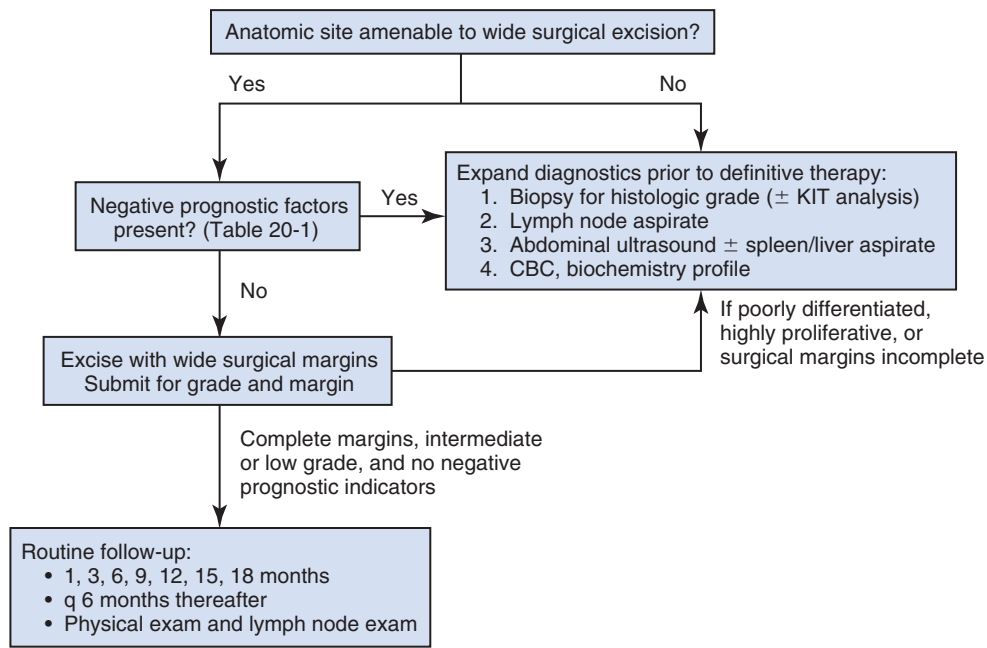

• **TABLE 20-5** World Health Organization Clinical Staging System for Mast Cell Tumors

STAGE	DESCRIPTION
0	One tumor incompletely excised from the dermis, identified histologically, without regional lymph node involvement <ol style="list-style-type: none"> 1. Without systemic signs 2. With systemic signs
I	One tumor confined to the dermis, without regional lymph node involvement <ol style="list-style-type: none"> 1. Without systemic signs 2. With systemic signs
II	One tumor confined to the dermis, with regional lymph node involvement <ol style="list-style-type: none"> 1. Without systemic signs 2. With systemic signs
III	Multiple dermal tumors; large, infiltrating tumors with or without regional lymph node involvement <ol style="list-style-type: none"> 1. Without systemic signs 2. With systemic signs
IV	Any tumor with distant metastasis, including blood or bone marrow involvement

Diagnostic Technique and Work-Up

MCTs are initially diagnosed on the basis of fine-needle aspiration (FNA) cytology. The Romanowsky or rapid hematologic-type stains used in most practices will suffice. Mast cells appear as small to medium-sized round cells with abundant, small, uniform cytoplasmic granules that stain purplish red (metachromatic; see Figures 7-2 and 7-5).^{1,120} A small percentage of MCTs have granules that do not stain readily, giving them an epithelial or macrophage-like appearance that has often been referred to as a “fried-egg” appearance (see Figure 7-2). In these cases, a Wright-Giemsa or toluidine blue stain will often reveal granules; however, histologic assessment may ultimately be necessary. Highly anaplastic, agranular MCTs can sometimes be challenging to definitively diagnose by routine light microscopy. Immunohistochemical techniques have been applied in an attempt to differentiate these from other anaplastic round cell tumors. MCTs are vimentin positive, and the majority are tryptase and CD117 (KIT) positive.^{37,121-123} Other markers that could potentially be useful include chymase, MCP-1, and IL-8.^{9,10}

Historically, complete staging has included a minimum database (complete blood count [CBC], serum biochemistry profile), a buffy coat smear to document peripheral mastocytosis, cytologic assessment of regional lymph nodes, abdominal ultrasound (US) with cytologic assessment of spleen or liver if warranted, thoracic radiographs, and bone marrow aspiration cytology. It is now likely that

• **FIGURE 20-4** Suggested diagnostic steps for canine cutaneous MCTs.

an extensive work-up is not necessary for dogs with MCTs that do not exhibit the previously discussed negative prognostic factors. **Figure 20-4** illustrates the diagnostic steps and the order in which they are pursued in the authors' practice. If the MCT is in a location amenable to wide surgical excision and no negative prognostic indicators are present (see **Table 20-1**), no further tests other than the minimum database and FNA of the regional lymph node (if possible) are performed prior to wide surgical excision. FNA cytology is not sufficient to grade MCT; thus histologic assessment following excision is strongly recommended to provide guidance regarding necessary further diagnostics and therapeutics.

If the tumor presents at a site that is not amenable to wide surgical excision (e.g., distal extremity) or if negative prognostic factors exist in the history or physical examination, ancillary diagnostics to further stage the disease are recommended prior to definitive therapy. An incisional/needle biopsy may be performed at this point for determination of histologic grade. The minimum staging that is advisable in those cases requiring presurgical staging consists of a minimum database, FNA cytology of the regional lymph node (even if normal size), and abdominal US. With respect to cytologic evaluation of lymph nodes, definitive criteria for metastatic disease can be challenging if mast cells are present in low numbers because mast cells are normally found in lymph nodes and their numbers can be increased in the presence of infection and ulceration, which are sometimes observed in MCTs. For example, in 56 healthy beagle dogs, approximately 24% of lymph node aspirates contained mast cells (range of 1 to 16 mast cells/slide, mean of 6.4 cells/slide).¹²⁴ Therefore an occasional solitary mast cell is not indicative of metastasis; rather, clustering and aggregates are more worrisome (**Figure 20-5**).¹¹¹ Surgical removal of a cytologically suspicious lymph node for histologic assessment may be necessary to accurately determine whether mast cells present in the lymph node truly represent metastatic disease. Abdominal US is now considered an important diagnostic test for the evaluation of dogs with potentially aggressive MCTs. Although FNA cytology of structurally normal livers or spleens is generally unrewarding,^{125,126} the presence of negative

• **FIGURE 20-5** Regional lymph node aspirate from a dog with a cutaneous MCT. Note the clustering of mast cells in a background of lymphocytes that is more indicative of true metastasis.

prognostic indicators (e.g., metastatic lymph node, clinical signs) is sufficient justification to perform cytologic evaluation of these organs even if they appear normal on US.¹²⁷

Thoracic radiographs rarely demonstrate metastasis; however, it is reasonable to procure them prior to an expensive or invasive procedure to rule out occult cardiopulmonary disease that could complicate anesthesia or unrelated disease processes (e.g., primary lung tumor). Occasionally, thoracic lymphadenopathy may be observed as a result of MCT metastasis. Knowledge of the extent of MCT margins prior to surgery, usually accomplished by digital palpation and occasionally local radiographs, can be enhanced with the use of diagnostic US or computed tomography (CT). Dogs bearing cutaneous MCTs or soft tissue sarcomas had the extent of

local tumor margins upgraded in 19% and 65% of cases when imaged by US and CT, respectively.¹²⁸ Such information allows more appropriate planning of definitive surgery or RT. The cost effectiveness of such a study depends on the location of the tumor and whether wide excision is technically simple or difficult.

With respect to evaluation of buffy coat smears for evidence of systemic mast cell disease, peripheral mastocytosis (1 to 90 mast cells/ μ L) is reported in dogs with acute inflammatory disease (in particular, parvoviral infections), inflammatory skin disease, regenerative anemias, neoplasia other than MCTs, and trauma.¹²⁹⁻¹³¹ One study revealed that peripheral mastocytosis is actually more likely to occur and may be more dramatic in dogs with diseases other than MCTs.¹³⁰ Therefore this test is no longer routinely performed in the staging of MCT patients. In a report evaluating 157 dogs with MCTs, the incidence of bone marrow infiltration at initial staging was only 2.8%.¹³² Although the presence of bone marrow involvement is indicative of systemic mast cell disease, it is usually easier to find evidence of systemic involvement in other organs (liver, spleen).⁶³ This is in contrast to dogs that present with visceral MCTs, in which 37% of buffy coat smears are positive for mast cells and 56% of bone marrow aspirates reveal mast cell dissemination¹⁰³; however, these constitute a small minority of all MCT cases. Therefore, with the exception of the extremely rare case of primary mastocytic leukemia,^{133,134} involvement of marrow or peripheral blood in the absence of disease in regional lymph node or abdominal organs is unlikely.¹³²

Treatment

Treatment decisions are predicated on the presence or absence of negative prognostic factors and on the clinical stage of disease. In tumors localized to the skin in areas amenable to wide excision, surgery is the treatment of choice. Historically, surgical excision to include a 3-cm margin of surrounding normal tissue has been recommended for MCT. More recently, evidence exists that 1- to 2-cm lateral margins may be sufficient for complete excision of many MCTs, particularly those that are lower grade and small.^{135,136} Indeed, in 100 dogs with 115 resectable MCTs (primarily intermediate and low grade), no local recurrence or metastasis was noted for greater than 2 years following excision with lateral histologic margins of 10 mm or larger and deep histologic margins of 4 mm or larger.⁷⁶ It should be noted that these microscopic, formalin-fixed margin parameters may not accurately reflect margin size at surgery: tissue shrinkage (up to 30% for cutaneous tissues) can occur subsequent to formalin fixation.¹³⁷⁻¹³⁹ Considering that the majority of naïve dermal MCTs encountered in practice are intermediate- or low-grade tumors, it can be said that most MCTs can be cured with surgery alone, provided the site is amenable to adequate surgical resection. The quality of the deep margin is as important as that of the lateral margins, and it is recommended that one uninvolved fascial plane deep to the tumor be removed in continuity with the tumor. If necessary, muscle layers may also be removed deep to the tumor. All surgical margins should be evaluated histologically for completeness of excision. It is recommended that tumors in areas not amenable to wide surgical margins, such as distal extremities, be evaluated by biopsy to determine histologic grade prior to definitive therapy.

If a distal extremity MCT is low or intermediate grade and complete excision is not achievable, four primary therapy options exist. The most aggressive option is amputation; however, although wide margins are guaranteed, it results in the least functional outcome and is generally not recommended given the availability of other effective therapies. The second option is external-beam RT

alone, which produces varying control rates in the literature when used as a primary therapy; doses between 40 and 50 Gy result in 1-year control rates of approximately 50%.^{105,140-145}

The third and, in the authors' opinion, the ideal option for low- or intermediate-grade MCTs in areas where wide surgical excision is not possible is a combination of surgery and RT. The veterinary literature has established that the complementary use of surgery to achieve clinical stage 0 disease (i.e., microscopically incomplete margins) and external-beam RT is associated with long-term control. Two-year control rates of 85% to 95% can be expected for low- or intermediate-grade stage 0 tumors.^{105,117,146-148} Some authors advocate prophylactic irradiation of cytologically negative regional lymph nodes (prophylactic nodal irradiation [PNI]).^{114,117,118,149} Due to the generally low risk of postsurgical metastasis in low- to intermediate-grade tumors, PNI is probably unwarranted in this group of patients, and at least one study has demonstrated no advantage in terms of disease-free or overall survival when PNI is employed in this group of dogs¹⁴⁸; however, in MCTs at high risk for metastasis, PNI may provide improvement in outcome over local site irradiation only.^{114,149}

The last option for low- or intermediate-grade MCTs in areas where wide surgical excision is not possible is a combination of surgery and chemotherapy (discussed later). There are now several published studies that have demonstrated a low rate of recurrence in dogs with incompletely excised MCTs that receive some form of chemotherapy postsurgery.^{150,151} Although not considered optimal, this approach can be used in cases in which RT is unavailable or unaffordable. Regardless of the local therapy chosen, dogs with low- and intermediate-grade tumors should be reevaluated regularly for local recurrence and possible metastasis. Local site and regional lymph node evaluation, complete physical examination, and aspiration of any new cutaneous masses or enlarged lymph nodes are performed at these intervals. More complete staging, including abdominal US, should be included if the dog has an MCT with negative prognostic indicators.

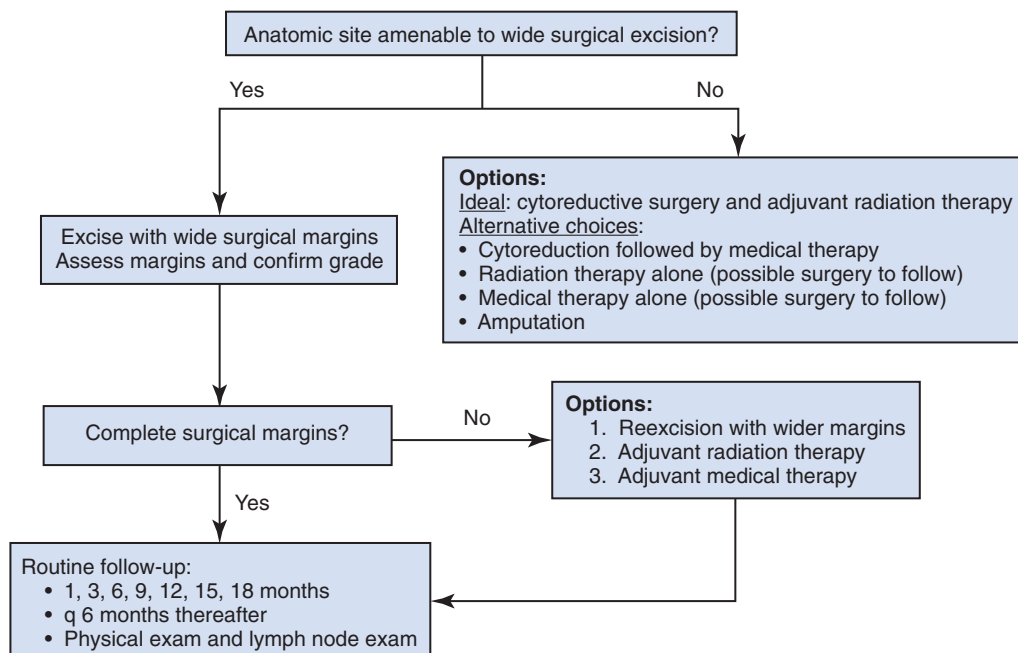

For cases in which planned curative excisional surgery is unsuccessful and histologic margins are incomplete, further local therapy is warranted. A second excision of the surgical scar with additional wide margins should be performed if possible (Figure 20-6) or adjuvant RT can be used in cases in which re-excision is not an option. Not all MCTs with surgically incomplete margins will recur; in some studies, only 20% to 30% of MCTs with histologically confirmed incomplete margins recurred.^{84,152} Although recurrence rates vary by study, several studies have demonstrated increased recurrence rates and/or decreased overall survival in dogs with incompletely resected MCTs.^{28,71,73,113} Figure 20-7 summarizes the treatment recommendations for clinical stage 0 and I, histologically low- or intermediate-grade MCTs. Alternative local therapies for MCTs have been reported and include hyperthermia in combination with RT,¹⁵³ intralesional brachytherapy,^{154,155} photodynamic therapy,^{156,157} intralesional corticosteroids,¹⁵⁸ cryotherapy, and electrochemotherapy.¹⁵⁹⁻¹⁶¹ Although some have advocated the use of intralesional deionized water at the site of an incompletely removed MCT, clinical data indicate that this approach is not effective at preventing local recurrence and should therefore not be used.¹⁶²⁻¹⁶⁷ It is important to note that none of these alternative local therapies are as thoroughly investigated, clinically effective, or practical as surgery, RT, or a combination of the two. Finally, despite its common use, there is no information available to suggest that adjuvant corticosteroid therapy is beneficial in cases of individual intermediate-grade MCTs that have been either excised completely or treated with local RT postsurgery.

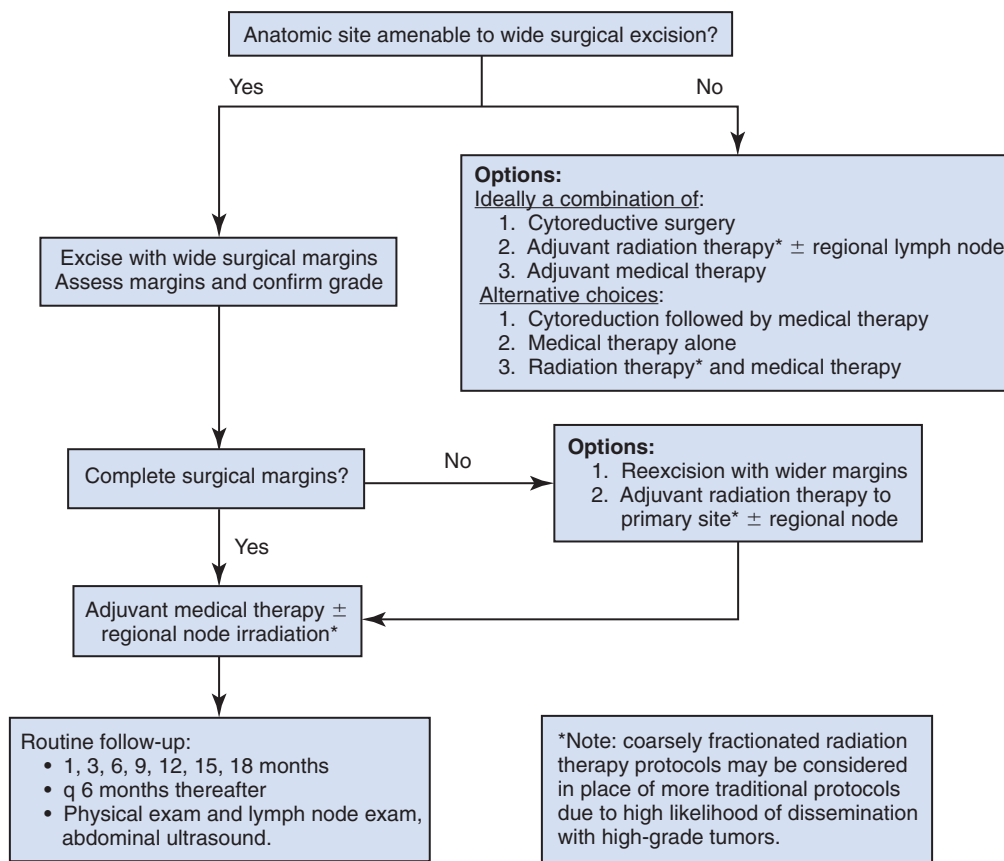

• **FIGURE 20-6** Re-excision of an MCT from the skin of a golden retriever. The first surgery resulted in incomplete surgical margins; thus 3-cm margins were taken around and deep to the previous incision and the entire sample was again submitted for margin analysis by the pathologist.

The treatment of anaplastic or undifferentiated MCTs remains a frustrating undertaking. This designation includes dogs with intermediate-grade tumors with regional or distant metastasis or high proliferative activity as assessed by MI or special stains, as well as those arising from a mucous membrane or mucocutaneous junction. There is some evidence to suggest that intermediate-grade tumors with only regional node involvement have a better prognosis than high-grade tumors.^{108,114} In the authors' opinion, until convincing evidence exists, such tumors should be treated as if they have a high capacity for metastasis. Figure 20-8 summarizes the treatment recommendations for high-grade MCTs. The long-term prognosis for such dogs is less favorable because regional and distant metastases are more likely.

Poorly differentiated and metastatic MCT will, in most instances, progress to kill the dog in the absence of effective postsurgical intervention. Systemic adjuvant therapy should be offered in such cases in an attempt to decrease the likelihood of systemic involvement, or at least potentially improve DFIs. Corticosteroids such as prednisone have been reported for many years in preclinical or anecdotal settings to be of some benefit.¹⁶⁸⁻¹⁷² Although corticosteroids can inhibit canine MCT proliferation and induce tumor cell apoptosis in vitro,¹⁷³ they may also contribute to apparent antitumor response by decreasing peritumoral edema and inflammation. The Veterinary Cooperative Oncology Group (VCOG) studied the efficacy of single-agent systemic prednisone therapy for intermediate- and high-grade canine MCTs.¹⁷² Of 21 dogs receiving 1 mg/kg daily by mouth (PO), only one complete response (CR) and four partial responses (PR) were noted, and these were short-lived, lasting only a few weeks in the majority of cases. More recent studies have reported 70% to 75% response rates; however, tumors were excised or irradiated following short-term prednisone treatment, thus duration of response was not evaluable.^{145,171} A recent study found that response of MCT to corticosteroids was dependent on expression of the glucocorticoid receptor; those dogs with tumors that expressed low levels of this receptor had MCTs that were resistant to prednisolone therapy.¹⁷⁴ These data suggest that

• **FIGURE 20-7** Suggested treatment approach for clinical stage 0 and stage I low- or intermediate-grade canine MCTs.

• **FIGURE 20-8** Suggested treatment approach for high-grade, biologically aggressive canine MCTs.

a subset of MCT may indeed benefit from corticosteroid therapy if there is adequate expression of the glucocorticoid receptor.

Recently, a number of studies have evaluated the response rates of measurable canine MCT to various cytotoxic chemotherapy drugs and protocols (Table 20-6).^{*} Objective response rates as high as 64% have been reported, and accumulating evidence suggests that multiagent protocols may confer a higher response rate than single-agent therapy.[†] It is important to note that in most instances, the response of a bulky MCT to any chemotherapy protocol tends to be short-lived, stressing the need for local control of disease prior to institution of adjuvant therapy.

A few single-arm studies have attempted to evaluate the efficacy of chemotherapy for “high-risk” MCTs in the postsurgical setting. One study evaluated the use of postoperative prednisone and vinblastine (VBL) for dogs with MCT considered to be at high risk for metastasis (node-positive, mucous membrane origin, or high histologic grade). In this study, dogs with high-grade MCTs had an MST of 1374 days.¹¹⁴ A second study reported 70% 1- and 2-year disease-free survival percentages following prednisone/VBL in high-grade MCT.¹⁸⁴ A combination of prednisone, lomustine, and VBL has been used for residual microscopic disease in dogs at high risk for dissemination. Dogs with microscopic disease had a median progression-free survival time of 35 weeks and an overall survival of 48 weeks.¹⁷⁷ Combination therapy using cyclophosphamide, VBL, and prednisone also yielded promising results in the microscopic residual disease setting for dogs considered at high risk of

recurrence or metastasis. The reported progression-free and overall survival times were 865 days and more than 2092 days, respectively.¹¹⁹ Most of the studies described used a dose of 2 mg/m² VBL; although there is now information suggesting that dogs may tolerate higher doses,¹⁸⁵⁻¹⁸⁷ it remains to be seen if dose escalation of VBL will translate into improved efficacy.

As previously discussed, virtually all canine mast cell neoplasms express the KIT RTK, and a large minority of canine MCTs (20% to 40%, depending on the study) possess a mutation in the *c-kit* gene, which renders the KIT protein constitutively active.^{41,44,188} New, orally available molecules have been developed that inhibit signaling through KIT called *small molecule TKIs*. The two veterinary-approved TKIs in this class are toceranib (Palladia, Pfizer) and masitinib (Masivet/Kinavet, AB Science); limited studies have also been performed with the human KIT inhibitor imatinib (Gleevec, Novartis).

Following encouraging *in vitro* and early-phase clinical trials,^{45,189,190} a multicenter, placebo-controlled, double-blind, randomized study of toceranib was performed in dogs with recurrent or metastatic intermediate- or high-grade MCT.¹⁹¹ During the blinded phase of the study, the objective response rate in toceranib-treated dogs (n = 86) was 37.2% (7 CR, 25 PR) versus 7.9% (5 PR) in placebo-treated dogs. When all 145 dogs that received toceranib were analyzed, including those that switched from placebo to drug, the objective response rate was 42.8% (21 CR, 41 PR), with an additional 16 dogs experiencing stable disease for an overall biologic activity of 60%. The median duration of objective response and time to tumor progression were 12.0 and 18.1 weeks, respectively. Interestingly, dogs whose MCT harbored activating

mutations in the *c-kit* gene were roughly twice as likely to respond to toceranib as those with wild-type *c-kit* (69% versus 37%). GI toxicity, in the form of inappetence, weight loss, diarrhea, and occasionally vomiting or melena, was the most common adverse effect and was generally manageable with symptomatic therapy, drug holidays, and dosage reductions as necessary. Other adverse effects reported include mild-to-moderate leukopenia and occasional muscle pain.¹⁹¹ Recent clinical experience with toceranib suggests that equivalent antitumor activity and reduced adverse effects may be observed if dosages lower than the label dosage are employed. A dosage of 2.5 to 2.75 mg/kg every other day or 3 days per week (Monday, Wednesday, Friday) is currently utilized by many.^{192,193}

A clinical trial of similar design was recently completed with masitinib in dogs with recurrent or unresectable MCT.¹⁹⁴ This study demonstrated significantly improved time to progression in masitinib-treated versus placebo-treated dogs, and outcome again was improved in dogs with MCTs harboring activating *c-kit* mutations. Subsequent follow-up of patients treated with long-term masitinib identified an increased number of patients with long-term disease control compared to those treated with placebo (40% versus 15% alive at 2 years),¹⁹⁵ underscoring the potential for long-term disease stabilization to be an acceptable and clinically meaningful outcome in patients treated with this class of agent. GI adverse effects (vomiting or diarrhea) were most common but were mild in the majority of cases and self-limiting. Myelosuppression was also observed and was mild in most cases. A small percentage of dogs developed a protein-losing nephropathy leading to edema. Increases in urea and creatinine were observed in some dogs, and hemolytic anemia was observed rarely.¹⁹⁴

Finally, small studies have evaluated the efficacy of imatinib for the treatment of measurable canine MCTs.¹⁹⁶⁻¹⁹⁸ Imatinib was well tolerated, and objective antitumor responses were observed in dogs with both *c-kit* mutant and wild-type MCTs. It is important to note that no studies have yet been performed in dogs with MCTs to assess the pharmacokinetics of imatinib; thus current dosing recommendations are based on observed clinical activity, not pharmacokinetic and pharmacodynamic relationships.

At this time, there are only a few published studies regarding the safety and efficacy of combination therapy with KIT inhibitors and standard forms of therapy such as RT or cytotoxic chemotherapy, and evidence of benefit when used in the postoperative setting has yet to be demonstrated. One recent clinical trial evaluated a combination of toceranib and VBL in dogs with measurable MCTs. Significant reductions in VBL dosage and frequency were necessary because of additive myelosuppression resulting in a maximally tolerated dose of VBL of 1.6 mg/m² every other week in combination with toceranib given every other day.¹⁹⁹ Nevertheless, encouraging biologic activity (71% objective response rate) was observed despite the necessary dosage reductions, indicating that future evaluation of this combination regimen is warranted. Finally, another study investigated the combination of toceranib, prednisone, and hypofractionated RT in dogs with nonresectable and/or metastatic MCT.¹⁹² The overall response rate (ORR) was 76.4%, with 58.8% of dogs achieving CR and 17.6% PR. The overall MST was not reached, and the median follow-up was 374 days. The combination of hypofractionated RT and toceranib was well tolerated and demonstrated efficacy in the majority of dogs, indicating that this may be a viable treatment option for nonresectable MCT.

Novel medical approaches that may hold promise for the future treatment of MCT include histone deacetylase inhibitors,²⁰⁰⁻²⁰² heat shock protein 90 (HSP90) inhibitors,^{203,204} retinoids,²⁰⁵⁻²⁰⁷ TNF-related apoptosis-inducing ligand (TRAIL),²⁰⁸ and polo-like kinase-1 inhibitors.²⁰⁹

Ancillary therapy to address the systemic effects of mast cell mediators is sometimes warranted in dogs with MCTs. Minimizing the effects of histamine release can be accomplished by administering the H₁ blockers diphenhydramine (2 to 4 mg/kg PO twice a day [BID]) or chlorpheniramine (0.22 to 0.5 mg/kg three times a day [TID]) and the H₂ blockers cimetidine (4 to 5.5 mg/kg PO TID), famotidine (0.5 to 1 mg/kg BID), or ranitidine (2 mg/kg BID). Omeprazole (0.5 to 1 mg/kg daily), a proton pump inhibitor, may be more effective, particularly in bulky mast cell disease. These agents are generally used in the setting of gross disease, particularly those cases in which (1) systemic signs are present, (2) the tumor

is likely to be entered or manipulated at surgery (i.e., cytoreductive surgery), or (3) treatment is undertaken where gross disease will remain and degranulation is likely to occur in situ (e.g., RT or medical therapy for tumors that are not cytoreduced). For cases with active evidence of gastric or duodenal ulceration, the addition of sucralfate (0.5 to 1.0 g PO TID) and occasionally misoprostol (2 to 4 µg/kg PO TID) to histamine blockers is prudent. Some experimental data suggest that the use of H₁ and H₂ blockers could also be beneficial for the prevention or resolution of histamine-mediated wound breakdown,^{32,210,211} but this has not been systematically evaluated. The use of protamine sulfate, a heparin antagonist, has been mentioned by some for use in cases of severe hemorrhage.¹⁰⁴

Feline Mast Cell Tumors

Unlike MCTs in the dog, which are primarily cutaneous/subcutaneous in nature, MCTs in the cat typically occur in three distinct syndromes, although there is some overlap among them. These syndromes are cutaneous MCT, splenic/visceral mast cell disease, and intestinal MCT. The etiology of feline MCTs is currently unknown and appears unrelated to viral infection.²¹² However, it is now evident that feline MCTs also possess somatic activating mutations in *c-kit*.²¹³⁻²¹⁵ In one study, 42/62 (67%) of cutaneous and splenic/visceral MCT had *c-kit* mutations that were primarily present in exons 8 (28/62) and 9 (15/62), both of which encode the fifth immunoglobulin domain of KIT. Similar to the canine juxtamembrane domain mutations, these feline *c-kit* mutations induce ligand-independent activation of KIT, which can be inhibited by imatinib in vitro.²¹⁵

The granules present in feline MCTs stain blue with Giemsa and purple with toluidine blue.^{1,2,4} As in the dog, granules present in feline mast cells contain vasoactive substances, such as heparin and histamine.^{2,216} In culture, feline mast cells express surface-bound immunoglobulins and are capable of secreting histamine, heparin, and probably other vasoactive compounds when appropriately stimulated.²¹⁶ Feline mast cells also have phagocytic capability and can endocytose erythrocytes in both experimental models and clinical samples.²¹⁷ Complications associated with degranulation of MCT can also occur in the cat, including coagulation disorders, GI ulceration, and anaphylactoid reactions.^{2,218,219} Since the biologic behavior of the three feline MCT syndromes is different, they will be described individually.

Cutaneous Feline Mast Cell Tumors

MCTs represent the second most common cutaneous tumor in the cat, accounting for approximately 20% of cutaneous tumors in this

species in the United States.^{2,4,12} The incidence of MCTs in cats appears to have increased dramatically since 1950.² Interestingly, MCTs appear to occur much less frequently in the United Kingdom than in the United States, accounting for only 8% of all cutaneous tumors.¹ The typical feline cutaneous MCT is a solitary, raised, firm, well-circumscribed, hairless, dermal nodule between 0.5 and 3 cm in diameter.^{2,4,220,221} They are often white in appearance, although a pink erythematous form is occasionally encountered. Approximately 20% are multiple, although one series reported multiple lesions in the majority of cases.¹ Superficial ulceration is present in approximately one-fourth of cases. Other clinical forms that have been described include a flat pruritic plaquelike lesion similar in appearance to eosinophilic plaques and discrete subcutaneous nodules.

Two distinct types of cutaneous MCTs in the cat have been reported (Table 20-7): (1) the more typical mastocytic MCT, histologically similar to MCTs in dogs, and (2) the less common histiocytic MCTs, with morphologic features characteristic of histiocytic mast cells, that may regress spontaneously over a period of 4 to 24 months.^{221,222} An overall mean age of 8 to 9 years is reported for cats with MCTs; however, the mastocytic and histiocytic forms occur at mean ages of 10 and 2.4 years, respectively.^{2,4,220} Siamese cats appear to be predisposed to development of MCTs of both histologic types.^{2,4,220-222} The distinct histiocytic form of MCTs in cats is reported to occur primarily in young (<4 years of age) Siamese cats, including two related litters.²²² In contrast to these reports, Siamese cats were not more likely to develop the histiocytic form of MCT than the mastocytic form in another series of cases.⁴ Earlier studies reported a male predilection for development of MCT^{219,220}; however, larger, more recent series have failed to confirm such a predilection.^{2,4}

The mastocytic form can be further subdivided on histologic appearance into two categories, previously referred to as *compact* (representing 50% to 90% of all cases) and *diffuse* (histologically anaplastic), which may be of prognostic significance.^{2,222,223} Well-differentiated compact tumors tend to behave in a benign manner, and metastasis is uncommon.^{220,224,225} In contrast, anaplastic tumors may have a high MI and marked cellular and nuclear pleomorphism, with infiltration into the subcutaneous tissues.²²¹ These tumors have been reported as behaving in a more malignant manner with metastasis to lymph nodes and the abdomen, although a more recent study evaluated pleomorphic cutaneous MCTs from 15 cats and found that the majority were behaviorally benign; only one cat was euthanized due to disease progression.²²⁶

Unlike in the dog, the head and neck are the most common site for MCTs in the cat, followed by the trunk, limbs, and

• TABLE 20-7 Histologic Classification of Mast Cell Tumors in Cats

TYPE	SUBTYPE	MICROSCOPIC DESCRIPTION
Mastocytic	Compact (well-differentiated)	Homogeneous cords and nests of slightly atypical mast cells with basophilic round nuclei, ample eosinophilic cytoplasm, and distinct cell borders. Eosinophils conspicuous in only half of cases.
	Diffuse (anaplastic)	Less discrete, infiltrated into subcutis. Larger nuclei (>50% cell diameter), 2-3 mitoses/HPF. Marked anisocytosis, including mononuclear and multinucleated giant cells. Eosinophils more commonly observed.
Histiocytic		Sheets of histiocyte-like cells with equivocal cytoplasmic granularity. Accompanied by randomly scattered lymphoid aggregates and eosinophils. Granules lacking in some reports, others report granules readily demonstrable.

• **FIGURE 20-9** **A**, Multiple MCTs on the head of a cat. The head and neck are the most commonly encountered location for MCTs in the cat. They often involve the area near the base of the ear. **B**, MCTs in the cat are less common on the limbs. (Courtesy S. Helfand, Oregon State University, Corvallis, OR.)

miscellaneous sites (Figure 20-9).^{2,4,220} Tumors on the head often involve the pinnae near the base of the ear. They rarely occur in the oral cavity. Intermittent pruritus and erythema are common, and self-trauma or vascular compromise may result in ulceration. Darier's sign, which is the erythema and wheal formation following mechanical manipulation of the tumor, has been reported in the cat.²¹⁹ Affected cats are usually otherwise healthy. The spontaneously regressing histiocytic form of cutaneous MCTs usually presents as multiple, nonpruritic, firm, hairless, pink, and sometimes ulcerated subcutaneous nodules (Figure 20-10).^{4,222}

As with canine tumors, most feline MCTs are usually easily diagnosed by cytologic examination of fine needle aspirates. In contrast, the uncommon histiocytic form of feline MCTs is more challenging to diagnose both by FNA and histopathology.^{221,222} Mast cells may comprise only 20% of the cells present, with the majority being sheets of histiocytes that lack distinct cytoplasmic granules and accompanied by randomly scattered lymphoid aggregates and eosinophils. In contrast, one report readily demonstrated metachromatic granules in seven cases of the histiocytic subtype. These tumors can be initially misdiagnosed as granulomatous nodular panniculitis or deep dermatitis.

Cats with cutaneous MCTs should be evaluated for evidence of additional tumors, as well as potential splenic involvement by abdominal US, because one study found that some cats with multiple cutaneous MCTs also had splenic disease.²²⁴ In addition, a minimum database is recommended, along with careful examination of local lymph nodes for evidence of lymphadenopathy. Interestingly, unlike dogs, cats rarely exhibit evidence of circulating mast cells on buffy coat smears when healthy or ill from non-mast

• **FIGURE 20-10** Histiocytic MCTs on the head of a young Siamese cat. This form of MCTs in cats typically regress spontaneously, as was the case in the cat pictured here. (Courtesy Dr. K. Moriello, University of Wisconsin-Madison.)

cell-related causes.²²⁷ In contrast, one study demonstrated that 43% of cats with mast cell disease have positive buffy coats, although most of these cats tended to have the splenic/visceral form of the disease.²²⁸

Feline MCTs are usually positive for vimentin, α -1 antitrypsin, and KIT.^{229,230} Although the histologic grading system described for canine MCT has provided no prognostic information for the cat in several series and is not used,^{220,231} tumors with a high MI appear

to be at greatest risk for local recurrence and metastasis, suggesting that this histopathologic feature may be useful for predicting biologic behavior.^{221,226} A more recent study evaluated the prognostic value of histologic and immunohistochemical features in feline cutaneous MCTs. Multiplicity of lesions, pleomorphic phenotype, KIT immunoreactivity score, MI, and Ki67 index correlated with an unfavorable outcome, although MI was the strongest predictive variable.²³²

The definitive treatment for cutaneous feline MCT is surgical excision. In a series of 32 cats with cutaneous MCTs, five tumors recurred following surgical excision, although none of the cats in this study died of disease. Completeness of excision and histopathologic factors such as nuclear pleomorphism and MI were not associated with tumor recurrence.²²⁵ In a more recent series of cats with MCTs of the eyelids, local tumor control in 19/23 cats was achieved with surgery alone and another 3 cats experienced control with surgery plus RT or cryotherapy, resulting in an MST of 945 days.²³³ Despite the fact that only 50% of the tumors were completely removed, only one cat developed disseminated cutaneous tumors and no cats developed metastatic disease to the lymph nodes or abdomen. Other reports have demonstrated local recurrence rates following excision between 0% and 24%.^{2,220,221,224,226} These data suggest that most cutaneous feline MCTs are behaviorally benign, and wide surgical margins may not be as critical in the cat as in the dog. Frequency of systemic spread following surgical excision varies from 0% to 22%, although those that metastasize are more likely to be anaplastic tumors.^{220,221,224-226} Therefore, for histologically anaplastic tumors or those with a high MI more likely to recur postsurgery or to metastasize, a more aggressive approach similar to that utilized for canine MCTs may be prudent.^{226,234} Following biopsy confirmation, conservative resection or a “wait and see” approach may be taken with the histiocytic form in young cats with multiple masses because these may spontaneously regress.^{2,4,222}

RT may be considered for tumors that are incompletely excised. In one study of feline cutaneous MCT, a 98% control rate was achieved with strontium-90 irradiation, with an MST of greater than 3 years.²³⁵ Limited information exists concerning the utility of chemotherapy in cats with MCTs. It is generally believed that feline MCTs are less responsive to prednisone than their canine counterparts; biologic activity of corticosteroids in cats with the histiocytic variant was found to be equivocal.²²² Objective responses to lomustine (CCNU) have been reported in cats.^{236,237} Of 20 cats with cutaneous MCTs, 10 exhibited CR (n = 2) or PR (n = 8) to lomustine.²³⁷ The authors have observed evidence of clinical activity in cats treated with prednisone and VBL as well. Some investigators have utilized a combination of prednisone and chlorambucil to treat metastatic or multiple tumors. This is generally well tolerated, although its effectiveness is not known.

Biologic activity of imatinib has been observed in cats with MCTs expressing activating mutations in *c-kit*, although the responses were all partial in nature.^{214,215,238} Studies in healthy cats have demonstrated that masitinib may be safe to administer to clinically normal cats, and plasma concentrations associated with MCT inhibitory activity are likely achievable. Cats should be monitored very closely for neutropenia, proteinuria, and increases in creatinine.^{239,240} Neither masitinib nor toceranib have been formally evaluated in cats with MCTs.

Splenic/Visceral Feline Mast Cell Tumors

MCTs represent the most common differential for splenic disease in cats, accounting for 15% of submissions in a series of 455

pathologic specimens.²⁴¹ This disease primarily affects older animals (mean age 10 years) with no sex or breed predilection.^{2,224,241} The majority of cats with splenic MCTs do not have a history of cutaneous MCTs, although recent evidence suggests that some cats with multiple cutaneous MCTs may also have splenic involvement.²²⁴ Although the spleen is the primary site affected by this disease, other organs may also be involved.^{2,218} Necropsy data on 30 cats with splenic MCTs revealed dissemination in the following organs in decreasing order of frequency: liver (90%), visceral lymph nodes (73%), bone marrow (40%), lung (20%), and intestine (17%).² Up to one-third of cases have peritoneal and pleural effusions rich in eosinophils and mast cells.^{2,218} Peripheral blood mastocytosis has been reported in 40% to 100% of cases with peripheral mast cell counts up to 32,000 cells/ μ L.^{2,228} In one clinical report of 43 cases, 23% had bone marrow involvement.²¹⁸

Cats with splenic MCTs may present with signs of systemic illness, including vomiting, anorexia, and weight loss.^{2,218} Dyspnea may be evident if pleural effusion is present. Abdominal palpation usually reveals a markedly enlarged spleen and/or liver. Other common differential diagnoses for splenomegaly in the cat include lymphoma, myeloproliferative disease, accessory spleen, hemangiosarcoma, hyperplastic nodules, and splenitis.²⁴¹ Clinical signs associated with the release of mast cell mediators, such as GI ulceration, hemorrhage, hypotensive shock, and labored breathing, may also be noted. Cats with suspected splenic MCTs should undergo a standard work-up, including a minimum database, as well as abdominal US and thoracic radiographs. FNA cytology is usually diagnostic for splenic MCTs, as is evaluation of thoracic or abdominal fluid. Anemia is a common hematologic finding, with eosinophilia less likely to be observed.^{2,218} In one report of 43 cats with splenic MCT, 90% had an abnormal coagulation profile, although this did not appear to be clinically significant.²¹⁸ Hyperglobulinemia has also been reported in cats with splenic MCTs, the cause of which remains unknown.

Splenectomy is the treatment of choice for cats with splenic MCTs, even if other organ involvement is noted. Pretreatment with H₁ and H₂ blockers prior to therapy is indicated; intraoperative death may occur due to the release of mast cell mediators. Two gross forms of splenic involvement are possible: a diffuse, smooth form and a less common nodular form (Figure 20-11).^{125,242} Surprisingly, even in the face of significant bone marrow and peripheral blood involvement, long-term survival with good quality of life is the norm following splenectomy, with MSTs from 12 to 19 months reported,^{2,218,243-245} although one recent study reported an MST of only 132 days following splenectomy.²⁴⁶ Anorexia, significant weight loss, and male gender were found to be negative prognostic indicators in one study.²¹⁸ Although peripheral mastocytosis usually does not completely resolve, it usually declines significantly and cats experience good quality of life for long periods of time. Cats should be followed postoperatively with buffy coat smears because a rise in the number of mast cells in the periphery may indicate disease progression. Adjunctive chemotherapy with prednisone, VBL, lomustine, and/or chlorambucil has been attempted in a limited number of cases, but it is not clear if these therapies are clinically valuable. As discussed previously, recent data indicate that cats with MCTs may respond to the KIT inhibitor imatinib if activating mutations in *c-kit* are present.^{214,215}

Feline Intestinal Mast Cell Tumor

Intestinal MCT is the third most common primary intestinal tumor in cats after lymphoma and adenocarcinoma.² No breed or gender predilection is known. Older cats appear to be at risk, with a mean

FIGURE 20-11 A, Diffuse massive splenomegaly in a cat with splenic mast cell disease. B, The less common nodular form of splenic MCT in a cat.

age of 13 years; however, cats as young as 3 years have been reported.²⁴⁷ Most cats have a history of vomiting, diarrhea, and anorexia, and a solitary palpable abdominal mass is usually evident on physical examination.^{2,247} Intestinal MCT more commonly involves the small intestine (equally divided between duodenum, jejunum, and ileum), with colonic involvement reported in less than 15% of cases; lesions can be solitary or multiple.^{2,247,248} Diarrhea with or without hematochezia is commonly observed with the intestinal form, and fever may be present. Affected cats may have been ill for several months. Metastasis is common with this disease; thus enlarged mesenteric lymph nodes and/or hepatomegaly may be noted on physical examination. A peritoneal effusion may be present, and this often contains mast cells and eosinophils. Diagnosis is usually made by FNA of the mass or involved organs; mast cells from intestinal lesions are often less differentiated than those of skin tumors and cytoplasmic granules may be less prominent, making diagnosis challenging in certain cases. Cats with intestinal MCTs should be staged with a minimum database, thoracic radiographs, and abdominal US, which may be required to determine the extent of intestinal involvement and presence of visceral dissemination. Buffy coat smear may also be performed, although unlike splenic MCT, peripheral mastocytosis is rarely associated with intestinal MCT and only two reports of peripheral eosinophilia exist in the literature.²⁴⁷

Intestinal MCTs in cats often have a poor prognosis^{2,247,248} because metastasis is commonly found at the time of diagnosis and many cats either die or are euthanized soon after they are diagnosed. Surgery is the treatment of choice, and wide surgical margins are necessary (5 to 10 cm) because the tumor typically extends histologically well beyond the obvious gross disease.^{2,247} Recently, a variant of feline intestinal MCT, termed *sclerosing MCT*, was described in 50 cats.²⁴⁸ Metastatic disease to the lymph nodes and/or liver was present in 23/36 cases evaluated. Of the 25 cases with clinical follow-up information, 23 died or were euthanized within 2 months of diagnosis, supporting the aggressive nature of this disease. Limited information exists regarding the use of chemotherapy for feline intestinal MCTs, although anecdotal responses to lomustine and chlorambucil have been reported. Recently, two cats exhibited objective responses (one CR, one PR) following treatment with lomustine, suggesting that this agent may be useful in cats with intestinal MCTs.²³⁷ The role of KIT inhibitors in the treatment of this disease is not yet known.

Comparative Aspects of Mast Cell Tumors

Neoplastic diseases of mast cells are considered rare in humans and present as three main clinical entities.^{176,249-252} Cutaneous mastocytosis, also known as *urticaria pigmentosa*, is a benign disease in which mast cell infiltration is confined to the skin. It primarily occurs in young children and usually regresses spontaneously before progression into adulthood. Systemic mastocytosis (SM) occurs primarily in adults and includes four major subtypes: (1) indolent SM, the most common form involving mainly skin and bone marrow that does not progress to aggressive disease; (2) a unique subcategory termed *SM with an associated non-mast cell clonal hematologic disease*; (3) aggressive SM, usually presenting without skin lesions; and (4) mast cell leukemia, probably representing the rarest variant of human leukemias. Finally, rare localized extracutaneous MCTs (either benign or malignant) have been reported. Dysregulation of KIT is also found commonly in human neoplastic mast cell diseases and is primarily driven by a point mutation in exon 17 of *c-kit* that induces ligand-independent activation.^{250,253} More recently, mutations have also been identified in exons 8 to 11, most of which are also activating.^{250,253}

Treatment of the benign human mast cell disorders is primarily focused on supportive therapy, including H₁ and H₂ antagonists, and topical or systemic therapy with corticosteroids. Unfortunately, there is no good therapy for cases of aggressive mastocytosis or mast cell leukemia. Treatment with interferon- α (IFN- α) and/or cladribine is often used, although response rates are typically low.^{249,253} Most of the currently available small molecule KIT inhibitors, including imatinib, nilotinib, and dasatinib, have not been effective in treating human mastocytosis.²⁵³ This may in part be due to the fact that inhibiting phosphorylation of KIT-expressing activating exon 17 mutations is extremely challenging. More recently, the protein kinase C inhibitor, midostaurin, has demonstrated activity in human mast cell disease.²⁵³

Soft Tissue Sarcomas

JULIUS M. LIPTAK AND LISA J. FORREST

Incidence and Risk Factors

Soft tissue sarcomas are a heterogeneous population of mesenchymal tumors that comprise 15% and 7% of all skin and subcutaneous tumors in the dog and cat, respectively.¹ The annual incidence of soft tissue sarcomas in companion animals is about 35 per 100,000 dogs at risk and 17 per 100,000 cats at risk.² In dogs, sarcomas have been associated with radiation, trauma, foreign bodies, orthopedic implants, and the parasite *Spirocerca lupi*.³⁻⁹

Most soft tissue sarcomas are solitary tumors in middle-aged to older dogs and cats. There is no specific breed or sex predilection for soft tissue sarcomas with the possible exception of synovial cell sarcomas in dogs. Earlier reports indicate a slight male predilection^{10,11}; however, in a recent study, males and females were equally represented.¹² Another exception is the occurrence of rhabdomyosarcoma in young dogs.¹³ Soft tissue sarcomas tend to be overrepresented in large breed dogs.

Pathology and Natural History*

Soft tissue sarcomas are a heterogeneous group of tumors whose classification is based on similar pathologic appearance and clinical behavior. Sarcomas arise from mesenchymal tissues and have features similar to the cell type of origin (Table 21-1). These tumors originate in connective tissues, including muscle, adipose, neurovascular, fascial, and fibrous tissue, and can give rise to benign and malignant entities. Only malignant soft tissue sarcomas will be covered in this chapter. Malignant neoplasms in this category include fibrosarcoma, peripheral nerve sheath tumor (PNST; also known as malignant schwannoma, neurofibrosarcoma, or hemangiopericytoma), myxosarcoma, undifferentiated sarcoma, liposarcoma, malignant fibrous histiocytoma, and rhabdomyosarcoma (Table 21-2).^{14,15} The term *soft tissue sarcoma* generally excludes those tumors of hematopoietic or lymphoid origin. Hemangiosarcoma (covered briefly here), mast cell sarcoma, oral sarcoma, osteosarcoma, and chondrosarcoma are covered separately in other chapters. Feline sarcomas and vaccine-associated sarcomas are covered in a separate section at the end of this chapter.

Soft tissue sarcomas may arise from any anatomic site in the body, although skin and subcutaneous sites are most common. Soft tissue sarcomas have the following important common features with regard to their biologic behavior:

- They tend to appear as pseudoencapsulated soft-to-firm tumors but have poorly defined histologic margins or infiltrate through and along fascial planes, and they are locally invasive.
- Local recurrence after conservative surgical excision is common.

- Sarcomas tend to metastasize hematogenously in up to 20% of cases.
- Regional lymph node metastasis is unusual (except for synovial cell sarcoma).¹⁰
- Histopathologic grade is predictive of metastasis, and resected tumor margins predict local recurrence.¹⁶
- Measurable or bulky (>5 cm in diameter) tumors generally have a poor response to chemotherapy and radiation therapy (RT).

Soft tissue sarcomas present a diagnostic challenge. Many of these tumors have histologic patterns with overlapping features not only among themselves but also with a variety of other neoplasms with different histogenesis. The development of immunocytochemical procedures, the availability of monoclonal antibodies and polyclonal antibodies to various tissue markers, and tissue microarray technology have improved diagnosis of soft tissue sarcomas in human pathology and, to a limited degree, in veterinary pathology.^{12,17-22}

The histologic nomenclature for some sarcomas may vary from pathologist to pathologist. Before the initiation of the appropriate therapy for the treatment of soft tissue sarcomas, it is necessary to know the histologic type, size, site, and grade and the stage of disease. Histologic grading (e.g., low, intermediate, or high or I, II, III) is assigned after histologic characterization from adequate biopsy specimens (Table 21-3).

Specific Tumor Types

Soft tissue sarcoma is a collective term used to describe a number of different types of tumors with similar histologic features and biologic behavior. The histogenesis of soft tissue sarcomas is controversial and may be difficult to differentiate on the basis of routine histologic and immunohistochemical analysis. Some pathologists have recommended the use of a more generic term such as soft tissue sarcoma or *spindle cell tumor of canine soft tissue* because of the difficulty in differentiating tumors such as fibrosarcoma, PNST, and hemangiopericytoma.²³ Moreover, histologic distinction of tumor type is not clinically important because most soft tissue sarcomas have a similar biologic behavior (i.e., locally aggressive with a low-to-moderate distant metastatic rate). Some types of soft tissue sarcomas covered briefly in this chapter are hemangiosarcomas, lymphangiosarcomas, and synovial cell sarcomas, which are atypical because their biologic behavior is different with a higher rate and different distribution of metastasis.

Tumors of Fibrous Origin *Nodular Fasciitis (Fibromatosis, Pseudosarcomatous Fibromatosis)*

Nodular fasciitis is a benign nonneoplastic lesion arising from the subcutaneous fascia or superficial portions of the deep fascia in

*Tables 21-1 and 21-3 and general pathology description courtesy Dr. Barbara Powers, Colorado State University.

• **TABLE 21-1** Histiogenic Classification and Metastatic Potential of Canine Soft Tissue Sarcomas

TISSUE OF ORIGIN	BENIGN	MALIGNANT	PRIMARY SITES	METASTATIC POTENTIAL	METASTATIC SITES
Fibrous tissue	Fibroma	Fibrosarcoma	Extremity and oral cavity	Low-to-moderate*	Lungs
Nervous tissue	—	PNST	Extremity	Low-to-moderate*	Lungs
Myxomatous tissue	Myxoma	Myxosarcoma	Extremity and joints	Low-to-moderate	Lungs
Adipose tissue	Lipoma	Liposarcoma	Extremity and ventrum ± abdominal or thoracic cavity	Low-to-moderate	Lungs ± liver, spleen, bone
Skeletal muscle	Rhabdomyoma	Rhabdomyosarcoma	Tongue, larynx, heart, and urinary bladder	Low-to-moderate	Lungs ± liver, spleen, kidneys
Smooth muscle	Leiomyoma	Leiomyosarcoma†	Gastrointestinal ± spleen, liver, vulva and vagina, and subcutaneous tissue	Moderate	Lymph nodes, liver ± spleen, kidneys, peritoneum
Synovial tissue	Synovioma	Synovial cell sarcoma†	Joints	Moderate-to-high*	Lymph nodes and lungs
Histiocytic cells	Histiocytoma	Histiocytic sarcoma†	Extremity	Moderate-to-high	Lymph nodes ± lungs, spleen, liver, kidneys
Lymph vessels	Lymphangioma	Lymphangiosarcoma†	Extremity	Moderate	Lymph nodes
Blood vessels	Hemangioma	Hemangiosarcoma†	Spleen, heart, liver ± skin, muscle, bone, kidneys, and retroperitoneum	High	Lungs, liver, lymph nodes, distant dermal sites

PNST, Peripheral nerve sheath tumor.

*Dependent on histologic grade.

†Atypical soft tissue sarcoma with higher metastatic rate of metastasis to regional lymph node.

• **TABLE 21-2** Types of Soft Tissue Sarcoma

TYPE OF SARCOMA	TUMORS
Soft tissue sarcoma	Fibrosarcoma PNST* Liposarcoma Myxosarcoma Malignant mesenchymoma
Other soft tissue sarcoma	Leiomyosarcoma Rhabdomyosarcoma Synovial cell sarcoma Lymphangiosarcoma
Non-soft tissue sarcoma	Histiocytic sarcoma Hemangiosarcoma Osteosarcoma Chondrosarcoma Melanoma Lymphosarcoma (lymphoma)

Tumors listed under “Soft tissue sarcoma” have similar biologic behavior characterized by local aggression and low-to-moderate metastatic potential. Tumors listed under “Other soft tissue sarcoma” are atypical soft tissue sarcomas because of different location (e.g., leiomyosarcoma and synovial cell sarcoma) or higher metastatic rate (leiomyosarcoma, rhabdomyosarcoma, lymphangiosarcoma ± synovial cell sarcoma). Some sarcomas not considered as soft tissue sarcomas are discussed in this chapter because of similarities in location to other soft tissue sarcomas (e.g., histiocytic sarcoma and dermal hemangiosarcoma).¹³³

PNST, Peripheral nerve sheath tumor.

*PNSTs include tumors previously classified as hemangiopericytoma, malignant schwannoma, and neurofibrosarcoma.

• **TABLE 21-3** Soft Tissue Sarcoma Grading System

SCORE	DIFFERENTIATION	MITOSIS*	NECROSIS
1	Resembles normal adult mesenchymal tissue	0-9	None
2	Specific histologic subtype	10-19	<50% necrosis
3	Undifferentiated	>20	>50% necrosis

Grade I: Cumulative score of ≤4 for the three categories.

Grade II: Cumulative score of 5-6.

Grade III: Cumulative score of ≥7.

*Mitosis is calculated as the number of mitotic figures/10 HPF.

dogs. These lesions are usually nodular, poorly circumscribed, and very invasive.²⁴ Histologically, nodular fasciitis is characterized by large plump or spindle-shaped fibroblasts in a stromal network of variable amounts of collagen and reticular fibers with scattered lymphocytes, plasma cells, and macrophages.²⁴ The morphologic and pathologic characteristics of nodular fasciitis can result in these lesions being misdiagnosed as fibrosarcoma. Infantile desmoid-type fibromatosis is a variant of nodular fasciitis and is characterized by fibroblast proliferation with a dense reticular fiber network and mucoid material.²⁵ Wide excision of both nodular fasciitis and infantile desmoid-type fibromatosis lesions is usually curative.²⁶ Local recurrence is possible with incomplete resection. These tumors do not metastasize.²⁴

Fibrosarcoma

Most fibrosarcomas arise from the skin, subcutaneous tissue, or oral cavity and represent malignant fibroblasts. Tumors can be well

differentiated, exhibiting spindle-shaped tumor cells with scant cytoplasm. The more anaplastic tumor is very cellular with closely packed spindle-shaped fibroblasts showing many mitotic figures and marked cellular pleomorphism.²⁷ Tumors tend to occur in older dogs and cats with no breed or sex predilection; however, one reference states a higher predilection in golden retrievers and Doberman Pinschers.²⁸ A unique form, histologically low-grade, yet biologically high-grade fibrosarcoma, is seen in the oral cavity and has a tendency to grow quite large and invade deeper structures, including bone. Metastasis can be seen in up to 20% of the cases.¹⁹ Metastasis is rare, but these tumors are infiltrative, with microscopic tumor cells invading along fascial planes, and often recur after surgical excision.

Tumors of the Peripheral Nerves

Peripheral Nerve Sheath Tumor (Neurofibrosarcoma, Malignant Schwannoma, Hemangiopericytoma)

The PNSTs are malignant tumors of nerve sheath origin and have been referred to as neurofibrosarcoma, malignant schwannoma, and hemangiopericytoma. The confusion regarding hemangiopericytoma is the fact that blood vessel pericyte origin has yet to be proven in dogs. Most hemangiopericytomas will have features of nerve sheath tumors histologically.²⁷ Malignant PNSTs will stain positive with S-100 and vimentin, indicating peripheral nerve origin.²⁹

Regardless of the nomenclature, these tumors can occur anywhere in the body. A PNST may involve nerves away from the brain or spinal cord (peripheral group), or they may involve nerves immediately adjacent to the brain or spinal cord (root group) or the brachial or lumbosacral plexus (plexus group).³⁰ The true peripheral form is much more treatable than the plexus or root form. Despite appearing encapsulated at surgery, these tumors are similar to fibrosarcomas and occur as poorly defined tumors without histologic encapsulation. Most of the tumors are adherent to deeper tissues and may infiltrate underlying fascia, muscle, and skin. Although these tumors are considered malignant, they have a modest metastatic rate. As with fibrosarcomas, local recurrence for PNSTs is common following conservative surgery. They tend to grow slowly and can range in size from 0.5 cm to over 10 to 12 cm in diameter. In some cases, they can easily be confused with lipomas on initial clinical examination.²⁷

PNSTs located in the proximal axial region may result in the compression of nerves. The vast majority of cases will show signs of unilateral lameness, muscle atrophy, paralysis, and pain.³⁰ They can invade the spinal cord, and about 50% will invade the cord if a grade III tumor is diagnosed.³⁰ However, local disease usually limits survival before metastasis occurs.

Histiocytic Disorders

The reader is referred to Chapter 33, Section F, for a complete discussion of histiocytic disorders because the biology, nomenclature, and management of this collection of benign and malignant conditions continue to evolve. Malignant fibrous histiocytoma as a histopathologic diagnosis, however, is considered to be more consistent with soft tissue sarcomas in general and is managed with guidelines discussed later in this chapter.

Tumors of Adipose Tissue

Lipoma

Lipomas are benign tumors of adipose tissue. Variants of lipomas have been reported and include angioliipoma and angiofibrolipoma.³¹ Lipomas are relatively common in older dogs,

especially in subcutaneous locations, and are rarely symptomatic. Lipomas can also occur in the thoracic cavity, abdominal cavity, spinal canal, and vulva and vagina of dogs and can cause clinical abnormalities secondary to either compression or strangulation.³²⁻⁴⁰

Parosteal and infiltrative lipomas have been rarely reported and these tumors can have a more aggressive behavior despite their benign histologic appearance.⁴¹⁻⁴⁶ Marginal resection is recommended for lipomas that interfere with normal function; however, the majority are asymptomatic and do not require surgical intervention. Lipomas can be differentiated from liposarcomas based on morphologic and histologic appearance. Histologically, lipomas have indistinct nuclei and cytoplasm resembling normal fat, whereas liposarcomas are characterized by increased cellularity, distinct nuclei, and abundant cytoplasm with one or more droplets of fat.³⁸ Surgical resection is usually curative, but local recurrence has been reported.³⁹

Intermuscular Lipoma

Intermuscular lipomas are a variant of the subcutaneous lipoma and are located in the intermuscular region of the caudal thigh of dogs, particularly between the semitendinosus and semimembranosus muscles (Figure 21-1).⁴⁷ Clinically, intermuscular lipomas appear as a slow-growing, firm, and fixed mass in the caudal thigh region and may occasionally cause lameness.⁴⁷ Cytologic analysis of fine-needle aspirates is usually diagnostic. The recommended treatment is surgical resection, involving blunt dissection and digital extrusion, and placement of either a Penrose or negative-suction drain. Seromas are a common complication in dogs in which a

• **FIGURE 21-1** An intramuscular lipoma arising from between the semitendinosus and semimembranosus muscles. Surgical dissection and removal was curative.

drain is not used. The prognosis is excellent with no recurrence reported in 11 dogs following surgical removal.⁴⁷

Infiltrative Lipoma

Infiltrative lipomas are uncommon tumors composed of well-differentiated adipose cells without evidence of anaplasia. These tumors cannot be readily distinguished from the more common simple lipoma by cytology or small biopsy specimens. They are considered “benign” and do not metastasize. However, infiltrative lipomas are locally aggressive and commonly invade adjacent muscle, fascia, nerve, myocardium, joint capsule, and even bone.^{42,48,49} Computed tomography (CT) is used to better delineate these tumors; however, they do not contrast enhance and differentiating infiltrative lipomas from normal fat is problematic.⁴⁷ One retrospective analysis of 16 cases reported a 4:1 female-to-male ratio.⁴⁴ Aggressive treatment, including amputation, may be necessary for local control. RT can be considered either alone or in combination with surgical excision.⁴⁶

Liposarcoma

Liposarcomas are uncommon malignant tumors originating from lipoblasts in older dogs.⁵⁰ Liposarcomas apparently do not arise from malignant transformation of lipomas. Specific causes are not known, but foreign body–associated liposarcoma has been reported in one dog.⁵ There is no breed or sex predilection.⁵⁰ They are commonly reported in subcutaneous locations, especially along the ventrum and extremities, but can also occur in other primary sites such as bone and the abdominal cavity. Liposarcomas are differentiated from lipomas based on morphologic appearance and cytologic characteristics. Liposarcomas are usually firm and poorly circumscribed. They are locally invasive with a low metastatic potential. Metastatic sites include the lungs, liver, spleen, and bone.^{27,50}

The prognosis for liposarcoma is good with appropriate surgical management. The median survival time (MST) following wide surgical excision is 1188 days; this is significantly better than either marginal excision or incisional biopsy, which have MSTs of 649 days and 183 days, respectively (Figure 21-2).⁵⁰ Liposarcoma is histologically classified as well-differentiated, myxoid, round cell (or poorly differentiated), pleomorphic, or dedifferentiated. This classification scheme has clinical and prognostic importance in humans because pleomorphic liposarcomas have a high metastatic rate, myxoid liposarcomas are more likely to metastasize to extrapulmonary soft tissue structures, and well-differentiated liposarcomas are unlikely to metastasize.⁵¹⁻⁵³ In a retrospective study in dogs, histologic subtype was not prognostic, but metastatic disease was more common in dogs with pleomorphic liposarcomas.⁵⁰

Tumors of Smooth Muscle

Leiomyoma and Leiomyosarcoma

Leiomyomas and leiomyosarcomas are tumors arising from smooth muscle cells. The gastrointestinal (GI) tract is most commonly affected, but other primary sites include the spleen, liver, genitourinary tract, retroperitoneal space, vessel wall, and subcutaneous tissue.⁵⁴⁻⁵⁷ Paraneoplastic syndromes associated with smooth muscle tumors, particularly GI leiomyomas and leiomyosarcomas, include hypoglycemia, nephrogenic diabetes insipidus, and secondary erythrocytosis.^{55,58-61}

Leiomyomas are benign and usually small, localized, and well encapsulated. Leiomyomas of the vagina and vulva are often pedunculated, protrude from the vulva, and are hormonally dependent. Ovariohysterectomy is recommended in the management of dogs with vulval or vaginal leiomyomas.

Rights were not granted to include this figure
in electronic media.
Please refer to the printed publication.

• **FIGURE 21-2** Kaplan-Meier survival curve of 56 dogs with liposarcoma treated with either incisional biopsy, marginal resection, or wide excision. The median survival time (MST) is significantly longer, at 1188 days, following wide surgical resection than less aggressive techniques. (Reprinted with permission from Baez JL, Hendrick MJ, Shofer FS, et al: *Liposarcomas in dogs: 56 cases (1989-2000)*, J Am Vet Med Assoc 224:887, 2004.)

Leiomyosarcomas are malignant tumors with a moderate metastatic potential, depending on the primary site.^{55,62} The metastatic rate for dogs with hepatic leiomyosarcoma is apparently 100% but is approximately 50% for other primary intraabdominal sites and 0% for dermal smooth muscle tumors.^{55,61,63,64} Regional lymph nodes, mesentery, and liver are the most common metastatic sites for GI leiomyosarcoma, although other sites include the spleen, kidneys, and peritoneum.^{55,61-64}

Leiomyosarcoma is the second most common GI tumor in dogs and has a predilection for the jejunum and cecum, but any region of the GI tract can be affected from the esophagus to the rectum.^{55,61-63,65} An immunohistochemical review of previously diagnosed GI leiomyomas and leiomyosarcomas has resulted in the vast majority of these tumors being reclassified as GI stromal tumors (GISTs) or GI stromal-like tumors.^{66,67} Leiomyosarcomas have strong immunoreactivity to actin and desmin and rarely stain positively with c-kit, CD34, or S-100 protein. In contrast, true GISTs are consistently associated with mutations of the tyrosine kinase receptor gene *c-kit* and will have strong immunoreactivity to c-kit and CD34 proteins with variable reactivity to actin, desmin, and S-100 protein.^{62,65-67} The GI stromal-like tumors have an identical immunohistochemical profile to GISTs, except they do not express c-kit.⁶⁶

Older dogs are more commonly affected and there is no sex or breed predisposition.^{55,61-63} In contrast, there is a male predisposition for GI leiomyomas and these tumors have a predilection for the stomach rather than the jejunum and cecum.^{62,68} Presenting signs can include inappetence, weight loss, vomiting, diarrhea, polyuria, polydipsia, anemia, and hypoglycemia.^{55,61-63}

Surgical resection is the recommended treatment for dogs with leiomyosarcomas. Intestinal perforation with localized to diffuse peritonitis is relatively common in dogs with GI leiomyosarcoma and is reported in up to 50% of cases.⁶¹ Local tumor control is good following complete resection, but recurrence has been reported following incomplete resection of a gastric leiomyoma and cutaneous leiomyosarcomas.^{64,66,68}

Prolonged survival and possibly cure has been reported following surgery in dogs with gastrointestinal leiomyosarcoma and GIST tumors.^{54,55,59,67} Prognostic factors in humans with GIST include tumor size, metastasis, and histologic criteria such as tumor necrosis, number of mitotic figures, and proliferating cell nuclear antigen (PCNA) index⁶⁹; however, prognostic factors have not been investigated in dogs with leiomyosarcoma. The MST for dogs with GI leiomyosarcoma and GIST surviving the immediate postoperative period is up to 37.4 months, with 1-, 2-, and 3-year survival rates of 75% to 83%, 62% to 67%, and 60%, respectively.^{55,61,63,66,67} In addition, metastasis did not have a negative impact on survival time in one report with a 21.7 month MST for dogs with documented metastasis at the time of surgery.⁶¹ However, other investigators have found metastasis significantly decreases survival time.⁶³ The MST is 8 months for dogs with splenic leiomyosarcoma, and all dogs with hepatic leiomyosarcoma in one series had evidence of metastasis at initial surgery and were euthanized.⁵⁵

Tumors of Skeletal Muscle

Rhabdomyosarcoma

Rhabdomyosarcomas are rare malignant tumors originating from myoblasts or primitive mesenchymal cells capable of differentiating into striated muscle cells.⁷⁰ In dogs, rhabdomyosarcomas are most frequently reported to arise from skeletal muscle of the tongue, larynx, myocardium, and urinary bladder. They are locally invasive with a low-to-moderate metastatic potential. Metastatic sites include the lungs, liver, spleen, kidneys, and adrenal glands.⁷⁰

Rhabdomyosarcomas are histologically classified as embryonal, botryoid, alveolar, and pleomorphic. The histologic diagnosis of rhabdomyosarcoma is difficult and immunohistochemical staining for vimentin, skeletal muscle actin, myoglobin, myogenin, and myogenic differentiation (MyoD) may be required for definitive diagnosis.⁷¹ Embryonal rhabdomyosarcomas have a predilection for the head and neck region of older dogs, such as the tongue, oral cavity, and larynx. In contrast, botryoid rhabdomyosarcoma commonly arises in the urinary bladder of young, female large breed dogs with Saint Bernard dogs possibly being overrepresented in one data set.⁷⁰ Botryoid tumors are characterized by their grapelike appearance. The histologic classification scheme for rhabdomyosarcoma has prognostic significance in humans, but this has not been investigated in dogs. In humans, botryoid rhabdomyosarcoma has a good prognosis, embryonal rhabdomyosarcoma has an intermediate prognosis, and alveolar rhabdomyosarcoma has a poor prognosis.^{70,72}

Rhabdomyosarcomas, particularly those involving the extremities, have a high rate of metastasis in humans; major metastatic sites include the lungs, lymph nodes, and bone marrow. The metastatic potential and prognosis in dogs with rhabdomyosarcoma have not been determined because it is rarely diagnosed and even more rarely treated with curative intent. However, disease-free and overall survival times have been encouraging in the few dogs treated with surgical resection with or without RT and chemotherapy.⁷³⁻⁷⁷ In humans, in contrast to many other types of soft tissue sarcomas, multimodality treatment with surgery, RT, and chemotherapy has significantly improved survival rates, particularly in children with embryonal and botryoid rhabdomyosarcoma.^{51,53,72}

Tumors of Vascular and Lymphatic Tissue

Lymphangiosarcoma

Lymphangiosarcomas are rare tumors seen in young dogs and cats that arise from lymphatic endothelial cells.^{27,78,79} They are usually

• **FIGURE 21-3** Lymphangiosarcoma of the ventral abdomen in a male cat. These tumors are often subcutaneous, soft and edematous, and with poorly defined margins.

soft, cystic-like, and edematous, usually occurring in the subcutis (Figure 21-3).²⁷ In most cases, clinical signs are associated with extensive edema and drainage of lymph through the skin or a cystic mass. Aspiration may reveal a fluid-filled mass. Histopathologically, these tumors resemble normal endothelial cells and may be confused with hemangiosarcomas because of the vascular channels; however, red blood cells are not seen.²⁷ Lymphangiosarcomas tend to have a moderate-to-high metastatic potential.⁸⁰ In a single case report, a dog treated with surgery that had local recurrence had a complete response following doxorubicin chemotherapy with no evidence of recurrence or metastasis 9 months after remission.⁸¹

Hemangioma

Hemangiomas and hemangiosarcomas (HSAs) are tumors of vascular endothelial origin. Hemangioma is a benign tumor that can occur in a variety of sites, including skin, liver, spleen, kidneys, bone, tongue, and heart.⁸²⁻⁸⁴ Dermal hemangiomas may be induced by ultraviolet (UV) light in short-haired dogs with poorly pigmented skin.²⁷ Despite their benign biologic behavior, hemangiomas can cause severe anemia secondary to tumor-associated blood loss.^{82,84} In humans, hemangiomas can spontaneously regress or be responsive to intralesional corticosteroids, but this has not been observed in dogs.²⁷ Complete surgical resection is usually curative.

Hemangiosarcoma

HSAs are highly malignant tumors. The most common primary sites in cats and dogs involve visceral organs, especially the spleen, right atrial appendage, and liver.²⁴ Other primary sites include the skin, pericardium, lung, kidneys, oral cavity, muscle, bone, genitourinary tract, and peritoneum and retroperitoneum.^{24,85} A thorough review of HSAs is presented in Chapter 33, Section A. The discussion here is limited to dermal and subcutaneous HSAs. Primary dermal HSAs have a predilection for light-haired or poorly pigmented skin on the ventral abdomen and preputial region of dogs, particularly those confined to the dermis, and solar radiation has been proposed as a cause of dermal HSAs in dogs.⁸⁶

Canine cutaneous HSAs are clinically staged according to depth of involvement with stage I tumors confined to the dermis, stage II tumors extending into subcutaneous tissue, and stage III HSAs

• **FIGURE 21-4** A dog with a subcutaneous hemangiosarcoma invading into the underlying musculature of the thoracic limb (stage III) with a typical bruised appearance. Local tumor control is more difficult in these cases and the prognosis is worse for dogs with higher grade dermal hemangiosarcoma if logoregional tumor control is not achieved.

involving the underlying muscle (Figure 21-4).⁸⁶ Stage II and III dermal HSAs are typically large and poorly circumscribed and have a bruised appearance that can be mistaken for a traumatic hematoma. The recommended treatment is wide surgical resection and adjuvant doxorubicin.⁸⁷ Doxorubicin-based chemotherapy protocols have been investigated in dogs with nonresectable stage II and III cutaneous HSAs, with approximately 40% of dogs showing a measurable response with a median response duration of 53 days.⁸⁸ Treatment with doxorubicin-based chemotherapy protocols may downstage dogs with large subcutaneous and intramuscular HSAs and thus decrease the size of the tumor, allowing for complete surgical excision.⁸⁸

Clinical staging provides prognostic information on the success of local treatment, metastatic potential, and survival time. Dogs with stage I dermal HSAs have a complete surgical resection rate of 78%, 30% metastatic rate with all metastases occurring in distant dermal sites, and a MST of 780 days.⁸⁶ In contrast, dogs with stage II and III hypodermal HSAs have a complete surgical resection rate of only 23%, principally because these tumors are larger and less well circumscribed; are 60% metastatic to lungs, regional lymph nodes, and distant dermal sites; and have a significantly lower MST of 172 to 307 days (Figure 21-5).⁸⁶ For dogs with aggressive local control (using adequate surgery with or without RT) of subcutaneous or intramuscular HSA, the use of adjuvant doxorubicin results in encouraging survival times. The median disease-free interval (DFI) and survival time for dogs with subcutaneous and intramuscular HSAs treated with surgery and doxorubicin are 1553 and 1189 days and 266 and 273 days, respectively.⁸⁷

Feline cutaneous HSAs are usually solitary tumors in older cats, with a mean age of 11.5 to 12.5 years and males possibly being overrepresented.^{89,90} Unlike cutaneous hemangiomas, which have no site predilection, cutaneous HSAs occur primarily in poorly

• **FIGURE 21-5** Kaplan-Meier survival curve for dogs with stage I (cutaneous), stage II (subcutaneous), and stage III (muscle) hemangiosarcoma. pigmented skin, particularly the skin of the pinna, head, and ventral abdomen and subcutaneous tissue of the inguinal region.⁸⁹⁻⁹¹ Local tumor control is poor following surgical resection, with local recurrence reported in 50% to 80% of cases at a median of 420 days postoperatively.⁸⁹⁻⁹¹ Metastasis has been reported but occurs less frequently than in dogs with dermal and hypodermal HSAs.⁸⁹⁻⁹¹ The MST of greater than 1460 days for cats treated with wide surgical resection is significantly better than the MST of 60 days reported for untreated cats with cutaneous HSAs.⁹⁰

Tumors of Synovial Tissue

Synovial Cell Sarcoma

Synovial cell sarcomas are malignant tumors arising from synovio-cytes of the joint capsule and tendon sheath. The two types of synovio-cytes are type A synovio-cytes, which are phagocytic and resemble macrophages, and type B synovio-cytes, which are fibro-blastic.⁹² Synovial cell sarcomas have been classified as monophasic or biphasic, depending on the proportion of malignant epithelial (synovio-blastic) and mesenchymal (fibroblastic) cells within the tumor. However, this classification scheme was adopted from human medicine and is probably not applicable in small animals because of the rarity of epithelial cells in canine synovial cell sarcomas.⁹² To add further confusion to the nomenclature, synovial cell sarcomas and histiocytic sarcomas are often considered to be different types of joint tumors, but both may originate from synovial cells, with synovial cell sarcomas arising from type B synovio-cytes and histiocytic sarcomas arising from type A synovio-cytes. Expression of CD18 does not differentiate between the macrophages (or type A synovio-cytes) and dendritic antigen-presenting cell (APC) lineage of histiocytic cells (P.F. Moore, personal communication). Recent immunohistochemical evidence, however, indicates that periarticular histiocytic sarcomas do arise from subsynovial dendritic APCs and not type A synovio-cytes (P.F. Moore, unpublished data). Rare canine synovial myxomas have been reported. They were most common in large breed middle-aged dogs⁹³ and were reported most often at the stifle or a digit and may be confused with the more common synovial cell sarcoma.

The diagnosis of synovial cell sarcoma is controversial and immunohistochemistry (IHC) is recommended to differentiate

synovial cell sarcomas from other types of joint tumors.^{12,94,95} The immunohistochemical panel should include vimentin and cytokeratin for synovial cell sarcoma, CD18 for histiocytic sarcoma, and actin for malignant fibrous histiocytoma.⁹⁴ However, other investigators have questioned the value of IHC in the diagnosis of synovial cell sarcoma.⁹⁵ Synovial cell sarcomas are histologically graded from I to III based on criteria such as nuclear pleomorphism, mitotic figures, and necrosis, and this grading scheme provides prognostic information.¹²

Synovial cell sarcomas are locally aggressive with a moderate-to-high metastatic potential, depending on histologic grade.¹² Up to 32% of dogs with synovial cell sarcomas have evidence of metastatic disease at diagnosis and 54% by the time of euthanasia.^{10,12} Regional lymph nodes and lungs are the most common metastatic sites.¹² Synovial cell sarcomas have a greater metastatic potential and a higher incidence of lymph node metastasis compared to typical soft tissue sarcomas. Synovial cell sarcomas are rare in cats, but feline and canine synovial cell sarcomas are similar in terms of histologic appearance, biologic behavior, and distribution of metastatic lesions.⁹⁶

In dogs, synovial cell sarcomas usually occur in large breeds, with a predisposition for flat-coated and golden retrievers. Middle-aged dogs are most commonly affected, and there is no sex predilection. Synovial cell sarcomas usually involve the larger joints, particularly the stifle, elbow, and shoulder, but any joint can be affected. Lameness is the most common presenting complaint and can be confused with other orthopedic conditions.¹² Radiographic features of synovial cell sarcomas in dogs include periarticular soft tissue swelling and bone invasion, ranging from an ill-defined periosteal reaction to multifocal punctate osteolytic lesions, involving bones on either side of the joint.^{12,92} Bone involvement is rare in cats.⁹⁶ Limb amputation is recommended for treatment of the local tumor because local tumor recurrence is significantly lower compared to marginal or wide resection.^{12,95} Local tumor recurrence following limb amputation, known as stump recurrence, occurs at a relatively higher rate than other types of tumors for which limb amputation is commonly performed.¹² Thus the level of amputation should be as proximal as possible to minimize the risk of local tumor recurrence, such as forequarter amputation for synovial cell sarcomas of the thoracic limb and coxofemoral disarticulation or hemipelvectomy for synovial cell sarcomas of the pelvic limb. The role of adjuvant therapy is unknown, but synovial cell sarcomas in humans are more responsive to chemotherapy agents such as anthracyclines and ifosfamide than many other types of soft tissue sarcomas.⁵¹ Doxorubicin-based chemotherapy protocols may be warranted in dogs with nonmetastatic grade III synovial cell sarcomas.^{12,97}

Prognostic factors in dogs with synovial cell sarcoma include clinical stage, histologic grade, and extent of surgical treatment. Dogs with evidence of lymph node or lung metastasis at diagnosis have a MST of less than 6 months compared to 36 months or greater if there is no evidence of metastasis.¹² The MST for dogs treated with limb amputation is 850 days, which is significantly better than the 455 days reported following marginal resection.⁹⁵ Finally, the MST for dogs with grade III synovial cell sarcomas is 7 months and significantly worse than either grade I or II synovial cell sarcomas, with MSTs greater than 48 months and 36 months, respectively.¹² In one study comparing canine joint tumors, the metastatic rate and MST for dogs with synovial cell sarcoma was 25% and 31.8 months, 0% and 30.7 months for dogs with synovial myxoma, 91% and 5.3 months for dogs with histiocytic sarcoma, and 100% and 3.5 months for dogs with other types of periarticular sarcomas.⁹⁴

Tumors of Uncertain Histogenesis

Myxosarcoma

Myxosarcomas are neoplasms of fibroblast origin with an abundant myxoid matrix composed of mucopolysaccharides. These rare tumors occur in middle-aged or older dogs and cats. The majority are subcutaneous tumors of the trunk or limbs,²⁷ but there are reports of myxosarcomas arising from the heart, eye, and brain.⁹⁸⁻¹⁰⁰ These tumors tend to be infiltrative growths with ill-defined margins.²⁷

Malignant Mesenchymoma

Malignant mesenchymomas are rare soft tissue sarcomas comprising a fibrous component with two or more different varieties of other types of sarcoma.²⁴ Malignant mesenchymomas have been reported in the lungs, thoracic wall, liver, spleen, kidney, digits, and soft tissue.¹⁰¹⁻¹⁰⁶ They have a slow rate of growth and can grow very large. Metastasis has been reported.^{105,106} The outcome for dogs with splenic mesenchymomas is better than other types of splenic sarcomas, with a MST of 12 months and a 1-year survival rate of 50%.¹⁰¹

History and Clinical Signs

Soft tissue sarcomas generally present as a slow-growing mass anywhere in the body. Rapid tumor growth, intratumoral hemorrhage, or necrosis can be seen in some cases. Symptoms are directly related to site of involvement and tumor invasiveness. However, one exception is tumor hypoglycemia, which has been reported in dogs with smooth muscle tumors.^{59,107} There is marked variability in the physical features of soft tissue sarcoma, but they are generally firm and adherent (fixed) to skin, muscle, or bone. Often, soft tissue sarcomas can be soft and lobulated, mimicking lipomas.

Intraabdominal tumors often compress the GI tract and patients may present with vomiting, diarrhea, and melena. A mass may be palpable, and weight loss and anorexia is common. Leiomyosarcomas are seen most commonly in the GI tract, spleen, and urogenital tract. GI leiomyosarcomas generally result in intestinal obstruction and may cause intestinal perforation leading to peritonitis.⁶¹ Rhabdomyosarcomas, seen in young dogs and involving the bladder, present with signs of hematuria, dysuria, and rarely, hypertrophic osteopathy.^{108,109}

PNSTs, involving the brachial or lumbosacral plexus, usually result in pain, lameness, muscle atrophy, and eventual paralysis. These tumors generally are located axially and are difficult to palpate, making early diagnosis difficult because patients do not present with clinical signs until the tumors are quite large and there is significant lameness and muscle atrophy.

Diagnostic Techniques and Work-Up

Fine-needle aspiration (FNA) is recommended to exclude other differentials (e.g., abscesses, cysts, or mast cell tumors [MCTs]). However, cytologic evaluation of FNA may not be sufficient for definitive diagnosis because false-negative results can occur because of nonrepresentative samples subject to variable degrees of necrosis and poor exfoliation of cells in comparison to epithelial and round cell tumors.²⁴ In one study in which FNA was performed on soft tissue sarcomas from 40 dogs, 15% of dogs were incorrectly diagnosed and a further 23% were nondiagnostic.¹¹⁰ Biopsy methods for

definitive preoperative diagnosis of soft tissue sarcomas include needle-core, punch, incisional, or excisional biopsies. The biopsy should be planned and positioned so that the biopsy tract can be included in the curative-intent treatment, whether it be surgery with or without RT, without increasing the surgical dose or size of the radiation field. Excisional biopsies are *not* recommended because they are rarely curative and the subsequent surgery required to achieve complete histologic margins is often more aggressive than surgery following core or incisional biopsies, resulting in additional morbidity and treatment costs. Furthermore, multiple attempts at resection, including excisional biopsy, prior to definitive therapy have a negative impact on survival time in dogs with soft tissue sarcomas.¹¹¹

Diagnostic tests performed for work-up and clinical staging depend on the type of soft tissue sarcoma, especially with atypical forms (e.g., HSAs, histiocytic sarcomas, lymphangiosarcomas, and synovial cell sarcomas), but usually involve routine hematologic and serum biochemical blood tests, three-view thoracic radiographs, and regional imaging of the soft tissue sarcoma. Blood tests are usually within the normal reference range for most dogs with soft tissue sarcomas; however, there are some notable exceptions. Hematologic abnormalities such as anemia and thrombocytopenia are relatively common in dogs with disseminated histiocytic sarcomas and HSAs.^{24,112,113} Hypoglycemia has been reported in dogs with intraabdominal leiomyomas and leiomyosarcomas.^{55,58,59,107} Excessive production of insulin-like growth factor II has been implicated as the cause of hypoglycemia in humans with mesenchymal tumors and this has also been demonstrated in one dog with a gastric leiomyoma.¹¹⁴⁻¹¹⁶

Imaging studies of the local tumor may be required for planning of the surgical approach or RT if the tumor is fixed to underlying structures or located in an area that may make definitive treatment difficult, such as the pelvic region. Three-dimensional (3D) imaging techniques such as CT and magnetic resonance imaging (MRI) are particularly useful for staging local disease.¹¹⁷ Other imaging modalities for staging of the local tumor include survey radiographs, ultrasonography, angiography, and nuclear scintigraphy.

Diagnostic tests for staging of metastatic disease include thoracic radiographs, abdominal ultrasonography or advanced imaging, and FNA or biopsy of the regional lymph nodes. Three-view thoracic radiographs should be performed prior to definitive treatment because the lungs are the most common metastatic site for typical soft tissue sarcomas.¹⁶ Lymph node metastasis is uncommon. FNA or biopsy of regional lymph nodes should be performed in dogs with clinically abnormal lymph nodes, high-grade (III) soft tissue sarcomas, or atypical soft tissue sarcomas having a high rate of metastasis to regional lymph nodes, such as HSAs, histiocytic sarcomas, lymphangiosarcomas, synovial cell sarcomas, leiomyosarcomas, and possibly rhabdomyosarcomas.* Abdominal imaging is recommended for the assessment of metastasis to intraabdominal organs, especially the lymph nodes, spleen, and liver, in animals with suspected intraabdominal neoplasia (e.g., GI leiomyosarcoma or splenic sarcoma) or advanced stage and high-grade pelvic limb soft tissue sarcoma.

Clinical Staging

A modified staging system has been described for soft tissue sarcomas in dogs.²⁴ The American Joint Committee on Cancer (AJCC)

staging system currently used in humans with soft tissue sarcomas has been substantially modified from the original staging system, on which the modified animal staging system is based. The most important change to the AJCC staging system is categorization of local disease, with less emphasis on tumor size, which is an arbitrary assignment, and greater emphasis on depth of invasion.^{51,120} A superficial tumor is defined as a soft tissue sarcoma located above the superficial fascia and that does not invade the fascia, whereas a deep tumor is located deep to the superficial fascia, invades the fascia, or both.¹⁰⁸ Based on the current AJCC staging system, an updated modified staging system for animals is summarized in [Box 21-1](#). The stage grouping takes into account both clinical staging criteria (TNM staging system) and histologic grade. The original and updated staging systems for animals with soft tissue sarcomas have not been investigated and the prognostic significance of either of these systems is unknown.

Treatment

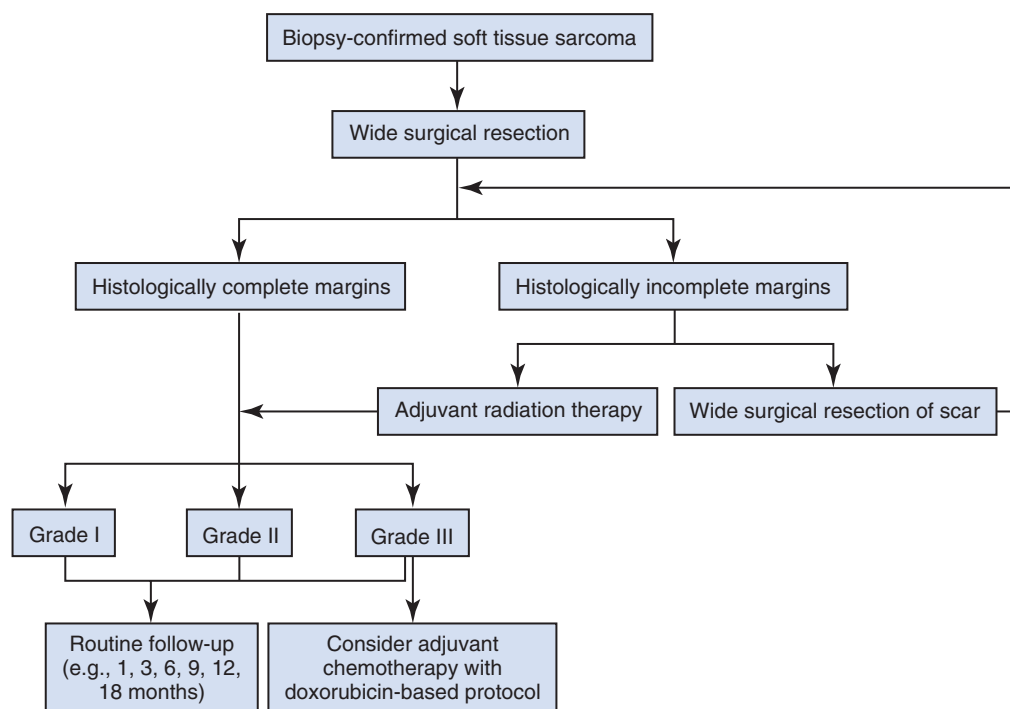

There are over 20 different histologic subtypes of soft tissue sarcomas described in dogs, but the vast majority of these subtypes have a very similar biologic behavior characterized by locally aggressive invasiveness and a low-to-moderate metastatic potential depending on histologic grade.¹⁶ Local tumor control is the most important consideration in the management of soft tissue sarcomas because of their locally aggressive behavior. As such, surgical resection is the principal treatment for dogs with soft tissue sarcomas. RT also plays an important role in local tumor control, especially for incompletely resected and unresectable soft tissue sarcomas. However, definitive treatment options depend on histologic subtype (especially for atypical soft tissue sarcomas such as HSAs, histiocytic sarcomas, and lymphangiosarcomas), tumor location, clinical stage, histologic grade, and completeness of surgical margins.^{24,121} A strategy for managing dogs with typical soft tissue sarcomas is presented in [Figure 21-6](#).

Surgery

Soft tissue sarcomas are locally aggressive tumors that grow along paths of least resistance and invade surrounding tissue, resulting in the formation of a pseudocapsule of compressed viable tumor cells.²⁴ The pseudocapsule gives the false impression of a well-encapsulated tumor. However, surgical removal of the encapsulated mass without adequate margins will result in incomplete resection and a high risk of local tumor recurrence.¹⁶ The minimum recommended margins for surgical resection are 3 cm lateral to the tumor and one fascial layer deep to the tumor ([Figure 21-7](#)).^{121,122} Biopsy tracts and any areas of fixation, including bone and fascia, should be resected en bloc with the tumor using the recommended surgical margins. Radical surgery such as limb amputation or hemipelvectomy may be required to achieve adequate surgical margins and local tumor control. Alternatively, planned multimodal therapy with marginal surgical excision and postoperative RT may be limb sparing and reduce patient morbidity.

The resected tumor should be pinned out to the original dimensions to prevent shrinkage during formalin fixation ([Figure 21-8](#)).¹²³; the lateral and deep margins should be inked to aid in histologic identification of surgical margins; and any areas of concern should be tagged with suture material, inked in a different color, or submitted separately for specific histologic assessment. Surgical margins and tumor grade are important in determining the need and type of further treatment. For instance, tumor grade is important in deciding whether a soft tissue sarcoma resected with complete but

Box 21-1 Modified Staging System for Canine Soft Tissue Sarcomas

Modified Staging System for Soft Tissue Sarcomas

Primary Tumor (T)

- T1 Tumor ≤5 cm in diameter at greatest dimension
 - T1a Superficial tumor
 - T1b Deep tumor
- T2 Tumor >5 cm in diameter at greatest dimension
 - T2a Superficial tumor
 - T2b Deep tumor

Regional Lymph Nodes (N)

- N0 No regional lymph node metastasis
- N1 Regional lymph node metastasis

Distant Metastasis (M)

- M0 No distant metastasis
- M1 Distant metastasis

Stage Grouping	Tumor (T)	Nodes (N)	Metastasis (M)	Grade
I	Any T	N0	M0	I-II
II	T1a-1b, T2a	N0	M0	III
III	T2b	N0	M0	III
IV	Any T	N1	Any M	I-III
	Any T	Any N	M1	I-III

close surgical margins (i.e., 1 to 3 mm) will require further local treatment because surgical margins may be adequate with a low-grade soft tissue sarcoma but not with a high-grade soft tissue sarcoma.^{121,122}

The first surgery provides the best opportunity for local tumor control as the management of incompletely resected tumors

increases patient morbidity and treatment costs, increases the risk of further local tumor recurrences, and decreases survival time.^{111,121,124-128} Traditionally, if a soft tissue sarcoma had been incompletely resected, then the surgical scar was managed with either a second aggressive surgery or RT because the entire surgical wound was considered contaminated and neoplastic.¹²¹ However,

• **FIGURE 21-7** Intraoperative image of a dog with a recurrent soft tissue sarcoma. The soft tissue sarcoma is being resected with 3-cm margins around the recurrent tumor and previous scar because both are considered contaminated. Deep margins are one fascial layer.

• **FIGURE 21-8** Following surgical resection, the lateral and deep margins should be inked (yellow ink was used in this case) to assist in identification of the margins histologically and pinned out on cardboard to prevent sample shrinkage during formalin fixation.

recent evidence suggests that this may not necessarily be true and a more conservative approach may be employed, particularly for low-grade soft tissue sarcomas. In one study, histologic evidence of residual tumor was identified in only 22% of 39 dogs with incompletely excised tumors.¹²⁹ Following excision of the surgical scar in these dogs with 0.5- to 3.5-cm margins, the local recurrence rate was 15%.¹²⁹ In a study of 104 canine soft tissue sarcomas managed with surgery alone in nonreferral practices, fewer than 10% were excised with 3-cm margins and local tumor recurrence was reported in 28% of dogs.¹³⁰ In a similar pathologic study, 75% of 139 canine subcutaneous soft tissue sarcomas were incompletely excised and the local tumor recurrence rate was significantly associated with histologic grade, with local tumor recurrence reported in only 7% of dogs with grade I soft tissue sarcomas compared to 34% and 75% of dogs with grade II and III tumors, respectively.¹³¹ This was further supported by another study in which 11% of 35 dogs with low-grade soft tissue sarcomas of the extremities (below the elbow and stifle) had local tumor recurrence following marginal excision.¹³² Thus, based on this evidence, dogs with incompletely excised soft tissue sarcomas, especially grade I and perhaps grade II tumors, can be managed with either active surveillance (i.e., frequent observation for local tumor recurrence and appropriate treatment if the tumor recurs) or a staging surgery. Staging surgery is a decision-making surgery. The surgical scar is excised with minimal margins (0.5 to 1.0 cm) with the aim being to determine if there is histologic evidence of residual tumor cells.¹²⁹ If there is no evidence of tumor cells, then no further treatment is required and these dogs should be monitored regularly for local tumor recurrence. If there is evidence of residual tumor cells, then wide resection of the surgical scar should be performed with the same margins recommended for primary soft tissue sarcomas, 3 cm lateral to the tumor and one fascial layer deep to the tumor,^{117,121,126,127} or the entire surgical scar should be irradiated.^{126,127} Surgery is preferred to RT for management of incompletely resected soft tissue sarcomas in humans because local tumor control is better with repeat surgical resection than adjunctive RT alone.^{126,127} Another option for the management of dogs with incompletely excised soft tissue sarcomas may include metronomic (i.e., low-dose continuous) chemotherapy. The administration of piroxicam and low-dose cyclophosphamide in 30 dogs with incompletely excised soft tissue sarcomas resulted in a significantly prolonged DFI when compared to a nonrandomized control group of 85 dogs with incompletely excised soft tissue sarcomas and no metronomic chemotherapy.¹³³ Additional studies are needed to confirm this treatment alternative.

Surgery and Radiation Therapy

RT can be used as an adjunct to surgery following either planned marginal resection or unplanned incomplete resection. Marginal surgical resection combined with full-course postoperative RT is an attractive alternative to limb amputation for extremity soft tissue sarcoma (Figure 21-9). This multimodality approach requires additional planning and expense but preserves the limb and limb function. Surgery involves completely removing all grossly visible tumor and then marking the lateral, proximal, and distal extents of the surgical field with radiopaque clips to assist in planning of RT. Migration of the radiopaque clips has been reported but does not significantly influence the planned radiation field.¹³⁴

RT should be started a minimum of 7 days postoperatively to minimize the risk of radiation-induced complications with the surgical wound, such as delayed healing and dehiscence.¹³⁵ Full-course fractionated protocols are recommended with reported schedules

including 3.0- to 4.2-Gy fractions on a Monday-to-Friday or Monday-Wednesday-Friday schedule for a total dose of 42 to 63 Gy.^{136,137} The optimal fractionation and total dose schemes for canine soft tissue sarcoma have not been determined, but cumulative doses greater than 50 Gy are recommended, and local tumor control is better with higher cumulative doses.¹³⁶ Acute side effects of RT such as moist desquamation are relatively mild and transient.¹³⁷

Local tumor control and survival time are excellent when incompletely resected soft tissue sarcomas are treated with postoperative RT. The median time to local recurrence is 700 days to more than 798 days, with local tumor recurrence reported in 5% to 30% of dogs by 1 year and 16% to 60% of dogs in the long term

• **FIGURE 21-9** Planned marginal resection of a soft tissue sarcoma in a dog. Marginal resection followed by full-course postoperative radiation therapy (RT) provides excellent local tumor control and preserves both the limb and limb function. RT should not involve the limb circumferentially to preserve both lymphatic and venous drainage of the distal extremity. If close but clean margins were obtained for a grade I soft tissue sarcoma, observation alone may be an acceptable alternative.

(Figure 21-10).^{111,136-140} The overall MST for incompletely resected nonoral soft tissue sarcomas treated with postoperative RT is 2270 days with 2-, 4-, and 5-year survival rates of 87%, 81%, and 76%, respectively (Figure 21-11).^{136,137}

Radiation Therapy

RT can be employed along with surgery in the treatment of soft tissue sarcomas with a curative intent, either preoperatively or postoperatively, or as a sole treatment for pain palliation. Radiotherapy alone as a single modality treatment using doses of 50 Gy resulted in 1-year tumor control rates of 50% that dropped to 33% at 2 years.¹⁴¹ Measurable and palpable (i.e., macroscopic) soft tissue sarcomas are resistant to long-term control with conventional doses of irradiation alone (40 to 48 Gy).^{142,143} Although one study reported a 30% complete response rate with RT alone,¹⁴⁴ these tumors do not rapidly regress after radiation, or if there is significant tumor shrinkage, it is not a durable response. As a single modality, RT is generally considered palliative with control defined as a slowly regressing or stable-in-size tumor mass. Palliative radiation, with 4 fractions of 8 Gy for a total dose of 32 Gy, has recently been investigated with similar results to full-course radiation with a 50% response rate in 16 dogs with measurable soft tissue sarcomas, median time to progression of 155 days, and a MST of 309 days.¹⁴⁵

Inadequate durable tumor control using RT as a single modality resulted in the development of combination therapies using RT with hyperthermia and surgery, yielding superior control rates.* Current results of therapeutic clinical studies in dogs demonstrate that RT is the best treatment for incompletely resected soft tissue sarcomas.^{15,136,137,149}

Although higher doses of irradiation will have higher control rates, the chances of normal tissue complications will also increase. In some studies, hyperthermia combined with irradiation showed promise for improved control versus irradiation alone and may also decrease the time to recurrence.^{144,146,147} The median duration of local control with RT plus hyperthermia is 750 days and significantly greater than the 350 days with RT alone. Difficulty in homogeneous heating of large tumors limits the routine use of

hyperthermia for treating soft tissue sarcoma in conjunction with radiation. Addition of whole-body hyperthermia does not improve response rate when compared to RT and local hyperthermia and may have increased the risk for metastasis.¹⁴⁸ The response rate and survival time in dogs treated with irradiation and hyperthermia may be predicted with dynamic contrast-enhanced MRI of soft tissue sarcomas before and after the first hyperthermia.¹⁵⁰

As mentioned previously, the combination of radiation and surgery provides long-term local control. Postoperative irradiation may be utilized if surgical removal is incomplete and further surgery is not feasible. Irradiation of microscopic tumors after excision is generally superior to radiation of measurable tumors. Control rates for adjuvant radiation after histologically incomplete resection of soft tissue sarcomas are 80% to 95% at 1 year and 72% to 91% at 2 years, with an expected 3-year and 5-year survival rate of 68% to 76%, respectively.^{136,137,151} Dogs with soft tissue sarcomas with a mitotic rate greater than 9/10 HPF were more likely to have local tumor recurrence and shorter survival times in one study of 39 dogs treated with orthovoltage and doxorubicin as a radiation sensitizer.¹⁵¹ Although not statistically significant, dogs with hemangiopericytoma had a 3-year survival rate of 92% in one retrospective study.¹³⁶

Preoperative RT is becoming commonplace in veterinary oncology. The rationale and advantage of administering RT prior to surgery are that (1) the radiation field is smaller because, after surgery, the entire surgical site must be included in the field and this may contribute to local toxicity; (2) a large number of peripheral tumor cells are inactivated (with reduced contamination of the surgical site); and (3) tumor reduction may make surgical resection less difficult.^{15,152-154} In a study of 112 human patients with soft tissue sarcomas, it was noted that there was no significant difference between preoperative or postoperative radiotherapy in terms of relapse-free survival, local control, or overall survival. However, wound complications were significantly more frequent in preoperative radiotherapy patients.¹⁵⁴ A subsequent review supported these findings.¹⁵⁵ Lower doses of preoperative radiotherapy (less than 50 Gy) are used to reduce the risk of surgical complications. The

therapeutic goal of preoperative radiotherapy is to eradicate the microscopic tumor cells at the peripheral margins. Generally, preoperative radiotherapy is reserved for initially inoperable tumors as an alternative to radical surgery.

Chemotherapy

The role of chemotherapy in the management of dogs with soft tissue sarcoma is not yet known. The metastatic rate for cutaneous soft tissue sarcoma is grade dependent and varies from less than 15% for grade I and II soft tissue sarcoma to 41% for grade III soft tissue sarcoma.¹⁶ Metastasis often occurs late in the course of disease, with a median time to metastasis of 365 days,¹⁶ and this may minimize the beneficial effects of postoperative chemotherapy on the development of metastatic disease. However, there are clinical situations in which postoperative chemotherapy should be considered, including dogs with grade III soft tissue sarcoma, metastatic disease, intraabdominal soft tissue sarcoma (e.g., leiomyosarcoma and splenic sarcoma), and histologic subtypes with a higher rate of metastasis, such as histiocytic sarcomas, hypodermal HSAs (stage II or III), synovial cell sarcomas, rhabdomyosarcomas, and lymphangiosarcomas.^{24,88,156-159}

Doxorubicin-based protocols, either alone or in combination with cyclophosphamide, have shown the most promise in dogs with soft tissue sarcoma with an overall response rate of 23%.¹⁶⁰ The need to combine cyclophosphamide with doxorubicin is debatable because single-agent doxorubicin has been shown to be equally as effective in the management of dogs with HSAs as doxorubicin combined with either cyclophosphamide or cyclophosphamide and vincristine.¹⁶¹ Mitoxantrone, a chemotherapeutic drug related to doxorubicin, has a variable effect against soft tissue sarcomas in dogs, with the response rate varying from 0% in 6 dogs to 33% in 12 dogs.^{162,163} Ifosfamide has also shown some potential with a complete response rate of 15% (2 dogs) in 13 dogs with solid sarcomas of the skin, bladder, and spleen.¹⁶⁴ Doxorubicin and ifosfamide are the most effective single agents in the management of soft tissue sarcoma in humans, but response rates are less than 30% and metaanalyses show single- and multiple-agent chemotherapy

protocols do not significantly increase overall survival times compared to surgery alone.^{165,166} A similar finding of no improvement in survival times has been reported in dogs with grade III soft tissue sarcomas treated with surgery alone compared to those treated with surgery and adjuvant doxorubicin.¹⁶⁷

Postoperative systemic chemotherapy has also been shown to significantly improve disease-free survival times, but not overall survival time, in humans with soft tissue sarcomas, regardless of histologic grade.^{165,166} Adjuvant chemotherapy has not shown the same effect on local tumor control in dogs with soft tissue sarcomas,¹⁶⁷ but metronomic and local chemotherapy protocols may be effective in decreasing the rate of local tumor recurrence and improving DFI in dogs with soft tissue sarcomas. Metronomic chemotherapy with piroxicam and low-dose cyclophosphamide significantly prolongs DFI in a small group of dogs with incompletely excised soft tissue sarcomas.¹³³ Local release of cisplatin from a biodegradable polymer implanted into the surgical bed of incompletely resected soft tissue sarcomas may also decrease the risk of local tumor recurrence, with a 31% rate of local tumor recurrence in 32 dogs at a median of greater than 640 days postoperatively.¹⁶⁸

Prognosis

The prognosis for dogs with soft tissue sarcoma is good. Local tumor control is often the most challenging aspect of managing soft tissue sarcomas.^{16,110} Local tumor recurrence rates following either surgery alone or surgery and RT varies from 7% to 32%.^{110,111,138,167,169} Poor prognostic factors for local tumor control include large tumor size, incomplete surgical margins, and high histologic tumor grade.¹⁶ In one study of 75 dogs, the local tumor recurrence rate following incomplete resection was 28% and 11 times more likely than soft tissue sarcomas resected with complete margins (Figure 21-12).¹⁶ Tumor size has been reported to have a negative effect on

local tumor control¹⁶ but probably influences the ability to achieve complete resection rather than having a direct effect on local tumor recurrence. Furthermore, tumor size has not been identified as a prognostic factor in other studies^{110,138,169} and does not influence local tumor control in dogs treated with surgery and adjuvant RT or RT alone.^{141,146,169,170} Management of recurrent soft tissue sarcomas is usually more difficult than management of primary tumors, which emphasizes the need for an aggressive approach initially. Curative-intent treatment of recurrent soft tissue sarcomas often requires a more aggressive approach, resulting in increased treatment-related morbidity, whereas the DFI is shorter, the metastatic rate higher, and survival times are decreased in comparison to dogs with naïve tumors.^{110,121,124-128} Local tumor recurrence is still possible after either complete resection or incomplete resection combined with adjunctive RT.^{16,136,137} Consequently, examination of the treatment site is recommended at regular intervals, such as monthly for the first 3 months, then every 3 months for the first 12 months, and then every 6 months thereafter.¹²¹ The median time to local tumor recurrence was 368 days in one report of 75 dogs with soft tissue sarcomas, which emphasizes the need for long-term follow-up in these cases.¹⁶

The overall metastatic rate in dogs with soft tissue sarcoma varies from 8% to 17% with a median time to metastasis of 365 days.^{16,136,137} Factors that increase the risk of metastatic disease include histologic grade, number of mitotic figures, percentage of tumor necrosis, and local tumor recurrence. As mentioned previously, the metastatic rate for dogs with grade I or II soft tissue sarcomas is less than 15% compared to 41% to 44% for grade III soft tissue sarcomas.^{16,167} Metastasis is 5 times more likely when tumors have a mitotic rate of 20 or more mitotic figures/10 HPF compared to fewer than 20 mitotic figures/10 HPF.¹⁶

The MST for dogs with soft tissue sarcoma ranges from 1416 days following surgery alone to 2270 days with surgery and adjunctive RT.^{16,136,137} Overall, up to 33% of dogs eventually die of

tumor-related causes.¹⁶ Tumor-related deaths in dogs with soft tissue sarcoma is 2.8 times more likely with greater than 10% tumor necrosis and 2.6 times more likely with a mitotic rate of 20 or more mitotic figures/10 HPF.¹⁶ The MSTs for dogs with 10 or fewer, 10 to 19, and 20 or more mitotic figures/10 HPF is 1444 days, 532 days, and 236 days, respectively (Figure 21-13).¹⁶ The prognosis for specific subtypes of soft tissue sarcoma are discussed separately earlier in this chapter in the section on specific tumor types.

Feline Sarcomas and Vaccine-Associated Sarcomas

Epidemiology and Risk Factors

The following events are linked to the development of postvaccinal sarcomas in the cat. The prevalence of feline rabies led to the enactment of a law requiring rabies vaccinations for cats in Pennsylvania in 1987.¹⁷¹ In addition, two changes in vaccines occurred in the mid-1980s: development of a killed rabies vaccine licensed for subcutaneous administration and a killed vaccine for feline leukemia virus (FeLV). Two pathologists, M. J. Hendrick and M. H. Goldschmidt, and their colleagues at the University of Pennsylvania School of Veterinary Medicine were the first to recognize the increased incidence of reactions and formation of sarcomas at sites of rabies vaccinations.¹⁷²⁻¹⁷⁴ Epidemiologic studies have shown a strong association between the administration of inactivated feline vaccines, such as FeLV and rabies, and subsequent development of soft tissue sarcoma at vaccine sites.¹⁷²⁻¹⁷⁶ Additionally, some authors report reaction to vaccines was additive and this increased the likelihood of sarcoma development with multiple vaccines given at the same site simultaneously.¹⁷⁵ The development of soft tissue sarcoma at sites of vaccine administration of FeLV or rabies is believed by some to be as high as 1/1000,^{177,178} whereas others report a prevalence between 1 and 3.6/10,000 cases.^{176,179,180}

The time to tumor development postvaccination has been reported to be 4 weeks to 10 years and is associated with a robust

inflammatory reaction around the tumor.¹⁷⁶ Adjuvant-containing vaccines have been proposed to be more likely to cause a vaccine site reaction and/or develop into a soft tissue sarcoma.¹⁷⁶ However, two large epidemiologic studies did not provide evidence that aluminum-containing vaccines pose a greater risk.^{165,182} Thus it remains unclear whether nonadjuvant vaccines are safer. A multicenter study of cats in the United States and Canada found that no single vaccine manufacturer or vaccine type had a higher or lower association with the development of soft tissue sarcoma.¹⁸² Additionally, vaccine practices such as needle gauge, syringe reuse, use and shaking of multidose vials, mixing vaccines in a single syringe, and syringe type had no role in the development of tumors.¹⁸²

The hypothesis that postvaccination inflammatory reactions lead to uncontrolled fibroblast and myofibroblast proliferation and eventual tumor formation either alone or along with immunologic factors is a popular theory.¹⁸³⁻¹⁸⁸ The thought that inflammation precedes tumor development is supported by histologic identification of transition zones from inflammation to sarcoma and microscopic foci of sarcoma located in areas of granulomatous inflammation. A similar phenomenon of intraocular sarcoma development exists in cats after trauma or chronic uveitis.¹⁸⁹⁻¹⁹¹

Growth factors regulate the cellular events involved in granulation tissue formation and wound healing. When these factors are added to fibroblast cultures, the cells develop a neoplastic phenotype. Immunohistochemical identification and localization of growth factors and their receptors are being investigated in vaccine-associated sarcomas. Through immunohistochemical study of growth factors and their receptors, Hendrick has found that vaccine-associated sarcomas are immunoreactive for platelet-derived growth factor (PDGF), epidermal growth factor (EGF) and its receptors, and transforming growth factor- β (TGF- β). Conversely, non-injection-site fibrosarcomas are negative or faintly positive.^{192,193} Hendrick also found that lymphocytes in vaccine-associated sarcomas are positive for PDGF, but lymphocytes in non-injection-site fibrosarcomas and normal lymph nodes are

negative.¹⁹² Regional macrophages also stain positively for PDGF receptor (PDGFR). Neoplastic cells that are closest to lymphocytes in these tumors have the strongest staining for PDGFR, which has led to a hypothesis that lymphocytes in vaccine-associated sarcomas may secrete PDGF, recruit macrophages, and lead to fibroblast proliferation.^{192,193} The expression of *C-jun*, a proto-oncogene coding for the transcriptional protein AP-1, has also been examined in vaccine-associated sarcomas. *C-jun* was found to be strongly positive in vaccine-associated sarcomas and not expressed in non-injection-site fibrosarcomas.^{192,193} It appears that FeLV and the feline sarcoma virus are not involved in the pathogenesis of feline vaccine-associated sarcomas. Using immunohistochemical analysis and polymerase chain reaction (PCR) techniques, FeLV was not detected in vaccine-associated sarcomas.¹⁹⁴

p53 mutations have been evaluated in feline vaccine-associated sarcomas.¹⁹⁵⁻¹⁹⁸ *p53* is a tumor suppressor gene that encodes a nuclear protein critical in the regulation of the cell cycle. Normal or wild-type *p53* will increase in response to DNA damage resulting in cell arrest at the G1 interphase, allowing for DNA repair before replication or apoptosis if damage is irreparable. Cells lacking normal *p53* proceed through the cell cycle unregulated, leading to aberrant clones and possible malignancy.¹⁸⁶ Anti-*p53* antibodies have immunoreactivity in feline sarcomas and may play a role in predicting clinical outcome.¹⁹⁸

Recent papers continue to link growth factors with development of vaccine-associated sarcomas in cats. Continued immunohistochemical probing of feline vaccine-associated sarcomas document expression of growth-regulating proteins: *p53* protein, basic fibroblast growth factor β (bFGF- β), and TGF- α .¹⁹⁸ Researchers recently concluded that PDGF and its receptor play an important role in the in vitro growth of vaccine-associated sarcoma cell lines, both alone and in the presence of chemotherapeutic agents. Furthermore, they found that a signal transduction inhibitor, imatinib mesylate, inhibits the PDGF-dependent cell growth in a dose-dependent manner.¹⁹⁹

The term *vaccine-associated sarcoma* has been used interchangeably with injection-site sarcoma because sarcomas arising at sites of injections other than vaccines, such as lufenuron and microchips, have been reported.²⁰⁰⁻²⁰² Vaccine-associated sarcoma has been used in this chapter because of the overwhelming prevalence of vaccines as a cause of these injection-site sarcomas.

Pathology

There are many similarities between the histologic subtypes and biologic behavior of soft tissue sarcomas in cats and dogs. The three principal exceptions in cats are vaccine-associated sarcomas, virally induced multicentric fibrosarcoma, and the relative rarity of PNST, synovial cell sarcoma, and histiocytic sarcoma.^{188,203} There are significant differences between vaccine-associated sarcoma and non-vaccine-associated sarcoma. Tumors that develop after vaccination are typically mesenchymal in origin and include fibrosarcomas, rhabdomyosarcomas, malignant fibrous histiocytomas, undifferentiated sarcomas, and extraskeletal osteosarcomas and chondrosarcomas.^{192,204,205} Vaccine-associated sarcomas have histologic features consistent with a more aggressive biologic behavior than non-vaccine-associated sarcomas, such as marked nuclear and cellular pleomorphism, increased tumor necrosis, high mitotic activity, and the presence of a peripheral inflammatory cell infiltrate consisting of lymphocytes and macrophages.^{187,192,206} In a series of 91 cats with histologically confirmed and graded vaccine-associated sarcomas, the prevalence of high-grade lesions was substantially higher than reported in dogs,¹⁶ with 59% of cats diagnosed with grade III tumors and only 5% with grade I tumors.²⁰⁷ Microscopically, areas

• **FIGURE 21-14** Contrast-enhanced magnetic resonance imaging (MRI) of a cat with a vaccine-associated sarcoma. Note the fingerlike projections of the tumor (arrows).

of transition between inflammation and tumor development are frequently observed in cats with vaccine-associated sarcoma.^{161,192,208} The macrophages in these peripheral inflammatory cell infiltrates often contain a bluish-gray foreign material that has been identified as aluminum and oxygen by electron probe x-ray microanalysis.¹⁸⁸ Aluminum hydroxide is one of several adjuvants used in currently available feline vaccines.¹⁸⁸ Injection-site sarcomas are histologically similar to mesenchymal tumors arising in the traumatized eyes of cats, which suggests a common pathogenesis of inflammation and the development of soft tissue sarcomas in these cats.¹⁹⁰⁻¹⁹³ The presence of inflammatory cells, fibroblasts, and myofibroblasts in and adjacent to vaccine-associated sarcomas supports this hypothesis.^{24,209,210}

Diagnosis and Work-Up

The diagnostic techniques and clinical staging tests recommended for cats with suspected vaccine-associated sarcoma are similar to those described in dogs earlier in this chapter. Advanced imaging such as contrast-enhanced CT or MRI is recommended for local staging of the tumor because these 3D-imaging modalities provide essential information for proper planning of surgery and/or RT (Figure 21-14).¹⁸⁸ The volume of tumor based on contrast-enhanced CT is approximately twice the volume measured using calipers during physical examination.¹⁸⁵ Accurate pretreatment knowledge of the extent of disease is important because vaccine-associated sarcomas are very invasive, are frequently located in areas in which regional anatomy can complicate an aggressive surgical approach (e.g., interscapular area, body wall, and proximal pelvic limb), and have a high rate of local tumor recurrence, especially if incompletely resected. Excisional biopsy of a suspected vaccine-associated sarcoma is not recommended because the risk of local tumor recurrence is increased, and DFI and survival time are significantly decreased.^{211,212}

Treatment

The Vaccine-Associated Feline Sarcoma Task Force has recommended that masses at vaccination sites be treated if the mass is still evident 3 or more months after vaccination, is larger than 2 cm in diameter, or is increasing in size more than 4 weeks after vaccine administration.¹⁸⁸ Vaccine-associated sarcomas are very invasive tumors, and aggressive treatment is required, with both wide

• **FIGURE 21-15** Kaplan-Meier curve for time to first local tumor recurrence in 47 cats with vaccine-associated sarcomas treated by referring veterinarians (squares) compared to 14 cats treated at referral institutions (triangles). (Reprinted with permission from Hershey AE, Sorenmo KU, Hendrick MJ, et al: *Prognosis for presumed feline vaccine-associated sarcoma after excision: 61 cases (1986-1996)*, J Am Vet Med Assoc 216:58, 2000.)

surgical resection and full-course RT, to achieve adequate local control.

Surgery

Vaccine-associated sarcomas are poorly encapsulated tumors with extension and infiltration along fascial planes.^{213,214} The Vaccine-Associated Feline Sarcoma Task Force has recommended surgical resection with a minimum of 2-cm margins both lateral and deep to the tumor.¹⁸⁸ Marginal resection or excisional biopsy should not be attempted. The median DFI and survival time are significantly decreased with marginal resection, with an increased number of surgical interventions, and if surgery is performed by nonreferral surgeons (Figure 21-15).^{205,211,212} The median time to first recurrence following marginal resection is 79 days compared to 325 to 419 days for wide resection or radical surgery.²¹² In addition, the median time to first recurrence is only 66 days when the first surgery is performed at a nonreferral institution compared to 274 days at referral institutions.²¹¹ Inadequate biopsy planning, preoperative staging, and/or attempts at first surgery will result in an increase in tumor margins and may make further surgical treatment impossible. The first attempt at surgical management of cats with vaccine-associated sarcomas should be performed by a referral surgeon with experience in aggressive resection, especially in the interscapular and pelvic regions, to increase the chance of a successful outcome.¹⁸⁵

Similar to dogs with soft tissue sarcomas, biopsy tracts and any areas of fixation, including bone and fascia, should be resected en bloc with the tumor. In cats with vaccine-associated sarcomas, wide surgical resection of tumors located in the interscapular region will often involve excision of dorsal spinous processes and perhaps the dorsal aspect of the scapula (Figure 21-16), whereas thoracic or body wall resection is often required for truncal tumors.^{211,212} Limb amputation or hemipelvectomy is usually required to achieve adequate surgical margins and local tumor control for vaccine-associated sarcomas located on the extremity.

Local tumor control is still disappointing with curative-intent surgery. Despite attempting aggressive surgery with 2- to 3-cm lateral margins and one fascial layer for deep margins, complete

• **FIGURE 21-16** Aggressive resection of vaccine-associated sarcomas is required for prolonged local tumor control. In this cat, the vaccine-associated sarcoma was resected with 5-cm margins, including the dorsal spinous processes (D). The scapulae (S) were spared because the tumor could be resected with two fascial planes without involving the scapula.

resection is achieved in less than 50% of cats.^{211,212} Furthermore, overall 1- and 2-year disease-free rates are only 35% and 9%, respectively.²¹¹ Median DFI and survival time are both greater than 16 months following complete histologic resection and significantly better than incompletely resected tumors. Local tumor control is improved for extremity vaccine-associated sarcomas, presumably because the lateral and deep surgical margins achieved with limb amputation are superior to other locations.²¹¹ However, aggressive surgery is possible in other locations with good results. Chest wall and body resection, using a minimum of 3-cm margins, was well tolerated in six cats and local tumor recurrence was not reported in any of these cats at a minimum of 12 months postoperatively.²¹⁵

A more aggressive surgical approach is recommended because of the low rate of complete resection and subsequent poor local tumor control, with surgical excision using 2 to 3 cm. This recommendation is based on a study of 91 cats with vaccine-associated sarcoma in various locations, including interscapular, trunk, and extremity, treated with surgery alone using 5-cm lateral margins and two fascial planes for deep margins.²⁰⁷ Major surgical complications were reported in 11% of cats. Wound dehiscence following excision of interscapular tumors was the most common complication.²⁰⁷ Complete histologic resection was achieved in 97% of cats and local tumor recurrence was reported in only 14% of cats.²⁰⁷ These findings are supported by an earlier study of 57 cats treated with 4- to 5-cm lateral margins and one fascial layer for deep margins in which complete histologic excision was achieved in 95% of cats.²¹⁶ These results suggest that extrapolation from the surgical management of canine soft tissue sarcomas and the recommendations of the Vaccine-Associated Feline Sarcoma Task Force are inadequate for the surgical treatment of feline vaccine-associated sarcomas and better rates of complete surgical resection and local tumor control can be achieved using a more aggressive surgical approach.

Surgery and Radiation Therapy

As a result of the high rate of local tumor recurrence following wide surgical resection with 3-cm margins, full-course RT is highly

recommended in the management of cats with vaccine-associated sarcoma.^{205,217-220} The timing of surgery and RT is controversial. The advantages of preoperative radiation include greater antitumor effect because of a smaller population of resistant hypoxic cells as blood supply to the tumor is not disturbed; a smaller radiation field because, after surgery, the entire surgical site must be included in the field; reduction in tumor size, which facilitates surgical resection; and decreased risk of disseminating tumor cells during surgery.¹⁵³ The principal disadvantage of preoperative RT is the increased risk of surgical complications, such as wound dehiscence.¹⁵³ Postoperative RT may provide better tumor control because RT is more effective against microscopic disease than gross tumor and does not delay definitive surgery.¹⁵³ However, surgery increases the size of the radiation field and the population of radio-resistant hypoxic tumor cells by altering the local blood supply, and there is a risk of tumor cells repopulating in the interval between surgery and the start of RT.^{153,205}

In two studies investigating preoperative RT, local tumor recurrence was reported in 40% to 45% of cats at a median of 398 to 584 days postoperatively.^{217,219} In both studies, complete resection significantly improved the time to local recurrence, with a 700- to 986-day median DFI for completely excised tumors and 112- to 292-day median DFI for tumors resected with incomplete margins. However, despite the prolonged interval to local tumor recurrence, complete resection following preoperative RT does not appear to improve local control rates because local tumor recurrence was reported in 42% of 59 cats with complete margins and 32% of 33 cats with incomplete margins.²¹⁹

The outcome following postoperative RT is similar to preoperative RT. In one study, local tumor recurrence was reported in 41% of 76 cats at a median of 405 days postoperatively.²¹⁷ In another study investigating the effects of chemotherapy in cats treated with surgery and postoperative RT, local tumor recurrence occurred in 28% of 25 cats with a median time to first recurrence not reached in cats treated with surgery and RT alone and 661 days in cats also treated with doxorubicin.²¹⁸ In a recent study of 46 cats treated with surgery and curative-intent postoperative RT, the median progression-free interval (PFI) was 37 months with 1- and 2-year progression-free rates of 63% and 60%, respectively.²¹⁹ In comparison, 27 cats treated with postoperative palliative coarse fractionation protocols had a median PFI of 10 months and a MST of 24 months.²¹⁹ Importantly, RT should start 10 to 14 days postoperatively as DFI and survival time decreases as the interval between surgery and starting RT increases.²⁰⁵ Local tumor recurrence does not influence survival time and, regardless of the timing of RT relative to surgery, survival data are encouraging with MSTs of 600 to 1300 days and 1-, 2-, and 3-year survival rates of 86%, 44% to 71%, and 28% to 68%, respectively.^{205,217,218,220}

Local tumor control is still disappointing with 28% to 45% of tumors recurring after multimodality treatment with surgery and RT.^{205,217-220} The radiation field used in these studies typically included a minimum of 3-cm margins around the tumor or surgical scar. The majority of tumors recur within the radiation field, although tumors have been reported to recur outside the radiation field.²¹⁸ Similar to surgery alone, a more aggressive approach may be warranted to improve local tumor control, such as higher radiation doses, larger radiation fields, and more aggressive surgical resections.

Radiation Therapy

Although RT alone is rarely effective for the management of cats and dogs with measurable soft tissue sarcomas, RT may have a role

in the palliative setting for cats with large and unresectable vaccine-associated sarcomas. In a pilot study of 10 cats with vaccine-associated sarcomas, 7 cats achieved partial responses and 2 cats had complete responses following treatment with liposomal doxorubicin as a radiation sensitizer and irradiation with a median of 5 fractions of 4 Gy for a total dose of 20 Gy; however, PFIs were not durable (median of 117 days).²²¹

Chemotherapy

The role of chemotherapy in the management of cats with vaccine-associated sarcoma remains undefined. Metastasis has been reported in 0% to 26% of cats with vaccine-associated sarcomas, despite the aggressive histologic appearance and prevalence of high-grade lesions in these tumors, with a median time to metastasis of 265 to 309 days.* Injection-site sarcoma cell lines have shown *in vitro* sensitivity at clinically relevant doses to doxorubicin, mitoxantrone, vincristine, and paclitaxel.^{222,223} Clinically, partial and complete responses to doxorubicin, either alone or in combination with cyclophosphamide, have been reported in 39% to 50% of cats with gross tumors, but these responses are often short-lived with a median duration of 84 to 125 days.^{224,225} However, MSTs are significantly prolonged in cats that respond to chemotherapy with 242 days for responders and 83 days for nonresponders.²²⁴ Furthermore, MSTs are significantly increased for cats with gross residual disease following surgical excision and treated with postoperative RT and chemotherapy with a MST of 29 months compared to 5 months for cats treated with surgery and postoperative RT.²²⁰

Postoperative chemotherapy has minimal impact on survival in cats treated with curative-intent surgery and RT.^{207,216-218,225} Chemotherapy may, however, have beneficial effects on local tumor control and time to local tumor recurrence. Doxorubicin and liposome-encapsulated doxorubicin significantly prolong the DFI following surgery, with a median DFI of 393 days for cats receiving chemotherapy and 93 days for those in which chemotherapy was not administered (Figure 21-17).²²⁵ The completeness of surgical margins may be a confounding factor in this analysis because the median DFI was greater than 449 days in cats with complete surgical margins compared to 281 days following incomplete resection.²²⁵ Carboplatin was associated with an insignificant but numerically superior median DFI of greater than 986 days in cats treated with preoperative RT and surgery.²¹⁹ Other studies have shown no effect of adjunctive chemotherapy on either local tumor control or survival time.^{217,218}

Novel treatments such as electrochemotherapy and immunotherapy are also being investigated with some encouraging results. In one study, cats with high-grade soft tissue sarcomas were treated either intraoperatively or postoperatively with intratumoral bleomycin followed by 8 biphasic pulses of up to 1300 V/cm.²²⁶ The median time to local tumor recurrence in the control (surgery only) group was 4 months compared to 12 months for cats treated intraoperatively and 19 months for cats treated postoperatively. Of further interest, the metastatic rate was only 1.7%.²²⁶

Immunotherapy, using recombinant viruses expressing interleukin-2 (IL-2), has shown some promise in improving local tumor control rates in cats with vaccine-associated sarcomas. Following surgical resection and iridium-based RT, the 1-year local tumor recurrence rate was 61% in cats receiving no adjunctive treatment, 39% in cats administered human IL-2 using a vaccinia virus vector, and 28% with feline IL-2 using a canary pox virus vector.²²⁷ In a phase I trial, two doses of intratumoral feline IL-2,

• **FIGURE 21-17** Kaplan-Meier curve for disease-free interval (DFI) in 75 cats with vaccine-associated sarcomas treated with surgery and postoperative chemotherapy (liposome-encapsulated doxorubicin or doxorubicin) or surgery alone (historic control). (Reprinted with permission from Poirier VJ, Thamm DH, Kurzman ID, et al: *Liposome-encapsulated doxorubicin (Doxil) and doxorubicin in the treatment of vaccine-associated sarcomas in cats*, J Vet Intern Med 16:726, 2002.)

interferon γ (IFN- γ), and granulocyte-macrophage colony-stimulating factor (GM-CSF) followed by magnetofection prior to surgical resection resulted in a 1-year local recurrence rate of 24%.²²⁸ In another phase I trial by the same research group, 2 doses of intratumoral GM-CSF followed by magnetofection prior to surgical resection resulted in a 1-year local recurrence rate of 50% and minimal treatment-related toxicities.²²⁹ Other immunotherapeutic agents such as IL-12 and acemannan have been investigated with less favorable results.²³⁰⁻²³²

Prognosis

It has become clear that the prognosis for cats with vaccine-associated sarcomas treated with surgical excision alone, using traditional recommendations, can be poor with respect to tumor control, especially when the first surgery is marginal and multiple surgeries are employed as the method of treatment. However, long-term survival, even in the face of multiple recurrences, is the norm with this disease. The median time to first recurrence was 2 months for cats treated by conservative surgery (referring veterinarian) and 9 months for those cats treated by more aggressive surgery (referral institution); the overall survival time was 19 months.²¹² Another study of single modality surgical excision reported an overall DFI of 10 months, which increased to longer than 16 months when excision was complete.²¹¹ The prognosis with surgery alone is improved with aggressive surgical excision using 5-cm lateral margins and two fascial layers for deep margins.²⁰⁷ A recent study looked at 3D histologic margins in 48 cats with vaccine-associated sarcomas and evaluated the predictive value of histologic margins and tumor grading on local recurrence.²³³ Tumor margins were noninfiltrated in 32 cats and the remaining 16 cases had infiltrated margins. Overall, 6/32 (19%) tumors with noninfiltrated margins and 11/16 (69%) with infiltrated margins had tumor recurrence. Tumors with infiltrated margins recurred about 10 times more frequently compared to tumors with noninfiltrated margins.²³³ The degree of infiltration of tumor margins may provide an indication for the need for adjuvant RT following surgical excision.

Outcomes are improved when cats with vaccine-associated sarcomas are treated with multimodality therapy, especially following surgical excision with less aggressive intent. Optimal outcome occurs when cats are treated aggressively initially and not after multiple failed resections.²²⁰ The combination of radiotherapy either preoperatively or postoperatively has improved the DFI and overall survival time in cats with vaccine-associated sarcomas. DFI and MSTs range from 13 to 37 months and 23 to 43 months, respectively.^{205,215-218} Injection-site sarcomas are locally invasive; however, approximately 15% to 24% will metastasize to the lungs or other sites.^{207,208,212,216,217} Continued research into the treatment of vaccine-associated sarcomas is needed because there is room for improvement in outcomes.

Prognostic factors were investigated in one study of 42 cats with surgically resected nonvisceral soft tissue sarcomas, including 8 cats with presumed vaccine-associated sarcomas.²³⁴ The overall MST was 608 days. The margins of excision lateral and deep to the tumor were not reported, but excision was incomplete in 74% of cats and local tumor recurrence was reported in 62% of cats. The median time to recurrence was 261 days and the MST in cats with local tumor recurrence was 576 days. Metastasis was suspected in 14% of cats and the MST in cats with suspected metastasis was 562 days. Prognostic factors included tumor size and histologic type. Cats with soft tissue sarcomas smaller than 2 cm in diameter had a MST of 643 days, which was significantly longer than the 558 days for cats with tumors 2 to 5 cm in diameter and 394 days for cats with soft tissue sarcomas larger than 5 cm in diameter. The MSTs for cats with fibrosarcoma (640 days) and PNST (645 days) were significantly better than for cats with malignant fibrous histiocytoma (290 days). Tumor location and injection-site versus non-injection-site sarcomas were not prognostic factors in this study.²³⁴ Although these results are encouraging, the rates of incomplete excision and local tumor recurrence suggest that a more aggressive surgical approach and multimodal therapy with adjuvant RT should also be considered for cats with non-vaccine-associated sarcomas.

In two studies, one with 57 cats with vaccine-associated sarcomas treated primarily with wide surgical excision (4- to 5-cm lateral margins and one fascial layer for deep margins)²¹⁶ and the other with 91 cats treated with aggressive surgery alone (5-cm lateral margins and two fascial layers for deep margins),²⁰⁷ prognostic factors for survival included histologic grade, local tumor recurrence, and distant metastasis. Local tumor recurrence was reported in 39% of the cats and was not associated with tumor diameter, tumor location, or histologic grade.²¹⁶ The MST for cats with local tumor recurrence was 365 to 499 days compared to 1098 to 1461 days for cats without local tumor recurrence.^{207,216} The MST for cats without distant metastasis was 929 to 1528 days compared to 165 to 388 days for the 20% to 21% of cats that developed distant metastasis.^{207,216} Furthermore, distant metastasis was more likely in cats with grade III sarcomas, suggesting that chemotherapy should be considered for cats with high-grade vaccine-associated sarcomas.²¹⁶

Prevention

The recommendations on preventing vaccine-associated sarcomas in cats are controversial. These include changing the sites of vaccine administration, decreasing the use of polyvalent vaccines, using nonadjuvanted vaccines, avoiding the use of aluminum-based adjuvants, and increasing the interval between vaccinations.^{24,178,235,236}

The Vaccine-Associated Feline Sarcoma Task Force has recommended that no vaccine be administered in the interscapular region, rabies vaccines be administered in the distal aspect of the right pelvic limb, FeLV vaccines be administered in the distal aspect of the left pelvic limb, and all other vaccines be administered in the right shoulder.²⁴ The location of each injection, the type of vaccine, and the manufacturer and serial number of the vaccine should be documented in the patient records. These recommendations are intended to provide epidemiologic information rather than prevent vaccine-associated sarcomas. Vaccines should be administered into the distal, rather than mid to proximal, aspects of the limb to aid in earlier detection and increase the chance of achieving complete resection. Subcutaneous and intramuscular administration can both cause local inflammatory reactions and result in the development of vaccine-associated sarcomas.²⁴ Subcutaneous administration is preferred to intramuscular injection because vaccine-associated sarcomas developing from subcutaneous sites are more readily palpable and diagnosed earlier in the course of disease. The Vaccine-Associated Feline Sarcoma Task Force has recommended that masses at vaccination sites be treated if the mass is evident 3 or more months after vaccination, is larger than 2 cm in diameter, or is increasing in size more than 4 weeks after vaccine administration.¹⁸⁵ Unfortunately, feline vaccine-associated sarcomas are still occurring at sites not recommended by the Vaccine-Associated Feline Sarcoma Task Force and are often difficult to cure with surgery and RT.²³⁷

Traditionally, annual boosters have been recommended for most vaccines in cats. The U.S. Department of Agriculture–Animal Plant Health Inspection Service (USDA-APHIS) does not require duration of immunity studies for licensing of vaccines. However, if a duration of immunity study has not been performed, the USDA-APHIS requires that vaccine labels include a recommendation for annual revaccination.¹⁸⁸ Recently, vaccine practices have been questioned by the profession and this has been supported by duration of immunity studies. The duration of immunity for a single commercially available inactivated, adjuvanted combination of feline panleukopenia, herpesvirus, and calicivirus is greater than 7 years with persistent antibodies against all three viruses for more than 3

years.^{238,239} Local and state requirements often mandate annual rabies boosters, despite a duration of immunity of at least 3 years, because of the significant public health concern of rabies infection.¹⁸⁸ The Vaccine-Associated Feline Sarcoma Task Force has recommended that the administration of vaccines is a medicinal procedure and vaccination protocols should be customized for individual cats.¹⁸⁸ A vaccine should not be administered until the medical importance and zoonotic potential of the infectious agent, risk of exposure, and legal requirements have been considered and balanced against the risk of vaccine-associated sarcomas and other adverse effects.¹⁸⁸

Comparative Aspects

In general, soft tissue sarcomas have a similar pathologic appearance, clinical presentation, and behavior in humans and animals. However, a higher incidence is seen in young people as opposed to young companion animals, with the exception of rhabdomyosarcoma, which is seen in young dogs. The distribution of soft tissue sarcoma in humans is similar to animals. In humans, 43% are in the extremities, with two-thirds occurring in the lower limb, and 34% are intraperitoneal, with 19% visceral in origin and 15% retroperitoneal. Soft tissue sarcomas of the trunk occur in 10% of human patients, and the remaining 13% occur at other sites. Metastasis is generally hematogenous and appears to be more common in human soft tissue sarcoma than in dogs, which may partially be explained by the higher numbers of nerve sheath tumors (with lower metastatic rate) seen in the dog.

Most sarcomas recognized in humans are also diagnosed in animals, although the specific incidences may vary markedly. There are many more histologic subtypes recognized in humans, which are often site dependent. With the exception of benign smooth muscle tumors and subcutaneous lipomas, there is little evidence that these lesions arise from their mature (differentiated) tissue counterparts. One current theory is that switching on a set of genes that programs mesenchymal differentiation in any mesenchymal cell may give rise to any type of mesenchymal tumor. Common subtypes of soft tissue sarcomas seen in the extremities of humans are liposarcomas, malignant fibrous histiosarcomas, synovial cell sarcomas, and fibrosarcomas. In the retroperitoneal location, liposarcomas and leiomyosarcomas are the most common histotypes noted in humans. The most common subtype noted visceroally are GISTs. Overall, leiomyosarcoma is the most common genitourinary sarcoma. Ten percent to 15% of all sarcomas occur in children, and the subtypes most commonly represented are rhabdomyosarcomas, Ewing's sarcoma, and primitive neuroectodermal tumors.

Prognostic variables in humans include clinical stage, histologic grade, necrosis, site, size, lymph node involvement, and aggressiveness of surgery or radiation. The histopathologic grading system used and shown to be predictive for metastasis in dogs is a grading system adopted from human pathology that is also predictive for survival.²⁴ Additionally, it appears that histologic grade is the predominant predictor of early recurrence, whereas tumor size plays a more important role for late recurrence. It is unclear whether age plays a prognostic role in human soft tissue sarcoma.

Surgical treatment is the mainstay of therapy for soft tissue sarcoma in the control of local disease. However, aggressive surgical resection combined with RT and chemotherapy, used before or after resection, allows effective limb-sparing treatment in 90% of patients. Amputation is reserved for patients with unresectable tumors, no evidence of metastasis, and the potential for good

long-term rehabilitation. Local recurrence is greater in those patients undergoing limb-sparing therapies as compared to amputation; however, there is no difference in disease-free survival between the two groups. Since size is a prognostic factor for both local recurrence and metastasis, the recommended treatment is different. In patients with tumors smaller than 5 cm, complete surgical resection with 1-cm margins is usually sufficient. Larger lesions are treated with a combination of therapies, including chemotherapy and RT. RT techniques include external-beam RT and/or brachytherapy. Because half the human patients develop distant metastasis, despite local control, adjuvant chemotherapy is often used (doxorubicin alone or in combination with other chemotherapeutics). Ifosfamide is currently the most active salvage agent for patients who have failed doxorubicin-based protocols. Metaanalysis of combination therapy for soft tissue sarcoma reports a disease-free survival of 52% and an overall survival of 57% with a median follow-up of 9.4 years. Permanent local control with the first treatment is related to long-term survival. High-risk soft tissue sarcoma patients are treated with combined chemoradiation prior to surgical resection. The chemotherapy protocol often used is doxorubicin, ifosfamide, mesna, and dacarbazine. Local and systemic toxicity included expected wound-healing complications. In human patients with metastatic disease, combination chemotherapy produces response rates of 20%, and most patients are candidates for investigational agents.

Cancer of the Gastrointestinal Tract

SECTION A Oral Tumors

JULIUS M. LIPTAK AND STEPHEN J. WITHROW

Incidence and Risk Factors

Collectively, oral cancer accounts for 6% to 7% of canine cancer and is the fourth most common cancer overall.^{1,2} In the cat, it accounts for 3% of all cancers.³ Oropharyngeal cancer is 2.6 times more common in dogs than cats, and male dogs have a 2.4 times greater risk of developing oropharyngeal malignancy compared to female dogs.^{4,5} A male sex predisposition has also been reported for dogs with malignant melanoma and tonsillar squamous cell carcinoma (SCC).^{6,7} Dog breeds with the highest risk of developing oropharyngeal cancer include the cocker spaniel, German shepherd dog, German shorthaired pointer, Weimaraner, golden retriever, Gordon setter, miniature poodle, Chow Chow, and Boxer.^{6,8,9} In one study, German shepherd dogs and Boxers had a decreased risk of developing oral melanoma.⁹

In dogs, the most common malignant oral tumors are, in descending order, malignant melanoma, SCC, and fibrosarcoma,¹⁰⁻²¹ although in other studies SCC is more common than malignant melanoma.² SCC is the most common oropharyngeal cancer in cats, followed by fibrosarcoma, which accounts for 13% of feline oral tumors.³ Other malignant oral tumors in dogs include osteosarcoma, chondrosarcoma, anaplastic sarcoma, multilobular osteochondrosarcoma, intraosseous carcinoma, myxosarcoma, hemangiosarcoma, lymphoma, mast cell tumor, and transmissible venereal tumor.¹⁰⁻²⁴ Tumors or tumorlike lesions of unusual sites, types, and biologic behavior (e.g., tonsillar SCC, tongue, malignancy of young dogs, viral papillomatosis, canine and feline eosinophilic granuloma complex, epulis, inductive fibroameloblastoma, and nasopharyngeal polyps) will be covered at the end of this chapter. A general summary of the common oral tumors is found in Table 22-1.

Pathology and Natural Behavior

The oral cavity is a very common site for a wide variety of malignant and benign cancers. Although most cancers are fairly straightforward histologically, some have confusing nomenclature or extenuating circumstances that warrant discussion.

Malignant Melanoma

In comparison to other malignant oral tumors, malignant melanoma tends to occur in smaller body weight dogs. Cocker spaniel, miniature poodle, Anatolian sheepdog, Gordon setter, Chow Chow,

and golden retriever are overrepresented breeds.⁹ A male predisposition has been reported,⁷ but this is not consistent.⁹ The mean age at presentation is 11.4 years.⁹ Malignant melanoma occurs in cats but is uncommon.²⁵

Malignant melanoma can present a confusing histopathologic picture if the tumor or the biopsy section does not contain melanin, and amelanotic melanomas represent one-third of all cases. A histopathologic diagnosis of undifferentiated or anaplastic sarcoma or even epithelial cancer should be viewed with suspicion for possible reclassification as melanoma. Melan A is an immunohistochemical stain with a moderate sensitivity and specificity for the diagnosis of melanoma in dogs and can be used to differentiate melanoma from other poorly differentiated oral tumors and may be helpful in differentiation.⁹

Melanoma of the oral cavity is a highly malignant tumor with frequent metastasis to the regional lymph nodes and then the lungs.^{7,26,27} The metastatic rate is site, size, and stage dependent and reported in up to 80% of dogs.* The World Health Organization (WHO) clinical staging system for oral tumors in dogs may have prognostic significance in dogs with oral melanoma (Table 22-2).^{7,26,31,36-38} Malignant melanoma is a highly immunogenic tumor, and molecular and immunomodulatory approaches to treatment are active areas of research.^{33,34,39-47} A review of the biology and molecular mechanisms of canine melanoma development and progression is provided in Chapter 19.^{48,49}

Squamous Cell Carcinoma

SCC is the most common oral tumor in cats and the second most common in dogs.^{1,3,18-21} In cats, the risk of developing oral SCC is significantly increased by over 3.5-fold with the use of flea collars and high intake of either canned food in general or canned tuna fish specifically.⁵⁰ Exposure to household smoke increases the risk of oral SCC by twofold in cats,⁵⁰ and although this was not statistically significant, smoke exposure is associated with a significant increase in expression of *p53* in SCC lesions compared to cats with oral SCC not exposed to environmental smoke.⁵¹ For this reason, mutations of *p53* may be involved in the development and progression of smoke-related oral SCC in cats.

SCC frequently invades bone in both cats and dogs, and bone invasion is usually severe and extensive in the cat. Increased tumor expression of parathyroid hormone-related protein in cats with oral SCC may play a role in bone resorption and tumor invasion.⁵² Paraneoplastic hypercalcemia has also been reported in two cats with oral SCC.⁵³ Metastasis in the cat is rare and the true incidence is unknown because so few cats have had their local disease controlled; thus an accurate estimate of the metastatic potential has not been confirmed. The metastatic rate for non-tonsillar SCC in dogs

• **TABLE 22-2** Clinical Staging (TNM) of Oral Tumors in Dogs and Cats

Clinical Staging System for Oral Tumors

Primary Tumor (T)

Tis	Tumor in situ
T1	Tumor <2 cm in diameter at greatest dimension
T1a	Without evidence of bone invasion
T1b	With evidence of bone invasion
T2	Tumor 2-4 cm in diameter at greatest dimension
T2a	Without evidence of bone invasion
T2b	With evidence of bone invasion
T3	Tumor >4 cm in diameter at greatest dimension
T3a	Without evidence of bone invasion
T3b	With evidence of bone invasion

Regional Lymph Nodes (N)

N0	No regional lymph node metastasis
N1	Movable ipsilateral lymph nodes
N1a	No evidence of lymph node metastasis
N1b	Evidence of lymph node metastasis
N2	Movable contralateral lymph nodes
N2a	No evidence of lymph node metastasis
N2b	Evidence of lymph node metastasis
N3	Fixed lymph nodes

Distant Metastasis (M)

M0	No distant metastasis
M1	Distant metastasis [specify site(s)]

STAGE GROUPING	TUMOR (T)	NODES (N)	METASTASIS (M)
I	T1	N0, N1a, N2a	M0
II	T2	N0, N1a, N2a	M0
III	T3	N0, N1a, N2a	M0
	Any T	N1b	M0
IV	Any T	N2b, N3	M0
	Any T	Any N	M1

Data from Owen LN: *TNM classification of tumors in domestic animals*, Geneva, 1980, WHO.

is approximately 20%,³² but the metastatic risk is site dependent—the rostral oral cavity has a low metastatic rate and the caudal tongue and tonsil have a high metastatic potential.

Fibrosarcoma

Oral fibrosarcoma is the second most common oral tumor in cats and the third most common in dogs.^{1,3,18-21,54} In dogs, oral fibrosarcoma tends to occur in large breed dogs, particularly golden and Labrador retrievers; at a younger age, with a median of 7.3 to 8.6 years; and with a possible male predisposition. Oral fibrosarcoma will often look surprisingly benign histologically and, even with large biopsy samples, the pathologist can find it difficult to differentiate fibroma from low-grade fibrosarcoma. This syndrome, which is common on the hard palate (Figure 22-1) and maxillary arcade between the canine and carnassial teeth of large-breed dogs, has been termed *histologically low-grade but biologically high-grade fibrosarcoma*.⁵⁴ Even with a biopsy result suggesting fibroma or low-grade fibrosarcoma, the treatment should be aggressive, especially if the cancer is rapidly growing, recurrent, or invading bone.

• **FIGURE 22-1** A histologically low-grade but biologically high-grade fibrosarcoma in the palate of a golden retriever. The tumor appears circumscribed and benign, but aggressive surgical resection and possibly postoperative radiation therapy (RT) are required for local tumor control.

• **FIGURE 22-2** Typical appearance of a peripheral odontogenic fibroma. The mass is firmly adhered to the underlying bone but does not invade bone. Conservative resection with cautery was curative in this dog.

Fibrosarcoma is locally invasive but metastasizes to the lungs and occasionally regional lymph nodes in less than 30% of dogs.^{10,18-21,32}

Epulides

Epulides are benign gingival proliferations arising from the periodontal ligament and appear similar to gingival hyperplasia (Figure 22-2). Three types of epulides have previously been described in the dog: acanthomatous, fibromatous, and ossifying.⁵⁶⁻⁵⁸ However, the terminology for these tumors has changed; acanthomatous epulis

is now termed *acanthomatous ameloblastoma* and peripheral odontogenic fibroma is the preferred nomenclature for fibrous and ossifying epulides.⁵⁹

Peripheral Odontogenic Fibroma

Epulides are relatively common in dogs but rare in cats. Multiple epulides have been described in cats with 50% of cases occurring in cats younger than 3 years.⁵⁵ The mean age at presentation for dogs with peripheral odontogenic fibromas is 8 to 9 years, and a male predisposition has been reported in one study.^{57,58} Peripheral odontogenic fibromas are slow-growing, firm masses that are usually covered by intact epithelium. They have a predilection for the maxilla rostral to the third premolar teeth.^{58,59}

Acanthomatous Ameloblastoma

Acanthomatous ameloblastoma has an aggressive local behavior and frequently invades bone of the underlying mandible or maxilla. Shetland and Old English sheepdogs are predisposed.^{57,58} The mean age at presentation is 7 to 10 years, and a sex predisposition is unlikely with three studies reporting conflicting results.^{57,60,61} The rostral mandible is the most common site.⁶⁰ They do not metastasize. *Acanthomatous ameloblastoma* is the preferred term, but some pathologists will refer to these tumors by their previous terminology of *acanthomatous epulis* or *adamantinoma*.⁵⁶

History and Clinical Signs

Most cats and dogs with oral cancer present with a mass in the mouth noticed by the owner. Cancer in the caudal pharynx, however, is rarely seen by the owner, and the animal will present for signs of increased salivation, exophthalmos or facial swelling, epistaxis, weight loss, halitosis, bloody oral discharge, dysphagia or pain on opening the mouth, or occasionally cervical lymphadenopathy (especially SCC of the tonsil).^{18-21,62} Loose teeth, especially in an animal with generally good dentition, should alert the clinician to possible underlying neoplastic bone lysis (Figure 22-3), especially in the cat.⁶³ Although paraneoplastic syndromes associated with oral tumors are rare, hypercalcemia has been reported in two cats with oral SCC⁵¹ and hyperglycemia in a cat with a gingival vascular hamartoma.⁶⁴

Diagnostic Techniques and Work-Up

The diagnostic evaluation for oral cancers is critical due to the wide ranges of cancer behavior and therapeutic options available. If the tumor is suspected of being malignant, thoracic radiographs and lymph node cytologic assessment can be performed prior to biopsy. The most likely cancers to metastasize visibly on thoracic radiographs at the time of diagnosis are melanoma and SCC of the caudal oral, pharyngeal, and tonsillar area. Most animals will require a short general anesthesia for careful palpation, regional imaging, and a biopsy.

Cancers that are adherent to bone, other than peripheral odontogenic fibromas, should have regional radiographs taken under general anesthesia. Regional radiographs include open mouth, intraoral, oblique lateral, and ventrodorsal or dorsoventral projections.⁶⁵ Bone lysis is not radiographically evident until 40% or more of the cortex is destroyed (Figure 22-4). However, apparently normal radiographs do not exclude bone invasion. This evaluation will assist in determining clinical staging information and the

• **FIGURE 22-3** An intraoral radiograph of the rostral mandible of a dog with an acanthomatous ameloblastoma. Note the bone lysis and loosening of the incisor teeth.

extent of resection when surgery is indicated. Computed tomography (CT) or magnetic resonance imaging (MRI) can be a very valuable staging tool, especially for evaluation of bone invasion and possible tumor extension into the nasal cavity or in the caudal pharynx and orbit, and is preferred to regional radiographs when available (Figure 22-5).⁶⁶

Regional lymph nodes should be carefully palpated for enlargement or asymmetry. However, caution should be exercised when making clinical judgments of whether neoplastic involvement of regional lymph nodes is present. Lymph node size is not an accurate predictor of metastasis. In one study of 100 dogs with oral melanoma, 40% of dogs with normal-sized lymph nodes had metastasis and 49% of dogs with enlarged lymph nodes did not have metastasis.²⁷ The regional lymph nodes include the mandibular, parotid, and medial retropharyngeal lymph nodes; however, the parotid and medial retropharyngeal lymph nodes are normally not palpable.⁶⁷ Furthermore, only 55% of 31 cats and dogs with metastasis to the regional lymph nodes had metastasis to the mandibular lymph node.⁶⁸ Lymphoscintigraphy or contrast-enhanced ultrasonography can be used to detect the sentinel lymph nodes and guide lymph node aspirates.⁶⁹ Lymph node aspiration should be performed in all animals with oral tumors, regardless of the size or degree of fixation of the lymph nodes.^{27,68} En bloc resection of the regional lymph nodes has been described and, although the therapeutic benefit of this approach is unknown, it may provide valuable staging information.^{67,68} Based on these diagnostic steps, oral tumors are then clinically staged according to the WHO staging scheme (see Table 22-2).³⁶

The last step, under the same anesthesia, is a large incisional biopsy. Cytologic touch or aspiration preparations of oral tumors

• **FIGURE 22-4** An intraoral radiograph of the rostral mandible of a cat with a SCC. Note the extensive, ill-defined bone lysis that is very common in cats with this type of tumor.

• **FIGURE 22-5** A CT image of a dog with a maxillary fibrosarcoma. Advanced imaging allows better planning of surgery and radiation therapy (RT) because the extent of bone involvement and extension into the nasal cavity is often much greater than can be appreciated grossly.

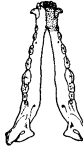

are usually not rewarding because of the necrosis and inflammation that commonly accompanies these cancers. Dogs with exophytic or ulcerated masses will generally tolerate a deep wedge or core punch biopsy without general anesthesia. Biopsy is recommended to differentiate benign from malignant disease, for owners basing their treatment options on prognosis, and when other treatment modalities such as radiation therapy (RT) are being considered. Oral cancers are commonly infected, inflamed, or necrotic, and it is important to obtain a large specimen. Electrocautery may distort the specimen and should only be used for hemostasis after blade incision or punch biopsy. Large samples of healthy tissue at the edge and center of the lesion will increase the diagnostic yield, but care must be taken not to contaminate normal tissue, which cannot be removed with surgery or included in the radiation field. Biopsies should always be performed from within the oral cavity and not through the lip to avoid seeding tumor cells in normal skin and compromising curative-intent surgical resection. For small lesions (e.g., epulides, papillomas, or small labial mucosal melanoma), curative-intent resection (excisional biopsy) may be undertaken at the time of initial evaluation. For more extensive disease, waiting for biopsy results to accurately plan treatment is strongly encouraged.

Therapy

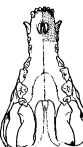

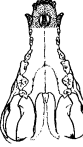

Surgery

Surgery and RT are the most common treatments used for the local control of oral tumors. Surgical resection is the most economic, expeditious, and curative treatment. The type of oral surgery depends on tumor histology and location. Except for peripheral odontogenic fibromas, most oral tumors have some underlying bone involvement and surgical resection should include bony margins to increase the likelihood of local tumor control. More aggressive surgeries such as mandibulectomy, maxillectomy, and orbitectomy are generally well tolerated by cats and dogs. These procedures are indicated for all aggressive and/or invasive oral tumors, particularly lesions with extensive bone invasion, with poor sensitivity to RT, or that are too large for cryosurgery (Tables 22-3 and 22-4).^{11-21,70-73} Margins of at least 2 cm are necessary for malignant cancers such as SCC, malignant melanoma, and fibrosarcoma in the dog. If possible, SCC in the cat should be treated with surgical margins greater than 2 cm because of high local recurrence rates. Bone reconstruction following bony resection has been described but is rarely necessary.^{13,74-76} Rostral and segmental resections (e.g., mandibulectomy and maxillectomy) may be sufficient for benign lesions and rostral SCC in dogs. Rim resections with a biradial oscillating saw, in which the ventral cortex of the mandible is preserved, may be possible for small benign tumors localized to the alveolar margin of the mandible (Figure 22-6).⁷⁷ Larger resections, including hemimandibulectomy, hemimaxillectomy, orbitectomy, and radical maxillectomy, are necessary for more aggressive tumors, especially fibrosarcoma, and malignant tumors with a more caudal location.^{11-21,70-72} Although these large resections carry some morbidity, owner satisfaction with the cosmetic and functional outcomes is in excess of 85%.^{11-21,71,73,78} Cosmesis is usually very good following most mandibulectomy and maxillectomy procedures (Figure 22-7) but can be challenging with aggressive bilateral rostral mandibulectomies and radical maxillectomies.^{11-21,70-72} Blood loss and hypotension are the most common intraoperative complications, particularly during caudal or aggressive maxillectomy procedures.^{19,71} Postoperative complications include incisional dehiscence, epistaxis, increased salivation, mandibular drift

• TABLE 22-3 Various Mandibulectomies

MANDIBULECTOMY PROCEDURE	INDICATIONS	COMMENTS	
Unilateral rostral	Lesions confined to rostral hemimandible; not crossing midline	Most common tumor types are squamous cell carcinoma and adamantinoma that do not require removal of entire affected bone; tongue may lag to resected side.	
Bilateral rostral	Bilateral rostral lesions crossing the symphysis	Tongue will be “too long,” and some cheilitis of chin skin will occur; has been performed as far back as PM4 but preferably at PM1.	
Vertical ramus	Low-grade bony or cartilaginous lesions confined to vertical ramus	These tumors are variously called <i>chondroma rodens</i> or <i>multilobular osteosarcoma</i> ; temporomandibular joint may be removed; cosmetics and function are excellent.	
Complete unilateral	High-grade tumors with extensive involvement of horizontal ramus or invasion into medullary canal of ramus	Usually reserved for aggressive tumors; function and cosmetics are good.	
Segmental	Low-grade midhorizontal ramus cancer, preferably not into medullary cavity	Poor choice for highly malignant cancer in medullary cavity because growth along mandibular artery, vein, and nerve is common.	

• TABLE 22-4 Various Maxillectomies

MAXILLECTOMY PROCEDURE	INDICATIONS	COMMENTS	
Unilateral rostral	Lesions confined to hard palate on one side	One-layer closure.	
Bilateral rostral	Bilateral lesions of rostral hard palate	Needs viable buccal mucosa on both sides for flap closure.	
Lateral	Laterally placed midmaxillary lesions	Single-layer closure if small defect, two-layer if large.	
Bilateral	Bilateral palatine lesions	High rate of closure dehiscence because lip flap rarely reaches from side to side; may result in permanent oronasal fistula.	

• **FIGURE 22-6** A rim resection has been performed for removal of an acanthomatous ameloblastoma with 1-cm margins. Note that the ventral cortex of the mandible has been preserved. Preservation of the ventral cortex prevents the development of mandibular drift and malocclusion.

• **FIGURE 22-7** The typical appearance of a dog 6 months postoperatively after subtotal unilateral mandibulectomy for an osteosarcoma. The tongue will often hang out and the remaining hemimandible will drift towards the resected side.

and malocclusion, and difficulty prehending food, particularly after bilateral rostral mandibulectomy caudal to the second premolar teeth.^{13-21,53,71} Elastic training, consisting of an orthodontic elastic rubber chain between an orthodontic button on the lingual aspect of the intact mandible tooth and buccal aspect of the maxillary fourth premolar tooth, has been described to maintain occlusion and prevent mandibular drift following mandibulectomy in dogs.⁷⁹ Enteral feeding tubes are not usually required following oral surgery

in dogs; however, they are recommended for cats treated with any type of mandibulectomy because eating can be difficult for 2 to 4 months following surgery.^{53,78}

Local disease control is the goal of treatment for most animals with oral tumors. Regional lymph node resection has been described in cats and dogs; although it adds to clinical staging information, its effectiveness in controlling local and metastatic disease is unknown.^{67,68}

Cryosurgery may be indicated for lesions less than 2 cm in diameter that are fixed or minimally invasive into bone. Larger lesions should generally be surgically resected. More extensive lesions in bone will often result in a fracture (mandible) or oronasal fistula (maxilla) if aggressively frozen. Cancer of soft tissue only should be surgically excised and not frozen.

Radiation Therapy

RT can be effective for locoregional control of oral tumors. RT can be used as a primary treatment, with either palliative or curative intent, or as an adjunct for incompletely resected tumors or tumors with an aggressive local behavior, such as oral fibrosarcoma. Malignant melanoma, canine oral SCC, and some benign tumors, such as the acanthomatous ameloblastoma, are known to be radiation responsive, and RT should be considered in the primary treatment of these tumors.^{31-33,80,81} For canine oral SCC, dental tumors, and fibrosarcoma, daily and alternate day protocols have been described consisting of 2.7 Gy to 4.2 Gy per fraction with a total dose ranging from 48 Gy to 57 Gy.^{32,82} Tumor control is better for smaller benign and malignant lesions (T1 and T2 tumors) treated with radiation alone.^{31,32,80} Local tumor control and survival time may be improved by combining RT with surgery and/or chemotherapy, especially for tumors considered radiation resistant, such as canine oral fibrosarcoma and feline oral SCC.^{53,83-88} Radiation sensitizers, such as etanidazole and gemcitabine, may improve response rates in cats with oral SCC, and platinum drugs have been used as radiation sensitizers in dogs with oral melanoma.^{28,37,84,87,88} However, gemcitabine is not recommended as a radiosensitizer in cats because of significant hematologic and local tissue toxicities.⁸⁹

Oral melanoma is moderately responsive to coarse fractionation protocols. Four different hypofractionated radiation protocols have been described: (1) three weekly 8- to 10-Gy fractions for a total dose of 24 to 30 Gy,^{30,37} (2) four weekly fractions of 9 Gy for a total dose of 36 Gy,^{31,37} (3) six weekly 6-Gy fractions for a total dose of 36 Gy,²⁸ and (4) eight weekly 6-Gy fractions for a total dose of 48 Gy.⁹⁰ In humans, the effect of total radiation dose is controversial, but fraction size does have an impact on response rates. Doses greater than 4 Gy per fraction are recommended as response rates are significantly better with fractions greater than 8 Gy compared to less than 4 Gy.⁹¹ However, in one study of dogs with oral melanoma comparing two hypofractionated protocols of 9 to 10 Gy per fraction to a fully fractionated protocol of 2 to 4 Gy per fraction, there were no significant differences in either local recurrence rates or survival time.³⁷ Coarse fractionation of oral melanoma has also been described in five cats with limited success, including one complete response and two partial responses.²⁵

Acute effects are common but self-limiting. These include alopecia and moist desquamation, oral mucositis, dysphagia, and ocular changes, such as blepharitis, conjunctivitis, keratitis, and uveitis.^{32,80,92-94} The acute effects of coarse fractionation are less than experienced with the full-course protocols used for oral SCC and dental tumors and usually resolve rapidly.³¹ Late complications are rare, occurring in less than 5% of cases, but can include permanent alopecia, skin fibrosis, bone necrosis and oronasal fistula formation,

development of a second malignancy within the radiation field, keratoconjunctivitis sicca, cataract formation, xerostomia, and retinal atrophy.^{32,61,80,95} Orthovoltage radiation may be associated with a higher incidence of second malignancies and bone necrosis than megavoltage irradiation.^{32,61,80}

Hyperthermia offers no advantage over cryosurgery or surgery if it is used alone. In fact, bone penetration is less reproducible with heat versus cold treatment. Hyperthermia at moderate temperatures (42 to 43°C) has been used as an adjunct to irradiation.^{29,96,97}

Chemotherapy

The major problem with most oral tumors is control of local disease. However, chemotherapy is indicated for some tumors with higher metastatic potential, especially oral melanoma in dogs and tonsillar SCC in cats and dogs. Expression of cyclooxygenase 2 (COX-2) has been noted in feline oral SCC⁹⁸; however, nonsteroidal antiinflammatory drugs (NSAIDs) such as piroxicam have not been effective in the management of this disease in cats in preliminary studies.⁹⁹ Piroxicam does appear to have some effect against oral SCC in dogs,¹⁰⁰ and response rate is improved when piroxicam is combined with either cisplatin or carboplatin.^{101,102} Liposome-encapsulated cisplatin is not effective in cats with oral SCC,¹⁰³ but mitoxantrone, in combination with RT, has shown some potential in a limited number of cats with good local responses and durable remission.^{85,86}

The platinum drugs show the most promise, albeit modest, in treating dogs with oral melanoma, including intralesional cisplatin¹⁰⁴ and systemic carboplatin.¹⁰⁵ Measurable responses to melphalan have also been reported.¹⁰⁶

Malignant melanoma is a highly immunogenic tumor. The use of immunomodulatory agents is an emerging and exciting approach for the adjunctive management of dogs with oral melanoma. A thorough discussion of the immunotherapeutic approach to management of canine melanoma is provided in Chapter 19.

Prognosis

Clinical series of over 500 dogs with various oral malignancies treated with either mandibulectomy or maxillectomy have been described.^{11-21,70-72} The majority of cases were treated with surgery alone. Unfortunately, the methods of reporting and outcome results vary with each paper, but an attempt to combine cases by tumor type and outcome is shown in Tables 22-5 and 22-6. Overall, the lowest rates of local tumor recurrence and best survival times are reported in dogs with acanthomatous ameloblastoma and SCC, whereas fibrosarcoma and malignant melanoma are associated with the poorest results.¹¹⁻²¹ Most of these reports suggest that histologically complete resection, smaller diameter, and a rostral location are favorable prognostic factors. In two studies of 142 dogs treated with either mandibulectomy or maxillectomy, tumor-related deaths were 10 to 21 times more likely with malignant tumors, up to 5 times more likely with tumors located caudal to the canine teeth, and 2 to 4 times more likely following incomplete resection.^{20,21} Rostral locations are usually detected at an earlier stage and are more likely to be resectable with complete surgical margins. Local tumor recurrence is more frequent following incomplete resection, with 15% to 22% and 62% to 65% of tumors recurring following complete and incomplete excision, respectively.^{20,21} Recurrent disease negatively impacts survival time because further treatment is more difficult and the response to treatment is poorer.³⁵ Fibrosarcoma continues to have an unacceptable local recurrence rate and needs to be addressed with wider resections or other adjuvant therapies, such as postoperative radiation.⁸² On the other hand, melanoma is controlled locally in 75% of cases, but metastatic disease requires more effective adjuvant therapy, such as RT, chemotherapy, or immunotherapy.

For dogs treated with megavoltage radiation, tumor type and tumor size are important factors in local tumor control for both benign and malignant oral tumors. As noted previously,

• **TABLE 22-5** Postoperative Outcome After Mandibulectomy for Different Tumor Types*

TUMOR TYPE	NUMBER	LOCAL RECURRENCE (%)	MEDIAN SURVIVAL TIME (MONTHS)	1-YEAR SURVIVAL RATE (%)
Malignant melanoma	81	0-40	7-17	21
Squamous cell carcinoma	74	0-23	9-26	80-91
Fibrosarcoma	58	31-60	11-12	23-50

*References 11-21, 56-58, 119-121.

acanthomatous ameloblastoma and SCC in dogs are radiation sensitive. Local recurrence is reported in 30% of oral tumors regardless of treatment, but recurrence is a function of tumor size. Compared to small tumors (T1: <2-cm diameter), recurrence is 3 times more likely in T2 tumors (2- to 4-cm diameter) and up to 8 times more likely in T3 tumors (>4-cm diameter).^{32,80} Tumor size is also associated with survival in dogs with malignant oral tumors, with 3-year progression-free survival (PFS) rates of 55%, 32%, and 20% for T1, T2, and T3 tumors, respectively.³²

Malignant Melanoma

The prognosis for dogs with oral melanoma is guarded. Metastatic disease is the most common cause of death with metastasis to the lungs reported in 14% to 67% of dogs.* Surgery or RT can provide good local control, but strategies to manage the high metastatic potential such as chemotherapy and immunotherapy require further investigation.

Surgery is the most common treatment for management of the local tumor. The local tumor recurrence rate varies from 22% following mandibulectomy to 48% after maxillectomy.^{7,18,19} The median survival time (MST) for dogs with malignant melanoma treated with surgery alone varies from 150 to 318 days with 1-year survival rates less than 35%.† Regardless, tumor control and survival time are significantly better when surgery is included in the treatment plan.³⁸ In comparison, the MST for untreated dogs with oral melanoma is 65 days.³⁵ Variables known to have prognostic significance in dogs treated with surgery alone or in combination with other modalities include tumor size, clinical stage, and ability of the first treatment to achieve local control.‡ Dogs with tumors less than 2-cm in diameter have a MST of 511 days compared to 164 days for dogs with tumors greater than 2-cm diameter or lymph node metastasis.³³ MSTs are significantly shorter for dogs with recurrent oral malignant melanomas compared to dogs with previously untreated oral melanomas.^{26,35}

Oral melanoma is responsive to hypofractionated RT protocols. Response rates are excellent with 83% to 100% of tumors responding and a complete response observed in up to 70% of melanomas.^{28,30-32,90} Local recurrence is reported in 15% to 26% of dogs experiencing a complete response with a median time to local recurrence of 139 days.^{28,30-32} Progressive local disease was observed in all dogs that did not achieve a complete response in one study.³⁰ The most common cause of death is metastasis and this is reported in 58% of dogs with a median time of metastasis of 311 days.²⁸ The MST for dogs treated with RT is 211 to 363 days, with a 1-year survival rate of 36% to 48% and a 2-year survival rate of 21%.^{28,30-32,37} Local tumor control and survival time are significantly improved with rostral tumor location, smaller tumor volume, no radiographic evidence of bone lysis, and postoperative irradiation of microscopic disease.^{31,32,37} The risk factors associated with poor outcomes in dogs with melanoma include nonrostral location, bone lysis, and macroscopic disease, and in one series of 140 dogs with oral melanoma, the MST was 21 months if none of these risk factors were present compared to a MST of 11 months with one risk factor, 5 months with two risk factors, and 3 months with all three risk factors.³⁷ Tumor size is important with median PFS for dogs with T1 oral melanomas of 19 months compared to less than 7 months for T2 and T3 tumors.³² Hypofractionated RT has also been

described in five cats with oral melanoma, resulting in a 60% response rate and MST of 146 days (range: 66 to 224 days).²⁵

Chemotherapy or immunotherapy is indicated in the adjunctive management of dogs with oral melanoma because of the high metastatic risk. A thorough discussion of malignant melanoma and its prognosis following definitive treatment with surgery, RT, chemotherapy, and/or immunomodulatory agents is provided in Chapter 19.

The location of malignant melanoma may also have some prognostic significance. Melanomas of the lip and tongue have a lower metastatic rate and survival is more dependent on local control of the tumor. In one series of 60 dogs with oral melanomas at various sites treated with combinations of surgery, RT, chemotherapy, and immunotherapy, the MST for dogs with lip melanomas was 580 days and was not reached and greater than 551 days for dogs with tongue melanomas.⁷ In comparison, the MST was 319 days for maxillary melanomas and 330 days for melanomas of the hard palate.⁷

In another study, only 5% of 64 dogs with well-differentiated melanomas of the mucous membranes of the lips and oral cavities treated with surgery alone had died from tumor-related reasons with an overall MST of 34 months.¹⁰⁹ This improved prognosis may reflect the location of these lesions (lip compared to oral cavity) or the degree of differentiation. Nuclear atypia and mitotic index has also been shown to be prognostic in dogs with oral malignant melanomas.¹¹⁰

Squamous Cell Carcinoma

Canine Oral Squamous Cell Carcinoma

The prognosis for dogs with oral SCC is good, particularly for rostral tumor locations. Local tumor control is usually the most important challenge, although metastasis to the regional lymph nodes is reported in up to 10% of dogs and to the lungs in 3% to 36% of dogs.³² In contrast, SCC of the tonsils and base of the tongue are highly metastatic, with metastasis reported in up to 73% of dogs, and locoregional recurrence is common.¹¹¹⁻¹¹³ Surgery and RT can both be used for locoregional control of oral SCC in dogs. Photodynamic therapy has also been reported with fair-to-good results in 11 dogs with smaller oral SCC.¹¹⁴

Surgery is the most common treatment for non-tonsillar SCC.¹¹ Following mandibulectomy, the local recurrence rate is 10% and the MST varies from 19 to 26 months with a 91% 1-year survival time.¹⁸ In comparison, the local recurrence rate is 29% after maxillectomy with a MST of 10 to 19 months and a 1-year survival rate of 57%.¹⁹ The higher local control and survival rates with mandibular resections probably result because the rostral mandible is the most common location for oral SCC in dogs, and complete surgical resection is more likely for rostral locations.

Full-course RT, either alone or as an adjunct following incomplete surgical resection, is also a successful treatment modality for the management of oral SCC in dogs.^{32,115,116} The local tumor recurrence rate is 31%. The MST for RT alone is 15 to 16 months and increases to 34 months when combined with surgery.^{115,116} In one series of 39 dogs with oral SCC, the overall median PFS time was 36 months with 1- and 3-year PFS rates of 72% and 55%, respectively.³² Local tumor control was more successful with smaller lesions; the median PFS time for T1 tumors (<2-cm diameter) was not reached and greater than 68 months compared to 28 months for T2 tumors (2- to 4-cm diameter) and 8 months for dogs with T3 tumors (>4-cm diameter).³² Additional favorable prognostic factors for dogs receiving orthovoltage irradiation include rostral tumor location, maxillary SCC, and young age.¹¹⁵ Younger age is

*References 7, 10, 18, 19, 26-35.

†References 7, 9, 18-21, 26, 34, 35, 58.

‡References 7, 26, 28, 29, 31-35.

also favorable for dogs treated with megavoltage radiation (< 9 years of age—1080 days; > 9 years of age—315 days).¹¹⁶

Chemotherapy is indicated for dogs with metastatic disease, dogs with bulky disease, and when owners decline surgery and RT. However, as the metastatic potential of oral SCC in dogs is relatively low, the role of chemotherapy in minimizing the risk of metastatic disease is unknown. In a series of 17 dogs treated with piroxicam alone, the response rate was 17%, with one complete response and two partial responses.¹⁰⁰ The median progression-free interval for dogs responding to piroxicam was 180 days and significantly longer than the 102 days for dogs with stable disease.¹⁰⁰ The outcome is better when piroxicam is combined with either cisplatin or carboplatin. In a series of nine dogs treated with piroxicam and cisplatin, the overall MST was 237 days, with the 56% of dogs responding to this chemotherapy protocol having a significantly better outcome than nonresponders with a MST of 272 days compared to 116 days.¹⁰¹ However, renal toxicity was reported in 41% of dogs in this study and such toxicities limit the clinical usefulness of this protocol. In another small series of seven dogs with T3 oral SCC treated with piroxicam and carboplatin, a complete response was observed in 57% of dogs and this response was sustained in all dogs at the median follow-up time of 534 days.¹⁰² Novel therapies under investigation include the combination of intralesional bleomycin and feline interleukin-12 (IL-12) DNA with translesional electroporation.¹⁰⁷

Feline Oral Squamous Cell Carcinoma

The prognosis for cats with oral SCC is poor.^{14,62,117,118} There is no known effective treatment that consistently results in durable control or survival. Local control is the most challenging problem. In one series of 52 cats, the 1-year survival rate was less than 10%, with MSTs of 3 months or less for surgery alone, surgery and RT, RT and low-dose chemotherapy, or RT and hyperthermia.⁶² However, 42% of these cats had SCC involving the tongue, pharynx, or tonsils. In another series of 54 cats treated in general practice, the MST was 44 days with a 9.5% 1-year survival rate.¹¹⁹ The oncologic outcome may be better for cats with mandibular SCC. The MST for seven cats treated with a combination of mandibulectomy and RT was 14 months with a 1-year survival rate of 57%.⁵³ Local recurrence was the cause of failure in 86% of these cats between 3 to 36 months after therapy. In another series of 22 cats treated with mandibulectomy alone, the median disease-free interval (DFI) was 340 days.⁷⁸ Tumor location and extent of resection had prognostic importance with a MST of 911 days for rostral tumors, 217 days following hemimandibulectomy, and 192 days when more than 50% of the mandible was resected.⁷⁸ Expansile, blastic, and discrete lesions are often more resectable than invasive, lytic, and ill-defined lesions in the experience of the authors. The use of esophagostomy or gastrostomy tubes may be necessary to provide supplemental nutrition in these cats for up to 4 months postoperatively.⁷⁸

RT alone is generally considered ineffective in the management of cats with oral SCC. In nine cats treated with an accelerated radiation protocol (14 fractions of 3.5 Gy delivered twice daily for 9 days), the overall MST was 86 days and, although not significant, the MST for cats with a complete response was 298 days.⁸¹ The combination of RT with radiation sensitizers or chemotherapy improves response rates and survival times. Using the same accelerated radiation protocol with carboplatin resulted in a MST of 163 days in 14 cats.⁸⁸ Intra-tumoral etanidazole, a hypoxic cell sensitizer, resulted in a 100% partial response rate in nine cats completing the RT course with a median decrease in tumor size of 70% and a MST of 116 days.⁸⁴ Gemcitabine was used at low doses as a radiation sensitizer in eight

cats with oral SCC with an overall response rate of 75%, including two cats with complete responses, for a median duration of 43 days and a MST of 112 days.⁸⁷ However, gemcitabine is not recommended as a radiosensitizer in cats because of significant hematologic and local tissue toxicities.⁸⁹ The combination of RT with mitoxantrone holds some promise because, in two series of 18 cats, a complete response was observed in 73% with a median duration of response of 138 to 170 days and an MST of 184 days.^{85,86} Palliative radiation protocols, consisting of 8 Gy fractions on days 0, 7, and 21, are not recommended because of poor disease control and radiation-induced adverse effects.¹²⁰ Localized irradiation with strontium-90 may be effective for selected cats with very superficial disease.¹²¹

Chemotherapy appears ineffective in the management of cats with oral SCC. No responses were observed in 18 cats treated with liposome-encapsulated cisplatin or 13 cats treated with piroxicam.^{99,103} In one study, the administration of a NSAID improved survival times in cats with oral SCC.¹¹⁹

Fibrosarcoma

The prognosis for dogs with oral fibrosarcoma is guarded. These are locally aggressive tumors and local control is more problematic than metastasis. Metastasis is reported to the regional lymph nodes in 19% to 22% of dogs and to the lungs in up to 27% of dogs.^{18,19,32} Multimodality treatment of local disease appears to afford the best survival rates, with combinations of surgery and RT or RT and hyperthermia.^{29,78}

Surgery is the most common treatment for oral fibrosarcoma. The median DFI for five cats treated with mandibulectomy was 859 days.⁷⁸ Following mandibulectomy, local recurrence is reported in 59% of dogs with a MST of 11 months and a 1-year survival rate of 50%.¹⁸ The outcome is similar following maxillectomy, with local recurrence in 40% of dogs and a MST of 12 months.¹⁹ One-year survival rates rarely exceed 50% with surgery alone.¹¹⁻²¹ The combination of surgery and RT provides the best opportunity to control local disease.

Oral fibrosarcomas are considered radiation resistant.^{83,122,123} The mean survival time of 17 dogs treated with RT alone was only 7 months.⁸³ RT combined with regional hyperthermia improved local control rates to 50% at 1 year in a series of 10 cases.²⁹ When RT is used as an adjunct to surgical resection, local tumor recurrence was reported in 32% of dogs overall and the MST increased to 18 to 26 months with a 1-year PFS rate of 76%.^{32,82} A smaller tumor size improves the outcome following RT, with a median PFS time of 45 months for dogs with T1 tumors compared to 31 months and 7 months for T2 and T3 tumors, respectively.³²

Osteosarcoma

Osteosarcoma of axial sites is less common than appendicular osteosarcoma and represents approximately 25% of all cases.¹²⁴ Of the axial osteosarcomas, the mandible and maxilla are involved in 27% and 16% to 22% of cases, respectively.^{124,125} The prognosis for dogs with oral osteosarcoma is better than appendicular osteosarcoma because of an apparent lower metastatic potential.¹¹⁹ A female sex predisposition has been reported.¹²⁴

The outcome following mandibulectomy alone is variable with MSTs of 14 to 18 months and 1-year survival rates of 35% to 71%.^{18,124,126} In 20 dogs treated with mandibulectomy alone, the cause of death was local recurrence in 15% of dogs and metastatic disease in 35% of dogs.¹⁸ Following maxillectomy, the MST varies from 5 to 10 months with a 1-year survival rate of 17% to 27% and local tumor recurrence in 83% to 100% of dogs.^{19,124} The majority of dogs with maxillary osteosarcoma die as a result of local tumor

recurrence with metastasis not reported in any dogs in two studies.^{106,125}

Local tumor control is the most challenging problem and resecting oral osteosarcomas with complete surgical margins is imperative. In one study of 60 dogs with osteosarcoma of the skull, including the mandible and maxilla, the median DFI and survival times were not reached at greater than 1503 days following complete excision and significantly better than incomplete resection with a median DFI of 128 days and a MST of 199 days.¹²⁷ The combination of surgery with either RT or chemotherapy did not improve the outcome in dogs with incompletely resected tumors, highlighting the necessity for an aggressive surgical approach. These results are supported by another study of 45 dogs with axial osteosarcoma in which favorable prognostic factors included complete surgical excision, mandibular location, and smaller body weight dogs.¹²⁵ Chemotherapy's role in the management of dogs with axial osteosarcoma is unknown but should be evaluated.

Epulides

Peripheral Odontogenic Fibroma

The prognosis for dogs with peripheral odontogenic fibromas is excellent following treatment with either surgery or rarely RT. These are benign tumors and metastasis has not been reported; hence local tumor control is the principal goal of therapy. For peripheral odontogenic fibromas, the local tumor recurrence rate following surgical resection without bone removal varies from 0% to 17%.^{57,128} RT is also effective with a 3-year PFS rate of 86%.⁸⁰ However, full-course RT is usually not required because these tumors can be adequately managed with simple surgical resection.⁵⁷ Local recurrence is common in cats with multiple epulides and is reported in 73% of 11 cats 3 months to 8 years after surgical resection.⁵⁵

Acanthomatous Ameloblastoma

Surgery or RT is also used in the management of dogs with acanthomatous ameloblastoma. Mandibulectomy or maxillectomy is required for surgical resection of acanthomatous ameloblastomas because of frequent bone invasion by this benign tumor. Local recurrence rates following bone-removing surgery are less than 5%.^{*} Megavoltage RT, consisting of an alternate day protocol of 4 Gy per fraction to a total of 48 Gy, results in a 3-year PFS rate of 80% in dogs with acanthomatous ameloblastomas.⁸⁰ The overall local recurrence rate with RT varies from 8% to 18% in two studies of 39 dogs and recurrence was 8 times more likely with T3 tumors compared to T1 and T2 tumors.^{61,80} The majority of tumors recur within the radiation field, which suggests a higher radiation dose may be required to achieve higher rates of local tumor control, particularly for tumors greater than 4 cm in diameter.⁸⁰ Other complications associated with RT include malignant transformation in 5% to 18% of dogs and bone necrosis in 6% of dogs.^{61,80} Intralesional bleomycin has been described in four dogs, and a complete response was observed in all dogs and was sustained for a minimum of 1 year with no local recurrence.¹²⁹

Selected Sites or Cancer Conditions in the Oral Cavity

Tonsillar Squamous Cell Carcinoma

Tonsillar SCC is 10 times more common in animals living in urban versus rural areas, implying an etiologic association with

environmental pollutants.¹³⁰ Primary tonsillar cancer is often SCC. Lymphoma can affect the tonsils but is usually accompanied by generalized lymphadenopathy and is often bilateral. Other cancers, especially malignant melanoma, can metastasize to the tonsils. Cervical lymphadenopathy is a common presenting sign, even with very small primary tonsillar cancers. Fine-needle aspirates of the regional lymph nodes or excisional biopsy of the tonsil will confirm the diagnosis. Thoracic radiographs are positive for metastasis in 10% to 20% of cases at presentation. In spite of disease apparently confined to the tonsil, this disease is considered systemic at diagnosis in over 90% of cats and dogs. Simple tonsillectomy is almost never curative but probably should be done bilaterally due to the high percentage of bilateral disease.¹⁰ Cervical lymphadenectomy, especially if the regional lymph nodes are large and fixed, is rarely curative and should be considered diagnostic only. Regional RT of the pharyngeal region and cervical lymph nodes is capable of controlling local disease in over 75% of the cases; however, survival still remains poor with 1-year survival rates of only 10%.^{111,113} Local tumor control and survival times were significantly improved in one study of 22 dogs with tonsillar SCC when RT was combined with a variety of different chemotherapy drugs.¹¹³ Cause of death is local disease early and systemic disease (usually lung metastasis) later. To date, no known effective chemotherapeutic agents exist for canine or feline SCC, although cisplatin, carboplatin, doxorubicin, vinblastine, and bleomycin have been used with limited success.^{113,131} In one study of 44 dogs with tonsillar SCC treated with surgery, RT, and/or chemotherapy, the MST was 179 days and dogs presenting with either anorexia or lethargy had a significantly shorter survival time.¹³²

Tongue

Cancer confined to the tongue is rare. In one study, 54% of tongue lesions were neoplastic and 64% of these were malignant.¹³³ White dogs appear to be at higher risk for SCC, even though lack of pigment would not seem to be as much a problem as it is in other more exposed areas of the body (e.g., nose, eyelids, and ears).¹³⁴ Other reported breed predilections include Chow Chow and Chinese Shar-Pei for malignant melanoma; poodle, Labrador retriever, and Samoyed for SCC; border collie and golden retriever for hemangiosarcoma and fibrosarcoma; and cocker spaniel for plasma cell tumors.¹³³ The most common cancer of the canine tongue is SCC, accounting for approximately 50% of cases, followed by granular cell myoblastoma, malignant melanoma, mast cell tumor, fibrosarcoma, adenocarcinoma, neurofibrosarcoma, leiomyosarcoma, hemangiosarcoma and hemangioma, rhabdomyoma and rhabdomyosarcoma, myxoma, and lipoma.¹³³⁻¹³⁵ Feline tongue tumors are usually SCCs, and most are located on the ventral surface near the frenulum. Presenting signs are similar to other oral tumors. Ulceration is common with SCC.

Under general anesthesia, the tongue may be biopsied with a wedge incision and closed with horizontal mattress sutures. Biopsies are necessary to differentiate malignant tumors from nonneoplastic lesions such as eosinophilic granuloma, inflammatory disease, and calcinosis circumscripta. Ultrasonography can be useful in delineating the margins of tongue masses to determine surgical resectability.¹³⁶ Regional lymph nodes should be aspirated for staging purposes and three-view thoracic radiographs evaluated for lung metastasis.

Surgical resection is recommended, whereas RT is reserved for melanomas, inoperable cancer, or tumors metastatic to the regional lymph nodes. Partial glossectomy of up to 60% of the tongue has been recommended for unilateral tumors not crossing the midline

*References 11, 13, 18, 19, 57, and 60.

or tumors confined to the rostral mobile portion of the tongue. However, 54% of canine tongue tumors are located in the midline or are bilaterally symmetrical, which limits the ability to achieve complete surgical resection.¹¹² Recently, 50% to 100% resection or avulsion of the tongue was reported in five dogs with minimal postoperative problems, which suggests more aggressive resections may be possible without compromising quality of life.¹³⁷ Feeding tubes are recommended for enteral nutrition during postoperative recovery but, in the long term, eating and drinking are usually only mildly impaired and good hydration and nutrition can be maintained postoperatively.^{134,137} Hypersalivation is the most common complaint following aggressive resections.¹³⁷ Thermoregulation can be a problem in hot and humid environments. Grooming in cats will be compromised and may result in poor hair-coat hygiene.

The prognosis for tongue tumors depends on the site, type, and grade of cancer.¹³⁴ Tongue SCCs in dogs are graded from I (least malignant) to III (most malignant) based on histologic features such as degree of differentiation and keratinization, mitotic rate, tissue and vascular invasion, nuclear pleomorphism, and scirrhous reaction.¹³⁴ The MST for dogs with grade I tongue SCC is 16 months following surgical resection, which is significantly better than the MSTs of 4 and 3 months reported for grade II and III SCC, respectively.¹³⁴ The 1-year survival rate is 50% following complete surgical resection and approaches 80% with complete histologic resection of low-grade SCC.¹³⁴ Cancer in the rostral (mobile) tongue has a better prognosis possibly because rostral lesions are detected at an earlier stage, the caudal tongue may have richer lymphatic and vascular channels to allow metastasis, and rostral tumors are easier to resect with wide margins. Long-term control of feline tongue tumors is rarely reported with 1-year survival rates for tongue SCC less than 25%.

Granular cell myoblastoma is a curable cancer.¹³⁸ These cancers may look large and invasive but are almost always removable by conservative and close margins (Figure 22-8). Permanent local control rates exceed 80%. They may recur late, but serial surgeries are usually possible. Metastasis is rare with this cancer. Local control in four of five tongue melanomas was obtained by surgery, and the metastatic rate was less than 50% in this small series.¹¹⁷ In another series of dogs with tongue melanoma, the MST was not reached and was greater than 551 days.⁷ The biologic behavior of other tongue cancers is generally unknown due to the rarity of these conditions.¹¹⁷

Undifferentiated Malignancy of Young Dogs

Undifferentiated malignancy is seen in dogs under 2 years of age (range: 6 to 22 months).¹³⁹ Most dogs are large breeds and there is no sex predilection. The disease is manifest by a rapidly growing mass in the area of the hard palate, upper molar teeth, maxilla, and/or orbit. Biopsies reveal an undifferentiated malignancy of undetermined histogenesis. The majority of dogs present with metastasis to the regional lymph nodes and distant sites beyond the head and neck. An effective treatment has not been identified, although chemotherapy would be necessary considering the high metastatic rate. Most dogs are euthanized within 30 days of diagnosis due to progressive and uncontrolled tumor growth.

Papillary SCC has been reported to occur in the oral cavity of very young dogs (2 to 5 months of age). Treatment recommendations include complete surgical resection or surgical cytoreduction and curettage followed by radiation (40 Gy in 20 fractions). Using

FIGURE 22-8 This large granular cell myoblastoma was easily removed surgically. The dog had a recurrence 2 years postoperatively, which was resected again, and the dog is tumor-free 3 years after the second surgery.

this latter combination therapy, no dog had metastasis and long-term control was achieved in all dogs for periods up to 4 years.¹⁴⁰

Multilobular Osteochondrosarcoma

Multilobular osteochondrosarcoma is an infrequently diagnosed bony and cartilaginous tumor that usually arises from the canine skull, including the mandible, maxilla, hard palate, orbit, and calvarium.^{23,24} Histologically, these tumors are characterized by multiple lobules with a central cartilaginous or bone matrix surrounded by a thin layer of spindle cells.^{23,24} On imaging, multilobular osteochondrosarcoma is characterized by a typical “popcorn” appearance (Figure 22-9). Surgery is recommended for management of the local tumor, although there are anecdotal reports that multilobular osteochondrosarcoma may also be responsive to RT. The overall rate of local recurrence following surgical resection is 47% to 58% and depends on completeness of surgical resection and histologic grade.^{23,24} The median DFI for completely resected multilobular osteochondrosarcoma is 1332 days and significantly better than the 330 days reported for incompletely excised tumors.²⁴ In terms of tumor grade, the local recurrence rate for grade III tumors is 78% and significantly worse than the recurrence rates of 30% and 47% for grade I and II multilobular osteochondrosarcoma, respectively.²⁴ This tumor has a moderate metastatic potential (usually to the lung), which is grade dependent, but usually occurs late in the

• **FIGURE 22-9** A CT image of a multilobular osteochondrosarcoma of the vertical ramus of the mandible. Note the characteristic “popcorn” appearance of the mass. Following resection of the vertical ramus, this dog was tumor-free 3 years after surgery.

course of disease. Metastasis is reported in up to 58% of dogs with the median time to metastasis of 426 to 542 days.^{23,24} Metastasis is significantly more likely following incomplete surgical resection, with a 25% metastatic rate in completely excised tumors and 75% following incomplete resection.²⁴ Tumor grade also has a significant impact on metastatic rate with metastasis reported in 78% of grade III multilobular osteochondrosarcoma compared to 30% of grade I and 60% of grade II tumors.²⁴ There is no known effective chemotherapy treatment for metastatic disease, but survival times greater than 12 months have been reported with pulmonary metastasectomy because of the slow-growing nature of this tumor.²⁴ The overall MST is 21 months and is grade dependent, with reported MSTs of 50 months, 22 months, and 11 months for grade I, II, and III tumors, respectively.^{23,24} Tumor location also has prognostic significance because the outcome for dogs with mandibular multilobular osteochondrosarcoma is significantly better with a MST of 1487 days compared to 587 days for these tumors at other sites.²⁴

Viral Papillomatosis

Viral papillomatosis is horizontally transmitted by a DNA viral agent (papovavirus) from dog to dog.¹⁴¹ Affected animals are generally young. The lesions appear wartlike and are generally multiple in the oral cavity, pharynx, tongue, or lips. A biopsy can be performed if necessary, but visual examination is usually diagnostic. Most patients never suffer any significant side effects of this disease, although an occasional dog will have such marked involvement as to require surgical or cryosurgical cyoreduction in order to permit swallowing. The majority of patients will undergo a spontaneous regression of disease within 4 to 8 weeks. For resistant cases, an immunodeficiency etiology is suggested and a wide variety of treatments have been attempted, including crushing lesions in situ to “release” viral antigens and using several immunomodulators, including autogenous vaccines, interleukins, levamisole,

• **FIGURE 22-10** An intraoral radiograph of the rostral mandible in a dog with an ameloblastoma. Note the smooth expansile mandibular mass. The tumor was curetted and filled with cancellous bone graft and the dog was tumor-free 1 year after surgery.

thiabendazole, imiquimod, and L-MTP-PE.¹⁴² However, these methods are seldom required or effective. Furthermore, autogenous vaccines are not recommended because malignant skin tumors have been reported at the site of inoculation.⁵⁶ The prognosis is usually excellent.

Odontogenic Tumors

Odontogenic tumors originate from epithelial cells of the dental lamina and account for up to 2.4% of all feline oral tumors.³ They are broadly classified into two groups depending on whether the tumors are able to induce a stromal reaction.¹⁴³ Inductive odontogenic tumors include ameloblastic fibroma, dentinoma, and ameloblastic, complex, and compound odontomas. Ameloblastomas and calcifying epithelial odontogenic tumors are examples of noninductive odontogenic tumors.¹⁴³

Inductive fibroameloblastoma is the most common odontogenic tumor in cats, usually occurs in cats less than 18 months of age, and has a predilection for the region of the upper canine teeth and maxilla.^{3,56,143-145} Radiographically the tumor site shows variable degrees of bone destruction, production, and expansion of the mandibular or maxillary bones (Figure 22-10). Teeth deformity is common. Smaller lesions are treated with surgical debulking and cryosurgery or premaxillectomy. Larger lesions will respond to

radiation. Local treatment needs to be aggressive, but control rates are good and metastasis has not been reported.^{3,56}

Odontomas are benign tumors arising from the dental follicle during the early stages of tooth development.¹⁴⁶ Odontomas induce both enamel and dentin within the tumor. Odontomas have a similar biologic behavior to ameloblastomas.

Dentigerous cysts are nonneoplastic, circumscribed cystic lesions originating from islands of odontogenic epithelium.¹⁴³ They contain one or more teeth embedded in the cyst wall. Radiographs show a characteristic radiolucent halo surrounding the nonerupted tooth originating at the cemento-enamel junction and enveloping the crown of the tooth.⁶⁵ Odontogenic cysts may represent an early stage of malignant epithelial tumors.¹⁴³ Surgical treatment is recommended, consisting of surgical removal of nonerupted teeth and the cyst lining with possible cancellous bone grafting, to prevent local tumor recurrence.⁶⁵

Eosinophilic Granulomas

Eosinophilic Granulomas in Dogs

Canine oral eosinophilic granulomas affect young dogs (1 to 7 years of age) and may be heritable in the Siberian husky and Cavalier King Charles spaniel.¹⁴⁷⁻¹⁴⁹ It is histologically similar to the feline disease, with eosinophils and granulomatous inflammation predominating. The granulomas typically occur on the lateral and ventral aspects of the tongue. They are raised, frequently ulcerated, and may mimic more malignant cancers in gross appearance. Treatment with corticosteroids or surgical excision is generally curative, although spontaneous regression may occur. Local recurrences are uncommon.

Eosinophilic Granuloma in the Cat

Eosinophilic granuloma, a condition also known as rodent ulcer or indolent ulcer, occurs more commonly in female cats with a mean age of 5 years.¹⁵⁰⁻¹⁵³ The etiology is unknown. Any oral site is at risk, but it is most common on the upper lip near the midline (Figure 22-11). The history is usually that of a slowly progressive (months to years) erosion of the lip. Biopsies are often necessary to differentiate the condition from true cancers.

Various treatments are proposed, including (in order of author preference): oral prednisone at 1 to 2 mg/kg twice a day (BID) for 30 days or subcutaneous methylprednisolone acetate* at 20 mg/cat every 2 weeks, megestrol acetate,† hypoallergenic diets, RT, surgery, immunomodulation, or cryosurgery. The prognosis for complete and permanent recovery is fair, although rare cases may undergo spontaneous regression.

Nasopharyngeal Polyps in Cats

Nasopharyngeal polyps are nonneoplastic, inflammatory masses originating from either the middle ear or eustachian tube and can extend into the external ear canal or nasopharynx.^{154,155} Young cats are usually affected, with a mean age of 13.6 months in one series of 31 cats.^{154,156} The cause is unknown, but a viral etiology and congenital abnormality of the branchial arches have been suggested.¹⁵⁵ Clinical signs include sneezing, change in voice, swallowing problems, rhinitis, and difficulty in breathing. Firm, fleshy masses can be seen or palpated in the caudal pharynx or above the soft palate. Occasionally, masses can be visualized in the external ear canal.^{157,158} Radiographs or advanced imaging of the skull may reveal fluid or tissue in the tympanic bullae.¹⁵⁹ Traction on the stalk

• **FIGURE 22-11** An extensive eosinophilic granuloma in a cat involving the lips and hard palate. These lesions can appear aggressive and similar to malignant oral tumors such as squamous cell carcinomas (SCCs). An incisional biopsy is often required to differentiate this benign nonsurgical disease from malignant diseases.

of the inflammatory polyp, either through the oral cavity or external ear canal depending on accessibility, is recommended for initial treatment of inflammatory polyps. However, recurrences have been reported in four of eight cats treated with this method alone.¹⁵⁴ A ventral bulla osteotomy is recommended for cats with either recurrent inflammatory polyps or evidence of tympanic bulla involvement on skull imaging. Less than 4% of cats have recurrence of inflammatory polyps following bulla osteotomy.^{154,158,160}

Comparative Aspects¹⁶¹

SCC accounts for the vast majority of oral cancer in humans. Oral tumors are associated with alcohol and tobacco use and usually occur in patients over 40 years old. Patients with oral cancer have an increased risk of developing esophageal and lung cancer. Tumors are staged similar to animals and clinical stage influences both treatment options and prognosis.

Surgery and RT are the only options that provide the opportunity for a cure. Surgery and radiation are occasionally combined, especially since neither modality is likely to achieve a cure rate greater than 70% when used as sole therapy. Chemotherapy has a limited role for control of local disease but has shown promise, often in combination with radiation, for advanced-stage cancer.

Prognosis is strongly correlated to histologic grade, stage, and site. Metastasis, particularly to the regional lymph nodes, is more frequent with tonsillar and pharyngeal SCC and larger sized tumors. Tumors of the pharynx and caudal tongue are associated with a worse prognosis than cancers of the rostral tongue and oral cavity

because of the higher incidence of nodal metastasis and difficulty in controlling disease once it has spread beyond the primary site.

SECTION B

Salivary Gland Cancer

STEPHEN J. WITHROW

Incidence and Risk Factors

Primary salivary gland cancer is rare in the dog and cat. Most cases are reported in older patients (10 to 12 years of age), and no specific breed or sex predilection has been determined in dogs.¹⁻³ The Siamese cat may be at higher risk than other breeds, with male cats being affected twice as often as female cats.⁴

Pathology

The vast majority of salivary cancers are adenocarcinomas, but a wide range of specific histologic types including osteosarcoma, mast cell tumor, sebaceous carcinoma, oncocytoma, and malignant fibrous histiocytoma have been reported.^{1,5-9} They can arise from major (parotid, mandibular, sublingual, zygomatic) or minor accessory glands throughout the oral cavity. Of 245 submissions of salivary tissue for histologic diagnosis in both species, 30% were neoplastic.³ Benign salivary gland tumors, including pleomorphic adenoma, are rare in animals^{10,11} compared to humans. The mandibular gland is most commonly affected.^{3,4} Malignancies are variably locally invasive, and metastasis to regional lymph nodes is common (39% for cats and 17% for dogs).^{4,12} Distant metastasis has been reported (16% for cats and 8% for dogs at presentation) but may be slow to develop.^{4,13} Benign lipomatous infiltration of the canine salivary gland has also been reported, and surgical excision was curative in all treated cases.^{14,15}

History and Clinical Signs

Symptoms are nonspecific and generally include halitosis, dysphagia, exophthalmus, or a unilateral, firm, painless swelling of the upper neck (mandibular and sublingual), base of the ear (parotid), upper lip or maxilla (zygomatic), or mucous membrane of the lip or tongue (accessory salivary tissue). Major differential diagnoses are mucocoeles, abscesses, salivary gland infarction, sialadenitis, lymphoma, or reactive or metastatic lymphadenopathy.^{3,16}

Diagnostic Techniques and Work-Up

Fine-needle aspiration (FNA) cytology of masses in these locations should help differentiate noncancer diseases from cancer. Regional radiographs will usually be normal but may reveal periosteal reaction on adjacent bones or displacement of surrounding structures. CT imaging may be helpful in determining extent of disease and infiltration into surrounding structures. Needle core or wedge biopsies will usually be necessary to make a definitive diagnosis.

Therapy

When possible, aggressive surgical removal should be performed. Unfortunately, many lesions are extracapsular and widely extensive throughout the regional area, which contains numerous vital structures. However, complete extirpation of the ipsilateral neck can be performed with good functional outcome. The primary clinical

impairment after a “radical” neck resection is the inability to blink the eye, which can be managed with a tarsorrhaphy or eye drops. If this surgery can be performed to the level of microscopic residual disease and RT is planned postoperatively, this complication is acceptable.

Postoperative RT resulted in good local control and prolonged survival in three reported cases.⁶ Chemotherapy for salivary gland adenocarcinoma has been largely unreported.

Prognosis

The prognosis for salivary gland cancer is generally unknown. Clinical experience on a limited number of cases would indicate that aggressive local resection (usually histologically incomplete) followed by adjuvant radiation can attain permanent local control and long-term survival.^{4,17} Incomplete removal will invariably result in local recurrence.² Histologic grade was not prognostic for outcome, whereas advanced stage was a negative prognosticator.⁴ Median survival for 24 dogs and 30 cats treated with surgical resection with or without adjuvant radiation was 550 and 516 days, respectively.⁴ The prognosis for long-term survival for cats is worse than for dogs.^{4,18} Another report of six dogs with salivary carcinoma treated with surgery alone had a median survival of only 74 days, and all six dogs developed pulmonary metastasis.¹⁹

Comparative Aspects²⁰

Salivary gland tumors are more common in older humans than in animals and account for 4% of head and neck neoplasms. The parotid gland is most commonly affected. A wide variety of benign and malignant neoplasms are recognized. Treatment is with surgical excision, and radiation is utilized for inoperable disease or after incomplete removal. Five-year survival usually exceeds 75% but depends on stage and histologic type.

SECTION C

Esophageal Cancer

STEPHEN J. WITHROW

Incidence and Risk Factors

Cancer of the esophagus is very rare and accounts for less than 0.5% of all cancer in the dog and cat.¹ Sarcomas, secondary to *Spirocerca lupi* infestation, have been reported in indigenous areas (Africa, Israel, and the southeastern United States).^{2–5} No cause is known for the more common carcinomas. Most animals are older, and no gender or breed predilection is evident.

Pathology and Natural Behavior

The more commonly reported histologic types include SCC, leiomyosarcoma, fibrosarcoma, and osteosarcoma. Rarely, benign neoplasms such as leiomyoma, adenomatous polyp,⁶ and plasmacytoma may be encountered, especially in the area of the terminal esophagus and cardia.^{7–10} Paraesophageal tumors such as thymic, heart base, or thyroid may also invade the esophagus.¹ In cats, SCCs are usually seen in females and are located in the middle third of the esophagus just caudal to the thoracic inlet.^{10–13} Most esophageal cancers are locally invasive, and metastasis is to draining lymph nodes, direct extension, or hematogenously to distant sites.

History and Clinical Signs

Signs other than those of general debilitation and weight loss include pain on swallowing, dysphagia, and regurgitation of undigested food. Pneumonia, secondary to aspiration, may also be

noted. Hypertrophic osteopathy has been reported, especially with *Spirocerca lupi*-induced sarcomas.^{2,4} *Spirocerca* usually affects the caudal thoracic esophagus and can be associated with thoracic spondylitis and a microcytic hypochromic anemia and a neutrophilia.^{3,4}

Diagnostic Techniques and Work-Up

It is generally evident from the history that the patient is suffering from a partial or complete upper gastrointestinal (GI) obstruction. Plain radiographs may reveal retention of gas within the esophageal lumen, a mass, or esophageal dilatation proximal to the cancer. A positive-contrast esophagogram with or without fluoroscopy will generally reveal a stricture or mass lesion in the lumen. Esophagoscopy allows visualization of the lesion, which is frequently ulcerated. Several biopsies should be taken because necrosis and inflammation are often prominent. The risk of esophageal perforation during the biopsy is generally minimal. Leiomyomas appear as circumscribed submucosal masses, with a normal and freely movable mucosa making endoscopic biopsy unrewarding. Advanced imaging such as CT or MRI may be helpful to determine extent of the lesion, especially when minimal mucosal involvement is evident on endoscopic evaluation.

Open surgical biopsy via thoracotomy or cervical exploration is another option to obtain tissue for a diagnosis. *Spirocerca lupi* ova may be detected in the feces.³

Therapy

Therapy for malignant cancer of the esophagus is difficult at best because of the advanced stage of disease in most cases.¹⁴ Intrathoracic resections are further complicated by poor exposure, lengthy resections, tension on the anastomosis, and unique healing problems of the thoracic esophagus. Low-grade leiomyosarcomas can be marginally excised with successful outcomes. They generally do not invade the mucosa and the muscular defect in the esophageal wall can be plicated with good postoperative function.¹⁵ For lesions in the caudal esophagus or cardia, gastric advancement through the diaphragm can be considered but carries a high complication rate, including reflux esophagitis.

Various procedures to partially replace the resected esophagus have been described, including microvascular transfer of colon or small bowel, but clinical reports on their use in the cancer patient are lacking.^{16–18} Chemotherapy has rarely been attempted. RT for the cervical esophagus can be attempted but is of limited value for the intrathoracic esophagus because of the poor tolerance of surrounding normal tissues such as the lung and heart. Short-term palliation can be achieved via esophagotomy or gastrostomy tubes. Benign leiomyomas of the esophagus or cardia can be approached via thoracotomy or celiotomy.⁹

Prognosis

Except for benign lesions,^{7,8} lymphoma, or low-grade leiomyosarcoma,¹⁵ the prognosis for esophageal tumors (primarily carcinomas) is very poor for cure or palliation due to poor resection options and high metastatic rate. One report describes a series of six dogs treated with partial esophagectomy for esophageal sarcomas associated with *Spirocerca*. Five of the six also received doxorubicin, and the median survival was 267 days.¹⁹

Comparative Aspects²⁰

Esophageal cancer (principally SCC) is rare in humans but still accounts for 7000 deaths per year in the United States. Marked geographic variance in worldwide incidence implies numerous environmental influences on development, including tobacco, alcohol, hot food, and nitrosamines.

Most esophageal cancers have extensive local tumor growth and lymph node involvement precluding curative treatment. Combinations or single use of surgery, radiation, and chemotherapy have resulted in 5-year survivals of less than 20% of the more common advanced-stage disease. A variety of palliative bypass procedures for inoperable disease are also performed (esophagogastrostomy, intraluminal intubation, dilatation, and feeding gastrostomies).

■ SECTION D

Exocrine Pancreatic Cancer

STEPHEN J. WITHROW

Incidence and Risk Factors

Cancer of the exocrine pancreas is very rare (<0.5% of all cancers) in the dog and the cat.^{1,2} Older female dogs and spaniels have been described as being at higher risk.^{3–5} Experimentally, N-ethyl-N'-nitro-N-nitrosoguanidine has been shown to induce pancreatic duct adenocarcinoma when administered intraductally in dogs.⁶

Pathology and Natural Behavior

Almost all cancers of the pancreas are epithelial and most are adenocarcinoma of ductular or acinar origin. Nodular hyperplasia is a common asymptomatic finding in older dogs or cats. "Benign" pancreatic pseudocysts and adenomas have been diagnosed by ultrasonography or surgery in dogs and cats.^{2,7} In the vast majority of cases, malignant cancer has metastasized to regional or distant sites before a diagnosis can be made.^{1,4,8}

History and Clinical Signs

The history and clinical signs of exocrine pancreatic cancer are vague and nonspecific and may mimic or be accompanied by pancreatitis. Weight loss and anorexia (marked in cats), paraneoplastic alopecia in cats,^{9,10} vomiting, rare associated diabetes mellitus,¹¹ abdominal distension due to mass effect or abdominal effusions secondary to tumor implantation on the peritoneum (i.e., carcinomatosis; common in cats), icterus (with common bile duct obstruction), and depression are common symptoms. Alternatively, patients may present for symptoms of metastatic disease.

Diagnostic Techniques and Work-Up

Most hematologic and biochemical evaluations are nonspecific but may include mild anemia, hyperglycemia, neutrophilia, and bilirubinemia (if occluding the common bile duct).^{1,2} Elevations of serum amylase and lipase are inconsistent.¹² In extreme cases, signs of pancreatic insufficiency may be exhibited.¹³ Positive-contrast upper GI radiographs may reveal slowed gastric emptying and occasionally compression or invasion of the duodenum.

Ascites may be a clinical sign and, when present, may reveal malignant cells on cytologic examination (carcinomatosis). Flow cytometry can be considered to help distinguish malignant from nonmalignant abdominal effusions. In the dog, most tumors are not palpable through the abdominal wall. In the cat, late stage, large palpable masses may be present.

Ultrasonography should be a useful diagnostic tool for localization of the primary tumor, documentation, and aspiration of fluid, as well as metastasis to liver and regional lymph nodes.¹⁴ A large (>2 cm), apparently single mass is suggestive of pancreatic cancer versus nodular hyperplasia in cats.¹⁵ The utility of advanced imaging such as CT and MRI has not been documented for pancreatic tumors in veterinary patients. At present, most diagnoses are made at exploratory laparotomy.

Therapy

Most non-islet cell carcinomas of the pancreas are metastatic (regional lymph nodes and liver) or locally and extensively invasive at the time of diagnosis. If the liver, peritoneal cavity, or draining lymph nodes are positive for tumor, aggressive surgery should generally not be performed. Complete pancreatectomy or pancreaticoduodenectomy (Whipple's procedure) has been described in humans and dogs,¹⁶ but it carries a high operative morbidity and mortality without significant cure rates. Palliative GI bypass (gastrojejunostomy) is a short-term option if bowel obstruction is imminent. Radiation and chemotherapy have shown limited value in humans and animals. Occasionally, uncomfortable effusions from carcinomatosis can be diminished with systemic or intracavitary chemotherapy (see Chapter 11); however, the palliative response tends to be short lived.

Prognosis

The outlook for this disease in animals is very poor due to its critical location and advanced stage at diagnosis. One-year survival after diagnosis, regardless of treatment, has not been reported.

Comparative Aspects¹⁷

Pancreatic exocrine carcinoma accounts for more than 27,000 deaths per year in the United States. Most patients have disease progression beyond the pancreas at the time of initial diagnosis. Seventy-five percent are located in the head of the pancreas and the remainder in the body and tail. Direct extension to duodenum, bile duct, and stomach, as well as common metastasis to lymph node and liver, make treatment difficult.

When possible, pancreaticoduodenectomy (Whipple's procedure) or complete pancreatectomy are the treatments of choice. However, operative mortality ranges from 5% to 30%. Palliative bypass of the biliary tree and duodenum is commonly performed for inoperable lesions.

Traditional external beam RT is generally palliative rather than curative. Intraoperative and interstitial radiation are being explored as means for high-dose delivery to the tumor while sparing normal radiosensitive structures.^{18,19} Chemotherapy alone (especially the taxols and gemcitabine) or in combination with radiation or surgery has demonstrated some improvement in quality of life, yet only very modest improvements in survival. Overall, 5-year survival for all patients remains less than 5%.

SECTION E

Gastric Cancer

STEPHEN J. WITHROW

Incidence and Risk Factors

Gastric cancer is more common than esophageal cancer but still accounts for less than 1% of all malignancies. No definitive etiology is known, although long-term administration of nitrosamines may induce carcinomas in dogs.¹ Several articles have described a high incidence of gastric carcinoma in related Belgian shepherds, Norwegian lundehunds, and Dutch Tervueren shepherd dogs, implying a genetic mechanism in development of this disease.^{2–5} The average age of affected carcinoma patients is 8 years, with a 2.5:1 male-to-female ratio.^{6,7} Males are also more commonly affected with gastric lymphoma than females.⁸ Leiomyomas tend to occur in very old dogs (average age 15 years).^{9,10} Chronic gastritis, *Helicobacter*, and common descent have been implicated in feline gastric cancer.^{11,12}

Pathology and Natural Behavior

Adenocarcinoma accounts for 70% to 80% of cancer of the canine stomach.¹³ It is often scirrhous (firm and white on the serosal surface) and has been termed *linitis plastica* (leather bottle) because of its firm and nondistensible texture. Lesions can be diffusely infiltrative, expansile (often with a central crater and ulceration), or may look more polypoid.¹⁴ Other reported malignancies include leiomyosarcoma,¹⁵ lymphoma,⁸ mast cell tumor,¹⁶ extramedullary plasmacytoma,^{17,18} and fibrosarcoma. GI stromal tumors (GISTs) have been described in the GI tract of the dog, with 20% occurring in the stomach, and were likely previously classified as leiomyomas.^{19–21} In humans and in approximately 50% of cases in dogs, GISTs express CD117 (c-kit), a tyrosine kinase receptor, and mutations in c-kit likely play a role in tumorigenesis of this cancer.¹⁹ In one series, one-third of GISTs in dogs had metastasized at the time of diagnosis.¹⁹ Adenocarcinoma will frequently spread to regional lymph nodes (70% to 80% at necropsy) followed by liver and lung.^{2,7,12,16} An unusual occurrence of metastasis of gastric adenocarcinomas to the testes has been reported in three dogs.²² Adenocarcinomas have been described as diffuse or interstitial, but little clinical significance can be associated with these variants.^{7,23} The tumor antigen C2-O-sLe(X) is unregulated in canine gastric carcinoma and may play a role in the metastatic potential.²⁴ Benign lesions are generally leiomyomas, hypertrophic gastropathy, hamartomas,²⁵ or adenomas.^{10,26–31} Feline gastric adenocarcinoma is rare, and the stomach is the least commonly affected GI site in the cat.^{31,32} Lymphoma is the most common gastric tumor in the cat and may be solitary or one component of systemic involvement. Most cats with gastric lymphoma are negative for feline leukemia virus (FeLV).

History and Clinical Signs

The most common history is one of progressive vomiting (often blood tinged or “coffee grounds” in nature), anorexia, and weight loss. The weight loss may be a result of poor digestion, loss of protein and blood from an ulcer, or generalized tumor cachexia. Duration of symptoms is from weeks to many months.

Diagnostic Techniques and Work-Up

Routine laboratory tests and noncontrast radiographs are generally not diagnostic. Hypoglycemia may be a paraneoplastic syndrome associated with leiomyomas or leiomyosarcomas.^{33,34} A microcytic hypochromic anemia is common. Occult blood in the feces may be detected. Liver “enzymes” may be elevated because of hepatic metastasis or obstruction of the common bile duct. Elevated gastrin levels are occasionally detected.^{5,35} Thoracic radiographs are only rarely positive for metastasis at the time of initial presentation.

Positive- or double-contrast gastric radiographs may reveal a mass lesion extending into the lumen (Figure 22-12). Ulceration is also a common sign. Delayed gastric emptying, poor motility, or delayed adherence of contrast material to an ulcerated tumor may also be detected. Fluoroscopy may aid in determining motility alterations. Ultrasonography may also be a useful imaging modality in concert with fine-needle or needle core biopsy.^{36,37} Ultrasound was of diagnostic utility in 27% of dogs with gastric adenocarcinoma of gastric lymphoma.³⁸ Malignancies tend to be sessile, and adenocarcinoma tends to occur most commonly on the lesser

• **FIGURE 22-12** Ventrodorsal view of a dog with gastric cancer. Note the filling defect and partial outflow obstruction of gastric antrum and pylorus.

• **FIGURE 22-13** Gross specimen of the stomach from a dog with gastric adenocarcinoma. Note the large ulcer and fibrous thickening of stomach wall in area of gastric antrum (arrows). This patient had metastasis to regional lymph nodes and liver.

curvature and gastric antrum (Figure 22-13). Benign lesions may be pedunculated or well circumscribed. Leiomyomas often occur at the cardia and will grow into the lumen as a smooth circumscribed mass.¹⁰

Gastroscopy with a flexible endoscope will generally reveal larger lesions that can be biopsied.^{39,40} Several “large” samples should be taken because most gastric tumors have superficial necrosis, inflammation, and ulceration. Endoscopic biopsies were more likely to detect gastric lymphoma than intestinal lymphoma

in cats.⁴¹ In some patients, the gastric lesions are submucosal only, making endoscopic biopsy difficult. False-negative biopsies through the gastroscope are common. Open surgical biopsy is the most definitive method of diagnosis. For suspected GIST tumors, a CD117 immunohistochemical stain should be applied for confirmation.

Therapy

Except for lymphoma, surgery is the most common form of treatment for gastric cancer. As with esophageal cancer, curative resection is complicated by advanced stage disease in a difficult operative area (lesser curvature, antrum, and pylorus) with a frequently debilitated patient. At the time of surgery, a careful evaluation of liver and regional lymph nodes should be made to adequately stage the cancer. Lymph node metastasis can be quite varied, and all abdominal lymph nodes should be examined. If the cancer is felt to be localized to the stomach at laparotomy, a curative resection may be attempted. If possible, wide partial gastrectomy or antrectomy followed by a gastroduodenostomy (Billroth I) should be performed because of the increased morbidity associated with more extensive surgery such as gastrectomy and gastrojejunostomy (Billroth II).^{42,43} Lesions requiring biliary bypass and very extensive surgery (complete gastrectomy) are generally too advanced to make these procedures worthwhile in terms of survival. For obstructive lesions felt to be inoperable for cure or for those that are metastatic, it is possible to perform a palliative gastrojejunostomy to allow passage of food into the intestine, although this procedure may be associated with significant postoperative morbidity.⁴²

Leiomyomas are usually discrete, solitary lesions in the area of the cardia. They are not premalignant but can cause symptoms because of a mass effect. They can be easily “shelled out” via a midline laparotomy, gastrotomy, and submucosal removal or via intercostal thoracotomy if the side of the lesion can be clearly delineated.¹⁰ In humans, GIST tumors may be responsive to inhibitors of c-Kit (e.g., toceranib, imatinib). The recent development of these agents in veterinary oncology could theoretically have efficacy for this tumor.

RT is rarely utilized due to the poor radiation tolerance of surrounding normal tissue (liver and intestine). Nonresectable lymphoma may be dramatically reduced with lower doses of irradiation than required for other tumors. No effective chemotherapy is known for adenocarcinoma.

Lymphoma may be excised if localized but does not generally respond well to conventional chemotherapy, although several exceptions exist in cats with gastric lymphoma (see Chapter 32, Section B).^{8,44} The need for postoperative chemotherapy after “complete” resection of lymphoma is unknown.

Prognosis

The prognosis for most malignant gastric cancer is poor. Even if surgery can be performed, most patients are dead within 6 months as a result of recurrent or metastatic cancer.^{3,11,45-49} In a series of 24 dogs undergoing pylorotomy and gastroduodenostomy, the perioperative mortality was 24% with a MST of 33 days. Preoperative weight loss was a negative indicator of outcome.⁴³ Few adenocarcinoma patients are operable for cure, and the short-term morbidity with radical resection can be high. Of 17 dogs treated with surgery for gastric adenocarcinoma, the median survival was 2 months.¹¹ Rare cases have survived as long as 3 years.³ Palliation via bypass can be achieved for 1 to 6 months. The median survival for seven

dogs with gastric leiomyosarcoma that lived at least 2 weeks post-operatively was 1 year.¹⁵ Another paper suggested median survivals for GI leiomyosarcomas, or GISTs, of 8 to 12 months.²¹ The hypoglycemia seen with some smooth muscle tumors is reversible after tumor resection. Patients with benign lesions can be cured with complete surgical excision.^{10,50,51} Gastric extramedullary plasmacytomas appear to carry an excellent prognosis with surgery and chemotherapy. GI mast cell tumors were usually metastatic to regional nodes, and fewer than 10% of patients survived 6 months.¹⁶⁻¹⁸

Comparative Aspects⁵²

Gastric cancer is the sixth most common cause of cancer death in humans. Adenocarcinoma constitutes over 90% of all malignant gastric cancer. Multiple socioeconomic, geographic, and environmental factors are associated with risk of tumor development. *Helicobacter* has been associated with the development of human gastric carcinoma and lymphoma but has not been correlated with carcinogenesis in the dog or cat, even though the organism is prevalent in the species.

Most lesions will be firm, ulcerative, and located in the antrum or lower third of the stomach, as in the dog. Most lesions are detected late in the course of disease and have direct tumor extension to surrounding organs, lymph node metastasis, or systemic metastasis, as with the dog.

Treatment is with surgical resection when possible or with less effective radiation and chemotherapy. Five-year survival for all patients is less than 10%, with a 30% survival for patients deemed operatively to have "localized" disease.

SECTION F

Hepatobiliary Tumors

JULIUS M. LIPTAK

Incidence and Risk Factors

Primary hepatic tumors are uncommon and account for less than 1.5% of all canine tumors and 1.0% to 2.9% of all feline tumors, but up to 6.9% of nonhematopoietic tumors in cats.^{1–4} Metastasis to the liver from nonhepatic neoplasia is more common and occurs 2.5 times more frequently than primary liver tumors in dogs, particularly from primary cancer of the spleen, pancreas, and GI tract.^{1,2} Primary hepatobiliary tumors are more common than metastatic disease in cats.⁴ The liver can also be involved in other malignant processes, such as lymphoma, malignant histiocytosis, and systemic mastocytosis.^{2,3} Nodular hyperplasia is a relatively common diagnosis in older dogs but is benign and probably does not represent a preneoplastic lesion.⁴

• **FIGURE 22-14** A solitary hepatic leiomyosarcoma with classic massive liver tumor morphology.

• **TABLE 22-7** Morphologic Types of Canine Hepatic Tumors

	MASSIVE (%)	NODULAR (%)	DIFFUSE (%)
Hepatocellular carcinoma	53-84	16-25	0-19
Bile duct carcinoma	37-46	0-46	17-54
Neuroendocrine tumor	0	33	67
Sarcoma	36	64	0

There are four basic categories of primary malignant hepatobiliary tumors in cats and dogs: hepatocellular, bile duct, neuroendocrine (or carcinoid), and mesenchymal.⁴ Malignant tumors are more common in dogs, whereas benign tumors occur more frequently in cats.^{2–8} There are three morphologic types of these primary hepatic tumors: massive, nodular, and diffuse (Table 22-7).⁵ Massive liver tumors are defined as a large, solitary mass confined to a single liver lobe (Figure 22-14); nodular tumors are multifocal and involve several liver lobes (Figure 22-15); and diffuse involvement may represent the final spectrum of neoplastic disease with multifocal or coalescing nodules in all liver lobes or diffuse effacement of the hepatic parenchyma (Figure 22-16).^{4,5}

The prognosis for cats and dogs with liver tumors is determined by histology and morphology. The prognosis is good for massive hepatocellular carcinoma (HCC) and benign tumors because complete surgical resection is possible and their biologic behavior is relatively nonaggressive.^{7–11} In contrast, the prognosis is poor for cats with any type of malignant tumor, dogs with malignant tumors other than massive HCC, and cats and dogs with nodular and diffuse liver tumors because metastasis is more common.^{2–14}

Pathology and Natural Behavior

Hepatocellular Tumors

Hepatocellular tumors include HCC, hepatocellular adenoma (or hepatoma), and hepatoblastoma.⁴ Hepatoblastoma is a rare tumor of primordial hepatic stem cells and has only been reported in one dog.¹⁵ Hepatocellular adenoma is usually an incidental finding and

• **FIGURE 22-15** Nodular morphologic appearance of a bile duct carcinoma in a cat.

• **FIGURE 22-16** Diffuse morphologic appearance in a dog with a bile duct carcinoma.

rarely causes clinical signs.² Of the hepatocellular tumors, hepatocellular adenoma is more common in cats and HCC occurs more frequently in dogs.^{2,5,6}

HCC is the most common primary liver tumor in dogs, accounting for 50% of cases, and second most common in cats.²⁻⁸ Etiologic factors implicated in the development of HCC in humans include infection with hepatitis virus B or C and cirrhosis.¹⁶ A viral etiology has also been demonstrated in woodchucks but not in cats or dogs, and cirrhosis is rare in dogs with HCC.⁶⁻⁹ In one study, 20% of dogs with HCC were diagnosed with additional tumors although most were benign and endocrine in origin.⁵

A breed and sex predisposition has not been confirmed in dogs with HCC, but miniature schnauzers and male dogs are overrepresented in some studies.^{5,9,11,17} Morphologically, 53% to 83% of HCCs are massive (Figure 22-17), 16% to 25% are nodular, and up to 19% are diffuse.^{2,5} The left liver lobes, which include the left lateral and medial lobes and papillary process of the caudate lobe, are involved in over two-thirds of dogs with massive HCC.^{5,9-11} Metastasis to

• **FIGURE 22-17** Liver lobectomy of a massive hepatocellular carcinoma using a thoracoabdominal surgical stapling device.

• **FIGURE 22-18** Intraoperative image of a bile duct cystadenoma in a cat. Surgical resection was curative in this cat.

regional lymph nodes, peritoneum, and lungs is more common in dogs with nodular and diffuse HCC.^{2,5,9} Other metastatic sites include the heart, kidneys, adrenal glands, pancreas, intestines, spleen, and urinary bladder.^{2,5,9} The metastatic rate varies from 0% to 37% for dogs with massive HCCs and 93% to 100% for dogs with nodular and diffuse HCCs.^{2,5-11}

Bile Duct Tumors

Bile Duct Adenoma (Biliary Cystadenoma)

There are two types of bile duct tumors in cats and dogs: bile duct adenoma and carcinoma.^{2,5-8,12,13,18-22} Bile duct adenomas are common in cats, accounting for more than 50% of all feline hepatobiliary tumors, and are also known as biliary or hepatobiliary cystadenomas due to their cystic appearance (Figure 22-18).^{6-8,18-20} Male cats may be predisposed.^{18,20} Bile duct adenomas usually do not cause clinical signs until they reach a large size and compress adjacent organs.¹⁸⁻²⁰ There is an even distribution between single and multiple lesions.^{6-8,18-20} Malignant transformation has been reported in humans and anaplastic changes have been observed in some feline adenomas.^{6,18}

• **FIGURE 22-19** Lung metastasis in the cat with bile duct carcinoma depicted in Figure 22-15. This cat also had diffuse peritoneal metastasis.

Bile Duct Carcinoma (Cholangiocarcinoma)

Bile duct carcinoma is the most common malignant hepatobiliary tumor in cats and the second most common in dogs.^{2,5-8} Bile duct carcinomas account for 22% to 41% of all malignant liver tumors in dogs.^{5,23} In humans, trematode infestation, cholelithiasis, and sclerosing cholangitis are known risk factors for bile duct carcinoma.²⁴ Trematodes may also be involved in the etiology of bile duct carcinoma in cats and dogs, but they are unlikely to be a major contributor because bile duct carcinomas also occur in geographic regions outside the normal distribution of trematodes.^{4,8,13}

A predilection for Labrador retrievers has been proposed.¹³ A sex predisposition has been reported for female dogs.^{5,12,17} In cats, however, the sex predisposition is conflicting, with both male and female cats reported to be predisposed.⁶⁻⁸ The distribution of morphologic types of bile duct carcinoma is similar to HCC, with 37% to 46% massive, up to 54% nodular (see Figure 22-15), and 17% to 54% diffuse.^{2,5,12,13} Bile duct carcinomas can be intrahepatic, extrahepatic, or within the gall bladder.^{2,5-8,12,13} Intrahepatic carcinomas are more common in dogs,^{5,12,13} whereas an equal distribution of intrahepatic and extrahepatic tumors to extrahepatic predominance has been reported in cats.⁶⁻⁸ Solid and cystic (or cystadenocarcinoma) bile duct carcinomas have been reported, but this distinction does not influence either treatment or prognosis.¹² Bile duct carcinoma of the gall bladder is rare in both species.^{2,5-8,12,13}

Bile duct carcinomas have an aggressive biologic behavior. Metastasis is common in dogs, with up to 88% metastasizing to the regional lymph nodes and lungs (Figure 22-19)—other sites include the heart, spleen, adrenal glands, pancreas, kidneys, and spinal cord.^{2,5,12,13} In cats, diffuse intraperitoneal metastasis and carcinomatosis occur in 67% to 80% of cases.⁶⁻⁸

Neuroendocrine Tumors

Neuroendocrine tumors, also known as carcinoids, are rare in cats and dogs.^{2,5-8,25} These tumors arise from neuroectodermal cells and are histologically differentiated from carcinomas with the use of

silver stains.^{3,14} Neuroendocrine hepatobiliary tumors are usually intrahepatic, although extrahepatic tumors have been reported in the gall bladder.^{14,21,22,25} Carcinoids tend to occur at a younger age than other primary hepatobiliary tumors.^{5,14} Morphologically, carcinoids are nodular in 33% and diffuse in the remaining 67% of cases.^{5,14} Primary hepatic neuroendocrine tumors have an aggressive biologic behavior with frequent involvement of more than one liver lobe and metastasis to the regional lymph nodes, peritoneum, and lungs in cats and dogs.^{5,14,25} Other metastatic sites include the heart, spleen, kidneys, adrenal glands, and pancreas.¹⁴

Sarcomas

Primary and nonhematopoietic hepatic sarcomas are rare in cats and dogs.^{2,5-8,24} The most common primary hepatic sarcomas are hemangiosarcoma, leiomyosarcoma (see Figure 22-14), and fibrosarcoma, with hemangiosarcoma the most frequently diagnosed primary hepatic sarcoma in cats and leiomyosarcoma the most common in dogs.* The liver is a common site for metastatic hemangiosarcoma in dogs, whereas only 4% to 6% of hemangiosarcomas occur primarily in the liver.^{28,29} Other primary hepatic sarcomas include rhabdomyosarcoma, liposarcoma, osteosarcoma, and malignant mesenchymoma.²⁻⁸ The liver, with lungs, lymph nodes, spleen, and bone marrow, is commonly involved in dogs with disseminated histiocytic sarcoma.^{30,31} Benign mesenchymal tumors such as hemangiomas are rare.²⁻⁸ There are no known breed predispositions, although a male predilection has been reported.⁵ Diffuse morphology has not been reported with massive and nodular types accounting for 36% and 64% of sarcomas, respectively.^{5,24} Hepatic sarcomas have an aggressive biologic behavior, with metastasis to the spleen and lungs reported in 86% to 100% of dogs.^{5,24}

Other Primary Hepatic Tumors

Myelolipoma is a benign hepatobiliary tumor in cats.^{3,4} Histologically, myelolipomas are composed of well-differentiated adipose tissue intermixed with normal hematopoietic elements.⁴ Chronic hypoxia has been proposed as an etiologic factor because myelolipomas have been reported in liver lobes entrapped in diaphragmatic herniae.⁴ Myelolipomas can be either single or multifocal.⁴

History and Clinical Signs

Hepatobiliary tumors are symptomatic in approximately 50% of cats and 75% of dogs, especially in animals with malignant tumors.¹⁻¹⁵ The most common presenting signs are nonspecific, such as inappetence, weight loss, lethargy, vomiting, polydipsia-polyuria, and ascites.¹⁻¹⁵ Weakness, ataxia, and seizures are uncommon and may be caused by hepatic encephalopathy, paraneoplastic hypoglycemia, or central nervous system metastasis.^{5,9,32} Icterus is more common in dogs with extrahepatic bile duct carcinomas and diffuse neuroendocrine tumors.^{2,5,12} Hemoperitoneum secondary to rupture of massive HCC has been reported in two dogs.³³ However, these symptoms rarely assist in differentiating primary and metastatic liver tumors from nonneoplastic hepatic diseases.³ Physical examination findings can be equally unrewarding. A cranial abdominal mass is palpable in up to three-quarters of cats and dogs with liver tumors, although palpation can be misleading because hepatic enlargement may be either absent in nodular and diffuse forms of liver tumors or missed due to the location of the liver in the cranial abdominal cavity deep to the costal arch.¹⁻¹⁵

*References 2, 5-8, 24, 26-29.

Diagnostic Techniques and Work-Up

Laboratory Tests

Hematologic and serum biochemical abnormalities are usually nonspecific. Leukocytosis, anemia, and thrombocytosis are common in dogs with liver tumors.¹⁻¹⁴ Leukocytosis is probably caused by inflammation and necrosis associated with large liver masses.^{9,10} Anemia is usually mild and nonregenerative.^{5,11} The cause of anemia is unknown, although anemia of chronic disease, inflammation, red blood cell sequestration, microangiopathic destruction, and iron deficiency may be involved.³⁴ Thrombocytosis, defined as a platelet count greater than $500 \times 10^3/\mu\text{L}$, is seen in approximately 50% of dogs with massive HCC.¹¹ Proposed causes of thrombocytosis include anemia, iron deficiency, inflammatory cytokines, and paraneoplastic production of thrombopoietin.³⁵⁻³⁷ Anemia and thrombocytopenia are relatively common in dogs with primary and metastatic hepatic hemangiosarcomas.³ Prolonged coagulation times (e.g., increased prothrombin time, thrombin time, and activated partial thromboplastin time) and specific clotting factor abnormalities (e.g., decreased factor VIII:C and increased factor VIII:RA and fibrinogen degradation products) have been identified in dogs with hepatobiliary tumors, although these are rarely clinically relevant.³⁸

Liver enzymes are commonly elevated in dogs with hepatobiliary tumors (Table 22-8). Increased activity of liver enzymes probably reflects hepatocellular damage or biliary stasis and is not specific for hepatic neoplasia.⁴ There is also no correlation between the degree of hepatic involvement and magnitude of liver enzyme alterations.^{4,11} The type of liver enzyme abnormalities may provide an indication of the type of tumor and differentiate primary and metastatic liver tumors.³⁹ Alkaline phosphatase (ALP) and alanine transferase (ALT) are commonly increased in dogs with primary hepatic tumors, whereas aspartate aminotransferase (AST) and bilirubin are more consistently elevated in dogs with metastatic liver tumors.^{1,39} Furthermore, an AST-to-ALT ratio less than 1 is consistent with HCC or bile duct carcinoma, whereas a neuroendocrine tumor or sarcoma is more likely when the ratio is greater than 1.⁵ In general, however, liver enzyme elevations are not specific for the diagnosis of hepatobiliary diseases.⁴¹ Other changes in the serum

biochemical profile in dogs with hepatic tumors may include hypoglycemia, hypoalbuminemia, hyperglobulinemia, and increased preprandial and postprandial bile acids.^{1,2,5,9-14} Hypoglycemia is a paraneoplastic syndrome reported secondary to hepatic adenoma and management is described in more detail in Chapter 5. In contrast to dogs, azotemia is often present in cats with hepatobiliary tumors and may be the only biochemical abnormality, although liver enzyme abnormalities, especially ALT, AST, and total bilirubin, are also common and are significantly higher in cats with malignant tumors.⁶⁻⁸

α -Fetoprotein, an oncofetal glycoprotein, is used in the diagnosis, monitoring response to treatment, and prognostication of HCC in humans.¹⁶ In dogs, serum levels of α -fetoprotein are increased in 75% of HCC and 55% of bile duct carcinomas.^{42,43} However, α -fetoprotein has limited value in the diagnosis and treatment monitoring of canine HCC as serum levels of α -fetoprotein are also increased in other types of liver tumors, such as bile duct carcinoma and lymphoma, and nonneoplastic hepatic disease.^{43,44} Hyperferritinemia is common in dogs with histiocytic sarcoma and immune-mediated hemolytic anemia (IMHA); thus, once IMHA has been excluded, serum ferritin levels may be useful in differentiating histiocytic sarcoma from other causes of liver disease.⁴⁵

Imaging

Radiographs, ultrasonography, and advanced imaging can be used for the diagnosis, staging, and surgical planning of cats and dogs with hepatobiliary tumors. A cranial abdominal mass, with caudal and lateral displacement of the stomach, is frequently noted on abdominal radiographs of cats and dogs with massive liver tumors.^{10,11,17} Mineralization of the biliary tree is a rare finding in dogs with bile duct carcinoma.⁴ Sonographic examination is recommended because these radiographic findings are not specific for the diagnosis of a hepatic mass and do not provide information on the relationship of the hepatic mass with regional anatomic structures.

Abdominal ultrasonography is the preferred method for identifying and characterizing hepatobiliary tumors in cats and dogs.^{20,46-50} Sonographic examination is useful in determining the presence of a hepatic mass and defining the tumor as massive, nodular, or diffuse⁴⁶⁻⁵⁰ and, in the case of cats, whether the tumor is cystic or not.²⁰ If focal, the size and location of the mass and its relationship with adjacent anatomic structures, such as the gall bladder or caudal vena cava, can be assessed.^{20,46-50} Tumor vascularization can be determined using Doppler imaging techniques.⁴ The ultrasonographic appearance of hepatobiliary tumors varies and does not correlate with histologic tumor type.^{20,46-50} However, contrast-enhanced ultrasonography is useful in differentiating malignant tumors from benign lesions.⁵¹⁻⁵³

Ultrasound-guided FNA or needle core biopsy of hepatic masses is a useful, minimally invasive technique to obtain cellular or tissue samples for diagnostic purposes.⁴⁷⁻⁵⁰ A coagulation profile is recommended prior to hepatic biopsy because mild-to-moderate hemorrhage is the most frequent complication, occurring in approximately 5% of cases.⁴⁷⁻⁵⁰ A correct diagnosis is obtained in up to 60% of hepatic aspirates and 90% of needle core biopsies.^{47-50,54} More invasive techniques, such as laparoscopy and open keyhole approaches, can also be used for the biopsy and staging of cats and dogs with suspected liver tumors. In humans, laparoscopy is recommended for local staging as up to 20% of cases do not proceed with open surgery because of either nodular or diffuse tumors or unresectable disease.⁵⁵ However, for solitary and massive hepatic masses, surgical resection can be performed without a preoperative biopsy because

TABLE 22-8 Common Clinicopathologic Abnormalities in Cats and Dogs with Hepatobiliary Tumors

PARAMETER	CAT (%)	DOG (%)
Leukocytosis		54-73
Anemia		27-51
Hypoalbuminemia		52-83
Increased ALP	10-64	61-100
Increased ALT	10-78	44-75

both diagnosis and treatment can be achieved in a single procedure.

Advanced imaging techniques, such as CT and MRI, are preferred in humans for the diagnosis and staging of liver tumors.¹⁶ Unlike ultrasonography, imaging appearance may provide an indication of tumor type.¹⁶ Furthermore, CT and MRI are more sensitive for the detection of small hepatic lesions and determining the relationship of liver masses with adjacent vascular and soft tissue structures.¹⁶ The use of advanced imaging in cats and dogs with hepatobiliary tumors has not been evaluated.

Imaging is also important for the staging of cats and dogs with liver tumors. Local extension and regional metastasis can be assessed with abdominal ultrasonography, CT, MRI, or laparoscopy. The sonographic and sometimes gross appearance of nodular hyperplasia and metastatic disease is similar. In two studies, 25% to 36% of dogs with ultrasonographically detectable focal hepatic lesions were diagnosed with nodular hyperplasia.^{47,56} Biopsy of such lesions is recommended prior to definitively diagnosing metastatic disease and excluding animals from curative-intent surgery.⁵⁷ Although rare at the time of diagnosis, three-view thoracic radiographs or advanced imaging techniques should be assessed for evidence of lung metastasis prior to treatment.

Therapy and Prognosis

Hepatocellular Tumors

Liver lobectomy is recommended for cats and dogs with any hepatic tumor that has a massive morphologic appearance, particularly HCC. Surgical techniques for liver lobectomy include finger fracture, mass ligation, mattress sutures, bipolar vessel sealant devices, and surgical stapling.⁵⁸ Mass ligation is not recommended for large dogs, tumors involving either the central or right liver divisions, or tumors with a wide base.⁵⁸ The finger-fracture technique, involving blunt dissection through hepatic parenchyma and individual ligation of bile ducts and vessels, is acceptable for smaller lesions. Surgical staplers or bipolar vessel sealant devices are preferred for liver lobectomy because operative time is shorter with fewer complications (Figure 22-20).^{11,58} A hilar dissection technique may be required for larger tumors extending to the hilus of the liver lobe because adequate margins may not be achievable with a surgical

stapler.⁵⁹ Advanced imaging and intraoperative ultrasonography may provide information on the relationship of right-sided and central liver tumors with the caudal vena cava prior to liver lobectomy. Right-sided liver tumors can be excised even if intimately associated with the caudal vena cava, with or without an ultrasonic aspirator, but the surgeon should be very familiar with the course of the caudal vena cava through the hepatic parenchyma. En bloc resection of the caudal vena cava with a right-sided HCC has been reported.⁶⁰ In one report of 42 dogs with massive HCC treated with liver lobectomy, the intraoperative mortality rate was 4.8% and the complication rate was 28.6%.¹¹ Complications include hemorrhage, vascular compromise to adjacent liver lobes, and transient hypoglycemia and reduced hepatic function.^{4,11,58}

Prognostic factors in dogs with massive HCC include surgical treatment, side of liver involvement, ALT and AST activity, and ratios of ALP-to-AST and ALT-to-AST.¹¹ The MST for 42 dogs with massive HCC following liver lobectomy was not reached after more than 1460 days of followup because the majority of dogs were either still alive or died of diseases unrelated to their liver tumor (Figure 22-21).¹¹ In comparison, the MST of 270 days was significantly decreased for six dogs managed conservatively and these dogs were 15.4 times more likely to die of tumor-related causes than dogs treated surgically.¹¹ Right-sided liver tumors, involving either the right lateral lobe or caudate process of the caudate lobe, had a poorer prognosis because intraoperative death was more likely due to caudal vena cava trauma during surgical dissection.¹¹ There was no difference in survival time if dogs with right-sided massive HCC survived surgery.¹¹ Increased ALT and AST were associated with a poor prognosis, which may reflect more severe hepatocellular injury secondary to either large tumor size or more aggressive biologic behavior.¹¹

The prognosis for dogs with massive HCC is good. Local tumor recurrence is reported in 0% to 13% of dogs with massive HCC following liver lobectomy.^{10,11} Metastasis to other regions of the liver and lungs has been documented in 0% to 37% of dogs, but

metastasis is rare in recent clinical reports and most deaths are unrelated to HCC.^{5,10,11}

In contrast, the prognosis for dogs with nodular and diffuse HCC is poor. Surgical resection is usually not possible due to involvement of multiple liver lobes. Treatment options for nodular and diffuse HCC in humans include liver transplantation or minimally invasive procedures for regional control, such as ablation or embolization.¹⁶ Bland embolization and chemoembolization have been reported with moderate success in the palliation of four dogs with HCC.^{61,62} The role of radiation and chemotherapy in the management of HCC is largely unknown. RT is unlikely to be effective as the canine liver cannot tolerate cumulative doses greater than 30 Gy.^{4,16} Hepatocellular carcinoma is considered chemoresistant in humans because response rates are usually less than 20%.^{4,16} The poor response to systemic chemotherapy is probably a result of rapid development of drug resistance due to either the role of hepatocytes in detoxification or expression of P-glycoprotein, a cell membrane efflux pump associated with multidrug resistance.⁴ However, single-agent gemcitabine has been investigated in dogs with unresectable HCC with encouraging results.⁶³ Novel treatment options currently being investigated in human medicine include immunotherapy, hormonal therapy with tamoxifen, and antiangiogenic agents.¹⁶

Bile Duct Tumors

Bile duct adenomas can present as either single (e.g., massive) or multifocal lesions. Liver lobectomy is recommended for cats with single bile duct adenoma (cystadenoma) or multifocal lesions confined to one to two lobes.^{6-8,18-20} The prognosis is very good following surgical resection with resolution of clinical signs and no reports of local recurrence or malignant transformation.^{8,18,19}

Liver lobectomy is also recommended for cats and dogs with massive bile duct carcinoma. However, survival time has been poor in cats and dogs treated with liver lobectomy because the majority have died within 6 months due to local recurrence and metastatic disease.^{8,64} There is no known effective treatment for cats and dogs with nodular or diffuse bile duct carcinomas because these lesions are not amenable to surgical resection and other treatments are often not successful.

Neuroendocrine Tumors

Carcinoids have an aggressive biologic behavior and are usually not amenable to surgical resection because solitary lesions and massive morphology are rare.^{5,14} The efficacy of RT and chemotherapy is unknown. Prognosis is poor because metastasis to the regional lymph nodes, peritoneum, and lungs occurs in 93% of dogs and usually early in the course of disease.^{5,14}

Sarcomas

Liver lobectomy can be attempted for solitary and massive sarcomas. However, prognosis is poor because metastatic disease is often present at the time of surgery.^{5,24} Chemotherapy has not been investigated in the treatment of primary hepatic sarcomas, although, similar to other solid sarcomas, response rates are likely to be poor. Doxorubicin-based protocols and ifosfamide have shown some promise with sarcomas in other locations and warrant consideration for cats and dogs with primary hepatic sarcomas.^{65,66}

Other Primary Hepatic Tumors

Surgical resection with liver lobectomy is recommended for cats with primary hepatic myelolipoma, and the prognosis is excellent with prolonged survival time and no reports of local recurrence.⁴

Comparative Aspects

Hepatocellular carcinoma is one of the most common malignancies in humans as a result of viral infections with hepatitis viruses B and C and cirrhosis induced by alcohol consumption and other disease.¹⁶ A number of paraneoplastic syndromes have been described including hypoglycemia, erythrocytosis, and hypercalcemia.¹⁶ Ultrasonography is considered a good screening imaging modality, but advanced imaging with contrast-enhanced CT or MRI is preferred to determine the location, size, and extent of hepatic lesions.¹⁶ Other tests include serum α -fetoprotein, serologic tests for hepatitis B and C viruses, and histologic confirmation with core liver biopsies.¹⁶ Unlike HCC in dogs, the morphology of HCC in humans is often nodular or diffuse, which makes definitive treatment more problematic. Treatment options depend on the stage of disease and include surgery (e.g., liver lobectomy and liver transplantation), local ablative therapies (e.g., cryosurgery, ethanol or acetic acid injection, and microwave or radiofrequency ablation), regional therapies (e.g., transarterial chemotherapy, embolization, chemoembolization, or RT), and systemic treatment with chemotherapy or immunotherapy.¹⁶ Response rates to single- and multiple-agent chemotherapy protocols are less than 25%, and chemotherapy is no longer recommended for human patients with HCC.¹⁶

Bile duct carcinomas are rare and, similar to cats and dogs, often associated with a poor prognosis.²⁶ Risk factors include primary sclerosing cholangitis, the liver flukes *Opisthorchis viverrini* and *Clonorchis sinensis* in endemic areas of Southeast Asia and China, and cholelithiasis.²⁶ Surgical resection is preferred but, because of the high rate of local or regional recurrence, adjuvant treatment with RT or chemotherapy is recommended.²⁶ However, because of the rarity of this tumor, studies supporting the efficacy of these adjuvant treatments are lacking. Papillary histology, extrahepatic location, and complete resection are favorable prognostic factors in humans with bile duct carcinomas.⁶⁷

SECTION G

Intestinal Tumors

KIM A. SELTING

Incidence and Risk Factors

Reports vary, but overall intestinal tumors are rare in dogs and cats.¹⁻³ In a survey of insured dogs in the United Kingdom, a standardized incidence rate of 210/100,000 dogs was reported for alimentary tumors. This accounted for 8% of all tumor submissions.⁴ Incidence of feline digestive neoplasia in a South African survey comprised 13.5% of all tumors, which likely included oral tumors.⁵ In the United States, a query of over 300,000 cat submissions to the Veterinary Medical Database (VMDDB) found 8% to relate to cancer and less than 1% (13% of the cancer cases) to be intestinal neoplasia.⁶ Less than 1% of over 10,000 dogs submitted for necropsy at one institution were diagnosed with intestinal adenocarcinoma, which agrees with other reports.^{2,7,8} Regarding specific tumor types, lymphoma comprises nearly 30% of all feline tumors and 6% of all canine tumors and is the most common intestinal tumor in most reports.^{2,9-11} Adenocarcinoma is the second most frequent tumor in both species, with mast cell tumors in cats and leiomyosarcomas or GISTs in dogs next.

As with many cancers, incidence of intestinal neoplasia increases in older dogs and cats. Mean ages of affected cats for small and large intestinal neoplasia generally range between 10 and 12 years, and increasing risk after age 7 has been reported.^{2,6,12-20} Dogs are also usually middle aged or older, with mean ages most often between 6 and 9 years, possibly older (12 years) for dogs with leiomyosarcoma.^{11,21-24} Some earlier studies of feline lymphoma report younger median ages, most likely a result of a larger percentage of FeLV-positive cats in the study population.^{25,26}

There is a slight sex predilection for males to develop intestinal tumors in some studies for both dogs and cats. Many studies report a near equal incidence among male and female dogs,^{24,27-29} although one study did find 76% of dogs with intestinal adenocarcinoma to be male.³⁰ Males also appear overrepresented in smooth muscle tumors, comprising 82% of GI leiomyomas³¹ and 76% of dogs with leiomyosarcoma.²³ Additionally, 90% of dogs with GI lymphoma were male.²² Furthermore, there is a slight male predominance in nonlymphomatous small intestinal tumors in dogs.^{11,32,33}

In cats, there also is a predominance of males in some studies,^{17,34} with males equaling or only slightly exceeding females in others.*

although three of four cats with large granular lymphoma were female.¹⁴

Siamese cats are 1.8 times more likely to develop intestinal neoplasia.⁶ Siamese cats are overrepresented in studies of intestinal adenocarcinoma, up to eight times greater than other breeds, suggesting a predisposition for this disease.^{2,6,15,32,38} Although small numbers of Siamese cats are included in many series of feline intestinal lymphoma, one study did show a significant overrepresentation.¹³ Otherwise, there is no breed predilection for intestinal lymphoma in cats.

In dogs, few studies of intestinal neoplasia report an overrepresentation of specific breeds. Large breed dogs in general constituted most cases in a series of smooth muscle tumors.²⁸ Collies and German shepherd dogs are overrepresented in some reports for intestinal tumors, especially adenocarcinoma and rectal carcinoma and polyps.^{21,39} It is interesting to note, however, that in 104 benign and malignant tumors diagnosed in a cohort of military working dogs (German shepherd dogs and Belgian Malinois), only one (a leiomyosarcoma) was intestinal.⁴⁰ Mast cell tumors have been reported primarily in Maltese, among other miniature breeds. Although these reports came from Japan where small breeds are popular, over 50% of reported cases in two series were in Maltese dogs, with a male predominance.^{41,42}

With the exception of retroviral influence on the development of feline lymphoma, there are no known etiologic organisms or chemical agents that reliably contribute to the development of spontaneously occurring intestinal neoplasia in dogs and cats. There is a known association of FeLV and feline immunodeficiency virus (FIV) with feline lymphoma. Older cats with intestinal lymphoma are usually negative for FeLV on serology, although evaluation of feline intestinal lymphoma by polymerase chain reaction (PCR) for the long terminal repeat region and immunohistochemistry (IHC) for gp70 antigen has shown some tumors to be positive for viral DNA, even when seronegative for FeLV p27 antigen. For intestinal lymphoma, PCR was more often positive than IHC.^{43,44} These results suggest FeLV exposure in the development of lymphoma in some cats serologically negative for FeLV, and they support PCR as the most useful of these tests for identifying possible occult, latent, replication-deficient, or partial genome virus infection in tissue. With younger cats more often IHC positive and IHC correlating well with seropositivity, PCR may identify cats with lymphoma that have been exposed to FeLV but are seronegative.⁴³ There is no association between retroviral infection and nonlymphomatous intestinal neoplasia in cats, with most cats testing negative for FeLV and/or FIV serologically.^{15,32}

In other species, type-A retrovirus particles have been found in a metastatic intestinal adenocarcinoma in a boa, and cytomegalovirus has been associated with GI epithelial masses in macaque monkeys infected with simian immunodeficiency virus.^{45,46}

Helicobacter pylori infection is associated with increased risk of gastric cancer in humans, although no such association has been confirmed in domestic animals. Concurrent lymphoma and *Helicobacter* infection has been reported in a cat, but causal association was not proved.⁴⁷ Multiple gastroduodenal adenocarcinomas and a rectal adenoma were found in a cougar with concurrent *Helicobacter*-like organisms and spirochetes.⁴⁸ Some cats shed *Helicobacter* species in the feces and thus may represent normal flora rather than pathogens.⁴⁹

Finally, lymphoma (although not specifically intestinal) has been reported in a dog 4 weeks after initiation of cyclosporine and ketoconazole therapy for anal furunculosis.⁵⁰ There is an

*References 12, 13, 15, 16, 18-20, 25, 26, 35-37.

association between cyclosporine use in human transplant patients and the development of lymphoma.

Pathology and Natural Behavior

Epithelial, mesenchymal, neuroendocrine, and discrete/round cell neoplasias can all be found in the intestinal tract. In both cats and dogs, lymphoma is the most common type of small intestinal neoplasia, followed by adenocarcinoma. Subtypes of feline intestinal lymphoma include lymphocytic, lymphoblastic, epitheliotropic, and large granular lymphocyte (LGL) types. Because of advances in novel targeted receptor tyrosine kinase inhibitors (TKIs) in human medicine, characteristics of GISTs have also been reported in dogs. Other tumors include leiomyosarcoma in both dogs and cats, carcinoids in dogs, and mast cell tumors in cats. There are scattered case reports of uncommon tumors, such as extramedullary plasmacytoma, extraskeletal osteosarcoma, and hemangiosarcoma. Although most small intestinal neoplasia is malignant in dogs, most rectal tumors are benign polyps, adenomas, or carcinoma in situ^{29,51} (Figure 22-22).

Most alimentary adenocarcinoma in cats is found in the small intestine.^{1,30,37} However, the colon and rectum are a more common site in dogs.^{7,8} Of colorectal adenocarcinomas, the rectum is a more common site than the colon.⁵² The cecum is more likely to develop leiomyosarcoma or GIST than adenocarcinoma.^{8,23} Histologic descriptors for carcinoma of the intestine include adeno- (forming glands), mucinous (>50% mucin), signet ring (>50% of cells have intracellular mucin), and undifferentiated or solid (no evidence of gland formation).⁷ Grossly, colorectal adenocarcinomas may demonstrate a pedunculated (especially in the distal rectum), cobblestone (middle rectum), or annular (middle rectum) appearance, which may relate to behavior and prognosis^{8,52,53} (Figure 22-23).

Adenomatous polyps are found in the rectum of dogs, and carcinoma in situ is found in both the colon and rectum. Most lesions are solitary, although multiple and diffuse lesions can be seen and

are associated with increased recurrence rates.²⁹ In cats, polyps are more common in the duodenum.

The term *carcinoid* refers to tumors that arise from the diffuse endocrine system rather than the intestinal epithelium, despite histologic similarity to carcinomas. Carcinoid cells arise from enterochromaffin cells of the intestinal mucosa and contain secretory granules that may contain substances such as 5-hydroxytryptamine (serotonin), secretin, somatostatin, and gastrin, among others.⁷ IHC for cytokeratin and for secretory substances such as serotonin may be positive, and serum concentration of serotonin has been documented at 10 times the normal range in one dog with a carcinoid.⁵⁴ Described in many species, carcinoids may occur in both the large and the small intestines and frequently metastasize to the liver.^{2,8,54} Carcinoids may follow an aggressive and debilitating clinical course.⁵⁴

• **FIGURE 22-22** Cobblestone appearance to a rectal adenocarcinoma. Dogs with this tumor type live an average of 12 months following surgical excision.⁵² (Courtesy Dr. Eric Pope, Ross University, College of Veterinary Medicine.)

• **FIGURE 22-23** An annular form of clonic adenocarcinoma causing a stricture. The thick band of tissue (**B**) creating the stricture is seen on cross-section (**A**). In one study, dogs with this type of tumor survived an average of only 1.6 months.⁵² (Courtesy Dr. Eric Pope, Ross University, College of Veterinary Medicine.)

GISTs are well documented in humans and have been reported in dogs.⁵⁵ These nonlymphoid tumors of mesenchymal origin were originally diagnosed as leiomyosarcomas and some but not all were leiomyomas. Histologically, GISTs are highly cellular mesenchymal tumors that do *not* show ultrastructural characteristics consistent with smooth muscle differentiation. GISTs are thought to arise from multipotential stem cells phenotypically similar to interstitial cells of Cajal, driven by activating mutations of Kit. These cells regulate intestinal motility via an autonomic pacemaker effect. Although these cells can differentiate into smooth muscle cells if deprived of Kit, GISTs are a discrete clinical entity from leiomyosarcoma.⁵⁶ GISTs are distinguished by high vimentin immunoreactivity, low alpha smooth muscle actin reactivity, CD117 (Kit) reactivity, and a site predilection for the large intestine (compared to the stomach for leiomyoma).^{31,57} Activating mutations were identified in Kit exon 11 encoding the juxtamembrane domain in two of four cases examined.³¹ CD117 reactivity is considered a major diagnostic criteria and in many studies is used to distinguish GISTs from leiomyosarcomas.^{58,59} When stratified as such, 28 of 42 leiomyosarcomas in dogs were reclassified as GISTs and only 2 of the 28 cases of GIST metastasized (7%). These investigators also found that GISTs were significantly more likely to occur in the large intestine, specifically the cecum, and leiomyosarcomas in the stomach and small intestine.⁵⁸ Considering these findings, the incidence of true leiomyosarcoma is likely low because many previously reported cases may have actually been GISTs. Leiomyomas occur more commonly in the stomach but have also been reported in the esophagus, small intestine, and colorectum.³¹

Intestinal lymphoma in dogs occurs in the stomach and small intestine equally and more often in both of these sites than the large intestine. Lesions are typically diffuse, and neoplastic cells infiltrate the submucosa and lamina propria. Additional visceral and systemic involvement may be seen.

Intestinal lymphoma in cats was originally thought to be predominantly of B-cell origin, resulting from its origin in Peyer's patches and germinal centers; however, some reports suggest that the incidence of T-cell lymphoma may equal or exceed that of B-cell lymphoma.^{20,34,44} IHC and PCR for antigen receptor rearrangement (PARR) can be useful in identifying predominant immunophenotype and clonality, as well as distinguishing lymphoma from severe inflammation.^{60,61} There is no clear association between the presence of FeLV antigens in tissue and clonality (B-cell versus T-cell).⁴⁴ Incidence of feline intestinal lymphoma appears to have increased over the past 2 decades to an extent that may exceed that attributed to an aging cat population.⁶² Within a diagnosis of intestinal lymphoma, subtype also impacts behavior. In one series, cats with lymphocytic/small cell lymphoma experienced a 69% complete remission rate with prednisone and chlorambucil for a MST of nearly 2 years, whereas cats with lymphoblastic lymphoma had only an 18% complete remission rate with combination chemotherapy for a MST of less than 3 months. Cats with lymphoblastic lymphoma were more likely to have a palpable abdominal mass and require surgery for intestinal obstruction than cats with lymphocytic lymphoma.³⁵

Other unique subsets of feline intestinal lymphoma include epitheliotropic and LGL lymphoma. Most of these cats are serologically negative for FeLV. Immunohistochemical evaluation of feline epitheliotropic lymphoma shows these tumors to be strictly T-cell in origin and 80% small/lymphocytic.^{34,63} In one study, although great overlap of values occurred, there was a significantly greater percentage of intraepithelial lymphocytes in neoplastic compared to normal cats and inflammatory bowel disease cases. The

determination of epitheliotropism depends on the pathologist's interpretation. As with epitheliotropic cutaneous lymphoma, microabscesses are often seen. Intraepithelial lymphocytes are richer in villous than crypt epithelium, suggesting that this diagnosis may be reliably made with endoscopic biopsies. This disease may represent a continuum from inflammatory bowel disease.³⁴

By contrast, LGL lymphoma of the intestine (also called globule leukocyte and granulated round cell tumor) often has a rapidly progressive and fatal course.^{64,65} These tumors are distinguished by heterogeneous cytoplasmic granules (azurophilic on cytology and eosinophilic on histopathology with routine hematoxylin and eosin [H&E] staining) and are commonly seen in the intestinal tract (especially jejunum), occasionally with leukemic cells.^{66,67} Perforin-like immunoreactivity has been demonstrated and may help distinguish these from other lymphomas.¹⁴

Extramedullary plasmacytoma (EMP) refers to solitary tumors with no evidence of systemic multiple myeloma. Case reports of GI EMP in dogs and cats exist, though uncommon. In one series, one-fourth of EMPs were found in the digestive system, most in the mouth.⁶⁸ One case report in a dog with EMP of the colon and rectum was associated with monoclonal gammopathy.⁶⁹ Another uncommon tumor type is extraskeletal osteosarcoma, which has been reported in the duodenum of a cat. This cat had no evidence of metastasis at diagnosis but did well for only 4 months after surgery when clinical signs recurred and the cat died.⁷⁰ Three of 55 extraskeletal and 145 total cases of feline osteosarcoma were of intestinal origin.⁷¹ A series of four cats was reported with intestinal hemangiosarcoma arising from four different locations within the intestines, with none surviving greater than 1 week.⁷² Finally, one dog was diagnosed with ganglioneuroma of the rectum and experienced long-term survival following surgical resection.⁷³

Intestinal mast cell tumors are cited as the third most common tumor following lymphoma and adenocarcinoma in cats, but incidence and behavior are poorly reported. They have been confused with carcinoids but are distinct.¹² They may present as an eosinophilic enteritis, and conversely, eosinophilic enteritis may mimic intestinal tumors.^{74,75} Intestinal sclerosing mast cell tumor in the cat is a potentially aggressive variant characterized by moderate-to-abundant dense stromal tissue, marked eosinophilic infiltrates, and some cases with tryptase and c-kit immunoreactivity. Ultrasonographic changes were transmural, and tumors were most commonly located in the small intestine. Outcome was reported for 25 of 50 cats, and survival was less than 2 months for 23/25; however, outcome was unknown for the remaining 25 cats.⁷⁶ In dogs, intestinal mast cell tumors occur primarily in the stomach and small intestine, are typically poorly granulated, and are often immunohistochemically positive for toluidine blue, c-kit, and tryptase. Mucosal mast cells may be structurally distinct from cutaneous mast cells.⁴¹

When tumors of the GI system metastasize, sites of predilection in decreasing frequency include mesenteric lymph nodes (especially adenocarcinoma), liver (especially leiomyosarcoma), mesentery, omentum, spleen, kidney, bone, peritoneum/carcinomatosis, and lung.^{11,32,37,53} Interestingly, metastasis from intestinal adenocarcinoma was discovered in three dogs initially presented for testicular masses.⁷⁷ One dog was presented for multiple cutaneous masses that suggested round cell or epithelial malignancy on cytology but for which IHC confirmed epithelial origin. A primary small intestinal adenocarcinoma with additional visceral metastasis was identified at necropsy.⁷⁸ Lymphoma is often a systemic disease, and one-fourth of dogs and four-fifths of cats with GI lymphoma will have concurrent involvement of other organs.^{13,22}

Molecular Aspects

With an increasing armamentarium of molecular diagnostics, insights as to the pathogenesis, progression, and prognosis of tumors are constantly emerging. Cellular adhesion and invasion (e.g., Tenascin-C,^{51,79} versican, hyaluronan,⁸⁰ β -catenin, and E-cadherin⁸¹⁻⁸³), stromal remodeling, and alterations in tumor suppressor genes (e.g., *p53*^{81,83-85}) may play a role in the development and progression of intestinal neoplasia. The importance of the relationship between a tumor cell and its stroma should not be overlooked. Although molecular markers/targets likely play an important role in intestinal tumors, the utility of these in diagnostics, prognostication, and therapy in companion animal species, with the exception of GIST and CD117 expression, is limited until further interrogations characterize their importance and provide avenues for their utility.⁵⁵

Measures of cellular proliferation include markers such as argyrophilic nucleolar organizer regions (AgNORs). In feline intestinal lymphoma, AgNORs did not correlate with remission rate or duration or with survival time.¹⁹

COX enzymes are responsible for prostaglandin synthesis, and COX-2 is overexpressed in many head/neck and genitourinary tumors, creating a possible therapeutic target. COX-2 has been identified in both benign and malignant small intestinal and colorectal epithelial tumors in dogs, although the number of positive cells varies and in some studies was very low.^{86,87} Additionally, one study found no COX-2 staining in 13 intestinal tumors in cats.⁸⁸ COX inhibitors are thus of questionable value in treating intestinal tumors.

History and Clinical Signs

The duration of clinical signs prior to presentation typically averages 6 to 8 weeks but can range from less than 1 day to several months.^{11,22,23} Clinical signs include (in varying order of frequency): weight loss, diarrhea, vomiting, and anorexia and less frequently melena, anemia, and hypoglycemia (with smooth muscle tumors).^{*} Clinical signs often relate to location of the tumor within the GI tract. Proximal lesions more commonly result in vomiting, small intestinal lesions in weight loss, and large bowel lesions in hematochezia and tenesmus.^{30,32} Although carcinoids may secrete endocrine substances, clinical signs do not always reflect hypersecretion.⁷ Dogs and cats may present with clinical signs relating to intestinal obstruction, such as anorexia, weight loss, and vomiting. Although uncommon, perforation and septic peritonitis can occur.³⁴ Smooth muscle tumors are located within the muscular layer of the intestines and not within the lumen and evidence of GI bleeding is often absent, but anemia and melena have been reported.^{23,24}

Paraneoplastic Syndromes

One dog was presented for alopecia and *Cheyletiella* infection within 2 months of euthanasia for abdominal carcinomatosis from intestinal carcinoma. The neoplasia was not identified with abdominal ultrasound at the original work-up, but immunosuppression resulting from an underlying neoplasia was thought to lead to opportunistic *Cheyletiella* infection. While pruritus resolved with ivermectin therapy, alopecia persisted, suggesting paraneoplastic origin.⁸⁹ Neutrophilic leukocytosis (in one dog associated with monocytosis and eosinophilia) has been reported in dogs with rectal tumors. Resolution or improvement of hematologic abnormalities occurred following treatment for adenomatous rectal

polyps.^{90,91} Hypereosinophilia and eosinophilic tumor infiltrates have been reported in a cat and several dogs with intestinal T-cell lymphoma; the suggested cause was IL-5 secretion by the neoplastic lymphocytes.⁹²⁻⁹⁴ Extramedullary plasmacytoma may lead to a hyperviscosity syndrome resulting from overproduction of immunoglobulin.⁹⁵

Erythrocytosis managed with periodic phlebotomy was related to a cecal leiomyosarcoma in a 14-year-old dog. The diagnosis was made at postmortem 2 years later, and erythropoietin mRNA and protein were isolated from tumor cells, suggesting ectopic erythropoietin production as the cause of the erythrocytosis.⁹⁶ Hypoglycemia is also reported with intestinal smooth muscle tumors as a paraneoplastic syndrome.⁹⁷ Nephrogenic diabetes insipidus has also been documented in one dog with intestinal leiomyosarcoma.⁹⁸

Diagnostic Techniques and Work-Up

Physical Examination

An abdominal mass may be palpated on initial examination in approximately 20% to 40% of dogs with lymphoma^{22,27} and 20% to 50% of dogs with nonlymphomatous solid intestinal tumors.^{11,30,32} Pain and fever were reported in 20% of dogs with lymphoma in one report.²² Digital rectal examination may identify masses or annular strictures due to rectal tumors or polyps in as high as 63% of dogs.^{30,32}

Abdominal masses are also often readily palpated in cats with both lymphoma and adenocarcinoma. Approximately 50% of cats with nonlymphomatous tumors will be presented with a palpable mass.^{15,32} Abnormal abdominal palpation is common in cats with lymphoma with up to 86% having a palpable mass.^{16,34} Dehydration is also common, occurring in 30% to 60% of cats with nonlymphomatous tumors.^{15,32}

Clinical Pathology

Complete Blood Count

Anemia is common in dogs and cats with intestinal tumors and is often not characterized but may occur in conjunction with melena and elevated blood urea nitrogen (BUN). Anemia affects nearly 40% of dogs in most studies and as low as 15% but up to 70% of cats.^{*} Leukogram changes are also common including leukocytosis in 25% to 70% of dogs and 40% of cats.^{11,15,24,32} Left shift may be seen as well as monocytosis in some patients.^{32,34}

Chemistry Profile

Biochemical abnormalities are similar between dogs and cats with intestinal tumors. As a result of malabsorption, hypoproteinemia may be present in one-fourth to one-third of patients.[†] Other common abnormalities include elevated liver enzymes, specifically alkaline phosphatase in 15% to 33% of dogs and up to 85% of cats with nonlymphomatous neoplasia.^{11,24,30,32,34} In one series a high cholesterol was seen in 41% of cats with nonlymphomatous tumors.³² An elevated blood urea nitrogen has been reported in 13% of dogs and 30% of cats with intestinal adenocarcinoma.^{11,15} This may be a result of concurrent renal insufficiency or intestinal bleeding due to the tumor or of dehydration. While some cats may have hyperglycemia,³² smooth muscle tumors can cause up to 55%

*References 2, 11, 15, 25, 27, 34, 35, 38.

*References 11, 16, 23, 24, 30, 32, 34.

†References 11, 15, 16, 24, 27, 30.

of patients to be hypoglycemic as a result of insulin-like growth factor secretion.²³ Dogs may also have increased amylase and electrolyte disturbances,³⁰ and patients with lymphoma may be hypercalcemic.¹⁶

Serum alpha 1-acid glycoprotein (AGP), an acute phase reactant protein, may be increased in cats with cancer but lacks specificity and prognostic relevance.^{99,100}

Cytology and Histopathology

As with other anatomic sites, cytology of the intestinal tract can help differentiate among major tumor types. Additionally, lymphocyte accumulations can be tested using PARR for clonality. If amplification of variable regions in the genome of lymphocytes using PARR reveals monotony consistent with a clonal expansion, then a diagnosis of lymphoma can be confirmed. This test can be performed using either stained or unstained slides from ultrasound-guided aspirates.^{60,101} PARR may detect clonal expansions not yet evident (as lymphoma) on histopathology of the same sample.¹⁰² Because of reported eosinophilia with intestinal lymphoma and reports of mast cell tumor with concurrent small T-cell lymphoma in cats, it may be challenging to distinguish between the two.¹⁰³ Despite concerns of complications following surgery in cats with intestinal lymphoma for the purpose of obtaining diagnostic samples for histopathology or for resection of a mass, the risk of perioperative dehiscence appears to be low.¹⁰⁴

Imaging

Plain and Contrast Abdominal Radiographs

In dogs and cats with intestinal lymphoma, concurrent enlargement of liver, spleen, and/or mesenteric lymph nodes may be seen.²² Plain abdominal radiographs may reveal an abdominal mass in approximately 40% of both dogs and cats, although some reports are higher for solid tumor types and lower for lymphoma.* Intestinal lymphoma may be more difficult to identify on plain radiography because of other organ involvement, peritoneal effusion, or diffuse intestinal lesions. An obstructive pattern may also be seen on plain radiographs, with incidence ranging from 10% to 75%.^{11,24,30,32} Other abnormalities may include poor serosal detail and thickened stomach wall.¹⁶

Contrast radiography, although used less following advances in ultrasound, has often been used to evaluate patients with signs of primary GI disease. Contrast radiography can help rule in or out an obstruction, localize a tumor, and view areas of the GI tract that are difficult to image with ultrasonography because of gas accumulation (Figure 22-24). Contrast radiographs may reveal filling defects in approximately half the cats and dogs with GI neoplasia.³² In dogs with GI lymphoma, all 12 dogs examined had abnormal contrast series.²² In one series, 87% of cats with intestinal adenocarcinoma showed evidence of partial or complete obstruction.¹⁵

Thoracic Radiographs

Thoracic radiographs are critical to the complete evaluation of the cancer patient. For dogs with nonlymphomatous intestinal tumors, yield is low with very few patients presenting with pulmonary metastasis.¹¹ This may be due to a bias in reporting because many reports detail outcome of treatment and patients with metastatic disease may not receive treatment. In fact, many case series report no evidence of metastasis on initial evaluation for solid tumors of the intestine in dogs.^{11,23,24,30,32} In cats, 2 of 14 cats in one series and no cats in another had pulmonary nodules at initial evaluation.^{15,32}

• **FIGURE 22-24** The arrow indicates an obstructing tumor on contrast radiography. The thin trail of barium is all that will pass through the lumen of the tumor and the obstruction is evidenced by the dilated segment of small bowel adjacent and oral to the tumor. (Courtesy Dr. Jimmy Lattimer, University of Missouri, College of Veterinary Medicine.)

For cats and dogs with lymphoma, enlarged sternal or perihilar lymph nodes, pleural effusion, or diffuse interstitial changes may be seen.^{16,22}

Abdominal Ultrasound

Ultrasound allows noninvasive localization of the tumor and identification of other sites of metastasis/involvement. It also can guide needle aspiration or needle biopsy or assist in treatment planning. Ultrasound is a more sensitive diagnostic test than radiographs for identifying a mass.^{11,23,28,105} Ultrasound is also less time consuming than contrast radiography, and the increased use, availability, and operator skill for the former has diminished the need for the latter.

Ultrasound findings in dogs and cats with intestinal neoplasia most consistently include bowel wall thickening and loss of normal wall layers.^{30,105,106} Degree of thickening, distribution of lesion(s), and symmetry are also used to help differentiate neoplasia from nonneoplastic disease.¹⁰⁷ Intestinal lymphoma in dogs more often results in long segments of involved bowel and either a solitary mass or diffusely thickened bowel loops with thickening of the muscularis propria in cats.^{35,106,108} Adenocarcinoma in cats has been described as having mixed echogenicity and was asymmetric in

*References 11, 15, 16, 22, 24, 32.

• **FIGURE 22-25** A cross-sectional ultrasound image of a segment of small intestine with lymphoma (**A**) is compared to a longitudinal view of a segment of normal small intestine (**B**). Note that the clearly defined intestinal layers in the normal tissue are completely effaced in the tumor tissue. A loss of layering is strongly supportive of neoplasia. The diseased bowel is also markedly thickened, suggesting neoplasia. (Courtesy Dr. Stephanie Essman, University of Missouri, College of Veterinary Medicine.)

three of five cats.¹⁰⁵ In one study, two-thirds of dogs with intestinal adenocarcinoma had hypoechoic tumors, and most had decreased motility. Masses averaged 4-cm long with a median wall thickness of 1.2 cm.^{8,30} Mast cell tumors have an eccentric appearance with alteration but not loss of wall layering, commonly involving the muscularis propria.¹⁰³ Smooth muscle tumors are characteristically large (median diameter 4.8 cm) and anechoic/hypoechoic, and a muscular layer origin may be identified. Leiomyomas may have a smooth contour.²⁸

Ultrasound has also proven useful in differentiating neoplastic from nonneoplastic intestinal disease. Dogs with tumors have significantly thicker intestinal walls, and 99% have a loss of wall layering compared to a maintenance of wall layering in 88% of dogs with nonneoplastic disease (Figure 22-25). In fact, dogs with a loss of wall layering are more than 50 times more likely to have a tumor than enteritis. Additionally, dogs with walls thicker than 1 cm are nearly 4 times as likely to have a tumor, and those with focal lesions are nearly 20 times as likely.¹⁰⁶ Nevertheless, possible differential diagnoses include fungal (Pythiosis and histoplasmosis) masses that can mimic neoplasia.¹⁰⁷ Lymphadenopathy can also be seen with both neoplasia (lymphoma and solid tumors), as well as with infectious or inflammatory bowel disease. In general, neoplasia exhibits more dramatic thickening with loss of wall layering and greater lymph node enlargement, as well as more frequent focal lesions than nonneoplastic intestinal disease.¹⁰⁷

In a series of 14 cats with carcinomatosis, 3 of which were a result of small intestinal tumors (2 carcinomas and 1 lymphoma), the hallmark ultrasonographic finding (100% of cats) was the presence of masses in the double sheet portion of peritoneum that connects the visceral and parietal portions. All cats also had free peritoneal fluid.³⁶

Endoscopy and Laparoscopy

Minimally invasive methods of collecting tissues to aid in diagnosis are increasingly used. Endoscopic findings in dogs with intestinal lymphoma include an irregular cobblestone or patchy erythematous appearance to the duodenal mucosa and poor distensibility and elasticity of the duodenal wall.²⁷

Significant interobserver variation may occur in the interpretation of biopsy samples. In one study, blinded pathologists assigned a degree of mucosal cellular infiltrate as severe as neoplasia in five clinically normal research dogs.¹⁰⁹ Interobserver variation is likely to be more pronounced with small tissue samples and this is a limitation of these less invasive approaches.

Exploratory Laparotomy

When noninvasive or minimally invasive diagnostics fail to confirm a diagnosis, an exploratory laparotomy may be indicated for a dog or cat with persistent signs of GI disease. Benefits include direct visualization of all abdominal viscera and the ability to collect full thickness biopsies of all segments of intestines and other viscera. Patients with resectable solid tumors may be both diagnosed and treated in one procedure with resection and anastomosis. In a series of dogs with GI lymphoma, endoscopic biopsies were sometimes difficult to interpret because of lymphoplasmacytic infiltrate, but biopsies obtained by laparotomy confirmed the diagnosis in all cases undergoing surgery.²² It should be noted that carcinomatosis should not always be seen as an indication for euthanasia (Figure 22-26). Following removal of the primary intestinal adenocarcinoma, two cats with malignant effusion lived 4.5 and 28 months after surgery.¹⁵

Therapy and Prognosis

Surgery

With the exception of lymphoma, surgical resection is the primary treatment for intestinal tumors. As long as severe extraserosal invasion and/or adhesions do not complicate the surgical approach, complete excision is often possible. For dogs and cats without evidence of local or distant metastasis, long-term survival is possible, although some tumors may later metastasize. Overall, the 1-year survival rate is approximately 40% for dogs with solid small intestinal tumors.¹¹ For cats with adenocarcinoma, approximately 50% will metastasize to the local lymph nodes, 30% to the peritoneal cavity (carcinomatosis), and 20% or less to the lungs.^{2,32,37} Dogs have similar rates of metastasis to lymph nodes for both adenocarcinoma

• **FIGURE 22-26** Carcinomatosis discovered at exploratory laparotomy. Note the irregular peritoneal surface instead of a normal glossy appearance (**A**) and the multiple serosal implants (**B**). (Courtesy Dr. F. A. Mann, University of Missouri, College of Veterinary Medicine.)

and leiomyosarcoma, although liver is usually the second most frequent site.^{8,11,32} Perioperative mortality can approach 30% to 50% as a result of sepsis, peritonitis, or owner decision for euthanasia when nonresectable tumors are present.^{11,23}

The benefit of surgery is questionable for dogs with intestinal mast cell tumors. In two case series, most dogs died within the first month. Only 2 of 49 dogs (combined total for two series, almost all GI) lived past 180 days and prednisone was not helpful in most cases.^{41,42}

Various surgical techniques have been used to treat small and large intestinal tumors. For dogs with colorectal adenocarcinoma, local excision via anal approach and rectal prolapse (when amenable) or other methods yielded a median survival of 2 to almost 4 years compared to 15 months for stool softeners alone^{52,110-112}; colorectal plasmacytomas and polyps also fare well with MSTs of 15 months and 2 years or more, respectively, following surgical excision.^{39,113} This is in contrast to small intestinal adenocarcinoma in which 12 days mean survival was reported without treatment, and a mean survival of only 114 days for dogs with surgical resection, though others report 7 and 10 months.^{11,30,32} Regarding surgical techniques for resection and anastomosis of small intestine, stapling techniques have been shown to be equivalent to hand suturing.¹¹⁴ Dogs with leiomyosarcoma who survive the perioperative period fare somewhat better with MSTs of 1.1 and almost 2 years.^{23,24} One case series found the median postoperative survival for 28 dogs with GIST to be approximately 38 months (1 year if postoperative deaths were included) versus 8 months for 10 dogs with leiomyosarcoma, although the difference was not statistically significant.⁵⁸ Additionally, another study found no difference between GIST and leiomyosarcoma with 1-year survival of approximately 80%.⁵⁹ Colostomy use has been reported to aid in management of dogs with nonresectable rectal tumors. In one report, skin excoriation was the most common complication, but colostomy bags were managed for up to 7 months.¹¹⁵

Transrectal endoscopic removal of benign canine rectal tumors that would have otherwise required rectal pull-through surgery or pubic osteotomy afforded five of six dogs significant improvement in quality of life, with three dogs cured.¹¹⁶ Standard treatment with

• **FIGURE 22-27** Intestinal obstruction as a result of adenocarcinoma (white arrow). Note the distension of the jejunum oral to the mass as compared to the normal diameter aboral to the mass. There is also an enlarged lymph node (black arrow). (Courtesy Dr. Eric Pope, Ross University, College of Veterinary Medicine.)

surgery yields a 41% recurrence of clinical signs, and 18% of dogs experienced transition to malignancy with tumor recurrence.²⁹ Surgical removal of duodenal polyps in cats typically also affords a cure.¹⁷

In cats with small intestinal adenocarcinoma, there is significant perioperative risk, but cats that live beyond 2 weeks may experience long-term control with surgery alone (Figure 22-27). In two series, all cats that did not have their tumors resected were euthanized or died within 2 weeks of surgery.^{15,32} One-half of cats in one report and all cats in another that had their tumors resected died within 2 weeks of surgery, and 4 of 11 died within 2 months in another of complications or nontumor causes.^{15,32,37} For the remaining cats that survived 2 weeks beyond surgery, mean survival was 15 months, although only 20 weeks in another report (median 5 weeks).^{15,38}

In cats with large intestinal neoplasia, survival following surgery alone was approximately 3.5 months for lymphoma, 4.5 months for adenocarcinoma, and 6.5 months for mast cell tumor. Adjuvant

FIGURE 22-28 Intestinal lymphoma in a dog (A). The specimen is shown after resection and anastomosis (B) and on cross-section (C) to illustrate the marked thickening of the bowel wall. (Courtesy Dr. Eric Pope, Ross University, College of Veterinary Medicine.)

chemotherapy improved survival for cats with adenocarcinoma but not for cats with lymphoma.¹⁸

Lymphoma is treated primarily with chemotherapy, except when intestinal perforation or the need for a biopsy necessitates surgery (Figure 22-28). Surgery and chemotherapy did not improve survival compared to chemotherapy alone for cats with alimentary lymphoma.²⁰ In cats with LGL lymphoma of the intestines, few attempts at therapy have been reported in the literature. Chemotherapy induced partial or complete remission in some cats, but MST was only 57 days.⁶⁴ One cat did well for over a year following surgical resection until the tumor recurred.

Chemotherapy

No randomized studies exist to confirm or deny any benefit of adjuvant chemotherapy following resection of epithelial intestinal tumors in dogs and cats. The benefit of adjuvant chemotherapy in humans is questionable, although current fluorouracil-based regimens are often considered to be the standard of care. One retrospective study in cats with colonic adenocarcinoma did show a significant survival advantage for cats receiving adjuvant doxorubicin, with a median survival of 280 days with and 56 days without chemotherapy.¹⁸ For carcinomatosis, intracavitary therapy may be helpful with carboplatin for cats or cisplatin or 5-fluorouracil (5-FU) for dogs.¹¹⁷ When attempted, adjuvant chemotherapy typically includes doxorubicin in veterinary medicine. Two dogs with leiomyosarcoma received adjuvant chemotherapy following surgical resection. One had metastasis at surgery and died 4 months later, and the other was lost at over 2 years, but there were several

other dogs in that series that were long lived that did not receive chemotherapy.²³ Two dogs with adenocarcinoma also received chemotherapy following surgery and both survived over 17 months.³⁰

In dogs with GI lymphoma, of the eight dogs treated in one report, all were euthanized by 14 weeks.²² In cats with intestinal lymphoma, MST is typically 6 to 9 months, although many studies comment that a subset of cats did very well, living over 2 years.^{16,25,35} This may relate to histologic subtype because cats with lymphocytic lymphoma (75% of cases, 70% to 90% response rate, approximately 2-year MST with chlorambucil and prednisone) fared vastly better than those with lymphoblastic lymphoma (25% of cases, <20% response rate, 2.7-month MST with multiagent chemotherapy).^{35,63} General treatment of feline lymphoma is discussed elsewhere (see Chapter 33, Section B), but treatment regimens reported typically include vincristine, doxorubicin, prednisone, and cyclophosphamide for lymphoblastic lymphoma and chlorambucil and prednisone for cats with lymphocytic lymphoma.³⁵

A reduction in the size and clinical signs of rectal polyps in eight dogs was noted following piroxicam therapy, either orally or in suppository form. Clinical response did not relate to whether there was inflammation associated with the tumor.⁹¹

Radiation Therapy

Because of concern for toxicity to surrounding abdominal viscera, the ability to often completely excise intestinal tumors for adequate local control, and the inability to reliably irradiate the same tissue each day because intestines are mobile, RT is seldom used in the treatment of intestinal tumors.

Prognostic Factors

Intestinal perforation does not appear to be a negative prognostic factor for leiomyosarcoma because dogs surviving the perioperative period enjoyed prolonged survival in one series.²³ For colorectal tumors, treatment is prognostic with local excision significantly better than palliative care. Gross appearance, although not statistically examined, may determine outcome because dogs with annular, obstructing masses survived a mean of 1.6 months; nodular or cobblestone masses 12 months; and single, pedunculated masses 32 months.⁵²

For nonlymphomatous small intestinal tumors in dogs, metastasis at the time of surgery resulted in significantly shorter survival times (3 months versus 15 months). One-year survival for dogs with lymph node metastasis was 20% as compared to 67% without.¹¹ In another study, however, dogs with and without visceral metastasis from leiomyosarcoma survived equally long following surgical resection (21 months).²³ In one study, males fared significantly better than females for small intestinal adenocarcinoma, although the number of females was small.³⁰

The strongest prognostic factor for cats with intestinal lymphoma is response to treatment. Cats achieving a complete resolution of clinical signs typically fare significantly better than those that do not.^{20,118} For cats with epitheliotropic lymphoma, those that did not achieve remission (euthanized within 3.5 months) had a worse survival than those that achieved remission (median 11 months).³⁴ For 103 cats with lymphoma, 28 of which were intestinal, negative prognostic factors were FeLV positivity (median survival 3 months if positive, 17 months if negative for early stage disease, not prognostic for advanced stages) and advanced stage of disease.²⁶ FeLV status did not affect outcome in other studies.^{20,25} For large intestinal neoplasia, cats with surgery for lymphoma fared equally poorly with and without adjuvant chemotherapy (median survival of just over 3 months in both groups). Cats with adenocarcinoma, however, survived significantly longer if they were treated with subtotal colectomy (138 days versus 68 days with mass excision), received postoperative doxorubicin (280 days with versus 56 days without), and had negative lymph nodes at surgery (259 days negative versus 49 days positive).¹⁸

Comparative Aspects

Although cancer of the large intestine and rectum is well characterized in humans, small intestinal neoplasia is rare. Theories for this discrepancy include more rapid small intestinal transit time as compared to the large intestine (creating less contact time for carcinogens), dilution of carcinogens with fluid as compared to solid stool, differences in pH, relative lack of bacteria to allow transformation of procarcinogens, presence of detoxifying enzymes, and increased presence of immunoglobulin A promoting local immunosurveillance of damaged cells as a result of increased lymphocytes in the small intestine. Intake of red meat, salt-cured foods, and fat are associated with an increased risk of small intestinal neoplasia, although tobacco and alcohol use were not.¹¹⁹ This is in contrast to veterinary medicine where in cats and sometimes dogs, malignant neoplasia is more common in the small than the large intestine. This may reflect differences in physiology, diet, or genetics among species. The difference in species may also be a matter of proportion in that humans develop a large number of colorectal cancers as a result of diet and genetic influences. As in animals, tumors of the small intestine of humans are usually malignant. Diagnostic evaluation is similar to that described in animals,

although advanced imaging such as CT is more often used. Most diagnoses are made at surgery and 5-year survival rates average just over 20%.¹¹⁹

In contrast to the rarity of small bowel neoplasia, large bowel/colorectal cancer is one of the most frequently diagnosed cancers in both men and women. Risk factors include genetic predisposition/familial history, tobacco and alcohol intake, advanced age, and predisposing medical conditions, among others. Colorectal cancer development may further be influenced by intake of red meat (especially fried), low-fiber and/or high-fat diet, obesity, fecal pH, and fecal mutagens. Among genetic risk factors, polymorphism in colonic enzymes and mutations leading to familial adenomatous syndromes are uncommon but are important as models of carcinogenesis. In most familial polyposis syndromes, the adenomatous polyposis coli (APC) gene is mutated. The multistage progression from benign polyp to carcinoma is well understood and underscores the importance of early detection.¹²⁰ In contrast, hereditary nonpolyposis colon cancer (HNPCC) develops without known premalignant polyps. It is inherited via autosomal dominance with high penetration and is characterized by microsatellite instability.¹²¹

Severe celiac disease in humans is associated with an increased risk of lymphoma. Progression to lymphoma from inflammatory bowel disease (IBD), especially in cats, has been postulated but not confirmed. Two of 97 cats with lymphoma had a history of IBD in a population of cats examined for comparison to a group of cats with IBD at one institution during the same time period.¹²²

The most clinically important aspects of comparative oncology when considering intestinal neoplasia in humans are the use of COX inhibitors in treatment, the prevention of colorectal neoplasia, and the use of TKIs. In people, KIT mutations in GI stromal tumors have led to the use of imatinib mesylate, a TKI that inhibits KIT.¹²³ This illustrates the notion of therapy directed at the molecular defect rather than the histologic diagnosis. KIT is mutated in some canine GISTs, and thus TKIs may benefit this population as well.

COX inhibition by NSAIDs will decrease the incidence of colorectal cancer and decrease mortality by 40% to 50%.¹²⁴ Among the proposed mechanisms of action, prostaglandin production is thought to be related to tumor progression and therefore inhibition leads to cancer prevention. Additionally, non-COX pathways include inhibition of transcription factors and induction of nuclear hormone receptors that lead to cellular differentiation.¹²⁴ Interestingly, a recent retrospective study found a significantly reduced incidence of cancer in dogs with a history of NSAID use (71% reduced risk).¹²⁵

Therapy in humans is similar to that in companion animals. Surgical resection is the primary mode of therapy, with adjuvant targeted or traditional chemotherapy in many cases, especially if patients present with lymph node metastasis or unresectable disease. Transanal endoscopic resection is used when possible for rectal tumors, and this technique has been performed with some success in dogs. TKIs may improve prognosis for unresectable and metastatic GISTs.¹²³ Adjuvant chemotherapy is used in colon cancer, with 5-FU–based combinations providing the best control often in combination with a platinum agent, with some studies showing decreased local recurrence but not increased overall survival.¹²⁶ RT is used primarily for areas of the GI tract that are not very mobile, such as the stomach and rectum.

SECTION H

Perianal Tumors

MICHELLE M. TUREK AND STEPHEN J. WITHROW

The perianal area of dogs contains several glands and structures from which tumors may develop. Perianal, or circumanal, glands are located in the dermis in a circular fashion around the anus and are also scattered in areas on the prepuce, tail, pelvic limbs, and trunk.¹ These are commonly referred to as *hepatoid glands* as a result of their cellular morphologic resemblance to hepatocytes and are considered nonsecretory, sebaceous glands in the adult dog.^{1–3} The anal sacs represent blind cutaneous diverticula that are located on each side of the anus at the four o'clock and eight o'clock positions. Located in the connective tissue surrounding these diverticula are distinct apocrine sweat glands that empty their secretions into the lumen of the anal sacs. The most frequently observed tumors of this region in dogs include perianal sebaceous adenomas, perianal sebaceous adenocarcinomas, and apocrine gland adenocarcinomas of the anal sac (Table 22-9).

Because cats do not have glands analogous to the perianal sebaceous glands in the dog, perianal adenoma and perianal adenocarcinoma are uncommonly recognized in this species. Apocrine gland adenocarcinoma of the anal sac occurs rarely in the cat.^{4–10}

Incidence and Risk Factors

Perianal adenomas (circumanal, hepatoid tumors) represent the majority, 58% to 96%, of canine perianal tumors.^{1,11} Development

• **TABLE 22-9** Perianal Tumors in Dogs

	PERIANAL GLAND		ANAL SAC
	BENIGN	MALIGNANT	MALIGNANT
Cell type	Sebaceous	Sebaceous	Apocrine
Tumor type	Perianal adenoma	Perianal adenocarcinoma	Anal sac adenocarcinoma
Frequency	Common in intact males, very rare in females	Rare	Low frequency
Hormonal factors	Male: Usually intact male, testosterone dependent Female: Ovariohysterectomized (i.e., lack of estrogen)*	None	None
Location and appearance	Superficial hairless perineum; single, multiple, or diffuse; may be on prepuce or tail head	Usually single; may be invasive; often ulcerated.	Subcutaneous at 4 or 8 o'clock, firm and fixed; primary tumor may be small with nodal metastasis.
Paraneoplastic syndromes	None	None (very rarely hypercalcemia).	25%-50% have hypercalcemia.
Metastatic pattern	None	First to regional nodes, then to distant sites; metastasis rate up to 50%, especially with multiple local recurrences.	Common to regional lymph nodes and then to distant sites.
Special work-up	None; cytology may have difficulty distinguishing between benign and malignant	Abdominal imaging (radiographs and/or ultrasound) with focus on caudal abdomen; thoracic radiographs.	Abdominal imaging (radiographs and/or ultrasound); thoracic radiographs; serum calcium levels and renal function.
Treatment	Castration, conservative surgical removal†	Wide excision of primary tumor and lymphadenectomy if lymph nodes involved; postoperative radiotherapy for residual microscopic disease; radiation or chemotherapy if inoperable; castration of little benefit.	Wide excision of primary tumor and lymphadenectomy if lymph nodes involved; consider postoperative radiotherapy to primary site and to regional lymph nodes, as well as chemotherapy.
Prognosis	Excellent, less than 10% recurrence rate if castrated	Fair to good (tumors <5 cm do well); recurrence is common but may take many months and several surgeries can be done.	Fair; good in some cases (appears to depend on stage and treatment).

*If multiple, recurrent, or large (male-like), consider testosterone secretion from adrenal glands; Cushing's signs may or may not be present.

†Estrogens will cause regression but carry risk of bone marrow suppression. Adenomas will respond to radiation therapy, but surgery is cheaper, faster, and safer. Electrochemotherapy and cryosurgery have been reported.

and progression of these benign tumors appear to be sex hormone-dependent, with growth stimulated by androgenic hormones and depressed by estrogenic hormones.^{1,12,13} The older, intact male is at high risk.^{1,11,12} The mean reported age is 10 years.¹¹ A high incidence of associated testicular interstitial cell tumors has been reported for males with adenomas, supporting testosterone production as a cause.¹² However, a true cause-and-effect relationship has not been clarified since interstitial cell tumors are a common incidental finding in non-adenoma-bearing, older intact males. Perianal adenomas in the female occur almost exclusively in ovariohysterectomized animals in which low levels of estrogen do not suppress tumor growth. Rarely, testosterone secretion from the adrenal glands, occasionally accompanied by signs of hyperadrenocorticism, may stimulate perianal adenoma formation in the female.^{14,15} Cocker spaniels, beagles, bulldogs, and Samoyeds may be predisposed.^{1,12}

Perianal adenocarcinoma, a malignant tumor of the perianal glands, occurs much less frequently than its benign counterpart,

representing only 3% to 21% of all tumors in this region.^{1,11} Average age of affected dogs is 11 years.^{11,16} Tumors occur in castrated or intact males, as well as in females, implying no hormonal dependency; however, this does not preclude earlier hormonal initiation.^{12,16} Large-breed males appear to be overrepresented.¹⁶

Apocrine gland adenocarcinoma of the anal sacs occurs at relatively low frequency in the dog, representing 17% of perianal malignancies and 2% of all skin and subcutaneous tumors.^{11,17} A breed survey of a large cohort of British dogs with anal sac adenocarcinoma suggests that spaniels, in particular English cocker spaniels, are at increased risk.¹⁸ Earlier reports suggested a female predilection^{11,19-21}; however, approximately equal sex distribution has been shown in multiple larger series.^{18,22-24} In male dogs, it has been proposed that neutering may be associated with increased incidence of anal sac apocrine gland adenocarcinoma.¹⁸ The average age of dogs diagnosed with this disease is 9 to 11 years.^{11,19,20,22-26} Dogs as young as 5 years have been reported,^{19,20,23,25,27} suggesting

that evaluation of the perineum and palpation of the anal sacs should be a routine part of the physical examination in every adult dog.²³ Benign tumors of the anal sac are very rare.

Anal gland apocrine gland adenocarcinoma occurs rarely in the cat, representing 0.5% of all feline skin and subcutaneous neoplasms.⁷ Median age of affected cats is 12 years, although animals as young as 6 years have been reported.^{7,10} Siamese cats may be at higher risk.⁷

Pathology and Natural Behavior

Almost any tumor can occasionally affect the perianal region, including lymphoma, soft tissue sarcoma, SCC, melanoma, leiomyoma, transmissible venereal tumor, and mast cell tumor. However, the most common tumors in the dog are those that arise from the sebaceous glands of the perineum. The histologic distinction between perianal adenoma and adenocarcinoma may not always be clear, and clinically there may be an intermediate condition called *invasive perianal adenoma*, which may look benign microscopically, yet be moderately invasive in the patient.

Perianal adenomas follow a benign clinical course. The tumors are slow-growing, and although local disease may be extensive, metastasis does not occur.^{1,11,12}

Perianal adenocarcinoma is generally associated with a low rate of metastasis (15%) at the time of original diagnosis.¹⁶ It has been suggested that metastasis is most likely to develop later in the course of disease as the primary tumor becomes larger and more invasive.¹⁶ The most frequent site of metastasis is the regional sublumbar and pelvic lymph nodes, including the iliac, hypogastric, and sacral nodes.^{1,16} Distant metastases may rarely affect lungs, liver, kidney, and bone.^{12,16} These tumors tend to be more rapidly growing, fixed, and firmer than the more common benign perianal adenomas.

Anal sac apocrine gland adenocarcinoma in the dog is distinct from perianal sebaceous gland adenocarcinoma clinically and histologically. Usually, only one anal sac is affected; however, bilateral tumors can occur.^{19,20,25,28} The metastatic potential of this tumor is well established with most reports identifying about 50% metastasis (range 46% to 96%) at the time of initial presentation.^{11,20-26,28} Regional sublumbar lymph nodes and pelvic nodes are by far the most common sites of metastasis early in the course of disease.^{22-26,28} The primary anal sac tumor may be as small as 0.5 cm, with greatly enlarged metastatic nodes. Distant metastatic sites, including lungs, liver, spleen, bone, and, less commonly, heart, adrenal glands, pancreas, kidneys, and/or the mediastinum, may rarely develop later.^{11,19,20,22-25} The association between anal sac apocrine gland adenocarcinoma and paraneoplastic hypercalcemia of malignancy, mediated by tumor secretion of parathyroid hormone-related peptide,²⁹⁻³¹ has been well documented.* Incidence of hypercalcemia is approximately 27% based on an analysis of 113 dogs with anal sac adenocarcinoma.²³ Along with lymphoma, plasma-ionized calcium concentrations tend to be higher with this tumor than with other types of neoplasia.³⁴

The pathogenesis of canine perianal tumors is not known. In a large study evaluating tumor growth characteristics of 240 perianal gland tumors, cell proliferation and apoptosis were quantified by proliferating cell nuclear antigen (PCNA) staining and microscopic detection of apoptotic corpuscles.³⁵ An increase in both parameters was observed in malignant lesions compared to benign ones.³⁵ Various other immunohistochemical studies have attempted

to elucidate possible molecular mechanisms involved in canine perianal gland tumorigenesis. Using a single polyclonal antihuman antibody, nuclear *p53* accumulation was detected in 50% (8 of 16) of perianal sebaceous gland adenocarcinomas in one study, suggesting that expression of a mutated *p53* tumor suppressor protein may play a role.³⁶ Discordant results were reported in another study in which *p53* reactivity was found in none of 11 perianal gland adenocarcinomas and in only a small percentage of adenomas.³⁷ In the same tumor samples, *Mdm2* expression was observed in both adenomas and adenocarcinomas.³⁷ A study that evaluated androgen receptor expression found no difference between perianal adenomas and their malignant counterparts; the authors concluded that the mechanism by which androgens may influence carcinogenesis is still unknown.³⁸ Finally, another proposed mediator of tumor growth or evolution is growth hormone. Growth hormone was detected immunohistochemically in 96% (23 of 24) of perianal adenomas and 100% (5 of 5) of perianal sebaceous gland adenocarcinomas.³⁹ With respect to anal sac adenocarcinoma, expression of E-cadherin, a protein known to mediate adhesion and communication between cells and the extracellular matrix, was evaluated in tumor biopsies from dogs using a polyclonal antihuman antibody that has been validated for use in canines.²⁶ E-cadherin expression correlated with the presence of metastasis and shorter survival time, suggesting that it may play a role in tumor progression.²⁶ *p53* expression has been detected immunohistochemically in a low-to-moderate proportion of anal gland adenocarcinoma tissue biopsies; however, no clinical implications have come from these findings.³⁶ A recent genetic analysis study in English cocker spaniels showed an association between tumor development and major histocompatibility complex haplotype (DLA-DQB1 allele), suggesting that a genetic factor may play a role in tumor development in this at-risk breed.⁴⁰

The biologic behavior of anal sac apocrine gland adenocarcinoma in the cat has not been clearly defined. Most reports suggest that it is a locally invasive disease associated with a moderate-to-high risk of tumor recurrence following surgery.^{5-8,10} The rate of metastasis is variable between studies ranging from low to high.^{6,7,10} Described sites of metastasis include sublumbar lymph nodes, liver, diaphragm, and lungs.^{6,7,10} Paraneoplastic hypercalcemia is not a common complication of this disease in cats.^{7,10} Bilateral tumors have not been reported.

History and Clinical Signs

The history for benign perianal adenoma is that of a slow-growing (over months to years) mass or masses that are nonpainful and usually asymptomatic. These may be single, multiple, or diffuse (similar to generalized hyperplasia or hypertrophy of the perianal tissue; Figure 22-29).¹ Most occur on the hairless skin area around the anus, although they may extend to haired regions and can develop on the prepuce, scrotum, or tail head (stud tail or “caudal tail gland”).¹ Benign lesions may ulcerate and become infected but are rarely adherent or fixed to deeper structures.¹ They are usually fairly well circumscribed, on average 0.5 to 3 cm in diameter, and elevated from the perineum.¹

The male perianal adenocarcinoma may look similar to adenomas but tends to grow more rapidly, be more firm, become ulcerated, adhere to underlying tissues, recur following conservative surgery, and generally be larger than its benign counterpart.¹⁶ Obstipation, dyschezia, or perianal pain/irritation can be seen with larger masses.¹⁶ Rarely, signs are related to obstruction of the pelvic canal by lymph node metastasis. Tumors can be multiple.¹⁶ Castrated males with new or recurrent perianal tumors should raise

*References 20-23, 25-28, 32-34.

• **FIGURE 22-29** **A**, Typical small and ulcerated perianal adenoma can be seen at 1 o'clock. Treatment with castration and cryosurgery was curative. **B**, Diffuse 360-degree involvement of the perianal region with perianal adenoma. Aggressive resection or cryosurgery should not be performed; instead, castration, a waiting period of several months for partial regression, and the local treatment for residual disease were applied.

• **FIGURE 22-30** An anal sac adenocarcinoma in a female dog. Note the typical 4 o'clock position.

the suspicion for malignant rather than benign disease because adenocarcinomas are not hormonally dependent.

Clinical signs of dogs with anal sac adenocarcinoma are often referable to either the presence of the primary mass (perianal discomfort, swelling [Figure 22-30], bleeding; scooting),

• **FIGURE 22-31** Lateral radiograph of the caudal abdomen in a male dog with anal sac adenocarcinoma. Note the metastatic involvement of sublumbar/iliac lymph nodes (arrows) and downward displacement of large bowel.

to obstruction of the pelvic canal by regional nodal metastasis (tenesmus, constipation [Figure 22-31]), or to hypercalcemia (polyuria, polydipsia; anorexia; lethargy; vomiting).^{22,23} In as many as 39% of dogs, the primary tumor can be an incidental finding on physical examination.²³ Rarely, regional bone metastasis or direct extension of tumor from sublumbar lymph nodes into the lumbar vertebrae with associated pain or fracture may be seen.

In cats, the most common history and clinical signs associated with anal sac adenocarcinoma are related to the presence of local disease. Like dogs, cats may be presented for tenesmus,

constipation, scooting, presence of a mass, hemorrhagic discharge, or excessive grooming of the perineal area.^{6-8,10} Lethargy and/or inappetence may be secondary to severe constipation.⁵ Not all cats present with clinical signs, and tumors can be detected incidentally during a routine physical examination.⁷ Clinicians should recognize anal sac adenocarcinoma as a distinct clinical entity in the cat and include it as a differential diagnosis for animals with anal sac disease.⁷ It is not uncommon for anal sac adenocarcinoma to be misdiagnosed as an anal sac abscess based on the presence of a mass, ulceration, or a fistulous tract in the perineal region.⁷

Diagnostic Techniques and Work-Up

In the intact male with suspected perianal adenoma, a routine geriatric work-up prior to anesthesia is desirable. Thoracic radiographs to evaluate for lung metastasis may not be cost effective unless indicated for other cardiopulmonary evaluation given the benign biologic behavior of these tumors. Evaluation of regional lymph node size is indicated if one suspects perianal adenocarcinoma based on signalment (neutered male), recurrent disease, or physical examination characteristics of malignancy. Ultrasonographic evaluation of regional lymph nodes is a superior staging tool in comparison to plain radiography which can both underestimate and overestimate lymph node disease.⁴¹ Although distant metastasis is uncommon, thoracic radiographs to evaluate for lung metastasis are recommended in dogs with perianal adenocarcinoma. FNA and cytology to differentiate benign from malignant tumors in the male can be unrewarding, although they are helpful in ruling out other forms of cancer or mass development. Tissue biopsy is necessary to make the distinction in most cases, and the most important histologic criteria supporting a diagnosis of perianal sebaceous gland adenocarcinoma is invasiveness of tumor cells into surrounding tissue.⁴² Disorderly arrangement of cells, increased nuclear pleomorphism, and increased numbers of mitotic figures also favor a diagnosis of malignancy.⁴² The use of monoclonal antibodies, MAb4A9 and 1A10, developed against a canine mammary cell line and screened for reactivity with perianal adenocarcinoma, has been proposed as a diagnostic tool to help distinguish benign perianal tumors from adenocarcinoma when routine light microscopy is not conclusive.⁴³ Clinical validation is needed to confirm the utility of this approach.

Since dogs with anal sac adenocarcinoma may present with signs unrelated to perianal disease (i.e., polyuria, polydipsia due to hypercalcemia), assessment of animals with suspicious clinical signs requires a careful rectal examination, including palpation of the anal sacs and evaluation for possible regional lymphadenopathy. Definitive diagnosis must be made cytologically or histologically, but a strong presumption of anal sac adenocarcinoma can be made for animals in which rectal examination identifies the presence of a firm and discrete mass in the area of the anal sac. This tumor has a characteristic cytologic appearance and is made up of polyhedral cells that have uniform round nuclei and light blue-gray, slightly granular cytoplasm. Features of malignancy may be subtle. In addition to suggesting the presence of cancer in the anal sacs, FNA is valuable for ruling out infection or inflammatory disease of the anal sac. The clinician should be aware that anal sac tumors can become secondarily infected or inflamed. Staging of disease includes thoracic radiographs for rare detection of pulmonary or mediastinal involvement. Abdominal radiographs may reveal regional lymphadenopathy in advanced cases (see Figure 22-31). Ultrasonographic

evaluation of regional lymph nodes is a superior staging evaluation because plain radiography can both underestimate and overestimate lymph node disease.⁴¹ A recent study evaluating sonographic features of abdominal lymph nodes found that alterations in shape, contour, cavitation, echogenicity and parenchymal uniformity do not reliably distinguish neoplastic from benign nodes. The only significant difference identified between neoplastic and benign lymph nodes was size.⁴⁴ Ultrasound also allows for evaluation of other possible sites of abdominal metastasis, particularly liver and spleen. Advanced imaging, including CT and MRI, may yield a more complete assessment of abdominal involvement.⁴⁵ In rare instances, pulmonary metastasis can be present without obvious regional lymph node disease. Lameness or bone pain should be evaluated with radiography and/or nuclear scintigraphy to rule out bone metastasis. Work-up also includes complete blood count, serum chemistry panel, and urinalysis. Hypercalcemia of malignancy can result in renal damage, which may modify prognosis and anesthetic risk. Medical management of hypercalcemia or impaired renal function may be necessary prior to surgery (see Chapter 5).

Careful rectal examination should be performed on all dogs with perianal tumors to detect the clinical degree of fixation prior to surgery, the probability of resection, and the risk of postoperative complications, particularly incontinence, although this is very rare with even aggressive unilateral resection. It is also important to palpate for the presence of enlarged sacral lymph nodes located along the ventral surface of the vertebrae because these are not easily detectable by ultrasound due to their position in the caudal pelvic canal.

Similarly to dogs, feline anal sac adenocarcinoma can be diagnosed cytologically and histologically. Complete staging of this tumor in cats includes thoracic radiographs to evaluate for pulmonary metastasis and abdominal imaging.^{4-6,8} Abdominal ultrasound is more sensitive than radiography for detection of metastasis involving abdominal organs or lymph nodes. Positive immunoreactivity with anticytokeratin monoclonal antibody, CAM 5.2, was recently reported in a series of 12 cats with anal sac adenocarcinoma.⁷

Therapy and Prognosis

Due to the hormonal dependence of perianal adenomas, the vast majority of these tumors will regress (at least partially) following castration, and recurrence is uncommon.¹² Surgery is recommended in males with ulcerated tumors or recurrence, as well as in females with typical small and focal masses.¹² For diffuse or large benign lesions situated on or in the anal sphincter, castration followed by an observation period of several months to allow reduction in tumor volume may permit safer and easier mass removal. This will only be effective for benign lesions that are hormone dependent. Over 90% of male dogs will be cured with castration and mass removal.^{1,12} Adenomas can be excised with minimal margins. In addition to standard surgical techniques, mass removal can be achieved using cryosurgery or carbon dioxide laser, which should only be used for focal lesions less than 1 to 2 cm in diameter.^{46,47} Use of either of these techniques precludes evaluation of the surgical margins for completeness of excision, which may be acceptable for benign masses; however, as the most consistent criterion for malignancy is invasiveness, lack of margin assessment is not without risk. Hyperthermia and RT have also been used successfully.^{48,49} The cost, added morbidity, and limited availability of these techniques make them a poor alternative to standard blade excision. Electrochemotherapy has been recently described^{50,51} and

consists of intratumoral injections of chemotherapy (cisplatin and/or bleomycin in recent reports) followed by local delivery of electric pulses to potentiate drug uptake. Treatments are delivered in one or two weekly sessions. Based on limited studies, the reported overall response rate is greater than 90%, with 65% complete responses.^{50,51} Smaller tumors (<5 cm) generally respond better than larger tumors.^{50,51} Larger tumors are more likely to develop local complications, including focal necrosis, erythema, and inflammation.^{50,51} Systemic effects are not reported.^{50,51} Castration and surgical excision remain the treatments of choice for adenomas. Adenomas may also regress following estrogen therapy; however, its use is contraindicated by the risk of myelosuppression. Cyclosporin is reported to have had a palliative effect in a single dog with multiple ulcerated perianal adenomas and a measurable reduction in tumor size was observed.⁵²

Perianal sebaceous gland adenocarcinoma is more locally invasive than its benign counterpart and generally does not respond to castration.¹² Aggressive surgical removal with adequate margins is indicated. Removal of one-half or more of the anal sphincter is possible with only rare transient loss of continence. Recurrent disease becomes more difficult to resect. Unfortunately, most perianal adenocarcinomas are not suspected or known until after a conservative resection, which contaminates further tissue planes and can make the second resection problematic. Due to common local recurrence, this tumor is difficult to cure and may require numerous palliative resections over several years. Preoperative diagnosis of malignancy (i.e., incisional biopsy) and more aggressive initial resection should improve local control and should be strongly encouraged. The utility of postsurgical RT should also improve local control; however, data for this approach are lacking. The use of electrochemotherapy has been reported in a small series of dogs.⁵¹ Although the study suggested a favorable outcome in the adjuvant setting, additional clinical studies are needed for validation of the efficacy of the approach.⁵¹

In a series of 41 dogs with perianal adenocarcinoma, stage of tumor had a significant influence on DFI and overall survival (Figure 22-32).¹⁶ Tumors less than 5 cm in diameter (T2) were

associated with 2-year tumor control rates in excess of 60%, suggesting that surgical removal of these masses at an early stage is relatively successful with respect to disease control. Fifteen percent of dogs had evidence of metastasis at the time of diagnosis, which related negatively to survival (see Figure 22-32).¹⁶ MST for dogs with lymph node or distant metastasis was 7 months; however, aggressive treatment was not attempted in five of six cases.¹⁶ If present, regional lymph node metastasis may be excised. Large nodal volume is not a contraindication to caudal abdominal exploratory and lymphadenectomy because some nodes “shell out” readily, whereas others are invasive. Enlarged lymph nodes should be considered for removal, especially if they are causing obstruction of the pelvic canal. The use of radiation and/or chemotherapy, including actinomycin D, has been reported anecdotally, but their role in local or distant control is largely undefined.^{16,53,54} Controlled clinical trials have not been performed. It has been suggested that nuclear size measured by computer-assisted image analysis in cytologic tumor samples may correlate with biologic behavior in this tumor type.⁵⁵

Apocrine gland adenocarcinoma of the anal sac is generally locally invasive, and aggressive surgical excision is recommended. Recurrence rate is high after marginal surgery alone.^{20,22} Complete resection of large perianal malignancies is difficult due to proximity to the rectum and poor definition of perineal tissue to define an adequate margin. Metastasis is present at the time of diagnosis in approximately 50% to 80% of cases,^{19,20,22,23,25} with regional lymph nodes being the most common site.

Enlarged lymph nodes should be considered for removal, especially if they are causing obstruction of the pelvic canal or contributing to hypercalcemia. Radiation and/or chemotherapy may be used adjuvantly or as the sole treatment.^{22-25,28}

Large-scale studies controlled for tumor stage and treatment are lacking in dogs with anal sac adenocarcinoma. There is discordance in the outcome and prognosis reported in the literature. Earlier small studies suggest a MST of 6 to 12 months.^{20,22,27} This is in contrast to recent reports in which the MST ranges from 16 to 18 months.^{23,24} These later studies involve larger groups of dogs (113

FIGURE 22-32 Survival duration in 41 male dogs with perianal adenocarcinoma based on stage. Note that dogs with small tumors (T1 or T2) without lymph node involvement will do well after aggressive removal of the primary tumor. T1 = tumor <2 cm, T2 = tumor 2-5 cm, T3 = tumor >5 cm, T4 = tumor invading other structures, such as fascia, muscle, or bone; N0 = no evidence of regional lymph node involvement, N3 = fixed lymph nodes; M0 = no evidence of distant metastasis, M1 = distant metastasis detected.

dogs and 80 dogs, respectively).^{23,24} However, there is variability in stage of disease and treatment in the study populations that leads to difficulty accurately predicting the prognosis of individual dogs with this tumor type. Negative prognostic indicators gleaned from these and other studies include increasing primary tumor size,^{23,24} presence of lymph node metastasis,²⁴ presence of distant metastasis,^{23,24,26} advanced clinical stage,²⁴ nonpursuit of surgery,²³ treatment with chemotherapy alone,²³ and lack of any therapy at all.²⁴ In one study, extirpation of involved sublumbar lymph nodes in dogs without distant metastasis correlated with improved survival compared to animals in which nodal metastases were not removed.²⁴ E-cadherin expression detected immunohistochemically in tumor biopsies has also been suggested to directly correlate with survival.²⁶ These prognostic variables should be confirmed in controlled clinical trials.

Although chemotherapy and RT are generally considered standard adjuvant treatment options for anal sac adenocarcinoma, the role of these modalities alone or in combination is not well defined. Chemotherapy is theoretically indicated given the high rate of metastasis. Chemotherapeutics with demonstrated antitumor activity in the gross disease setting include carboplatin, cisplatin, and actinomycin D.^{22,24,52} Other drugs reported in the adjuvant setting include mitoxantrone and melphalan.^{25,28} Gross tumor responses have not been described for these agents when used alone, and their true role in combination therapies is not known. Toceranib phosphate, a TKI, has been associated with modest tumor responses with median response durations of 19 to 25 weeks in a series of 33 dogs with multiple prior failed therapies.⁵⁶ This antitumor effect may be mediated through inhibition of the platelet-derived growth factor receptor β (PDGFR- β) based on immunoreactivity of tumor biopsies to anti-PDGFR antibody.⁵⁷ Controlled clinical trials are needed to determine the role of toceranib in the treatment of anal sac adenocarcinoma. Adjuvant electrochemotherapy using cisplatin is reported in a single dog following an incomplete primary tumor excision.⁵⁸

The optimal combination of therapies for anal sac adenocarcinoma is not known. In three clinical studies with controlled treatment regimes, MSTs ranged from 17 to 31 months.^{24,25,28} A study of 14 dogs that underwent surgical excision and melphalan chemotherapy reported an overall MST of 20 months (95% CI, 11.6 to 28.4 months).²⁸ Seven dogs had known nodal metastasis at the time of diagnosis, and nodal metastasis was not prognostic for survival in this small study. A significant relationship between a modified clinical staging scheme and survival was found in a study of 50 dogs treated prospectively according to a predetermined management algorithm.²⁴ Treatment included various combinations of surgery, carboplatin chemotherapy, and hypofractionated (9 Gy \times 4 weekly fractions) RT. Fifteen dogs had sublumbar lymphadenopathy and/or distant metastasis at the time of treatment. MST was 17 months (95% CI, 7 to 27 months). Toxicity associated with the treatment was not reported. The third study utilized a standardized RT protocol with concurrent chemotherapy in a cohort of 15 dogs.²⁵ Dogs were treated with combination surgery (primary tumor \pm metastatic lymph nodes), curative-intent radiation (3.2 Gy \times 15 daily fractions for a total dose of 48 Gy) to the primary tumor site and regional lymph node beds, and mitoxantrone chemotherapy. Seven dogs had lymph node metastasis at diagnosis. Median event-free survival was 9 months (range: 2.5 to 35 months), and overall survival was 31 months (range: 5 to 47 months). Measurable responses were observed in bulky metastatic lymph nodes. The relative importance of radiation versus mitoxantrone chemotherapy is not clear from this study. Without more rigorously controlled clinical

trials, strong statements about the “best” treatment and prognosis are difficult to support. In a case series of five dogs selected for resectability of metastatic lymph nodes, a MST of 20 months was achieved with surgery alone.⁵⁹ One dog underwent repeated lymph node debulking surgeries and survived for 54 months. Another dog survived 18 months following omentalization of cystic sublumbar lymph node metastasis for palliation of tenesmus and dysuria.⁶⁰ Taken together, these findings of prolonged survival, despite varying tumor stages and varying treatments, strongly suggest the need for prospective, controlled clinical trials to elucidate any benefits of treatment modalities, such as radiation, chemotherapy, molecular-targeted drugs, and their combinations. Identification of reliable prognostic criteria predictive of outcome or treatment response is also needed. It has been suggested in a small study using computer-assisted analysis that nuclear size of tumor cells may correlate with biologic behavior; nuclear size parameters were larger in metastatic anal gland adenocarcinomas than in nonmetastatic tumors.⁶¹ Further validation of this approach is needed before it can be considered clinically useful. Finally, when short-term palliation is the therapeutic goal, treatment options include surgery, palliative RT, chemotherapy and/or toceranib, even though efficacy of these approaches has not been definitively established.

Curative-intent RT of the perineal and pelvic regions is associated with self-limiting, acute radiation effects, including mild-to-severe moist desquamation, colitis, and perineal discomfort lasting 2 to 4 weeks posttherapy. Radiation prescriptions should be designed to minimize the risk of late effects, including rectal stricture or perforation. Two studies have demonstrated that radiation doses of less than 3 Gy per fraction should be used to minimize this risk.^{62,63} In the only report of standardized curative-intent RT for anal sac adenocarcinoma,²⁵ none of the side effects were reported as life-threatening, and all dogs maintained reasonable quality of life as assessed by owners. Chronic complications included tenesmus and narrow stool, diarrhea, and rectal stricture. The daily radiation dose in this study was 3.2 Gy. Future studies should be designed with daily radiation doses of less than 3 Gy to reduce the risk of chronic complications.

There is discordance in the data reported regarding the prognostic significance of hypercalcemia of malignancy accompanying anal sac adenocarcinoma. Hypercalcemia has generally been associated with shorter survival^{20,23}; however, other studies have not supported this finding.^{22,25,26,28} Complete or near-complete removal of the tumor results in reversal of hypercalcemia. Return of hypercalcemia after therapy usually signals recurrence or metastasis.

Prognosis associated with feline anal sac adenocarcinoma has not been clearly established and some reports are conflicting. Local recurrence after surgical resection appears relatively common. The reported rate of metastasis is variable. In a study involving 39 cats that underwent incisional biopsy or tumor resection, survival time ranged from 0 to 23 months.⁷ Eighty-five percent of cats succumbed to local disease or presumptive metastasis. MST in this group was 3 months; 1- and 2-year survival rates were 19% and 0%, respectively.⁷ This is in contrast to a recent retrospective study of 23 cats that reported a median DFI and survival time of over 300 days.¹⁰ The role of chemotherapy and RT is not known. A short-lived partial response to carboplatin was reported in a cat with recurrent anal sac adenocarcinoma.⁸ In another report, outcome following concurrent adjuvant curative-intent RT (48 Gy) and chemotherapy (carboplatin) resulted in local recurrence and/or metastatic disease within 6 months of treatment in two cats.⁶ In both cases, RT was well tolerated with minimal acute effects.⁶ Although these survival data are not encouraging, more studies are needed to determine the

true role of radiation and chemotherapy in this disease. Based on individual cases of long-term survival, it has been suggested that early detection and completeness of excision may positively impact outcome.^{6,7}

Comparative Aspects⁶⁴⁻⁶⁶

No similar hormonally dependent perianal disease state exists in humans. The most common cancer of the anal margin is squamous cell (epidermoid) carcinoma. These tumors arise from the junction of haired skin and mucous membrane of the anal canal. Risk of developing cancer in this location is positively correlated with sexual activity, and most tumors are associated with human papillomavirus infection. Precancerous changes (dysplasia) in the epithelium of the anal canal may precede tumor development. Regional lymph nodes are the most common site of metastasis. Previously considered a surgical disease requiring a permanent colostomy, improved outcomes have been achieved with definitive chemoradiation. The standard approach to therapy is concomitant radiation and chemotherapy using 5-FU and mitomycin C. Surgery is reserved for locally recurrent or persistent disease. Mean 5-year disease-free survival and overall survival are 60% and 75%, respectively. Size and degree of invasion of the primary tumor, regional lymph node involvement, and presence of distant metastases are important prognostic factors. Identification of biomarkers that may serve as predictors of outcome or targets for therapy is being explored.

■ SECTION A

Cancer of the Nasal Planum

STEPHEN J. WITHROW

Incidence and Risk Factors

Cancer of the nasal planum is uncommon in the dog and relatively common in the cat. The development of squamous cell carcinoma (SCC) has been correlated with ultraviolet (UV) light exposure and lack of protective pigment.¹ One paper suggests a papillomavirus may be involved in feline SCC development.² Classically, it is seen in older, lightly pigmented cats.

Pathology and Natural Behavior

By far the most common cancer is SCC. Depending on when the biopsy is performed, the tumors may be reported as carcinoma in situ, superficial SCC (<2 mm deep), or deeply infiltrative SCC. They may be very locally invasive but only rarely metastasize.

Other cancers reported in the nasal planum are lymphoma, fibrosarcoma, hemangioma, melanoma, mast cell tumor, fibroma, and eosinophilic granuloma. Immune-mediated disease may manifest as erosive or crusty lesions on the nose, but it is rarely proliferative, and other sites on the body usually are affected. Immune-mediated disease probably is not a contributing factor in tumor development.

History and Clinical Signs

Invasive SCC usually is preceded by a protracted course of disease (months to years) that progresses through the following stages (Figure 23-1): crusting and erythema, superficial erosions and ulcers (carcinoma in situ or early SCC), and, finally, deeply invasive, erosive lesions. In cats SCC usually originates on the cornified external surface of the nasal planum, whereas in dogs it often occurs in the mucous membrane of the nostril or the external planum. Associated lesions on the eyelid, preauricular skin, and ear pinna may be seen in cats if these sites lack protective pigment. Patients often have been treated with corticosteroids or topical ointments, with minimal response.

Diagnostic Techniques and Work-Up

For erosive or proliferative lesions, a deep wedge biopsy may be done to determine the degree of invasion and the histologic type of

disease. These biopsies require a brief general anesthetic because of the sensitivity of the nasal planum. Hemorrhage can be temporarily profuse and usually requires one or two deep sutures to appose the edges. Cytologic scrapings and superficial biopsies are of little value because they frequently reveal only inflammation, which may accompany both cancer and noncancerous conditions. Lymph nodes are rarely involved except in very advanced disease, and thoracic radiographs are almost invariably negative for metastasis. Regional radiographs generally are unrewarding. Computed tomography (CT) and magnetic resonance imaging (MRI) have proved to be valuable staging tool in dogs with SCC of the nostril. They can help define the posterior extent of the tumor and guide the posterior level of resection or the posterior extent of the radiation field.

Therapy

Limiting exposure to the sun or tattooing to add pigment protection may prevent or arrest the course of the preneoplastic disease. Topical sunscreens are easily licked off and rarely help. Maintaining the tattoo is very difficult when inflammation and ulceration are present because it is rapidly removed by macrophages. Even under the best of circumstances, tattooing must be repeated regularly and reports of success are anecdotal. Attempts to increase epithelial differentiation with synthetic derivatives of vitamin A generally have been unsuccessful for advanced disease but may be of help in reversing or limiting the growth of preneoplastic lesions.^{3,4}

SCC and probably other neoplasms as well fall into two general categories: superficial, minimally invasive disease versus deeply infiltrating disease. Superficial cancers can be managed effectively by almost any method, including cryosurgery, lasers,^{5,6} photodynamic therapy,⁷⁻⁹ intralesional carboplatin chemotherapy,¹⁰ intralesional carboplatin combined with radiation therapy (RT),¹¹ hyperthermia, and irradiation alone.¹²⁻¹⁹ A distinct disadvantage with these techniques is the inability to obtain a surgical margin by which to document the adequacy of treatment. RT, in particular, which would have the greatest chance of preserving the cosmetic appearance of the nose, has had poor local control rates for larger and more invasive SCC in the dog but is more effective treating SCC of the nasal planum in the cat.^{14,15,20} Expectations for radiation with other tumor types must be extrapolated from results achieved in more conventional sites.

In the cat, invasive cancer of the nasal planum can be completely excised with an acceptable cosmetic result.²¹ The nasal planum is removed with a 360-degree skin incision that also transects the underlying turbinates (Figure 23-2). A single cutaneous purse-string suture of 3-0 nylon is placed to pull the skin into an open circle (1 cm in diameter) around the airways. The purse-string suture must not be pulled too tight or it may heal across the

• **FIGURE 23-1** **A**, Crusting and erythema on the nose of a white cat. The condition had been slowly progressive for 8 months, and 6 months later, the lesion was confirmed through biopsy as carcinoma in situ. **B**, A cat with an invasive SCC that has caused some erosion of the nasal planum but is still confined to the nasal planum. Nosectomy was curative. **C**, This cat had a 2-year history of progressive nasal ulceration and deformity. The nasal planum is markedly deformed, and the surrounding skin up to the eyelids is swollen and infiltrated with SCC. Even nosectomy would not be curative. Note the concomitant eyelid lesions, which were carcinoma in situ.

airways. The site subsequently crusts and scabs over. The scab is removed at suture removal (this often requires sedation or anesthesia), and healing of the skin with two patent airways (“nostrils”) is complete by 1 month. An occasional problem with “nosectomy” is stricture of the combined nasal orifice. This can be frustrating and has been variously managed with wide skin excision and removal of the nasal septum rostrally, laser ablation, rubber stents, or permanent placement of a stainless steel intraluminal expansile

stent.²² Functional and cosmetic results are good in the cat (Figure 23-3), and fair to good in the dog^{23,24} (Figure 23-4). This procedure probably is the treatment of choice for invasive lesions that have not spread extensively to the lip or surrounding skin. The author has found that adjuvant RT has been successful if the margins of removal are incomplete. Combined removal of the premaxilla and nasal planum has been reported in the dog with extensive, invasive lesions.^{23,25,26}

• **FIGURE 23-2** Operative view of resected nasal planum in a cat with invasive carcinoma that was confined to the nasal planum.

• **FIGURE 23-3** One-year postoperative view of a cat after nosectomy for SCC. Note the well-healed skin around patent airways. This cat remains free of disease 28 months after surgery.

Prognosis

The outlook for SCC is good for early, noninvasive disease. However, the development of new sites of neoplasia on other areas of the planum after localized treatment is common because the underlying causes are not reversed.²⁷ Later-stage disease can be cured with aggressive surgery but is poorly responsive to most other treatments.^{20,21,25} More than 80% of cats with invasive SCC of the nasal planum treated with wide resection (nosectomy) are free of recurrent disease at 1 year.^{5,21} Newer reports of proton irradiation¹⁶ and irradiation with intralesional chemotherapy¹¹ suggest control rates in cats exceeding 60%. Strontium (Sr) 90 plesiotherapy can achieve 75% complete response (CR) rates for superficial SCC, and retreatment is possible. In a study of nosectomy (with or without removal of the pinnae) in 38 cats, the median survival time (MST) exceeded 22 months.⁵ Photodynamic therapy can be effective in treating cats with SCC of the nose, but the lesions must

• **FIGURE 23-4** Two-year postoperative view of a dog after nasal planum resection for SCC.

be small and minimally invasive for a good result.⁷⁻⁹ In dogs, the local recurrence rate after nosectomy is low.^{20,26} Delayed lymph node metastasis (longer than 1 year after surgery) in dogs with SCC has been successfully treated with lymphadenectomy. Because SCC rarely metastasizes from the nasal planum, even untreated

animals with advanced cancer can live a long time, albeit with an ulcerated and deforming cancer.

Comparative Aspects²⁸

As in the cat, cancer of the human nasal skin and nasal vestibule (anterior entrance to the nasal cavity) may be induced by exposure to UV light. Lack of protective pigment is also a contributing factor in humans. SCC of the vestibule is treated with irradiation (interstitial or external beam) or surgery. Surgery generally involves resection of the nasal skin and cartilage, followed by reconstruction using composite ear skin and cartilage, nasolabial flaps, or a prosthesis. Local control generally is good.

SECTION B

Nasosinal Tumors

MICHELLE M. TUREK AND SUSAN E. LANA

Canine Nasosinal Tumors

Incidence and Risk Factors

Tumors of the nasal cavity and paranasal sinuses account for approximately 1% of all neoplasms in dogs.¹ The average age of dogs with this disease is approximately 10 years, although canine patients as young as 9 months have been reported.^{2,3} Medium-to-large breeds may be more commonly affected.² A slight male predilection has been suggested.^{2,4} It has been speculated, but is unproved, that dolichocephalic breeds (long-nosed) or dogs living in urban environments, with resultant nasal filtering of pollutants, may be at higher risk for developing nasal cancer.^{4–6} Exposure to environmental tobacco smoke has been associated with an increased risk of nasal cancer in a group of dogs in one study,⁷ but the same was not true in another.⁶ Indoor exposure to fossil fuel combustion products, such as those produced by coal or kerosene heaters, may contribute to the suggested environmental component of this cancer.⁶

Pathology and Natural Behavior

Carcinomas, including adenocarcinoma, SCC, and undifferentiated carcinoma represent nearly two-thirds of canine intranasal tumors.⁸ Sarcomas (usually fibrosarcoma, chondrosarcoma, osteosarcoma, and undifferentiated sarcoma) comprise the bulk of the remaining

cancers.⁹ Both carcinomas and sarcomas are characterized by progressive local invasion. The metastatic rate is generally considered low at the time of diagnosis but may be as high as 40% to 50% at the time of death, which is usually attributable to the primary disease rather than metastatic lesions.² The most common sites of metastasis are the regional lymph nodes and the lungs.^{2,9,10} Less common sites include bones, kidneys, liver, skin, and brain.¹¹⁻¹⁴

Rare tumors of the nasosinal region in dogs include round cell tumors, such as lymphoma (unlike in cats, in which this is a common nasal tumor); mast cell tumors; and transmissible venereal cancer. Other malignancies include hemangiosarcoma, melanoma, neuroendocrine carcinoma, nerve sheath tumor, neuroblastoma, fibrous histiocytoma, multilobular osteochondrosarcoma, hamartoma, rhabdomyosarcoma, and leiomyosarcoma.^{2,15-28} The biologic behavior of these less common malignancies is not well defined. Benign lesions such as polyps, fibromas, dermoid cysts, and angiomatous proliferation can also be seen.

A number of studies have attempted to elucidate possible molecular mechanisms associated with canine nasosinal tumorigenesis. In one study using a single polyclonal antihuman antibody, nuclear *p53* accumulation was detected in nearly 60% of nasal adenocarcinomas (11 of 19), which suggests that overexpression of a mutated *p53* tumor suppressor protein may play a role.²⁹ Cyclooxygenase-2 (COX-2) expression has been detected to varying degrees in most nasosinal epithelial tumors sampled³⁰⁻³³ and in normal paratumoral respiratory epithelium and stromal tissue.³³ In a recent study, epidermal growth factor receptor (EGFR) expression and vascular endothelial growth factor (VEGF) expression were detected in over 50% and 90% of the 24 nasal carcinomas evaluated, respectively.³⁴ All tumors expressed either EGFR or VEGFR, but there was no association between the immunoreactivity for each protein.³⁴ Expression of peroxisome proliferator-activated receptor γ (PPAR- γ), a nuclear receptor involved in glucose metabolism and fatty acid storage, has also been shown in canine nasal carcinomas.³⁵ The authors of that study suggested that expression patterns may differ in tumor tissue compared to normal nasal epithelium.³⁵ The role of these proteins in carcinogenesis is not clear, and further investigation is needed before clinical relevancy can be determined. Evaluation of the inflammatory infiltrate in 31 canine nasal carcinomas revealed an abundance of neutrophils and macrophages, which were present in greater numbers than in normal canine mucosa.³⁶ Plasma cells were also detected in the majority of tumors but varied in number compared to normal tissue. T-lymphocytes were detected less commonly, in lower numbers than in the normal mucosa, and predominately at the periphery of the tumors. Activity of matrix metalloproteinase-2 (MMP-2) in nasal adenocarcinomas was negligible in one small study.³⁷

History and Clinical Signs

Although many intranasal diseases will have overlapping clinical signs, a strong suspicion of cancer is appropriate for older animals with an intermittent and progressive history of unilateral (initially) epistaxis or mucopurulent discharge (or both). The average duration of clinical signs prior to diagnosis is 2 to 3 months^{1,38}; these most commonly include epistaxis, bloody or mucopurulent nasal discharge, facial deformity due to bone erosion and subcutaneous extension of tumor, unwillingness to open the mouth, sneezing, dyspnea or stertorous breathing, exophthalmus, and ocular discharge as a result of mechanical obstruction of the nasolacrimal duct.^{2,8,38} Differential diagnoses for animals with these clinical signs include fungal (*Aspergillus* sp.) or bacterial rhinitis, idiopathic non-specific rhinitis (usually lymphoplasmacytic), rare nasal parasites,

bleeding disorders, hypertension, foreign body, trauma, and developmental anomalies (e.g., cystic Rathke's clefts).³⁹⁻⁴¹ If facial deformity is present, the diagnosis is almost always cancer^{42,43}; however, aspergillosis, sporotrichosis, and a rare, benign condition, angiomatous proliferation of the nasal cavity, also can cause facial deformity. Dogs with epistaxis and concurrent clinical signs of systemic disease, including lethargy, inappetence, weight loss, hemorrhage at extranasal sites and concurrent neurologic disease, are more likely to have nonneoplastic systemic disorders such as bleeding disorders, hypertension, and tick-borne or bacterial infections.^{43,44}

Clinical signs can be temporarily alleviated by a variety of symptomatic treatments, including antibiotics, steroids, and nonsteroidal antiinflammatory drugs (NSAIDs).³⁸ An initial response to these treatments should not diminish the index of suspicion for neoplasia in older dogs with clinical signs consistent with cancer.³⁸

On rare occasions, animals with tumors involving the caudal region of the nasal cavity may have only neurologic signs (e.g., seizures, acute blindness, behavior change, paresis, circling, and obtundation) caused by direct invasion of the cranial vault.⁴⁵ However, absence of neurologic signs does not rule out tumor extension into the cranial vault because most dogs with nasal tumors that extend beyond the cribriform plate do not exhibit neurologic signs.

Diagnosis and Staging

A definitive diagnosis of nasosinal cancer requires a tissue biopsy, even though diagnostic imaging and historic information can be highly suggestive. Coagulation disorders must be ruled out before biopsy because bleeding during the procedure is to be expected. Attention should be paid to the platelet count, appropriate clotting at venipuncture sites, and the presence of hematuria, retinal hemorrhage, or petechial hemorrhages. A clotting profile (prothrombin time [PT], activated partial thromboplastin time [APTT]), bleeding time, or activated clotting time (ACT) can also be done.

The superior imaging value of CT and MRI over conventional radiographs for canine nasal disease, including neoplasia, is well documented.^{3,23,39,46-52} Cross-sectional imaging provides improved anatomic detail, which allows accurate determination of the extent of tumor (staging) and localization of nasal cavity abnormalities (Figure 23-5).^{3,23,39,46-53} It also facilitates evaluation of the integrity of the cribriform plate and identification of potential tumor extension into the cranial vault, which are important prognostic criteria. Although, in general, MRI allows for better resolution of soft tissue structures, a recent study showed no clinically relevant benefit to using MRI over CT to evaluate nasal tumors that do not extend into the cranial vault.⁴⁹ CT enables better visualization of lysis of bones bordering the nasal cavity, which is important for accurate radiation treatment planning. It has been proposed that tumor signal intensity on MRI may help distinguish sarcomas from carcinomas,⁵⁰ although this application requires further validation before it can be used clinically. Both modalities are useful for imaging nasal tumors, although CT is used more commonly than MRI due to its lower cost in most facilities, wider availability, and usefulness for computer planning of radiation treatments.

Certain CT or MRI findings have been correlated with a diagnosis of cancer in dogs with nasal disease.^{23,39,53} None of these, alone or in combination, is definitive for neoplasia.^{23,39,53} These findings include bony destruction (e.g., ethmoid bones, cribriform plate, and the bones surrounding the nasal cavities), destruction of the sphenoid sinus, abnormal soft tissue in the retrobulbar space, nasopharyngeal invasion, hyperostosis of the lateral maxilla, and patchy areas of increased density within abnormal soft tissue opacity.^{23,53} It

• **FIGURE 23-5** **A**, Contrast-enhanced CT image of a dog with nasosinal cancer taken in the transverse plane at the level of the orbit and the olfactory bulb of the brain. Note the contrast-enhancing mass (*M*) in the nasopharynx, which is causing erosion of the frontal and palatine bones. The tumor has invaded the left retroorbital space and the cranial vault, resulting in deviation of the falx cerebri. Non-contrast-enhancing material in the left frontal sinus (*S*) suggests accumulation of nasal exudates. **B**, Non-contrast-enhanced CT image of a dog with nasosinal cancer taken in the transverse plane at the level of the orbit. Note the soft tissue attenuating mass in the right nasal cavity. Erosion of the frontal bone has allowed the tumor to extend into the subcutaneous tissues on the dorsum of the head; erosion of the palatine bone has allowed invasion of the right retroorbital space.

is important to recognize that detection of a mass in the nasal cavity of a dog is not specific for a diagnosis of neoplasia.²³ Idiopathic inflammatory disease and fungal infections can present in this manner.²³

Conventional radiography can still have a place in the diagnostic work-up of dogs suspected of having nasal tumors. Despite the inherent limitation of tissue superimposition, the sensitivity of radiography in detecting major nasal cavity abnormalities in dogs with nasal tumors is comparable to that of CT or MRI when tumors are sufficiently advanced to cause clinical signs.^{46,52,54} Certain radiographic signs have been correlated with a positive predictive value for neoplasia.⁵⁵ These include the presence of a soft tissue opacity, loss of turbinate detail affecting the entire ipsilateral nasal cavity, invasion of bones surrounding the nasal cavity, and soft tissue/fluid opacities within the ipsilateral frontal sinus (Figure 23-6).⁵⁵ As is true for CT and MRI changes, no radiographic sign is definitively diagnostic for neoplasia.^{52,55} Nasal radiography therefore represents an easily accessible and less costly screening procedure that can guide further diagnostics, including biopsy, additional imaging, or both.^{52,56} Standard radiographs taken under anesthesia include lateral, dorsoventral (DV), frontal sinus, and open-mouth oblique views. The most informative views are the open-mouth DV oblique view (to show the caudal nasal cavity and cribriform plate) and the isolated nasal cavity exposure with the film placed in the mouth and exposed in the DV plane.

A tissue biopsy should be obtained while the patient is under anesthesia for diagnostic imaging. Suitable samples can be acquired by a variety of techniques.^{57,58} These include vigorous nasal flushing to dislodge mass lesions, transnostril blind biopsy using cup forceps or a bone curette, fiberoptic-guided biopsy, fine-needle aspiration (FNA) or punch biopsy of facial deformities, rhinotomy, and transnostril aspiration and core biopsy (Figure 23-7). Transnostril aspiration and core biopsy involves passing either a punch biopsy

needle or a large bore (3 to 5 mm) plastic cannula into the nasal cavity through the nostril and directing it to the tumor (Figure 23-8).⁵⁷ With any transnostril technique, it is important to avoid penetrating the cribriform plate. The biopsy instrument should be marked with tape or cut off at a length that ensures that the instrument does not penetrate farther than the distance from the tip of the naris to the medial canthus of the eye (Figure 23-9). Mild-to-moderate hemorrhage is to be expected and subsides within several minutes. It is important to ensure the integrity and inflation of the endotracheal tube cuff during any of these procedures. If hemorrhage is severe, the ipsilateral carotid artery can be permanently ligated, but this is rarely indicated.⁵⁹ Inadequate biopsy size or sampling outside the region of the tumor may preclude an accurate diagnosis. Further testing may be necessary when clinical and histologic findings are incongruent. In cases in which imaging results are suggestive of an aggressive process yet histopathologic changes are consistent with nonspecific inflammatory disease, a surgical biopsy obtained by rhinotomy may be required for definitive diagnosis.^{3,23}

Attempts at nasal washing and fluid retrieval for cytologic examination generally have been unrewarding and are not recommended as the sole means of diagnosis.¹ Brush cytology also has been described, but it often is not diagnostic.⁶⁰ Rhinoscopy can be used to visualize the nasal cavity, if necessary, and to guide biopsy, although samples collected in this manner often are small and superficial.⁶¹

Multiple staging systems for canine nasosinal neoplasia have been proposed on the basis of local tumor extent and bony erosion (Table 23-1).^{4,63-65,67} The least clinically relevant is the World Health Organization (WHO) staging method because no correlation has been found between primary tumor extent and prognosis using this system.^{38,65,67,68} The prognostic significance of the other staging systems remains controversial. A recent review of 94 dogs with

• **FIGURE 23-6** Radiographs of a dog with an intranasal anaplastic carcinoma. **A**, In this open mouth ventrodorsal view of the maxilla, note the asymmetry from side to side. A soft tissue opacity in the left nasal cavity (arrows) suggests the presence of a space-occupying mass. **B**, Rostral-caudal skyline view of the frontal sinuses. A soft tissue opacity in the left frontal sinus suggests extension of tumor or obstructive rhinitis. (Courtesy Dr. David Jimenez.)

• **FIGURE 23-7** **A**, Several techniques can be used to procure tissue biopsy material from dogs with nasal tumors. A bulb syringe (a) can be used to flush out tumor material, or a biopsy forceps (b), plastic cannula (c), or bone curette (d) can be inserted through the nostril. **B**, To flush biopsy tissue in an anesthetized dog with an endotracheal tube, the contralateral passage is occluded and flushing pressure is created with a saline-filled bulb syringe; the tissue is flushed back through the nasopharynx and out the mouth into a collection bowl.

nasal tumors treated with definitive RT showed that the CT-based Adams staging system and its recently modified version in which stage 4 represents cribriform plate involvement alone correlate with disease outcome.⁶⁵ Prognostic significance improved when CT findings were combined with histologic category.⁶⁵

Regional lymph node cytology is positive for metastasis in as many as 10% to 24% of cases and is most commonly associated with carcinoma.^{10,38,66,68} Enlarged regional (mandibular and superficial cervical) lymph nodes should be sampled for cytology to differentiate between a reactive process and metastasis. Thoracic

radiographs usually are negative for metastasis at initial presentation.^{1,2,10,38}

Hematologic and biochemical findings generally are noncontributory in dogs with nasosinal tumors. In rare cases, paraneoplastic erythrocytosis and hypercalcemia have been documented.⁶⁹⁻⁷¹

Treatment and Prognosis

Therapy is directed primarily at control of local disease, which usually manifests in a relatively advanced stage in a critical location near the brain and eyes (Figure 23-10). Without treatment, the MST

• **FIGURE 23-8** **A**, A caudally situated tumor (T) in a dog. To avoid injury to the brain, the plastic cannula for the core aspirate has been shortened so that it extends no deeper than the medial canthus of the eye. **B**, The cannula is introduced into the nasal cavity through the nares. Slight resistance usually is felt as the tumor is entered. Negative pressure is applied as the cannula is redirected at various angles. **C**, Tissue and blood are expelled onto a gauze sponge, where blood is separated from tissue. The tissue is submitted for histologic evaluation.

of dogs with nasal carcinoma is 95 days as reported in a retrospective case series of 139 dogs.³⁸ Prognosis of dogs with epistaxis appears worse than in dogs without epistaxis (MST 88 days versus 224 days).³⁸ Bone invasion occurs early, with nasosinal neoplasia, and curative surgery is virtually impossible. Although surgical removal by means of rhinotomy has been recommended, a high rate of morbidity without significant extension of life greatly limits the utility of this procedure as a sole form of treatment.^{1,8,10,72,73} The median survival time after surgery is approximately 3 to 6 months, similar to that reported for no treatment.^{1,10,72,73} In one study, surgery in conjunction with low-energy orthovoltage irradiation provided the best clinical outcome, MST, compared to other treatment modalities⁷⁴; however, more recent reports have not supported this finding (Table 23-2).^{13,75}

RT using high-energy megavoltage (MeV) equipment (cobalt source or linear accelerator) as the sole treatment modality has become the therapy of choice for canine nasosinal tumors (Table 23-3; see also Table 23-2). It has the advantage of treating the entire nasal cavity, including bone, and its use has been associated with

the greatest improvement in survival. Although surgical removal of the tumor before MeV irradiation has not been shown to improve clinical outcome,^{10,74,83} controlled studies have not been done for this combination. MST after MeV irradiation with curative intent (i.e., full-course or definitive radiation) alone ranges from 8 to 19.7 months.* The 1- and 2-year survival rates range from 43% to 68% (1 year) and 11% to 44% (2 years).^{63,64,76-78,86} Doses of 42 to 54 Gy are usually delivered in 10 to 18 treatments of 3- to 4.2-Gy fractions over 2 to 4 weeks to the nasal cavity and frontal sinuses as dictated by imaging.^{63-65,74,77-79} True statistical comparisons between reports are not possible because of inconsistencies in methodology (even within individual reports) with respect to total dose, fraction number, dose per fraction, treatment schedules, use of CT staging, use of computerized treatment planning, response monitoring, and statistical assessment. Furthermore, differences in tumor type and tumor stage also affect patient outcome.⁶⁵ CT-based computerized

<i>M: Distant Metastasis</i>			
M1 No evidence of distant metastasis			
M2 Distant metastasis detected (including nodes)			
Clinical Relevance			
Primary tumor stage (T value) not useful in predicting clinical outcome in any study where it was evaluated.	Predicted risk of relapse when applied to radiographic findings: Stage 2 tumors were 2.3 times more likely to relapse than stage 1 tumors. ⁶³	Predicted relapse-free interval and survival on CT findings: Stage 1 and 2 tumors had improved clinical outcomes (median relapse-free interval 615 days; median survival 745 days) compared to stage 3 and 4 tumors (median relapse-free interval 745 days; median survival 315 days). ⁶⁴	Based on CT findings: Predicted shorter DFI and survival in stage 4. Stronger association with outcome than original Adams stage 4. Cribriform involvement had the shortest survival (median 6.7 months). Stage 1 had the longest median survival (23.4 months). ⁶⁵
		Predicted shorter DFI and survival in stage 4 dogs in an expanded cohort. ⁶⁵	
		Predicted DFI and survival in a study of palliative RT (stage 1 and 2 more than stage 3 and 4). ⁶⁶	

CT, Computed tomography; DFI, disease-free interval; RT, radiation therapy.

• **FIGURE 23-9** Regardless of the biopsy technique chosen, any instrument that is passed through the naris must be measured; it also should be marked with tape or cut off at a length that ensures that the instrument does not penetrate farther than the distance from the tip of the naris to the medial canthus of the eye. This ensures that the instrument does not pass through a potentially compromised cribriform plate.

• **FIGURE 23-10** Cross-section of a dog's skull with a typical intranasal carcinoma. Note the middle to caudal position of the tumor in the nasal cavity, the erosion of the dorsal nasal bones, the dark mucus in the frontal sinus secondary to obstruction, and the proximity of the tumor to the cribriform plate. Complete surgical resection is impossible.

treatment planning can greatly enhance normal tissue sparing while ensuring optimized dose distribution within the tumor. The MST ranges from 11 to 19.7 months in dogs treated with CT-staged, computer-planned MeV irradiation to a minimum of 41 Gy.* As computer-based radiation planning becomes more advanced in veterinary medicine, it follows that clinical outcomes may continue to improve.⁶⁶

• **FIGURE 23-11** Potential acute effects of radiation therapy (RT) in dogs. **A**, Resolving desquamation one month after definitive RT for a nasal tumor. Note the hair loss in the radiation field. **B**, Oral mucositis on the last day of a definitive radiation protocol. Note the yellowish material on inner aspect of the upper lip. This represents dead epithelium that is being shed from the mucosa.

RT can induce normal tissue complications in the radiation treatment field (see Chapter 12). Acute and late toxicities affect rapidly and slowly renewing tissues, respectively, and depend on daily dose to the tissue, total dose, overall treatment time, and volume of tissue treated.⁸⁷ The severity of side effects can therefore vary among protocols and also between individuals on the same treatment schedule, depending on the tissues included in the radiation field. Acute toxicities associated with definitive, full-course irradiation of nasosinal tumors typically involve the oral cavity (oral mucositis), eye (keratoconjunctivitis and blepharitis), nasal cavity (rhinitis), and skin (desquamation) (Figure 23-11).^{63,64,76,79,88} Acute effects develop during the course of RT and resolve within 2 to 8 weeks after treatment.^{63,64,76,88} Oral antibiotics, pain medication, and/or ocular medication including artificial tears may be needed to support the patient during this period. Rarely, temporary esophagostomy or gastrostomy tube feedings may be indicated if oral mucositis is severe in order to maintain adequate nutritional intake.

Late radiation effects, although less common than acute effects, are more detrimental and long lasting. Their development should be prevented, if possible, with thoughtful radiation treatment planning. Tissues that may be affected include the ocular lens (cataracts), cornea (keratitis, atrophy, keratoconjunctivitis sicca),

anterior uvea (uveitis), retina (hemorrhage and degeneration), neuronal tissue (brain necrosis, causing neurologic changes and/or seizures, and optic nerve degeneration), bone (osteonecrosis), and skin (fibrosis).^{*} Late complications develop months to years after therapy and are generally irreversible. The most commonly observed clinically relevant late effects in dogs treated with definitive RT for nasosinal tumors are those affecting ocular structures.^{68,76} Late ocular changes in the dog typically occur 6 to 9 months following RT and most often include keratoconjunctivitis sicca, cataract formation, and blindness in the irradiated eye if radiation doses are not limited.⁷⁹ Other late effects are rare.

Overall, although most dogs with nasosinal neoplasia experience a favorable tumor response to RT, the long-term prognosis is poor (see Table 23-2). Even when treated with a definitive (curative-intent) radiation protocol, most dogs die or are euthanized as a result of local disease progression. An investigation of treatment failure patterns following full-course MeV irradiation showed that the median duration of local control in 24 dogs was 312 days.⁹² Marked tumor regression (90% reduction in size) was observed using CT in 46% of cases and was associated with a longer duration of local control than that seen in dogs in which tumor response to radiation was less favorable (389 versus 161 days).⁹² Most of the dogs in that series experienced local progressive disease, which affirms the need for more effective treatment strategies.

The following approaches have been investigated in an attempt to improve local control.

1. Full-course preoperative RT followed by surgical exenteration of residual or recurrent disease showed promise in a small series of dogs ($n = 13$), with a MST of 47 months compared to 19 months for dogs treated with radiation alone (see Table 23-2).⁷⁸ The combination treatment was associated with an increased incidence of late effects, including rhinitis (bacterial and fungal), osteomyelitis, and fistula formation.⁷⁸ A larger group of dogs must be treated in this manner to confirm these findings.
2. A logical and intuitive approach to improve local control is to increase radiation dose. This has been investigated using a boost technique in one study in which the total radiation dose was escalated to 57 Gy without an increase in overall treatment time. The treatment proved too toxic with respect to acute effects and resulted in radiation-related deaths in one-third of evaluated dogs.⁸⁸ It appears that normal tissue tolerance may not allow dose escalation within standard overall treatment times using conventional radiation planning and delivery techniques.
3. The use of radiosensitizers in conjunction with ionizing radiation has been reported. A Veterinary Radiation Therapy Oncology Group (VROG) pilot study described the use of gemcitabine as a radiosensitizer for nasosinal carcinoma.⁹³ Gemcitabine was given intravenously at a dosage of 50 mg/m² twice weekly before daily RT. The authors reported significant hematologic toxicity (neutropenia) and local acute tissue complications associated with this dose and schedule. In another report, low-dose cisplatin (7.5 mg/m² given intravenously every other day) administered in conjunction with full-course RT was well tolerated and did not appear to cause an increase in acute or late radiation effects.⁸⁴ The efficacy of this approach with respect to improvement of clinical outcome is not known. A combination of radiation and cisplatin, administered intramuscularly throughout therapy using a slow-release polymer system (open cell polylactic acid polymer impregnated with platinum [OPLA-Pt]), has

been shown to be well tolerated; however, survival times were similar to those in other studies that used RT alone (MST: 474 days).⁷⁷

4. The goal of RT is to deliver the maximum radiation dose to the tumor while limiting the dose to surrounding normal tissues to their tolerance level.⁹⁴ Currently, in veterinary medicine, maximally optimized radiation delivery is most widely achieved through the use of conventional computerized treatment planning that allows the use of multiple treatment fields directed at the patient from different angles, with differential weighting of beams, and beam shape modulators to tailor the distribution of radiation dose to each patient as much as possible. Even with the development of more advanced planning systems (i.e., 3-dimensional [3D] versus 2-dimensional [2D]), these conventional methods have limitations that prevent escalation of the radiation dose without also increasing complications.⁸⁸

A potential solution to this challenge is the rapidly emerging technology called intensity-modulated RT (IMRT). IMRT achieves conformal distribution of radiation dose to the tumor while sparing sensitive normal tissues.^{79,95-98} Multiple radiation fields of nonuniform beam intensity are delivered with the goal of distributing the radiation dose among larger volumes of normal tissue. This results in modest (tolerable) doses to normal tissues and integration of the multiple beams into a higher total dose throughout the volume of the tumor. IMRT treatment plans are generated by “automated optimization” in which the computer itself determines the optimal non-uniform radiation exposure that must be delivered to give the desired conformal dose pattern.

Through specialized software, the delivery of IMRT is achieved by using a large number of beams of varying radiation intensity that are modulated spatially and temporally.⁹⁵ Modulation of beam intensity is realized using a multileaf collimator, which is a collimator that is made of multiple leaves that move rapidly and independently under computer control, customizing beam shape and intensity to the patient. As a result, IMRT has the potential to achieve a much higher degree of target conformity and normal tissue sparing than conventional (2D or 3D conformal) treatment-planning techniques.^{79,95-97} The complex shape of nasosinal tumors and the surrounding critical structures, including eyes and brain, provide a strong rationale for application of IMRT with this tumor type. RT-related morbidity can be significantly reduced in dogs with nasosinal tumors when IMRT is used.^{79,96} A recent clinical study compared radiation-induced ocular toxicity in dogs with nasal tumors treated with IMRT to that of historical controls treated with conventional 2D RT.⁷⁹ IMRT reduced the radiation dose delivered to the eyes and resulted in bilateral ocular sparing. This was in contrast to profound ocular morbidity observed in the historical control group. MSTs for both groups were similar. Paramount to the success of highly conformal RT is precise daily patient positioning.⁹⁵ Millimeter variation in patient setup can result in underdosing of the tumor or overdosing of normal tissues. A recent study suggested that daily setup variation associated with conventional nonrigid immobilization techniques used in veterinary RT may be insufficient to ensure high-quality IMRT delivery over a multiple-week course of treatment for nasal tumors.⁹⁸ In that study, daily image guidance was necessary to ensure daily setup precision. Rigid immobilization techniques (head and cranial body fixation devices) have been developed for veterinary patients⁹⁹⁻¹⁰² and, in conjunction with daily image guidance, permit successful implementation of highly conformal therapy.^{98,99} Image-guided RT (IGRT) refers to the use of “on-board” imaging, most commonly CT, integrated into IMRT delivery units. Advanced IGRT systems, such as Varian’s

*References 63, 64, 76, 79, 88-91.

Trilogy, Tomotherapy, and CyberKnife, are in use at select veterinary RT facilities,^{98,99,103} and availability is growing. IMRT/IGRT provides the theoretical opportunity for tumor dose escalation without increasing the number of radiation treatments and overall treatment time. This in principle could translate into improved tumor control.⁹⁷ A newly emerging application of IMRT/IGRT in veterinary medicine is stereotactic RT (SRT). SRT refers to the delivery of high-dose (ablative) radiation in a single dose or a few fractions.¹⁰⁴ The treatment is delivered with extreme accuracy, and the dose is pinpointed to the tumor, minimizing the effect on nearby organs. This technique is optimally suited for small, well-defined tumor targets, although the advancement of radiation delivery technology has allowed for successful application in larger tumors.¹⁰⁴ The high degree of precision is achieved by delivering many (up to hundreds) irregular subfields using specialized software and sophisticated multileaf collimation to create a complex intensity pattern.¹⁰⁴ SRT fractionation schedules usually involve daily treatment for 1 to 3 days, which has obvious practical advantages compared to conventionally fractionated schedules that take weeks to complete. SRT requires highly reproducible patient immobilization, high-fidelity image guidance and an intensity modulated radiation beam to achieve extreme precision.¹⁰⁴ Nasal tumors provide an excellent rationale for use of SRT; however, efficacy with respect to tumor control and survival rates associated with this hypofractionated treatment has not yet been proved. Initial experiences in dogs with nasal tumors include treatment with doses up to 30 Gy delivered in three fractions or in single fraction treatments of up to 15 Gy.^{105,106} Toxicity and tumor control data are preliminary but appear favorable.^{105,106} Despite the multiple apparent advantages of IMRT and SRT, the high financial costs and logistical challenges associated with optimal use of this technology must be balanced. Controlled clinical trials that rigorously examine normal tissue effects and tumor responses are needed to validate superiority of IMRT/IGRT to conventional RT in veterinary medicine.

In contrast to curative-intent radiation protocols, treatment schedules that are less intensive can be used to palliate tumor-related clinical signs. The goal of palliative radiation is to improve quality of life without aiming to maximize tumor sterilization. Most palliative protocols involve coarse fractionated treatments (6 to 9 Gy) delivered weekly or biweekly.^{33,66,80-82} The result of this approach is temporary improvement of clinical signs in 66% to 100% of dogs and limited morbidity associated with acute side effects.^{66,80-82} The reported median duration of control of clinical signs ranges from 120 to 300 days.^{66,81} Acute toxicities affecting the oral mucosa and skin are generally mild and short lived.^{66,80-82} A multiinstitutional retrospective study reported development of chronic ocular toxicities in 13% of 39 dogs that had at least one eye irradiated.⁸¹ Reported MSTs range from 146 days to 300 days.^{33,66,80-82} Tumor stage (Adams stage I) and duration of clinical signs (>90 days) have been correlated with longer survival in cases receiving this type of radiation.^{66,81} While true statistical comparisons between studies are not possible because of inconsistencies in methodology, the best clinical outcome in terms of duration of resolution of clinical signs and survival (approximately 300 days for both) is reported in a study of 38 dogs in which radiation treatment planning was performed using CT-staging and 3D-conformal computerized treatment planning software.⁶⁶ In contrast to other studies, radiation delivery was planned using standardized dose and volume specifications ensuring uniform tumor dose distributions. The authors suggested that sophisticated radiation treatment planning in canine nasal tumor patients treated palliatively may result in more favorable clinical outcomes than previously reported.⁶⁶

A recent report suggested that some dogs with recurrent nasal tumors can experience a second clinical remission following reirradiation of the tumor.¹⁰⁷ The study evaluated a selected cohort of nine dogs in which the median time to tumor progression after a first full course of RT was 513 days. The first course of radiation delivered a median of 50 Gy in a median of 18 fractions. The median total dose used in the second protocol was 36 Gy, delivered in approximately 2-Gy fractions. The overall MST for this small, selection-biased cohort of dogs was 927 days (95% confidence interval [CI] 423 days to 1767 days). All dogs developed one or more late effects involving the skin, eyes, and nasal cavity. Late effects in seven of the nine dogs were considered mild and did not affect quality of life. Severe late effects were reported in two dogs, and both had sudden blindness that led to euthanasia. The authors concluded that there is a population of canine nasal tumor patients (i.e., those with slowly progressive tumors) that will benefit from reirradiation. Further work is needed to refine time-dose prescriptions to minimize radiation-induced late effects. Conformal techniques such as IMRT could play a role in this setting to limit morbidity.

Chemotherapy is used rarely as a sole therapy for canine nasosinal tumors. Treatment with cisplatin alone has been shown to benefit some dogs.¹⁰⁸ A clinical response rate of 27%, including one radiographically confirmed complete remission, was reported in a small series of 11 dogs.¹⁰⁸ All of the dogs experienced alleviation of clinical signs, and the MST was 5 months. Another report evaluated a combination chemotherapy protocol of doxorubicin, carboplatin, and oral piroxicam in eight dogs with advanced nasal tumors.¹⁰⁹ A clinical response rate of 75% was observed, including 4 CRs confirmed by CT imaging. All dogs experienced resolution of clinical signs, and the protocol was well tolerated. MST in these eight dogs was 210 days (range 150 days to 960 days). These preliminary results are favorable, but the case number is small and more dogs need to be treated in this manner to confirm these findings.

Other therapeutic approaches to nasal tumors that have been investigated include proton-beam therapy, brachytherapy, immunotherapy, cryotherapy, and photodynamic therapy (PDT). Charged particles like protons have a well-defined tissue range and sharp dose fall off, which could potentially be exploited for conformal tumor targeting and normal tissue sparing.¹¹⁰ A small clinical trial involving nine dogs with nasal tumors treated with proton-beam therapy resulted in tumor responses and survival times similar to those reported for MeV irradiation.¹¹⁰ Acute effects of the skin and eyes were pronounced in some dogs, and 50% of dogs developed radiation-induced cataracts. Due to limited availability of proton irradiators, this technology is unlikely to be optimized for use in dogs. Intracavitary radiation using radioactive isotopes (brachytherapy) has been evaluated after surgical removal of nasosinal tumors in dogs.^{111,112} Potential problems associated with this type of radiation include dose distribution and radiation exposure to personnel. The question of whether brachytherapy improves survival over traditional external-beam radiation has not been answered. Immunotherapy and cryosurgery have not improved survival times.^{1,113} A recent case report described the use of image-guided cryotherapy in the treatment of a rapidly recurrent nasal carcinoma that resulted in long-term tumor control and survival.¹¹⁴ The authors suggested that further investigation of this technique may be warranted for the management of focal residual or recurrent nasal tumors. Reports evaluating PDT have been published; however, results are too preliminary to draw any conclusions.^{115,116}

When all treatments fail to control epistaxis, unilateral or bilateral carotid artery ligation can palliate the symptoms in dogs for up to 3 months or longer without damage to the brain.⁵⁸

The importance of prognostic factors in the treatment of canine nasosinal tumors remains controversial. Negative predictors of survival from various studies include age (>10 years),⁶⁸ epistaxis,³⁸ duration of clinical signs,⁸¹ advanced local tumor stage,^{63-66,68} metastatic disease,^{10,68} histologic subtype (carcinoma, particularly squamous cell or undifferentiated),^{63,65,74} and failure to achieve resolution of clinical signs.⁸¹ An analysis of 94 dogs with varying subtypes of nasal carcinoma or sarcoma treated with curative RT at three veterinary facilities was recently performed.⁶⁵ A correlation was demonstrated between clinical outcome and the original Adams tumor staging scheme,⁶⁴ as well as the modified Adams tumor system.⁶⁵ Based on these findings, dogs with cribriform plate involvement as determined by CT imaging have the shortest disease-free survival (DFS) and overall survival (OS). This subset of dogs had a median DFS of 3.8 months and a median OS of almost 7 months, compared to dogs with unilateral tumors without bone involvement in which DFS and OS were 6.5 and 23 months, respectively. The study also showed that prognosis varied based on histologic category. When grouped together, dogs with anaplastic carcinoma, undifferentiated carcinoma, and SCC had a shorter DFS. There was no effect on clinical outcome when all carcinomas were compared with all sarcomas. The statistically strongest association with clinical outcome was made when clinical stage was combined with histologic findings.

A major pitfall of many veterinary studies with respect to assessment of treatment efficacy in canine nasosinal cancer is the evaluable endpoint. Tumor response and time to tumor progression are the most representative measures of treatment efficacy. Regular diagnostic imaging, ideally CT or MRI, would be required to allow accurate determination of these endpoints. Due to high costs associated with imaging and the need for anesthesia, follow-up is rarely done in this manner. Analyzing the return of clinical signs as an indication of tumor recurrence is problematic since similar signs can result from rhinitis secondary to therapy (radiation and/or surgery) or residual tumor.¹¹⁷ Assessment of the survival time, as is commonly done in most veterinary nasosinal cancer studies, may be biased by the use of additional treatments on suspicion of progressive disease and by the decision for euthanasia, which can vary greatly from one pet owner to another. Furthermore, inconsistencies in methodology between studies and even within individual reports, as well as lack of controlled studies, are other limitations that have prevented the informed development of the optimal treatment approach to nasosinal tumors in dogs.

Feline Nasosinal Tumors

Nasal and sinus cavity tumors in the cat are malignant in more than 90% of the histologically diagnosed cases. They occur in an older population of cats with a mean age reported between 9 and 10 years.¹¹⁸⁻¹²⁰ In general, these tumors are locally invasive and associated with a low metastatic rate at the time of diagnosis.^{119,121}

Clinical signs related to nasosinal tumors in cats overlap with those of other causes of chronic nasal disease.^{118,120} These include nasal discharge, upper respiratory tract dyspnea, sneezing, epistaxis, facial swelling, ocular discharge, and weight loss.^{118-120,122-124} Although each of these signs can occur with both neoplasia and rhinitis, in some reports, certain signs are more commonly associated with neoplasia such as unilateral discharge or epistaxis,¹¹⁸ whereas in others, the character of the clinical signs does not distinguish the underlying cause.¹²⁰ The median duration of clinical signs prior to diagnosis is several months, and many cats will experience temporary alleviation of clinical signs with use of antibiotics

and/or glucocorticosteroids.¹¹⁸⁻¹²⁰ Differential diagnoses for chronic nasal signs include chronic rhinitis, infectious rhinitis, foreign body, nasal polyp, nasopharyngeal stenosis, and trauma.

Lymphoma is the most commonly diagnosed tumor type in the feline nasal cavity and sinuses followed by epithelial neoplasms (carcinoma, adenocarcinoma, SCC). Less frequently reported tumor types include sarcomas (fibrosarcoma, osteosarcoma, chondrosarcoma), mast cell tumor, melanoma, plasmacytoma, olfactory neuroblastoma, and benign lesions such as nasal hamartoma, chondroma, and neurofibroma.^{118-120,125,126}

Diagnostic principles are similar to those in the dog. A tissue sample is required to make a definitive diagnosis of cancer in most cases. DeLorenzi et al evaluated cytology from squash preparations obtained from endoscopic biopsies of nasopharyngeal masses in cats and found that cytologic results were in good agreement with histopathology with an overall accuracy of 90%.¹²⁷ However, distinguishing lymphoma from lymphoid inflammatory disease was not as accurate and histopathologic confirmation was recommended.¹²⁷ Another study evaluated the histopathologic and cytologic features of nasal lymphoma in 50 cases. These authors found that 91% of cases were classified as immunoblastic lymphoma according to the National Institutes of Health (NIH) working formulation. The majority of cases were B-cell (68%) and 20% were T-cell, with 12% having a mixed population of B- and T-cells.¹²⁵

Radiographs of the nasal cavity have been reported as a diagnostic tool in cats with both chronic rhinitis and nasal neoplasia. Although no radiographic sign is entirely specific for neoplasia, findings with the highest predictive value for cancer include displacement of midline structures, unilateral changes such as soft tissue opacity and loss of turbinate detail, and evidence of bone invasion.¹²⁸ Similarly, as CT scan becomes a common imaging tool, reports of the characteristic findings of scans from cats with nasosinal disease of all etiologies have been published.¹²⁹⁻¹³¹ One retrospective assessment of CT imaging in 62 cats with nasosinal disease showed that, although certain findings such as osteolysis of paranasal bones, extension of disease into the orbit of facial soft tissues, the presence of a space-occupying mass, and turbinate destruction may suggest a CT diagnosis of neoplasia over rhinitis, nasal biopsy is necessary for confirmation.¹²⁹ Another study evaluated the clinical characteristics and CT findings in 43 cats and found that those with neoplasia were significantly more likely to have unilateral lysis of the ethmoturbinates as well as dorsal and lateral maxilla, lysis of the vomer bone and ventral maxilla, and unilateral soft tissue or fluid in the sphenoid recess, frontal sinus, or retrobulbar space. Interestingly, in that study population, cribriform plate lysis was not significantly associated with neoplasia.¹³⁰ In another report describing CT findings in cats with confirmed fungal rhinitis, they found that some of the features overlap with those seen in neoplasia patients, including older age at the time of diagnosis, soft tissue mass, and osteolysis. Although these studies confirm the utility of CT scan determining extent of disease, no one group of features replaces histopathology for definitive diagnosis.

Even though the metastatic rate of feline nasosinal cancer at the time of diagnosis is reportedly low, any enlarged regional lymph nodes should be evaluated cytologically to differentiate a reactive process from metastasis. In a recent report of 123 cases of feline nasosinal cancer, 21 cats had regional lymphadenopathy. None showed cytologic evidence of metastasis.¹¹⁹

As in the dog, RT continues to be the predominant local therapy of choice for this disease. Reports of treatment for feline nonlymphoma nasosinal tumors are few, and case numbers are small.^{121,132} In the largest published study, 16 cats with nonlymphoproliferative

• **TABLE 23-4** Summary of Selected Reports Describing Clinical Outcomes for Nasosinal Tumors in Cats

If CR achieved	749	536	NR
If PR achieved	54	120	NR
Distant disease at time of death	NR	10/79 (13%)	3/19 (16%)
Prognostic indicators/conclusions	Chemotherapy is effective for nasal LSA, and cats achieving a complete remission have a significantly longer survival.	Histopathologic grade, cribriform lysis, and treatment type did not significantly impact survival. Total RT dose >32 Gy improved survival; achieving CR improved survival.	Cribriform plate destruction negatively influenced survival; distant disease still occurs in a small number of patients.

NA, Not applicable; COP, cytoxan, oncovin, prednisone; RT, radiation therapy; OOR, overall response, CR, complete response, PR, partial response, NR, not reported; LSA, lymphosarcoma.

neoplasms were treated using a definitive course of radiation to a total dose of 48 Gy. The therapy was well tolerated, and MST was 12 months with 44% and 16% of cats alive at 1 and 2 years, respectively.¹²¹ In another report of radiation treatment for nonlymphoproliferative tumors, this time treated using a coarse fractionation regime, results showed that the protocol was well tolerated, with a median survival of almost 13 months and a 63% 1-year survival rate reported.¹³²

Recent reports of feline nasal and nasal pharyngeal lymphoma treated with radiation and/or chemotherapy indicate the potential for long-term survival (Table 23-4).^{122-125,133} Although treatment protocols vary between reports, in general, overall response rate for feline nasal lymphoma is high, between 70% and 90%. The inclusion of RT appears to enhance overall survival with median survival for combination therapy ranging from 174 to 955 days.^{123,124} Interestingly, systemic failure of disease at nonnasal sites is also reported in 13% to 16% of cases, indicating that a combination of RT and chemotherapy may be warranted in some patients. However, the timing of such treatment remains to be determined (concurrent versus sequential), as does which patients are at highest risk for local failure. Furthermore, improved radiation treatment planning along with optimized radiation treatment schedules and doses may prove to ameliorate local control rates

and reduce the risk of systemic failure without the addition of chemotherapy.

Comparative Aspects¹³⁴

In humans, cancer of the nasal cavity and paranasal sinuses is classified with other cancers of the upper aerodigestive tract under the all-encompassing title, tumors of the head and neck. Tumors of four anatomically defined regions are included: nasal cavity and paranasal sinuses, nasopharynx, oral cavity, and oropharynx. The majority of tumors affecting these sites are SCCs (head and neck SCC [HNSCC]). However, a large variety of histologically distinct cancers can develop in the nasal cavity and paranasal sinuses, including adenocarcinoma, esthesioneuroblastoma, lymphoma, melanoma, angiosarcoma, and tumors of connective tissues.

Tumors specifically of the nasal cavity and paranasal sinuses are rare in humans and represent the smallest proportion of head and neck cancers, with a yearly risk of 1 in every 100,000 people. They generally affect persons between the ages of 45 and 85 years old and are twice as common in males as females. The etiologic factors for the disease are predominantly environmental and workplace in nature and include exposure to wood, textile, and leather dusts, as well as flour, nickel, chromium, and radium. Other factors

associated with increased risk for all head and neck cancers include smoking and alcohol use, which may have an additive effect.

Tumors at this site are locally invasive. They are typically advanced at the time of diagnosis because lesions in this area can go undetected for extended periods of time and clinical signs can mimic those of infectious or inflammatory disease. The likelihood of lymph node metastasis at the time of diagnosis is low—reportedly between 10% and 15%, depending on the location of the primary tumor.

Surgery and RT are the mainstay of curative treatment when considered possible, based on stage and location of disease. Chemotherapy can be useful in an adjuvant setting, but it is not curative when used alone. Both radiation and surgery have advantages and disadvantages as primary therapies. Overall, survival at 5 years is approximately 60% and 30% for nasal cavity and paranasal tumors, respectively. More favorable prognoses are associated with smaller lesions in which complete surgical resection is achievable. The main form of treatment failure is local recurrence, which is caused by incomplete local control of advanced tumors in many cases. When adequate margins cannot be obtained, surgery and radiation are often combined.

The role of chemotherapy in cancer of the nasal cavity and paranasal sinuses is not clear because these cases are usually reported in conjunction with other head and neck tumors. Active chemotherapy agents include the taxanes, 5-fluorouracil (5-FU), and the platinum drugs. Several studies have reported improved local control and, in some cases, improved overall survival in treatment protocols that combine traditional fractionated radiation and chemotherapy; however, the toxicity may also be increased. The optimal case selection, chemotherapy agents, and radiation schedule has yet to be defined.

Clinical trials of targeted therapies for head and neck cancer have been done and most involve EGFR antagonists. Cetuximab (Erbix), a chimeric (mouse/human) monoclonal antibody against EGFR, has been shown to improve locoregional control and survival when used as a radiation sensitizer in people with HNSCC undergoing RT with curative intent. It has been approved by the Food and Drug Administration (FDA) for this indication, as well as for use as a single agent in patients whose cancer has progressed on platinum-containing therapy. Positive results associated with cetuximab have had a significant impact on the standard of care for advanced HNSCC. The subset of patients who might benefit from these types of treatments will need to be identified in order to maximize their use and improve outcome for this disease.

Cancer of the Larynx and Trachea

STEPHEN J. WITHROW

Incidence and Risk Factors

Cancer in either the larynx or the trachea is rare in dogs and cats.^{1,2} Young patients with active osteochondral ossification sites are at higher risk for benign tracheal osteocartilaginous tumors, which

grow in synchrony with the rest of the musculoskeletal system.^{1,3} Laryngeal oncocytomas also appear to occur in younger mature dogs.^{4,5} No breed or gender predilection is known for either site.

Pathology and Natural Behavior

Reported canine laryngeal tumors include rhabdomyoma (oncocytoma), osteosarcoma, extramedullary plasmacytoma,^{4,6} chondrosarcoma, osteosarcoma, undifferentiated carcinoma, fibrosarcoma, granular cell tumor, mast cell tumor, adenocarcinoma, and SCC.^{7–10} Rhabdomyomas in the dog may be large, are minimally invasive, and do not appear to metastasize.^{4,5,11,12} A 6-month-old dog with a laryngeal cyst has been reported.¹³ Most other laryngeal tumors are very locally invasive and have a significant metastatic potential. Feline laryngeal neoplasms most commonly are lymphomas, although SCC and adenocarcinoma have been reported.^{2,8,10,14,15} Benign tracheal tumors and cysts in cats are rare.^{2,14,16}

Reported tracheal cancer includes lymphoma, chondrosarcoma, histiocytic sarcoma, adenocarcinoma, and SCC.^{17,18} Tracheal leiomyomas and polyps have also been reported.^{19–21} Several reports of benign tracheal osteochondral tumors exist in the literature.^{3,22} These lesions grow from the cartilaginous rings and are composed of cancellous bone capped by cartilage. They may reflect a malfunction of osteogenesis rather than true cancer and are benign.²² The larynx and trachea may be secondarily invaded by neoplasms such as lymphoma and thyroid adenocarcinoma.

History and Clinical Signs

Patients with laryngeal tumors usually have a progressive change in voice or bark, exercise intolerance, or dysphagia. Patients with tracheal tumors usually have coughing and exercise intolerance. Because osteochondral lesions of young dogs grow at the same rate as the rest of the skeleton, symptoms become most noticeable during the skeletal growth spurt.

Diagnostic Techniques and Work-Up

Laryngeal tumors usually can be biopsied under direct visualization. Small samples or cytology alone may yield false negative results.² Regional radiographs may reveal the general location of the lesion, but CT images will yield more precise localization.²³

Tracheal tumors offer more of a diagnostic challenge but can be biopsied with the use of fiberoptic instruments or a rigid bronchoscope (Figure 23-12, A). Alternatively, open surgical biopsy, often coupled with excision, can be performed. Plain radiographs or a tracheogram may reveal a mass narrowing the lumen (Figure 23-12, B). CT or MRI may aid localization of the lesion.²³

Therapy

Benign laryngeal cancers such as rhabdomyomas and cysts can be removed successfully with preservation of function.^{4,11–13,16} Temporary tracheostomy will provide short-term relief of upper airway obstruction and is well tolerated in dogs and some cats.²⁴ Complete laryngectomy with a permanent tracheostomy is another option used in humans, but it has had limited use in veterinary medicine.^{11,25–29} Depending on their suspected radioresponsiveness, invasive cancers can be treated with irradiation to better preserve laryngeal function. Radiation should control lymphoma or

• **FIGURE 23-12** A, Fiberoptic view of tracheal osteochondroma in a 5-month-old dog. B, Lateral thoracic radiograph of the dog in A.

plasmacytoma in the dog or cat larynx or trachea. Chemotherapy, with or without surgery, may also be effective.^{6,30}

Tracheal tumors should be treated with resection, especially benign osteochondral tumors (Figure 23-13).^{3,31} Full thickness removal with end-to-end anastomosis can easily be performed on up to three or four rings. Experimentally, up to 50% of tracheal length has been removed with successful closure.³² Intraluminal stents may provide temporary palliation.

Phototherapy via bronchoscopy has been used successfully in humans for small lesions (carcinoma in situ or early carcinoma), but these lesions are only rarely recognized in the dog or cat.

Prognosis

Benign lesions of the trachea and larynx have a good prognosis if they can be resected.¹⁶ Most dogs with resectable rhabdomyomas live longer than 1 year and may be presumed cured.^{4,11,12} Long-term outcomes may be expected with treatment of extramedullary plasmacytomas or granular cell tumors.^{6,9} Very limited information is

• **FIGURE 23-13** Resected tumor and associated tracheal cartilage rings of the dog in Figure 23-12. The tumor is bisected and has the typical appearance of cancellous bone with a cartilaginous cap. The patient recovered uneventfully from surgery and survived for longer than 5 years, when it was lost to follow-up.

available for the malignancies because very few have been treated and reported.^{10,17} In one study in cats, the MST for 27 cats with a variety of laryngeal and tracheal lesions was 5 days and only 7% were alive at 1 year.²

Comparative Aspects³³

Laryngeal cancer is common in humans (2% of all cancers) and is related to smoking and alcohol consumption. The lesion is nearly always SCC. Earlier detection prompted by voice changes makes treatment more feasible. In humans, the disease appears to progress through stages of development from dysphagia, to carcinoma in situ, to minimally invasive carcinoma, to invasive carcinoma. Of patients with carcinomas, 60% have local disease only, 30% have regional nodal metastasis, and 10% have distant metastasis. The disease is treated with surgery (partial or complete laryngectomy) or irradiation. Local control and cure rates are good to excellent.

Tracheal cancer independent of lung cancer is very rare in humans.

■ SECTION D

Pulmonary Neoplasia

ROBERT B. REBHUN AND WILLIAM T.N. CULP

Incidence and Risk Factors

Lung cancer is the leading cause of cancer-related human deaths worldwide, but primary lung cancer remains relatively uncommon in pet dogs and cats. The incidence of primary lung cancer in pet dogs and cats presenting for necropsy is less than 1%.^{1–4} Incidence rates in pet dogs range from 4.2 per 10,000 dogs per year in the United States to 15 per 100,000 dogs per year in the United Kingdom.^{5,6} In contrast, the incidence of pulmonary neoplasia was 8.8% in a closed colony of “normal” beagles and was dominated by a high incidence of pulmonary tumors in dogs dying after the median lifespan of 13.6 years.⁷

The average age of pet dogs diagnosed with primary lung tumors is approximately 11 years,^{1,8} with the exception of anaplastic carcinomas that occur at an average age of 7.5 years.⁹ The Boxer, Doberman, Australian shepherd, Irish setter, and Bernese Mountain dog breeds are possibly overrepresented.^{1,8,10} The average age of cats with pulmonary tumors is 12 to 13 years.^{3,9,11} No breed or gender predisposition has been reported in cats with the possible exception of Persian cats.⁴

In people, the risk of developing primary lung cancer is strongly associated with smoking, but no such definitive risk factors have been identified in the pet population. Urban living and second-hand smoke exposure have both been implicated as potential causes of lung cancer in dogs but are yet to be clearly demonstrated.^{12,13} An increased risk of lung cancer was found in dogs with increased amounts of anthracosis, suggesting an association between inhalation of polluted air and lung cancer.¹⁴ Cytologic analysis of bronchoalveolar lavage fluid also revealed increased anthracosis in dogs that had been exposed to passive tobacco smoke when compared to dogs without a history of exposure.¹⁵ In the experimental setting, laboratory dogs trained to smoke cigarettes through a tracheostoma (in the presence or absence of asbestos exposure) did develop lung cancer at a higher rate than control dogs.^{16,17} Experimentally induced exposure to radiation such as that found in plutonium also significantly increases the occurrence of lung cancer when inhaled as an aerosol in research dogs.^{18,19}

Pathology and Natural Behavior

Pulmonary tumors can arise from any tissue in the lung but most commonly originate from epithelium of the airways or alveolar parenchyma. Tumors derived from epithelium of large airways are typically located near the hilus, whereas parenchymally derived tumors tend to be peripherally located. However, the most recent WHO guidelines on classification of pulmonary neoplasms largely classify lung tumors of domestic animals by histologic pattern and not by site of origin.¹⁰

Approximately 85% of canine lung tumors are bronchoalveolar in origin, whereas adenocarcinoma, adenosquamous carcinoma, and SCC collectively comprise the remaining 13% to 15% of primary lung tumors.^{7,8} Adenocarcinoma represents 60% to 70% of feline lung tumors, whereas bronchoalveolar carcinoma, SCC, and adenosquamous carcinoma are less common.^{4,10,11} Small cell carcinoma represents approximately 25% of human pulmonary neoplasms but rarely occurs in the dog or cat.

Lung tumors can spread by local invasion or hematogenous and lymphatic routes, resulting in locoregional spread to other areas of the lung or lymph nodes or distant metastasis. Intrapulmonary metastases are believed to occur through vascular and lymphatic invasion or intra-airway seeding. Seventy-one percent of canine pulmonary malignant tumors had evidence of local vascular or lymphatic invasion, and 23% had distant metastasis beyond hilar lymph nodes.⁸ SCC and anaplastic carcinomas have metastatic rates that exceed 50% and 90% of cases, respectively, and thus are believed to be more likely to metastasize than adenocarcinoma or bronchoalveolar carcinoma.³

Metastasis is common in the cat, with a metastatic rate of 76% in feline patients with pulmonary tumors.^{4,11} The incidence of lymph node metastasis and the incidence of intrathoracic metastasis are equivalent at 30% of patients, whereas extrathoracic metastases occurred in only 16% of cats. Metastasis to bone or the nervous system is not uncommon in dogs or cats. Metastasis to the digits is a common and well-described clinical phenomenon in cats.²⁰

Distinguishing poorly differentiated primary lung tumors from metastatic carcinoma can occasionally provide a diagnostic challenge. Immunohistochemistry using antibodies directed against thyroid transcription factor-1, cytokeratin, or vimentin may be useful in differentiating primary lung tumors from metastatic disease.²¹⁻²³ Antibodies against CD18 may also be useful for differentiating pulmonary tumors of histiocytic origin.²⁴

Clinical Signs and Physical Examination Findings

Veterinary patients will often be diagnosed with a primary pulmonary tumor incidentally during a routine geriatric screen.^{1,7,25} Up to 30% of cases of primary pulmonary tumors will be diagnosed without the presence of clinical signs.²⁵ The most common clinical sign reported in dogs with pulmonary neoplasia is coughing, which is noted in 52% to 93% of dogs.^{1,25-28} Other clinical signs that have been recorded include dyspnea (6% to 24%), lethargy (12% to 18%), anorexia (13%), weight loss (7% to 12%), hemoptysis (3% to 9%) and lameness likely secondary to hypertrophic osteopathy (4%).²⁵⁻²⁷

The clinical signs in cats are similar to dogs; however, the occurrence of these signs is variable and gastrointestinal signs may be noted as well.^{29,30} As in dogs, signs referable to the respiratory tract are common, with dyspnea (24% to 65%), cough (29% to 53%), tachypnea (14%), and hemoptysis (10%) being noted regularly.^{29,30} Nonspecific signs such as lethargy and anorexia can be seen in 24% to 43% and 19% to 71% of cats, respectively.^{30,31} Vomiting/regurgitation and diarrhea are seen in approximately 19% of cats with primary pulmonary neoplasia.^{29,30}

Abnormal physical examination findings consistent with pulmonary neoplasia are often not seen.²⁵ Increased bronchovesicular sounds may be auscultated in dogs with extensive pulmonary involvement.²⁶ As pulmonary effusion can occur in many cases, dull lung and heart sounds may also be noted.^{25,29,30} Metastasis to the nervous system has been reported in several cases of primary pulmonary tumors, and neurologic abnormalities can be diagnosed on physical examination.³¹⁻³⁴

Lameness can occur in dogs and cats associated with primary pulmonary neoplasia for a variety of reasons. Hypertrophic osteopathy is a paraneoplastic syndrome that has been most commonly associated with primary and metastatic lung tumors, although

other malignant and nonmalignant diseases have resulted in hypertrophic osteopathy.^{27,35-39} The disease is characterized by periosteal new bone formation at a site distant to the primary tumor. Lameness may improve with removal of the lung tumor.^{35,38}

Several reports of cats with concurrent pulmonary neoplasia and digital metastasis can be found in the veterinary literature; this phenomenon has been noted with both pulmonary adenocarcinoma and SCC.^{4,20,40-43} Of 36 cats with metastatic bronchogenic carcinoma to the digit, all were presented for lameness and none were presented for respiratory signs.⁴³ The authors of that study concluded that thoracotomy with lung lobectomy and digital amputation should not be recommended because nonrespiratory disease often progressed and metastatic lesions in other digits resulted in continued lameness.⁴³ The MST for cats undergoing digital amputation alone was only 67 days.⁴³

Diagnostic Techniques and Work-Up

Clinical Laboratory Findings

A complete blood count (CBC) and serum chemistry panel are unlikely to signal a clinician to the presence of a pulmonary mass. Nonspecific changes in these diagnostics have been reported in veterinary cases, and routine blood tests are often within normal limits.^{11,43} These diagnostics, however, are essential to the preanesthetic and overall evaluation of a patient undergoing treatment for a pulmonary neoplasm.

The presence of pleural effusion at diagnosis is less common in dogs than cats. When pleural effusion is noted, a sample should be obtained via thoracocentesis. The pleural fluid tends to be a clear or blood-tinged modified transudate.^{25,29} Thirty percent (26/86) of cats in one study were noted to have pleural effusion, and thoracocentesis was performed in 13; fluid analysis was diagnostic for a primary lung tumor in 12/13 cats.¹¹ However, in a separate feline study, fluid analysis was diagnostic for a malignant effusion secondary to a malignant neoplasm in only 1/8 cases.²⁹ Of three dogs with pleural effusion in one study, one was diagnosed with carcinoma based on evaluation of fluid obtained by thoracocentesis.²⁵

Bronchoalveolar lavage (BAL) and transtracheal washes have been advocated as a method of diagnosing pulmonary neoplasia.^{25,44-46} In a series of cases that underwent BAL to aid in the diagnosis of respiratory tract diseases, 14 carcinomas were identified. Of those 14 cases, the BAL was definitive, supportive, or not helpful in eight, four, and two cases, respectively.⁴⁵ Transtracheal washes have been less successful; in one study, in six dogs with confirmed primary pulmonary neoplasia, none of the washes yielded neoplastic cells.²⁵

The majority of pulmonary tumors are diagnosed on thoracic radiographs (see Chapter 6). When evaluating 277 canine cases from two large case series, 83% of pulmonary tumors were viewed on thoracic radiographs.^{25,27} In cats with primary pulmonary tumors, 67% to 91% will have radiographic evidence of solitary or multiple pulmonary masses on thoracic radiographs.^{11,30}

Several studies have evaluated tumor location and number within the lungs.^{1,26,27} In a series of 210 dogs with primary pulmonary tumors, tumor location was determined in 191 cases.²⁷ Of the total dogs in that study, 53.8% were found in a single lung lobe and 37.1% were found in multiple lung lobes.²⁷ Only 2 dogs were found to have a tumor in multiple lobes in a smaller study of 15 total dogs; of the 17 affected lobes in that study, 13 were on the right and 4 were on the left.²⁶ Of 29 dogs with primary pulmonary tumors in

• **FIGURE 23-14** A, Right lateral radiograph. B, Ultrasound image of a pulmonary carcinoma in the left caudal lung lobe of a cat.

a separate study, the side of the tumor was recorded in 26 with 13 left-sided and 13 right-sided tumors.¹ One study has reported that clinical signs were not noted until the pulmonary tumor grew to at least 3 cm in size.⁷

In a study of 86 cats with primary pulmonary neoplasia, the location was determined in all cases.¹¹ Tumors were left-sided in 26 cats, right-sided in 27 cats, and bilateral in 33 cats.¹¹ In 45 cats, the tumors were found in a single lung lobe and the right and left caudal lobes were more commonly diagnosed with pulmonary tumors (34) versus the right and left cranial (9) and right middle lung lobes (2), which was likely the result of increased tissue at risk in caudal lobes.¹¹ Nineteen cats in one study were found to have a single lung lobe affected, whereas two cats had multiple lesions.³⁰ Of 17 cats in a separate study, all single lesions were left-sided; however, 10/17 had multiple lesions (both right- and left-sided).²⁹

The radiographic pattern of primary pulmonary neoplasia has been variably reported in dogs and cats. Four radiographic patterns were described in a study evaluating 41 cats with primary pulmonary tumors: focal, localized, diffuse, and normal.⁴⁷ In the focal group, 65% demonstrated solitary masses and 35% demonstrated multiple masses.⁴⁷ Of the cases with focal (solitary and multiple) and localized masses, 17 were on the right side and 20 were on the left side.⁴⁷

Thoracic ultrasound may be employed to assess pulmonary neoplasia or to obtain a sample of tissue via FNA or pretreatment biopsy (Figure 23-14). The ultrasonographic appearance of pulmonary neoplasia has been described in several studies.⁴⁸⁻⁵⁰ Pulmonary masses may be hypoechoic or may exhibit variable echogenicity, and tumors are generally considered to have both a lack of discernable bronchi and normal branching vessels.^{48,49}

Thoracic CT scans are gaining popularity for the preoperative assessment of pulmonary neoplasia and many clinicians feel this diagnostic is a necessity (Figure 23-15). Recently, the CT findings of primary lung tumors were described.⁵¹ Several characteristics of solitary lung tumors were noted with CT in a majority of cases; 17/18 were well circumscribed, 16/19 were located in a cranial or caudal lobe, and 14/18 were located in the center to periphery of the lobe.⁵¹ Internal mineralization was an uncommon finding being diagnosed in only 3/19 cases.⁵¹

Thoracic CT has been shown to be more accurate than thoracic radiographs in the assessment of tracheobronchial lymph node metastasis.²⁸ In 14 dogs diagnosed with primary pulmonary tumors, the accuracy of CT to determine tracheobronchial lymph node

metastasis was 93% compared with 57% for thoracic radiography.²⁸ Additionally, five dogs deemed to be free of pulmonary metastasis with thoracic radiographs were found to have pulmonary metastasis with CT.²⁸

In a study evaluating the assessment of pulmonary metastatic disease in 18 dogs (two of which had bronchoalveolar carcinoma) by thoracic radiography and CT, only 9% of CT-detected pulmonary nodules were noted on thoracic radiographs.⁵² CT was able to detect pulmonary nodules down to approximately 1 mm in size, whereas thoracic radiography required a size of 7 to 9 mm for detection.⁵¹ Overall, CT was significantly more sensitive than thoracic radiography in the identification of pulmonary nodules.^{52,53}

Fine-Needle Aspiration

FNA of a pulmonary mass may be performed prior to lung lobectomy to attempt to obtain a cytologic diagnosis. FNA is often performed with ultrasound or CT guidance; however, blind aspirates have been reported.^{11,50,54,55} Sedation is generally required to prevent iatrogenic trauma during the aspiration process. In dogs, preoperative FNA with cytology has resulted in a diagnosis in 38% to 90% of cases in which it is performed.²⁵⁻²⁷ Diagnosis of primary pulmonary neoplasia in cats is reportedly higher, with 80% to 100% of cases being diagnosed by FNA and cytology.^{11,30,54}

A pretreatment biopsy (biopsy performed prior to definitive therapy) can be performed prior to lung lobectomy, although the clinical relevance is questionable.⁵⁶ If there is suspicion that a pulmonary neoplasm is not a primary lesion (i.e., either metastatic or systemic neoplasia such as lymphoma), a pretreatment biopsy may be considered; however, if the eventual goal is to treat the pulmonary tumor by lung lobectomy, a pretreatment biopsy is not necessary. Multiple techniques for performing a pretreatment biopsy have been described, including utilizing a biopsy needle, bronchoscopic biopsy, keyhole incision with staple application, and thoracoscopy.*

To perform a pretreatment biopsy with a biopsy needle, sedation or anesthesia is required. Additionally, the use of ultrasound, fluoroscopic, or CT guidance is recommended to improve the targeting of the lesion and decrease the chance of iatrogenic trauma to normal structures.^{50,55-56} In a study of dogs and cats undergoing CT-guided tissue core biopsy of intrathoracic lesions (including

*References 11, 25, 27, 46, 55-57.

• **FIGURE 23-15** Transverse CT scan images of a right caudal lung lobe histiocytic sarcoma (**A**) in a 9-year-old Bernese Mountain dog and a right caudal pulmonary carcinoma (**B**) in a 10-year-old Fox terrier.

pulmonary tumors), the accuracy of diagnosis for the biopsy technique was 92% and the sensitivity for neoplasia was 80%.⁵⁵ A procedural complication rate of 43% was reported in that cohort; pulmonary hemorrhage and pneumothorax were seen in 30% and 27% of cases, respectively.⁵⁵

Bronchoscopic biopsy has been performed in dogs and cats with pulmonary neoplasia with mixed success.^{11,27} Findings that have been reported during bronchoscopic examination in veterinary patients with primary pulmonary neoplasia include narrowing of bronchi, mucosal erosions, and mucosal swelling and hyperemia.⁵⁸ In one series of cats, 5/7 cases were successfully diagnosed by means of endoscopic bronchiolar brushing.¹¹

A keyhole lung biopsy technique has been described for non-neoplastic lung disease.⁴⁶ For this technique, a small thoracotomy (3 to 7 cm) was performed and a surgical stapler was applied across the lung lobe to seal vessels and small airways.⁴⁶ Thoracoscopy is a minimally invasive surgical option that may be utilized to obtain a pretreatment biopsy.⁵⁹ In a study describing the use of thoracoscopy to determine the cause of pleural effusion, biopsies of several suspicious intrathoracic lesions were performed.⁶⁰ In 8/18 cases, neoplasia was the cause of the pleural effusion, although the number of primary pulmonary tumors resulting in pleural effusion was unknown.⁶⁰ Performing a biopsy with thoracoscopy allowed for sufficient sample acquisition and the opportunity to perform an exploration of the thoracic cavity.⁶⁰

Treatment

Surgery is the treatment of choice for primary pulmonary tumors. The surgical approach to a pulmonary tumor is clinician dependent, but certain overarching criteria exist. For unilateral tumors, a lateral thoracotomy or median sternotomy may be performed. Thoracoscopic lung lobectomy can be considered if the mass is deemed to be peripherally located and is in a suitable location. If nodules in multiple lobes are found bilaterally and the goal is to remove all gross disease, a median sternotomy should be performed.

Both partial and complete lung lobectomies have been described, and the elected technique is based on the location of the tumor. In

general, a complete lung lobectomy should be performed; however, partial lung lobectomy may be an option for small tumors located in a peripheral position on the lung lobe. A cuff of normal tissue should be removed with the tumor to increase the chance of obtaining a wide margin.

Partial and complete lung lobectomies are generally performed with either a suturing method or the use of a surgical stapler. When performing a partial lung lobectomy with the suture method, the area to be removed is delineated by placing crushing forceps proximal to the lesion.⁶¹ A continuous overlapping suture can then be placed proximal to the clamps.⁶¹ For complete lung lobectomy utilizing suture ligation, the pulmonary artery and vein are individually ligated, and the bronchi are oversewn to prevent air leakage. Pneumonectomy can be performed when indicated.⁶²

Several studies have evaluated the use of stapling equipment for lung lobectomy.^{26,63,64} In a study of 37 dogs and cats undergoing resection of pulmonary lesions (67% were neoplastic) by surgical staples, the complications were minimal and the surgery was determined to be safe, fast, and efficient.⁶³ Use of surgical staplers is considered by many to be the technique of choice for partial and complete lung lobectomy (Figure 23-16).

Thoracoscopy is being employed more commonly for both diagnostic and treatment purposes. Thoracoscopy can be utilized to localize pulmonary lesions and to obtain biopsies.^{59,60} Additionally, thoracoscopic lung lobectomy and thoracoscopic-assisted lung lobectomy have been recently described in several reports.⁶⁵⁻⁶⁷ In one study of nine dogs with pulmonary neoplasia (seven metastatic and two primary), successful thoracoscopic lung lobectomy was performed in five cases.⁶⁵ Cases that were deemed to be good candidates for thoracoscopic removal in that study included those with small masses located away from the hilus. Caudal lung lobectomy was determined to be easier than cranial lung lobectomy; however, both were performed successfully.⁶⁵ Conversion from a thoracoscopic technique to an open procedure was most commonly performed because of poor operative vision.⁶⁵ One-lung ventilation should be considered in cases of thoracoscopic lung lobectomy to improve visualization.^{65,66,68}

FIGURE 23-16 **A**, Operative view of lung cancer. Note the typical raised lesion with superficial neovascularization. **B**, The lung lobe is lifted up, and surgical staples are placed at the level of the proximal mainstem bronchus. **C**, Firing the stapler releases a double row of B-shaped, stainless steel staples. The lung mass then is removed, and the instrument is released. The artery, vein, and bronchus are inspected for any small leaks, which are sutured.

Biopsy of hilar lymph nodes is recommended as a staging tool because metastatic disease to the lymph nodes significantly affects prognosis.²⁸ Lymph node biopsy is relatively easy to perform via a lateral thoracotomy, but the position of the lymph nodes during a median sternotomy increases the difficulty. In the largest thoracoscopic lung lobectomy study in veterinary patients to date, none of the hilar lymph nodes were biopsied; however, thoracoscopic lymph node biopsy is performed regularly in human patients.^{65,69}

Cisplatin-based chemotherapy protocols are considered the standard of care for human patients that receive chemotherapy in the adjuvant or palliative setting.⁷⁰ Relatively little is known about the efficacy of chemotherapy treatment for pulmonary tumors in domestic animals; however, chemotherapy treatment has been largely unrewarding in the gross disease setting. Early clinical trials evaluating the safety and efficacy of doxorubicin in cancer-bearing pet dogs included one evaluable dog with papillary pulmonary adenocarcinoma that experienced progressive disease.⁷¹ No responses were seen in three dogs with lung adenocarcinoma that were treated with mitoxantrone.⁷² Minimal responses were reported in two dogs treated with vindesine, whereas two dogs treated with the combination of vindesine and cisplatin both experienced greater than 50% reduction in measurable disease.²⁶ Treatment with vinorelbine resulted in partial responses in two out of seven dogs with measurable bronchoalveolar carcinoma.⁷³ Three additional dogs with microscopic disease were treated with adjuvant vinorelbine in the microscopic disease setting and those patients achieved survival

times of 113, 169, and greater than 730 days.⁷³ Pharmacokinetic studies in humans have concluded that vinorelbine treatment results in 300-fold higher concentration in the lung when compared to plasma, which is 3.4- to 13.8-fold higher than lung concentrations of vindesine and vincristine, respectively.⁷⁴ Based on observed partial responses in dogs and pharmacokinetic data in humans, treatment with vinorelbine or cisplatin appears to hold the most promise.

Delivery of aerosolized chemotherapy or cytokines has been described and appears well tolerated in dogs with primary or metastatic pulmonary neoplasia. Complete and partial responses have been described in dogs treated with inhalational therapy for metastatic tumors, whereas stable or progressive disease was reported in dogs with primary lung tumors.^{75,76}

Treatment with monoclonal antibodies or small-molecule tyrosine kinase inhibitors (TKIs) directed against cell signaling pathways has been shown to be beneficial in distinct subpopulations of human patients with non-small-cell lung cancer (NSCLC). Such targeted therapies are yet to be thoroughly examined in dogs with this disease. With the recent availability of receptor TKIs toceranib (Palladia) and masitinib (Kinavet) for use in veterinary patients, future interrogation of such therapeutics may be warranted. In a phase I study, monotherapy with toceranib resulted in stable disease for more than 10 weeks in the only dog with primary lung carcinoma.⁷⁷

Malignant pleural effusions can be responsive to systemic chemotherapy, intrapleural chemotherapy, or a combination of both routes. Cisplatin, carboplatin, or mitoxantrone have been used

successfully for this purpose, resulting in temporary palliation of clinical signs.⁷⁸⁻⁸¹ Sclerosing agents such as talc or tetracyclines have been also been used in a palliative setting.⁸²

RT in physician-based medicine is most often reserved for tumors that are unresectable.⁷⁰ Elective nodal irradiation for locally advanced NSCLC of human patients has traditionally been recommended but is a current source of controversy. Technologies such as IMRT, gamma-knife, or tomotherapy can now be used to provide more precise delivery of radiation while sparing unaffected tissues, especially when used together with respiratory gating or breath-hold techniques. Use of such modalities in veterinary patients is now becoming more accessible but remains to be investigated in dogs and cats with lung tumors.

Interventional oncology is a specialty that utilizes minimally invasive, image-guided techniques to perform diagnostic and therapeutic procedures in the treatment of cancer. Interventional oncologic techniques for the treatment of primary pulmonary neoplasia have not been described in the veterinary literature; however, several treatment options exist in human medicine for pulmonary neoplasia.⁸³⁻⁸⁶ These options are generally reserved for cases of pulmonary metastatic disease, cases of nonresectable pulmonary tumors, or patients in which surgery is contraindicated due to existing comorbidities.⁸⁴⁻⁸⁷ Significant research and proper case selection would need to be performed before these techniques could be routinely performed in clinical veterinary patients.

Radiofrequency ablation (RFA) and regional chemotherapy administration are two interventional oncology techniques that have been reported in the treatment of pulmonary neoplasia. RFA is performed by placing an electrode within a tumor and generating heat; the heat results in coagulative necrosis in a defined region.^{83,85,86} The goal is to produce a 360-degree region of necrosis around the tumor, with a 1-cm thick margin of normal tissue included.^{83,85}

RFA has been performed in dogs with experimentally induced transmissible venereal tumor of the lung.⁸⁸ In this group of five dogs, RFA was applied percutaneously with CT guidance to 14 tumors. On harvest of the affected lung lobes, gross and histopathologic evaluations demonstrated complete thermal coagulation necrosis of all the lesions that had been treated; no viable tumor was identified in any dogs.⁸⁸

Regional chemotherapy has been developed with the goal of increasing the efficacy of chemotherapy agents and decreasing systemic side effects.⁸⁹ Regional delivery allows for increased concentrations of chemotherapy to be delivered to the tumor by selective catheterization of the tumoral arterial supply.⁸⁹ Regional techniques involving the administration of chemotherapy into the bronchial arteries and pulmonary arteries have been described in several human studies.^{87,89,90} Recently, a study demonstrated that significantly higher concentrations of chemotherapy agents (gemcitabine and carboplatin) were noted in pulmonary tissue that had been treated with regional techniques (selective pulmonary artery perfusion) as compared to the concentration after intravenous administration in an experimental model.⁹⁰ As stated previously, the indications for these treatments remain to be determined in veterinary patients.

Prognosis

Several studies have evaluated prognostic variables in both dogs and cats with primary pulmonary neoplasia (Table 23-5).*

• **TABLE 23-5** Factors Associated with Survival Time for Pulmonary Tumors in Dogs and Cats

FACTOR	REFERENCE
Dogs	
Size >100 cm ³	26
TNM stage	25, 27, 92
Lymph node involvement	25, 27, 28
Clinical signs at diagnosis	25
Gross disease postoperatively	91
Histologic type	25, 26, 92
Involvement of entire lung lobe	26
Histologic grade	25
Cats	
Histologic grade	30

Dogs with clinical signs at the time of diagnosis have been found to have significantly shorter disease-free intervals (DFIs) and survival times versus those in which a pulmonary tumor was found incidentally.²⁵ Metastatic disease within the lymph nodes is also associated with a significantly decreased DFI and survival time in dogs.^{25,27,28} In one study, dogs with well-differentiated tumors lived longer and had longer DFIs than dogs with moderately or poorly differentiated tumors.²⁵ Similarly, histologic grade is predictive of outcome in cats. The MST for cats undergoing surgical resection of pulmonary tumors was 2.5 months and 23 months for poorly differentiated and well differentiated tumors, respectively.³⁰

One study evaluated the effect of several variables on remission and survival in dogs with primary lung tumors.⁹¹ Dogs for which surgery was successful in rendering them free of macroscopic disease lived significantly longer than dogs that had gross disease postoperatively.⁹¹ Factors significantly associated with remission included limited degree of primary tumor involvement, normal-sized lymph nodes, and lack of metastatic disease.⁹¹ In a separate study of 15 dogs, trends for longer survival times were noted in dogs with adenocarcinoma versus SCC, in dogs with peripheral lesions versus lesions that involved an entire lobe, and in dogs with tumor volume smaller than 100 cm³ when compared to dogs with tumor volume larger than 100 cm³.²⁶

Dogs without clinical signs at the time of diagnosis have a MST of 545 days versus 240 days in dogs with clinical signs.²⁵ Tumor stage (T) is also prognostic for MST, with T1 (solitary), T2 (multiple), and T3 (invasive into adjacent tissues) tumors having MSTs of 26 months, 7 months, and 3 months, respectively.²⁵ Dogs with lymph node metastasis had a MST of 1 month compared with dogs without lymph node involvement that survived for a median of 15 months.²⁵ In another study, dogs with lymph node enlargement diagnosed prior to surgery survived for a median time of 60 days, whereas dogs without lymph node enlargement had a MST of 285 days.⁹¹ A similar finding was noted in a more recent study in which dogs with lymphadenopathy had MSTs of 126 days versus a MST that had not been reached in the dogs without lymphadenopathy.²⁸ In dogs for which a surgical remission could be achieved, the MST is 330 days versus 28 days in dogs that could not be rendered free of visible disease.⁹¹ Although not statistically significant, the MST of dogs with SCC was 8 months and the MST of dogs with

*References 25, 27, 28, 30, 91, 92.

adenocarcinoma was 19 months in one study.²⁶ Finally, dogs with well-differentiated, moderately differentiated, and poorly differentiated lung tumors have MSTs of 790 days, 251 days, and 5 days, respectively.²⁵

A recent study evaluated 42 dogs with primary lung tumors and based the prognostic evaluation on the WHO classification scheme.⁸⁹ In these cases, 34 tumors were determined to be carcinomas (26 papillary adenocarcinomas) and eight were determined to be sarcomas. Fourteen of the carcinomas and two of the sarcomas were T1N0M0. Dogs with papillary adenocarcinomas and a clinical stage of T1N0M0 had the best overall prognosis with an MST of 555 days; this survival time was significantly longer than dogs with any other tumor type or dogs with a worse clinical stage.⁹² Dogs with other tumor types had a MST of 72 days.⁹²

Comparative Aspects⁷⁰

Lung cancer is the leading cause of cancer deaths in the United States and worldwide.⁹³ Approximately 85% of human lung cancers are NSCLCs, with the remainder being small-cell lung cancer. NSCLCs are comprised of three distinct histologic subtypes: SCC, adenocarcinoma, and large-cell lung cancer. Large airway origin tumors predominated in humans through the 1960s and were commonly associated with smoking cigarettes. Adenocarcinoma arising from the smaller airways now predominates in human patients, which is likely a result of changes to tobacco blends and the use of cigarette filters.⁹⁴

If curative-intent resection can be performed, prognosis for human patients with NSCLC is largely dependent on stage, with 5-year survival rates greater than 60% to 70% for patients with stage I disease. Five-year survival rates are roughly 30% to 40%, 10% to 30%, and less than 5% for patients with stage II, stage III, and stage IV disease, respectively.⁷⁰

Inherited cancer syndromes caused by germline *p53* mutations, retinoblastoma, EGFR, and other genes have been reported to increase the risk of lung cancer. Furthermore, an association between single-nucleotide polymorphism variations has been linked to lung carcinogenesis and may cooperate with nicotine exposure. DNA synthesis and repair genes may also play a role in the development and prognosis of lung cancer. Commonly acquired molecular abnormalities in human lung cancer include but are not limited to microsatellite instabilities, EGFR mutations, *p53* inactivation, RB inactivation, P16INK4a inactivation, allelic loss, and high telomerase activity. *K-ras* mutations have been found in up to 30% of human NSCLCs.⁹⁵ Close homology exists between canine and human *K-ras*. Interestingly, *K-ras* mutations were detected in 5 of 21 canine NSCLC specimens by direct sequencing. Further studies concluded that the frequency and type of mutations in canine NSCLC tissues more closely matched those for tumors from human nonsmokers with *K-ras* mutations than those for smokers.⁸

The FDA has approved the use of two EGFR-targeted molecules, gefitinib (Iressa, Astra Zeneca) and erlotinib (Tarceva, Genentech/Roche), in the second- and third-line treatment of human lung cancer. Gefitinib monotherapy confers substantial clinical benefit in terms of progression-free survival and overall survival in NSCLC patients with EGFR mutations. These mutations were commonly found in patients fitting the responsive profile observed in initial and subsequent clinical studies: specifically female, nonsmokers, Asian descent, and adenocarcinoma, which suggest a distinctive biology in this subgroup of individuals.⁹⁶

Miscellaneous Lung Conditions

Canine Pulmonary Lymphomatoid Granulomatosis

Canine pulmonary lymphomatoid granulomatosis is a poorly understood disease occurring most commonly in young to middle-aged dogs with no breed or gender predilection.⁹⁷ The most common laboratory abnormalities occurring in seven cases included basophilia and leukocytosis. Lung lobe consolidation or large pulmonary granulomas and tracheobronchial lymph node enlargement are typically seen on thoracic radiographs. Transthoracic FNA is not often diagnostically rewarding. Differential diagnoses include heartworm granulomas, metastatic neoplasia, and primary lung tumors. Traditionally, a definitive diagnosis requires biopsy and histopathology. Characteristic histopathology often demonstrates angiocentric and angiodestructive infiltration of the pulmonary parenchyma by large lymphoreticular and plasmacytoid cells in addition to normal-appearing lymphocytes, eosinophils, and plasma cells. This infiltrate is typically centered around small-to-medium arteries and veins.

The etiology of this disease is not known but is suspected to be neoplastic or preneoplastic. A recent case report indicates evidence of clonality based on polymerase chain reaction testing for antigen-receptor rearrangements (PARR), but this finding needs to be investigated in a larger series of cases.⁹⁸ It is not known whether flow cytometry or PARR testing may improve the diagnostic power of FNA.

In a very limited number of cases, the response to chemotherapy is quite variable.^{99,100} Of five dogs that were treated with cyclophosphamide, vincristine, and prednisone, three achieved a CR. The remaining dogs showed either worsening in clinical signs or progressed to lymphoid leukemia within 2 months. Dogs achieving a complete response were alive at 7, 12, and 32 months.

Histiocytic Sarcoma

Histiocytic sarcoma (HS) was originally reported in a series of 11 Bernese Mountain dogs and is believed to be inherited with a polygenic mode of inheritance in this breed^{101,102} (see Chapter 33, Section F). *Histiocytic sarcoma* is currently the preferred term for identifying malignant tumors of antigen-presenting dendritic cell origin, whereas the original term *malignant histiocytosis* refers to the systemic (disseminated) form of the disease. Other breeds at risk include the Rottweiler, golden retriever, and flat-coated retriever. Dogs often present with respiratory signs but nonspecific presenting complaints of weight loss, lethargy, fever, and anorexia are also common. HS commonly metastasizes to lymph nodes, the kidneys, the liver, and the central nervous system. HS can occur in a hemophagocytic form, resulting in anemia, hypoalbuminemia, thrombocytopenia, and leukopenia. Paraneoplastic hypercalcemia can also occur with this disease. Dogs presenting with the hemophagocytic form of HS have a particularly poor prognosis, with hypoalbuminemia and thrombocytopenia being associated with a dismal prognosis.^{103,104} In contrast to dogs with disseminated HS, dogs with localized HS that underwent surgical excision and adjuvant therapy with CCNU had a reported MST of 568 days.¹⁰⁵ Interestingly, 5 out of 16 dogs within that study had localized pulmonary lesions that were resected prior to therapy with CCNU.

Tumors of the Skeletal System

24

NICOLE P. EHRHART, STEWART D. RYAN, AND TIMOTHY M. FAN

Osteosarcoma in Dogs

Incidence and Risk Factors

Osteosarcoma (OS) is the most common primary bone tumor in dogs, accounting for up to 85% of malignancies originating in the skeleton.¹⁻⁵ OS is estimated to occur in more than 10,000 dogs each year in the United States; however, this is probably an underestimation, since not all cases are confirmed or recorded.^{6,7} The demographics of canine OS have been well reported.^{1-5,8-19} It is largely a disease of middle-aged to older dogs, with a median age of 7 years. There is a large range in age of onset, with a reported case in a 6-month-old pup²⁰ and a small early peak in age frequency at 18 to 24 months.¹³ Primary rib OS tends to occur in younger adult dogs with a mean age of 4.5 to 5.4 years.^{21,22} OS is classically a cancer of large and giant breeds. In a review of 1462 cases of canine OS, dogs weighing more than 40 kg accounted for 29% of all cases and only 5% of their tumors occurred in the axial skeleton. Only 5% of OSs occur in dogs weighing less than 15 kg, but 59% of their tumors originated in the axial skeleton. Increasing weight and, more specifically, height appear to be the most predictive factors for the disease in the dog.²³ In the United States, the breeds most at risk for OS are Saint Bernard, Great Dane, Irish setter, Doberman pinscher, Rottweiler, German shepherd, and golden retriever; however, size seems to be a more important predisposing factor than breed.* A hereditary basis for the formation of OS has been suspected, based primarily on the (large) breed prevalence of the disease, as well as the subjective assessment of increased incidence in some related families. Males are reported to be slightly more frequently affected than females (1.1 to 1.5:1),† with the exception of the Saint Bernard, Rottweiler, and Great Dane and for dogs with primary OS of the axial skeleton (except rib and spine) in which affected females outnumber males.^{2,22} However, in 1775 cases of canine OS of all sites treated at Colorado State University between 1978 and 2005, the male-to-female ratio was 1:1 (unpublished data, Colorado State University Animal Cancer Center [CSU-ACC] OS Database). Intact males and females were reported to have an increased risk for OS²³; however, in the Rottweiler breed, male and female dogs that underwent gonadectomy before 1 year of age had an approximate one in four lifetime risk for bone sarcoma and were significantly more likely to develop bone sarcoma than dogs that were sexually intact.²⁴ There was a highly significant inverse dose-response relationship between duration of lifetime gonadal exposure and incidence rate of bone sarcoma independent of adult height or body weight.

†References 2, 3, 9, 12, 13, 15.

Approximately 75% of OSs occur in the appendicular skeleton, with the remainder occurring in the axial skeleton.^{2,22} The metaphyseal region of long bones is the most common primary site, with front limbs affected twice as often as rear limbs, and the distal radius and proximal humerus are the two most common locations.¹¹ It is extremely rare for OSs to be located in bones adjacent to the elbow, although there is one report of 12 cases located at the proximal radius or distal humerus.²⁵ There was no prognostic difference in these cases as compared to more common appendicular sites. In the rear limbs, tumors are fairly evenly distributed between the distal femur, distal tibia, and proximal tibia, with the proximal femur a slightly less common site.² Primary OS distal to the antebrachiocondylar and tarsocrural joints is relatively rare in dogs.²⁶ In 116 cases of canine primary OS in the axial skeleton, it was reported that 27% were located in the mandible, 22% in the maxilla, 15% in the spine, 14% in the cranium, 10% in ribs, 9% in the nasal cavity or paranasal sinuses, and 6% in the pelvis.²² Single reports of OS development in the os penis²⁷ and the patella²⁸ exist for the dog. Clinically documentable multicentric OS at the time of initial diagnosis occurs in less than 10% of all cases.²⁹ OS of extraskeletal sites is rare, but primary OS has been reported in mammary tissue, subcutaneous tissue, spleen, bowel, liver, kidney, testicle, vagina, eye, gastric ligament, synovium, meninges, and adrenal gland.³⁰⁻³⁵

Etiology

The etiology of canine OS is generally unknown. Some have speculated a viral cause because OS can occur in litter mates and may be experimentally induced by injecting OS cells into canine fetii.³⁶ However, an etiologic virus has not been isolated.

Physical Factors

A simplistic theory based on circumstantial evidence is that because OS tends to occur in major weight-bearing bones adjacent to late-closing physes and heavy dogs are predisposed, multiple minor trauma and subsequent injury to sensitive cells in the physal region may occur. This may initiate the disease by inducing mitogenic signals, increasing the probability for the development of a mutant lineage. One in vitro study comparing the incidence of microdamage in cadaver radii of small- and large-breed dogs found no difference between the groups.³⁷ OS has been associated with metallic implants used for fracture repair, with chronic osteomyelitis, and with fractures in which no internal repair was used.³⁸⁻⁴² OS has also been reported at the site of a bone allograft used for fracture repair 5 years previous.⁴³ Exposure to ionizing radiation can induce OS.^{35,44-52} In humans exposed to plutonium, 29% and 71% of the OSs were in the appendicular and axial skeleton, respectively, with the spine having the most tumors (36%). An almost identical distribution of plutonium-induced OS was reported for dogs injected with ²³⁹Pu as young adults in experimental studies. This

distribution of OS is quite different from the distributions of naturally occurring OS for both species and appears to be related to bone volume and turnover. Similar findings were seen for dogs injected with 226R (radium).⁵² A distribution favoring bone marrow volume was seen for dogs exposed to strontium-90.⁵¹ OS is a rare, late complication of radiation therapy (RT) in humans and dogs.^{44,46,48-50} Three of 87 (3.4%) spontaneous tumor-bearing dogs treated for soft tissue sarcomas developed OS within the field of radiation.⁴⁴ In another experimental study, 21% of dogs undergoing intraoperative RT (>25 Gy) followed by external-beam RT to the vertebral column developed OS following treatment.⁴⁸ Secondary OS developed between 1.7 and 5 years after radiation in that study, and the authors speculated that high dose of radiation per fraction or total dose may predispose to this serious late effect of irradiation. OS was reported in 3% of 57 dogs irradiated for acanthomatous epulis of the oral cavity in another study.⁴⁶ Postirradiation OS in humans comprised approximately 2% to 4% of all OSs reviewed in two large series.^{53,54}

OSs have been concurrently seen in dogs with bone infarcts, but it is not clear whether there is any causal relationship.⁵⁵⁻⁵⁹ Bone infarcts are uncommon, are of unknown etiology, and may be identified as incidental findings by radiography. Bone infarcts are probably not associated with tumor emboli and appear to be more common in smaller breeds. A single report exists of OS occurrence secondary to a bone infarct caused by total hip arthroplasty.⁶⁰ A case of OS was also reported to be associated with osteochondritis dissecans in the humeral head,⁶¹ and another report documents malignant transformation of an aneurysmal bone cyst.⁶²

Genetic Factors

Ample evidence exists implicating the involvement of genetic and heritable factors for the development of OS in dogs. Currently, the most thoroughly described gene mutation that contributes to OS formation and/or progression in dogs is *p53*.⁶³⁻⁷⁰ Initial studies performed in immortalized canine OS cell lines demonstrated that the functionality of the *p53* gene was defective based on the incapacity of *p53* to regulate appropriately the transcriptional expression of downstream target genes including *p21* and *mdm2* following genotoxic insult.⁶⁵ Furthermore, *p53* mRNA and protein were overexpressed in 60% of cell lines and correlated with the presence of missense point mutations within the DNA-binding domain.⁶⁵ Corroborating in vitro cell line studies, mutations in *p53* have also been demonstrated in dogs with spontaneously arising OS. Several studies using either single-strand conformational polymorphism, polymerase chain reaction, or southern blotting, followed by nucleotide sequence analysis have identified missense mutations involving exons 4 to 8 of *p53* in 24% to 47% of all spontaneously arising OS samples.^{63,67,69,70} In addition to exons 4 to 8, the entire gene sequence of *p53* has also been assessed by polymerase chain reaction (PCR) and single-strand conformational polymorphism from 59 spontaneously arising appendicular and axial OS samples.⁶⁴ In 41% of tumors, *p53* mutations were identified, with the majority of abnormalities being point mutations (74%), which resulted in an amino acid substitution, with a lesser percentage of mutations (26%) being deletions.⁶⁴ Finally, through the implementation of targeted microarray-based comparative genomic hybridization analysis of 38 canine OS cases, similar recurrent cytogenetic aberrations classically present in human OS samples were also identified in OS specimens collected from dogs, including loss of heterozygosity (LOH) of the *p53* gene in 18% of tumors.⁷¹

Substantiation for the presence of *p53* mutations in sporadic canine OS has also been documented by immunohistochemical

studies because a hallmark of many *p53* mutations is enhanced protein stability of this normally labile protein, enabling detection of protein with methodologies such as immunohistochemistry (IHC).⁷² In one study evaluating *p53* protein expressions in 106 osteogenic tumors, a greater percentage of appendicular (84%) OSs overexpressed *p53* protein in comparison with OSs arising from the axial skeleton (56%) and other non-OS bone tumors (20%).⁶⁸ Finally, loss of *p53* gene function in 167 osseous tumors has been characterized by *p53* nuclear staining frequency and intensity expressed as a *p53* index. Of 103 OS samples, 67% stained positively for *p53* protein, and the *p53* index was significantly greater in OS derived from the appendicular ($n = 84$) versus axial ($n = 38$) skeleton.⁶⁶ Interestingly, the *p53* index of appendicular OS derived from Rottweilers was significantly higher than in Great Danes or other commonly affected breeds, supporting the notion that *p53* gene mutations may be associated with breed susceptibilities to OS development.²⁴

Another tumor suppressor gene likely to be permissive for OS development is the *RB* gene. Based on investigations using five tumorigenic immortalized canine OS cell lines, the *RB* gene signaling pathway was found to be dysregulated with the persistence of hyperphosphorylated *RB* protein in the absence of mitogen stimulation. Despite apparent aberrant *RB* gene signaling, reduction in *RB* protein was identified in only one of five cell lines.⁶⁵ Corroborating these in vitro findings, the evaluation of 21 spontaneously arising OSs failed to identify gross *RB* gene alterations by Southern blotting, and protein expressions of *RB* were identified in all OS samples evaluated.⁶⁷

Despite normal protein expression of *RB* in canine OS samples, the observed translational normalcy does not exclude the possibility for allelic deletion of the *RB* gene because prior studies in human OS samples have demonstrated that LOH at the *RB* gene locus does not absolutely correlate with inactivation of *RB* at the protein level.⁷³ Substantiating the possibility that *RB* gene may have allelic deletion in spontaneously arising canine OS, analysis of 38 OS samples with comparative genomic hybridization techniques identified copy number loss in 11/38 cases (29%), resulting in a correlative reduction or absence of *RB* protein expression in 62% of OS samples tested.⁷¹ Based on these recent findings, it is probable that aberrations in the *RB* gene indeed participate in sporadic OS formation and/or progression in dogs.

In addition to *p53* and *RB* gene abnormalities, the phosphatase and tensin homolog (*PTEN*) tumor suppressor gene is suspected to participate in the genetic pathogenesis of canine OS. Original in vitro studies conducted with canine OS cell lines demonstrated that the majority of cell lines (60%) harbored mutations in *PTEN*, resulting in the absence of gene transcription and protein translation. Corroborating the cell line findings, expression of *PTEN* was either absent ($n = 6$) or variable ($n = 4$) in 15 spontaneously arising OS samples.⁷⁴ Further support for the loss of *PTEN* gene in canine OS pathogenesis has been the identification of specific recurrent chromosome copy number aberrations (CNAs) through targeted microarray-based comparative genomic hybridization studies.^{71,75} In one study utilizing 38 OS samples derived from Rottweilers and golden retrievers, deletion of a chromosomal region (CFA 26q25), which encompasses the *PTEN* tumor suppressor gene locus, occurred in 42% of OS samples.⁷¹ In a subsequent study analyzing 123 OS samples predominantly derived from Rottweilers, greyhounds, golden retrievers, and great Pyrenees, high-resolution comparative genomic hybridization studies similarly identified high recurrent copy number loss encompassing the *PTEN* gene in 30% of samples.⁷⁵ In addition to the *PTEN* gene, other genes

identified by high-resolution comparative genome hybridization studies potentially involved in the genetic pathogenesis of OS included overexpression of *RHOC* and *RUNX2* and underexpression of *TUSC3*.⁷⁵

A growing body of evidence in dogs supports breed-associated inheritance of OS, especially in Scottish deerhounds, Rottweilers, greyhounds, Great Danes, Saint Bernards, and Irish wolfhounds.^{24,30,76-79} Many domestic dog breeds have narrow genetic diversity as a consequence of selective breeding practices; this has provided the opportunity to more clearly elucidate the heritability of OS in dogs. For Scottish deerhounds in particular, the reported incidence of OS formation is 15%,^{76,77} and the narrow heritability in this breed was 0.69, indicating that 69% of the cause for OS development in Scottish deerhounds is due to heritable trait, likely a Mendelian major gene with dominant expression.⁷⁷ Further studies in Scottish deerhounds using a whole genome linkage approach have mapped a novel locus (*OSA1*) for OS formation in this breed to CFA34 and provide the opportunity to pinpoint specific candidate genes directly involved in OS etiology for this specific dog breed.

Molecular Factors

Because of the heterogeneous and chaotic nature of OS, it has been difficult to definitively ascribe specific molecular derangements responsible for the etiopathogenesis of OS.⁸⁰ Nonetheless, substantive progress has been achieved through experimental, preclinical, and comparative investigations to identify dysregulated intracellular signaling and cell survival pathways likely to participate in the pathogenesis of OS. Significantly, the identification and tumorigenic consequences of several putative pathways have been recently characterized not only in immortalized OS cell lines but also in spontaneously arising OS samples.

The *MET* proto-oncogene encodes a tyrosine kinase receptor that on ligation with hepatocyte growth factor (HGF) mediates multiple cellular functions, including cell scattering, motility, and proliferation. Given its biologic activities, excessive or dysregulated *MET* signaling in canine OS has been demonstrated to promote tumorigenic phenotypes in cell lines.⁸¹⁻⁸³ Furthermore, in a small pilot study with spontaneously arising OS samples, the expression of *MET* proto-oncogene was identified in the majority (5/7, 71%) of tumor specimens by northern blot analysis.⁸⁴ Additionally, a novel germline mutation that results in constitutive receptor phosphorylation and aberrant *MET* signaling has been identified primarily in the Rottweiler breed.⁸⁵ In a larger study of 59 primary OS samples, mRNA expressions for *MET* and HGF were detected by real-time PCR (RT-PCR) in all specimens and suggested the existence of a putative *MET*/HGF autocrine or paracrine feedback loop.⁸⁶ In a subset of OS samples, proteolytically activated HGF was identified in homogenized tumor lysates ($n = 6$) by western blot, and *MET* protein was expressed by 100% of tumors analyzed ($n = 16$) by IHC. Increased expression of *MET* mRNA correlated with regional lymph node metastases, supporting the participation of *MET* signaling for metastases and cell invasion.

The cellular effects of growth hormone (GH) are mediated through the hepatic production of insulin-like growth factor-1 (IGF-1). In osteoblasts, IGF-1 induces cell mitogenesis and protection from apoptosis, as well as promoting angiogenesis. Derived from experimental and preclinical investigations, aberrant or excessive IGF-1 signaling likely participates in OS pathogenesis. In three canine OS cell lines, the expression and functionality of the IGF-1/IGF-1 receptor (IGF-1R) signaling cascade has been reported.⁸⁷ In all cell lines, IGF-1R expression was confirmed by northern blot

analysis and radioligand binding studies; however, despite uniform receptor expression, IGF-1-mediated promotion of anchorage independent growth and invasion appeared to be cell-line specific.⁸⁷ Furthermore, to validate IGF-1/IGF-1R as a molecular target, dogs treated with definitive surgery and systemic chemotherapy received a long-acting somatostatin analog (OncoLAR) in an adjuvant setting to attenuate the protumorigenic effects of IGF-1. Despite significant reductions in circulating IGF-1 concentrations, no clinical benefit was detected in dogs treated with OncoLAR compared to placebo.⁸⁸

The proto-oncogene *erbB-2* encodes human epidermal growth factor receptor-2 (HER-2), which is a tyrosine kinase receptor capable of promoting cell transformation and growth. In both dogs and humans, the overexpression of HER2 protein as a result of gene amplification is a negative prognostic factor in mammary carcinoma; however, less clarity exists for the role of HER2 overexpression in OS.^{89,90} To better characterize HER2 expressions in canine OS, one study evaluated *HER2* mRNA transcript and protein expressions in seven cell lines and 10 OS tumor specimens.⁹¹ Based on RT-PCR, the majority of OS cell lines (6/7) and 40% of primary OS tumor samples overexpressed HER2. Similarly, the overexpression of HER2 protein was confirmed by IHC. Although not adequately powered, the results of the study suggested the possibility of HER2 overexpression as a negative prognostic factor for survival.

The mammalian target of rapamycin (mTOR) is an evolutionary conserved protein kinase downstream of Akt, which acts as a central hub for the integration of cellular signals induced by growth factors, nutrients, energy, and stress for the purposes of regulating cell cycle progression and growth. As such, aberrant signaling through the mTOR pathway contributes to growth, survival, and chemotherapy resistance in multiple tumor types. To characterize the functionality of the mTOR pathway in canine OS, one study using three canine OS cell lines investigated the expressions of mTOR and p70S6K, a downstream effector protein of mTOR.⁹² Study results indicated that the mTOR pathway was active in canine OS cells, and phosphorylation of mTOR and p70S6K could be inhibited by rapamycin, resulting in apoptosis and reduced growth of OS cells in vitro. In a complementary phase I dose-escalation study to assess the feasibility of mTOR inhibition as a treatment strategy, the pharmacokinetics and pharmacodynamics of rapamycin were investigated in dogs with primary OS.⁹³ Results from the phase I trial demonstrated that biologically effective concentrations of rapamycin were safely obtainable in dogs and that modulation of mTOR target proteins by rapamycin was achievable within the bone tumor microenvironment.

The tropomyosin-related kinase (*Trk*) proto-oncogenes encode for high-affinity receptor tyrosine kinases (RTKs), including TrkA, B, and C. Specifically in osteoblasts, TrkA receptor binds nerve growth factor (NGF), resulting in cellular mitogenesis and the inhibition of apoptosis. To characterize the possible involvement of TrkA signaling in OS pathogenesis, one study investigated the expression of TrkA and the functional consequences of TrkA receptor ligation in OS cell lines and tumor samples.⁹⁴ All canine OS cell lines ($n = 2$) and the majority of primary OS tumors (10/15) and pulmonary metastatic lesions (9/12) expressed TrkA receptors. Additionally, although TrkA signaling did not induce OS cell mitogenesis, blockade of basal TrkA signaling with either a small molecule inhibitor or blocking antibody increased serum starvation-induced apoptosis. The inhibition studies suggest that TrkA signaling participates in OS cell survival and may serve as a novel druggable target.

Telomeres are highly conserved nucleoprotein complexes at the ends of linear chromosomes that safeguard against harmful recombination events. The maintenance of telomere length and thus prevention of cellular senescence is through the activity of telomerase, a ribonucleoprotein complex that catalyzes the addition of telomeric sequences to the 3' ends of chromosomes. Telomerase endows cells with infinite replicative capacity, and given its protumorigenic potential, telomerase has been investigated in canine OS. In an exploratory study, telomerase activity was identified in 100% of OS cell lines (5/5) and in the majority of primary tumors (5/6, 83%).⁹⁵ In a larger corroborative study using 67 OS tumors, telomerase activity was identified in 73% of OS samples and supported the hypothesis that the majority of OSs possess the enzymatic machinery required for infinite replicative capacity.⁹⁶

In addition to various growth and survival pathways that potentially contribute to OS pathogenesis, the ability of OS cells to interact with their immediate microenvironment found in bone and lung tissues likely influences OS progression and metastases. Tissue invasion and focal osteolysis are hallmark characteristics of OS, and local disease progression is promoted by several OS-associated proteins, including matrix metalloproteinases (MMPs), receptor activator of NF- κ B ligand (RANKL), and lysosomal cathepsin K.⁹⁷⁻¹⁰⁰ Similar to the ability of OS cells to invade local tissues, specific proteins have been identified to participate in the progression of canine OS metastases, including ezrin,¹⁰¹ a cytoskeletal linker protein, as well as CXCR4,¹⁰² a chemokine receptor.

Pathology and Natural Behavior

OS is a malignant mesenchymal tumor of primitive bone cells. These cells produce an extracellular matrix of osteoid, and the presence of tumor osteoid is the basis for the histologic diagnosis, differentiating OS from other sarcomas of bone. The histologic pattern may vary between tumors or even within the same tumor. Small biopsy samples of an OS may lead to misdiagnoses such as chondrosarcoma, fibrosarcoma, hemangiosarcoma, or simply reactive bone. These histologic diagnoses from small biopsies must be interpreted with caution. It is important to obtain a histologic analysis of the entire tumor following definitive excision to confirm the diagnosis. There are many histologic subclassifications of OS based on the type and amount of matrix and characteristics of the cells: osteoblastic, chondroblastic, fibroblastic, poorly differentiated, and telangiectatic OS (a vascular subtype). Alkaline phosphatase staining on histopathologic and aspiration cytology specimens has been shown to aid in differentiating OS pathologically from other connective tissue tumors.¹⁰³⁻¹⁰⁵ In dogs, it has not been well established that there is a difference in the biologic behavior of the different histologic subclassifications; however, histologic grade, based on microscopic features, may be predictive for systemic behavior (metastasis).¹⁰⁶ Newer techniques (see previous section) designed to recognize molecular or genetic alterations are being evaluated to determine their potential use in predicting behavior of OS.¹⁰⁷ The degree of aneuploidy, as measured by flow cytometry, of primary and metastatic tumors is potentially indicative of biologic behavior.⁸⁰ OS has very aggressive local effects and causes lysis, production of bone, or both processes, which can occur concurrently (Figure 24-1). The local disease is usually attended by soft tissue swelling. Pathologic fracture of the affected bone can occur. Pathologic fracture at presentation in humans and dogs with OS does not necessarily preclude limb salvage and does not carry a worse prognosis than patients without fracture at presentation.¹⁰⁸⁻¹¹¹ OS rarely will cross a joint surface. This confinement to the bone may be

secondary to collagenase inhibitors limiting progression through synovium.^{112,113}

Metastasis is very common and arises early in the course of the disease, although usually subclinically. Although less than 15% of dogs have radiographically detectable pulmonary or osseous metastasis at presentation, approximately 90% will die within 1 year (median survival time [MST]: 19 weeks) with metastatic disease, usually to the lungs, when amputation is the only treatment.^{2,15} Metastasis via the hematogenous route is most common; however, on rare occasions, extension to regional lymph nodes may occur.¹¹⁴ Although the lung is the most commonly reported site for metastasis, tumor spread to bones or other soft tissue sites occurs with some frequency.¹¹⁵ An increase in the incidence of bone metastasis following systemic chemotherapy has also been documented in humans and is suspected in dogs.^{116,117} Possible explanations for this change include a change in the behavior of this cancer independent of treatment; selective killing of metastatic cancer by chemotherapy in certain sites such as the lung, which allows metastasis in other sites to become clinically relevant; lung resection and chemotherapy have improved survival, and bone sites become clinically relevant; more sensitive detection methods, which allow previously undetectable metastases to be seen; or more complete and detailed necropsies compared to those performed previously, which identify asymptomatic metastatic sites. The concept of concomitant tumor resistance has been described in which animals harboring large primary tumors are resistant to the growth of smaller metastatic tumors by systemic angiogenic suppression.¹¹⁸ Development and growth of metastatic lesions can be rapid after the removal of the primary tumor and consequent increase in angiogenic activity in animal OS models.¹¹⁹ Suspected locoregional synchronous regional bone metastases (skip metastases) have also been reported.¹²⁰ Skip metastases in human patients are a rare (1% to 6%) presentation and have a poor prognosis.¹²¹ Whole body magnetic resonance imaging (MRI) or positron emission tomography/computed tomography (PET/CT) imaging can aid in detection of occult skip metastases. Some differences in metastatic behavior have been observed based on the anatomic location of the primary OS site. For example, mandibular OS and, to a degree, other calvarium locations may have a less aggressive metastatic behavior, although contradictory evidence exists (see the later section on [Therapy and Prognosis](#)).^{122,123}

There is a report of four cases of histologically confirmed OS that subsequently underwent spontaneous regression without tumor-specific treatment.¹²⁴ This phenomenon, while extremely rare, has also been reported in humans.

History and Clinical Signs

Dogs with OS of appendicular sites generally present with a lameness and swelling at the primary site. There may be a history of mild trauma just prior to the onset of lameness. This history can often lead to misdiagnosis as another orthopedic or soft tissue injury. The pain is likely due to microfractures or disruption of the periosteum induced by osteolysis of cortical bone with tumor extension from the medullary canal. The lameness worsens and a moderately firm-to-soft, variably painful swelling arises at the primary site. Dogs may present with acute, severe lameness associated with pathologic fractures, although pathologic fractures account for less than 3% of all fractures seen.⁵⁹ Large- and giant-breed dogs that present with lameness or localized swelling at metaphyseal sites should be evaluated with OS as a likely diagnosis.

The signs associated with axial skeletal OS are site dependent. Signs vary from localized swelling with or without lameness to

• **FIGURE 24-1** **A**, Gross, longitudinally split specimen of a proximal femoral OS lesion in a dog showing cortical destruction, soft tissue, and osteoid neoplastic components. **B**, Lateral radiograph of a proximal femoral OS lesion from the case in **A**. Radiographic features include (a) Codman's triangle, (b) cortical lysis, (c) loss of trabecular pattern in the metaphyses, and (d) tumor bone extension into the soft tissues in a sunburst pattern.

dysphagia (oral sites), exophthalmos and pain on opening the mouth (caudal mandibular or orbital sites), facial deformity and nasal discharge (sinus and nasal cavity sites), and hyperesthesia with or without neurologic signs (spinal sites). Dogs with tumors arising from ribs usually present because of a palpable, variably painful mass. Respiratory signs are not common even where the lesions have large intrathoracic components, and malignant pleural effusion is quite rare.

Dogs rarely have respiratory signs as the first clinical evidence of pulmonary metastasis; rather, their first signs are usually vague. With radiographically detectable pulmonary metastasis, dogs may remain asymptomatic for many months, but most dogs develop decreased appetites and nonspecific signs such as malaise within 1 month. Hypertrophic osteopathy may develop in dogs with pulmonary metastasis (see Chapter 5).

Systemic Alterations

Alterations in energy expenditure, protein synthesis, urinary nitrogen loss, and carbohydrate flux have been documented in dogs with OS, similar to results documented in humans with neoplasia. Changes were documented in resting energy expenditure and protein and carbohydrate metabolism in dogs with OS. These changes were evident even in dogs that did not have clinical signs of cachexia.¹²⁵ Systemic, metabolic derangements reported for dogs with OS include lower chromium and zinc levels, lower iron and

iron-binding capacity, and increased ferritin levels as compared to normal dogs.¹²⁶ Hypercalcemia is extremely rare. The impact of these changes on patient treatment, response, or outcome is unknown.

Diagnostic Techniques and Work-Up

Radiology

Initial evaluation of the primary site involves interpretation of good quality radiographs taken in lateral and craniocaudal projections. Special views may be necessary for lesions occurring in sites other than in the appendicular skeleton. The overall radiographic abnormality of bone varies from mostly bone lysis to almost entirely osteoblastic or osteogenic changes (see Figure 24-1, B). There is an entire spectrum of changes between these two extremes, and the appearance of OS can be quite variable. There are some features, however, that are commonly seen. Cortical lysis is a feature of OS and may be severe enough to leave obvious areas of discontinuity of the cortex leading to pathologic fracture. There is often soft tissue extension with an obvious soft tissue swelling, and new bone (tumor or reactive bone) may form in these areas in a palisading pattern perpendicular or radiating from the axis of the cortex (i.e., “sunburst”). As tumor invades the cortex, the periosteum is elevated and new bone is laid down by the cambium layer providing a triangular-appearing deposition of dense new bone on the cortex at the periphery of the lesion. This periosteal new bone has been

called “Codman’s triangle,” but this is not pathognomonic for OS. OS does not directly cross articular cartilage, and primary lesions usually remain monostotic. The tumors may extend into periarticular soft tissues, however, and adjacent bones are at risk because of extension through adjacent soft tissue structures. Other radiographic changes that can attend OS are loss of the fine trabecular pattern in the metaphysis, a vague transition zone at the periphery of the medullary extent of the lesion (rather than a sharp sclerotic margin), or areas of fine punctate lysis. Any one or combinations of these changes may be seen, depending on the size, histologic subtype, location, and duration of the lesion. The radiographic appearance of OS is similar to osteomyelitis, specifically of fungal etiology.¹²⁷ In cases in which the travel or clinical history might support the possibility of osteomyelitis, a biopsy with submission for histology and culture may be warranted.

Based on signalment, history, physical examination, and radiographic findings, a presumptive diagnosis of OS can be made. Differential diagnoses of lytic, proliferative, or mixed pattern aggressive bone lesions identified on radiographs include other primary bone tumors (chondrosarcoma, fibrosarcoma, hemangiosarcoma); metastatic bone cancer; multiple myeloma or lymphoma of bone; systemic mycosis with bony localization; bacterial osteomyelitis; and, albeit rare, bone cysts.

Other primary bone tumors are far less common but may be suspected, especially in dogs with unusual signalment or tumor location. Metastatic cancer can spread to bone from almost any malignancy. A careful physical examination is important, including a rectal examination, with special attention paid to the genitourinary system to help rule out the presence of a primary cancer. Dogs with a history of cancer in the past should have their original biopsy reviewed and should be restaged for the original disease. Common sites for metastatic bone cancer are lumbar and sacral vertebrae, pelvis, and diaphyses of long bones. There are usually other clues for the diagnosis of multiple myeloma, such as hyperproteinemia, and both multiple myeloma and lymphoma of bone are usually attended by radiographic lesions that are almost entirely lytic. Two classic radiographic appearances of myeloma bone lesions are described: “punched-out” areas of lysis or a generalized osteoporotic thinning of cortices.

Tissue Biopsy

A diagnosis of primary malignant bone tumor may be suggested by signalment, history, physical examination, and radiographic findings. Cytology has not been thought to be definitive for diagnosis; however, it may support the tentative diagnosis, and enough confidence in the diagnosis, combined with clinical features and radiographic appearance, may exist to facilitate a discussion of treatment options. Consistent cytologic criteria of OS has recently been described, and with repeated evaluations, dependent on experience, cytopathologists may be more definitive in making a diagnosis from cytology alone.^{128,129} Alkaline phosphatase staining of cytologic samples has been shown to differentiate OS from other vimentin-positive tumors.¹⁰³ However, in most cases, a definitive diagnosis lies in procurement and interpretation of tissue for histopathology. With new treatments such as limb sparing (see subsequent sections), knowledge of the specific tumor type may avoid overextension or inappropriate treatment of bone tumors thought to be OS (e.g., chondrosarcoma, myeloma, or lymphoma). It is crucial to the success of a limb-sparing surgery that the biopsy procedure is planned and performed carefully with close attention to asepsis, hemostasis, and wound closure.¹³⁰ The skin incision for the biopsy must be small and placed so that it can be completely excised with

the tumor at limb sparing without compromising the procedure. Transverse or large incisions must be avoided. It has been recommended that the surgeon who is to perform the definitive surgical procedure (especially if limb sparing) should be the person to perform the preoperative bone biopsy.¹³¹

Bone biopsy may be performed as an open incisional, closed needle (Figure 24-2), or trephine biopsy. The advantage of an open technique is that a large sample of tissue is procured, which presumably improves the likelihood of establishing an accurate histologic diagnosis. Unfortunately, this advantage may be outweighed by the disadvantages of an involved operative procedure and risk of postsurgical complications such as hematoma formation, wound breakdown, infection, local seeding of tumor, and pathologic fracture.^{132,133} Although biopsy with a trephine yields a diagnostic accuracy rate of 93.8%, there is the increased risk of creating pathologic fracture when compared with using a smaller gauge needle.¹³⁴ This underscores some of the advantages of a closed biopsy using a Jamshidi bone marrow biopsy needle (Jamshidi bone marrow needle, American Pharmaseal Co, Valencia, CA; bone marrow biopsy needle, Sherwood Medical Co, St. Louis, MO) or similar type of needle. Jamshidi needle biopsy has an accuracy rate of 91.9% for detecting tumor versus other disorders and an 82.3% accuracy rate for diagnosis of specific tumor subtype.¹³⁵ Accuracy of diagnoses from needle core samples can depend on the pathologist’s experience and comfort level with examining small samples. Histology reports indicating the presence of reactive bone should not rule out the presence of a primary bone tumor or other pathology, especially if the radiographic changes suggest tumor. In some cases, it can be very difficult to get the diagnosis by preoperative biopsy (i.e., repeated biopsy attempts yield “reactive bone”) and yet the pathologist has no trouble identifying tumor when the entire specimen is available for histopathologic analysis (e.g., postamputation). This is likely a result of the heterogeneity of the tumor tissue itself and the large amount of reactive bone present within the tumor.

The biopsy site is selected carefully. Radiographs (two views) are reviewed, and the center of the lesion chosen for biopsy. Biopsy at the lesion periphery will often result in sampling the reactive bone surrounding the tumor growth without a resulting diagnosis.¹³⁵ The skin incision is made so the biopsy tract and any potentially seeded tumor cells can be completely removed at the time of definitive surgery. Care is used to avoid major nerves, vessels, and joint spaces. A 4-inch, 8- or 11-gauge needle is used. With the dog anesthetized, prepared, and draped for surgery, a small stab incision (2 to 3 mm) is made in the skin with a #11 scalpel blade. The bone needle cannula, with the stylet locked in place, is pushed through the soft tissue to the bone cortex. The stylet is removed, and the cannula is advanced through the bone cortex into the medullary cavity using a gentle twisting motion and firm pressure. The opposite cortex is not penetrated. The needle is removed, and the specimen is gently pushed out of the base of the cannula by inserting the probe into the cannula tip. One or two more samples can be obtained by redirecting the needle through the same skin incision so that samples of the transition zone may also be obtained. Ideal specimens should be 1 or 2 cm in length and not fragmented. Biopsy is repeated until solid tissue cores are obtained. Material for culture and cytology may be taken from the samples prior to fixation in 10% neutral buffered formalin. Diagnostic accuracy is improved when samples are evaluated by a pathologist thoroughly familiar with bone cancer. Fluoroscopy or advanced imaging (CT) can assist in obtaining needle-core biopsy samples of suspected bone lesions, especially for axial sites.¹³⁶

After tumor removal (amputation or limb sparing), histology should be performed on a larger specimen to confirm the preoperative diagnosis. If the clinical and radiographic features are typical for OS, especially when there is little possibility of fungal or bacterial infection, confirmation of histologic diagnosis following surgical treatment of local disease (amputation or limb sparing) can be considered. Few diseases causing advanced destruction of the bone can be effectively treated without removal of the local disease. If the owners are willing to treat aggressively, surgical removal of local disease with biopsy submission following surgery may be acceptable.

Staging and Patient Assessment

Systemic Staging Examination for evidence of apparent spread of the disease is important. Regional lymph nodes, although rarely involved, should be palpated, and fine needle cytology should be performed on any enlarged node.¹¹⁴ Sites of bone metastasis may be detected by a careful orthopedic examination with palpation of long bones and the accessible axial skeleton. Organomegaly may be detected by abdominal palpation. Usually, pulmonary metastases are undetectable by clinical examination, but careful thoracic auscultation is important to detect intercurrent cardiopulmonary disorders. High-detail thoracic radiographs should be taken during inspiration with the patient awake. Although some controversy exists,¹³⁷ it is still considered important by most oncologists to include three views: a ventrodorsal or a dorsoventral view and both right and left lateral views. OS pulmonary metastases are generally soft tissue dense and cannot be detected radiographically until the nodules are 6 to 8 mm in diameter. It is uncommon to detect pulmonary metastatic disease at the time of diagnosis (<10% of dogs). Advanced imaging (e.g., CT, MRI, PET/CT) may play a role in patient staging and is used to evaluate for pulmonary metastases and for evaluation of tumor vascularity, soft tissue and medullary involvement, metabolic or functional activity, and response to treatment.^{138,139} Currently, published treatment recommendations and prognoses are based on the results of plain radiographs. As advanced imaging becomes more commonplace for staging dogs with OS, comparisons to previous protocols will be subject to stage-migration and lead-time bias because earlier diagnosis will result.¹⁴⁰

Bone survey radiography has been useful in detecting dogs with second skeletal sites of OS.²⁹ Bone surveys include lateral radiographs of all bones in the body and a ventrodorsal projection of the pelvis using standard radiographic technique appropriate for the region radiographed. In one study, 171 dogs with primary bone tumors underwent radiographic bone surveys and thoracic radiography; at presentation, there was a higher yield in finding other sites of OS with radiographic bone survey (6.4%, 11 of 171 dogs) than with thoracic radiographs (4%, 7 of 171 dogs).¹⁴¹ There are conflicting reports on the usefulness of nuclear scintigraphy (bone scan) (Figure 24-3) for clinical staging of dogs with OS.¹⁴²⁻¹⁴⁶ Bone scintigraphy was used in one study to identify suspected second bone sites of OS in 14 of 25 dogs with appendicular primaries.¹⁴³ Seven of these lesions were biopsied and confirmed to be OS. Another study of 70 dogs with appendicular primary bone tumors resulted in only one scintigraphically detectable occult bone lesion.¹⁴² In a third report, of 23 dogs with suspected skeletal neoplasia that were evaluated with scintigraphy and radiography, 4 dogs had second skeletal sites suspected to be neoplastic.¹⁴⁶ The suspicious site in one of these dogs was found on histologic evaluation to be normal bone. Another study found secondary sites considered highly suspect of bony metastasis in 7.8% of 399 cases; however, most suspected lesions were not subjected to histologic conformation.¹⁴⁴ Nuclear

FIGURE 24-3 Scintigraphic view of a distal radial OS lesion in a dog following Technetium^{99m}-hydroxymethylene diphosphonate injection. A, Uptake within the tumor. B, Mild uptake within the elbow joint secondary to degenerative joint disease.

bone scan can be a useful tool for the detection and localization of bone metastasis in dogs presenting for vague lameness or signs such as back pain, and, although very sensitive, it is not specific for identifying sites of skeletal tumor. Any region of osteoblastic activity will be identified by this technique, including osteoarthritis and infection. Follow-up with high-detail radiographs of sites found suspicious on scintigraphy will generally help rule out nonneoplastic disease; however, definitive biopsy may be necessary.

Surgical Staging A surgical staging system for sarcomas of the skeleton has been devised for humans.¹⁴⁷ This system is based on the histologic grade (G), the anatomic setting of the primary tumor (T), and regional or distant metastasis (M). There are three stages: stage I, the low-grade (G1) lesions without metastasis; stage II, the high-grade (G2) lesions without metastasis; and stage III, the lesion with regional or distant metastasis regardless of histologic grade. The stages are subdivided by the anatomic setting: A is intracompartmental (T1) and B is extracompartmental (T2). According to this system, most dogs with OS present with stage IIB disease. Scintigraphy can be used to evaluate the degree of bone involvement from a primary bone tumor.¹⁴⁸ In one study, scintigraphy overestimated the length of OS disease in limb-sparing patients by 30%, allowing for adequate margin prediction, preoperatively.¹⁴⁹ CT may be useful to plan surgery, especially for tumors located in the axial skeleton; however, one study reported that plain radiographs were as accurate as advanced imaging (CT, MRI) in predicting true length of tumor involvement.¹⁵⁰ In contrast, MRI was more accurate than plain radiographs or CT in predicting length of tumor involvement for appendicular canine OS in another study.¹⁵¹ This could prove invaluable for limb-sparing patients, and further evaluation is warranted.

Patient Assessment The patient's overall health status requires careful assessment. Advancing years do not preclude treatment; however, prolonged anesthesia and chemotherapy may not be tolerated in dogs with organ compromise. Particular attention to the cardiovascular system is important. Coexisting cardiomyopathy or any degree of heart failure may lead to serious complications, particularly during fluid diuresis, anesthesia, or administration of certain chemotherapy agents. Electrocardiogram and echocardiogram should be performed on dogs in which the history or physical

findings implicate a cardiac disorder. Renal function must be evaluated prior to administration of cisplatin. A minimum database should include a complete blood count (CBC), platelet count, serum biochemical analysis, and urinalysis.

Known or Suggested Prognostic Factors

Anatomic Location and Signalment

In a multiinstitutional study of 162 dogs with appendicular OS treated with amputation alone, dogs younger than 5 years of age had shorter survival than older dogs.¹⁵ Additional studies have related large tumor size^{13,152,153} and humerus location^{154,155} to poor outcome. Large tumor size has been reported to be a negative prognostic factor for humans with OS.¹⁵⁶ For OS originating from flat bones, small dog size and completeness of excision were positive prognostic indicators.¹⁵⁷ Although there are differences in disease distribution and prevalence, documentation of improved survival for small dogs with OS is lacking.¹⁵⁸ A negative prognosis can also be predicted by a higher tumor grade and mitotic index, based on the results of one study.¹⁰⁶

The biologic behavior for nonappendicular sites of OS appears to be similar (aggressive) with the exception of the mandible and possibly the rest of the calvarium.^{122,123,159-162} OS affecting the head (mandible, maxilla, and skull) is locally aggressive but has a lower metastatic rate (37%) than appendicular OS.¹⁶² Reported median disease-free intervals (DFIs) and survival times for skull OS are 191 days and 204 days, respectively. Dogs with OS of the mandible treated with mandibulectomy alone had a 1-year survival rate of 71% in one study.¹²² In contrast, maxillary OSs have demonstrated a median survival of 5 months following maxillectomy.^{159,160} A study evaluating response to treatment for orbital OS reported long-term survival following complete surgical excision.¹⁶³ Similar behavior is seen for OSs of flat bones in humans.¹⁶⁴ Median survival for rib OS lesions is reported to be 3 months for dogs treated with rib resection alone and 8 months for dogs treated with resection and adjuvant chemotherapy.¹⁶⁵⁻¹⁶⁸ OS of the canine scapula has been reported to have a poor prognosis when treated with subtotal scapulectomy surgery and chemotherapy.^{157,169,170} DFI and MST in dogs diagnosed with scapula OS was 210 days (range 118 to 245 days) and 246 days (range 177 to 651 days), respectively.¹⁷¹ Use of adjunctive chemotherapy was prognostic for both increased DFI and survival. Limb function after subtotal scapulectomy is good to excellent.¹⁷¹ Survival of dogs with OS distal to the antebrachiocondylar or tarsocrural joints was somewhat longer (median: 466 days) than survival of dogs with OSs of more common appendicular sites; however, OS in these sites is aggressive, with a high potential for metastasis.²⁶ Vertebral OS is uncommon; however, reported cases indicate aggressive local and systemic behavior.^{22,172} In 15 dogs treated with a combination of surgery, radiation, and chemotherapy, the median survival was 4 months.¹⁷² The biologic behavior of OS in other nonappendicular bone sites (e.g., pelvis) has not been thoroughly evaluated.

Extraskelletal OS is rare and most commonly affects visceral sites (gastrointestinal tract, spleen, liver, kidney, urinary bladder), skin or subcutaneous tissue, or mammary glands. Extraskelletal (soft tissue) OS sites also appear to have aggressive systemic behavior with a high metastatic rate. In one report, extraskelletal OS treated with surgery alone had a median survival of only 1 month, and a median survival of 5 months was obtained for cases treated with surgery and adjuvant chemotherapy.³¹ In a larger study, soft tissue OSs were separated from mammary gland OSs; median survival of nonmammary gland soft tissue lesions was 1 month and mammary gland lesions 3 months following primarily surgical resection alone.³² The major cause of death was local recurrence (92%) in the

soft tissue OS cases and pulmonary metastasis (62.5%) in the mammary gland OS cases.

Dogs presented with stage III disease (measurable metastases) have a very poor prognosis.¹¹⁵ MST of 90 dogs with stage III disease at presentation was 76 days, with a range of 0 to 1583 days. No significant differences in survival times on the basis of age, sex, breed, or primary site were observed. Dogs with bone metastases (132 days) had a longer survival time than dogs with lung (59 days) or lung and other soft tissue (19 days) metastases. Dogs with lymph node metastasis had short survivals with a median of only 57 to 59 days, compared to 318 days for dogs without nodal spread.^{114,115} Dogs with stage III disease treated palliatively with RT and chemotherapy had a significantly longer survival time (130 days) than dogs in all other treatment groups.

Serum Alkaline Phosphatase Elevated alkaline phosphatase (AP) has been clearly associated with a poorer prognosis for dogs with appendicular OS in several studies.^{114,154,173-175} A preoperative elevation of either total (serum) or the bone isoenzyme of AP (>110 U/L or 23 U/L, respectively) is associated with a shorter DFI and survival (Figure 24-4). Likewise, dogs that have elevated preoperative values that do not return to normal within 40 days following surgical removal of the primary lesion also develop earlier metastasis. One study substantiated the predictive nature of elevated preoperative AP levels; however, no association was found for elevated postoperative serum levels.¹⁷³

Molecular, Genetic, and Immunologic Indices of Prognosis Although our understanding of the pathogenesis of OS remains incomplete, the availability of canine-specific reagents, as well as sequencing of the canine genome, has permitted the discovery of key molecular, genetic, and immunologic events that might participate in OS progression and metastases. With increased clarity for the critical events involved in directing OS biology, specific tumor- and host-associated characteristics have recently been identified as important factors that influence OS prognosis.

The expression of several molecular proteins, including ezrin, recepteur d'origine nantaise (RON), survivin, vascular endothelial growth factor (VEGF), and cyclooxygenase-2 (COX-2), has been reported to influence DFI and survival times in dogs.^{101,176-179} Ezrin is a cellular protein belonging to the ERM (ezrin-radixin-moesin) family and serves as a physical and functional anchor site for cytoskeletal F-actin fibers. Because of ezrin's involvement in cytoskeletal remodeling, it has been demonstrated in murine preclinical models that ezrin is necessary for OS metastases.¹⁰¹ Through the use of a canine tissue microarray with known clinical outcome data (n = 73), it was shown that the presence of high ezrin staining in primary tumors was associated with a significantly shorter median DFI compared to dogs with low primary tumor ezrin staining, 116 versus 188 days, respectively.

HGF receptor (MET) and RON are members of the *MET* proto-oncogene family of RTKs, and signaling through MET or RON promotes tumorigenesis and the formation of metastases. MET and RON are capable of heterodimerization with one another, resulting in cellular cross-talk that might alter the strength and duration of signal transduction, with resultant protumorigenic effects. Given the role of MET and RON in metastases, their expression in OS has been evaluated in dogs.¹⁷⁶ Through the use of a canine OS tissue array with linked outcome data (n = 105), expression of RON but not MET was prognostic for survival. Dogs with high RON expression in their primary tumors lived significantly shorter than dogs with absent, low, or intermediate RON expression.

(Reprinted with permission from Erhart N, Dernell WS, Hoffmann WE, et al: *Prognostic importance of alkaline phosphatase activity in serum from dogs with appendicular OS: 75 cases (1990-1996)*, J Am Vet Med Assoc 213:1003, 1998.)

Survivin is a small protein belonging to the inhibitor of apoptosis (IAP) family and participates in the processes of cell division, as well as apoptosis inhibition. As a dimer, survivin inhibits both caspase-dependent and caspase-independent mediated apoptosis, and its expression can promote tumorigenesis. Given survivin's antiapoptotic properties, its overexpression might provide a survival advantage to cancer cells and be associated with a negative prognosis. In a recent study, the expression of survivin was characterized in 67 primary OS samples with known outcome data.¹⁷⁸ Survivin expression was detected in the majority of tissue samples (65/67), and expression intensity was associated with DFIs. Dogs

with primary tumors expressing low survivin immunoreactivity scores achieved significantly longer DFIs than dogs with high survivin immunoreactivity scores within the primary tumor, 331 and 173 days, respectively.

VEGF and the enzymatic activities of COX-2 serve as potent regulators of angiogenesis, and their independent expressions have been associated with a poorer prognosis for a variety of cancers. Angiogenesis is a necessary step for tumor growth and metastases; thus both VEGF and COX-2 have been investigated in dogs with OS.^{177,179} In one study with 25 dogs treated with definitive surgery and systemic chemotherapy, baseline platelet-corrected serum VEGF concentrations were associated with DFI but not survival time.¹⁷⁹ Dogs with VEGF concentration in the lower 50 percentile achieved significantly longer DFIs than dogs with VEGF levels in the upper 50 percentile, 356 and 145 days, respectively. In another study, COX-2 expression was characterized in primary tumors derived from 44 dogs treated with amputation and doxorubicin.¹⁷⁷ Immunoreactivity for COX-2 was identified in 88% of primary tumors, although intratumoral COX-2 staining was variable and heterogeneous. A COX-2 immunoreactivity score, a product of stain intensity and percentage of positive cells, was potentially correlated with disease outcome. Dogs with primary tumors demonstrating strong stain intensity (n = 4) had a significantly shorter MST of 86 days in comparison with dogs with tumors staining negative (n = 10, MST: 423 days), poor (n = 19, MST: 399 days), or moderate (n = 11, MST: 370 days) for COX-2. However, given the small sample size of dogs with strong COX-2-staining intensity, the prognostic value of COX-2 expression in OS warrants a more thorough evaluation.

With the near complete sequencing of the canine genome and the commercial availability of canine-specific gene microarrays, it has become possible to characterize and validate specific tumor-associated genetic determinants associated with clinical outcomes and prognosis. In one gene expression profiling study, primary OS tissues were analyzed from two groups of dogs with different clinical outcomes, specifically dogs achieving DFIs either less than 100 days (n = 10) or greater than 300 days (n = 10) following uniform treatment with amputation and systemic chemotherapy.¹⁰⁷ Derived from microarray analysis and confirmed by RT-PCR, eight specific gene transcripts were significantly different between poor responders (<100 days) and good responders (>300 days). In dogs categorized as poor responders, six transcripts, including IGF-2 and alcohol dehydrogenase, were downregulated and two transcripts were upregulated in comparison to good responders. To better characterize the molecular pathways associated with the differentially expressed genes identified in microarray analysis, a broader systems approach was used to identify changes in groups of interacting genes or pathways that might contribute to metastatic progression or chemotherapy resistance. In general, pathway expression differences between good and poor responders involved oxidative phosphorylation, bone development, protein kinase A (PKA) signaling, cell adhesion, cytoskeletal remodeling, and immune response.

In a similar expression profiling study, prognostic gene profiles were derived from 32 primary OS tumors derived from two groups of dogs based on survival time.¹⁸⁰ Dogs surviving for less than 6 months or greater than 6 months were categorized as either poor or good responders, respectively. Gene profiling identified 51 gene transcripts to be differentially expressed; within the poor responder group, genes uniformly overexpressed were associated with biologic pathways involved in proliferation, drug resistance, and metastases. In addition to identifying differentially expressed genes and

associated pathways between dogs categorized as good and poor responders, the findings from the study further substantiated the molecular pathway similarities shared between humans and dogs, including Wnt signaling, integrin signaling, and chemokine/cytokine signaling.

Finally, a highly impactful study was conducted that leveraged the more homogeneous genetic background of dogs diagnosed with OS to detect underlying and conserved gene expression patterns previously undetectable in historic canine and human gene microarray analysis.¹⁸¹ By differential gene expression profiling of early passage immortalized OS cell lines derived from primary tumors, the investigators were able to identify gene signatures associated with G2/M transition and DNA damage checkpoint, as well as microenvironment interactions, which permitted the unbiased segregation of OS samples into distinct molecular subclassification and predicted outcome. Most significantly, the same genetic signatures identified in dogs, also allowed for prognostic molecular classification of human OS—powerfully underscoring the scientific merit derived from comparative oncologic studies.

Perturbations of the immune system are common among cancer patients, and regulatory T-cells (Tregs) and myeloid-derived suppressor cells have the capacity to attenuate effective antitumor immunity responses, with the potential to negatively impact prognosis. Tregs have been characterized in healthy and cancer-bearing dogs,¹⁸²⁻¹⁸⁴ with some studies demonstrating that dogs with OS have increases in the percentage and absolute counts of circulating Tregs.¹⁸⁵ The clinical significance of Tregs on OS prognosis has recently been characterized in a study of 12 dogs treated uniformly with amputation and systemic chemotherapy.¹⁸⁵ Dogs with high (above mean) versus low (below mean) percentages of Tregs identified in blood or tumor tissue did not have differences in DFI or survival time. However, a high or low CD8/Treg ratio in the blood was associated with clinical outcomes because dogs with low CD8/Treg ratios ($n = 6$) were observed to have a significantly shorter survival time than dogs with high CD8/Treg ratios ($n = 6$).

In addition to Tregs and their potential prognostic value in OS, one study demonstrated that routine hemogram parameters, specifically lymphocyte and monocyte counts, can also predict clinical outcomes in dogs with OS.¹⁵⁵ In 69 dogs treated with amputation and systemic chemotherapy, baseline lymphocyte and monocyte counts were associated with DFIs. Shorter DFIs were observed in dogs ($n = 69$) initially presenting with relative lymphocytosis (≥ 1000 cells/ μ L) and relative monocytosis (≥ 400 cells/ μ L), and these original conclusions were further substantiated by a second population of OS dogs ($n = 21$) treated in an identical manner. Mechanistically, it was hypothesized that the association of relative monocytosis and reduced DFI could be the presence of myeloid-derived suppressor cells, a population of cells characterized by their ability to suppress antitumor immune response.

Therapy Directed at the Primary Tumor Surgery

Table 24-1 provides an overview of surgical options for primary bone tumors based on anatomic site.

Amputation Amputation of the affected limb is the standard local treatment for canine appendicular OS. Even large- and giant-breed dogs usually function well after limb amputation, and most owners are pleased with their pets' mobility and quality of life after surgery.^{210,211} Even moderate preexisting degenerative joint disease at the level found in most older, large-breed dogs is rarely a contraindication for amputation. Most dogs will readily compensate, and

although the osteoarthritis may progress more rapidly in the three-legged dog, this rarely results in a clinical problem. Severe preexisting orthopedic or neurologic conditions may cause poor results in some cases, and careful preoperative examination is important. A complete forequarter amputation for forelimb lesions is generally recommended, as is a coxofemoral disarticulation amputation for hind leg lesions. This level of amputation ensures complete local disease removal and also results in a more cosmetic and functional outcome. For proximal femoral lesions, a complete amputation and en bloc acetabulectomy is recommended to obtain proximal soft tissue margins (Figure 24-5). Surgery alone must be considered palliative for OS because microscopic metastatic disease is present in the vast majority of cases at diagnosis, and amputation does not address these.

Limb-Sparing Surgery Although most dogs function well with amputation, in some dogs limb sparing would be preferred, such as dogs with severe preexisting orthopedic or neurologic disease or dogs with owners who absolutely will not permit amputation. Until recently, only a few reports of limb sparing in dogs, with limited follow-up, have appeared in the literature.¹⁸⁹⁻¹⁹³ To date, more than 600 limb-sparing procedures have been performed at Colorado State University Animal Cancer Center (CSU-ACC). Limb function has generally been good to excellent in most dogs, and survival has not been adversely affected by removing the primary tumor with marginal resection.¹⁹⁴

Suitable candidates for limb sparing include dogs with OS clinically and radiographically confined to the leg, dogs in which the primary tumor affects less than 50% of the bone (as determined radiographically), and dogs that are in otherwise good general health. Other criteria for consideration include absence of pathologic fracture, less than 360-degree involvement of soft tissues, and a firm/definable soft tissue mass versus an edematous lesion. Early in the development of limb-sparing procedures, many dogs treated at CSU-ACC received some form of preoperative treatment (i.e., primary or neoadjuvant intraarterial [IA] cisplatin, intravenous [IV] cisplatin, RT to the tumor bone, or a combination of radiotherapy with IV or IA cisplatin). Results from 21 dogs treated with RT alone given in large doses per fraction prior to limb sparing were unsatisfactory for preservation of life or limb.¹⁹¹ Many of the dogs treated with two preoperative IA cisplatin doses 21 days apart, with the last treatment 21 days prior to surgery, showed marked decrease in the degree of vascularization of the tumor. This represented a high degree of induced tumor necrosis in the resected specimen, especially when combined with RT, and facilitated limb sparing.^{193,212} Currently at CSU-ACC, case selection predetermines the use of local chemotherapy or preoperative downstaging for limb-sparing cases, and most dogs receive systemic carboplatin, doxorubicin, or combination therapy after surgery (see the later section on Systemic Adjuvant Therapy for Dogs with Osteosarcoma).

The most suitable patients for limb sparing are dogs with tumors in the distal radius or ulna because function following limb sparing and carpal arthrodesis is good. Arthrodesis of the scapulohumeral, coxofemoral, stifle, or tarsal joints following limb sparing generally results in only fair to poor function.¹⁵⁴ Resulting poor function, combined with a high complication rate, has generally led surgeons away from recommending limb sparing near these joints. Limb sparing is a complicated process and requires a coordinated team effort between surgical and medical oncologists, radiologists, pathologists, and technical staff. Several methods of limb sparing have been described, each with unique advantages and limitations.

• **TABLE 24-1** Surgical Treatment Options for Osteosarcoma by Site

SITE	TREATMENT OPTIONS	COMMENTS
Humerus, femur, tibia	Amputation Limb sparing in limited cases	Generally high complication rate for limb sparing ¹⁵⁴ Diaphyseal locations amenable to intercalary allografts ¹⁸⁶ Total hip sparing possible for proximal femoral lesions ¹⁸⁷ Intraoperative extracorporeal radiation technique may apply ¹⁸⁸
Radius	Amputation Limb-sparing allograft ¹⁸⁹⁻¹⁹⁴ Endosteal prosthesis ¹⁸⁷ Intercalary bone graft ¹⁸⁶ Ulnar transposition ^{195,196} Bone transport osteogenesis ¹⁹⁷⁻²⁰⁰ Pasteurized autograft ^{201,202} Extracorporeal intraoperative RT ¹⁸⁸	Can combine radius/ulna resection (graft radius only)
Ulna	Amputation Ulnectomy ²⁰⁴	Often does not require allograft reconstruction
Scapula	Amputation Scapulectomy ^{169,205}	Proximal lesions best; complete scapulectomy described
Pelvis	Pelvectomy with or without amputation ²⁰⁶	Lateral portion of sacrum can be excised; may include body wall
Metacarpus/metatarsus	Amputation ²⁵ Local resection ²⁶	Limb-sparing function dependent on bone(s) involved
Mandible	Mandibulectomy ¹²²	Often requires total hemimandibulectomy Bilaterally limited to fourth premolar
Maxilla/orbit	Maxillectomy ²⁰⁷ Orbitectomy ²⁰⁸	Limited by midline palate or cranial vault invasion Combined approach may assist exposure
Calvarium	Resection ± radiation	Resection dependent on venous sinus involvement
Vertebrae	Decompression (palliative) ± radiation/ chemotherapy ¹⁷²	Vertebrectomy techniques not well developed; limited local disease control
Rib	Rib resection ^{165,168,209}	Requires removal of additional cranial and caudal rib

RT, Radiation therapy.

The choice of limb-sparing method depends on several factors, including owner choice, patient personality, surgeon experience, and individual risk factors. At the CSU-ACC, owners are given a choice of limb-sparing procedures and informed about the risks and benefits of each method compared with amputation. A brief description of the surgical options for a distal radial location (most common) follows. In all cases, cephalosporin antibiotics are administered via IV immediately preoperatively, intraoperatively, and for 24 hours postoperatively. Meticulous aseptic technique is essential.

Allograft Limb Sparing For a distal radial site, the dog is placed in lateral or dorsal recumbency, with the affected limb uppermost. A skin incision is made on the dorsolateral aspect of the antebrachium from a point just distal to the elbow, to just proximal to the metacarpophalangeal joint. Any biopsy tracts are excised en bloc. Soft tissue is dissected to the level of the tumor pseudocapsule. Care is taken not to enter the tumor. The bone is cut with an oscillating bone saw 3 to 5 cm proximal to the proximal radiographic (or scintigraphic) margin of the tumor. Extensor muscles attached to the tumor pseudocapsule are transected at a level to maintain 2 to 3 cm soft tissue margins. The joint capsule is incised, keeping close to the proximal row of carpal bones. For tumors of the middiaphysis, tumor resection follows similar guidelines with the exception that an attempt to spare extensor and flexor

muscle groups is undertaken so the joint (above and below) may be spared.¹⁸⁶ The ulna is sectioned sagittally with an osteotome, and the medial ulnar cortex adjacent to the tumor is removed en bloc with the radius. For tumors that have extension to the ulna (rare), the ulna is also cut with a bone saw, and the distal one-third or more is removed with the tumor. Care is taken to preserve as much vasculature as possible, especially on the palmar surface.

Large vessels associated with the tumor are ligated and divided. Surgical hemostatic staples (Surgiclip, United States Surgical Corp, New York) are very useful. The specimen is radiographed, then submitted for histologic evaluation, including assessment of completeness of surgical margins and percentage of tumor necrosis. In addition, a sample of bone marrow proximal to the resection level (radius) is obtained for histologic evaluation of marrow involvement. Intraoperative frozen section histology is used in humans to assess the adequacy of surgical resection of primary bone tumors during limb sparing.²¹³ Although this technique is being used in veterinary medicine, it is still considered somewhat unreliable for bone specimens.

A fresh-frozen cortical allograft is thawed in 1 L of an antibiotic and saline solution (Neomycin 1 g, polymyxin B 500,000 U, potassium penicillin 5,000,000 U), the articular cartilage is removed, the graft is cut to fit, and the medullary cavity reamed to remove fat and cellular debris.^{214,215} The articular cartilage of the proximal carpal bones is removed, and the allograft is stabilized in

• **FIGURE 24-5** **A**, Ventrodorsal radiographic view of an OS of the ilium of a dog. **B**, Ventrodorsal radiographic view of the dog in **A** 3 years after hemipelvectomy and amputation followed by cisplatin chemotherapy.

compression using Association for the Study of Internal Fixation (ASIF/AO) principles. A dynamic compression plate with a minimum of three screws proximal and four screws distal to the graft is used; 3.5-mm broad locking plates of up to 22 hole size or a custom-designed limb salvage plate are appropriate in most cases, but for very large dogs, 4.5-mm narrow or broad plates are selected. The plate is fastened in the patient to the allograft with two or three screws, removed from the surgery site, and the medullary canal of the allograft is filled with polymethyl methacrylate (Palacos radiopaque bone cement, Smith & Nephew Richards, Inc., Memphis, TN) bone cement containing amikacin (1 g amikacin to 40 g of polymer powder). This provides support for the screws during revascularization of the graft and acts as a reservoir for antibiotics. The healing of the allograft is not significantly impeded by the presence of the cement and has been shown to significantly decrease the incidence of orthopedic failure, including allograft fracture and screw pullout.^{216,217} The plate extends proximally in the host radius and distally to a level just proximal to the metacarpophalangeal joint (Figure 24-6). For intercalary limb spares, the plate extends proximally and distally to meet or exceed ASIF standards with the intent to spare joint motion.

The wound is thoroughly lavaged with saline, and it is at this point that local (polymer) chemotherapy may be implanted. A closed suction drain is inserted adjacent to the allograft, and the wound is closed. The leg is supported in a padded bandage. The drain is removed the day after surgery in most cases. It is most important to prevent self-mutilation (licking) after surgery, and

Elizabethan collars should be used as necessary. No external coaptation is used and most dogs use the limb fairly well by 10 days after surgery. Postoperative foot swelling can be considerable but usually resolves by 2 weeks. Although decreased exercise is recommended for the first 4 to 6 weeks to allow soft tissues to heal, no exercise restriction need apply after this time. In fact, it is important that limb use is encouraged, even in early postoperative times, so that flexure contracture of the digits does not occur. Early weight bearing will often decrease the occurrence and incidence of postoperative swelling.

The advantages to allograft limb sparing include the absence of external fixation, and little owner involvement is required in the postoperative period aside from bandage changes in the first 2 weeks. The disadvantages are the high infection rate, potential for local recurrence, and the need for permanent internal hardware. Canine limb spare patients have an infection rate of approximately 40% and 50%. Once an infection occurs, it may be controlled with long-term antibiotic therapy but is rarely, if ever, resolved.²¹⁸ Infection may result in soft tissue defects from draining tracts, exposure of the plate or allograft, and hardware loosening. Revision surgeries, either for hardware complications or soft tissue reconstruction, are not uncommon. Additionally, amputation for catastrophic implant failure, local recurrence, or unmanageable infection is sometimes required.

Metal Endoprosthesis Limb Sparing. The metal endoprosthesis limb-sparing technique utilizes a commercially available metal endoprosthesis with a modified bone plate (Figure 24-7). The

• **FIGURE 24-6** Limb sparing. **A**, Preoperative lateral radiograph of a distal radial OS lesion in a dog. **B**, Craniocaudal specimen radiograph following tumor resection of the case in **A**. **C**, Lateral postoperative radiograph following allograft placement and plate fixation of the case in **A** and **B**.

surgery is nearly identical to the procedure described earlier; however, instead of reconstruction with an allograft, the endoprosthesis is used to span the radial defect. A prospective comparison of complications between allograft limb sparing and metal endoprosthesis limb sparing was published in 2006.¹⁸⁷ No significant differences in the number of complications were noted between metal implants and allografts in the patient population studied. An endoprosthesis is an attractive alternative to cortical allografts for limb salvage of the distal aspect of the radius in dogs because surgical and oncologic outcomes are similar, but the endoprosthesis is an immediately available off-the-shelf implant that is not complicated by the bone harvesting and banking requirements associated with cortical allografts.

Pasteurized Tumoral Autograft. Two reports exist of a limb-sparing technique that involves removal of the segment of bone with the tumor and pasteurizing the bone segment at 65° C for 40 minutes, followed by reimplantation.^{201,202} Limb function was good in 12 of 13 dogs with a 15% local recurrence, 31% infection, and 23% implant failure rate. The advantages of this method are that there is no need for an allograft, and anatomic apposition is excellent. The disadvantages are similar to the allograft technique in terms of complications; however, overall survival and disease-free progression were similar to other studies.

Longitudinal Bone Transport Osteogenesis. The longitudinal bone transport osteogenesis (BTO) technique for limb sparing has been reported in veterinary patients (Figure 24-8).^{197,198} This

• **FIGURE 24-7** Lateral radiographic projection of a limb-sparing technique using a commercially available metal endoprosthesis with a modified bone plate in a dog with distal radial and ulnar OS. A limb-sparing plate spans host radius and metacarpus, connecting to the implant, which abuts the host radius proximally and the radial carpal bone distally. A negative suction drain has also been placed at the surgical site to decrease postoperative fluid accumulation.

method utilizes Ilizarov (circular) fixators and the principles of distraction osteogenesis to create bone in the defect following tumor resection. Prior to surgery, a five- to six-ring circular fixator is constructed to allow one central ring (termed a *transport ring*) to move independently from the rest of the fixator. Following the same procedure for removal of the tumor and preparation of the radiocarpal bone described earlier, the circular fixator is placed on the limb and attached to the remaining radius using tensioned 1.6-mm diameter wires. A longitudinal section of normal bone (termed the *transport segment*) from the radius immediately proximal to the defect is osteotomized and attached to the transport ring with wires. Following a 3- to 7-day delay period, the osteotomized bone segment is slowly transported into the defect at a rate of 1 mm per day. Distraction osteogenesis occurs in the trailing distraction pathway. New bone continues to form longitudinally within the defect proximal to the transport segment for as long as the steady, slow distraction continues. When the transport segment reaches the radiocarpal bone (docking), the transport segment is compressed to the radiocarpal bone and heals to create an arthrodesis. The circular fixator remains on the limb while the newly formed bone remodels and the arthrodesis occurs. This technique is compatible with cisplatin, carboplatin, and combination chemotherapy.^{197,199}

The advantages to BTO limb sparing are the lack of internal hardware; the low risk of infection due to the autologous, vascularized nature of the replacement bone; and the ability of the new bone

• **FIGURE 24-8** Lateral radiographic projection of a limb-sparing technique known as *longitudinal bone transport osteogenesis* (BTO). In this case, a distal radial OS was removed and BTO was accomplished using circular fixators and the principles of distraction osteogenesis to create bone in the defect remaining following tumor resection. Briefly, a longitudinal section of normal bone (A), termed the *transport segment*, from the radius is osteotomized and attached to the transport ring, and the osteotomized bone segment is slowly transported into the defect at a rate of 1 mm per day. Distraction osteogenesis occurs in the trailing distraction pathway (B).

tissue to remodel over time. Patients are typically weight bearing within the first 48 hours and once the incision is healed do not require exercise restriction. The disadvantage of the BTO procedure is the extensive client involvement needed to perform the daily distractions on the fixator and the extended amount of time the fixator remains on the limb. Double level longitudinal transport and translational transport of the ulna can significantly diminish the time required for distraction and have been used successfully in a case of limb salvage for a distal tibial OS.²⁰⁰

Ulna Transposition Limb Sparing. The vascularized ulna transposition technique uses the ipsilateral distal ulna as an autograft to reconstruct the distal radial defect by rotating the graft into position while preserving the caudal interosseous artery and vein.^{195,196} Following excision of the tumor as described previously, two transverse osteotomies of the ulna are made. The distal osteotomy is performed at the level of the isthmus proximal to the facet that articulates with the radius. The proximal ulna osteotomy is performed 1 to 2 mm distal to the level of the radial osteotomy. Direct visualization of the caudal interosseous artery and vein allows these structures to be preserved during dissection of the autograft. The ulna graft is “rolled over” into the radial defect and fixed using a bone plate that extends from the proximal radius to the distal one-third of metacarpal IV (i.e., carpal arthrodesis).

Advantages to the ulna transposition technique are that there is no distant donor site morbidity; the replacement bone is autologous; and the graft is vascularized, making it less likely to get

infected, and possibly speeding healing. The disadvantages to this technique are that the ulna transposition technique may be more prone to biomechanical complications in the postoperative period due to its smaller size relative to the radius and the need for permanent internal hardware.¹⁹⁵

Nonsurgical Alternative Methods of Limb Salvage

Intraoperative Radiation Therapy and Extracorporeal Intraoperative Radiation Therapy

The extracorporeal intraoperative RT (IORT) technique for limb sparing has been utilized in a small number of canine OS patients,^{188,219} as well as in human patients with extremity bone tumors.²²⁰⁻²²² This limb-salvage technique involves a surgical approach to the bone with osteotomy above or below the affected site (depending on the anatomic location of the tumor) and reflection of normal soft tissues from the tumor-affected bone. The neurovascular bundle, muscle, and skin are held away from the affected bone, and the tumor is pivoted from the site on the intact joint tissue. The patient is then transported to the radiation suite and a single dose of 70 Gy radiation is then directed to the tumor, taking care to spare the distracted neurovascular bundle. The irradiated bone is then anatomically replaced and surgical fixation of the osteotomy applied with dynamic compression plating, an interlocking nail system or a combination. One advantage of IORT for limb salvage over surgical limb salvage is that it can be used to preserve limb function in anatomic sites that are not amenable to reliable surgical limb salvage (e.g., proximal humerus).¹⁵⁴ Patients treated with IORT had good limb function in the immediate postoperative period; however, complications related to surgery or radiation led to implant revisions in 69% of cases within 5 to 9 months of initial surgery, including four amputations. Pathologic fracture of the irradiated bone was the most common complication. Additionally, local tumor recurrence occurred in four patients and infection in four patients. A modification of this technique includes complete temporary removal of diaphyseal tumors, performing extracorporeal radiation, and then reimplantation and stabilization. In situ radiation of distal femur and any tibial tumors can be performed without osteotomy. The disease-free and overall success rates for limb and joint salvage for extracorporeal IORT were 46% and 54%, respectively. The MST for dogs with appendicular sarcoma treated with limb- and joint-sparing extracorporeal IORT was 298 days (range: 116 to 1775 days).

A small case series of five distal radius IORT cases described joint sparing of the radiocarpal joint by avoiding transcarpal plating.²¹⁹ Radiocarpal joint function could not be preserved long term in any dog due to complications related to implant failure, deep tissue infection, and pathologic fracture that was treated by amputation or pancarpal plating. The IORT technique for limb salvage cannot be recommended currently due to the high complication rate associated with orthopedic implants and infection in irradiated bone.

Stereotactic Radiosurgery

Stereotactic radiosurgery (SRS) offers the ability to deliver high-dose RT to the tumor volume with relative sparing of the surrounding normal tissues by use of image guidance and a sharp drop off in dose intensity (Figure 24-9). In this respect, it is a refinement of the IORT technique that avoids the need for surgical exposure. A nonsurgical limb-salvage technique using SRS was developed at the University of Florida, and initial results were reported in 11 dogs.²²³

FIGURE 24-9 Dose color wash map of radiation distribution for SRT of distal radius OS lesion showing steep dose-gradient drop-off between tumor volume and normal tissues.

Adjuvant carboplatin chemotherapy was used in six dogs immediately prior to radiation treatment for its potential radiosensitization action in addition to its conventional cytotoxic qualities, and five dogs received radiosurgery alone. Five dogs developed pathologic fractures, and one dog developed infection. Acute effects to the skin were mild to moderate in most dogs. Limb use in the dogs that received SRS and chemotherapy was excellent. The reported overall median survival was 363 days in this series; however, the population size was small. Advantages of this technique include limb preservation for anatomic sites not amenable to reliable surgical limb salvage, the normal tissue-sparing effects of stereotactic RT (SRT) compared to conventional RT, no surgical procedures, and good-to-excellent limb function. Disadvantages of the technique include access to equipment that is not typically available to veterinarians and the high complication rate with postirradiation pathologic fracture. These initial results suggested that SRS could provide a viable nonsurgical limb-sparing alternative. Since the publication of this first report, other veterinary centers with linear accelerators capable of delivery of SRT have adapted the SRT limb-salvage technique.

At CSU, an SRT protocol using a Varian Trilogy linear accelerator was developed for treatment of canine extremity OS. The current SRT protocol utilizes a 3×12 Gy (total dose 36 Gy) SRT protocol with fractions delivered on consecutive days. Carboplatin chemotherapy is administered within 2 hours before or after the first or second SRT fraction. Standard adjuvant chemotherapy with either single-agent carboplatin or doxorubicin or combination chemotherapy is continued after SRT at 3 weeks interval for 4 to 6 cycles. We have seen two suspected cases of “radiation recall” skin effects associated with the use of doxorubicin, so care is recommended with use of this chemotherapeutic agent when used in conjunction with SRT. We recommend administration of pamidronate (a bisphosphonate) as soon as possible after diagnosis and ideally 24 to 72 hours before SRT. We do not recommend continued bisphosphonate therapy after SRT because there is no ongoing tumor-associated osteolysis or bone remodeling processes in the irradiated field based on histopathologic examination. Local tumor control has been excellent as assessed by static radiographic findings on serial evaluation, repeat scintigraphic imaging in a few cases, and decreases in urine N-telopeptide (NTx) levels. A mean percentage of tumor necrosis of greater than 90% has been

• **FIGURE 24-10** Radiographs of internal fixation after fracture (A) and preemptive stabilization (B, C, and D) for SRT limb-salvage cases with lytic lesions.

observed on 12 retrieved limb specimens collected at a variety of time points after SRT. Pathologic fracture has been the most frequent complication after SRT. This is due to the amount of preexisting tumor-associated osteolysis and postirradiation bone necrosis and the loss of dynamic bone remodeling and healing capacity after SRT. Smaller, more blastic lesions are better candidates for SRT limb salvage than larger, more lytic lesions. Pathologic fracture has been treated by internal fixation, external coaptation, or amputation. In more recent cases, preemptive stabilization has been used for more lytic tumors immediately after the third fraction of SRT to help prevent fracture (Figure 24-10). Using data in which surgical stabilization is employed when needed, the overall limb survival rate is 83%. The MST for the first 50 dogs treated with this SRT and adjuvant chemotherapy limb-salvage technique is 275 days, which is similar to reported survival times for amputation or surgical limb salvage and adjuvant chemotherapy. Further research into the potential beneficial roles for total radiation dose reduction and adjuvant therapies such as radioprotectant and other bisphosphonates and parathyroid hormone is indicated.

Isolation of Limb Circulation and Perfusion

Isolated limb perfusion with chemotherapy has been used in humans and dogs with sarcomas and melanomas as a sole treatment or to downstage local disease and allow limb sparing.²²⁴⁻²²⁶ Isolated limb perfusion (ILP) allows delivery of high concentrations of chemotherapy, as well as delivery of compounds that are poorly tolerated systemically. Varying degrees of local toxicity are reportedly dependent on the drugs used. Successful use of ILP in canine OS has been reported.²²⁴ One study determined that appendicular bone tumors have significantly higher interstitial fluid pressure and lower blood flow than do adjacent, unaffected soft tissues.²²⁷ ILP may be a method to facilitate delivery of therapeutic drug concentrations to primary tumors for preoperative downstaging prior to limb salvage.

Systemic administration of ¹⁵³samarium ethylenediaminetetramethylene phosphonate (¹⁵³Sm-EDTMP) is limited by systemic myelotoxicity (see [Radioisotopes](#) section later). In a study at CSU, ¹⁵³Sm-EDTMP (37 MBq/kg) was administered via ILP through the isolated limb circulation for 1 hour in nine dogs with primary OS of the appendicular skeleton 3 weeks prior to amputation to evaluate the potential for decreased systemic toxicity and to induce a clinically meaningful percentage of tumor necrosis prior to primary tumor removal. No systemic toxicity was observed. Despite good dosimetry to the lesion, the mean percent tumor necrosis was 27.6% (Std Dev \pm 17.6%; range 3.4% to 56.4%), which was similar to mean percent tumor necrosis of 26.8% in untreated OS cases.²²⁸ This low tumor necrosis percentage may be due to incomplete perfusion of the ¹⁵³Sm-EDTMP, the heterogeneous nature of OS, and the inability of the beta particles to exert a cytotoxic effect on the noncalcified regions of the tumor due to their short track length (3 mm). Future experiments should evaluate dose escalation in the perfused limb now that systemic safety has been demonstrated with the ILP technique.

Summary of Outcome Following Limb Salvage for Dogs with Osteosarcoma

There is no significant difference in survival rates for dogs treated with amputation and cisplatin compared to dogs treated with limb sparing and cisplatin.¹⁹⁴ Overall, limb function has been satisfactory, with approximately 80% of dogs experiencing good-to-excellent limb function.¹⁶ Limb-sparing surgery is usually combined with some form of adjuvant therapy, and complications can arise in any or all phases of treatment (chemotherapy, radiation, or surgery). High-dose external-beam RT may complicate wound and bone healing and potentiate infection.¹⁹¹ Moderate-dose external-beam radiation in combination with chemotherapy may, however, be useful for control of local disease, as indicated by percentage of tumor necrosis data.^{193,228} The major complications related to limb-sparing surgery are recurrent local disease, allograft infection, and

implant complications. In a review of 220 limb-sparing surgeries performed at CSU-ACC, the 1-year local recurrence-free rate determined by Kaplan-Meier life table analysis is over 76% with 60% alive at 1 year.¹⁹⁴

In two case series, 40% and 47.5% of dogs, respectively, developed allograft infections.^{194,229} The majority had their infections adequately controlled with systemic antibiotics with or without local antibiotics (antibiotic-impregnated polymethyl methacrylate beads).²¹⁸ Many of these dogs continued to have evidence of infection; however, their function was not severely affected. In severe and uncontrolled infections, allografts had to be removed and a small number of dogs required amputation. An unexpected finding has been that dogs with allograft infections experienced a statistically significant prolongation of overall survival times compared to dogs with limb sparing without infected allografts.²³⁰ This finding has also been reported in humans with deep infections after limb-salvage surgery for OS.²³¹ A mouse model of OS examined the effects of infection on tumor angiogenesis and innate immunity and demonstrated that chronic localized bacterial infection could elicit significant systemic antitumor activity, depending on natural killer (NK) cells and macrophages.²³²

Surgery for Nonappendicular and Less Common Appendicular Sites of OS

Certain primary bone tumors of the pelvis can be removed by hemipelvectomy and, although these surgeries are difficult, function and cosmetic outcome have been excellent (see [Figure 24-5](#)).^{206,233} Kramer et al provide an excellent review of the technique for hemipelvectomy and the surgical and oncologic factors to be considered with this surgery.²³³ SRT has been used for long-term palliation of primary bone tumors arising from the pelvis. The total radiation dose that can be delivered to tumors in this location is limited by the dose tolerance of the colon, rectum, nerves, and perineum within the treatment field. A 5-fraction SRT protocol is used at CSU in preference to the 3-fraction protocol used for extremity OS to help spare these normal tissues. Concurrent administration of carboplatin during SRT for intrapelvic or pelvic tumors is avoided due to the increased frequency of complications observed.

Vertebral OS sites are the most difficult sites to adequately treat local disease. Techniques of complete vertebrectomy are not well established in veterinary medicine,²³⁴ and surgery often is an attempt to decompress dogs with neurologic deficits or intractable pain and to obtain a diagnosis.¹⁷² Present recommendations are to perform surgery in cases that require decompression (with or without stabilization) and institute RT (discussed later) and chemotherapy. SRT is an emerging treatment option for vertebral body tumors. RT likely plays a role in the treatment of OS of the vertebrae. In a series of 14 dogs with vertebral OS treated between 1986 and 1995, 12 had surgery to decompress the spinal cord, 7 were treated with OPLA-Pt implanted in a distant intramuscular site, and 11 were given IV cisplatin. Nine dogs were treated with fractionated external-beam RT. All dogs had surgery, RT, or both, and no dog was treated with chemotherapy alone. Four dogs improved neurologically, four dogs worsened, and six dogs remained the same. The median survival of 135 days after treatment was relatively short.¹⁷² Local disease recurrence rather than metastasis was the usual cause of death.

A combination allograft and custom total joint arthroplasty has been described for successful limb salvage of a proximal femur OS.²³⁵ An intraosseous transcatheter amputation prosthesis (ITAP) for limb salvage has been described in a case series of four

dogs for distal radius and distal tibia OS lesions.²³⁶ A case report using an ITAP prosthesis for a traumatic distal tibia injury has also been reported.²³⁷ The success of an ITAP prosthesis requires a biologic seal to be formed between the skin and the prosthesis to prevent the possibility of deep infection.

Bone tumors originating in proximal sites of the scapula can be successfully removed by partial scapulectomy ([Figure 24-11](#)).^{169,171,205} Dogs function well with partial scapulectomy but take 1 to 3 months to improve. Seroma formation is common in the immediate postoperative period. Intensive postoperative physical therapy is important in these cases to regain normal function. Significant gait abnormalities may occur after complete scapulectomy by disarticulation at the scapulohumeral joint.¹⁷¹ Small primary tumors of the ulna can be removed by partial ulnectomy, and reconstruction is rarely needed.²⁰⁴ Tumors located in the metatarsal and metacarpal bones can be treated with local resections or partial foot amputation.^{237a} Experience at our institution supports removal of a single bone or the central two bones in most dogs, with good functional outcome. In small dogs, removal of the medial or lateral two bones can result in normal function. Resection to this extent has not been attempted in larger dogs. Mandibulectomy and maxillectomy are appropriate surgeries for primary bone tumors of oral sites.^{160,161,238,238a,239} In a survey of owners of dogs undergoing partial mandibulectomy or maxillectomy, 85% were satisfied with the outcome despite 44% citing difficulty in eating as a complication.²³⁶ Tumors of periorbital sites can be removed by orbitectomy.²⁰⁸ Rib tumors can be removed by thoracic wall resection, and the defect can be reconstructed with polypropylene mesh (Marlex mesh, CR Bard Inc, Billerica, MD) with plastic plates (Lubra plates, Lubra Co, Fort Collins, CO) for large defects or by muscle flap techniques.^{165,167,168} Diaphragmatic advancement can be used for caudally located defects.

Radiation

At present, the role of RT for curative-intent local tumor control is still evolving in veterinary medicine. Currently, the most common role of RT in dogs with appendicular OS is for palliation of bone pain (see later section on [Palliative Treatment: Primary and Metastatic Bone Cancer Pain](#)). RT at relatively high total doses can cause considerable necrosis of primary OS in dogs and humans, either before limb salvage to downstage the primary tumor to improve the success of local disease control following removal or as a primary therapy for unresectable tumors.^{191,193,240-242} As a primary therapy, an MST of 209 days was reported in 14 dogs with appendicular OS treated with fractionated high-dose radiation (median dose of 57 Gy) to the primary tumor and systemic chemotherapy for micrometastasis.²⁴³ Similar results are seen in humans with extremity OS treated with high-dose radiation, with and without surgical stabilization.²²⁰ The introduction of SRT has allowed delivery of high doses of radiation to the tumor volume with excellent local tumor control and relative sparing of the surrounding normal tissues.

Radioisotopes

The bone-seeking, beta emitter radioisotope, ¹⁵³Sm-EDTMP, has been used to treat primary OS and metastatic bone neoplasia in dogs and humans via systemic IV administration (see later section on [Palliative Treatment: Primary and Metastatic Bone Pain](#)). Radium-223 chloride (Alpharadin, Algeta ASA, Oslo), a high linear energy transfer (LET) alpha-emitting radioisotope, has been recently approved by the Food and Drug Administration (FDA) and European regulatory authorities for treatment of multifocal

• **FIGURE 24-11** **A**, Preoperative radiograph (scapula technique) of an OS of the proximal scapula. **B**, Specimen radiograph of the case in **A** after partial scapulectomy.

metastatic bone cancer in men affected by hormone refractory prostate cancer.^{244,245} Radium-223 chloride is a natural bone-seeking radioisotope that has been shown to prolong survival in patients with advanced prostate cancer in phase II and III clinical trials.²⁴⁶ In acute and long-term repeat dose toxicity studies in normal beagles, the main side effect was temporary and reversible myelosuppression (leukocytopenia and thrombocytopenia). Radium-223 chloride was tolerated well when administered at 50 KBq/kg IV once per month for 6 consecutive months and at single doses up to 450 KBq/kg.

Systemic Adjuvant Therapy for Dogs with Osteosarcoma

For the most effective management of canine OS, multimodality therapy is required to address both local and metastatic disease. Although amputation and limb-sparing surgeries, as well as non-surgical techniques such as SRT, have proved highly effective for local OS management, the ability to control the progression of OS metastases remains an urgent clinical challenge, and substantive improvements in DFIs and survival times await advances in systemic antimetastatic treatment options.

Systemic chemotherapy remains the backbone for the management of OS metastases, and it is improbable that the discovery of new chemotherapeutic agents or dose-intensification with existing agents will dramatically improve current clinical outcomes. The future of OS management will likely depend on combining conventional cytotoxic agents with targeted molecular therapeutics or immunomodulatory agents. As such, considerable research focus

has been committed to discovering and validating new combination therapies for improving the long-term prognosis of canine OS. Current adjuvant chemotherapies, used singly or in combination with other cytotoxic agents, are discussed in the following section.

Chemotherapy

Table 24-2 provides an abbreviated summary of conventional chemotherapeutic agents used in the adjuvant setting, evaluated as single agents or in combination in at least 20 dogs. More detailed information regarding the studies highlighted in Table 24-2 is provided in the following section.

Cisplatin: Single Agent

Similar to its activity in an adjuvant or neoadjuvant setting for the treatment of pediatric OS, cisplatin has been demonstrated to improve survival in dogs with OS after amputation in several studies with small-to-modest patient population sizes.^{16,189} In one report, 36 dogs received 2 treatments of cisplatin every 21 days at a dosage of 70 mg/m².¹⁶ In approximately half of the dogs (group 1, n = 17), cisplatin was administered postoperative; for the remaining dogs (group 2, n = 19), cisplatin was administered at diagnosis (preamputation) and again 21 days later immediately following amputation (perioperative). The median survival for group 1 (262 days; 1- and 2-year survival rates of 38% and 18%, respectively) was not significantly different from that of group 2 dogs (282 days; 1- and 2-year survival rates of 43% and 16%, respectively); suggesting that the administration of cisplatin in a neoadjuvant setting did not improve clinical outcomes. In a second study, 22 dogs with appendicular OS were treated with definitive surgery (amputation or

• **TABLE 24-2** Abbreviated Summary of Historic and Current Adjuvant Chemotherapy Protocols Derived from Studies with at least 20 Dogs*

DRUG	DOSE REGIMEN (NO.)	DISEASE FREE	SURVIVAL	COMMENTS
Cisplatin ¹⁶ (single agent)	70 mg/m ² IV on 2 occasions, every 21 days (36)	Median 177-226 days	38%-43% at 1 year, 16%-18% at 2 years, median 262-282 days	No significant difference between survival data for dogs given cisplatin before amputation compared to those treated after amputation.
Cisplatin ¹⁸⁹ (some dogs treated with limb sparing; single agent)	60 mg/m ² IV on 1-6 occasions, every 21 days (22)	Not reported	45.5% at 1 year, 20.9 at 2 years, median 325 days	Apparent increase in treatment failures due to bone metastases.
SPI-77 ²⁴⁷ (liposome-encapsulated cisplatin, single agent)	350 mg/m ² IV every 21 days for 4 cycles (20)	Median 156 days	Median 333 days	Dramatic increase in cumulative cisplatin dosage without the need for diuresis.
Carboplatin ¹⁵² (single agent)	300 mg/m ² every 21 days for 4 cycles (48)	Median 257 days	34.5% at 1 year, median 321 days	Well-tolerated with low incidence (<10%) of hematologic toxicity requiring dose delay.
Carboplatin ⁸⁸ (comparator arm, single agent)	300 mg/m ² every 21 days for 3 cycles (21)	Median 196 days	Median 230 days	Well-tolerated and safely combined with long-acting somatostatin analog.
Carboplatin ²⁴⁷ (comparator arm, single agent)	300 mg/m ² every 21 days for 4 cycles (20)	Median 123 days	Median 207 days	Well-tolerated, with no patient requiring any treatment delays.
Carboplatin ²⁴⁸ (single agent)	Variable dosage and schedule (155)	Median 256 days	36.8% at 1 year, 18.7% at 2 years, median 307 days	Retrospective VCOG study inclusive of diverse patient and drug variables.
Carboplatin ²⁴⁹ (single agent)	300 mg/m ² every 21 days for 4-6 cycles (65)	Median 137 days	36% at 1 year, 22% at 2 years, median 277 days	Well tolerated with <5% grade III or higher toxicity.
Lobaplatin ²⁵⁰ (single agent)	35 mg/m ² every 21 days for 4 cycles (28)	1-year disease free survival rate of 21.8%	1-year overall survival rate of 31.8%	No need for diuresis with this platinum analog.
Doxorubicin ²⁵¹ (single agent)	30 mg/m ² every 2 weeks for 5 cycles (35)	Not reported	50.5% at 1 year, 9.7% at 2 years, median 366 days	Percentage necrosis of tumor predicted survival.
Doxorubicin ¹⁷⁵ (comparator arm, single-agent)	30 mg/m ² every 2 weeks for 5 cycles (303; comparator and BAY 12-9566)	Not reported	35% at 1 year, 17% at 2 years, median 8 months	Data not presented to allow segregation of placebo versus BAY 12-9566.
Doxorubicin and cisplatin ²⁵² (concurrent combination)	Doxorubicin at 12.5-25 mg/m ² followed in 2 hours by cisplatin at 60 mg/m ² for 3 cycles (102)	Not reported	48% at 1 year, 28% at 2 years, median 345 days	Unacceptable toxicity with doxorubicin at 25 mg/m ² .
Doxorubicin and cisplatin ²⁵³ (concurrent combination)	Cisplatin at 50 mg/m ² day 1 and doxorubicin at 15 mg/m ² day 2 for 4 cycles (35)	Median 240 days	Median 300 days	Better tolerated protocol compared to reference 252.
Doxorubicin and carboplatin ²⁵⁴ (concurrent combination)	Carboplatin at 175 mg/m ² on day 1 and doxorubicin at 15 mg/m ² on day 2, every 21 days for 4 cycles (24)	Median 195 days	Median 235 days	The combination at these dosages was well tolerated in most cases.

VCOG, Veterinary Cooperative Oncology Group.

• **TABLE 24-2** Abbreviated Summary of Historic and Current Adjuvant Chemotherapy Protocols Derived from Studies with at least 20 Dogs (continued)

DRUG	DOSE REGIMEN (NO.)	DISEASE FREE	SURVIVAL	COMMENTS
Doxorubicin and cisplatin ²⁵⁵ (alternating combination)	Doxorubicin at 30 mg/m ² , followed by cisplatin 60 mg/m ² 21 days later, every 3 weeks for 2 cycles (38)	Not reported	Median 300 days	Alternating combination well tolerated with no grade III or IV dose-limiting toxicities.
Doxorubicin and carboplatin ²⁵⁶ (alternating combination)	Carboplatin at 300 mg/m ² on day 1 and doxorubicin at 30 mg/m ² on day 21, alternating at 3-week intervals for 3 cycles for 6 total treatments (32)	Median 227 days	48% at 1 year, 18% at 2 years, median 320 days	Includes both amputation and limb-salvage therapies for the primary.
Doxorubicin and carboplatin ²⁵⁷ (alternating combination)	Carboplatin at 300 mg/m ² on day 1 and doxorubicin at 30 mg/m ² on day 21, alternating at 3-week intervals for 3 cycles for 6 total treatments (50)	Median 202 days	Median 258 days	Initial sequencing of carboplatin and doxorubicin not uniformly instituted.
Carboplatin and gemcitabine ²⁵⁸ (concurrent combination)	Carboplatin at 300 mg/m ² then gemcitabine 2 mg/kg as a 20-minute infusion 4 hours post-carboplatin every 21 days for 4 cycles (50)	Median 203 days	29.5% at 1 year, 11.3% at 2 years, median 279 days	Well-tolerated protocol with low incidence of grade III or IV hematologic toxicity.

IV, Intravenous.

*Few of these protocols include sufficient numbers for adequate statistical power and fewer compare treatment protocols in a randomized prospective fashion. In addition, staging, inclusion, and response criteria vary considerably among protocols presented. Therefore evaluations of efficacy among protocols are subject to bias, making direct comparisons difficult and indeed precarious.

limb-sparing), and 1 week after surgical recovery began treatment with cisplatin at 60 mg/m² every 21 days for 1 to 6 treatment cycles.¹⁸⁹ The MST achieved by dogs receiving cisplatin was estimated to be 46.4 weeks, and 1- and 2-year survival rates were estimated to be 45.5% and 20.9%, respectively.

Despite the fact that some studies have documented cisplatin's antimetastatic effects at relatively low-dose intensities (50 mg/m² every 4 weeks), the recommended dose for cisplatin is 70 mg/m² body surface area, given intravenously every 3 weeks. Although cisplatin is relatively well tolerated, it is highly emetogenic and preemptive treatment with antiemetics such as maropitant should be recommended.^{259,260} In addition to its emetogenic potential, a more serious side effect of cisplatin is the induction of nephrotoxicity. Therefore normal baseline renal function is essential prior to administration, and diuresis protocols must be performed concurrent with treatment. The diuresis protocol used most commonly involves a 4-hour pretreatment diuresis with 18.3 mL/kg/hr of 0.9% NaCl, followed by a 20-minute infusion of cisplatin diluted in a volume of 0.9% NaCl that will allow the same (18.3 mL/kg/hr) fluid infusion rate as the rate before diuresis. The cisplatin infusion is then followed by an additional 2 hours of diuresis with 18.3 mL/kg/hr of 0.9% NaCl.²⁶¹

Carboplatin: Single Agent

Carboplatin is a second-generation platinum compound that is less nephrotoxic than cisplatin with comparable antitumor activity.

Given its ease of administration, carboplatin has largely supplanted the use of cisplatin in the postoperative setting. In the first study reporting the tolerability and activity of carboplatin, 48 dogs with OS were treated with amputation and intent-to-treat with 4 doses of carboplatin (300 mg/m² every 21 days).¹⁵² Carboplatin was well tolerated, with neutropenia being identified as the dose-limiting toxicity. For the entire study population (n = 48), the median DFI and survival time achieved was 257 and 321 days, respectively.

Despite the initial report of carboplatin's comparable activity to cisplatin,¹⁵² two prospective randomized studies using single-agent carboplatin as a comparator arm demonstrated less impressive anti-metastatic effects.^{88,247} In one study, dogs were treated with a single neoadjuvant dose of carboplatin and amputation 7 days later, then received 2 additional treatments with carboplatin (300 mg/m²) every 21 days. On completion of carboplatin, dogs were then randomized to receive either placebo (n = 21) or a long-acting somatostatin analog (n = 23).⁸⁸ For dogs treated with carboplatin and placebo, the median DFI and survival time achieved was 196 and 230 days, respectively. In a second study comparing the activity of a liposome-encapsulated cisplatin formulation (SPI-77) versus single-agent carboplatin, 40 dogs were treated with a single neoadjuvant dose of either SPI-77 (350 mg/m²) or carboplatin (300 mg/m²) 1 week prior to amputation, then received an additional 3 treatments of SPI-77 or carboplatin every 21 days.²⁴⁷ No difference was identified between treatment groups, with dogs receiving

single-agent carboplatin achieving median DFI and survival time of 123 and 207 days, respectively.

Two relatively large, retrospective studies have been conducted to substantiate the activity of carboplatin for managing pulmonary micrometastases.^{248,249} In a study initiated by the Veterinary Cooperative Oncology Group (VCOG), 155 dogs treated with amputation and carboplatin (variable dosage and schedule) achieved median DFI and survival times of 256 and 307 days, respectively.²⁴⁸ In a second retrospective investigation, 65 dogs undergoing amputation and subsequent carboplatin at a dosage of 300 mg/m² every 21 days for 4 to 6 treatment cycles achieved median DFI and survival time of 137 and 277 days, respectively.²⁴⁹

Lobaplatin: Single Agent

Lobaplatin, a third-generation platinum compound, has been investigated in the adjuvant setting for the treatment of canine OS. In a study of 28 dogs, lobaplatin at 35 mg/m² was administered as an IV bolus every 21 days for 4 treatments.²⁵⁰ Lobaplatin was well tolerated, with a low incidence of vomiting. Transient and reversible hematologic toxicity manifested as neutropenia and thrombocytopenia were observed 7 to 10 days following lobaplatin administration. The 1-year survival percentage was reported to be 32%, which is comparable to what is achieved with cisplatin or carboplatin.

Doxorubicin: Single Agent

Doxorubicin is considered effective for delaying the development and progression of micrometastatic disease in dogs with OS. However, doxorubicin's antimetastatic effects are more definitively substantiated when administered every 2 weeks, rather than every 3 weeks. In one study, doxorubicin was given at a dosage of 30 mg/m² every 2 weeks for 5 treatments to 35 dogs with appendicular OSs in a neoadjuvant setting. Dogs were treated with 2 or 3 dosages of doxorubicin prior to amputation and continued to receive doxorubicin postsurgery for a total of 5 treatments.²⁵¹ The 1- and 2-year survival rates were 50.5% and 9.7%, respectively. In a second study evaluating the activity of an MMP inhibitor (BAY 12-9566), 303 dogs were treated with amputation and doxorubicin (30 mg/m² every 2 weeks for a total of 5 treatment cycles) and then randomized to receive daily oral placebo or BAY 12-9566.¹⁷⁵ No difference in survival time was identified between dogs receiving placebo or BAY 12-9566, and the MST for all 303 dogs was 8 months.

Doxorubicin/Cisplatin: Concurrent Combination

With the establishment of single-agent activity of doxorubicin and cisplatin for the management of canine OS in the postoperative setting, two studies were conducted to evaluate the tolerability and activity of doxorubicin/cisplatin combinations producing summation dose intensities of greater than one.^{252,253,262} In one study, 102 dogs treated with combination doxorubicin/cisplatin either 2 or 10 days postamputation were evaluated.²⁵² Doxorubicin was administered at a dosage of 12.5-25 mg/m² during saline diuresis and before cisplatin administration. The dosage of cisplatin was 60 mg/m² and was given with 6-hour saline diuresis. Dogs received combination doxorubicin/cisplatin every 21 days for a total of 3 treatments. Unacceptable toxicity was associated with doxorubicin administered at 25 mg/m² in conjunction with cisplatin at 60 mg/m², which resulted in approximately 10% treatment-associated mortality. With the exclusion of deaths associated with therapy, dogs capable of tolerating the protocol achieved MST of 11 to 11.5 months, with 1-year, 2-year, and 3-year survival rates of 48%, 28%, and 18%, respectively. In a second, less dose-intense combination study, 35 dogs with appendicular OS underwent amputation and

chemotherapy with cisplatin and doxorubicin every 21 days for up to 4 cycles.²⁵³ Cisplatin was administered at a dosage of 50 mg/m² in conjunction with 6-hour saline diuresis, and doxorubicin was administered at a dosage of 15 mg/m² 24 hours later. Of the original 35 dogs, only 16 patients completed all four treatment cycles. For all dogs, the median DFI and survival time achieved was 240 and 300 days, respectively.

Doxorubicin/Carboplatin: Concurrent Combination

Given the modest-to-severe toxicity associated with doxorubicin/cisplatin combination therapy, one study investigated if combination tolerability could be improved by replacing cisplatin with carboplatin. The rationale to use carboplatin was based on its comparable anticancer activities and improved side effect profile relative to cisplatin, which excludes the need for saline diuresis and minimizes the likelihood of severe emesis. Twenty-four dogs were treated with definitive surgery, followed by combination chemotherapy consisting of carboplatin (175 mg/m²) administered on day one and followed by doxorubicin (15 mg/m²) on day two.²⁵⁴ Combination doxorubicin/carboplatin was administered every 21 days for a maximum of 4 treatment cycles. Nineteen dogs completed four treatment cycles, and the tolerability of the combination was good with mild gastrointestinal toxicity reported in approximately 50% of patients and rare frequency of grade III hematologic toxicity or greater. The median DFI and survival time achieved was 195 and 235 days, respectively, and not considered superior to historic single-agent studies.

Doxorubicin/Cisplatin: Alternating Combination

To minimize toxicosis associated with concurrent combination protocols with summation dose intensities greater than 1.0 but to still exploit differing mechanisms of action of two compounds, alternating two drug protocols has been investigated for canine OS. In one of the first alternating two drug protocols described, 38 dogs were treated with definitive surgery alone (n = 19) or with adjuvant chemotherapy (n = 19) alternating doxorubicin and cisplatin.²⁵⁵ Doxorubicin (30 mg/m²) was the first drug to be administered 14 days after surgery, and cisplatin (60 mg/m²) was given 21 days later; treatment was repeated for a total of 4 treatments (2 doxorubicin and 2 cisplatin). For dogs treated with amputation alone, the MST was 175 days; whereas for dogs treated with amputation (n = 17) or complete resection (n = 2; rib OS) followed by alternating doxorubicin and cisplatin therapy, the MST was 300 days. The alternating combination of full-dose doxorubicin and cisplatin did not result in any grade III or IV dose-limiting toxicities and significantly improved survival time in comparison to amputation alone.

Doxorubicin/Carboplatin: Alternating Combination

The tolerability and activity of full-dose, alternating combinations with doxorubicin and carboplatin have been recently conducted. In one study, 32 dogs were treated with amputation or limb-sparing surgery, then subsequently treated with carboplatin (300 mg/m², or 10 mg/kg if <15 kg) and 21 days later received doxorubicin (30 mg/m², or 1.0 mg/kg if <15 kg).²⁵⁶ Dogs received up to 3 treatment cycles (3 carboplatin and 3 doxorubicin). Alternating carboplatin and doxorubicin therapy was well tolerated, and out of 88 doses of carboplatin and 82 doses of doxorubicin administered, only one grade III neutropenia, one grade III thrombocytopenia, and one grade III vomiting were recorded. The median DFI and survival times were 227 and 320 days, respectively; with 1- and 2-year survival rates being 48% and 18%, respectively.

In a second confirmatory study, 50 dogs were treated with amputation and 10 to 14 days postoperative received alternating combination chemotherapy with carboplatin (300 mg/m²) and doxorubicin (30 mg/m²) every 21 days for 3 cycles (3 carboplatin and 3 doxorubicin).²⁵⁷ However, dogs were not standardized to receive carboplatin first and doxorubicin second; and of the 50 dogs, 30 received carboplatin first, and the remaining 20 dogs received doxorubicin as their initial treatment. Adverse toxicities, including grade III or IV hematologic toxicity in 18% of dogs, and grade III or IV gastrointestinal toxicity in 12% of dogs were recorded. The median DFI and survival time were 202 and 258 days, respectively.

Carboplatin/Gemcitabine: Concurrent Combination

Based on in vitro data demonstrating strong synergism between carboplatin and gemcitabine in canine OS cell lines at pharmacokinetically achievable concentrations and durations of exposure,²⁶³ a prospective study was conducted to assess if combination chemotherapy with carboplatin and gemcitabine could improve clinical outcomes in dogs with OS.²⁵⁸ Fifty dogs were treated with amputation, and 14 days postsurgery were treated first with carboplatin (300 mg/m²) and then gemcitabine was administered as a 20-minute IV infusion 4 hours postcarboplatin administration. Dogs were treated every 21 days for up to 4 dosages of carboplatin and gemcitabine. The combination of carboplatin and gemcitabine was well-tolerated with 74% of patients receiving all 4 treatment cycles, and only 5 episodes of grade III or IV hematologic toxicity was recorded. The median DFI and survival time were 203 and 279 days, respectively; with 1- and 2-year survival rates being 29.5% and 11.3%, respectively.

Preliminary Agents

Satraplatin, by virtue of its lipophilicity, is a platinum drug formulation with high oral bioavailability. Given the advantages of novel oral drug formulations, the pharmacokinetics and tolerability of oral satraplatin was determined in tumor-bearing dogs in a phase I dose-escalation study.²⁶⁴ Oral satraplatin was administered daily for 5 consecutive days every 3 to 4 weeks for up to a total of 4 treatment cycles. Dose-limiting toxicity was myelosuppression, with grade III and IV neutropenia and/or thrombocytopenia being documented with satraplatin doses equal to or greater than 35 mg/m²/day for 5 consecutive days. Out of the 23 dogs enrolled in the phase I study, 12 dogs had a diagnosis of appendicular OS (6 micrometastatic and 6 gross macroscopic). In the six dogs receiving satraplatin in the adjuvant setting, the median DFI and survival time were 456 and 659 days, respectively. Based on these early findings derived from a small subset of dogs with OS, satraplatin should be investigated more formally for appendicular OS.

Immunotherapy

Harnessing and directing the immune system for controlling micrometastatic disease remains a highly desirable anticancer strategy. Despite the various forms of immunotherapies such as monoclonal antibodies and dendritic cell vaccines currently instituted for the treatment of metastatic tumor histologies in humans, only a few immunotherapy studies in dogs have been conducted as randomized, double-blind trials. The best documented and clinically effective immunotherapy trials for dogs with OS have evaluated the anticancer immune effects associated with the administration of liposome-encapsulated muramyl tripeptide-phosphatidylethanolamine (L-MTP-PE). Being a lipophilic derivative of muramyl dipeptide, a synthetic analog of a *Mycobacterium*

cell wall component, L-MTP-PE has been demonstrated to augment canine alveolar macrophage tumoricidal properties as supported by enhanced cytotoxicity against OS cells in vitro.²⁶⁵

In an initial clinical study of 27 dogs, the single-agent activity of intravenously administered L-MTP-PE was assessed immediately following amputation. Dogs were treated twice weekly with either L-MTP-PE (n = 14) or empty liposomes (n = 13) for a duration of 8 weeks. Dogs receiving L-MTP-PE achieved a significant prolongation in median DFI compared to dogs treated with empty liposomes (168 versus 58 days). Similarly, the MST was significantly longer for dogs receiving L-MTP-PE than dogs treated with empty liposomes (222 versus 77 days).²⁶⁶ Based on these comparisons, it was concluded that L-MTP-PE induced beneficial immunobiologic effects capable of delaying the progression of pulmonary micrometastatic disease.

After establishing the anticancer activity of single-agent L-MTP-PE when used in the adjuvant setting, two subsequent randomized, double-blind studies were conducted to determine the effectiveness of combining L-MTP-PE with cisplatin.²⁶⁷ In trial 1, dogs underwent limb amputation and received cisplatin every 4 weeks for 4 treatments. On completion of cisplatin therapy, dogs (n = 25) without overt evidence of pulmonary metastases were randomized to receive either L-MTP-PE (n = 11) or empty liposomes (n = 14) twice a week for 8 consecutive weeks. Dogs receiving L-MTP-PE had a significantly longer MST in comparison to dogs treated with empty liposomes, 14.4 versus 9.8 months.

Unlike trial 1 in which the cisplatin and L-MTP-PE were administered serially, the study design of trial 2 sought to characterize the anticancer activities of concurrently administered cisplatin and L-MTP-PE. All dogs (n = 64) were treated with limb amputation and cisplatin every 3 weeks for 4 treatments. Within 24 hours following the first cisplatin treatment, dogs were randomized to concurrently receive either L-MTP-PE twice a week (n = 21), L-MTP-PE once a week (n = 21), or empty liposomes once a week (n = 22) for a duration of 8 weeks. Disappointingly, dogs receiving concurrent L-MTP-PE (twice or once weekly) and cisplatin failed to demonstrate any improvement in DFI or survival time when compared to dogs treated with concurrent empty liposome (once weekly) and cisplatin. The reported MSTs for L-MTP-PE and empty liposome groups were 10.3, 10.5, and 7.6 months, respectively.

Molecular-Targeted Therapies for Dogs with Osteosarcoma

Micrometastatic Adjuvant Setting

The molecular pathogenesis for OS remains incomplete; however, a growing body of scientific evidence supports the participatory role of several cell signaling pathways that promote OS growth and survival. One particular growth factor signaling cascade more thoroughly investigated in OS has been GH and IGF-1. The putative roles of GH and IGF-1 in OS pathogenesis is supported by several clinical observations in both humans and dogs. For pediatric OS, the peak incidence of OS development occurs during the adolescent growth spurt,²⁶⁸ which coincides with the greatest circulating concentrations of GH and IGF-1. Similarly in dogs, large to giant skeletal size is a strong positive determinant for appendicular OS development. Given the central roles of GH and IGF-1 in skeletal growth and homeostasis, as well as their role in cell survival, it has been hypothesized that aberrant or excessive GH and IGF-1 signaling is likely involved in OS pathogenesis.²⁶⁹ To investigate the biologic consequences of attenuating GH and IGF-1 autocrine and/or paracrine signaling in OS, a randomized clinical trial in 44 dogs

with OS was conducted in which circulating IGF-1 concentrations were suppressed with the administration of a long-acting analog of somatostatin (OncoLAR).⁸⁸ All dogs were treated with amputation and carboplatin in combination with either OncoLAR ($n = 23$) or vehicle ($n = 21$). The administration of OncoLAR resulted in a 43% reduction in circulating IGF-1 concentrations in comparison to baseline values; however, disappointingly, the suppression in IGF-1 did not translate result in improved DFIs or overall survival times in comparison to dogs receiving vehicle.

Molecular therapies with the capacity to delay or inhibit the development of pulmonary metastases would dramatically improve current treatment outcomes. As such, novel anticancer agents have been designed to selectively inhibit obligate steps necessary for successful tumor cell invasion and metastasis. One specific strategy has been the inhibition of MMPs, which are proteolytic enzymes involved in local tissue invasion and metastases. Based on documented gelatinolytic activities of MMP-2 and MMP-9 in canine cell lines and OS samples,^{97,99} it has been rationalized that specific inhibitors of MMP activity might have the potential to increase the metastasis-free period after amputation and systemic chemotherapy. As such, a prospective, double-blind, randomized, placebo-controlled clinical trial evaluating the adjuvant activity of a MMP-2 and -9 inhibitor (BAY 12-9566), was evaluated in dogs with OS.¹⁷⁵ Following amputation and doxorubicin therapy, dogs without radiographic evidence of pulmonary metastatic disease ($n = 223$) were randomized and treated with either BAY 12-9566 (10 mg/kg) or placebo control daily until clinical failure. The addition of BAY 12-9566 did not improve DFI or survival time in comparison to placebo control. Correlating with the absence of biologic effect, serum MMP-2 and -9 activities were not different between dogs receiving BAY 12-9566 or placebo.

Treating Gross Metastatic Disease

Surgery

Resection of pulmonary metastasis from OSs or other solid tumors has been reported in humans.²⁷⁰ One report of 36 dogs treated with pulmonary metastasectomy for OS exists.²⁷¹ Lesions located subpleurally were gently lifted from the lung parenchyma by thumb forceps and a single pursestring of 2-0 or 3-0 polygalactin 910 (Vicryl, Ethicon, Sommerville, NJ) suture was tied around the base of normal tissue. Larger lesions located deeper in the lung parenchyma were removed by complete or partial lobectomy using surgical staples (TA30 or TA55, United States Surgical Corp, New York). No chemotherapy was given after these surgeries. Although the initial treatments varied between dogs, the MST of the entire group was 487 days. The median survival after pulmonary metastasectomy was 176 days (range 20 to 1495 days). The criteria established for case selection for pulmonary metastasectomy in order to maximize the probability of long survival periods are (1) primary tumor in complete remission, preferably for a long relapse-free interval (>300 days); (2) one or two nodules visible on plain thoracic radiographs; (3) cancer only found in the lung (negative bone scan); and perhaps (4) long doubling time (>30 days) with no new visible lesions within this time. Pulmonary metastasectomy can also be performed for palliative relief in dogs with hypertrophic osteopathy.²⁷² Thorascopic lung lobectomy has been described for removal of primary and metastatic lung tumors.²⁷³

Surgical intervention to treat metastatic skeletal lesions with limb-sparing surgery alone or combined with stereotactic RT have been used in a few selected cases at the authors' institution, but this is not routinely recommended. A whole body technetium bone scan or PET/CT scan with F-18 is strongly recommended to

identify the complete extent of metastatic skeletal disease prior to any surgical intervention. A recent report describes the feasibility of aggressive cancer treatment consisting of fracture fixation and postoperative chemotherapy as a treatment option for dogs with fractures associated with primary OS.¹⁰⁸ Dogs with stage III OS with bone metastases without pulmonary metastases are reported to have longer survival times than dogs with pulmonary metastases.¹¹⁵ With the increased availability of locking plates, intraoperative imaging and minimally invasive osteosynthetic techniques, stabilization of metastatic bone lesions or fractures is a palliative treatment option that may provide increased quality of life for selected patients and owners.

Chemotherapy and Receptor Tyrosine Kinase Inhibitors for Gross (Macroscopic) Osteosarcoma

The treatment of gross measurable OSs with conventional cytotoxic agents or RTK inhibitors remains unsatisfactory. In part, the ineffectiveness of systemic therapies to cytorreduce gross measurable OS lesions is due to the development of drug-resistant clones, in conjunction with unfavorable and altered drug biodistribution within large tumor microenvironments. Because formidable biologic barriers are operative within macroscopic tumors that favor cancer cell survival, the majority of studies demonstrate only marginal effectiveness of conventional cytotoxic agents or RTK inhibitors for the management of gross, measurable OS.

In one study, 45 dogs that had either developed gross metastatic OS following standard-of-care therapy (amputation and systemic chemotherapy) or diagnosed at presentation with metastatic OS were treated with single-agent chemotherapies, including cisplatin ($n = 31$), doxorubicin ($n = 11$), or mitoxantrone ($n = 3$).²⁷⁴ Out of the 45 dogs treated, only 1 dog achieved a short-lived (21-day) partial response, findings which suggest that conventional cytotoxic agents that are effective in the adjuvant setting are not efficacious for managing macroscopic metastatic OS. In a second study evaluating the tolerability and anticancer activities of paclitaxel in dogs with measurable tumor burdens, two out of nine dogs with macroscopic pulmonary metastatic OS achieved a partial response, suggesting that inhibitors of microtubule depolymerization might have modest activity for the management of gross measurable OS lesions.²⁷⁵

In addition to cytotoxic agents, the RTK inhibitor, toceranib phosphate (Palladia), has recently demonstrated preliminary anticancer activity across a broad range of tumor histologies, including metastatic pulmonary OS. Targets of toceranib include several members of the split-kinase family such as VEGF receptor, platelet-derived growth factor (PDGF) receptor, and c-kit.²⁷⁶ Based on toceranib's ability to inhibit multiple signaling pathways, its potential activity was evaluated in 23 dogs with measurable pulmonary OS metastases.²⁷⁷ Toceranib was orally administered at a median dose 2.7 mg/kg (every other day or Monday/Wednesday/Friday) and resulted in a partial response rate of 4.3% (1/23 dogs) and stable disease rate of 43.5% (10/23 dogs).

Strategies to enhance the susceptibility of metastatic cancers to conventional chemotherapeutic agents have also been recently conducted. By virtue of their chromatin remodeling effects, histone deacetylase inhibitors (HDACi) used in combination with cytotoxic agents might enhance the nuclear accumulation of cytotoxic agents and improve therapeutic outcomes. Based on this premise, a phase I dose-escalation study combining valproic acid and doxorubicin was conducted in dogs with various spontaneous tumors to determine the tolerability and activity of this HDACi/chemotherapy combination.²⁷⁸ Three dogs with macroscopic OS pulmonary

metastases were treated with valproic acid and doxorubicin, with one dog achieving durable disease stabilization.

Investigational Therapies for Gross Metastatic Disease

Aerosol Drug Delivery

Because the pulmonary parenchyma has a large absorptive surface area and high blood flow, the administration of therapeutic agents directly to it remains a potential tractable and noninvasive method for localized and systemic drug delivery. Although the majority of clinical indications for aerosol drug delivery are the management of inflammatory airway pathologies (i.e., bronchitis), the ability of inhalation therapy to achieve high drug concentrations directly to the lungs with the minimization of systemic toxicities provides justification to test this method of drug delivery for the management of macroscopic pulmonary OS metastases in dogs.

Two studies have been conducted to evaluate the feasibility, tolerability, and anticancer activities of aerosolized cytotoxic therapies in dogs diagnosed with macroscopic pulmonary OS metastases.^{279,280} In one study, six dogs with macroscopic pulmonary OS metastases were treated every 14 days for a total of 6 treatment cycles with inhalation doxorubicin, paclitaxel, or both.²⁷⁹ Aerosolization therapy was well tolerated, with no dose-limiting hematologic or biochemical toxicity associated with inhalation therapy. However, in dogs treated with aerosolized doxorubicin, pulmonary histologic changes were identified at necropsy in some patients consisting of toxin-induced pneumonitis, multifocal interstitial fibrosis, alveolar histiocytosis, and type II pneumocyte proliferation. Measurable anticancer activity was documented in two dogs (partial remission) treated with inhalation doxorubicin and one dog (complete remission) treated with inhalation paclitaxel. The duration of complete remission in the one responder dog treated with inhalation paclitaxel was durable, lasting greater than 325 days.

In addition to doxorubicin and paclitaxel, aerosolized gemcitabine has also been evaluated in dogs with metastatic OSs. Although categorized as a pyrimidine antimetabolite that belongs to the nucleoside analog family, it was demonstrated in preclinical mouse OS xenograft models that the anticancer activity of aerosolized gemcitabine was mediated through the upregulation of Fas receptor expression on the surface of pulmonary metastatic OS cells.²⁸¹ Because lung epithelium basally expresses Fas ligand, the restoration of Fas receptor expression by OS cells would consequently render them susceptible to Fas receptor-/Fas ligand-mediated apoptosis. Based on this preclinical information, a comparative study with aerosolized gemcitabine was conducted in 20 dogs with macroscopic pulmonary OS metastases.²⁸⁰ Dogs were treated twice weekly with inhalation gemcitabine and monitored for toxicity and anticancer activity. Aerosolized gemcitabine was well tolerated with no dose-limiting hematologic or biochemical toxicity reported and minimal histologic lung pathology following inhalation therapy. Mechanistic anticancer activities of aerosolized gemcitabine were supported by the identification of increases in percentage of necrosis, Fas receptor expression, and terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) positivity in macroscopic pulmonary OS metastatic lesions; however, clinically relevant tumor reductions, either partial or complete, were not achieved in any of the dogs treated.

Augmentation of Antitumor Immunity

Cytokines are cellular peptides, some of which actively aid or stimulate the immune system to recognize and attack cancer

cells. Although numerous cytokines participate in shaping the strength, specificity, and longevity of antitumor immune responses, interleukin-2 (IL-2) is a critical cytokine necessary for stimulating the growth, differentiation, and survival of antigen-specific cytotoxic T-cells. Additional immune effects orchestrated by IL-2 include the facilitation of immunoglobulin production by B-cells, as well as the differentiation and proliferation of NK cells. Despite the pleiotropic and desirable antitumor immune activities of IL-2, its systemic administration has been clinically limited due to severe toxicities. As such, alternative delivery strategies have been investigated to attenuate IL-2-associated toxicities, yet maximize its potent immunomodulatory effects.

For the treatment of pulmonary metastases, the localized deposition of IL-2 or the preferential gene expression of IL-2 within the lung parenchyma has been investigated as a novel and effective treatment option in dogs with macroscopic OS metastases. Initial studies evaluated the antitumor activities of liposomal IL-2 when delivered directly to the pulmonary parenchyma in the form of inhalation therapy.²⁸² Dogs were nebulized with liposomal IL-2 daily for 30 days, and immunomodulatory effects of IL-2 were confirmed by increases in bronchoalveolar lavage effector cell numbers and lytic activities, with resultant complete regression of macroscopic pulmonary OS metastases in two of four dogs. The duration of complete regression was durable in responder dogs, lasting between 12 and 20 months. Alternatively to inhaled liposomal IL-2 delivery strategies, IV gene therapy as liposome-DNA complexes encoding IL-2 has also been investigated.²⁸³ Based on its preferential accumulation and subsequent transgene expression within the lung parenchyma, the tolerability, immunomodulatory effects, and antitumor activity of IV liposome DNA complexes encoding IL-2 were evaluated in 20 dogs with chemotherapy-resistant macroscopic OS metastases. Following administration, the immunomodulatory effects of liposome DNA complexes were substantiated by the induction of fever, leukogram changes, monocyte activation, and increased NK cell activities. On completion of 12 consecutive weekly IV treatments with liposome DNA complexes, measurable responses were achieved in 3 out of 20 dogs, with one complete remission and two partial remissions.

Additional to IL-2 therapy, other investigations have evaluated alternative strategies for activating the immune system including the IV administration of a genetically-modified and attenuated bacterial species, *Salmonella typhimurium* (VNP20009).²⁸⁴ Based on the premise that anaerobic bacteria have potential as novel immunomodulatory cancer therapeutics, a phase I dose escalation study was conducted with VNP20009 in 41 dogs with spontaneous cancers. Dose-limiting toxicity associated with VNP20009 administration included fever and vomiting, symptoms associated with systemic immune activation. Importantly, preferential tumor tissue tropism of VNP20009 was confirmed by gene transcription and bacterial culture techniques in a substantial proportion of tumor samples. In a subset of four dogs with macroscopic OS pulmonary metastases, one partial remission was achieved for a duration of 68 days.

Palliative Treatment: Primary and Metastatic Bone Cancer Pain

Bone Cancer Pain Physiology

Although pain is an evolutionarily conserved protective mechanism, its categorization can be differentiated based on temporal aspects (acute, chronic, or intermittent), intensity (mild, moderate, severe, or excruciating), and anatomic origin (somatic, visceral, or

neuropathic). The sensation of pain is mediated by specialized afferent nerve endings, called *nociceptors*, that initiate sodium channel opening and subsequent neuronal depolarization events within small, myelinated A δ and unmyelinated C fibers. Generated neuronal impulses are propagated through the dorsal horn of the spinal cord via the dorsal root ganglia, where they synapse with second-order neurons of the gray matter with subsequent modulation of impulse intensity. The resultant nociceptive information is carried to the brain via the spinothalamic tracts, where it can be integrated, processed, and recognized in multiple areas of the brain.²⁸⁵

The greatest density of afferent nociceptors responsible for pain-impulse generation is found at the periosteal surface and medullary cavity, specifically in bone. As such, malignant perturbations affecting these bone anatomic compartments are associated with intense pain.^{286,287} In dogs with OS, the generation of bone cancer pain is attributed to two specific host responses. First, the invasive growth of malignant osteoblasts in the bone microenvironment results in the release of chemical mediators by nonneoplastic stromal cells, which in turn stimulate nociceptors and lead to the generation of painful sensations. Second, the genesis, maintenance, and exacerbation of bone cancer pain are directly attributed to dysregulated and pathologic osteoclastic bone resorption.^{286,287} Based on these mechanisms of bone cancer pain generation, the most effective management of malignant osteolytic pain would combine the eradication of malignant osteoblasts in bone matrix and the inhibition of tumor-induced osteoclastic bone resorption.

Palliative Radiation Therapy

RT is considered the most effective treatment modality for the management of osteolytic bone pain in human cancer patients and likewise has been investigated and extensively applied to alleviating bone cancer pain in dogs diagnosed with OS. Mechanistically, the analgesic effects of ionizing radiation may be attributed to the induction of apoptosis in both malignant osteoblasts and resorbing osteoclasts,²⁸⁸ and in dogs, these effects have been supported by percent tumor necrosis assessment.^{193,228,289} As such, ionizing radiation reduces overall tumor burden and attenuates the degree of osteoclastic resorption within the focal OS microenvironment.

Multiple palliative radiation protocols have been evaluated and reported in the veterinary literature, with the majority of dosing schemes utilizing 2 to 4 individual treatments of 6 to 10 Gy fractions. Although variable and subjectively reported in these studies, the alleviation of bone cancer pain was achieved in the majority of OS dogs treated and ranged from 74% to 93%. Although the majority of dogs symptomatically improved following palliative RT, the median time interval of subjective pain alleviation was not durable and ranged from 53 to 130 days.²⁹⁰⁻²⁹⁵ Because most conventional palliative radiation protocols only utilize 2 to 4 treatment fractions, the total cumulative radiation dose administered is relatively low (<32 Gy); therefore acute and late radiation toxicity is not a limiting factor for the majority of patients treated. This also may allow repetition of palliative radiation protocols in the same patient subsequent to return of pain as the tumor ultimately advances. Although megavoltage palliative RT appears effective when used as a single-agent treatment option for short-term pain management, some investigations suggest that the concurrent administration of IV systemic chemotherapy along with palliative radiation might enhance analgesic response rates and durations.²⁹³ Systemic chemotherapy is indicated for the delay of micrometastatic disease development in dogs diagnosed with appendicular OS, thus the adjuvant institution of chemotherapy combined with palliative RT might have the dual benefit of improving local pain control and improving overall

survival time through the delay of micrometastatic disease development.

Radiopharmaceuticals

¹⁵³Samarium is a radioisotope that undergoes gamma and beta decay, allowing for concurrent biodistribution tracking studies, as well as therapeutic ionizing radiation delivery within a 2- to 3-mm deposition radius. When ¹⁵³Samarium is conjugated to EDTMP, which is a bisphosphonate, the resultant compound ¹⁵³Sm-EDTMP preferentially concentrates in areas of increased osteoblastic activity and binds to exposed hydroxyapatite crystals.²⁹⁶ By virtue of its osteotropism and defined radius of ionizing radiation deposition, ¹⁵³Sm-EDTMP is currently used as a radiopharmaceutical for the palliative treatment of multifocal, skeletal metastases in humans afflicted with breast or prostate carcinoma.²⁹⁷

Similar to humans diagnosed with skeletal malignant osteolysis, the use of ¹⁵³Sm-EDTMP has been investigated and reported for alleviating bone cancer pain in dogs with appendicular and axial OS.²⁹⁸⁻³⁰¹ In dogs treated with ¹⁵³Sm-EDTMP, the predicted radiation dose equivalent achieved within the immediate bone tumor microenvironment has been estimated to approximate 20 Gy,²⁹⁸ although its intratumoral biodistribution is expected to be nonhomogeneous based on regional differences in reparative osteoblastic activities. Following IV ¹⁵³Sm-EDTMP administration, the majority (63% to 83%) of dogs with OS demonstrate improved lameness scores and activity levels, suggesting the achievement of pain palliation.²⁹⁸⁻³⁰¹ Despite clinical improvement in most dogs treated, the duration of pain alleviation has not been extensively documented but appears to approximate similar durations of pain control achieved with megavoltage teletherapy. In a small fraction (<5%) of treated dogs, ¹⁵³Sm-EDTMP has resulted in the complete involution of malignant skeletal lesions, resulting in durable pain alleviation and prolonged survival times. Overall, ¹⁵³Sm-EDTMP is well-tolerated; however, side effects associated with treatment include transient decreases in platelet and white blood cell counts as a consequence of beta energy deposition within the proximity of pluripotent marrow stem cells.³⁰⁰

Aminobisphosphonates

Aminobisphosphonates (NBPs) are synthetic analogs of inorganic pyrophosphate that were initially utilized for diagnostic purposes in bone scanning, based on their ability to preferentially adsorb to sites of active bone mineral remodeling. The pharmaceutical use of NBPs has gained wide acceptance in the therapy of human non-neoplastic bone resorptive disorders, such as osteoporosis and Paget's disease.³⁰² In addition to the management of these metabolic disorders, NBPs are considered first-line treatment for malignant skeletal osteolysis, including paraneoplastic hypercalcemia, multiple myeloma, and metastatic bone diseases in human cancer patients.^{303,304}

The effective treatment of bone disorders by NBPs is attributed to their differential effect on bone resorption and bone mineralization. At concentrations safely obtainable in vivo, NBPs inhibit bone resorption without inhibiting the process of bone mineralization. Mechanistically, the bone protective effects exerted by NBPs are through the induction of osteoclast apoptosis, which results in the net attenuation of pathologic bone resorption.^{305,306} Specifically, NBPs interfere with posttranslational prenylation of small guanosine triphosphate (GTP)-binding proteins, including Ras, Rho, and Rac,³⁰⁷ and the disruption of these small GTP-binding proteins results in the failure of normal intracellular signaling and interaction with the extracellular matrix, thereby triggering osteoclast apoptosis.

Although NBP are commercially available in different formulations, the effective management of tumor-induced hypercalcemia, osteolytic bone metastases of breast cancer, and osteolytic lesions of multiple myeloma appear to require the administration of IV NBP and at relatively high doses. Historically, pamidronate and zoledronate have been the two most commonly utilized IV NBP formulations in human oncology for their ability to decrease bone pain, improve quality of life, delay progression of the bone lesions, and decrease the frequency of malignant skeletal events.

Because OS is characterized by focal and aggressive malignant osteolysis, the investigation of NBPs has been a focus of clinical interest, and several studies have demonstrated the cytotoxic effects of NBPs against canine OS cell lines *in vitro*. In three independent studies, it was concluded that various NBPs, including alendronate, pamidronate, and zoledronate exerted dose- and time-dependent cytotoxicity in immortalized canine OS cell lines.³⁰⁸⁻³¹⁰ Although the *in vitro* studies were in agreement with the cytotoxic effects of NBPs on canine OS cell viability, the inhibitory concentration 50% (IC50) derived from the experiments varied among the studies. Nonetheless, the documented direct cytotoxic effects of NBPs on canine OS cell lines served as a springboard to rationally investigate the bone pain-alleviating effects of NBPs in dogs with OS.

The first reported description in the veterinary literature was the use of oral alendronate for the palliative management of two dogs with OS.³¹¹ Based on the unexpectedly long survival times reported in this anecdotal study, the authors suggested that NBP therapy might have a role in managing canine malignant bone disorders. Given that IV NBPs have been historically used for the management of malignant osteolysis in humans, a prospective study principally evaluating the safety of IV pamidronate was conducted in 33 dogs diagnosed with primary and secondary skeletal tumors.³¹² IV pamidronate (1.0 mg/kg diluted with 0.9% sodium chloride to a total volume of 250 ml) as a 2-hour constant rate infusion (CRI) every 28 days was well tolerated, and in a subset of dogs, the bone biologic and clinically relevant therapeutic effects of IV pamidronate were documented as significant reductions in urine NTx concentrations, increases in relative primary tumor bone mineral density (rBMD) as assessed by dual-energy x-ray absorptiometry (DEXA), and subjective pain alleviation.

Following the established safety of IV pamidronate in dogs with skeletal tumors, a second study of 43 dogs treated with IV pamidronate (comparing 1.0 mg/kg versus 2.0 mg/kg) was conducted to further characterize the biologic activity of pamidronate specifically for the management of appendicular OS-associated bone pain and pathologic bone resorption.³¹³ Overall, 12/43 (28%) OS-bearing dogs treated with single-agent IV pamidronate achieved pain alleviation for greater than 4 months. In addition to the subjective analgesic effects of pamidronate reported by pet owners, changes in urine NTx concentrations and DEXA-assessed rBMD correlated with therapeutic response.

Although original studies have focused on the palliative effects of pamidronate when used as a single-agent, a recent study has documented the synergistic activity of pamidronate when coupled with palliative RT in dogs with appendicular OS through the use of subjective and objective surrogate endpoints. In a prospective, double-blind, randomized, placebo-controlled clinical trial, dogs with appendicular OS were to receive palliative RT (8 Gy, days 1 and 2) plus 0.9% saline infusion or pamidronate once every 4 weeks for 3 treatments (12-week study).³¹⁴ Prior to initial palliative RT and subsequent to each IV treatment with either 0.9% saline or pamidronate, all dogs were evaluated by force plate gait analysis, urine NTx concentrations, numeric lameness evaluation, and owner

quality-of-life questionnaires. Out of 17 dogs, 8 received 0.9% saline and 9 received IV pamidronate (1.0 mg/kg). The saline placebo group dogs experienced a significant increase in numeric lameness score between weeks 0 and 12, and pamidronate significantly lowered the lameness scores on week 12 compared to saline. In addition, dogs receiving pamidronate had a significantly greater vertical impulse and total stance time on weeks 4 through 12 compared to saline placebo-treated dogs. Based on these findings, the addition of pamidronate to palliative therapy appeared to improve limb function compared to palliative RT alone.

In another study evaluating the benefit of combining pamidronate with conventional therapies for managing bone cancer pain, a double-blind, placebo-controlled study of 50 dogs with OS receiving palliative radiation, doxorubicin, and either saline placebo or pamidronate was conducted.³¹⁵ The median pain-free interval for dogs receiving adjuvant pamidronate or saline was 76 days and 75 days, respectively. Despite the apparent lack of pet owner-perceived analgesia, dogs that received adjuvant pamidronate did demonstrate improved quality-of-life scores and more importantly, superior bone biologic effects representative of decreased malignant bone resorption at the level of the primary tumor. Collectively, the findings from this clinical trial suggest that adjuvant pamidronate may not subjectively improve analgesia when dogs are already receiving treatment with megavoltage radiation and doxorubicin but still exert beneficial bone biologic effects within the bone tumor microenvironment in dogs with OS.

Although the majority of palliative studies have documented the effects of pamidronate, other more potent IV NBPs for managing malignant bone pain have also been evaluated in dogs with skeletal tumors. Zoledronate possesses 100-fold greater antiresorptive potency in comparison with pamidronate and has the advantage of being safely administered over a shorter period of time than other NBPs. In one case report, the use of IV zoledronate administered every 28 days was effective for the long-term pain management of a dog diagnosed with OS affecting the distal radius.³¹⁶ In a larger study, the bone biologic effects of IV zoledronate were evaluated in dogs diagnosed with primary and secondary skeletal tumors.³¹⁷ In this study, zoledronate was administered at a dose of 0.25 mg/kg as a 15-minute CRI every 28 days and was well tolerated with no overt biochemical evidence of renal toxicity in patients receiving multiple monthly infusions. In 10 dogs with appendicular OS, 50% of dogs treated achieved pain alleviation for greater than 4 months and also demonstrated significant increases in rBMD. The observation for increased rBMD in conjunction with pain alleviation suggests that zoledronate inhibits local malignant osteolysis and the generation of pain within the immediate bone-tumor microenvironment.

Comparative Aspects

Animal models for the study of human diseases are important to our understanding of the mechanism and etiology of disease and for the development and refinement of therapeutic strategies. Spontaneously developing diseases in animal populations are particularly useful for study.³¹⁸⁻³²⁰ Canine OS has many similarities to human OS in terms of genetic similarities, clinical presentation, biologic behavior, and metastatic progression and has been shown through many studies to be a valuable comparative model for study (Table 24-3).^{7,320} OS is more common in dogs than in humans; therefore case accrual is more rapid. Because disease progression is more rapid in dogs than in humans, results of novel treatment protocols can be reported earlier than those of similar trials in humans. Research costs for clinical trials in dogs are less compared to those in human clinical trials, and, from an animal welfare

• **TABLE 24-3** Comparison of Canine and Human Osteosarcoma Characteristics

VARIABLE	DOG	HUMAN
Incidence in United States	>10,000/year	1000/year
Mean age	7 years	14 years
Race/breed	Large or giant purebreds	None
Body weight	90% >20 kg	Heavy
Site	77% long bones Metaphyseal Distal radius > proximal humerus Distal femur > tibia	90% long bones Metaphyseal Distal femur > proximal tibia Proximal humerus
Etiology	Generally unknown	Generally unknown
Percentage clinically confined to the limb at presentation	80%-90%	80%-90%
Percentage histologically high grade	95%	85%-90%
DNA index	75% aneuploid	75% aneuploid
Recognized genetic and molecular alterations	<i>p53</i> , <i>RB</i> , <i>PTEN</i> , <i>c-Met</i> , GH, and IGF-1	<i>p53</i> , <i>RB</i> , RecQ Helicase, <i>c-Met</i> , GH, and IGF-1
Prognostic indicators ^{173,174}	Alkaline phosphatase	Alkaline phosphatase
Metastatic rate without chemotherapy	90% before 1 year	80% before 2 years
Metastatic sites	Lung > bone > soft tissue	Lung > bone > soft tissue
Improved survival with chemotherapy	Yes	Yes
Regional lymph node metastasis	<5%, negative prognostically	Poor prognosis

standpoint, no disease is induced and dogs with cancer can potentially be helped through the course of the research.

OS is an uncommon cancer of humans affecting mainly children in their second decade of life and remains a very serious, aggressive solid tumor. Fortunately, there has been a great improvement in survival rates with the use of established multidrug adjuvant protocols. The long-term survival rate for human OS is presently 60%, which contrasts to the 20% expected 5-year survival rates of the early 1980s. A retrospective study of 648 human OS patients reported a mean survival of 3 years; however, this represented all cases at one institution since the 1970s and therefore improvements over time were not presented.³²¹ Factors that negatively affected outcome included older age, advanced local or systemic stage, axial location, larger size, and a lower percentage of necrosis following neoadjuvant treatment. The type of surgery (amputation or limb sparing) did not impact outcome, supporting the need for advancement of systemic medical therapy to impact survival. Limb-sparing programs are becoming more common, and many survivors of OS retain functional, pain-free limbs. In two reports, one from the United States³²² and one from Italy,^{323,324} aggressive neoadjuvant chemotherapy resulted in limb-sparing success of 93.5% and 83%, respectively, and a projected 10-year survival of 93%.

Bone Surface Osteosarcoma

OS usually originates from elements within the medullary canal of bones (intraosseous OS); however, there are forms of this cancer that originate from the outside surface of bones. Periosteal OS is a high-grade form of surface OS and seems to arise from the periosteal surface but has invasive characteristics seen radiographically.³²⁵ There is cortical lysis with extension of the tumor into the bone and surrounding soft tissues. These tumors are histologically similar to intraosseous OS and have similar aggressive biologic behavior.

In contrast, parosteal OS, or juxtacortical OS, arises from the periosteal surface of bones but appears less aggressive than periosteal OS both radiographically and in terms of biologic behavior. Parosteal OS is relatively uncommon and has a moderately well-circumscribed radiographic appearance. The tumors grow out from the periosteal side of a cortex and cortical lysis is usually very mild on radiographs. Histologically, these tumors look more benign compared to intraosseous or periosteal OS. These tumors contain well-differentiated cartilage, fibrous tissue, and bone with sparse regions of sarcoma cells adjacent to tumor osteoid. Histologic specimens must be evaluated carefully because it is often easy to miss the areas of tumor cells and misdiagnose the lesion as osteoma, chondroma, or reactive bone. These tumors generally do not invade the medullary canal and tend to grow out from the bone on broad pedicles. Diagnosis is based on typical histologic and radiographic findings.

Parosteal OS is usually slow growing but can induce pain at the local site. Metastases can occur, but the prognosis for long-term survival is much better than for intraosseous OS.^{326,327} Control of parosteal OS can be achieved by en bloc resection of the tumor with the adjacent cortical bone. This has been reported for tumors of the zygomatic arch (Figure 24-12).³²⁷ If full-thickness cortex needs to be removed for tumors on long bones, reconstruction may be performed using autogenous corticocancellous bone, such as a rib, ileal crest, or allogeneic cortical bone. A report described a surface OS without cortical destruction (similar to parosteal) that had an aggressive histology and biologic behavior.³²⁸

Other Primary Bone Tumors of Dogs

Primary bone tumors other than OS make up somewhere between 5% and 10% of bone malignancies in dogs. These tumors are chondrosarcomas, hemangiosarcomas, fibrosarcomas, lymphomas

• **FIGURE 24-12** **A**, CT scan of a low-grade parosteal OS of the zygomatic arch in a dog. Low-grade primary bone tumors are often more radiodense and well circumscribed. **B**, Specimen radiograph of the case in **A** after zygomatic arch resection.

(see Chapter 32, Section A), and plasma cell tumors (see Chapter 32, Section D).

It can be difficult to distinguish chondroblastic OS from chondrosarcoma, fibroblastic OS from fibrosarcoma, and telangiectatic OS from hemangiosarcoma when only small amounts of biopsy tissue are evaluated.¹³⁵ This makes interpretation of older reports difficult in terms of trying to establish the true incidence of the different types of primary bone tumors. This also underscores the importance of evaluating the entire excised specimen to validate the preoperative biopsy. All too often a bone malignancy thought to be relatively low grade from preoperative biopsy is upgraded to a true OS once the histology of the surgical specimen is reviewed. This may change the prognosis and postsurgical treatment plan.

Chondrosarcoma

Chondrosarcoma is the second most common primary tumor of bone in humans and dogs and accounts for approximately 5% to 10% of all canine primary bone tumors.^{2-5,329} Chondrosarcomas are characterized histologically by anaplastic cartilage cells that elaborate a cartilaginous matrix. There is a spectrum of degree of differentiation and maturation of the cells within and between each tumor. Histologic grading systems have been devised.³³⁰ The etiology is generally unknown, although chondrosarcoma can arise in dogs with preexisting multiple cartilaginous exostosis.³³¹⁻³³³ In a clinicopathologic study of 97 dogs with chondrosarcoma, the mean age was 8.7 years (ranging from 1 to 15 years) and golden retrievers were at a higher risk of developing chondrosarcoma than any other breed.³³⁴ There was no sex predilection, and 61% of the tumors occurred on flat bones. Chondrosarcoma can originate in the nasal cavity, ribs, long bones, pelvis, extraskelatal sites (such as the mammary gland, heart valves, aorta, larynx, trachea, lung, and omentum), vertebrae, facial bones, digits, and os penis.^{35,330,334-341} The nasal cavity is the most common site for canine chondrosarcoma.^{330,334}

Chondrosarcoma is generally considered to be slow to metastasize. Tumor location rather than histologic grade was prognostic in one study.³³⁰ The reported median survival of dogs with nasal chondrosarcoma ranges from 210 days to 580 days with various treatments (RT, rhinotomy and RT, and rhinotomy alone; see Chapter 23, Section B).^{334,342} Metastatic disease is not a reported feature of nasal chondrosarcoma in dogs. The reported median survival for dogs with rib chondrosarcoma varies widely.^{21,167,330,343} Reports prior to 1992 contained few cases that were treated with intent to cure, but 15 dogs with rib chondrosarcoma treated with en bloc resection in a more recent study had a median survival of 1080 days.¹⁶⁵ The median survival for dogs with chondrosarcoma was 540 days in a study of five dogs treated with amputation alone.³³⁴ Death was usually associated with metastatic disease. A reliable adjuvant chemotherapeutic agent is not known for canine chondrosarcoma. In humans, chondrosarcoma is considered a local disease, with a moderate rate of metastasis, which can be predicted by histologic grade. Aggressive surgical resection often results in long-term tumor control.³⁴⁴ Although this tumor is generally considered resistant to standard RT, the authors have noted objective responses to coarse-fraction radiation protocols in a handful of cases in which surgery was not an option.

Hemangiosarcoma

Primary hemangiosarcoma of bone is rare and accounts for less than 5% of all bone tumors (see Chapter 33, Section A). This disease generally affects middle-aged to older dogs and can occur in dogs of any size. This is a highly metastatic tumor, and virtually all dogs affected will develop measurable metastatic disease within 6 months of diagnosis. Metastases can be widely spread throughout various organs such as lungs, liver, spleen, heart, skeletal muscles, kidney, brain, and bones. Dogs can present with multiple lesions, making it difficult to determine the site of primary disease. Histologically, hemangiosarcoma is composed of highly anaplastic mesenchymal cells, which are precursors to vascular endothelium. The cells are

arranged in chords separated by a collagenous background and may appear to be forming vascular channels or sinuses. Cellular pleomorphism and numerous mitotic figures are features of this highly malignant disease. There is profound bone lysis, and the malignant cells aggressively invade adjacent normal structures. The lesion, however, may be confused with telangiectatic OS, especially if the diagnosis is based on small tissue samples. Often the dominant radiographic feature is lysis; however, hemangiosarcoma does not have an unequivocally unique radiographic appearance, and diagnosis is based on histology.

If hemangiosarcoma is diagnosed, the dog must be thoroughly staged with thoracic and abdominal films, bone survey radiography or bone scintigraphy, and ultrasonographic evaluation, particularly of the heart and abdominal organs. Right atrial hemangiosarcoma may be present without clinical or radiographic signs of pericardial effusion. The prognosis is poor, and even dogs with hemangiosarcoma clinically confined to one bony site have less than a 10% probability of surviving 1 year following complete excision. Cyclophosphamide, vincristine, and doxorubicin have been used in combination as an adjuvant protocol, and the reported median survival of dogs with nonskeletal hemangiosarcoma is 172 days.³⁴⁵ In a patient population represented by a variety of primary tumor sites, doxorubicin as a single-agent adjuvant seemed to be as effective as the combination of drugs, with an MST of 172 days in patients in which all gross disease is surgically resected.³⁴⁶ In a group of dogs with splenic hemangiosarcoma, L-MTP-PE resulted in a median survival of 277 days, compared to 143 days for dogs receiving empty liposomes.³⁴⁷

Fibrosarcoma

Primary fibrosarcoma is also a rare tumor of dogs and accounts for less than 5% of all primary bone tumors.⁴ Unfortunately, the difficulty in distinguishing fibrosarcoma from fibroblastic OS histologically (especially from small tissue samples) renders study of this tumor difficult. In one report, 11 dogs thought to have fibrosarcoma were reevaluated after complete resection and the histologic diagnosis was changed to OS in 6 dogs.³⁴⁸ Histologic characteristics of fibrosarcoma have been described as interwoven bundles of fibroblasts within a collagen matrix permeating cancellous and cortical bone but not associated with osteoid produced by the tumor cells. Host-derived new bone can be seen, however, especially at the periphery of the tumor.

Complete surgical resection of the primary lesion is recommended for dogs with fibrosarcoma clinically confined to the primary site. This treatment may be curative, although metastatic potential may be considerable. There is no good evidence that adjuvant chemotherapy is of any benefit in preventing metastatic disease. It has been postulated that primary fibrosarcoma of bone has a propensity to metastasize to such sites as the heart, pericardium, skin, and bones rather than lung.³⁴⁸

Multilobular Osteochondrosarcoma

Multilobular osteochondrosarcoma (MLO) is an uncommon tumor that generally arises from the skull of dogs.³⁴⁹⁻³⁵¹ Many names have been used to describe this disease, including chondroma rodens and multilobular osteoma. These tumors have a characteristic appearance on radiographs, CT, and MRI: generally the borders of the tumor are sharply demarcated with limited lysis of adjacent bone, and there is a coarse granular mineral density throughout (Figure 24-13).^{352,353} However, there is one report of an MLO of the vertebra that did not have radiographic abnormalities.³⁵⁴ Histologically, these tumors are composed of multiple lobules, each centered

• **FIGURE 24-13** Specimen radiograph of a multilobular osteochondrosarcoma arising from the vertical ramus of the mandible in a dog. These tumors have a granular radiographic appearance often referred to as “popcorn ball.”

on a core of cartilaginous or bony matrix that is surrounded by a thin layer of spindle cells. A histologic grading system has been described.^{350,351} These tumors have the potential to recur locally following incomplete resection, and metastasis can occur. In one report of 39 dogs, the median age of affected dogs was 8 years, the median weight was 29 kg, and there was no breed or sex predilection.³⁵¹ Slightly less than 50% of dogs had local tumor recurrence following resection at a median time of approximately 800 days. A little over half the dogs developed metastases after treatment; however, time to metastasis was prolonged with a median of 542 days. The MST was 800 days. Local tumor recurrence and metastasis after treatment appears to be predicted by histologic grade and the ability to obtain histologically complete resection. Local tumor excision with histologically complete surgical margins appears to offer a good opportunity for long-term tumor control, especially for low-grade lesions. When metastatic lesions are identified by thoracic radiography, dogs may remain asymptomatic for their lung disease for up to 1 year or more. The role of chemotherapy and RT in the management of MLO is not well defined.

Metastatic Tumors of Bone

Almost any malignant tumor can metastasize to bone via the hematogenous route. The lumbar vertebrae, femur, humerus, rib, and pelvis are common sites for cancer spread, possibly because these are predilection sites for bone metastasis from the common

• **FIGURE 24-14** Lateral radiograph of a multiple cartilaginous exostosis lesion of the dorsal spinous process in a dog (A).

urinogenital malignancies, such as prostate, bladder, urethral, and mammary cancer.^{355,356} Metastatic lesions in long bones frequently affect the diaphysis, likely because of the proximity to a nutrient foramen. Nuclear scintigraphy is a sensitive technique to detect bone metastasis. A whole-skeleton bone scan is recommended when metastatic bone cancer is suspected because it is common for multiple sites of metastasis to be present, even if the patient is symptomatic for only one bone.

Benign Tumors of Bone

Osteomas

Osteomas are benign tumors of bone.³⁵⁷ Radiographically, these are well-circumscribed, dense bony projections, which are usually not painful to palpation. Histologically, they are composed of tissue nearly indistinguishable from reactive bone. The diagnosis is made after considering the history and physical examination, as well as radiographic and histologic findings. The most important differential diagnosis is MLO when the lesion occurs on the skull. Treatment for osteoma is simple surgical excision, which is usually curative.

Multiple Cartilaginous Exostosis

Multiple cartilaginous exostosis (MCE) is considered a developmental condition of growing dogs. There is evidence that the etiology of this condition may have a heritable component.^{332,358} The actual incidence of MCE is difficult to determine because affected dogs may show no signs and the diagnosis is often incidental. Lesions occur by the process of endochondral ossification when new bone is formed from a cartilage cap analogous to a physis. Lesions are located on bones, which form from endochondral ossification, and lesions stop growing at skeletal maturity. Malignant transformation of MCE lesions has been reported, but generally, they remain as unchanged, mature, bony projections from the surface of the bone from which they arose.³³³

Dogs typically present because of a nonpainful or moderately painful palpable mass on the surface of a bone or bones. The pain

and lameness is thought to be due to mechanical interference of the mass with the overlying soft tissue structures. In the case of MCE of vertebral bodies, animals can present with clinical signs associated with spinal cord impingement. Radiographically, there is a bony mass on the surface of the affected bone, which has a benign appearance with fine trabecular pattern in the body of the mass (Figure 24-14). To obtain a histologic diagnosis, biopsy material must be collected so sections can include the cartilaginous cap and the underlying stalk of bone. Histologically, this cartilaginous cap gives rise to an orderly array of maturing bone according to the sequence of endochondral ossification. The cortical bone surfaces of the mass and the adjacent bone are confluent.³³¹ A strong presumptive diagnosis is made by evaluation of the physical findings, history, and radiographic findings.

Treatment involves conservative surgical excision, but this is only necessary if signs do not abate after the dog is skeletally mature. Because of the likelihood of a heritable etiology, affected dogs should not be bred. Owners should also be advised of the possibility of late malignant transformation. Dogs with a previous history of MCE should be carefully evaluated for bone malignancy if signs return later in life.

Bone Cysts

Cysts are rare, benign lesions of bone. The majority of the veterinary literature pertaining to bone cysts centers on several small series of cases or single case reports.³⁵⁹⁻³⁶³ Affected animals are often young and present because of mild or moderate lameness; however, pathologic fracture can occur through cystic areas of long bones, leading to severe lameness. There appears to be a familial tendency in Doberman pinschers and Old English sheepdogs. The nomenclature in various reviews of canine bone cysts is confusing. By definition, a cyst is a fluid-filled sac lined by epithelium. The only true cyst of primary intraosseous origin is a simple bone cyst (SBC, or unicameral bone cyst). These lesions are usually in metaphyseal regions of long bones, and they can adjoin an open growth plate. Sometimes, however, unicameral bone cysts can be diaphyseal or

epiphyseal. Neither the etiology nor the pathogenesis is known, but it is speculated that the lesions may be the result of trauma to the growth plate interfering with proper endochondral ossification. Others have theorized that with the rapid resorption and deposition of bone occurring in the metaphysis of a young animal, a cyst might develop if resorption is so rapid that a focus of loose fibrous tissue forms. The focus of fibrous tissue may then obstruct the thin-walled sinusoids, causing interstitial fluid to build up and form a cyst. The theory that appears to be partially substantiated is the synovial “rest” thesis. It is suggested that during fetal development a “rest” of synovial or perisynovial tissue becomes misplaced or incorporated into the adjacent osseous tissue. If this tissue remains or becomes functional, subsequent synovial secretion results in a cyst developing in the bone. Cysts have been described in bone just below articular cartilage (subchondral bone cysts or juxtacortical bone cysts).^{361,362,364} In these, it has often been possible to demonstrate direct communication with the articular synovial membrane. Radiographically, SBCs are single or, more commonly, multilocular, sharply defined, centrally located, radiolucent defects in the medullary canal of long bones. Variable degrees of thinning of the cortex with symmetric bone “expansion” are often a feature of the radiographs (Figure 24-15). The diagnosis cannot be reliably made from interpretation of radiographs alone. Lytic OS can be misdiagnosed as SBC. Diagnosis of an SBC relies on the histologic finding of a thin, fibrous wall lined by flat to slightly plump layers of mesothelial or endothelial cells. Treatment consists of meticulous curettage and packing the space with autogenous bone graft.

Aneurysmal bone “cysts” (ABCs) are spongy, multiloculated masses filled with free-flowing blood. The walls of an ABC are rarely lined by epithelium, and the lesion is possibly an arteriovenous malformation. A proposed pathogenesis of ABCs is that a primary event such as trauma or a benign bone tumor occurs within the bone or periosteum. This event disrupts the vasculature, resulting in a rapidly enlarging lesion with anomalous blood flow, which damages the bone mesenchyme. The bone reacts by proliferating. As the vascular anomaly becomes stabilized, the reactive bone becomes more consolidated and matures. It is important to differentiate these lesions from OS or other malignant lesions of bone. The age of affected dogs ranges from 2 to 14 years, but it has been reported in a 6-month-old dog.³⁶⁰ Treatment can be achieved by en bloc resection and reconstruction, but extensive curettage with packing of the defect with autogenous bone graft can be effective.

Primary Bone Tumors of Cats

Incidence and Risk Factors

Primary tumors involving the bones of cats are rare. An estimate of the incidence of all bone tumors in cats is 4.9 per 100,000.³⁶⁵ Between 67% and 90% of bone tumors in cats are histologically malignant. OSs are the most common primary bone tumor in cats accounting for 70% to 80% of all primary malignant cancer of cats. Feline OS occurs in appendicular or axial skeletal sites and extraskeletal sites. OS occurs in appendicular long bones approximately twice as often as in axial skeleton sites.³⁶⁶ However, in one study, 50 of 90 skeletal OS cases were appendicular and 40 of 90 were axial.³⁶⁷ Axial OS originates most commonly in the skull (especially oral cavity) and pelvis but is also reported in the ribs and vertebrae. The disease in cats differs from that in dogs in that the primary lesions occur more often in hind limbs in cats (distal femur and proximal tibia) and the disease is reported to be far less metastatic than in dogs.³⁶⁸ In a large feline OS case study, 56 of 146

FIGURE 24-15 Lateral radiograph of a distal radial bone lesion histologically confirmed as a simple bone cyst (SBC). Typical radiographic features include a multilocular, sharply defined, centrally located radiolucency, without evidence of cortical destruction.

cases were extraskeletal in origin, with the most commonly affected sites being those commonly used for vaccination: interscapular, dorsal lumbar, or thigh areas. Other locations included ocular/orbital, oral, intestinal, and mammary sites. No mention is made of any differences in the pathology of these tumors in comparison to skeletal sites.³⁶⁷ There are case reports of feline extraskeletal OSs in the flank, liver, and duodenum.³⁶⁹⁻³⁷¹

OS generally affects older cats (reported mean ages of 8.5,³⁶⁶ 10,³⁶⁸ 10.2,³⁶⁸ and 10.7³⁷² years), but the age range of reported cases is large (1 to 20 years), so bone lesions in younger cats cannot be ruled out as OSs based on age criteria alone. The age at presentation for axial OS is greater than appendicular OS.³⁶⁷ Conflicting reports on gender predisposition exist with either no difference between sexes or a slight male predisposition.^{366-368,372} OS was reported to arise after a limb fracture was repaired with an intramedullary pin in one cat and following RT in another.³⁸

MCE is a disease that occurs after skeletal maturity in cats. This is in contrast to dogs in which exostoses develop before closure of

growth plates. Also, in contrast to dogs, the lesions seldom affect long bones, are rarely symmetric, and are probably of viral rather than familial origin. There does not appear to be any breed or sex predisposition, although early reports of this condition were in the Siamese.³⁷³ Affected cats range in age from 1.3 to 8 years (mean 3.2 years).³⁷⁴ Virtually all cats with MCEs will test positive for feline leukemia virus (FeLV) antigenemia. This disease has an aggressive natural behavior.

Pathology and Natural Behavior

The histologic characteristics of feline OS are similar to canine OS. OS of cats is composed of mesenchymal cells embedded in malignant osteoid. There may be a considerable amount of cartilage present, and osteoid may be scant. A feature of some feline OS cases is the presence of multinucleate giant cells, which may be numerous. Reactive host bone and remnants of host bone are often present in specimens. Tumors are seen to be invasive; however, some surrounding soft tissue may be compressed rather than infiltrated. There is often variation of the histologic appearance within the tumor, with some portions having a more fibrosarcomatous appearance and others more cartilaginous. Some authors have described subtypes that resemble those seen in dogs: chondroblastic, fibroblastic, and telangiectatic, as well as the giant cell variant. These histologic subtypes, however, do not appear to confer any prognostic predictive value.^{375,376} OSs in cats are locally aggressive but have a low metastatic rate compared to canine OS. Feline OS can be of the juxtacortical type.

Osteochondroma may occur as a solitary lesion in cats, but there is a form that is multicentric (osteochondromatosis). The lesions are composed of hard, irregular exostoses with a fibrous and cartilaginous cap.³⁷⁷ Endochondral ossification occurs from the cartilage cap, which extends to a variable thickness. This cap tends to blend with adjacent tissue, making its surgical removal difficult. Cats usually develop multiple sites of disease, and there is a potential for malignant transformation and metastasis. The presence of FeLV antigenemia is also a foreboding prognostic finding for these cats.

History and Clinical Signs

The most common signs of OS are lameness, swelling, and deformity, depending on the location of the lesion. The lesions may appear radiographically similar to the OS in dogs with mixed osteoblastic and osteolytic aggressive bone lesion with an ill-defined zone of transition between normal and tumor-affected bone; however, some cats have lesions arising from the periosteal surface (juxtacortical OS).³⁶⁶ Tumors can reach a large size without evidence of severe clinical signs. It is rare for cats to have metastatic OS at presentation.

Cats with viral-associated MCE have rapidly progressing, conspicuous, hard swellings over affected sites causing pain and loss of function. Common sites for lesion development are the scapula, vertebrae, and mandible; however, any bone can become affected. Radiographically, the lesions are either sessile or pedunculated protuberances from bone surfaces with indistinct borders with the normal bone. There may be a loss of smooth contour with evidence of lysis, particularly if there is malignant transformation.

Diagnostic Work-Up

Both OS and MCE may be suspected, based on the radiographic appearance of the lesions and the FeLV status of the cat. Definitive diagnosis is made by histopathologic evaluation of properly collected biopsy tissue. Metastatic rates for cats with primary bone tumors are low compared to dogs (5% to 10% versus >90%), and

three-view thoracic radiographs are recommended as part of the staging process. Presurgical evaluation with a CBC, chemistry profile, and urinalysis is recommended to rule out concurrent disease.

Therapy and Prognosis

Amputation is the recommended treatment for feline appendicular OS in which there are no clinically detectable metastatic lesions. Complete surgical excision of the primary tumor is prognostic for increased survival time, DFI, and recurrence-free interval.³⁷² Due to the low metastatic rate and prolonged MSTs of 24 to 44 months with amputation alone,^{366,368} adjuvant chemotherapy is not indicated or recommended in cats, which is in contrast to the situation in dogs. No adjuvant therapy is known to be efficacious in extending survival time in cats. The MST for feline OS in axial sites (6.7 months) is lower than that of appendicular and extraskeletal OS sites.³⁶⁷ This likely reflects the difficulty of achieving complete resection and local tumor control in these anatomic sites rather than a difference in biologic behavior. A combination of surgical resection and RT may be appropriate in these cases. SRT has been used in several cats for local tumor control in appendicular and axial sites.

Histologic grade, using a grading scheme that evaluates tumor vascular invasion, pleomorphism, mitotic index, and tumor matrix and cell necrosis, is prognostic for survival.³⁷² Specifically, tumors with high number of mitoses have a higher hazard ratio for decreased recurrence-free intervals. The metastatic potential of OS in cats (5% to 10%) is much less than for the same disease in dogs or humans. Reported anatomic sites for metastases are lung, kidney, liver, brain, and spleen. Cats with MCE have a guarded prognosis. Lesions may be removed surgically for palliation; however, local recurrences are common, or new, painful, debilitating lesions may occur. No reliably effective treatment is known for this condition in cats.

Fibrosarcoma, Chondrosarcoma, and Hemangiosarcoma

Non-OS primary bone tumors in cats are rare. Fibrosarcoma is the second most common primary bone tumor of cats.³⁷⁵ Chondrosarcoma is reported to be next in terms of frequency, and hemangiosarcomas rarely involve bones of cats.³⁶⁸ Little is known about the biologic behavior of these rare lesions. Aggressive surgical resection is the preferred treatment for these tumors. The metastatic rate is low; however, metastases have been seen in cats with chondrosarcoma and hemangiosarcoma.^{368,376}

Tumors of the Endocrine System

KATHARINE F. LUNN AND RODNEY L. PAGE

Endocrine tumors may be classified as nonneoplastic hyperplasias, benign adenomas, or malignant carcinomas. These conditions represent points on a continuous spectrum of endocrine function-dysfunction. Nonneoplastic hyperplasia is the consequence of aberrant secretion of trophic hormones resulting in growth and increased function. Hyperplasia is often focal but not necessarily reversible when the inciting trophic factor is removed, illustrating the overlap between nonneoplastic and neoplastic endocrine disease.¹ Adenomas and carcinomas grow autonomously in the absence of trophic stimulation. Distinguishing between benign and malignant lesions can be challenging. In particular, the cellular morphologic features of adenomas and carcinomas are often similar, making cytologic samples, small biopsies, and even entire tumors difficult to accurately classify.¹ The clinical manifestations of endocrine tumors may be the result of growth, expansion, and metastasis of the tumor, producing traditional sequelae due to compression of normal tissue (adenoma), invasion and destruction of regional or systemic normal tissue function (carcinoma), secretion of hormones or hormone-like substances that produce signs of disease specific to the downstream tissue impact, and often a combination of these effects.

In this chapter, we will review the common endocrine tumors of dogs and cats. A discussion of endocrine neoplasia in ferrets is beyond the scope of this chapter; however, a thorough review is available for the interested reader.² Multiple endocrine neoplasia is not discussed here because it remains rarely reported in companion species.

Pathogenesis of Endocrine Tumors

Endocrine tissue is distinct from nonendocrine tissue in several ways that influence the pathogenesis of cancer. Endocrine glands normally expand in secretory capacity by an increased number of cells, increase in size and productivity of individual cells, or both, when the necessary stimulus is applied. They then return to a relatively quiescent state when the trophic substance is removed. Growth (cellular enlargement and division) and function (production of hormone) are therefore tightly linked and controlled by the same physiologic stimulus. Cells within endocrine organs are relatively stable. For example, the thyroid gland is expected to have only six to eight renewals in the lifespan of an adult human, dog, or mouse.³ This low turnover rate (2.3 years in dogs) is associated with longer intermitotic intervals compared to many other cell types in nonendocrine tissues. Such quiescence may result in a lower mutation rate, although any mutations acquired may be retained for longer periods.⁴ Prolonged stimulation of mutation-bearing endocrine tissue by a trophic substance may result in transformation. Clinically, this may be observed when longstanding hyperplasia ultimately progresses to neoplasia. In this situation, growth and

function within the endocrine organ ultimately become independent of trophic hormone stimulation.

The orchestrated accumulation of somatic mutations leading to dedifferentiation from mature to anaplastic cells is considered the classic theory of carcinogenesis in thyroid tissue, and this area is where the majority of research has occurred.⁵ Loss of tumor suppressor gene function, or oncogene activation, may lead to neoplasia. Only recently has a cancer stem cell theory of carcinogenesis emerged for endocrine neoplasia, in particular for thyroid neoplasia.⁶⁻⁹ Although a cancer stem cell has not yet been isolated from human thyroid cancer tissue, the strong appearance of an epithelial-to-mesenchymal transition in the morphology of thyroid anaplastic carcinoma suggests the potential of cancer stem cells. Additional well-known pathways of carcinogenesis include the germline alterations predisposing to tumor development and conventional agents such as exposure to ionizing radiation or environmental exposures to endocrine disruptors and thyroid mimics.

Growth factors such as growth hormone (GH), insulin-like growth factors (IGFs), and epidermal growth factor (EGF) also play an integral role in the pathogenesis of endocrine neoplasia.¹⁰ However, normally differentiated and neoplastic endocrine cells respond similarly to growth factor stimulation, and it is unlikely that any single growth factor can cause transformation of a cell. The role of growth factors within endocrine oncogenesis therefore is thought to be that of a tumor promoter, whereby growth factor-stimulated hyperplasia increases the probability of mutational events that may eventually release the cell from growth control.

Pituitary Tumors

Primary tumors of the pituitary gland can arise from several different cell types, including corticotrophs, somatotrophs, thyrotrophs, gonadotrophs, and lactotrophs. The clinical signs associated with these tumors depend on their size and their secretory properties. The most clinically important pituitary tumor in the dog is the corticotroph adenoma. This tumor produces chronically excessive amounts of adrenocorticotrophic hormone (ACTH) and is associated with clinical signs of hypercortisolism. In the cat, the most clinically significant pituitary tumor is the GH-secreting somatotroph adenoma, causing acromegaly and insulin-resistant diabetes mellitus.

Nonfunctional pituitary tumors become clinically significant when they are large enough to cause neurologic signs, including obtundation, stupor, behavioral changes, decreased appetite, gait abnormalities, seizures, blindness, and other cranial nerve abnormalities.¹¹⁻¹⁴ In one case series, pituitary tumors were the second most common type of secondary brain tumor, accounting for 25% of 177 cases.¹⁵

The pituitary gland may also be affected by secondary tumors, either through direct extension or by metastatic spread from a distant site.¹ Locally invasive or compressive primary or secondary pituitary tumors also have the potential to cause loss of pituitary function, resulting in hypothyroidism, hypocortisolism, gonadal atrophy, or central diabetes insipidus.¹⁶

Pituitary Corticotroph Tumors: Hypercortisolism (Hyperadrenocorticism or Cushing's Syndrome)

Pathogenesis

Hypercortisolism (HC), also termed *hyperadrenocorticism* or *Cushing's syndrome*, is a common endocrine disease of middle-aged and older dogs.¹⁷ It is uncommon in cats. This clinical syndrome results from chronic exposure to excessive blood levels of glucocorticoids. Naturally occurring canine and feline HC are almost always either pituitary-dependent or a result of excessive glucocorticoid secretion from an adrenocortical tumor.^{17,18}

HC in human medicine is differentiated into ACTH-dependent and ACTH-independent disease.¹⁹ ACTH-dependent disease most commonly results from excessive ACTH secretion from a pituitary tumor but may also be caused by ectopic secretion of ACTH from an extrapituitary tumor or very rarely by ectopic secretion of corticotrophin-releasing hormone (CRH). There is only one clearly documented report of ectopic ACTH secretion in the dog,²⁰ which may reflect the fact that it is very difficult to prove this diagnosis.

Pituitary-dependent hypercortisolism (PDH) is the most common form of spontaneous HC in dogs and cats, accounting for 80% to 85% of cases in these species.^{17,18,21,22} This disorder is a consequence of autonomous synthesis and secretion of ACTH from a pituitary tumor. The secretion of ACTH from the pituitary tumor is chronically excessive, leading to bilateral adrenal cortical hyperplasia and hypercortisolemia. The pituitary tumor is relatively insensitive to negative feedback by cortisol and there is also a loss of hypothalamic control over ACTH release because CRH secretion is suppressed by the chronic hypercortisolemia.¹⁸

Pituitary tumors that secrete ACTH are derived from pituitary corticotroph cells. Expression of several proteins and their receptors thought to be involved in the etiology of human pituitary tumors responsible for ACTH hypersecretion has been studied. Leukemia inhibitory factor and its receptor are expressed in canine pituitary adenoma samples, although no mutations were identified in the receptor that might account for autonomous ACTH production.^{23,24} Dopamine and somatostatin receptor subtype expressions were evaluated in normal canine pituitary tissue and compared to adenomatous tissue. The type 2 dopamine receptor and somatostatin type 2 (SST2) receptor were most prevalent in canine pituitary tumors but expressed at low levels.

Pituitary tumors may be described as macrotumors or microtumors.¹⁸ The latter distinction is derived from human medicine: microtumors are less than 1 cm in diameter and macrotumors are 1 cm or larger in diameter. The use of this size-based classification is controversial in veterinary medicine, at least partly due to variability in patient size and conformation.¹² Pituitary tumors may also be classified as noninvasive adenomas, invasive adenomas, or adenocarcinomas. The latter term is reserved for tumors in which there is demonstrated evidence of metastatic disease. Canine pituitary

adenocarcinomas are uncommon. A recent study of 33 dogs with pituitary tumors, all of which underwent necropsy evaluation after brain imaging, revealed that 61% had a pituitary adenoma, 33% had an invasive adenoma, and 6% had an adenocarcinoma.¹¹

ACTH-independent HC refers to disease of the adrenal cortex, including neoplasia, dysplasia, or hyperplasia. This will be referred to as adrenal-dependent hypercortisolism (ADH) in this chapter and will be discussed in the section on adrenal gland tumors.

Clinical Findings and Diagnostic Evaluation in Dogs

The majority of dogs with PDH are older than 9 years of age, and female dogs are slightly overrepresented. Breed predispositions have been noted in Dachshunds, terrier breeds, German shepherd dogs, and poodle breeds.^{17,18} The onset of canine Cushing's syndrome is often slow, and the signs may progress slowly. Affected dogs are often not considered by their owners to be sick; they have a good appetite and do not show signs such as vomiting, diarrhea, coughing, or weight loss. Because spontaneous HC typically affects elderly dogs, the signs may initially be attributed to normal aging. The progress of the disorder is generally insidious, but eventually the owners of affected dogs seek veterinary care due to the frustration associated with signs such as polyuria, polydipsia, panting, and exercise intolerance.

The most common signs of canine HC are polyuria, polydipsia, polyphagia, abdominal enlargement, lethargy, panting, exercise intolerance, muscle weakness, alopecia, calcinosis cutis, thinning of the skin, and reproductive abnormalities.^{17,18} These clinical signs are the result of the gluconeogenic, catabolic, immunosuppressive, and antiinflammatory effects of excessive circulating glucocorticoids. Glucose intolerance and insulin resistance have been shown to be common in dogs with HC,²⁵ and overt diabetes mellitus may develop in as many as 10% of these patients.²⁶ The catabolic effects of glucocorticoids result in thinning of the skin, poor wound healing, muscle wasting, and decreased bone density.²⁷ The antiinflammatory and immunosuppressive properties of glucocorticoids are responsible for the increased susceptibility to infections in dogs with hypercortisolemia.¹⁷ This most often manifests as an increased incidence of urinary tract infections in canine patients. In one study, 46% of dogs with HC were found to have a urinary tract infection.²⁸

More serious disorders associated with canine HC include hypertension and proteinuria.^{17,29} These are particularly insidious because they may not initially be associated with overt clinical signs. If untreated, hypertension can damage end organs such as the eye, brain, and kidneys, leading to complications that may include blindness or glomerular disease. Over 80% of dogs with canine Cushing's syndrome were reported to be hypertensive in one case series.³⁰ Although uncommon, pulmonary thromboembolism is another potentially life-threatening complication of HC.^{26,31}

Spontaneous HC is suspected when typical clinical signs are detected in a middle-aged or older dog that is not receiving exogenous glucocorticoid therapy. The diagnosis is further investigated when initial laboratory tests reveal classic abnormalities, including neutrophilia, monocytosis, lymphopenia, eosinopenia, thrombocytosis, elevated serum alkaline phosphatase levels, a mild increase in alanine aminotransferase, and elevated cholesterol. Urinalysis may demonstrate minimally concentrated, isosthenuric, or hyposthenuric urine. Ancillary tests recommended in dogs suspected to have HC include urine culture, blood pressure measurement, thoracic radiographs, and abdominal ultrasonography.^{17,18,32}

The tests that are most commonly used to screen for the presence of spontaneous HC are the urine cortisol:creatinine ratio, the ACTH stimulation test, and the low-dose dexamethasone suppression test (LDDST). These tests should be reserved for patients in which there is clinical suspicion of HC. Due to space considerations, readers are directed to several excellent references for more in-depth discussion of the comparative aspects of these tests.^{17,18,32,33} The urine cortisol:creatinine ratio is very sensitive, but specificity is low and it should not be used in patients with concurrent illnesses. The ACTH stimulation test has a lower sensitivity and higher specificity in comparison to the LDDST. The LDDST is highly sensitive and therefore less likely to give false-negative results. An additional advantage of this test is that it is capable of distinguishing between PDH and ADH in some cases.¹⁷ For patients with typical clinical signs of HC and positive results on the ACTH stimulation test, further testing is generally performed to differentiate between pituitary and adrenal-dependent disease. These further tests are also necessary after positive results on the LDDST for those patients in which this test does not additionally confirm the presence of PDH. Differentiation tests that are commonly used include the high-dose dexamethasone suppression test (HDDST) and the measurement of endogenous ACTH levels.^{17,32} In dogs with ADH, it is expected that endogenous ACTH levels will be low due to feedback inhibition of pituitary ACTH release by chronic hypercortisolemia. Patients with PDH would be expected to have elevated endogenous ACTH levels.³⁴⁻³⁶

The results of imaging studies, including ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI), may assist in differentiating between PDH and ADH.^{17,18} Abdominal ultrasonography should not be used as a screening test for HC, and it should also not be used as the sole mechanism for discriminating between PDH and ADH; however, it can provide useful information.^{35,37-40} The adrenals of patients with PDH are often bilaterally enlarged with increased thickness, and they typically maintain a normal shape and are homogeneous in echogenicity.³⁷ However, there can be overlap between adrenal gland measurements in normal dogs, dogs with nonadrenal disease, and dogs with HC. Adrenal gland asymmetry may also be detected in dogs with PDH due to nodular hyperplasia. In some cases, this appearance can be confused with adrenal neoplasia. To further complicate the diagnostic accuracy of abdominal ultrasonography, a small percentage of patients with HC may have concurrent PDH and ADH.⁴¹ Bilateral adrenal tumors may also occur, including both functional or nonfunctional adrenocortical tumors and pheochromocytomas.^{39,42-45} Thus ultrasound findings must always be interpreted concurrently with clinical findings and endocrine test results. Abdominal CT is used less commonly than ultrasonography to evaluate the adrenals, but CT findings may also assist in the discrimination between PDH and ADH.^{46,47} This technique also demonstrates overlap between adrenal volume in dogs with PDH and dogs with nonadrenal disease and also confirms that dogs with PDH can have nodular adrenal lesions.⁴⁷

Although 80% to 85% of dogs with spontaneous HC have PDH and almost all cases of PDH are due to the presence of a pituitary tumor, canine patients do not often show clinical signs directly referable to the local effects of the tumor.¹⁷ The vast majority of cases are initially presented for veterinary care due to the typical clinical signs of HC, as described previously. Pituitary tumors may be detected by CT,^{12,14} dynamic CT,^{48,49} MRI,^{12,14,50-53} or dynamic MRI⁵⁴; however, these techniques are not routinely performed in all dogs that are diagnosed with PDH.¹² In most cases, the diagnosis is based on the presence of typical clinical signs and

clinicopathologic changes of hypercortisolemia, together with the results of endocrine testing.¹⁷

As noted previously, brain imaging is not performed in the great majority of dogs with PDH, and most receive treatment to address adrenal hyperfunction rather than the pituitary tumor itself. This is most likely due to the fact that brain imaging and pituitary surgery or radiation therapy (RT) are not affordable or accessible to many clients. Although medical therapy for PDH (see later) has a long history of successful use, it is important to note that the pituitary lesion in dogs with PDH will progress over time. In a study of 13 dogs that underwent MRI evaluation of the brain at the time of diagnosis of PDH and before medical therapy was instituted, 8 of the dogs had a visible pituitary mass and none of the dogs had clinical signs of neurologic disease.⁵³ Four of the dogs showed enlargement of the pituitary tumor on MRI 1 year later, and a pituitary tumor was also detected in two dogs that did not have a visible mass on the initial MRI. Two of the 13 dogs had developed neurologic signs at the time of the 1-year follow-up MRI. A recent study evaluated diagnostic imaging findings in 157 dogs with PDH with and without neurologic signs.¹⁴ Central nervous system (CNS)-specific signs such as circling, seizures, or ataxia were neither sensitive nor specific for predicting the presence of a pituitary macrotumor. However, signs such as lethargy, mental dullness, and decreased appetite were highly specific for detection of a pituitary macrotumor but not highly sensitive. Other studies have also documented that mentation and appetite changes are the most common signs associated with pituitary tumors.^{13,55}

When considering brain imaging in dogs with PDH, several factors should be taken into account: 40% to 50% of dogs with PDH have tumors that are not visible on CT or MRI, and these dogs are unlikely to develop neurologic signs associated with the tumor; 15% to 25% of dogs with PDH are at risk for the development of neurologic signs due to the presence of an enlarging tumor, and these signs typically develop within 6 to 18 months of the diagnosis of PDH; brain imaging may be helpful in predicting dogs likely to develop neurologic signs in patients with PDH that initially have no signs directly attributable to the tumor¹⁷; and if RT is being considered, early treatment will likely improve prognosis.^{13,56} It is also possible that measurement of plasma ACTH precursor concentrations could help in the selection of patients for brain imaging because it has been shown that pro-opiomelanocortin/pro-ACTH levels in plasma are correlated with pituitary tumor size in dogs with PDH.^{57,58} However, plasma cortisol concentrations at baseline and 4 or 8 hours after administration of a low dose of dexamethasone do not appear to correlate with the development of neurologic signs.¹⁴

Treatment of Canine Pituitary-Dependent Hypercortisolism

Options for management of canine PDH include medical therapies that address adrenocortical hyperfunction, as well as direct treatment of the pituitary lesion through surgery or RT. The decision to treat patients with PDH should be guided by the patient's quality of life, the owner's wishes, and consideration of the risks of serious or life-threatening complications of the disease, such as neurologic signs, hypertension, recurrent infections, or thromboembolic disease. Some dogs with PDH have mild clinical signs and a good quality of life when initially diagnosed. There is no clear evidence that early treatment of these patients is necessary to improve long-term survival. Treatment of PDH is rarely an emergency, and more serious concurrent illnesses should be addressed first.

Surgery

Hypophysectomy is the treatment of choice for PDH in humans and can be successful in dogs.⁵⁹⁻⁶¹ A recent prospective study of 150 dogs that underwent transsphenoidal hypophysectomy for PDH gave 1-, 2-, 3-, and 4-year estimated survival rates of 84%, 76%, 72%, and 68%, respectively. Twelve dogs died postoperatively and 127 went into remission, with 32 of those dogs later experiencing a recurrence of disease. Complications included central diabetes insipidus in 53% of dogs undergoing remission and incomplete hypophysectomy in nine dogs. The overall success rate of transsphenoidal hypophysectomy was determined to be 65% in this study.⁶¹ Unfortunately, this approach requires a high degree of specialized surgical skill and experience, and it is not readily available outside of one center in Europe.

Radiation Therapy

There are several reports of the successful use of radiation in the treatment of canine PDH.^{13,56,62-64} Dow and colleagues treated six dogs with functional pituitary macrotumors with 40 Gy given in 10 equal fractions. Median survival was reported to be 743 days, neurologic signs resolved in all dogs, and ACTH levels remained high for at least 1 year after therapy.⁶² Goossens et al used cobalt 60 RT to treat six dogs with PDH caused by a pituitary tumor that was detectable on MRI, and tumor size was significantly reduced in all cases. However, clinical signs of PDH were only adequately controlled in one dog.⁶³ Théon and Feldman evaluated the effects of megavoltage irradiation on pituitary tumors in 24 dogs with neurologic signs. Ten dogs experienced complete remission of neurologic signs, and another 10 dogs achieved partial remission. As in previous studies, these authors noted a correlation between relative tumor size and the severity of neurologic signs in dogs with pituitary tumors. They also noted a correlation between tumor size and remission of neurologic signs after pituitary irradiation, suggesting that early treatment of these tumors should improve prognosis, although control of ACTH secretion was unlikely.⁵⁶ A recent retrospective study of RT for the treatment of pituitary masses demonstrated significantly improved survival times and control of neurologic signs in 19 dogs that received RT, compared to 27 untreated control dogs with pituitary masses. Mean survival time in the treated group was 1405 days, compared to 551 days in the nonirradiated group. The 1-, 2-, and 3-year estimated survival rates were 93%, 87%, and 55% for the irradiated and 45%, 32%, and 25% for the nonirradiated dogs, respectively. Treated dogs with smaller tumors lived longer than those with larger tumors, again suggesting that early diagnosis and treatment of pituitary tumors are beneficial. Five of 14 dogs with PDH in this study were reported to show resolution of clinical signs of HC together with at least one normal ACTH stimulation test result after completion of RT.¹³

Most of the reports that document the use of RT for the treatment of pituitary tumors in dogs provide little detailed information regarding the progress of the clinical syndrome of HC in these patients.^{13,56,62-64} Thus, although RT appears effective in controlling neurologic signs and increasing survival,¹³ it is difficult to predict the endocrinologic outcome of RT for dogs with PDH.

Medical Therapy

A detailed review of medical therapy for PDH is beyond the scope of this chapter, and the information here should be regarded as a brief introduction. Readers are strongly encouraged to consult any of several excellent discussions of this subject before initiating medical therapy in any patient.^{17,18} The two medications that are most commonly used to treat PDH in dogs are mitotane

and trilostane. Other drugs such as ketoconazole, L-deprenyl, metyrapone, bromocriptine, and retinoic acid are used rarely and will not be discussed further in this chapter.

Mitotane (o,p'-DDD, Lysodren) is a potent adrenocorticolytic agent that is cytotoxic to the adrenal cortex, particularly the zona fasciculata and zona reticularis. Mitotane therapy is most commonly divided into a loading or induction phase that typically lasts between 5 and 9 days, followed by maintenance therapy. Patients should be monitored very closely during loading with mitotane, and this phase is regarded as being complete when the post-ACTH cortisol is less than 5 (or 4) µg/dL on an ACTH stimulation test. This usually coincides with a decrease in appetite or in polyuria/polydipsia in the patient, but not always. Thus an ACTH stimulation test should be performed as soon as the patient shows any change in clinical signs or within 5 to 7 days of starting mitotane, whichever occurs first. A typical induction dose of mitotane is 30 to 50 mg/kg day, and maintenance therapy with mitotane typically requires giving the initial induction dose weekly, although the exact dose depends on how the patient responded to the induction course. Thus a patient requiring 500 mg per day for induction will often be started on 500 mg weekly for maintenance, with the weekly dose typically divided between 2 to 4 days. The mitotane dose should always be divided when possible and given with food, and clients should be instructed to wear gloves when handling the medication. An ACTH stimulation test is typically performed 1 month after initiation of maintenance therapy and then several times a year thereafter. The frequency of testing will depend on the dog's clinical signs and the frequency with which dose adjustments are made. An alternate mitotane protocol has also been described for dogs with PDH. In contrast to the selective adrenocorticolysis protocol summarized earlier, which is designed to spare the zona glomerulosa, mitotane can also be used to achieve nonselective complete adrenocorticolysis. In this protocol, the medication is given at a higher dose for a fixed time period, and glucocorticoid and mineralocorticoid supplementation are started shortly after initiation of mitotane therapy and continued thereafter.⁶⁵ This approach may be preferred in dogs that relapse frequently on the selective protocol and in dogs with concurrent diabetes mellitus. It may also be less expensive in some patients. However, this protocol was reported to cause adverse effects requiring temporary cessation of therapy in 29% of dogs, and relapse occurred in 39% of dogs that underwent remission.⁶⁵ Thus the use of this protocol does not eliminate the need for careful long-term follow-up.

Trilostane (Vetoryl) is an orally active synthetic corticosteroid analog that competitively inhibits 3-β-hydroxysteroid dehydrogenase.⁶⁶ This enzyme is essential for synthesis of cortisol and other steroids such as corticosterone, androstenedione, and aldosterone. Trilostane has been used in Europe for several years for the management of canine PDH and recently was approved for use in the United States. Initial publications suggested a starting dose of trilostane of around 6 mg/kg once daily, with the first follow-up ACTH stimulation test performed at 10 to 14 days.⁶⁷ As more experience has been gained with this medication, it has become apparent that much lower starting doses may be effective and potentially associated with fewer adverse effects.^{68,69} It is also appears that trilostane should be used twice daily in most dogs,⁷⁰ with a recent study suggesting a starting dose in the range of 0.2-1.1 mg/kg every 12 hours.⁶⁸ The response to trilostane is also monitored with ACTH stimulation testing, with the aim of achieving a post-ACTH cortisol value in the range of 1.5 to 5 µg/dL. Values slightly above this range are acceptable if the patient's clinical signs are well controlled.⁶⁶ It is recommended that the ACTH stimulation test be started 3 to 4

• **FIGURE 25-1** A 14-year-old male neutered domestic longhair cat with pituitary-dependent hypercortisolism. **A**, The patient appears weak, with muscle atrophy and an unkempt haircoat. **B**, The abdomen has a potbellied appearance with thinning of the skin.

hours after trilostane is given for dogs receiving twice daily therapy. Although most authors suggest performing the first ACTH stimulation test at 10 to 14 days, the reason for this is unclear because the results of this test generally continue to improve beyond 2 weeks, even when the dose is not changed.

Both mitotane and trilostane are highly effective for the treatment of canine PDH. A retrospective comparison of mitotane and trilostane in dogs with PDH demonstrated a median survival time (MST) of 662 days for trilostane and 708 days for mitotane.⁷¹ It is important to note that both mitotane and trilostane can have adverse effects in dogs. Both medications can be associated with anorexia, vomiting, or diarrhea, and both can cause hypoadrenocorticism.^{17,18,66} Trilostane therapy has also been associated with adrenal necrosis.^{72,73} It should also be noted that the adrenal glands of dogs receiving mitotane therapy for PDH will become smaller over time, whereas the adrenal glands of dogs on trilostane therapy have been shown to increase in size by 6 weeks after initiation of therapy and may develop an irregular nodular ultrasonographic appearance after several months of therapy.⁷⁴

In deciding whether to use trilostane or mitotane in a patient with PDH, the clinician should consider his or her own comfort level and experience with each medication and also the wishes of the client. A cost analysis should also be performed, including the cost of follow-up office visits and ACTH stimulation testing, as well as the cost of the medication itself. It is recommended that clinicians exercise caution in using compounded trilostane as any potential cost savings may be offset by the highly variable drug concentrations that have been detected within and between batches of medications obtained from compounding pharmacies.⁷⁵

Feline Pituitary-Dependent Hypercortisolism

As noted previously, approximately 80% to 85% of cases of HC in the cat are due to pituitary disease.^{17,21,22} However, Cushing's syndrome is considerably less common in cats than in dogs. The mean age of cats with PDH is reported to be around 10 years.²¹ Feline HC is often associated with insulin-resistant diabetes mellitus, with signs of polyuria, polydipsia, polyphagia, and weight loss. Cats with HC often have a potbellied appearance due to hepatomegaly and muscle weakness, and they frequently have thin fragile skin that tears and bruises easily. Additional signs include lethargy,

generalized muscle atrophy, weakness, alopecia, and an unkempt haircoat (Figure 25-1). On routine laboratory testing, elevated alkaline phosphatase is much less frequently detected in cats with HC compared to dogs. Cats may have elevated alanine aminotransferase, hypercholesterolemia, azotemia, and minimally concentrated urine. Hyperglycemia and glycosuria are expected in cats with concurrent diabetes mellitus. No consistent complete blood count (CBC) changes have been reported in cats with HC.^{21,22}

Tests used to screen for spontaneous HC in cats include the urine cortisol:creatinine ratio, the ACTH stimulation test, and the LDDST. It is important to note that the details of these protocols differ between dogs and cats, and readers are directed to more complete references for further information.^{21,22} The HDDST, endogenous ACTH levels, and abdominal ultrasound examination may be used to assist in differentiation of PDH from ADH in the cat.

Because PDH is relatively uncommon in the cat, there are few case series and case reports on which to base treatment recommendations.^{76,77} Direct treatment of the pituitary tumor has been reported, with either surgical hypophysectomy or RT.^{59,78-80} Surgical bilateral adrenalectomy has also been described and was considered the treatment of choice for some time.⁸¹ However, these cats are often poor surgical candidates, they have poor healing ability, and complications are common. Laparoscopic adrenalectomy is potentially a better option for these patients because the incisions are much smaller and more likely to heal; however, this has not yet been reported in cats with PDH. Medical therapy with trilostane may be a reasonable option for these cats, based on the authors' experience and a small number of published cases.^{82,83} This drug could be used as the sole therapy or to prepare cats for surgery or RT.

Pituitary Somatotroph Tumors (Feline Acromegaly)

Feline acromegaly is a disease of older cats resulting from chronic excessive GH secretion, usually from a functional somatotroph adenoma of the pars distalis of the pituitary gland.⁸⁴ Feline acromegaly has historically been regarded as a rare condition; however, recent findings suggest that it may be significantly underdiagnosed. In a study of 184 diabetic cats, 59 had markedly increased IGF-1 concentrations, and acromegaly was confirmed in 17 of 18 cats that

• **FIGURE 25-2** A and B, A 12-year-old female spayed domestic longhair cat with acromegaly due to a pituitary tumor. Note the broad forehead and large mandible.

were examined by CT, MRI, or necropsy.⁸⁵ These findings have prompted the suggestion that any cat with clinical features of acromegaly, including insulin resistance, should be screened for this disorder.⁸⁶

Acromegaly is reported to be more common in male cats, with no apparent breed predilection, and most affected cats are middle-aged or older.⁸⁷ The typical history is of insulin-resistant diabetes mellitus, with affected cats requiring 10 to 20 units of insulin per dose or more, often with inadequate control of the diabetes. This insulin resistance is due to a GH-induced postreceptor defect in the action of insulin on target cells. Affected cats remain polyuric, polydipsic, and polyphagic and continue to gain weight. Most cats with poorly regulated diabetes mellitus will lose weight, and therefore weight gain in this situation is highly suggestive of feline acromegaly. The physical changes of acromegaly develop slowly and are often not noted by the owner until they are advanced. These changes may include enlarged feet, broadening of the face, protrusion of the mandible (Figure 25-2), increased spacing between the teeth, and abdominal enlargement.^{85,87-90} Owners of affected cats also frequently note noisy or stertorous breathing or respiratory stridor.^{85,89-91} Physical examination may reveal additional abnormalities, such as enlarged abdominal organs and cardiac murmurs, arrhythmias, or a gallop rhythm.^{85,87,90}

Neurologic signs associated with the pituitary tumor appear to be generally uncommon but may be underrecognized or underreported. Lethargy, mental dullness, or impaired vision may occur but can often be subtle. Affected cats may also demonstrate signs of diabetic neuropathy or lameness, possibly due to acromegaly-associated arthropathy.^{85,87} Additional complications of acromegaly may include cardiac disease and protein-losing nephropathy.⁸⁷

Acromegaly is the result of excessive GH secretion from a pituitary gland tumor, and elevated GH levels have been reported in several cats with acromegaly.* Overlap between GH values in diabetic cats with and without acromegaly has also been noted.⁹³ An ovine GH assay has been validated for the diagnosis of feline

acromegaly and is available in Europe.⁹⁴ This assay clearly differentiated between normal cats and cats with acromegaly. Unfortunately, at the time of writing, a feline GH assay was not reliably available in the United States.

The physical changes in patients with acromegaly are due to the anabolic effects of GH, which are mediated by peripherally synthesized IGF-1.⁸⁴ This hormone is predominantly produced in the liver, and levels of IGF-1 increase in the presence of chronically increased GH production. Because GH secretion may be pulsatile, even in some acromegalics, and because it has a short half-life, increased serum IGF-1 has been suggested to be a more sensitive test for acromegaly because it may reflect GH levels over the preceding 24 hours.^{84,86} Serum IGF-1 values are widely reported in acromegalic cats.* A recent study confirmed that IGF-1 measurement is a useful screening test for feline acromegaly, with sensitivity and specificity of 84% and 92%, respectively.⁸⁹ There was no difference in serum IGF-1 concentrations among well-controlled diabetic cats, poorly controlled diabetic cats, and healthy cats.⁸⁹ The highest IGF-1 noted in a diabetic cat was 153 nM, with a normal reference range of 12-92 nM; thus there is some overlap between the IGF-1 values found in acromegalic cats and those found in poorly regulated diabetic cats. However, it is these authors' experience that IGF-1 levels in cats with acromegaly are usually at least twice the value of the high end of the reference range. Feline IGF-1 measurement is currently readily available to veterinarians in the United States, and this test should be considered in cats with diabetes mellitus that appear to be insulin resistant.⁸⁶

The presence of a pituitary tumor can be demonstrated by either CT or MRI in cats with acromegaly, and both have been reported in the literature.[†] MRI is likely more sensitive than CT,⁸⁵ but both imaging modalities may reveal a normal pituitary in a cat with acromegaly, if the size of the mass is below the limit of detection.

Treatment options for acromegaly in human medicine include surgery, conventional external-beam RT, stereotactic RT (SRT), and

*References 63, 79, 85, 87, 91-96.

*References 79, 84, 85, 89, 91, 96-101.

†References 63, 79, 85, 87, 89, 95-100, 102.

medical therapy.¹⁰³⁻¹⁰⁵ Some of these therapies are also used in feline patients, but not all are available and many have not been adequately evaluated in cats.

In humans, transsphenoidal surgery to remove the pituitary tumor is generally regarded as the treatment of choice¹⁰⁶; however, there are only rare reports of the use of surgery for treatment of feline acromegaly.^{79,96,99}

RT is rarely used as a first-line therapy in human medicine.¹⁰⁵ In contrast, RT is the treatment for feline acromegaly that is most widely reported in the veterinary literature.* Conventional fractionated RT is administered in multiple fractions typically spread over a period of weeks. Protocols range from 5 fractions given weekly to as many as 20 fractions given over a period of 4 weeks.^{80,98,108} A recent study showed that RT improved diabetic control in 13 of 14 cats, although IGF-1 concentrations did not correlate with this improved control.¹⁰⁰ Improved control of diabetes mellitus has also been noted in other studies.[†]

There are few reports of long-term follow-up of acromegalic cats receiving RT; thus it is difficult to assess the risk of complications of this modality in this species. Published case reports and case series of cats receiving conventional RT suggest that short- and long-term adverse effects of this therapy are relatively uncommon.^{80,100,107,108}

Disadvantages of RT as a treatment for feline acromegaly include cost, availability, and the necessity for repeated anesthetic events. The latter disadvantage can be lessened by the use of SRT (see Chapter 12). SRT is widely used in the treatment of pituitary tumors in human patients.¹⁰⁹ There is one case series in veterinary medicine in which cats with pituitary tumors received treatment with a linear accelerator-based modified radiosurgical approach.¹⁰¹ Cats received a single large dose of radiation, but it was delivered in a nonconformal fashion. The technique was reported to be safe and effective. At Colorado State University (CSU), SRT is routinely used in the treatment of feline acromegaly, with promising results.¹¹⁰ Cats typically receive 2 to 4 fractions of radiation administered over a period of up to 5 days. This offers considerable advantages in terms of owner time commitment and the risks of anesthesia and hospitalization in elderly diabetic cats.

Medical therapy for acromegaly is commonly used in humans, either as a first-line treatment or as an adjunct to surgery or RT. The classes of drugs used are somatostatin analogs, GH-receptor antagonists, and dopamine agonists.¹⁰³⁻¹⁰⁶ GH-receptor antagonists have not been evaluated in cats, and dopamine agonists do not appear to be useful in this species.¹¹¹

Somatostatin analogs, also termed *somatostatin receptor ligands* (SRLs), bind to somatostatin receptors, suppressing the release of GH from the pituitary gland. The medications are available as long- or short-acting preparations, and response to SRLs is assessed by measurement of IGF-1 and GH levels and tumor size and evaluation of clinical signs.¹⁰³ Octreotide has been evaluated in a small number of cats with acromegaly. In five cats, short-acting octreotide was used for up to 4 weeks, with no apparent improvement in GH levels.^{87,92} However, a more recent study showed that GH levels were significantly decreased for up to 120 minutes postinjection in five cats with acromegaly that received a single dose of octreotide.⁹⁵ These studies used the short-acting form of octreotide and were performed over a very short time period without assessment of clinical response. A study is currently underway at CSU to evaluate

the use of a long-acting octreotide preparation for the treatment of feline acromegaly.

For many cats with acromegaly, insulin therapy is the only treatment that is available or acceptable to the owner. In general, these patients should receive the amount of insulin that is necessary to control their diabetes, although adequate blood glucose regulation can be difficult to achieve in many cases. The use of home blood glucose monitoring, with close cooperation between the owner and veterinarian, is strongly recommended. The feeding of a low-carbohydrate diet may also be beneficial.¹¹¹ It should be expected that these patients will receive insulin doses in the range of 10 to 20 units per dose or more. Concurrent illnesses and complications of acromegaly and diabetes mellitus should also be addressed.

The short-term prognosis for cats diagnosed with acromegaly is generally fair to good, but the long-term prognosis is poor. Patients may succumb to cardiac or renal failure, neurologic disease, or complications of poorly regulated diabetes mellitus.⁸⁴ The median survival was reported to be 20.5 months in one case series.⁸⁷

Adrenal Gland Neoplasia

The prevalence of primary adrenal gland tumors in the dog and cat is difficult to discern from the literature. A search of the Veterinary Medical Database from 1985 to 1996 revealed that primary adrenal tumors were reported in approximately 0.17% to 0.76% of pet dogs (representing 1% to 2% of all canine tumors) and 0.03% of cats (representing 0.2% of feline tumors).¹¹² However, this likely underestimates the true prevalence because gross pathologic or histopathologic records were not available for the majority of these patients. For dogs and cats undergoing necropsy or adrenal surgery, it appears that tumors of the adrenal cortex are more common than those of the medulla. A retrospective study of patients with adrenal tumors identified from surgical biopsies or necropsy during a 20-year period at the University of California, Davis (UC Davis), demonstrated that 195 (41%) of 472 neoplastic canine adrenal lesions were adrenocortical tumors (154 adenomas; 41 carcinomas), 151 (32%) were pheochromocytomas (84 benign; 67 malignant), and 126 (27%) were metastatic lesions.¹¹³ Of 20 feline adrenal neoplastic lesions, 6 (30%) were adrenocortical tumors (3 adenoma; 3 carcinoma), 2 (10%) were pheochromocytomas (1 benign; 1 malignant), and 12 (60%) were metastatic lesions.¹¹³ Less than half of these metastatic lesions were grossly visible at necropsy. Lymphoma was the most common cancer to spread to the adrenal glands in both species. Other metastatic tumors commonly identified in the dog included hemangiosarcoma, mammary carcinoma, histiocytic sarcoma, pulmonary carcinoma, and melanoma. Right and left adrenal glands were affected equally, as were the cortex and medulla. The only notable exception was that all metastatic melanomas were restricted to the adrenal medulla.¹¹³

A number of case series in the last decade have documented the outcome of adrenal surgery in dogs.^{43,45,114,115} When the data from these cases are combined, a histopathologic diagnosis was reported for a total of 191 adrenal tumors, with 153 (80%) arising from the adrenal cortex and 33 (17%) from the medulla. The remaining tumors included two myelolipomas and one each of fibrosarcoma, lymphoma, and leiomyosarcoma. For the adrenocortical tumors that were further classified, 63 of 125 (50%) were carcinomas, 54 of 125 (43%) were adenomas, and 8 of 125 (6%) were described as hyperplastic lesions. It is important to note the bias inherent in these data because only dogs that underwent surgery are included.

Advanced imaging techniques such as ultrasonography, CT, and MRI have now greatly enhanced our ability to identify both clinical

*References 63, 80, 87, 90, 98, 100, 107, 108.

†References 63, 80, 87, 98, 107, 108.

and subclinical adrenal abnormalities,^{38,43,116,117} and it appears that the adrenal gland is affected with neoplasia more commonly than was previously suspected. The ability to detect these adrenal lesions also leads to diagnostic dilemmas as the clinician attempts to elucidate whether the lesions arise from the cortex or medulla, whether they are functional or nonfunctional, and whether they are benign or malignant. Functional adrenal tumors may secrete cortisol, catecholamines, aldosterone, sex hormones, or steroid hormone precursors, and these may be associated with specific clinical and laboratory findings. Hormonal testing and imaging techniques are central to the diagnostic evaluation of these patients so that the most appropriate course of therapy can be pursued. Large adrenal masses may be detected on abdominal radiographs,^{34,118,119} and the presence of mineralization suggests an adrenal tumor; however, this finding is not highly specific, and it cannot be used to differentiate between benign and malignant masses. The normal ultrasonographic appearance of canine adrenal glands has been described,^{116,120} and there are many reports of the ultrasonographic appearance of adrenal lesions in dogs. Abdominal ultrasound examination is frequently used to detect metastatic disease and determine the local invasiveness of adrenal tumors. Ultrasonography has been reported to be 80% to 100% sensitive and approximately 90% specific for the detection of adrenal tumor invasion into the caudal vena cava.^{43,45}

The CT appearance of both normal and abnormal canine adrenal glands has been described.^{46,119,121-124} Contrast-enhanced CT has been shown to provide accurate preoperative evaluation of canine adrenal masses, with 92% sensitivity and 100% specificity for the detection of vascular invasion by adrenal tumors.¹²⁵ The MRI appearance of presumed normal canine adrenal glands has also been described,¹²⁶ but as yet there are few reports that document the systematic use of MRI for evaluation of adrenal lesions in dogs and cats. The characterization of adrenal lesions by imaging techniques has undergone recent significant advancement in human medicine. Malignant and benign lesions can frequently be differentiated using modalities such as contrast-enhanced ultrasound, CT densitometry, CT washout characteristics, chemical shift MRI, positron emission tomography (PET), and PET/CT.¹²⁷⁻¹³⁰ Most of these techniques have yet to be explored in veterinary medicine.

Adrenocortical Tumors

Functional cortisol-secreting tumors of the adrenal cortex are responsible for 15% to 20% of canine and feline cases of naturally occurring HC, with PDH accounting for 80% to 85%.^{17,18,21,22} In the necropsy and surgical biopsy data from UC Davis, adrenocortical adenomas were almost 4 times more common than carcinomas¹¹³; however, the functionality of these tumors was not assessed. A review of case reports of functional adrenocortical tumors in dogs suggests that approximately 60% of surgically removed tumors are carcinomas.* Adenomas are typically smaller, with tumors larger than 2 cm more likely to be carcinomas.¹³² However, adenomas up to 6 cm have been reported.¹⁷ On histopathologic examination, adenocarcinomas appear more likely to exhibit a trabecular growth pattern, peripheral fibrosis, capsular invasion, necrosis, and/or hemorrhage.¹³² They are less likely to exhibit cytoplasmic vacuolization, extramedullary hematopoiesis, or fibrin thrombi. Approximately 20% of adrenocortical carcinomas locally invade into the phrenicoabdominal vein, with extension into the renal vein and/or caudal vena cava.^{42,131} Intravascular invasion has the potential to

cause severe and life-threatening intraabdominal or retroperitoneal hemorrhage.^{45,133} Metastasis was identified in approximately 50% of dogs with adrenocortical carcinomas.^{131,132} Although involvement of the liver and lungs is most common, other organs reported to be affected with metastases include the kidney, ovary, mesenteric lymph nodes, peritoneal cavity, and thyroid gland. In the absence of evidence of tumor invasion or metastasis, there are no consistent clinical, biochemical, or imaging findings that reliably distinguish between functional adrenocortical adenomas and carcinomas in dogs and cats. The cellular and molecular events underlying the development of canine adrenocortical tumors are unknown. Recent studies have demonstrated downregulation of ACTH receptors in cortisol-secreting adrenocortical carcinomas and ectopic expression of gastric-inhibitory polypeptide and vasopressin (2) receptor proteins in neoplastic zona fasciculata tissue from canine adrenocortical tumors.^{134,135} The significance of these findings in tumorigenesis remains to be elucidated.

Dogs with PDH and dogs with ADH are similar in age, but almost 50% of dogs with ADH weigh more than 20 kg, compared to approximately 25% of dogs with PDH.³⁴ The historic features, physical changes, clinical signs, and basic laboratory findings in canine Cushing's syndrome are essentially the same in dogs with PDH and dogs with ADH and are described in the earlier section on **Pituitary Corticotroph Tumors**. Similar screening tests are used to confirm the diagnosis of HC; however, the sensitivity of the ACTH stimulation test for the diagnosis of ADH is only around 60%.³² Thus the LDDST is a better screening test when ADH is suspected. Dogs with ADH fail to show suppression on the LDDST or the HDDST, and differentiation from PDH is generally determined by imaging studies, particularly abdominal ultrasound examination,³³ and measurement of endogenous ACTH levels.³⁴ Excessive secretion of glucocorticoids by a functional adrenocortical adenoma or adenocarcinoma occurs independent of pituitary control, with secondary atrophy of the normal adrenocortical cells in both the affected and contralateral adrenal glands. Unfortunately the functional atrophy of the contralateral adrenal gland is not always easily detected on abdominal ultrasonography.³⁹ This finding, termed *equivocal adrenal asymmetry*, is also observed in some dogs with PDH, associated with asymmetric hyperplasia of the glands.³⁷ The results of a recent ultrasound study of dogs with equivocal adrenal asymmetry suggested that a maximal dorsoventral thickness of the smaller gland of less than 5.00 mm was consistent with a diagnosis of ADH.⁴⁰

Surgical adrenalectomy is the treatment of choice for dogs with ADH,* and surgical management is further addressed later. An early case series of dogs undergoing surgical removal of adrenocortical tumors revealed that 60% of patients were euthanized during surgery or died within 2 weeks.¹³¹ In a more recent case series, the perioperative mortality has ranged from 19% to 28%.^{17,42,43,136} In one series of 144 dogs undergoing surgical removal of a functional adrenocortical tumor, the prognosis was described as excellent for patients that survived 4 weeks postoperatively, with an average life expectancy of 3 years. Nine of 144 dogs were euthanized at the time of surgery, and 29 dogs died during surgery or immediately postoperatively.¹⁷ Median survival times of 230 to 778 days have been reported for dogs undergoing adrenalectomy for adrenal carcinomas,^{42,114,115} compared to a MST of 687.5 days for dogs with adenomas.¹¹⁴ Laparoscopic adrenalectomy has been described for noninvasive adrenocortical carcinomas in a small number of dogs; further studies are needed to determine if this technique can reduce

*References 34, 42, 45, 114, 115, 131.

*References 42, 43, 114, 115, 131, 136.

the postoperative complications associated with conventional surgery.¹³⁷

Medical therapy for ADH should be used when surgery is not a good option for the patient or client, or it may be used prior to adrenalectomy in patients that are significantly debilitated by HC. The primary options for medical therapy are mitotane and trilostane. Treatment with mitotane as an alternative to surgical adrenalectomy utilizes the drug as a true cytotoxic agent. Detailed protocols are readily available,¹³⁸ and clinicians should be aware that this approach typically requires higher doses of mitotane than those used in PDH¹³⁹ and that relapses are common. However, this treatment can be effective, with a mean survival of 16.4 months reported in a series of 32 dogs. Dogs without evidence of metastatic disease may show a better response to mitotane therapy.¹⁴⁰ Trilostane is not a cytotoxic drug, but it has been used to successfully manage patients with ADH,^{68,69,141} including a small number of dogs with metastatic disease.¹⁴² A recent retrospective study comparing trilostane and mitotane in dogs with ADH reported a median survival of 353 days with trilostane therapy compared to 102 days for mitotane. These survival times were not significantly different; however, this study did further confirm that survival times are significantly decreased in the presence of metastatic disease.¹⁴³

Functional adrenocortical tumors in dogs and cats can also secrete one or more sex hormones, including androstenedione, progesterone, 17-hydroxyprogesterone, testosterone, and estradiol. These tumors may or may not secrete glucocorticoids, and some patients have been reported to show signs of HC in the absence of elevated cortisol levels on typical screening tests.¹⁴⁴⁻¹⁴⁹ Signs of sex hormone excess appear uncommon in dogs with sex-hormone-secreting adrenal tumors but have been reported in a small number of cats.^{150,151}

Aldosterone-secreting adrenocortical tumors have rarely been reported in dogs,¹⁵²⁻¹⁵⁴ but there is increasing evidence that primary hyperaldosteronism (also termed *primary aldosteronism* or *Conn's syndrome*) may be an underrecognized condition in cats. In fact, it has been suggested to be the most common adrenocortical disorder in this species.¹⁵⁵ Affected cats are middle-aged or older, and the most common clinical sign is muscle weakness due to hypokalemia. Arterial hypertension is frequently detected in these patients and may be associated with ocular changes. Routine laboratory testing often reveals hypokalemia, but hyponatremia is uncommon, presumably due to intact water balance mechanisms in these patients. Some cats may also have evidence of concurrent renal disease. Plasma aldosterone can be measured in cats, and normal or elevated levels in the face of hypokalemia would be regarded as inappropriate. However, definitive diagnosis using aldosterone levels is difficult without the measurement of plasma renin activity and the calculation of an aldosterone:renin ratio.¹⁵⁶ Unfortunately, a plasma renin activity assay is not readily available to most clinicians. An oral fludrocortisone suppression test has recently been suggested to be a useful diagnostic test for feline hyperaldosteronism,¹⁵⁷ but the use of this tool has not yet been widely reported. Imaging of the adrenal glands is often performed in the evaluation of these patients,^{158,159} and this may distinguish between unilateral and bilateral lesions and also reveal the presence of vascular invasion or metastatic disease. Most cats with hyperaldosteronism have an adrenal adenoma or carcinoma.¹⁶⁰ Bilateral adenomas have been reported,¹⁶⁰ and some cats have adrenal hyperplasia.¹⁵⁶ Adrenalectomy is the treatment of choice for cats with unilateral disease, and good outcomes have been reported for both adenomas and carcinomas, as well as for tumors associated with vena cava thrombosis.¹⁶⁰⁻¹⁶³ Medical management with potassium

supplementation, antihypertensive drugs, and the aldosterone antagonist spironolactone can give reasonable survival times in patients that are not surgical candidates.^{156,160,161}

Adrenal Medullary Tumors

Chromaffin cells are part of the sympathetic nervous system and are present in the adrenal medulla and other locations throughout the body. Neoplastic chromaffin cells in the adrenal medulla give rise to pheochromocytomas, which are tumors that predominantly secrete catecholamines. Chromaffin cell tumors (termed *paragangliomas* or *extraadrenal pheochromocytomas*) can arise in other parts of the body, but these are rare in veterinary medicine. Pheochromocytomas are uncommon in dogs and rare in cats.^{164,165} In past decades, the diagnosis of pheochromocytoma was most often made incidentally at necropsy,^{166,167} but these tumors are now likely to be detected antemortem because advanced abdominal imaging techniques are routinely used in small animal patients. Pheochromocytomas are generally considered to be malignant tumors in dogs.¹⁶⁴ Metastasis is reported in up to 40% of affected dogs; sites include liver, spleen, lung, regional lymph nodes, bone, and CNS.¹⁶⁶⁻¹⁶⁸ Vascular invasion by the tumor has been reported in as many as 82% of cases.^{43,45,169} This finding is not specific for pheochromocytoma because vascular invasion can also occur with adrenocortical tumors.

Pheochromocytoma is usually diagnosed in older dogs,^{164,167} and males may be overrepresented.¹⁶⁹ Catecholamine release by pheochromocytomas is typically episodic, and thus clinical signs may be intermittent and often absent at the time of physical examination. Signs may include weakness, episodic collapse, panting, anxiety, restlessness, exercise intolerance, decreased appetite, weight loss, polyuria, and polydipsia. Physical examination of dogs with pheochromocytoma may be normal due to the episodic nature of catecholamine release or may reveal tachypnea, panting, tachycardia, weakness, pallor, cardiac arrhythmias, or hypertension.^{164,166,167} Some dogs have signs referable to an abdominal mass, and acute collapse may occur secondary to tumor rupture with abdominal or retroperitoneal bleeding.¹³³ There are no consistent abnormalities on the CBC, serum biochemistry profile, or urinalysis in dogs with pheochromocytomas.

Diagnostic imaging, particularly abdominal ultrasound examination, is central to the evaluation of patients with pheochromocytoma. In many dogs, evaluation for pheochromocytoma occurs after an adrenal mass is found when abdominal ultrasonography is performed for other reasons. In addition to revealing the presence of an adrenal tumor, abdominal ultrasonography may reveal metastatic disease and is sensitive and specific for detecting vascular invasion by adrenal tumors.^{43,45} CT and MRI are the imaging modalities of choice for humans with pheochromocytomas, and early experience in canine patients has been encouraging.¹⁷⁰⁻¹⁷² Abdominal radiographs may reveal the presence of a large adrenal mass^{166,170} but are generally less informative than ultrasound examination. Thoracic radiographs are recommended to evaluate the cardiovascular system and for detection of pulmonary metastases in any patient with a suspected adrenal tumor. There are rare reports of PET or nuclear scintigraphy imaging in dogs with pheochromocytomas.^{173,174} Immunohistochemical staining for chromogranin A can distinguish pheochromocytomas from adrenocortical tumors on tissue obtained at surgery or necropsy.¹⁷⁵

Plasma and urinary concentrations of catecholamines and their metabolites are routinely measured in humans for the diagnosis of pheochromocytoma.¹⁶⁴ Recent reports have suggested that urinary catecholamine and metanephrine to creatinine ratios hold promise

as a diagnostic tool in dogs.¹⁷⁶⁻¹⁷⁸ Plasma-free metanephrine and normetanephrines have also been evaluated in cats and dogs, with encouraging preliminary results.^{165,179}

Surgery is the only definitive treatment for pheochromocytoma.^{43,164,166,167,169} This should be performed by an experienced surgical and anesthesiology team because potentially life-threatening complications, including hypertension, hypotension, cardiac arrhythmias and hemorrhage,¹⁶⁹ may occur during anesthetic induction and handling of the tumor. It has been shown that dogs receiving phenoxybenzamine, a noncompetitive α -adrenergic antagonist, prior to surgery are significantly more likely to survive adrenalectomy. Specifically, dogs that received this medication at doses ranging from 0.1 to 2.5 mg/kg every 12 hours, for a median period of 20 days, had a 13% mortality rate, compared to a mortality rate of 48% in dogs that did not receive this therapy.¹⁶⁹ Chemotherapy and RT have not been evaluated in dogs with pheochromocytoma. RT using ¹³¹I-metaiodobenzylguanidine (¹³¹I-MIBG) was recently reported in one case.¹⁸⁰

The prognosis for dogs with pheochromocytoma is affected by tumor size, presence of metastases, and local invasion. A MST of 374 days has been reported after surgical treatment of pheochromocytoma,¹¹⁴ and some dogs may survive for as long as 2 to 3 years.^{167,181} Dogs without metastatic disease that survive the perioperative period appear to have a good prognosis.¹⁶⁴

Surgical Management of Adrenal Tumors

Prior to adrenalectomy, every attempt should be made to determine whether an adrenal tumor is functional, whether there is evidence of metastatic disease, and whether there is vascular invasion. Patients suspected to have a pheochromocytoma should be treated preoperatively with phenoxybenzamine. If tachyarrhythmias are present, a β -blocker such as propranolol or atenolol may also be administered but should only be started after α -adrenergic blockade has been initiated to prevent unopposed α -adrenergic stimulation and severe hypertension.¹⁶⁴ Patients with HC due to ADH may be medically managed with trilostane or mitotane prior to surgery if they are significantly debilitated by their disease, although this is rarely necessary. The potential for intraoperative and postoperative complications associated with adrenalectomy is significant¹⁸²; these cases are best managed by an experienced team, including a surgeon, anesthesiologist, internist, and critical care specialist. Particular concerns with pheochromocytomas include cardiovascular complications and hemorrhage, as noted previously. Patients with functional adrenocortical tumors are at risk for adrenocortical insufficiency, pulmonary thromboembolism, pancreatitis, renal failure, and wound dehiscence.* Protocols are available to guide the perioperative management of adrenalectomy patients.¹⁷ At CSU, patients with pheochromocytoma are treated preoperatively with phenoxybenzamine as described earlier. Patients with functional adrenocortical tumors receive heparin and corticosteroid therapy during and after surgery. Postoperatively, an ACTH stimulation test is performed 24 to 48 hours after surgery, and electrolytes and blood glucose are measured frequently. The duration of prednisolone therapy and the necessity for mineralocorticoid supplementation are each determined on an individual case basis. For patients with adrenal tumors of unknown origin, preoperative phenoxybenzamine is recommended, and the protocol for functional adrenocortical tumors is followed, until postoperative ACTH stimulation test results and histopathology results are available to guide further management.

The overall perioperative mortality rate for dogs undergoing adrenalectomy for all adrenal tumors is around 10% to 20%,^{43,45,114,115} and MSTs of 690 to 953 days have been reported.^{114,115} A number of investigators have evaluated prognostic factors and predictors of outcome in these patients. In two studies, the presence of caval tumor thrombus did not affect perioperative morbidity and mortality, although the long-term prognosis for dogs with an adrenocortical tumor may be poorer in the presence of a thrombus.⁴³ In contrast, a more recent study suggested that vein thrombosis was associated with a poorer prognosis.¹¹⁵ In the latter study, vein thrombosis was associated with tumors with major axis length of 5 cm or larger, and the presence of metastases or tumor size of 5 cm or larger were both associated with a poorer prognosis.¹¹⁵ Large tumors were also associated with increased perioperative mortality in a series of dogs undergoing elective or emergency adrenalectomy. The dogs in this report that had emergency surgery for acute adrenal bleeding experienced a 50% perioperative mortality rate.⁴⁵

Incidental Adrenal Masses

Advances in abdominal imaging have led to the diagnostic dilemma of the incidental adrenal mass ("incidentaloma") in both human and veterinary medicine. When an incidental adrenal mass is identified in a dog or cat, a thorough history and physical examination, including blood pressure measurement and fundic examination, are indicated. Endocrinologic testing should be pursued to rule out a functional adrenocortical tumor. Given the high incidence of metastatic lesions in canine and feline adrenal glands, imaging of the thorax and abdomen should be performed to rule out another primary tumor. Aspiration cytology and ultrasound- or CT-guided biopsies are not routinely recommended for incidentalomas because of the high risk of complications and the inability to reliably differentiate benign and malignant lesions.^{38,112} Adrenalectomy should be considered for masses that are functional, locally invasive, or larger than 2.5 cm in maximum dimension. Masses smaller than 2 cm with no evidence of hormonal activity should be monitored with abdominal ultrasonography. A suggested interval is to repeat the sonogram 1 month after the initial study and then after 2, 4, and 6 months, with further intervals determined by the appearance of the mass and the clinical status of the patient.¹⁶⁴

Thyroid Gland Neoplasia in Dogs

Thyroid tumors account for 1.1% to 3.8% of all tumors in dogs.¹⁸³⁻¹⁸⁵ In necropsy studies, it is estimated that 30% to 50% of canine thyroid tumors are benign adenomas.^{183,186} A recent Veterinary Medical Database review reported that 90% of 545 canine thyroid cancers submitted to the database from veterinary teaching hospitals were carcinomas or adenocarcinomas, with 9.3% being adenomas.¹⁸⁵ Most adenomas are small, noninvasive, and clinically silent. Consequently, almost all canine thyroid masses associated with clinical signs are malignant.^{184,187,188} Thyroid tumors of follicular cell origin are subclassified as papillary, follicular, compact (solid), or anaplastic. All subgroups stain positive for thyroglobulin and thyroid transcription factor-1.¹⁸⁹⁻¹⁹¹ Papillary carcinomas are most common in humans,^{10,192} whereas follicular and compact forms are most common in dogs.^{1,184,189,193} Medullary thyroid carcinomas, also called *parafollicular* or *C-cell carcinomas*, are relatively uncommon in both humans and dogs.¹⁹¹ Positive immunohistochemical staining for calcitonin is the most accurate way to identify these tumors, but they also often stain positive for calcitonin gene-related peptide, thyroid transcription factor-1, chromogranin A, and neuron-specific enolase.^{175,189-191,194}

*References 17, 42, 43, 114, 131, 182.

The etiology of thyroid neoplasia in dogs is largely unknown. The molecular pathogenesis of thyroid neoplasia is best defined in humans.^{5,7,10} The classic hypothesis involves a discrete series of mutations. Activation of receptor tyrosine kinases such as *RET* and *TRK* are common in papillary carcinomas, activating mutations in *RAS* are frequently identified in follicular carcinomas, and inactivation of *p53* is commonly seen in anaplastic carcinomas. Thyroid-stimulating hormone (TSH) or the TSH receptor may play a contributing role in carcinogenesis.¹⁹⁵ The TSH receptor in humans with thyroid neoplasia is frequently affected with either hyperfunctioning or silencing mutations. Canine thyroid tumors retain TSH receptors, and hypothyroid beagles that did not receive thyroid hormone supplementation had an increased incidence of thyroid tumors, presumably due to TSH trophic effects without feedback in the context of potential mutations.^{196,197} Thyroid irradiation is associated with an increased incidence of thyroid tumors in all species, including humans, rodents, and dogs.^{1,10,186,192} In dogs, one report identified a *p53* mutation in 1 of 23 primary thyroid carcinomas.¹⁹⁸ Another report confirmed trisomy 18 in a canine thyroid adenoma.¹⁹⁹

Thyroid tumors typically arise in older dogs, with a median reported age of 9 to 11 years.^{184,193,200-202} A sex predilection has not been reported. Predilection of breeds for thyroid tumors includes golden retrievers, beagles, Boxers, and Siberian huskies.^{184,185} Familial medullary thyroid carcinoma has also been described in a family of dogs with an Alaskan malamute influence.²⁰³ The right and left lobes are affected with equal frequency in canine thyroid tumors, and as many as 60% of patients will have bilateral involvement.^{200,204} On rare occasions, ectopic thyroid tissue can give rise to tumors at the base of the tongue, cervical ventral neck, cranial mediastinum, and heart.²⁰⁴⁻²¹⁰ Up to 35% to 40% of dogs have visible metastatic disease at initial presentation, and as many as 80% will ultimately develop metastasis.^{184,191,204,211} Metastatic potential is reported to increase when the primary tumor volume exceeds 23 cm³ and approaches 100% when tumor volume exceeds 100 cm³.¹⁸⁶ Bilateral tumors are 16 times more likely to metastasize than unilateral tumors.²⁰⁰ The lungs and regional lymph nodes, including the retropharyngeal, cranial cervical, and mandibular lymph nodes, are affected most commonly, but a wide variety of tissues can be affected. Medullary carcinomas may have a lower metastatic potential than follicular and solid carcinomas.¹⁹¹

The majority of canine thyroid carcinomas are nonfunctional. Based on clinical signs and serum T₄ concentrations, approximately 60% of patients are euthyroid, 30% are hypothyroid secondary to destruction of the normal thyroid parenchyma, and 10% are hyperthyroid.^{188,202,212-214} Most dogs are presented for a palpable ventral cervical mass.^{184,191,193} Less common abnormalities include coughing, rapid breathing, dyspnea, dysphagia, dysphonia (change in bark), laryngeal paralysis, Horner's syndrome, and facial edema. Acute severe hemorrhage can occur secondary to invasion into the cervical vasculature.²¹⁵ In addition to clinical signs referable to the physical thyroid mass, dogs with hyperthyroidism frequently exhibit polyphagia, weight loss, muscle wasting, polyuria, and polydipsia.^{188,212-214}

The differential diagnosis for a mass in the region of the thyroid gland in dogs includes abscesses or granulomas, salivary mucoceles, lymphatic metastasis from tonsillar squamous cell carcinoma, lymphoma, carotid body tumor, and sarcomas. In humans, thyroid cytology is very accurate for identifying thyroid tumors and distinguishing whether they are benign or malignant.^{10,192} Accuracy of cytology in dogs with thyroid masses is reported to be problematic. In several reports, cytology confirms the mass to be of thyroid origin in only half of affected dogs, and definitive recognition of

malignancy occurs less often.^{184,188} Use of a needle without physical aspiration and thorough examination of the feathered edge may improve diagnostic accuracy. Malignant thyroid tumors have a higher vascular density than normal thyroid tissue and benign tumors,²⁰² and hemodilution is a common problem (see Chapter 6). This increased vascularity also adds significant risk to large core needle biopsy procedures.

Routine staging for dogs with thyroid carcinoma includes general health assessment with laboratory evaluation (CBC, serum biochemistry profile, and urinalysis), three-view thoracic radiographs, and cytologic or histologic evaluation of the mandibular lymph nodes. Cervical ultrasonography can be used to confirm if a mass is of thyroid origin and to assess invasiveness and vascularity.^{216,217} The retropharyngeal and cranial cervical lymph nodes can also be examined for evidence of metastasis. The MRI and CT appearances of the normal canine thyroid have been described,^{218,219} and these modalities are useful in the investigation of cervical masses in the dog and in the staging of thyroid carcinomas.^{215,218,219} Scintigraphy using ^{99m}Tc-pertechnetate or, less commonly, radioactive iodine (¹²³I or ¹³¹I) is performed primarily to identify local residual disease after surgery, ectopic tumors, or metastatic disease.* Most primary tumors are visualized, although the pattern of uptake is often heterogeneous. Metastatic disease is identified less consistently. To be visualized with scintigraphy, a thyroid tumor must be capable of trapping ^{99m}Tc-pertechnetate or trapping and organifying ¹²³I or ¹³¹I. It may or may not be able to complete the remaining steps necessary for synthesis and secretion of functional thyroid hormone.

Treatment of canine thyroid carcinomas is dictated by the size of the mass, extent of invasion, presence or absence of gross metastatic disease, and any concurrent symptoms of thyrotoxicosis. Surgical excision provides the best outcome with the least morbidity when tumors are freely movable without extensive deep tissue invasion.^{191,193,222} Thyroidectomy is not recommended when the tumor is not freely movable in all directions or extensively invades adjacent structures, including major vasculature, recurrent laryngeal nerves, the vagosympathetic trunk, the larynx, the trachea, or the esophagus. Extensive hemorrhage can result from the vascularity of the tumor, invasion into adjacent blood vessels, and local coagulopathies.²⁰² Other potential complications of thyroidectomy include hypocalcemia due to hypoparathyroidism if the parathyroid glands are removed, damage to the recurrent laryngeal nerve(s), and hypothyroidism after bilateral thyroidectomy.^{193,223} According to limited, retrospective data sets, it was estimated that only 25% to 50% of thyroid carcinomas were mobile and amenable to surgery at the time of initial diagnosis.^{191,193} Palpation under anesthesia and preoperative imaging are current general recommendations for surgical evaluation at the authors' institution, with some extracapsular extension and invasion considered acceptable. Median survival after thyroidectomy is around 3 years if the tumor is freely movable and 6 to 12 months if the tumor is more invasive.^{191,193} Recently, a report describing resection of mobile, discrete bilateral thyroid tumors in a limited number of dogs suggested reasonable overall survival with persistent postoperative management of thyroid and parathyroid endocrinopathies.²²⁴

Nonresectable thyroid carcinomas may be managed with radiation as a primary therapy or as a means to achieve a surgical option. External-beam RT is used most commonly for dogs. One study evaluated definitive RT (48 Gy delivered in 4 Gy fractions on an alternate-day schedule) in 25 dogs with unresectable thyroid

*References 184, 200, 204, 217, 220, 221.

carcinomas and no visible metastasis.²⁰⁰ Tumors either stabilized or decreased in size. The time to maximal tumor reduction ranged from 8 to 22 months in dogs whose tumors did respond. The progression-free survival rates were 80% at 1 year and 72% at 3 years. The first cause of treatment failure was local progression in three dogs, metastasis in four dogs, and concurrent local progression and metastasis in three dogs. Limited information exists regarding the use of definitive radiation in the adjuvant or neoadjuvant settings.^{201,225} This same RT protocol described was evaluated in an additional eight dogs, seven of which had undergone incomplete thyroidectomy prior to irradiation.²⁰¹ Median survival was just over 2 years (range 1 to 3 years). None developed local recurrence, although four died from metastatic disease. Radiation-induced toxicoses to the larynx, trachea, and esophagus are usually well tolerated. Hypothyroidism may develop months to years after treatment.^{200,225}

For dogs that present with gross metastatic disease, hypofractionated RT may still provide effective palliation of the primary tumor, due to a generally slow rate of progression in both the primary and metastatic lesions. In a study evaluating palliative RT as the sole treatment modality, 13 dogs received 36 Gy in four weekly 9 Gy fractions.²¹¹ Complete or partial reduction of the primary tumor occurred in one and nine dogs, respectively. Local progression occurred in five dogs, 11 to 24 months after irradiation. Gross metastatic disease was present in five dogs at initial presentation and developed in an additional two dogs during the study. Overall median survival was around 22 months, with local and metastatic progression occurring equally in all dogs.

In humans with well-differentiated thyroid carcinoma, ¹³¹I is routinely administered postoperatively to destroy occult microscopic local or metastatic carcinoma.^{10,192} Experience with ¹³¹I thyroid ablation in dogs is substantial, with two recent, relatively large clinical studies providing evidence of efficacy of ¹³¹I for advanced unresectable, metastatic, or residual thyroid neoplasia.^{226,227} Collectively, from all reports, over 80 dogs with stage II (2 to 5 cm diameter; fixed or unfixed), stage III (>5 cm diameter, fixed or unfixed), or stage IV metastatic thyroid carcinoma have received ¹³¹I for the intent of managing tumor burden and clinical signs. MSTs for stage II and III patients exceed 2 years, and dogs with metastatic carcinoma experienced survival times of approximately 1 year. Such results are comparable to external-beam RT. Interestingly, similar survival times were noted in dogs that were hypothyroid, euthyroid, or hyperthyroid. Recommendations for ¹³¹I dosimetry remain unresolved. Fatal myelosuppression was observed in three dogs in one report, although no specific dose-effect relationship was defined.²²⁷ The biologic effect both on tumor and normal tissue is a complex function of ¹³¹I uptake that depends on extent of the tumor burden, degree of organification and excretion of ¹³¹I, bone marrow sensitivity, and administered dose of radiation. Dosing regimens are currently empiric in dogs but could be more carefully defined by administering a ¹³¹I tracer for calculation of definitive dosing, as in humans. Until such time as dosing is individualized, the maximum dose administered should be 0.2 GBq/kg (5 mCi/kg), and bone marrow monitoring posttreatment is recommended. Additional doses may be administered if necessary, as determined by persistent hyperthyroidism or activity on posttreatment nuclear scans. Dogs receiving ¹³¹I will require thyroid hormone supplementation.

Chemotherapy has been evaluated in dogs with thyroid tumors. Of those dogs treated with either doxorubicin or cisplatin, 30% to 50% demonstrated a partial response (>50% reduction in volume).^{228,229} Individual responses have also been reported using

mitoxantrone or actinomycin D.^{230,231} Chemotherapy may be considered for dogs with large nonresectable primary tumors and/or gross metastatic disease.

Thyroid Gland Neoplasia in Cats

Hyperthyroidism (thyrotoxicosis) is the most common endocrine disorder in cats.^{232,233} It is almost always caused by a primary thyroid abnormality that results in the production and secretion of excessive thyroxine (T₄) and triiodothyronine (T₃). Multinodular adenomatous hyperplasia is identified histologically in the majority of thyrotoxic cats.^{1,232-234} Both thyroid lobes are affected in 70% to 90% of cases,²³³⁻²³⁵ although they may be asymmetrically enlarged at the time of diagnosis. Malignant carcinomas are the least common cause of hyperthyroidism, occurring in only 1% to 3% of thyrotoxic cats.^{1,232-234} Nonfunctional thyroid carcinomas are uncommon.^{236,237} Feline thyroid carcinomas are more locally invasive than their benign counterparts, and their metastatic rate is up to 70%, with regional lymph nodes and lungs being affected most commonly.^{238,239}

TSH from the pituitary regulates both the secretion of thyroid hormones and the proliferation of thyroid cells. The interaction of TSH with receptors on the surface of thyroid cells activates G protein-mediated cyclic adenosine monophosphate (cAMP) signal transduction pathways.²⁴⁰ Some of the components of the TSH receptor-G protein-cAMP system have therefore been evaluated for changes that could result in feline hyperthyroidism. Decreased expression of the inhibitory subunit G_{iα} has been identified in adenomatous feline thyroid glands,²⁴¹ and a further study demonstrated that G₁₂ was decreased.²⁴² Mutations in the G_{sα} gene were also reported in 4 of 10 hyperthyroid cats evaluated.²⁴³ Both of these changes could lead to stimulation of adenyl cyclase with the potential for increased levels of cAMP. However, a more recent study showed that ligand-stimulated activation of G proteins was the same in thyroid cell membranes obtained from hyperthyroid and euthyroid cats.²⁴⁴ Therefore the role of alterations in inherent G(s) or G(i) activities in the pathogenesis of hyperthyroidism in cats remains unresolved. Mutations in the TSH receptor in hyperthyroid cats have been investigated and were not documented in early studies.^{243,245} However, a more recent study that targeted hyperplastic or adenomatous thyroid nodules from 50 hyperthyroid cats detected a total of 11 different mutations in the TSH receptor gene.²⁴⁶ Oncogene expression has also been evaluated in thyroid tissue from hyperthyroid cats. Overexpression of one or more RAS oncogenes was identified in adenomas and hyperplasias from 18 of 18 cats diagnosed with hyperthyroidism but not in adjacent normal thyroid tissue or in thyroid tissue from 14 unaffected cats.²⁴⁷ In the same tumors that overexpressed RAS, Bcl-2 and p53 proteins were undetectable using immunohistochemistry.

Hyperthyroidism was not recognized as a clinical disorder in cats until 1979, yet currently it is estimated to affect as many as 1 out of every 300 cats.²³² This may reflect a true increase in incidence, heightened awareness and testing by veterinarians, or both. If there has been a true increased incidence, environmental factors may have contributed. Several risk factors have been associated with hyperthyroidism, including the consumption of commercially prepared canned cat food, indoor residence, use of cat litter, exposure to brominated flame retardants, and use of flea-control products, but none have been incriminated as a primary inciting cause.²⁴⁸⁻²⁵³ The iodine content of cat food has also been suggested to play a role in the development of hyperthyroidism, but this relationship is unproven.²⁵⁴

Due to space constraints, only a brief overview of the clinical features, diagnosis, and treatment of feline hyperthyroidism will be presented here, with an emphasis on malignant thyroid tumors. The reader is directed to several excellent and detailed reviews of feline hyperthyroidism for additional information.^{232,233}

Most hyperthyroid cats are older, with mean and median ages of 12 to 15 years.^{234,255-257} The disease is rare in cats under 8 years of age.²³² There is no gender predilection, but Siamese and Himalayan breeds were found in one study to be at decreased risk.²⁴⁸ The most common signs reported by owners include weight loss, polyphagia, polydipsia, polyuria, gastrointestinal signs (vomiting, diarrhea, increased stool production), and increased activity.^{232,233,235,255} Additional abnormalities commonly identified on physical examination include the presence of a palpable thyroid nodule, cardiovascular abnormalities (tachycardia, heart murmur, gallop rhythm, premature beats), and poor hair coat. Hyperthyroidism may also contribute to hypertension in elderly cats.²⁵⁸ Definitive diagnosis of hyperthyroidism is routinely based on an elevated serum total T₄ level.^{235,255,259} Less than 10% of hyperthyroid cats will have a total T₄ level within the reference range. This is usually due to normal fluctuations in serum thyroid hormone concentrations and/or the presence of concurrent nonthyroidal illness.^{259,260} If hyperthyroidism is suspected in a cat with a normal total T₄ level, total T₄ should be measured again in 1 to 2 weeks, particularly if the total T₄ is in the upper half of the reference range. Free T₄ measurement may also aid in the diagnosis of hyperthyroidism when total T₄ is within the reference range. However, this test should only be used in cats with clinical signs of hyperthyroidism in which the total T₄ is high-normal. Free T₄ concentrations can be high in cats with nonthyroidal illness,^{259,261,262} and these patients would be expected to have low total T₄ values. Thus free T₄ should never be used as a screening test for hyperthyroidism. For those patients in which hyperthyroidism is suspected, but not confirmed by measurement of total or free T₄, additional tests have been used to confirm the diagnosis. These include thyroid scintigraphy (see later), the TSH stimulation test or the thyrotropin-releasing hormone (TRH) stimulation test (both of which are of limited utility^{263,264}), or the triiodothyronine suppression test. The latter test can provide useful information but relies on significant owner and patient compliance.^{265,266} Thyroid function tests cannot be used to differentiate benign and malignant tumors.

Staging for cats with hyperthyroidism should minimally include baseline CBC, serum biochemistry profile, urinalysis, and blood pressure measurement. Additional diagnostic tests that may be recommended include thoracic radiography, electrocardiography, and echocardiography.^{235,267,268} ^{99m}Tc-pertechnetate scintigraphy is very useful for determining the anatomic extent of functional thyroid tissue and planning therapy, as well as for confirming the diagnosis.^{257,269} Unilateral uptake occurs in cats with a solitary adenoma and atrophy of the normal contralateral gland. Bilateral uptake, even if asymmetric, is indicative of adenomatous hyperplasia. Thyroid scintigraphy is particularly useful for revealing the presence of ectopic thyroid tissue or multiple areas of hyperfunctioning thyroid tissue. In one study, these were present in 20% to 25% of hyperthyroid cats undergoing thyroid scintigraphy.²⁵⁷ Metastatic disease due to thyroid carcinoma may be detected by scintigraphy,²³⁵ and the pattern of uptake of radionuclide may be suggestive of the presence of malignant disease; however, two recent studies demonstrated that there are no scintigraphic findings that can definitively distinguish between benign and malignant thyroid disease in all hyperthyroid cats.^{237,257}

Treatment options for feline hyperthyroidism include antithyroid drugs, surgical thyroidectomy, and radioactive iodine therapy.

Methimazole is the most widely used antithyroid drug in North America.²⁷⁰ Carbimazole is more widely used in Europe.²⁷¹ These are thioureyne drugs that inhibit thyroid hormone synthesis by interfering with oxidation of iodide, iodination of tyrosyl residues in thyroglobulin, and the coupling of iodotyrosines to iodothyronines.^{233,270,271} These drugs are often used for assessing the effect of resolution of hyperthyroidism on renal function (see later) and preparing a cat for anesthesia and thyroidectomy. They are also frequently used as a long-term treatment modality, but it is important to note that they have no antitumor activity and no cytotoxic effect on thyroid follicular cells. Methimazole and carbimazole are both highly effective in lowering serum thyroid hormone concentrations and controlling hyperthyroidism. Carbimazole is converted to methimazole in the body, and a dose of 5 mg of carbimazole is considered to be equivalent to 3 mg of methimazole.²³³ Methimazole is usually administered at a starting dose of 2.5 mg orally twice daily for 2 weeks. Based on clinical signs and serum T₄ levels, the dosage can be adjusted incrementally, with monitoring of serum T₄ concentrations. Once-daily administration of methimazole has been reported to be less effective,²⁷² but this approach can be successful in some cats, particularly those that need very low doses to control their disease. Carbimazole is usually administered 2 to 3 times daily, but a controlled-release formulation has recently been shown to be effective when administered once daily.²⁷³ For cats that are difficult to medicate orally or that have gastrointestinal side-effects, methimazole compounded in pluronic lecithin organogel (PLO) can be applied topically to the pinna.²⁷⁴⁻²⁷⁶ Transdermal carbimazole has also been shown to be effective.²⁷⁷ Approximately 10% to 15% of patients treated with methimazole develop adverse effects, including lethargy, anorexia, vomiting, facial excoriations, hepatotoxicity, and blood dyscrasias.^{232,233,270,278} Gastrointestinal side effects are often self-limiting or can be avoided by transdermal drug delivery. Blood dyscrasias are rare but most likely to occur within the first 3 months of treatment; therefore CBCs should be monitored most closely during that time. Medication should be discontinued in patients that experience facial excoriations, blood dyscrasias, or hepatotoxicity. Carbimazole or transdermal methimazole are likely to have the same effects and should therefore not be used in patients experiencing these adverse effects with oral methimazole. Other medical therapies that have been used to treat feline hyperthyroidism include ipodate and iopanoic acid^{279,280}; however, these are unlikely to be effective for long-term therapy and are rarely used. A potentially interesting new development in the management of feline hyperthyroidism is the use of an iodine-restricted diet to control the disease.²⁸¹⁻²⁸³ At the time of writing, a feline prescription diet for the management of hyperthyroidism had been recently released, but no peer-reviewed manuscript was available for evaluation.

Definitive therapy for feline hyperthyroidism currently consists of surgical thyroidectomy or radioactive iodine. Surgical excision of the affected thyroid lobe(s) is an effective treatment.^{234,284,285} Although the majority of cats have bilateral disease, this may be asymmetric and not apparent on palpation or surgical exploration. Thus thyroid scintigraphy is recommended before surgery in order to determine whether unilateral or bilateral thyroidectomy is necessary.²³⁴ Intracapsular and extracapsular thyroidectomy techniques have been described.^{284,286} Intracapsular techniques better preserve adjacent parathyroid tissue, whereas extracapsular ones more consistently remove all hyperplastic or neoplastic thyroid tissue. Hyperthyroid cats are often poor anesthetic candidates, and pre-operative stabilization with oral antithyroid medications or β -adrenergic blockers should be considered. The most significant

intraoperative complication of thyroidectomy in hyperthyroid cats may be cardiac dysrhythmias.²⁸⁵ Otherwise, the surgery is not considered to be technically demanding.^{234,285} Hypocalcemia due to transient hypoparathyroidism is the most commonly reported postoperative complication, with rates ranging from 6% to 15%.^{234,285} Other potential complications include hypothyroidism and rarely, Horner's syndrome or laryngeal paralysis. All surgically excised tissue should be submitted for histopathology to rule out the presence of a thyroid carcinoma. Cats with thyroid carcinoma that undergo thyroidectomy usually experience improvement in their clinical signs, but most remain hyperthyroid or develop recurrent hyperthyroidism within a few months of surgery.^{236,238} Cats with ectopic hyperplastic thyroid tissue are also at risk for postoperative recurrence of hyperthyroidism.²³⁴ Radioactive iodine therapy is recommended for patients with thyroid carcinoma or ectopic hyperplastic thyroid tissue.

Radioactive iodine, or ¹³¹I therapy, is often regarded as the treatment of choice for cats with hyperthyroidism, particularly those with bilateral thyroid hyperplasia, ectopic thyroid tissue, or thyroid carcinoma.^{236-238,287,288} ¹³¹I has a half-life of 8 days and emits both beta and gamma radiation.²³³ Beta particles, which account for 80% of the tissue damage, travel a maximum of 2 mm in tissue and have an average path length of 400 μ m. They therefore cause local destruction while sparing adjacent hypoplastic thyroid tissue, parathyroid glands, and other cervical structures. The dose of ¹³¹I can be calculated from tracer kinetic studies,^{289,290} but these are rarely performed. The administration of a fixed dose of ¹³¹I is reported by some authors,^{288,291} whereas others use doses that take into account variables, such as the number or size of thyroid nodules, patient body weight, severity of clinical signs, or magnitude of elevation in serum total T₄.^{232,287,292,293} ¹³¹I is usually administered by the subcutaneous route because it is effective, less stressful for the patient, and safer for personnel.²⁹² For cats with benign thyroid disease, ¹³¹I doses typically range from 2.0 to 6.0 mCi based on clinical signs, serum T₄ concentration, and thyroid nodule size.²⁸⁷ Using this dosing strategy, less than 5% of cats remain hyperthyroid or experience relapse of clinical signs. When this occurs, a second treatment is usually curative. The proportion of cats that develop persistent hypothyroidism requiring thyroid hormone supplementation varies among studies, and the risk of this has been suggested to be higher in cats with scintigraphic evidence of bilateral disease.²⁹⁴ Cats with thyroid carcinomas usually have larger tumor burdens, and malignant cells trap and retain iodine less efficiently.^{233,236} These cats are therefore treated with higher ablative doses of ¹³¹I, in the range of 20 to 30 mCi.^{232,233,236-238} In one large study of hyperthyroid cats treated with ¹³¹I, median survival was reported to be 2 years, with survival rates at 1, 2, and 3 years of 89%, 72%, and 52%, respectively.²⁸⁷ The most common causes of death or euthanasia were cancer or renal disease,²⁸⁷ which is perhaps not surprising in this population of older cats. A more recent study reported a MST of 4 years for cats treated with ¹³¹I, compared to 2 years for cats that were treated with methimazole.²⁵⁶

Ultrasound-guided percutaneous ethanol injection has also been evaluated as a treatment for feline hyperthyroidism. Cats with solitary adenomas have a good response, with resolution of clinical signs persisting for over 12 months.²⁹⁵ This technique is not recommended for bilateral hyperplasia.²⁹⁶ Ultrasound-guided percutaneous radiofrequency heat ablation has been shown to be ineffective for long-term control of hyperthyroidism.²⁹⁷ Given the ready availability of permanent effective treatments for unilateral or bilateral disease, these alternative treatments are unlikely to be widely used.

Chronic kidney disease (CKD) is a relatively common problem in older cats, and therefore concurrent CKD and hyperthyroidism frequently occur in this population. The hyperthyroid state increases glomerular filtration rate (GFR)^{298,299} and therefore decreases serum creatinine values. The implications of this are that hyperthyroid cats with normal serum creatinine values may in fact have concurrent "masked" CKD and that decline in renal function is a risk of all effective forms of treatment of feline hyperthyroidism, with some nonazotemic cats becoming azotemic, or the potential for worsening of preexisting azotemia.^{293,298,300,301} This decline in renal function occurs within 1 month after treatment and appears to remain stable thereafter.^{293,302} Measurement of pretreatment GFR may help to predict which cats will become azotemic after resolution of hyperthyroidism^{293,301}; however, this is impractical for most patients. Unfortunately, no readily available clinical data can predict the effects of therapy on renal function in an individual cat.³⁰³ For this reason, many clinicians recommend a therapeutic trial with methimazole prior to definitive therapy for feline hyperthyroidism.³⁰³ This may have value in providing owners with information about the likely consequence of therapy for these cats, but regardless of the detected change in renal function, effective therapy for hyperthyroidism is still required in these patients. One recent study showed that the development of azotemia was not significantly associated with survival of cats treated for hyperthyroidism,³⁰⁴ but the same group also demonstrated a significantly shorter survival time in cats with iatrogenic hypothyroidism that became azotemic after treatment compared with those that remained nonazotemic.³⁰⁵

Parathyroid Tumors

Parathyroid tumors are uncommon in dogs and rare in cats. These tumors arise from the chief cells and autonomously secrete parathyroid hormone (PTH), leading to hypercalcemia due to primary hyperparathyroidism. Hypercalcemia is the result of direct effects of PTH on bone and the kidneys and indirect effects on the intestine, mediated by vitamin D. Approximately 90% of dogs and cats with primary hyperparathyroidism have a single parathyroid mass,³⁰⁶⁻³¹² with adenomas being most commonly diagnosed and cystadenoma, carcinoma, and hyperplasia diagnosed less frequently.^{306-309,311-314} Two or more parathyroid masses may be found in some canine and feline patients, and they may not necessarily all be of the same histologic type. The presence of four hyperplastic parathyroid masses should prompt careful evaluation for causes of secondary hyperparathyroidism.

Primary hyperparathyroidism is most common in older dogs and cats, with reported mean ages of approximately 11 years in dogs^{309,311} and 13 years in cats.³⁰⁶ A breed predisposition has been reported in Keeshonden dogs^{307,309,314,315} in which the disease appears to follow an autosomal dominant mode of inheritance, although the affected gene has not yet been identified in this breed.^{314,315} It is not clear if there is a breed predilection in cats. The clinical signs of hyperparathyroidism result from hypercalcemia and include polyuria/polydipsia, weakness, lethargy, decreased appetite, weight loss, muscle wasting, vomiting, and trembling. It is not uncommon for owners to detect no clinical signs in affected dogs or cats, with hypercalcemia being diagnosed when blood is drawn for a routine health check or for investigation of an unrelated problem. However, it is also the case that signs can be subtle and are only recognized in retrospect after the hyperparathyroidism has been treated and the hypercalcemia has resolved. In a large case series, the most common clinical problems reported in dogs with

hyperparathyroidism were related to the lower urinary tract, usually associated with urolithiasis or urinary tract infection.³⁰⁹ Specific physical examination abnormalities are rare in dogs and cats, although a palpable parathyroid mass has been reported in a proportion of cats with hyperparathyroidism; the latter is an extremely rare finding in dogs.^{308,309}

Hyperparathyroidism is usually diagnosed after finding hypercalcemia on a serum biochemistry profile, either as an incidental finding or when investigating a problem such as calcium oxalate urolithiasis, polyuria/polydipsia, or weakness. The presence of hypercalcemia should be verified by measuring serum ionized calcium, with appropriate careful sample handling.^{316,317} There are many causes of hypercalcemia in dogs and cats,^{318,319} and diagnostic tests may be performed to investigate several possible causes simultaneously. The reader is directed to Chapter 5 for a further discussion of the causes of hypercalcemia in dogs and cats. Hypercalcemia due to primary hyperparathyroidism is often accompanied by hypophosphatemia or serum inorganic phosphorus at the low end of the reference range. This finding is not pathognomonic for hyperparathyroidism and can be associated with humoral hypercalcemia of malignancy, but it can assist in ranking the differential diagnoses because vitamin D toxicosis and renal failure would both be expected to cause hyperphosphatemia. The diagnosis of hyperparathyroidism is confirmed by documenting an inappropriately high serum PTH level in the presence of ionized hypercalcemia. It is important to note that PTH is frequently within the reference range in patients with hyperparathyroidism, with 73% of cases reported to have a normal PTH in one large series.³⁰⁹ A normal PTH in the face of hypercalcemia is an abnormal finding because PTH should be suppressed as calcium increases. The lack of suppression of PTH is indicative of loss of the normal negative feedback effects of calcium due to autonomous hormone secretion by hyperplastic or neoplastic parathyroid tissue. Ultrasound examination of the neck is commonly used in the diagnosis of hyperparathyroidism in dogs and cats^{309,310,320,321} and is particularly useful for localizing parathyroid mass(es) prior to surgery or other ablative procedures. The normal sonographic appearance of canine parathyroid glands has been described,³²² and parathyroid masses as small as 3 mm in greatest diameter have been identified ultrasonographically.³⁰⁹ Parathyroid scintigraphy and selective venous sampling to assess local PTH concentrations do not appear to be helpful in localizing hyperplastic or neoplastic parathyroid tissue.^{320,323,324}

The management of hypercalcemia is further addressed in Chapter 5. Primary hyperparathyroidism in dogs and cats is usually associated with slowly progressing hypercalcemia, and the calcium elevation itself rarely requires emergency treatment. Hypercalcemia is a risk factor for renal failure. Mechanisms include altered glomerular capillary permeability, decreased renal blood flow, and mineralization of the kidneys. The risk of mineralization is increased when the calcium \times phosphorus product exceeds 70. As noted previously, decreased or low-normal phosphorus often occurs in patients with hyperparathyroidism, thus decreasing the risk of renal mineralization. In fact, it appears that renal failure occurs rarely in dogs with primary hyperparathyroidism. In a large canine case series, it was found that mean blood urea nitrogen (BUN) and serum creatinine were both significantly lower in 210 dogs with primary hyperparathyroidism, compared with 200 control dogs.³⁰⁹ In addition, 95% of the hyperparathyroid dogs had BUN and serum creatinine values within or below the reference range. This may partly be a result of the secondary nephrogenic diabetes insipidus that causes polyuria/polydipsia in these patients.

Definitive therapy for primary hyperparathyroidism requires removal of the hyperfunctioning gland(s). This is most commonly achieved by surgery in both dogs and cats; however, percutaneous ultrasound-guided ethanol ablation and percutaneous ultrasound-guided heat ablation are also well described in the dog.^{311,325,326} The latter techniques may not be as widely available as surgery, and success likely depends on the experience of the operator.³¹¹ In a retrospective comparison of surgery, ethanol ablation, and heat ablation, all three techniques performed well, but surgical parathyroidectomy had the highest success rate and lowest rate of complications.³¹¹ Ultrasound examination of the neck is strongly recommended prior to surgery, and the surgeon should carefully evaluate all the parathyroid glands because approximately 10% of patients have masses in more than one gland. Up to three of the four parathyroid glands can be removed without risk of permanent hypoparathyroidism. Patients with involvement of all four glands present a dilemma, and it is important to ensure that hyperplasia in these cases is not secondary. If the hyperparathyroidism is believed to be primary, removal of all parathyroid tissue is required to control hypercalcemia, but this will necessitate life-long supplemental therapy. In human medicine, total parathyroidectomy may be followed by autotransplantation of one of the glands or may be accompanied by cryopreservation of parathyroid tissue.³²⁷ These approaches have not been explored in veterinary medicine.

Hypocalcemia is a potential complication of surgical parathyroidectomy, ethanol ablation, or heat ablation. This happens because chronic hypercalcemia inhibits PTH secretion by the normal parathyroid glands and leads to parathyroid atrophy. It is logical to assume that the risk of this posttreatment complication increases with duration and severity of hypercalcemia; however, it is still difficult to predict whether an individual patient will become hypocalcemic. Thus it is recommended that serum ionized calcium levels be monitored at least twice daily for as long as 5 to 7 days after surgery or other ablative procedures. Hypocalcemia should be treated if the ionized calcium falls below 0.8 to 0.9 mmol/L, the total calcium is less than 8 to 9 mg/dL, or the patient has signs of tetany. Intravenous (IV) calcium salts are used for acute therapy for hypocalcemia; subcutaneous (SQ) administration should be avoided. Vitamin D and oral calcium are used for subacute and chronic therapy. Several excellent references are available regarding treatment of hypoparathyroidism.^{312,328} In summary, 1,25-dihydroxyvitamin D₃ (calcitriol) is recommended for vitamin D supplementation because it has a rapid onset of action and a short half-life. This facilitates dose adjustments and reduces the risk of hypercalcemia. Oral calcium supplementation alone is not sufficient to treat hypoparathyroidism, and in fact this therapy can be gradually withdrawn once the calcium is stable because most maintenance diets contain an adequate amount of calcium. Calcitriol therapy can be started up to 24 hours prior to surgery or parathyroid ablation, if the risk of hypocalcemia is thought to be high. This allows the medication to reach therapeutic levels more quickly, but it will not necessarily prevent the development of hypocalcemia. When adjusting the dose of calcitriol, the goal is to maintain the calcium barely below the normal reference range rather than within normal. This reduces the risk of hypercalcemia and provides the stimulus for recovery of function of the remaining normal parathyroid glands. Once the serum calcium has been stable for at least 1 to 2 weeks in an outpatient, the dose of calcitriol can be gradually reduced, with careful monitoring. The time for return of normal parathyroid function is unpredictable, and therefore clients should expect frequent rechecks of the patient's calcium levels for several weeks to months after treatment of hyperparathyroidism.

The long-term prognosis after surgical or ablative treatment for hyperparathyroidism is very good. Metastatic disease is extremely rare, and the complication of hypocalcemia is generally amenable to medical therapy. A small number of patients may appear resistant to the postoperative management of hypocalcemia, and this may be the result of the “hungry bone syndrome” in which there is aggressive unregulated uptake of calcium by the bones. In human medicine, this syndrome has been managed with preoperative bisphosphonate administration³²⁹ or the use of recombinant PTH.³³⁰ Neither of these approaches has been used in veterinary medicine, and most patients will eventually respond to high doses of calcitriol and calcium supplementation. Less than 10% of dogs and cats treated for hyperparathyroidism will experience a recurrence of the disease.^{308,312} If this occurs, a second surgery or ablative procedure should be performed. The short-term prognosis for dogs and cats that do not undergo definitive surgical or ablative therapy for hyperparathyroidism may still be favorable because the disease tends to be slowly progressive, clinical signs may be mild, and renal failure may be a less common outcome than previously suspected.³⁰⁹

Pancreatic Beta-Cell Tumors (Insulinomas)

Pancreatic beta-cell tumors are rare in humans and cats and uncommon in dogs.³³¹⁻³³³ These tumors are often functional, but the neoplastic beta-cells fail to appropriately inhibit insulin secretion at low blood glucose concentrations. Thus the hallmark of insulinoma is a normal or elevated blood insulin concentration in the presence of low blood glucose levels. A feline insulinoma was recently shown to demonstrate abnormal glucokinase and hexokinase expression.³³² These changes may contribute to enhanced glucose sensitivity and hence an abnormal insulin secretory response in insulinoma cells. Although the clinical signs of insulinoma result from hypoglycemia associated with unregulated insulin secretion, immunocytochemical analysis reveals that these tumors often produce many additional hormones, including glucagon, somatostatin, pancreatic polypeptide, GH, IGF-1, and gastrin.^{332,334-338}

In humans, 90% of insulinomas are solitary and benign, and 5% to 10% are associated with multiple endocrine neoplasia type 1 (MEN1). Insulinomas in dogs are much more likely to be malignant, although morphologic classification into adenoma or adenocarcinoma does not consistently reflect the biologic behavior of these tumors.^{331,336,339} Metastatic lesions are detected in approximately 50% of canine insulinomas, with the regional lymph nodes and liver most commonly affected. Pulmonary metastases are very rare in dogs.^{337,340-344}

Beta-Cell Tumors in Dogs

The cellular and molecular events causing beta-cell tumors in dogs are unknown. Canine insulinomas have been shown to express somatostatin receptors, which may have implications for both diagnosis and therapy (see later).³⁴⁵ Local production of GH and IGF-1 have also been demonstrated in canine insulinomas, with a higher level of expression of GH and IGF-1 mRNA in metastases compared to primary tumors.^{338,346} It has been suggested that the locally produced hormones may have autocrine or paracrine effects on cell proliferation, and tumor growth and progression. Furthermore, it is speculated that locally produced somatostatin has inhibitory effects on insulinomas within the pancreas, but that these effects are decreased in metastases, leading to increased GH production.³⁴⁶

The World Health Organization (WHO) recommendations have been used to stage canine pancreatic tumors.³⁴¹ Thus clinical stage I tumors involve only the pancreas with no evidence of local or distant lymph node involvement and no distant metastasis (T1N0M0). Stage II tumors have lymph node involvement (T1N1M0), and stage III tumors have distant metastasis (T1N1M1 or T1N0M1). A recent study evaluated several clinicopathologic and morphologic criteria of canine insulinomas with the goal of establishing prognostic biomarkers for this tumor.³³⁹ It was found that tumor size was predictive for disease-free interval (DFI) in a multivariate analysis, and Ki67 index, a marker of proliferation, was predictive for both DFI and survival time.

Canine insulinomas are most commonly reported in medium- and large-breed dogs, particularly Labrador retrievers, Golden retrievers, German shepherd dogs, German pointers, Irish setters, Boxers, and mixed breed dogs. Small-breed dogs can also be affected; West Highland white terriers appear overrepresented in some reports. Depending on the case series, the median reported age is 9 to 10 years, with a range of 3 to 15 years, and no sex predilection.^{337,340-342,346,347}

The clinical signs of insulinoma result from the effects of hypoglycemia on the nervous system, which is termed *neuroglycopenia*, and these signs include weakness, ataxia, collapse, disorientation, behavioral changes, and seizures. Catecholamine release stimulated by low blood glucose levels may also cause muscle tremors, shaking, anxiety, and hunger. Clinical signs may be present for days to months and are often intermittent or episodic. They may be precipitated by fasting, exercise, excitement, or eating. Signs may be less pronounced with more chronic hypoglycemia, and patients may be clinically normal with significantly low blood glucose levels. Physical examination findings are usually otherwise unremarkable in these patients. A paraneoplastic peripheral neuropathy has been described in dogs with insulinoma. This appears to be rare, although subclinical neuropathies may be present and undetected.³⁴⁸⁻³⁵² Brain lesions associated with hypoglycemia have also been reported in rare cases.^{353,354}

The diagnosis of insulinoma is confirmed by documenting hypoglycemia (blood glucose <60 mg/dL) with a concurrent normal or elevated serum insulin concentration. In some cases, it may be necessary to fast the patient, with careful monitoring, and repeat blood glucose measurements every 30 to 60 minutes. Once the blood glucose is less than 60 mg/dL, a serum sample should be submitted for concurrent insulin measurement. The presence of normal or high serum insulin concentration in the face of hypoglycemia is inappropriate and generally sufficient to confirm the diagnosis of insulinoma. This insulin-glucose pair should be performed more than once if the initial sample provides equivocal results.³⁵⁵ The use of insulin:glucose or glucose:insulin ratios is not recommended because these do not improve diagnostic accuracy. Provocative testing is also rarely used in veterinary medicine because of risks, expense, and poor sensitivity.³⁴² Serum fructosamine and glycosylated hemoglobin concentrations can also be measured in dogs to support a suspicion of insulinoma.³⁵⁶⁻³⁵⁹ Concentrations of these glycosylated proteins would be expected to be lower than normal in dogs with chronic hypoglycemia, although this is not necessarily pathognomonic for insulinoma.

Imaging studies are often used in the evaluation of insulinoma patients, particularly in preparation for surgical management. Thoracic and abdominal radiographs are usually unremarkable but are often obtained to investigate other potential causes of hypoglycemia. Abdominal ultrasonography is commonly performed but has been reported to clearly identify and localize a pancreatic mass in

less than 50% of cases.^{344,347,360,361} Abdominal ultrasonography is also used to identify metastatic lesions in dogs with insulinoma but has low sensitivity and specificity for this purpose. Thus, although abdominal ultrasonography is widely available and often used in the evaluation of patients with hypoglycemia, it cannot be used to rule in or rule out a diagnosis of insulinoma. In human medicine, endoscopic and intraoperative ultrasonography are used to identify small pancreatic tumors, but these techniques have yet to be reported in canine patients.³⁶²

CT findings have been reported in a small number of dogs with insulinoma.^{361,363,364} In a study comparing ultrasound, CT, and single-photon emission CT (SPECT), CT was found to be the most sensitive technique, identifying 10 of 14 confirmed primary insulinomas. However, CT also identified a significant number of false-positive metastatic lesions.³⁶¹ The results of SPECT with ¹¹¹In-DTPA-D-Phe¹-octreotide have been reported in a total of 19 dogs with insulinoma, with an overall sensitivity of 50% for detection and correct localization of the primary tumor.^{345,361} Enhanced CT techniques such as dynamic CT or dual-phase CT angiography hold promise for greater sensitivity of detection of insulinomas in dogs, but large-scale studies have yet to be reported in the veterinary literature.^{363,364} Somatostatin receptor scintigraphy (SRS) is an important imaging modality in humans with pancreatic endocrine tumors, including insulinomas. Indium In-111 pentetreotide SRS has been reported in a total of six dogs with insulinoma, with positive results reported in five cases, although an accurate anatomic localization was only obtained in one case.^{365,366} PET has been used in human patients to localize insulinomas when CT, MRI, and ultrasound are negative.³⁶⁷ This modality has yet to be explored in canine insulinoma patients.

Therapy for canine insulinoma involves acute and chronic treatment of hypoglycemia and long-term management of the tumor. Acute treatment of hypoglycemia is accomplished through administration of intravenous dextrose, often as a slow bolus, followed by continuous rate infusion (CRI). This should be given with caution because this treatment can stimulate further unregulated insulin secretion and worsened hypoglycemia. A CRI of glucagon has also been used in the management of hyperinsulinemic-hypoglycemic crisis in a dog.³⁶⁸

Exploratory laparotomy is indicated in dogs with hypoglycemia and inappropriately elevated serum insulin concentrations, regardless of the results of abdominal imaging studies.^{340-342,344,347} Blood glucose levels should be stabilized before surgery and monitored throughout the procedure. Surgery allows confirmation of the diagnosis of insulinoma, resection of primary and metastatic neoplasia, and staging of the disease. Details of the technique of partial pancreatectomy are described elsewhere.¹⁸² The majority of canine insulinomas are visible or palpable at surgery, and tumors are identified in both lobes of the pancreas with equal frequency. Suspected metastatic lesions should be resected whenever possible, and the liver and regional lymph nodes should always be biopsied. Potential postoperative complications include pancreatitis, persistent hypoglycemia, transient hyperglycemia or diabetes mellitus, and exocrine pancreatic insufficiency.^{187,331,342}

Medical treatment of insulinoma is used to stabilize patients preoperatively, as an alternate therapy if surgery is not possible, and in conjunction with surgical management. Medical therapies are primarily used to control hypoglycemia, but cytotoxic agents have also been used to destroy pancreatic beta-cells. Streptozocin (streptozotocin) is the chemotherapeutic drug that has been used most often, albeit infrequently, in dogs. Its use in dogs was historically limited by its nephrotoxicity,³³¹ but more recent reports suggest that

the risk of nephrotoxicity is significantly reduced if the drug is given in combination with intensive saline diuresis.^{369,370} Other side effects of this drug include vomiting during administration, diabetes mellitus, hypoglycemia, and mild hematologic changes.^{369,370} The administration of streptozocin does not significantly increase the duration of normoglycemia in dogs with insulinoma compared with control dogs treated medically or surgically.³⁶⁹ Although individual dogs have demonstrated reductions in tumor size or resolution of paraneoplastic neuropathy with streptozocin, it is still unclear if the risks of therapy outweigh the benefits of this treatment for dogs with insulinoma.

Strategies used to control hypoglycemia consist of dietary modification and medical therapy with prednisone, diazoxide, or octreotide. Excitement should be avoided in these patients, and exercise limited. Diets high in fat, protein, and complex carbohydrates should be fed in small, frequent meals, and simple sugars avoided.³³¹ Prednisone is used for its insulin-antagonizing, gluconeogenic, and glycogenolytic effects.³³¹ A starting dose of 0.25 mg/kg by mouth (PO) twice daily is recommended, with gradual dose increases as needed to control hypoglycemia.^{331,342} Typical glucocorticoid side effects should be anticipated. Diazoxide is a nondiuretic benzothiadiazine that suppresses insulin release from beta-cells. It also stimulates hepatic gluconeogenesis and glycogenolysis and inhibits cellular uptake of glucose. Diazoxide is not cytotoxic and does not inhibit insulin synthesis. A starting dose of 5 mg/kg PO twice daily is recommended, and the dose can be gradually increased to 30 mg/kg PO twice daily if necessary.^{331,342} Approximately 70% of canine insulinoma patients respond to diazoxide therapy.^{331,340} Side effects are uncommon but may include ptialism, vomiting, anorexia, and diarrhea.^{331,342,371} The use of diazoxide has been limited by its cost and inconsistent availability. Octreotide is a somatostatin receptor ligand that inhibits synthesis and secretion of insulin by pancreatic beta-cells. It has been reported to alleviate hypoglycemia in up to 50% of dogs with insulinoma, although some may become refractory to treatment.^{331,345} The suggested dose is 10 to 50 µg SQ 2 to 3 times daily, and side effects appear to be rare. In a more recent study, a single 50 µg dose of octreotide was administered to 12 dogs with insulinoma. Plasma insulin concentrations decreased significantly after administration of octreotide in dogs with insulinoma, but GH, ACTH, cortisol, and glucagon levels did not change and glucose levels increased.³⁷² These findings suggest that the use of octreotide warrants further investigation in canine patients with insulinoma, although the cost of the medication may be a significant impediment.

The prognosis for dogs with insulinomas is good in the short term but guarded to poor in the long term. Patients that undergo surgery followed by medical management are more likely to become euglycemic, remain euglycemic for longer periods, and have longer survival times compared to patients that receive only medical therapy.^{344,347} MSTs following partial pancreatectomy range from 12 to 14 months over several different studies.³⁷¹ The prognosis following surgery depends on the clinical stage of the disease. Dogs in stage I have a longer DFI compared to dogs in stages II and III, with 50% of dogs in stage I free of hypoglycemia 14 months after surgery compared to less than 20% of dogs in stages II and III being free of hypoglycemia at this time.³⁴¹ Dogs in clinical stage III have a significantly shorter survival time than dogs in stages I and II, with approximately 50% of dogs with metastasis dead by 6 months.³⁴¹ A more recent retrospective study showed improved survival in dogs with insulinoma compared to earlier reports.³⁴⁷ The authors reported a MST of 785 days for 19 dogs undergoing partial pancreatectomy, with a median DFI of 496 days. The subset of nine dogs

that received surgery followed by medical therapy with prednisolone had a MST of 1316 days. For eight dogs receiving medical therapy alone, the MST was 196 days. When all the dogs that received medical therapy were considered as a group, the MST after institution of the medical treatment was 452 days.³⁴⁷ These results lend strong support to the use of medical therapy in canine patients with insulinoma, particularly when clinical signs recur after surgery.

Beta-Cell Tumors in Cats

Compared to dogs, there are significantly fewer reports of insulinomas in cats. History, clinical signs, and biologic behavior in this species appear to be similar to those in the dog, and concurrent measurements of blood glucose and serum insulin concentrations are used to confirm the diagnosis. However, it is important to use an insulin assay that has been validated in cats. Siamese cats may be overrepresented,³⁷¹ but because the disease is rarely reported, firm conclusions on breed predisposition should not be drawn. Surgical management has been reported in feline patients, with survival times ranging from 1 to 32 months.^{331,373-377} Medical therapy with dietary management and prednisolone have also been used in cats. Octreotide may also be considered, although there is little evidence to support its use, and no evidence to support the use of diazoxide or streptozotocin in this species.³³¹

Gastrointestinal Endocrine Tumors

Gastrinoma

Gastrinomas are neuroendocrine tumors that secrete excessive amounts of gastrin. Zollinger-Ellison syndrome refers to the triad of a non-beta-cell neuroendocrine tumor in the pancreas, hypergastrinemia, and gastrointestinal ulceration. Gastrinomas are rare in dogs and very rare in cats.^{378,379} Almost all reported gastrinomas in these species were identified in the pancreas, although there is one report of a duodenal gastrinoma in a dog.³⁸⁰ In contrast, the majority of gastrinomas in humans arise in the duodenum, with fewer detected in the pancreas.¹⁰ Although gastrin-producing G cells normally exist in the duodenum and gastric antrum, they are not present in the pancreas. The cell of origin for primary pancreatic gastrinomas is not known, but D cells (which secrete gastrin in the fetus and neonate) are the most likely candidates.^{378,379} Gastrinomas are highly metastatic, with involvement of the liver, regional lymph nodes, spleen, peritoneum, small intestine, omentum, or mesentery identified in 85% of dogs and cats at the time of initial diagnosis.^{378,379,381-383}

Gastrinomas are typically reported in middle-aged dogs and older cats.^{378,379} No obvious breed or sex predilections have been identified. Clinical signs result from gastric acid hypersecretion and gastric mucosal hyperplasia.^{378,379,381-389} The most common signs are vomiting and weight loss. Melena, abdominal pain, anorexia, hematemesis, hematochezia, and diarrhea may also occur. Physical examination findings range from unremarkable to a patient in hypovolemic shock due to perforation of an ulcer. Serum biochemistry profile, CBC, and urinalysis may demonstrate changes associated with protein loss and bleeding due to gastrointestinal ulceration or may reflect the consequences of severe or persistent vomiting or the presence of hepatic metastases. One case of common bile duct obstruction due to a duodenal gastrinoma has been reported in a dog.³⁸⁰ Abdominal radiographs may be unremarkable unless gastrointestinal perforation has occurred. Contrast radiographs and abdominal ultrasound examination may show evidence of gastrointestinal ulceration and thickened pyloric antrum and gastric wall. Ultrasound examination may also reveal metastatic lesions in the

liver or regional lymph nodes; however, the primary tumor in the pancreas is usually too small to be detected with this modality.³⁸³ The results of techniques such as CT and MRI have not been widely reported in dogs and cats with gastrinomas. Endoscopy may reveal esophagitis with ulceration, gastric and duodenal ulceration, thickened gastric rugae, and hypertrophy of the pyloric antrum. The diagnosis may be supported by measuring basal serum gastrin levels or levels after provocative testing or by scintigraphy using radiolabeled pentetreotide.³⁹⁰ Basal gastrin levels have been significantly elevated in dogs and cats with gastrinoma; however, gastrin levels can also be elevated in renal, hepatic, or gastric disease, and after therapy with antacids such as H₂-receptor antagonists and proton pump inhibitors.³⁹¹ Provocative testing has rarely been reported in veterinary medicine.^{187,378,379}

Exploratory laparotomy is recommended for dogs and cats suspected to have a gastrinoma. Even though the majority of dogs and cats have visible metastasis at the time of initial diagnosis, surgical debulking will reduce gastrin secretory capacity and enhance the efficacy of medical therapy.³⁷⁹ In addition, deep or perforated gastrointestinal ulcers can be identified and excised. Long-term medical management includes the use of proton pump inhibitors, H₂-receptor antagonists, and sucralfate.^{384,388} Octreotide has been used in two dogs with success.^{390,392} Survival times for dogs and cats with gastrinoma have ranged from 1 week to 26 months.^{378,379,388}

Glucagonoma

Glucagonomas are rare in dogs and humans, and there are no case reports in cats.^{10,378,379} These tumors are associated with a crusting dermatologic condition referred to as superficial necrolytic dermatitis, diabetic dermatopathy, hepatocutaneous syndrome, or necrolytic migratory erythema (NME). Other associated problems include hyperglycemia or overt diabetes mellitus, hypoaminoacidemia, and increased liver enzyme values. Lesions associated with NME include hyperkeratosis, crusting, ulceration and erosions of the footpads, mucocutaneous junctions, external genitalia, distal extremities, pressure points, and ventral abdomen.^{187,378,379,393-397} Glucagonomas arise from alpha-cells in the pancreas and are sometimes detected on abdominal ultrasound examination or CT.^{379,395,397} Plasma glucagon levels may be measured, and amino acid concentrations have also been evaluated in a small number of patients,³⁹⁴⁻³⁹⁶ but the sensitivity and specificity of these diagnostic tests is unknown. Surgical resection or debulking is the treatment of choice for canine glucagonoma, but metastasis is common at the time of surgery, and prognosis is generally poor.^{187,378,379,395} There are rare reports of the use of somatostatin analogs.^{396,397} The dermatologic lesions of NME may improve after surgery or medical therapy, and lesions may also respond to treatment with amino acid infusions, oral protein supplementation (with protein powders or egg yolks), zinc, or essential fatty acids.³⁷⁹ When NME is suspected, it is important to rule out liver disease because this is a more common cause of this dermatologic condition in dogs.

Intestinal Carcinoid

Intestinal carcinoid tumors are rare in dogs and cats. They arise from enterochromaffin cells that are found in a variety of locations; hence these tumors have been reported in several sites throughout the gastrointestinal tract, liver, gallbladder, and pancreas.^{378,379,398-403} Clinical signs are generally associated with the anatomic location of the tumor; the physiologic effects of vasoactive substances released from the tumor were suspected in one dog with an intestinal carcinoid.⁴⁰² In general, the prognosis for these tumors is guarded because metastasis is common at the time of diagnosis.³⁷⁹

Surgical removal is recommended,³⁷⁸ and there is a single case report describing adjuvant chemotherapy in a canine patient.⁴⁰⁴

Tumors of the Female Reproductive System

COREY F. SABA AND JESSICA A. LAWRENCE

Ovarian Tumors

Incidence

Ovarian tumors are uncommon in dogs and cats, resulting in part from the routine practice of ovariohysterectomy (OHE) in many areas of the world. The overall reported prevalence in dogs is 0.5% to 1.2%,¹⁻³ with an estimated prevalence of 6.25% in intact bitches.⁴ Ovarian tumors are equally rare in cats, with a reported prevalence of 0.7% to 3.6% in intact queens.^{5,6} These numbers are primarily derived from pathology surveys and likely overestimate the true incidence in the pet population. Breed predilections are also difficult to discern; however, German shepherd dogs, Boxers, Yorkshire terriers, poodles, and Boston terriers appear to be most commonly affected.^{2,7,8} Aside from germ cell tumors and specifically teratomas, most ovarian tumors develop in older dogs (approximately 6 years of age and older).^{2,7-9} Teratomas are often found in younger dogs (≤ 6 years of age).^{7,8,10,11} Ovarian tumors have been reported in cats ranging from less than 1 year to 20 years (mean age: 6.7 years).¹²⁻¹⁵

Pathology and Natural Behavior

Canine Ovarian Tumors

Due to the complexity of the canine ovary, a variety of histologic tumor types may occur. Historically, canine ovarian tumors have been classified based on the World Health Organization (WHO) classification scheme for human ovarian tumors, with primary tumor types including epithelial tumors, germ cell tumors, sex cord stromal (gonadostromal) tumors, and mesenchymal tumors.^{2,8,16,17} Recently, the human WHO classification system was revised to subdivide each of the aforementioned categories into histologic types based on morphologic similarities; the use of immunohistochemistry has aided in further differentiating ovarian tumors.¹⁸ Attempts to recapitulate such classification schemes in dogs have been reported but are not routinely employed.^{19,20}

Epithelial Tumors

Epithelial tumors arise from the outer surface of the ovary⁹ and according to several reports are most common.^{2,8,16} Malignant tumors outnumber benign tumors,^{7,8,16} and larger size is suggestive of malignancy.^{8,16} Malignant histologies include papillary adenocarcinomas, tubular adenocarcinomas, and undifferentiated carcinomas; benign tumors such as rete adenomas, papillary adenomas and cystadenomas also occur.^{2,8,16} Reportedly, 48% of adenocarcinomas will metastasize, generally within the peritoneal cavity to the intraabdominal lymph nodes, omentum, and liver.⁸ Direct tumor cell implantation and subsequent malignant effusion may also occur.^{3,8} Although most are unilateral, bilateral epithelial ovarian tumors have been described.⁸ Cysts in the contralateral ovary, as well as cystic endometrial hyperplasia, may also be found.

Epithelial ovarian tumors routinely express cytokeratin AE1/AE3 (CK AE1/AE3), vimentin, and desmin.^{19,20} Although papillary adenocarcinomas also demonstrate placental alkaline phosphatase (PLAP) and cytokeratin 7 (CK 7) immunoreactivity, positive immunoreactivity appears to be less frequent in tubular adenocarcinomas.¹⁹ Alpha fetoprotein (AFP),¹⁹ S100,¹⁹ and endothelin-A (ET-A)²¹ are variably expressed. Faint to strong intracytoplasmic cyclooxygenase-2 (COX-2)²² and endothelin-1 (ET-1)²¹ immunoreactivity has been reported in 81% and 83% of canine ovarian carcinomas, respectively. Inhibin- α (INH- α), a glycopeptide synthesized in gonadal cells of the ovaries, inhibits pituitary secretion of follicle-stimulating hormone (FSH), and it has been described as a sensitive and specific marker for granulosa-theca cell tumor (GTCT).²³ Therefore epithelial tumor cells should not express INH- α , and demonstration of INH- α expression has resulted in reclassification of epithelial tumors as GTCT.²⁰

Sex Cord Stromal Tumors

Sex cord stromal tumors, specifically GTCT, are also common and likely second in occurrence to epithelial tumors. Less common histologies include Sertoli-Leydig tumors, thecomas, and luteomas. These tumors arise from the specialized estrogen- and progesterone-producing gonadal stroma of the ovary and therefore have the potential to secrete these steroid hormones if functional.^{3,4,8,16} The metastatic rate of GTCT is low, occurring in approximately 20% of cases.^{3,8,9,16} Metastatic sites include sublumbar lymph nodes, pancreas, and lungs, with peritoneal carcinomatosis noted in some cases.^{1,3,8,16} Although rare, thecomas and luteomas are for the most part considered benign.^{8,16}

Although most sex cord stromal tumors are unilateral, bilateral tumors are possible, especially among Sertoli-Leydig tumors.⁸ Concomitant cystic endometrial hyperplasia and cysts in the contralateral ovary appear common within this group.⁸

Solid, nest, cord, palisade, cystic, and spindle are the histologic patterns described for GTCT, and a mixture of these may exist within a single tumor.^{8,19} GTCTs are generally vimentin,¹⁹ S100,¹⁹ and INH- α ²⁰ positive, although one study has reported INH- α negative GTCT.¹⁹ Variable expression of CK AE1/AE3,²⁰ CK 7,²⁰ and ET-A²¹ has been described, and moderate-to-strong intracytoplasmic ET-1 immunoreactivity has been detected in 88% of canine GTCT.

Germ Cell Tumors

Germ cell tumors, including dysgerminomas, teratomas, and malignant teratomas (teratocarcinomas), arise from primordial germ cells of the ovary.^{8,16,24} Concurrent cysts in the contralateral ovary and uterine abnormalities such as pyometra and cystic endometrial hyperplasia are common.²⁴

Dysgerminomas, also known as *ovarian seminomas*, are most common in this group and arise from undifferentiated germ cells. Histologically, these tumors consist of a uniform population of cells resembling ovarian primordial germ cells.^{3,8,16} Bilateral dysgerminomas have been reported; however, most are unilateral.^{8,16,24} The reported metastatic rate is low (10% to 30%), with sites of metastasis including lymph nodes, liver, kidney, omentum, pancreas, and adrenal glands.^{3,8,9,24-26}

Teratomas are composed of germ cells that undergo differentiation into at least two germinal cell layers and any combination of tissues can be seen. These tissues are usually well differentiated, and tissues from virtually any organ (excluding ovary or testis) may be present. Malignant teratomas are composed of predominantly immature, undifferentiated tissues resembling those of the embryo.²⁴ Metastasis has been noted in up to 50%. Although distant visceral metastasis can occur, peritoneal metastasis with carcinomatosis is most common.^{8,9,24}

Germ cell tumors, specifically dysgerminomas, are vimentin positive and PLAP, CK 7, desmin, S100, CK AE1/AE3, and INH- α negative.¹⁹

Mesenchymal Tumors

Mesenchymal ovarian tumors are rare. Reported tumor types include hemangiosarcoma,^{2,16} hemangioma,¹⁶ and leiomyoma.^{2,16} Behavior of this group is difficult to predict because information in the literature is sparse.

Miscellaneous

In addition to the various primary ovarian tumors, other differential diagnoses should be considered. These include ovarian cysts, paraovarian cysts, cystic rete tubules, vascular hamartomas, and adenomatous hyperplasia of the rete ovarii. Although rare, metastasis to the ovary has been reported in cases of mammary (especially inflammatory carcinoma),²⁷ intestinal, and pancreatic carcinoma, as well as lymphoma.¹⁶

Feline Ovarian Tumors

Reported feline ovarian tumor classifications include epithelial, germ cell, and sex cord stromal tumors. Although mesenchymal ovarian tumors have not been reported in cats, it seems plausible that they may occur. Ovarian involvement in cats with lymphoma has been documented.¹⁵

Sex cord stromal tumors are most common in cats, accounting for at least half of reported cases. They are often unilateral. Of these, GTCTs are most common and approximately 50% are malignant. Metastatic sites include the peritoneum, regional lymph nodes, omentum, diaphragm, kidney, spleen, liver, and lungs.¹⁵ Luteomas, thecomas, and Sertoli-Leydig cell tumors are rare and typically benign.

Germ cell tumors are also rare in cats. Of these, dysgerminomas are most common.¹⁵ They are generally considered benign, yet metastasis has been reported in 20% to 33% of cases.¹⁵ Teratomas have been rarely documented.^{15,28}

Epithelial tumors are perhaps the least common ovarian tumor in the cat. Cystadenomas and adenocarcinomas have been described. Metastasis to the lungs, liver, and abdominal peritoneum was seen in one case of ovarian adenocarcinoma.¹⁵

History and Clinical Signs

Canine Ovarian Tumors

History and clinical signs associated with canine ovarian tumors vary, depending on the tissue of origin. Although initially insidious,

• **FIGURE 26-1** Right lateral caudal abdominal radiograph of a dog with an ovarian tumor. (Courtesy Dr. T. Schwarz, University of Edinburgh.)

ovarian tumors grow to the point of being palpable and clinical signs are typically referable to a space-occupying abdominal mass (Figure 26-1).^{9,29-31} Functional sex cord stromal tumors may produce one or multiple hormones, or they may be nonfunctional.^{8,16,32} Sex cord stromal tumors that produce steroid hormones such as estrogen may cause vulvar enlargement, sanguineous vulvar discharge, persistent estrus, alopecia, and aplastic pancytopenia, whereas excessive progesterone production may cause cystic endometrial hyperplasia and pyometra.^{3,8,9,16,30} Hyperadrenocorticism was reported in a dog with an ovarian-steroid tumor resembling a luteoma, and the associated clinical signs resolved following OHE.³³ Germ cell tumors have been associated with evidence of hormonal dysfunction, although they are most often associated with clinical signs referable to a space-occupying abdominal mass.²⁴

Feline Ovarian Tumors

Ovarian tumors in cats also have an insidious onset and eventually grow to the point of being detectable by abdominal palpation. Signs referable to a space-occupying abdominal mass such as weight loss, lethargy, vomiting, ascites, and abdominal distension are often noted. GTCTs are most common, and they are generally functional, producing estrogen, progesterone, or testosterone. Clinical signs of hyperestrogenism, including persistent estrus, alopecia, and endometrial hyperplasia, have been reported.¹⁵ Virilizing behavior secondary to a testosterone-producing thecoma of the ovarian stump was reported in a 6-year-old domestic shorthair cat.³⁴

Diagnostic Techniques and Work-Up

Laboratory abnormalities attributable to ovarian tumors are generally not noted. However, hypercalcemia secondary to tumor production of parathyroid hormone-related peptide (PTH-rP) has been reported in a dog with ovarian adenocarcinoma.³¹ Thoracic radiographs should be evaluated for evidence of metastatic disease. Abdominal imaging, specifically ultrasound, is useful in identifying ovarian masses and associated abdominal metastasis or uterine abnormalities (Figure 26-2). Ultrasonographic patterns include solid, solid with cystic component, and cystic. Malignant tumors are typically solid, whereas benign tumors are generally cystic with smooth borders. Concurrent uterine abnormalities such as pyometra and cystic endometrial hyperplasia may be detectable via ultrasound in up to 50% of dogs.³⁵ Because the risk of tumor seeding is high, transabdominal needle biopsies of ovarian tumors are not

• **FIGURE 26-2** A large, irregularly shaped mixed echogenic left ovarian mass identified on abdominal ultrasound. The mass was histologically consistent with a granulosa cell tumor. (Courtesy Dr. D. Jimenez, University of Georgia.)

• **FIGURE 26-3** Ovarian dysgerminoma population of highly pleomorphic round cells. These cells have a scant amount of lightly basophilic cytoplasm and round to irregularly shaped nuclei with a coarsely granular to smudged chromatin pattern with occasional indistinct nucleoli. Binucleated and multinucleated cells are seen and occasional micronuclei are observed. There is moderate-to-marked anisocytosis and anisokaryosis. (Courtesy Dr. M. Camus, University of Georgia.)

recommended. If present, abdominal fluid may be safely collected, and cytologic evaluation of fluid often is suggestive of malignant effusions. In a series of 19 cases with a variety of ovarian tumors, cytologic diagnosis was consistent with histopathology in 94.7% (Figure 26-3).² Finally, if a functional tumor is suspected, evaluation of vaginal cytology for evidence of estrogen-induced cornification is also indicated.

Therapy

Complete OHE is the treatment of choice for most localized ovarian tumors. Standard oncologic surgical principles must be practiced

to minimize tumor seeding of the abdominal cavity. A thorough exploration of the abdominal cavity with biopsy of any abnormalities is recommended for definitive diagnosis and to rule out metastatic lesions.⁹

Use of chemotherapy and/or radiation therapy in the treatment of ovarian tumors has not been widely investigated in veterinary medicine; therefore recommendations are difficult to make. Palliation of malignant effusions with intracavitary instillation of chemotherapeutics such as the platinum agents may be considered.³⁶ It is important to remember that the use of cisplatin is considered unsafe in cats.³⁷

Prognosis

Prognosis for both dogs and cats with ovarian tumors is difficult to predict due to lack of evidence in the literature. Intuitively, it seems the prognosis is good with complete excision of benign or localized malignant tumors but poor with detection of metastatic disease.

Comparative Aspects

As in dogs, ovarian cancer in women includes tumors of epithelial, germ cell, or sex cord stromal origin. Epithelial tumors are most common and generally occur in postmenopausal women (median age: 60 years), whereas germ cell tumors are often diagnosed in younger women. An increased incidence of epithelial tumors has been noted in Caucasian women as compared to African-American women, and ovarian cancer risk (specifically epithelial tumors) appears lower in women who have had children, who have breast-fed, or who have taken oral contraceptives. Although uncommon, germline mutations in the *BRCA1* or *BRCA2* genes have been identified in women with familial ovarian cancer. Such mutations also convey an increased risk of other cancers, specifically breast cancer.³⁸

Epithelial ovarian tumors in women also resemble the canine counterpart in terms of biologic behavior. They typically metastasize locoregionally within the abdomen; however, distant metastasis may also occur. Patients are often asymptomatic until the disease spreads to the upper abdomen, and presenting symptoms, including abdominal discomfort, bloating, and ascites, are nonspecific. Approximately 70% of women present with advanced disease; as a result, epithelial ovarian cancer is the leading cause of gynecologic cancer mortality.³⁸

Cytoreductive surgery and chemotherapy are preferred treatments in epithelial ovarian cancer patients. Even in cases with advanced disease, cytoreductive surgery appears beneficial. Removal of large, necrotic tumors with poor blood supply theoretically improves chemotherapy delivery. Platinum agents (primarily cisplatin) and taxanes are commonly used chemotherapeutic agents. Radiation therapy (RT) has fallen out of use in high-risk early stage patients because it has proven less effective and more toxic than platinum-containing chemotherapy regimens.³⁸

Stage is the most important predictor of prognosis. The 5-year survival rate in patients with stage III, optimally debulked, gross residual disease is 20% to 30%.³⁸

Uterine Tumors

Incidence

Uterine tumors are rare, accounting for 0.3% to 0.4%⁶ and 0.29%³⁹ of all canine and feline tumors, respectively. Middle-aged to older animals are most commonly affected, although uterine carcinoma has been reported in dogs as young as 10 months.⁴⁰ No specific breed predilections have been reported.

Pathology and Natural Behavior

Benign mesenchymal tumors (leiomyomas) are most common in the canine uterus.^{9,41-43} Other reported but rare uterine tumors include leiomyosarcoma, fibroma, fibrosarcoma, hemangioma, angiolipoleiomyoma, lymphoma, and lipoma.^{41,44} Epithelial tumors are rarely reported but may occur in dogs.⁴² Most epithelial tumors are malignant,⁴⁵ but benign histologies have been reported.⁴⁶

Leiomyomas generally are slow growing, noninvasive, and not metastatic.⁹ Grossly, they are difficult to distinguish from their malignant counterparts.⁴¹ A syndrome characterized by multiple uterine leiomyomas, bilateral renal cystadenomas, and nodular dermatofibrosis has been characterized in German shepherd dogs.^{47,48} This syndrome has been noted to have a hereditary component associated with a mutation in the canine *Birt-Hogg-Dube* (*BHD*) gene.⁴⁹

A majority of studies suggest that adenocarcinoma is the most common tumor in the feline uterus.^{15,39,50,51} Less common histologies include müllerian tumor (adenosarcoma), leiomyoma, leiomyosarcoma, rhabdomyosarcoma, fibrosarcoma, lymphoma, fibroma, hemangioma, and lipoma.^{15,39,52-57} Metastasis to the cerebrum, eyes, ovaries, adrenal glands, lungs, liver, kidneys, bladder, colon, diaphragm, and regional lymph nodes has been reported.^{15,39,50,58,59}

One study evaluating immunohistochemical reactivity of six feline endometrial adenocarcinomas suggests these tumors routinely express CK AE1/AE3, COX-2, E-cadherin, and β -catenin. Five of six tumors demonstrated expression of progesterone receptors, and infrequent vimentin and estrogen receptor staining was seen.⁵¹

History and Clinical Signs

Although it seems logical that uterine tumors occur in intact animals, it is important to note that these may arise from uterine stumps after incomplete OHE (Figure 26-4).⁴⁴ Clinical signs associated with uterine tumors are not commonly reported, and most are incidental findings.⁹ However, in some cases, they grow large enough to produce abdominal distension and signs referable to a space-occupying abdominal mass. Abnormal estrus cycles,

vaginal discharge, stranguria, constipation, pyometra, polyuria, polydipsia, vomiting, abdominal distension, and weight loss may also occur.*

Diagnostic Therapeutics and Work-Up

Although abdominal imaging helps confirm the presence of an abdominal or uterine mass, histologic evaluation via complete surgical excision is required for definitive diagnosis. As a result, complete staging, including thoracic radiographs and abdominal ultrasound, should be considered prior to surgery to rule out the possibility of locoregional and distant metastasis.

Therapy

Complete OHE is the treatment of choice for uterine tumors. At the time of surgery, thorough examination of the abdominal cavity must be performed with biopsy of any suspected metastatic foci. Little is known about the role of chemotherapy.

Prognosis

As most uterine tumors in dogs are benign, surgery is often curative. The prognosis is also potentially good for completely excised, localized malignant tumors. However, the presence of metastatic disease warrants a grave prognosis.

Feline uterine adenocarcinomas have well-documented metastatic potential^{39,50}; therefore the prognosis must be considered guarded.

Vaginal and Vulvar Tumors

Incidence

Vaginal and vulvar tumors account for 2.4% to 3%^{43,60} of all canine tumors. Excluding skin tumors arising on the labia of the vulva, most are benign smooth muscle tumors (leiomyomas). These generally occur in middle-aged to older intact female dogs. Lipomas often occur in younger dogs ranging in age from 1 to 8 years (mean age: 6.3 years).^{43,60}

Incidence rates are not available for the cat. Leiomyomas are reported most commonly, occurring in older intact queens.^{15,61}

Pathology and Natural Behavior

Benign smooth muscle tumors including leiomyoma, fibroleiomyoma, fibroma, and polyps comprise approximately 83% of reported vaginal tumors.^{9,60} The most common malignant tumor is leiomyosarcoma, and associated distant metastasis has been reported.^{43,60} Other less common tumor types include lipoma, fibrous histiocytoma, benign melanoma, myxoma, myxofibroma, adenocarcinoma, hemangiosarcoma, osteosarcoma, epidermoid carcinoma, and, in endemic areas, transmissible venereal tumor (TVT).^{60,62} Carcinomas arising from the bladder or urethra may manifest as vaginal masses near the urethral papilla, and any skin tumor (e.g., mast cell tumors) may develop on the labia of the vulva.⁶⁰

Macroscopically, tumors of the vestibule or vagina are described as extraluminal or intraluminal.⁹ Extraluminal tumors appear as slowly growing, well-encapsulated, perineal masses. Intraluminal tumors are attached to the vestibular or vaginal wall by a pedicle, and multiple tumors may occur.⁹ In one study, all pedunculated or polypoid tumors were benign; however, it is important to note that definitive diagnosis requires histopathology.⁶⁰

It has been suggested that vaginal leiomyomas may be hormone dependent, as most dogs with these tumors are intact at

• **FIGURE 26-4** Irregular, hypoechoic mass at the uterine stump in a dog following ovariectomy. (Courtesy Dr. D. Jimenez, University of Georgia.)

*References 9, 15, 30, 39, 44, 45, 50.

diagnosis.^{9,43,60} Furthermore, one study reported a recurrence rate of 0% in dogs undergoing OHE at the time of tumor removal, whereas 15% of dogs that were left intact experienced local recurrence.^{9,60}

History and Clinical Signs

Presence of a mass protruding from the vulva is the most common clinical sign, although vaginal bleeding or discharge is often noted. Other clinical signs may include dysuria, hematuria, tenesmus, constipation, excessive vulvar licking, and dystocia.^{9,60}

Lipomas are generally slow growing but eventually impinge on adjacent structures. These tumors can arise from the perivascular and perivaginal fat and lie within the pelvic canal and may attach to the tuber ischium. All lipomas are reported to be well circumscribed and relatively avascular.⁶⁰

Concurrent cystic ovaries and mammary adenocarcinoma have also been reported in a cat with vaginal leiomyoma.⁶⁰

Diagnostic Techniques and Work-Up

A presumptive diagnosis may be made based on patient signalment and tumor location, although definitive diagnosis requires histopathology. Vaginal and rectal palpation, vaginoscopic examination, and vaginal cytology are often the first steps performed in evaluation of vaginal and vulvar tumors. Retrograde vaginography or urethrocytography may also be used to help delineate the extent of the mass. For some tumor types (e.g., TVT), aspiration cytology of the tumor may be diagnostic; alternatively, incisional biopsy may be performed. Although most vaginal and vulvar tumors are benign, complete staging, including thoracic radiographs and thorough abdominal ultrasound, should be considered in cases in which malignancy is suspected (e.g., rapidly growing, nonpedunculated tumors) or confirmed.

Therapy

Surgical excision combined with OHE is the treatment of choice for most vaginal and vulvar tumors. For benign tumors, this is likely curative, and wide resections are not necessary, especially if OHE is performed. Intraluminal tumors can be removed easily by transecting the pedicle. A dorsal episiotomy may be performed if needed for adequate visualization and exposure.^{9,60}

Surgical removal of extraluminal tumors also can be accomplished through a dorsal episiotomy. Because these tumors are often well encapsulated and poorly vascularized, blunt dissection generally removes them entirely. On rare occasions, a perineal approach or pelvic split may be required. Urethral catheterization prevents accidental damage to the urethra during tumor excision. Malignant, infiltrative vaginal neoplasms can be addressed with complete vulvovaginectomy and perineal urethrostomy in carefully selected cases. OHE is indicated in cases with multifocal disease because stable disease or regression may be obtained with hormone ablation.

Prognosis

For benign tumors, surgical excision and OHE are nearly always curative. The prognosis for malignant tumors must be considered guarded due to high rates of local recurrence and metastasis.⁶⁰ Surgery with OHE was curative in the one feline leiomyoma reported.

Tumors of the Mammary Gland

KARIN U. SORENMO, DEANNA R. WORLEY, AND MICHAEL H. GOLDSCHMIDT

Mammary Gland Tumors in Dogs

Epidemiology and Risk Factors

Epidemiology

Mammary gland tumors are common in dogs and represent the most common neoplasms in sexually intact female dogs.¹⁻⁶ The incidence rates reported vary, depending on the origin of the studies and characteristics of the source population. The current incidence of mammary tumors in the United States is lower than in many other countries due to the common practice of performing ovariectomy (OHE) at a young age. Data from several European national or regional canine cancer registries, including Norway, Denmark, and Italy, provide information regarding tumor incidence in general, as well as details regarding the relative frequency of various tumors according to site, age, and breed. These registries consist of a population of predominantly sexually intact dogs and thus provide insight into the natural or true mammary tumor risk in unaltered dogs. Results from these registries show that mammary tumors are the most common tumors in female dogs and represent 50% to 70% of all tumors in this subset of the population.^{2,6} In general, open population-based and insurance-based studies may underestimate the true incidence of disease, especially if the diagnosis and subsequent registration require a surgical biopsy. Furthermore, the insured dog population may be skewed toward younger animals because of age restriction and may be void after the tenth year of age, which coincides with the peak incidence age of mammary tumor diagnosis.^{3,4} Early data from the surveys of Alameda and Contra Costa counties reported an estimated annual incidence rate of 257.7 malignant mammary tumors per 100,000 in intact female dogs.¹ A more recent large Swedish study based on 80,000 insured female dogs, most of which were sexually intact, reported a rate of 111 mammary tumors (including both benign and malignant) per 10,000 dog-years at risk.³ This study also reported an increasing risk for tumors with advancing age; 6% of all 8-year-old dogs and 13% of all 10-year-old dogs were diagnosed with at least one mammary tumor. Another large insurance-based study from the United Kingdom reported an annual incidence rate of 205 mammary tumors per 100,000 dogs. This study included all mammary tumors regardless of histology.⁴

In addition to these open and more heterogeneous population-based studies, closed population studies provide another source of incidence and natural progression data. Longitudinal studies may provide a more accurate estimate of the total lifetime risk of mammary tumors because dogs are monitored closely and all tumors are noted, biopsied, and reported. In a large beagle colony morbidity and mortality study, 71% of female dogs developed at least one mammary gland neoplasm in their lifetime.⁷ However, this may not accurately represent the incidence in other breeds.

Many of the various tumor registries have reported significant breed variations in mammary tumor incidence, suggesting that, in addition to age and hormonal factors, hereditary breed-associated genetic susceptibility also contributes to mammary tumor risk.

Risk Factors

As noted, the incidence of mammary tumors varies, depending on where the studies are performed and the specific characteristics of the population in terms of spay status, age, and breed distribution. Thus, in addition to providing data regarding incidence, the epidemiologic studies also help identify risk factors for mammary tumors. Three main factors have been identified that play important roles in mammary tumor risk: age, hormonal exposure, and breed. To a lesser degree, diet and body weight or obesity may also contribute to risk.

Age

Mammary tumors affect middle-aged and older dogs.^{1,8-11} Mammary tumors, especially malignant tumors, are extremely rare in dogs younger than 5 years old.^{1,8,12} The tumor risk increases with age and becomes significant when dogs turn 7 or 8 years old and continues to increase until the age of 11 to 13 years.^{8,12} Dogs with malignant tumors have been found to be significantly older than dogs with benign tumors: mean age of dogs with malignant tumors is 9 to 11 years and 7 to 9 years with benign tumors.^{13,14} The peak incidence age also depends on the lifespan of various breeds. In general, larger breeds have a naturally shorter lifespan and therefore tend to be younger than smaller breeds when they are diagnosed. These differences may be further exaggerated in high-risk breeds such as the English Springer spaniels.^{3,15}

Hormonal Exposure

Many mammary tumors in dogs are preventable. Dogs spayed prior to their first estrus have only a 0.5 % risk of developing mammary tumors in their lifetime.¹⁶ The protective effect of OHE decreases quickly over the first few estrus cycles, and most studies have not found significant benefit after 4 years of age. According to Schneider's original study, the risk increases and the benefit diminishes with each estrus cycle, as illustrated by an increasing risk of 8% and 26%, depending on whether the OHE was performed prior to the second or third heat cycle.¹⁶ This study found no significant risk reduction in dogs spayed after the second heat cycle, although other researchers have found some modest benefit in dogs spayed later.^{12,17,18} There is general agreement that the greatest benefit on mammary tumor prevention is seen if the dog is not allowed to go through any heat cycles, suggesting that the pivotal and irreversible effects of ovarian hormones on the mammary glands in terms of cancer risk occur early in life, likely during puberty when the mammary gland develops and matures. These findings may also

explain why other factors resulting in physiologic variation in hormonal influence on the mammary tissues such as pseudopregnancy, pregnancy, or parity, which typically occur after a few estrus cycles, have not been found to significantly influence the tumor risk.^{12,16,19} Exposure to exogenous or pharmacologic doses of hormones (both progestins and estrogens), however, has been found to increase the risk for developing mammary tumors in dogs. Dogs treated with progestins are more likely to develop tumors and are younger when they do. According to the Norwegian Canine Cancer Registry, dogs treated with progestins to prevent estrus had a 2.3 times higher risk for mammary tumors when compared to dogs not receiving such treatment.²⁰ Similarly, a Dutch study found that privately owned dogs with mammary tumors were significantly more likely to have received progestins.¹⁸ Numerous studies have investigated the effect of dose, duration, and type of hormones (progestins, estrogens, or combination of both) on mammary tumor development in laboratory dogs. Although some discordance exists, most conclude that low-dose progestins alone increase the risk for predominantly benign tumors, whereas a combination of estrogens and progestins tends to induce malignant tumors.²¹⁻²⁵

Breeds and Genetic Susceptibility

In general, mammary tumors tend to be more common in the smaller breeds. Purebred dogs are more commonly affected¹; poodles, Chihuahuas, dachshunds, Yorkshire terriers, Maltese, and cocker spaniels are frequently listed as high-risk breeds in the small-breed category.^{1,2,14,26} However, some of the larger breeds are also at increased risk, including the English Springer spaniel, English setters, Brittany spaniels, German shepherds, Pointers, Dobermans, and Boxers.^{1-3,14,26} Some noteworthy discrepancies exist, specifically between the U.S. and the European reports. Boxers are noted to have a decreased risk for mammary tumors according to data from the University of Pennsylvania, whereas Scandinavian studies reflect an increased risk in Boxers.^{2,3,14} A closed population beagle study also has shown that two different lines or families of beagles have very different mammary tumor risk.²⁷ These results collectively support a genetic influence on mammary cancer development. Familial or inherited germline mutations in *BRCA1* and *BRCA2* account for 5% to 10% of all human breast cancers and are associated with an 85% cumulative lifetime risk of breast cancer in affected individuals.²⁸⁻³¹ Studies of *BRCA* mutations in canine mammary tumors have so far been limited to tumor gene expression studies and the results have varied; some found underexpression of *BRCA1* in malignant tumors and others have documented overexpression of *BRCA2* in metastatic tumors.^{32,33} Germline mutations in both *BRCA1* and *BRCA2* were found to be associated with significantly increased risk in English Springer spaniels in a large Swedish study.^{3,15}

Other Risk Factors

Body weight, specifically during puberty (9 to 12 months), is found to have a significant effect on later mammary tumor risk; being underweight during this time period provides significant protection against later tumor development.¹⁷ This study did not find an increased risk for tumors in dogs fed a high-fat diet or dogs that were obese around the time of tumor detection. However, a subsequent case-control study did document an association between diet and mammary cancer in which obesity early in life and a diet high in red meat were found to increase risk.³⁴ Obesity has also been recognized as a risk factor for developing postmenopausal breast cancer in women.^{35,36} One of the proposed mechanisms by which diet/obesity may be linked to breast carcinogenesis is via its effect

on serum estrogen levels. Obesity is associated with decreased concentration of sex hormone-binding globulin and thus results in elevated serum free estrogen levels.³⁷⁻⁴¹ In addition, adipose tissues may be a source of increased estrogen production via aromatase-mediated conversion of androgens. Interestingly, the mammary cancer-sparing influence of being underweight is most significant during the first year of life when the effects of the endogenous hormones are the greatest.

Tumor Biology: Development, Hormones, Growth Factors, and Clinical Implications

Based on the previous discussion of risk factors, it is clear that exposure to ovarian hormones is important in the development of mammary tumors in dogs. Both estrogens and progesterone are necessary for normal mammary gland development and maturation. The mammary glands undergo distinct clinical and histopathologic changes as hormone levels fluctuate according to the phases of the estrus cycle.^{42,43} Estrogens and progesterone are mitogens of breast epithelium and induce proliferation of intralobular ductal epithelium and development of ducts and lobules, resulting in expansion of the mammary glands. Historically, the tumorigenic effects of estrogen in human breast cancer were thought to be mediated via their receptor binding and enhanced production of growth factors resulting in increased cellular proliferation.⁴⁴ However, more recent research shows that estrogen and its metabolites also have direct genotoxic effects by increasing mutations and induction of aneuploidy independent of the estrogen receptors.⁴⁵⁻⁴⁷ The tumorigenic effects of progesterone are in part thought to be mediated via a progesterone-induced increased mammary gland production of growth hormone (GH) and growth hormone receptors (GHR).⁴⁸⁻⁵⁰ GH has direct stimulatory effects on mammary tissues, as well as indirect effects via increasing insulin-like growth factor-1 (IGF-1).⁵¹ The GH/IGF-1 axis has been implicated in human breast carcinogenesis. IGF-1 is both a proliferative and a survival factor for breast epithelial cells and regulates the expression of numerous genes involved in breast cancer development.⁵²⁻⁵⁷ The complex dysregulation of growth factors and hormones that precedes, initiates, and potentially drives canine mammary tumorigenesis is far from understood; evidence exists indicating that both growth factors and steroid hormones are intrinsically implicated and contribute in an autocrine/paracrine manner. Malignant tumors have significantly higher tissue concentrations of GH, IGF-1, progesterone, and 17 β -estradiol than benign tumors, and moreover, levels correspond with important clinicopathologic parameters, such as growth rate, size, and specific histopathologic type.^{58,59} A complete review of the biologic and molecular aspects of mammary tumor carcinogenesis is beyond the scope of this chapter, but recent reviews provide more complete information.^{60,61}

The entire mammary chains are exposed to growth factors and sex hormones, resulting in a field carcinogenesis effect. Consequently, most dogs develop tumors in multiple glands.^{7,12,13,62-64} Histologic progression with increasing tumor size is often noted in dogs with multiple tumors and areas of transitions such as carcinoma in situ can be seen in benign tumors.^{13,62} This provides direct evidence that benign and malignant mammary tumors are not separate entities—instead, they are part of a biologic and histopathologic continuum in which the malignant invasive carcinomas are the endstage of the process. Earlier publications support this hypothesis and document associations between tumors of benign and malignant histology. For instance, dogs with carcinomas often had concurrent benign tumors of the same cell type and dogs with

benign mammary tumors were at increased risk for developing subsequent malignant tumors.⁶³ Furthermore, risk was even higher in dogs diagnosed with carcinomas or carcinoma in situ.^{13,62,64} Evidence of histologic progression has also been reported in which a high incidence of carcinoma in situ and intraepithelial lesions with atypia was noted adjacent to invasive carcinomas.^{62,65} These studies provide support for the hypothesis that mammary tumors develop initially from benign lesions and progress to invasive malignant lesions as part of a continuum influenced by hormonal field effects on mammary tissues. There are likely regional variations in terms of exposure, resulting in a range of histopathologic and clinical changes. Some tumors may never change and remain small and benign, whereas others progress and become malignant and many develop new tumors in other glands. This suggests that canine mammary tumors provide unique comparative opportunities to study mammary carcinogenesis and progression with direct applications to human breast cancer research.

Tumor Hormone Receptors: Prognostic, Clinical, and Therapeutic Implications

Hormonal exposure plays an important role in mammary tumor development, and many tumors, specifically tumors of epithelial origin, express hormone receptors (HRs), suggesting continued hormonal influence and dependence. Benign tumors are more likely than malignant tumors to retain HRs—both estrogen receptors (ER) and progesterone receptors (PR).⁶⁶⁻⁷⁰ The HR status is also influenced by age and hormonal status: dogs that are intact, younger, and in estrus are more likely to have receptor-positive tumors than dogs that are spayed, older, and anestrus.^{70,71} Furthermore, the HR expression is inversely correlated with tumor size and histopathologic differentiation; larger tumors and undifferentiated or anaplastic tumors are less likely to express receptors than tumors with more differentiated histology, reflecting a biologic drift toward hormone independence and corresponding with aggressive histology and clinical behavior.⁷¹⁻⁷³ HR expression analysis is most commonly performed by immunohistochemistry (IHC). Results from various studies are quite disparate, especially in terms of ER-alpha positivity in malignant tumors, and range from 10% to 92%.⁶⁶⁻⁷⁴ These variations may in part be due to differences between study populations (tumor size, castration status, tumor types) and the fact that IHC methods vary and are neither standardized nor validated. This makes it difficult to consider HR expression results when making treatment decisions. Despite these discrepancies, several studies have documented that tumor expression of ER and PR is associated with a more favorable outcome.⁷¹⁻⁷³ Endocrine therapy is recommended to all women with ER-positive tumors, regardless of intensity of staining, and results in significant improvement in the adjuvant setting.⁷⁵⁻⁸⁰ Currently, there are no published prospective studies on the predictive value of HR status and the effect or benefit of hormonal therapy in dogs with mammary tumors. Until results from such studies are available and found to be predictive, routine IHC for HRs is not likely to influence treatment decisions. In addition to the presence of HRs, the overexpression of human epidermal growth factor receptor-2 (HER2/erb-2), a member of the epidermal growth factor receptor (EGFR) family involved in signal transduction pathways that regulate cell growth and differentiation, may also provide clinical and prognostic insight, as well as therapeutic opportunities in mammary tumors. Overexpression or amplification of HER2 is found in 20% to 25% of all human breast cancer patients and is associated with aggressive behavior, resistance to hormonal therapy, and a poor prognosis.⁸¹⁻⁸³ HER2

overexpression has also been documented in canine mammary tumors using the same HercepTest scoring systems used in human breast cancer and documented positive staining ranging from 17% to 29% in malignant tumors.^{84,85} HER2 staining was associated with negative histologic features and short survival according to one of these studies,⁸⁴ but contrary to the human studies, HER2 expression was associated with an increased survival in two other independent studies.^{85,86}

History and Clinical Presentation

Mammary tumors are usually easy to detect through routine physical examinations. However, high-risk dogs, specifically older intact female dogs, should undergo a thorough examination of the mammary glands. Mammary tumors typically affect the two caudal pairs, where the mammary glands or tissues are naturally larger; thus careful palpation may be necessary to detect small tumors.^{7,12,63,64} The mammary glands should be palpated again under general anesthesia to ensure that all tumors are found and included in the surgical planning, and both chains should be carefully evaluated. A recent study documented that 70% of intact females had more than one tumor at diagnosis.¹³ The size of the tumor(s), stage of disease, and presence of systemic signs of illness vary widely. Inflammatory mammary carcinomas represent a rare but clinically important subset of mammary tumors in dogs. Affected dogs may easily be misdiagnosed as having mastitis or severe dermatitis because, rather than presenting with discrete well-circumscribed tumors, the entire mammary chain may appear edematous, swollen, warm, and painful (Figure 27-1).^{87,88} In addition to the extensive locoregional involvement, most dogs with inflammatory carcinomas have distant metastatic disease and signs of systemic illness.^{87,88} These dogs are therefore poor surgical candidates. The majority of dogs with mammary tumors are systemically healthy, and the tumors are confined to the mammary glands when they are diagnosed.

Clinical Assessment, Diagnosis, Work-Up, and Staging

Due to the risk of metastasis associated with mammary tumors, staging prior to initiating therapy is strongly recommended, especially if benign disease cannot be histologically confirmed. Minimal staging can include complete blood count (CBC), serum

• **FIGURE 27-1** Inflammatory mammary carcinoma in a dog. (Courtesy Dr. Nicholas Bacon, University of Florida, Gainesville, Florida.)

biochemistry, three-view thoracic radiographs, and fine-needle aspiration (FNA) of regional lymph nodes, even if palpably normal. Abdominal ultrasound may be indicated in dogs with suspected regional lymph node involvement or changes on preoperative blood work suggesting tumor-related or non-tumor-related serum biochemistry changes. Even though osseous metaplasia occurs occasionally with mammary adenocarcinoma and the mammary glands are a common site for extraskeletal osteosarcoma, there has been no prognostic value found for serum alkaline phosphatase activity.^{89,90} There may be value in performing mammary tumor cytology to help rule out nonmammary dermal and subcutaneous tumors (e.g., mast cell tumors, lipomas). Additionally, correlations between cytopathology and ex vivo histopathology have been reported to be between 67.5% and 93%,^{91,92} and the reported cytologic sensitivity and specificity for a malignant mammary tumor diagnosis were 88% and 96%, respectively.⁹³ Computed tomography (CT) imaging of the thoracic cavity provides more sensitive detection of pulmonary nodules than does thoracic radiography, but this may not be applicable for every patient due to a need for general anesthesia, the increased expense, and decreased availability.^{93,94} Distant metastatic sites can include lymph nodes, liver, lungs, and bone.⁹⁵

Lymphatic drainage of normal mammary glands is very complex, with documented drainage occurring to multiple ipsilateral lymph nodes and even to contralateral lymph nodes.⁹⁶⁻⁹⁸ The amount of variation in lymphatic drainage increases in the neoplastic mammary gland.⁹⁶ Tumor-induced lymphangiogenesis, well documented in human breast cancer, may be responsible for the unpredictable and erratic location of susceptible or “at-risk” lymph nodes in dogs having malignant mammary tumors.⁹⁹ Thus exclusive anatomic sampling of nearby lymph nodes is not sufficient for accurate lymph node staging and may miss the presence of locoregional disease.¹⁰⁰

Staging System

Mammary tumors are staged according to the T (tumor), N (lymph node), and M (metastasis) system. A modified version of the original staging system published by Owens¹⁰¹ is currently used by most oncologists and stage advances from I to II to III as the size of the primary tumor increases from smaller than 3 cm, to between 3 and 5 cm, to larger than 5 cm.¹⁰² These size categories capture important changes in prognosis and outcome. Lymph node metastasis represents stage IV disease, regardless of tumor size, and distant metastasis constitutes stage V disease. This staging system should be used for dogs with epithelial tumors (noninflammatory) and not sarcomas (Table 27-1).

• TABLE 27-1 Staging of Canine Mammary Tumors

STAGE	TUMOR SIZE	LYMPH NODE STATUS	METASTASIS
Stage 1	T1 <3 cm	N0	M0
Stage 2	T2 3-5 cm	N0	M0
Stage 3	T3 >5 cm	N0	M0
Stage 4	Any	N1 (positive)	M0
Stage 5	Any	Any	M1(metastasis)

Data from Rutteman G, Withrow S, MacEwen E: Tumors of the mammary gland. In Withrow S, MacEwen E, editors: *Small animal clinical oncology*, ed 3, Philadelphia, 2001, WB Saunders.

Histopathology

The normal mammary gland is a complex branching structure and the histologic and immunohistochemical characteristics are equally complex—the interested reader is referred to a thorough review on the subject.¹⁰³

Classification Systems

Two early classifications of canine and feline mammary tumors were published in 1974¹⁰⁴ and 1999,¹⁰⁵ and a revised system for the dog was published in 2011.¹⁰⁶ In dogs, although there may be histopathologic evidence of malignancy, only a small percentage of cases will have lymphatic and vascular invasion and metastatic disease, whereas in cats the majority are malignant and metastasis to local lymph nodes is more common. The classification used in this text is based on both morphology¹⁰⁶ and prognosis.¹⁰⁷ When discussing the classification of mammary neoplasms the terms *simple* and *complex* are commonly used. *Simple* denotes that the neoplasm is composed of *one* cell type resembling either luminal epithelial cells or myoepithelial cells, whereas *complex* neoplasms are composed of *two* cell types, both luminal and myoepithelial cells.¹⁰⁶

Canine Mammary Hyperplasia and Dysplasia

Several hyperplastic and dysplastic lesions are considered precursor lesions to the development of mammary neoplasms.¹⁰⁶ These include duct ectasis, lobular hyperplasia (with or without secretory activity), lobular hyperplasia with fibrosis, epitheliosis, papillomatosis, fibroses (fibrosclerosis), and fibroadenomatous change (fibroepithelial hyperplasia, fibroepithelial hypertrophy, mammary hypertrophy).

Benign Mammary Neoplasms

Several types of benign mammary neoplasms exist in the dog and include adenoma, intraductal papillary adenoma (duct papilloma), ductal adenoma, fibroadenoma, myoepithelioma, complex adenoma (adenomyoepithelioma), and benign mixed tumors. A histologic description of these various entities is beyond the scope of this chapter, and interested readers are directed to a more thorough review.¹⁰⁶

Malignant Canine Mammary Neoplasms

Malignant Epithelial Tumors

Several types of malignant epithelial tumors (Table 27-2) exist, including carcinoma in situ (well-demarcated, noninfiltrative nodule[s] that have not extended through the basement membrane) and a variety of carcinomas. In addition, several less common subtypes of malignant epithelial neoplasms are squamous cell carcinomas, adenosquamous carcinomas, mucinous carcinomas, lipid-rich carcinomas, and spindle cell carcinomas (including malignant myoepithelioma, squamous cell carcinoma–spindle cell variant, and carcinoma–spindle cell variant).¹⁰⁶

Malignant Mesenchymal Neoplasms: Sarcomas

Malignant mesenchymal neoplasms include osteosarcoma, chondrosarcoma, fibrosarcoma, hemangiosarcoma, and carcinosarcoma (malignant mixed mammary tumor).¹⁰⁶

Osteosarcoma is the most common mesenchymal neoplasm of the canine mammary gland, and there is often a history of recent rapid growth of a mammary mass that might have been present for some time. A proliferation of cells varies from fusiform to stellate to ovoid, and there is an association with islands of tumor

• **TABLE 27-2** Classification of Malignant Epithelial Mammary Tumors

CLASSIFICATION	HISTOLOGIC CHARACTERISTICS
Carcinoma in situ	<ul style="list-style-type: none"> Well-demarcated, noninfiltrative nodule(s) of closely packed cells arranged in irregular tubules or nests that have not extended through the basement membrane. Loss of normal architecture, cell and nuclear polarity with anisocytosis, anisokaryosis, and increased numbers of mitotic figures.
Carcinomas: Simple	<ol style="list-style-type: none"> Tubular carcinoma <ul style="list-style-type: none"> Cells arranged in tubules and intertubular stroma consists of vessels and fibroblast. Neoplastic cells can infiltrate the surrounding mammary tissue and evoke a stromal response. Tubulopapillary <ul style="list-style-type: none"> Papillae extend into tubular lumina and are supported by a fine fibrovascular connective tissue stroma. Cystic-papillary <ul style="list-style-type: none"> Papillae extending into cystic tubular lumina. Cribriform <ul style="list-style-type: none"> Proliferation of neoplastic cells forming a sieve-like arrangement. Lumina formed are very small and surrounded by bridges of neoplastic cells.
Carcinoma: Micropapillary invasive	<ul style="list-style-type: none"> Intraductal neoplastic population forms small intraluminal irregular aggregates and small papillae that do not have a supporting fibrovascular stalk.
Carcinoma: Solid	<ul style="list-style-type: none"> Closely packed cells arranged in nests and cords form dense, irregularly sized lobules surrounded by fine fibrovascular stroma.
Comedocarcinoma	<ul style="list-style-type: none"> Necrotic areas within the center of neoplastic cell aggregates. Necrotic areas characterized by abundant amorphous eosinophilic material admixed with cell debris.
Carcinoma: Anaplastic	<ul style="list-style-type: none"> Most malignant of the carcinomas. Neoplastic cells individualized or in small nests. Invading cells often evoke a desmoplastic host response. Inflammatory carcinoma is a clinical diagnosis. Anaplastic histology characterized by extensive histologic invasion with neoplastic emboli in the overlying dermal lymphatic vessels.
Carcinoma arising in a complex adenoma/mixed tumor	<ul style="list-style-type: none"> Benign counterpart detectable with areas of more pleomorphic epithelial cells has increased numbers of mitoses when compared to the preexisting benign epithelial component.
Carcinomas: Complex	<ul style="list-style-type: none"> Malignant epithelial component, but myoepithelium is benign. Only the epithelial cells exhibit considerable anisokaryosis and anisocytosis.
Ductal carcinoma	<ul style="list-style-type: none"> Cells arranged in cords and tubules that surround slitlike lumina lined by a double layer of epithelial cells. Exhibit anisokaryosis, anisocytosis, and increased mitotic figures.
Intraductal papillary carcinoma	<ul style="list-style-type: none"> Proliferation of multilayered epithelial cells. Fibrous connective tissue and normal myoepithelial cells are retained as the supporting stroma for the papillae.

osteoid and/or bone formation. Mitoses are frequently found. Metastasis occurs via the hematogenous route, mainly to the lungs.

Carcinosarcoma (malignant mixed mammary tumor) is composed partly of cells morphologically resembling the epithelial component and partly of cells morphologically resembling connective tissue elements, both types of which are malignant. It is an uncommon mammary neoplasm, but it most often presents as a carcinoma and osteosarcoma (see previous paragraph). The epithelial component metastasizes via lymphatic vessels to regional lymph nodes and the lungs, and the mesenchymal component metastasizes via the hematogenous route to the lungs.

Hyperplasia/Dysplasia/Neoplasia of the Nipple

Ductal adenoma and carcinoma are rare and involve only the nipple, with no neoplastic tissue in the underlying mammary gland.

The nipple is enlarged and firm. The histopathology mimics that of ductal adenomas and carcinomas. Carcinoma with epidermal infiltration (Paget-like disease) is a neoplasm occasionally seen in the dog that mimics Paget's disease of the nipple in women. The carcinoma is present within the mammary gland, and carcinoma cells, either as individual cells or small aggregates, are present within the epidermis of the nipple.

Histopathologic Prognostic Factors and Grading

The epithelial tumors are also graded according to specific histopathologic criteria. Several systems for both canine and feline tumors exist, most of which are based on the Elston and Ellis grading system,¹⁰⁸ which incorporates information regarding (1)

• **TABLE 27-3** Criteria Used for Histologic Grading of Malignancy in Feline and Canine Mammary Carcinomas

TUBULE FORMATION	NUCLEAR PLEOMORPHISM	MITOSES/10 HPF	
		CANINE	FELINE
Tubule formation >75% of the specimen: 1 point	Uniform or regular small nucleus and occasional nucleoli: 1 point	0-9: 1 point	0-7: 1 point
Moderate formation of tubular arrangements (10%-75% of the specimen) admixed with areas of solid tumor growth: 2 points	Moderate degree of variation in nuclear size and shape, hyperchromatic nucleus, and presence of nucleoli (some of which can be prominent): 2 points	10-19: 2 points	8-14: 2 points
Minimal or no tubule formation (<10%): 3 points	Marked variation in nuclear size and hyperchromatic nucleus, often with one or more prominent nucleoli: 3 points	>20: 3 points	>15: 3 points

• **TABLE 27-4** Tumor Grade Based on Histologic Score in Felines and Canines

TOTAL SCORE	GRADE OF MALIGNANCY
3 to 5	I (low) Well differentiated
6 to 7	II (intermediate) Moderately differentiated
8 to 9	III (high) Poorly differentiated

Data from Misdorp W: Tumors of the mammary gland. In Meuten DJ, editor: *Tumors in domestic animals*, ed 4, Ames, Iowa, 2002, Iowa State Press; Clemente M, Perez-Alenza MD, Illera JC, et al: Histological, immunohistological, and ultrastructural description of vasculogenic mimicry in canine mammary cancer, *Vet Pathol* 47:265-274, 2010; and Castagnaro M, Casalone C, Bozzetta E, et al: Tumour grading and the one-year post-surgical prognosis in feline mammary carcinomas, *J Comp Pathol* 119:263-275, 1998.

tubule formation, (2) nuclear pleomorphism, and (3) mitosis per 10 HPF (Table 27-3).¹⁰⁹⁻¹¹¹ Based on the total score derived from this system, the grade of the tumor will be determined: grade 1 (low score) is a well-differentiated tumor, grade 2 (intermediate score) is moderately differentiated, and grade 3 (high total score) is poorly differentiated (Table 27-4). Tumor grade has been found to provide consistent and reliable prognostic information.^{71,106-111} In addition to the grading system, information regarding vascular/lymphatic invasion, surrounding stromal invasion, lymph node involvement, and tumor type may also predict behavior.* Sarcomas are typically not graded according to this system, but the majority tend to be biologically aggressive tumors and associated with a very poor long-term survival.^{111,112}

Mammary tumors in dogs represent a wide histologic spectrum with both benign and malignant lesions originating from different tissue types or a combination of tissues. Many dogs present with several different tumors and tumors of different types and can as such represent a rather daunting histopathologic picture; prognosis is determined by the most aggressive tumor, and decisions regarding adjuvant treatments should be based on the largest or the most aggressive histology. In many cases, the most aggressive tumor is the largest.¹³

Clinical Prognostic Factors

The three prognostic factors that are most consistently reported to be associated with prognosis include tumor size, lymph node involvement, and World Health Organization (WHO) stage (modified and original). These are the only factors that will be discussed here.

Tumor Size

According to MacEwen et al, dogs with tumor volume larger than 40 cc (approximately 3.4 cm in diameter) have a statistically significant worse outcome than smaller tumors, both in terms of remission and survival.¹¹⁴ Other investigators have classified tumors as stage I, smaller than 3 cm; stage II, between 3 cm and 5 cm; and stage III, larger than 5 cm.^{101,114} Dogs with tumors smaller than 3 cm were reported to have a significantly longer survival.^{11,71,115} Others, however, have found that a change in prognosis only becomes significant when tumors are larger than 5 cm.^{26,116} The change in prognosis is likely gradual as tumors increase in size. The modified WHO staging system has incorporated these three size categories representing stage I, stage II, and stage III, respectively.¹⁰² These stages are commonly used in mammary tumor staging. Importantly, however, the size of the tumor becomes irrelevant if the local lymph node is involved; according to Kurzman et al, the size of the primary tumor was not significant in dogs with local lymph node involvement.¹¹ A positive lymph node constitutes stage IV disease according to the revised WHO system, attributing a worse prognosis to lymph node involvement rather than tumor size.

Lymph Node

A large retrospective study, including only dogs with carcinomas, all of which had the local or draining lymph node removed and biopsied, found that the status of the local lymph nodes was highly prognostic.¹¹ Others have confirmed these findings.* Therefore information regarding the status of the local lymph node is extremely important when considering the need for adjuvant or systemic therapy in dogs with mammary tumors.

WHO Staging System

Both the original and the revised WHO staging system provide prognostic information. When performing a side-by-side comparison of the two systems, the revised system appears to better reflect the stronger impact of lymph node status on prognosis.¹⁰³

*References 11, 26, 62, 107, 111-113.

*References 26, 71, 73, 111, 112, 117.

Nevertheless, the original staging system also provides useful prognostic information as illustrated in two larger separate retrospective studies in which dogs with higher WHO stage disease had a significantly worse prognosis than dogs with lower stage disease.^{26,117}

Therapy

Surgical Treatment

The challenge in preparing surgical recommendations is the lack of uniform, robust prospective clinical trials that clarify the extent or “dose” of surgical excision: simple lumpectomy, mastectomy, regional mastectomy, chain mastectomy, or staged bilateral mastectomies. The goal of the surgery must be defined through staging and counseling with the owner. Is the goal to remove the current tumor(s) with clean margins or remove the current tumor(s) with clean margins *and* prevent new tumors in the remaining glands? The latter option would require prophylactic mastectomies of clinically normal glands in addition to affected glands.

Several studies have evaluated the effect of surgical dose in canine mammary tumors. A prospective randomized trial of 144 dogs with naïve malignant tumors comparing the overall survival benefit and disease-free interval (DFI) relative to either chain mastectomy or simple mastectomy found no differences.¹¹⁴ Similarly, a retrospective case series of 79 dogs treated at a single institution found no difference in overall survival or DFI comparable to the type of surgical procedure performed, whether lumpectomy, mastectomy, regional mastectomy with en bloc lymph node excision, or chain mastectomy with en bloc lymph node excision.¹¹⁷ However, the relative hazard for death within the first 2 years after surgery was slightly higher for dogs receiving a regional mastectomy over a chain mastectomy.¹¹⁷ Interestingly, in the study by MacEwen et al, the hazard curves for DFI and survival were quite similar, suggesting that most dogs that experienced recurrence developed metastasis and not new tumors. However, the rate of new tumors was not reported in this study.¹¹⁴ A differing study indicates that surgical “dose” is important. In this case series of 99 dogs, all intact female dogs underwent either a regional or chain mastectomy for a single mammary gland tumor with unknown histology.¹¹⁸ Of these, 58% of dogs developed a new tumor in the remaining ipsilateral mammary gland tissue following a regional mastectomy and those whose initial tumor was subsequently determined to be malignant were more likely to develop an ipsilateral tumor. The authors advocated for an initial unilateral chain mastectomy for female intact dogs with a single mammary tumor, although, in their population, 42% of dogs did not develop a subsequent tumor and would have experienced a larger surgical dose than needed.¹¹⁸ Unfortunately, other large useful studies investigating the association between OHE and survival did not report on the completeness or extent of mammary tumor removal.^{18,119,120} Development of second mammary tumors is well documented and has been reported in over 70% of dogs with malignant mammary tumors following lumpectomy, although the impact of second mammary tumor development on survival is not clear.^{16,114,118} It seems intuitive that a single standardized guideline for surgical treatment omits consideration of factors such as the dog's age, tumor size, tumor number, previous mammary tumors, and stage and may not provide the optimal outcome. Future carefully constructed clinical trials may offer more tailored recommendations based on the individual patient's risk.

Current recommendations based on available data suggest that for dogs with a single mammary tumor of known or unknown histotype, surgical excision wide enough to completely remove the mammary gland tumor is adequate. Incomplete excision or

• **FIGURE 27-2** Regional mastectomy in a dog. (Courtesy Dr. Julius Liptak, Alta Vista Animal Hospital, Ottawa, Canada.)

cytoreductive procedures are not endorsed.⁹⁵ Tumors that are fixed or have skin ulceration and are less than 1 cm in diameter may be sufficiently managed with a mamnectomy (Figure 27-2).⁹⁵ “Wide excision” has not been well defined, but for larger tumors, this may be generalized to a 2-cm lateral margin and modified according to the size of the patient and tumor.⁹⁵ The deep margin may need to include the abdominal muscular fascia and/or portions of the abdominal wall to be excised en bloc with the mammary tumor, depending on size and fixation.⁹⁵ If abdominal surgery is to be performed simultaneously for OHE, penetration of the tumor prior to abdominal entry is to be avoided to prevent direct spread of tumor cells; rather, tumor removal should follow abdominal closure. For animals with multiple mammary tumors, more extensive resections such as a regional mastectomy or unilateral chain mastectomy may need to be pursued. As with other tumor resections, surgical margin assessment is critical for malignant mammary tumors, and additional surgery should be pursued if incompletely excised. Elective unilateral or bilateral chain mastectomies may be reasonable for young intact bitches with multiple tumors because there is a suggestion for development of additional tumors (Figure 27-3).⁹⁵ In spite of the evidence for recurrent mammary gland tumor development, there is no sufficiently compelling evidence at this time for routine recommendation of complete, unilateral or bilateral chain mastectomies.

Surgical excision is questionable as an adjuvant treatment for dogs presenting with inflammatory carcinoma due to the profound diffuse microscopic extent of cutaneous disease, the significant metastatic rate, and the local tissue coagulopathy that may be present. In 43 dogs with inflammatory carcinoma, only three dogs were considered suitable for unilateral chain mastectomy based on physical examination, yet all three had residual neoplastic cells at the surgical margins.⁸⁸ Interestingly, two of the dogs also received adjuvant chemotherapy and were among the longer survivors in that study.⁸⁸

In women, the use of sentinel lymph node mapping has dramatically altered the surgical treatment of breast cancer. As canine mammary carcinoma has been demonstrated as a relevant model for human disease,^{121,122} incorporation of human lymph node staging techniques should be reconsidered for the dog.¹⁰⁰ Sentinel lymph node mapping is a means of detecting which nodes are receiving draining tumor lymph and thus most at risk for

lymph node metastasis. Some techniques described for sentinel lymph node mapping in the dog include lymphoscintigraphy using technetium, contrast-enhanced ultrasonography, autogenous hemosiderin, and intraoperative dyes (Figure 27-4).^{97,100,123-125} The first description of sentinel lymph node mapping in any animal was done in cats 20 years ago.¹²⁶ Benefits include greater

ease in identifying the at-risk lymph nodes intraoperatively with minimal surgical incisions and with efficiency, especially for the rarely assessed axillary nodes. The prognostic value of sentinel lymph node mapping is currently unknown for the dog as is the presence of mammary carcinoma lymph node micrometastasis.¹²⁷

Systemic Treatment

Few clinical studies investigate systemic therapy for mammary tumors, and its efficacy has not been evaluated and confirmed according to the highest evidence-based standards. Despite this uncertainty, systemic therapy is routinely recommended and administered in dogs with high-risk tumors. This practice is based on the recognition that dogs with large tumors, positive lymph nodes, and aggressive histology are not treated effectively with surgery alone. The use of hormonal therapy in canine mammary tumors is based on tumor hormone dependence (tumor risk and HRs), as well as the potential to significantly reduce recurrence and prolong survival in HR-positive cancers similar to human hormonal therapy. This can be achieved by surgical means (ovariectomy [OVE] or OHE) or medical means, including specific ER

modulators (SERMs) and suppression of estrogen synthesis by aromatase inhibitors or luteinizing hormone-releasing hormone (LHRH) agonists. Tamoxifen, an ER antagonist commonly used in women with ER-positive breast cancer, has been evaluated in dogs both with and without mammary tumors. Due to the side effects, mostly from proestrogenic signs, this strategy may not be tolerable or feasible in dogs.^{128,129} Surgical ovarian ablation, specifically OVE/OHE, is a more practical solution in the dog. The results are in discordance, however. The majority of earlier publications did not report survival benefit in ovariectomized dogs compared to intact dogs.^{16,114,115,128,130}

Despite some study flaws, it is also possible that hormonal therapy is not effective. Dogs with large primary tumors, lymph node involvement, and undifferentiated histology have a poor

[‡]Dogs with stage III disease according to the original WHO staging system were included.¹³¹ Stage III disease includes dogs with tumors >5 cm. with or without lymph node metastasis.¹⁰¹

prognosis and are less likely to have HR-positive tumors; thus they are less likely to benefit from hormonal ablation. A few studies have found that OHE significantly improves survival in dogs with mammary carcinomas or complex carcinomas. One study found the timing of OHE in relation to tumor surgery was important because only dogs with OHE within 2 years prior to or concurrently with tumor removal benefited. Dogs with OHE more than 2 years prior to surgery had a similar survival to dogs that remained intact.¹²⁰ Another study found that the benefit of OHE was only significant in dogs with complex carcinomas.¹¹⁷ It is clear that only an adequately powered prospective randomized trial in which the effect of OHE is analyzed in context of HR status can answer questions regarding hormonal therapy in dogs with mammary tumors.

Chemotherapy is often administered to dogs with mammary tumors considered to be at risk for metastasis or recurrence. Most of the evidence regarding the efficacy of adjuvant chemotherapy is weak. A prospective nonrandomized study on dogs with high-risk mammary tumors (stage III or IV) did show a significant survival benefit in dogs receiving a combination of 5-fluorouracil and cyclophosphamide adjuvant to surgery compared to dogs treated with surgery alone.¹³¹ Today, anthracycline or taxane combinations are considered part of first-line protocols in human breast cancer therapy in women requiring adjuvant therapy^{75,132-134}; however, only inadequately powered studies on the efficacy of doxorubicin or docetaxel in dogs with mammary tumors exist and they did not establish benefit.¹³⁵ Similarly underpowered investigations of adjuvant gemcitabine in dogs with advanced stage (IV or V) mammary carcinoma did not establish benefit.¹³⁶ Adequately powered, randomized prospective trials are needed to determine the future role of adjuvant chemotherapy in dogs with high-risk mammary tumors. Systemic treatment, including nonsteroidal antiinflammatory drugs (NSAIDs), with or without chemotherapy, was found to be effective in prolonging survival in dogs with inflammatory carcinomas according to two independent retrospective case series.^{88,137} Chemotherapy may also have a role in the treatment of primary mammary gland osteosarcoma. The mammary gland is one of the most common sites for extraskelatal osteosarcoma and according to a small retrospective case series (including primary mammary gland osteosarcoma, as well as other extraskelatal sites), dogs treated with adjuvant chemotherapy were significantly less likely to die from tumor-related causes than dogs treated with surgery alone.¹³⁸ More recently, a prospective randomized trial documented significant improvement in survival in dogs with histologic grade

2 or 3 carcinoma treated with perioperative desmopressin.¹³⁹ The antimetastatic properties of desmopressin are not fully understood, but it is hypothesized that they in part are mediated through improving hemostasis and preventing cancer cells from gaining access to the vasculature during surgical manipulation.^{140,141} The results are intriguing, and further confirmatory studies are warranted. As illustrated previously, there is currently a paucity of high-quality trial evidence from which to draw information and guidance for treating dogs with malignant high-risk mammary tumors. Table 27-5 provides general guidance and treatment consideration/options and the level of supporting evidence.

Mammary Tumors in Cats

Epidemiology and Risk Factors

Epidemiology

There are fewer epidemiologic studies regarding the incidence of mammary neoplasia in cats compared to dogs. Furthermore, due to differences in veterinary care for cats, the available data likely underestimate the true incidence of disease. According to data from one of the largest Swedish insurance companies, approximately 40% to 50 % of all dogs had insurance to cover veterinary expenses, whereas only 20% of cats had such coverage.^{143,144} Another study from the United States also reported that a significantly lower percentage of cats than dogs receives regular veterinary care.¹⁴⁵

The overall mammary tumor incidence is lower in cats than in dogs. According to the California Animal Neoplasia Registry (CANR), mammary tumors represent the third most common tumor type in female cats (after skin tumors and lymphoma), with an annual incidence rate of 25.4/100,000 (compared to 198/100,000 in female dogs), and 12% of tumors in cats regardless of sex.¹ Data from an animal tumor registry from two provinces in northern Italy reported that mammary tumors represented 16% of all tumors in cats and 25% in female cats.¹⁴⁶ Data from the Swedish insurance company indicate that mammary tumors were the most common cancer, representing 40% of all tumor-related claims in cats.¹⁴³ It is unclear whether the higher relative incidence of mammary tumors in the latter studies is due to differences in neutering practices or use of progestins in the source population because no information regarding spay status was provided.

Risk Factors

Three main risk factors in cats have been identified: age, breed, and hormonal influence.

Age As in the dog, mammary neoplasia is a disease seen predominantly in middle-aged to older cats. The mean age of diagnosis is between 10 and 12 years of age.^{1,147-150} Risk increases incrementally with age but does not become significant until 7 to 9 years, according to the age-specific incidence curves from the CANR, and continues to increase up until 12 to 14 years.¹

Breed Siamese cats are significantly younger when diagnosed with mammary tumors, and risk plateaus at 9 years of age.¹⁵¹ In general, genetic predisposition for a disease is often associated with a younger age of diagnosis. Siamese cats appear overrepresented when compared to other breeds.^{151,152} However, Siamese cats have an increased risk for many tumor types, not only mammary tumors.¹⁵³⁻¹⁵⁷ It is therefore possible that the increased incidence in Siamese cats is due to breed-associated germline alterations in common tumor susceptibility genes or defective tumor suppressor gene function that confers increased risk for many different malignancies.

Hormonal Association Exposure to ovarian hormones is also strongly implicated in mammary tumorigenesis in the cat. According to Dorn et al, sexually intact cats have a sevenfold higher risk than spayed cats.¹ The increased risk in intact cats has been confirmed by others.^{148,151,158} Similar to findings in dogs, exposure from ovarian hormones in cats at an early age appears crucial. The protective effect of OHE diminishes quickly over the first few years; risk reductions of 91%, 86%, and 11% are seen in cats that are ovariohysterectomized before 6 months, between 7 and 12 months, or 13 and 24 months, respectively. No benefit was found after 24 months.¹⁵⁸ According to the same study, parity did not influence risk for mammary tumors.

In addition to endogenous ovarian hormonal influence, exposure to exogenous progestins also increases risk. Cats treated with progestins have an overall relative risk of 3.4 compared to those not receiving such treatments, although benign tumors arise more commonly than malignant tumors (relative risk 5.28 versus 2.8).¹⁴⁸ Unlike in dogs, progestin-treated cats were not younger than non-treated cats when they developed tumors.¹⁴⁸ The tumorigenic effects of oral progestins in cats are supported by reports of male cats with mammary tumors. Mammary tumors are rare in males, but in a report of 22 cases, 8 (36%) had a history of progestin use.¹⁵⁹ In a recent case series of three male cats with mammary tumors, all had received multiple injections of a long-lasting (depot) progestin over 5 to 6 years prior to tumor development. All had malignant tumors and all developed subsequent malignant tumors in other glands after initial surgery.¹⁶⁰ Shorter duration of treatment or inconsistent administration is less likely to result in malignant tumors but nevertheless induce changes in the mammary glands.¹⁶¹ Fibroepithelial hyperplasia is the most common histopathologic change in cats treated for shorter periods of time and can occur relatively quickly, even after one injection. However, studies show that regular and prolonged administration is needed for malignant tumors to develop.¹⁴⁸

Tumor Biology: Development, Hormones, Growth Factors, and Prognostic Implications

The risk for mammary tumor development in cats is determined by exposure to ovarian hormones early in life, but the latency period appears long because most cats are older when diagnosed. In many species, ovarian hormones are necessary for normal

mammary gland development and maturation, but few studies have examined hormonal effects on mammary tumorigenesis in cats. The complex interactions between sex hormones, growth hormones, and IGF have been discussed in more detail in the section on canine mammary tumors, but progestin-induced mammary production of growth hormone has been documented in the cat.^{162,163} It is, however, biologically plausible that the tumorigenic effects on mammary tissues are similar across species and that the same general mechanisms are involved, specifically sex hormones and growth hormones. Despite ER and PR expression being implicated in the initial stages of mammary tumor development, many investigators have reported that most feline mammary carcinomas are ER and PR negative, although slightly more than one-third are PR positive.^{69,164-167} The percentage of ER/PR expression varies between studies and is likely the result of differences in case selection, methods, and interpretation of the results. The biochemical method, the dextran-coated charcoal (DCC) method, may be more sensitive than IHC when analyzing ER in cats.¹⁶⁶ Standardized IHC methods have high concordance with DCC methods; 38.5% of the malignant tumors and 66.7% of the benign lesions expressed PR according to IHC.¹⁶⁶ In this particular study, sexually intact cats were more likely to have PR-positive tumors. Lower concordance was found between ER analysis by DCC and IHC, with IHC being less sensitive than DCC; only 20% of the malignant tumors expressed ER according to IHC compared to 44% according to the DCC assay.¹⁶⁶ These results are consistent with other publications showing a relatively low ER expression in feline mammary tumors when using IHC.

The low HR-positivity in the tumors is consistent with the higher rate of malignancy and a more aggressive clinical behavior in feline mammary tumors. In contrast to malignant tumors, normal mammary tissue and dysplastic lesions in the mammary gland express both ER and PR.^{69,164,165} However, this hormone dependence appears to wane with histologic progression from benign to malignant. None of the intermediate- or high-grade ductal carcinomas in situ were ER or PR positive, whereas the normal and hyperplastic adjacent mammary tissue expressed receptors.^{69,164,165} Fibroepithelial hyperplasia, a progesterone-induced change, has been reported to have high PR expression¹⁶¹ and can be effectively treated by OHE or antiprogesterones (Figure 27-5).¹⁶⁸

In human breast cancer, an inverse relationship between the HR status and HER-2/neu expression is documented. HER-2/neu expression tends to be higher in cats than in dogs and humans; however, a wide range (5.5% to 90%) of HER-2/neu-positive tumors is reported.¹⁶⁹⁻¹⁷² Although the clinical and histologic association with HER-2/neu expression varies, cats with spontaneous mammary carcinomas may be good models for HER-2/neu-positive, hormone refractory breast cancer in women.

History and Clinical Presentation

Cats with mammary tumors are often older and may be sexually intact or spayed after they were 2 years old. Tumors are easy to detect on physical examination and appear as firm discrete mass(es) in the mammary gland(s). One study reported that all glands are equally susceptible to tumor development, but a later study showed that the anterior glands were less commonly affected.^{173,174} Multiple tumors are common; 60% of cats had more than one tumor at diagnosis in one report.¹⁴⁹ Careful examination of the remaining mammary glands is important when evaluating a cat with a prior history of mammary tumors, especially if treated with simple mastectomy, because new primary tumors are common. Tumor(s) size

• **FIGURE 27-5** Fibroepithelial hyperplasia in a cat. (Courtesy Dr. Lisa Mestrinho, Faculdade de Medicina Veterinária, Universidade Lusofona de Humanidades e Tecnologias, Lisboa, Portugal.)

at diagnosis depends on how early it is detected and how aggressive the tumor behaves. Larger tumors may become ulcerated, inflamed, and infected. Local lymph nodes may or may not appear enlarged. Inflammatory mammary carcinomas are rare in cats, and the clinical picture and outcome are similar to those described in the dog.¹⁷⁵

Clinical Assessment, Diagnosis, Work-Up, and Staging

Cats with mammary masses tend to be older and their tumors are commonly malignant; therefore, a thorough work-up is recommended to ascertain any comorbidity as well as advanced disease. This may include at a minimum a CBC, serum biochemistry, serum T₄ concentration, three-view thoracic radiographs, abdominal ultrasound, and urinalysis, in addition to FNA of any mammary masses and any palpable (including normal-sized) regional lymph nodes.

Staging System

Feline mammary tumors are staged similar to canine tumors using a modification of the original system published by Owens.^{101,176} In the modified system, stage advances from I to II to III as the size increases from smaller than 2 cm, to between 2 and 3 cm, to larger than 3 cm.¹⁰² Unlike the canine system, stage III disease also includes T1 or T2 tumors with concurrent lymph node metastasis and lymph node metastasis does not need to be present with T3 tumors. Stage IV disease is any tumor with any lymph node metastasis and distant metastasis.¹⁷⁶ This staging system should not be used with mammary gland sarcomas (Table 27-6).

Histopathology

The vast majority of feline mammary tumors are malignant (85% to 95%), with an aggressive biologic behavior, and lymphatic invasion and lymph node metastasis are more common at the time of initial diagnosis than in dogs. Early classifications of feline mammary tumors were simpler than that used for canine tumors¹⁰⁵; however, several new tumor types have subsequently been reported.

• **TABLE 27-6** Staging of Feline Mammary Tumors

STAGE	TUMOR SIZE	LYMPH NODE STATUS	METASTASIS
Stage 1	T1 <2 cm	N0	M0
Stage 2	T2 2-3 cm	N0	M0
Stage 3	T1 or T2	N1 (positive)	M0
	T3 >3 cm	N0 or N1	M0
Stage 4	Any	Any	M1

Data from McNeill CJ, Sorenmo KU, Shofer FS, et al: Evaluation of adjuvant doxorubicin-based chemotherapy for the treatment of feline mammary carcinoma, *J Vet Intern Med* 23:123-129, 2009.

Hyperplasia and Dysplasia¹⁰⁵

The various hyperplastic and dysplastic lesions included in this group include duct ectasia, lobular hyperplasia, lobular hyperplasia with secretory (lactational) activity, lobular hyperplasia with fibrosis (interlobular fibrous connective tissue), epitheliosis (intralobular ducts), papillomatosis (interlobular ducts), and fibroadenomatous change.¹⁷⁷ Fibroadenomatous change (fibroepithelial hyperplasia, fibroepithelial hypertrophy, mammary hypertrophy) is more common in the cat than the dog and is characterized by the proliferation of interlobular ducts and periductal stromal cells. The stroma is often edematous or myxomatous, and both the ductal and stromal cell nuclei exhibit some pleomorphism with mitoses. This lesion is hormonally induced and occurs in progestin-treated female and male cats, as well as being associated with pregnancy. Most cases regress at the end of pregnancy or cessation of progestin treatment.

Benign Feline Mammary Neoplasms¹⁰⁵

Benign tumors in cats are uncommon and include adenoma, ductal adenoma, fibroadenoma, and intraductal papillary adenoma (duct papilloma).

Malignant Feline Mammary Neoplasms^{105,172,175,177-183}

The predominant malignant tumor types in cats are simple and epithelial in origin and as such represent carcinomas of various types. Adenocarcinomas, tubular carcinomas, or a combination of tubular, papillary, and solid carcinomas are most common. Other variants include cystic papillary carcinoma, cribriform carcinoma, micropapillary invasive carcinoma, comedocarcinoma, and less commonly, squamous cell carcinoma, mucinous carcinoma, and lipid-rich carcinoma.

Histopathologic Prognostic Factors and Grading

Grading was initially thought not to be prognostic in cats; therefore the classification of mammary tumors was based on morphologic criteria only. More recently, grading, using a system similar to that in dogs (based on the Elston and Ellis scoring system; see Tables 27-3 and 27-4), has been shown to be prognostic in cats. In addition to grade, lymphovascular invasion and lymph node metastasis are independent prognostic factors.^{178,184} Thus the histopathologic criteria used in dogs (i.e., grade, vascular invasion, lymph node status) can be used in cats when assessing risk for metastasis and prognosis and should be incorporated into decisions regarding the need for systemic treatment in cats with mammary tumors (Table 27-7).

Clinical Prognostic Factors

Few studies reporting prognostic factors in cats with mammary tumors are prospective, only one is randomized, and most are

• **TABLE 27-7** Prognostic Factors and Indications for Adjuvant Chemotherapy with Level of Supporting Evidence in Cats with Malignant Mammary Tumors

TUMOR SIZE	LYMPH NODE INVOLVEMENT	HISTOPATHOLOGIC PARAMETERS	INDICATION FOR CHEMOTHERAPY –(NO) OR +(YES)	EVIDENCE LEVEL*
<2 cm/8 cm ³	Negative	Carcinoma	– + [†]	–1 ¹⁸⁵ +3 ^{178,184,186}
2–3 cm/8–27 cm ³	Negative	Carcinoma	– + [†]	–3 ¹⁸⁷ +3 ^{178,184,186}
>3 cm/27 cm ³	Negative	Carcinoma	+	1, ¹⁸⁵ 2, ¹⁷⁴ 3 ¹⁸⁷
Any	Positive	Carcinoma	+	2, ¹⁷⁴ 3, ¹⁸⁴ 5 ⁷⁵

*Evidence level 1: Prospective randomized trial (PRT); level 2: Prospective, nonrandomized trial (PT); level 3: Retrospective (RT); level 5: Extrapolation from human breast cancer studies (EH).

[†]Vascular invasion and high grade were found to be independent negative prognostic factors in multivariate analysis.

underpowered or not stratified according to treatment. Therefore the results vary and may be significantly affected by bias. Tumor size has, however, consistently been reported to have prognostic significance, including the results of two large prospective studies.

Tumor Size and Prognosis

Three size categories have shown prognostic significance: (1) smaller than 8 cm³ or smaller than 2 cm diameter; (2) larger than 8 to 27 cm³ or larger than 2 to 3 cm diameter; and (3) larger than 27 cm³ or larger than 3 cm diameter. Cats with small tumors (<2 cm) can be effectively treated with surgery alone with a median survival time (MST) of more than 3 years, whereas cats with tumors larger than 3 cm have a MST of only 6 months according to a large, high-quality retrospective study.¹⁸⁷ Cats with 2- to 3-cm diameter tumors survived an average of 2 years. Several other publications have confirmed this association between survival and tumor size.^{150,152,174,185,186} Tumor size is one of the most important factors when assessing risk for metastasis and the need for adjuvant treatments.

Lymph Nodes and Prognosis

Surprisingly few studies have evaluated lymph node status and its prognostic significance in cats with mammary tumors. In a large prospective study of 202 cats, those with lymph node metastasis had a significantly shorter survival than cats with negative lymph nodes.¹⁷⁴ A recent retrospective study with 92 cats supported these findings; all cats with lymph node metastasis died within the first 9 months of diagnosis.¹⁸⁴

Breed and Prognosis

Domestic shorthair cats had significantly better outcomes than purebred cats in a prospective randomized trial of cats with mammary carcinomas.¹⁸⁵ A recent retrospective case series reported that Siamese cats had a worse prognosis than domestic shorthairs.¹⁸⁸ These studies may in fact complement each other; however, the first study did not provide information regarding how many Siamese cats were included in the purebred group. Several other studies have not found breed to be prognostic when adjusted for other factors.

Age

The results regarding age and prognosis are conflicting. Several studies report that older cats have a worse prognosis; however, bias due to differences in treatments or differences in tumor size and stage may exist. Importantly, a prospective randomized trial found

no difference according to age when comparing cats that were younger or older than 10 years.¹⁸⁵

Surgical Treatment

The surgical dose recommended for treating feline mammary tumors is much clearer than in the dog. A chain mastectomy (unilateral for cats possessing a single tumor or a 2-staged bilateral chain mastectomy for cats with bilateral tumors) resulted in a favorable statistically significant DFI, as opposed to cats receiving conservative tumor excision in a series of 100 cats.¹⁸⁷ In that same case series, there was a trend for improved survival times for cats receiving chain mastectomies.¹⁸⁷ In a retrospective case series of 53 cats, while no significant relation was found between the type of surgical procedure performed, cats experienced longer DFIs following either unilateral or bilateral chain mastectomies.¹⁵² In a multiinstitutional retrospective case series comparing patients receiving surgery versus surgery with adjuvant doxorubicin-based chemotherapy, the subset of cats having unilateral chain mastectomies followed with chemotherapy had significantly longer MSTs than cats having unilateral chain mastectomies performed without chemotherapy (1998 versus 414 days).¹⁷⁶ In that series, local recurrence developed in 50% of cats and, although not statistically significant, appears to support the use of chain mastectomies for feline mammary carcinomas.¹⁷⁶ In a report of male cats diagnosed with mammary carcinomas, a trend toward more frequent local recurrence correlated with more conservative resections.¹⁵⁹ Thus, for cats, a unilateral or staged bilateral chain mastectomy is recommended for treatment of mammary carcinoma. For some cats with excessively loose mammary tissue, a bilateral chain mastectomy can be performed during a single surgical session if minimal postsurgical tension can be achieved, but subjectively these cats may have a more difficult recovery (Figure 27-6). For tumors that are fixed, muscular fascia or portions of the body wall should be included with en bloc resections.

The high malignancy rate of mammary carcinoma and the poor prognosis associated with lymph node metastasis supports aggressive lymph node assessment. This could include ultrasound-guided FNA of difficult to palpate regional nodes and inguinal lymphadenectomy concurrent with chain mastectomy. Sentinel lymph node mapping has been described in the cat and was the original model for the procedure, which is common for human breast cancer patients.^{126,189} Published techniques in the cat include CT evaluation following intramammary injection of iopamidol and radiographic imaging following intramammary ethiodized oil injections.¹⁸⁹

FIGURE 27-6 A, Cat having mammary adenocarcinoma prepared for bilateral simultaneous chain mastectomies. B, Intraoperative view following excision of all mammary tissue. C, Immediate postsurgical appearance following the bilateral chain mastectomies. (Courtesy Dr. Julius Liptak, Alta Vista Animal Hospital, Ottawa, Canada.)

There are no clinical reports utilizing nuclear lymphoscintigraphy in the cat. Use of blue dyes for node visualization is not recommended because their use may cause Heinz body anemia and methemoglobinemia in this species.

Fibroepithelial hyperplasia has a classic appearance that is very difficult to mistake for malignant mammary tumors. This condition is typically treated with either OHE or medical hormone therapy management. Inflammatory mammary carcinoma has very rarely been reported in cats; in a sole case series of three cats, the disease was described as occurring secondary to postsurgical mastectomy with nonhealing incisions, edema, and suture rejections.¹⁷⁵

Systemic Treatment

Early detection and aggressive surgery (including prophylactic chain mastectomy) can result in long-term survival in cats with early stage mammary tumors. However, cats with delayed diagnosis, large primary tumors, or metastatic local lymph nodes are not treated effectively with surgery alone. The incidence of distant metastasis, primarily to the lungs and pleura, is high, although other organs are also frequently involved.¹⁷⁴ Despite the high rate of metastasis after surgery, very few advances have been made in identifying effective adjuvant systemic treatments.

Due to low HR expression in feline mammary carcinoma, hormonal therapy is not likely to be effective; however, randomized trials have not been performed to confirm this.

Several studies, all retrospective, have evaluated the use of chemotherapy in cats with mammary cancer. Two case series of cats with macroscopic primary and/or metastatic tumors documented objective responses in 40% to 50% of the cats treated with a combination of doxorubicin and cyclophosphamide.^{190,191} The relatively high response rate in the macroscopic setting suggests that this may be an effective protocol in patients with microscopic minimal

residual disease (i.e., following surgical cytoreduction). However, results from adjuvant studies do not reflect this, albeit none of the studies were prospective or randomized. A multiinstitutional retrospective study describing outcome in cats treated with adjuvant single-agent doxorubicin reported a median survival of 450 days in cats with tumors less than 2 cm in diameter.¹⁷⁶ This is shorter than survival times reported in cats treated with surgery alone (3 years). Interestingly, another study evaluating the combination of a doxorubicin-based chemotherapy protocol and an NSAID (meloxicam) reported similar MSTs of 460 days.¹⁸⁸ No control arm consisting of cats treated with surgery alone was included; thus the additive benefit of chemotherapy was not possible to determine. A more recent retrospective, nonrandomized study also compared outcome in cats treated with surgery alone to cats treated with surgery and adjuvant chemotherapy.¹⁷⁶ No significant differences in terms of surgical procedure, tumor size, stage, or histopathologic parameters existed between the groups. No difference in overall survival was found between treatment groups. Further subgroup analysis failed to reveal differences in survival between the groups when comparing cats with tumors less than 2 cm (611 days with surgery alone versus 729 with surgery and chemotherapy). However, cats treated with chain mastectomy and adjuvant chemotherapy survived significantly longer than cats treated with chain mastectomy alone (1998 days versus 414 days). These results support the use of adjuvant chemotherapy in this setting. It is interesting that none of these retrospective studies reported survival times as long as earlier studies using surgery alone, especially in the subset of cats with small tumors. This further illustrates the difficulty in comparing outcomes between retrospective studies, especially noncontemporaneous ones. Ultimately, prospective, randomized trials will be necessary to determine the appropriate use of chemotherapy in cats with mammary tumors. Despite the lack of quality evidence in the

literature to support it, veterinary oncologists continue to make decisions regarding the use of chemotherapy in cats with mammary tumors. Table 27-7 summarizes the most important prognostic factors, general guidelines for systemic treatments, and the strength of supporting evidence.

Tumors of the Male Reproductive System

JESSICA A. LAWRENCE AND COREY F. SABA

28

Canine Testicular Tumors

Prevalence/Incidence

Testicular tumors are the most common tumors of the canine male genitalia and account for approximately 90% of all cancers in the male reproductive tract.¹⁻⁴ In the intact male dog, the testis is overall the second most common anatomic site for tumor development, with an overall prevalence ranging between 6% and 27%.^{1,3-7} Many of these reports are case series and involve dogs submitted for routine necropsy and/or castration for cryptorchidism, making comparisons between study prevalence data difficult. However, a recent population-based study conducted in Norway, where elective castration is rare, reported a similar prevalence of 7% for testicular tumors.⁸

The rate of development of testicular cancer in humans has increased in some populations over time and across successive birth cohorts, and a similar phenomenon has been suggested in dogs.^{7,9-13} A recent population-based study did not find increased rates of testicular tumors among intact dogs; however, only an 8-year period was evaluated.⁸ Testicular tumors are most often diagnosed in geriatric male dogs with a median age of approximately 10 years.^{1,3,4,14,15}

The three most common testicular tumors arise from distinct testicular subsets: sustentacular cells of Sertoli, the spermatogenic germinal epithelium, and the interstitial cells of Leydig, giving rise to Sertoli cell tumors, seminomas, and interstitial cell tumors, respectively (Table 28-1).² The World Health Organization (WHO) classification of tumors of domestic animals differentiates the major types of testicular tumors in dogs as sex cord stromal tumors (Sertoli cell tumors, interstitial cell tumors), germ cell tumors (seminoma, teratoma), and mixed germ cell sex cord stromal tumors.¹⁶ Sertoli cell tumors, interstitial cell tumors, and seminomas have historically developed with equal frequency, although recent studies have suggested that the prevalence of Sertoli cell tumors is lower (8% to 16%).^{*} In one study evaluating lifetime occurrence of neoplasia in German shepherds and Belgian Malinois, seminoma occurred most frequently.¹⁷ Human testicular tumors are often divided into seminoma and nonseminoma, with the former further subdivided as classical seminoma (SE), atypical seminoma, and spermatocytic seminoma (SS) according to WHO, and some effort has been made to apply this to canine tumors.^{9,13,19-23} Sertoli cell tumors and seminomas occur with higher frequency in cryptorchid testes.^{3,24,25}

Rarely, other cell lineages can give rise to testicular tumors such as hemangiomas, granulosa cell tumors, teratomas, sarcomas, embryonal carcinomas, gonadoblastomas, lymphomas, schwannoma, mesothelioma, and rete testis mucinous

adenocarcinomas.²⁶⁻³⁰ Many dogs diagnosed with testicular cancer have more than one primary tumor.^{3,6,18,31} In three separate studies evaluating relatively large numbers of dogs with testicular tumors, between 4% and 20% of dogs had more than one type of testicular tumor.^{3,8,32}

Risk Factors

Several factors may influence the development of testicular tumors in the dog, including cryptorchidism, age, breed, and carcinogen exposure. There is a significant association between cryptorchidism and the development of Sertoli cell tumors and seminomas but not interstitial cell tumors.^{4,15,25} An early prospective epidemiologic study compared the incidence of testicular tumors in cryptorchid dogs to age- and breed-matched control dogs.¹⁵ None of the control dogs developed testicular tumors during the study, in which the average duration of monitoring was 2 years. The incidence of testicular neoplasia in the cryptorchid dogs was 12.7 per 1000 dog-years at risk, whereas for cryptorchid dogs older than 6 years, the incidence increased to 68.1 per 1000 dog-years at risk. Inguinal cryptorchidism may further increase the risk of testicular tumor development compared to abdominal cryptorchidism (Figure 28-1).^{4,15,25} In cryptorchid dogs, tumors more frequently develop in the right testicle; however, this is probably due to the fact that the right testicle is more likely to be retained.^{4,15,32} One study of cryptorchid dogs found that chronologic age was a risk factor for development of a primary testicular tumor and dogs older than 10 years were more likely to develop tumors compared to dogs younger than 6 years.¹⁵ A recent study indicated that the detection rate of testicular tumors in dogs younger than 10 years was significantly associated with cryptorchidism, with over 60% of cryptorchid testicular tumors identified in middle-aged dogs (6 to 10 years).⁴

Several breeds have been reported to have increased risk of developing primary testicular tumors, including the Boxer, German shepherd, Afghan hound, Weimaraner, Shetland sheepdog, Collie, and Maltese.^{*} The flat-coated retriever, Rottweiler, Bouvier de Flandres, and Leonbergers may have a reduced risk of developing testicular tumors, although low numbers of the latter two breeds were evaluated.⁸

Two studies evaluating military working dogs suggested evidence of environmental carcinogen exposure during the Vietnam War.^{35,36} Pathologic changes in the testicles such as hemorrhage, epididymitis, orchitis, sperm granuloma, testicular degeneration, and seminoma were noted, although the causative factor of these could not be definitively determined. These epidemiologic studies postulated that exposure to phenoxy herbicide, dioxin, or tetracycline may have promoted the development of testicular tumors.^{35,36}

• **TABLE 28-1** Characteristics of the Three Most Common Testicular Tumors in the Dog

TUMOR TYPE	INCIDENCE (% OF ALL TESTICULAR TUMORS)	ORIGIN	HORMONE PRODUCTION	CLINICAL FINDINGS	GROSS APPEARANCE	BIOLOGIC BEHAVIOR AND POTENTIAL FOR METASTASIS
Sertoli cell tumor	8-33	Sustentacular cells of seminiferous tubules	≥50% Estrogen	Feminization syndrome Pancytopenia	Firm Lobulated White-gray “Greasy”	<15% regional or distant metastasis
Interstitial cell tumor (Leydig cell tumor)	33-50	Leydig cells between seminiferous tubules	Rarely estrogen Testosterone	Often incidental finding Perianal gland hyperplasia/adenomas	Soft Expansive Yellow-orange Often cystic	Rarely metastasize
Seminomas	33-52	Germinal epithelium of seminiferous tubules	Rarely estrogen	Often incidental finding Metastasis may cause lethargy	Soft Homogeneous May be lobulated Ivory	<15% regional or distant metastasis

• **FIGURE 28-1** Cross-sectional CT image demonstrating an enlarged, minimally rim-enhancing Sertoli cell tumor in a dog with inguinal cryptorchidism. (Courtesy Dr. T. Schwarz, University of Edinburgh.)• **FIGURE 28-2** Sectioned seminoma in a dog demonstrating its ivory, homogenous appearance in comparison to a mildly atrophied contralateral testicle.

Pathology and Pathogenesis

Sertoli cell tumors arise from the sustentacular cells of seminiferous tubules, and seminomas arise from the germinal epithelium of seminiferous tubules. Interstitial cell tumors arise from Leydig cells located between seminiferous tubules. All three tumors have relatively distinct gross appearance but require histopathology for definitive diagnosis. Sertoli cell tumors are firm, lobulated, white-to-gray in appearance, and characterized as “greasy” on palpation.³⁷ Seminomas tend to be homogeneous, soft, and occasionally lobulated and have an ivory appearance when sectioned (Figure 28-2).³⁷ Interstitial cell tumors are soft, expansive, and yellow-to-orange in color when sectioned and often contain cysts with serous or sero-sanguineous fluid.³⁷

The molecular and cellular biology of primary testicular tumors has been investigated. Proliferation markers (proliferating-cell nuclear antigen [PCNA], Ki67, and argyrophilic nucleolar organizer regions [AgNORs]) and TERT expression (the catalytic reverse transcriptase subunit of telomerase) have been interrogated as indicators of degree of malignancy, local progression, and

metastasis with discordant results.³⁸⁻⁴³ Investigators sought to relate TERT to proliferation indices and p53 expression; however, due to the fact that PCNA and TERT were expressed in all testicular tumors, this limited their prognostic potential.⁴⁰ However, aggressive testicular tumors did tend to express high levels of all markers examined: TERT, p53, PCNA, and Ki67.⁴⁰ Proliferative activity in seminomas was assessed using AgNORs in a separate study, in which mean AgNOR scores were higher in invasive or diffuse tumors compared to well-differentiated intraductal seminomas.⁴³ Results suggest that testicular tumors develop a proliferative advantage as they become less differentiated, although larger studies should be performed before proliferative indices can be definitively relied on for prognostication in canine testicular tumors. Cyclins, which are intracellular proteins that form complexes with cyclin-dependent kinases to regulate cell-cycle checkpoints, have also been evaluated in normal and neoplastic testes; however, their significance is yet to be determined.⁴⁴

The neoplastic and stromal cellular environment plays an important role in tumor invasion and progression, and a few studies

have attempted to investigate changes in canine testicular tumors. Laminin is an extracellular matrix protein that plays a role in anchoring cells to the basement membrane. As tumors became more invasive, laminin expression became fragmented or lost in Sertoli cell tumors and seminomas and correlated to increasing proliferative activity as assessed by PCNA scoring, Ki67 index, and mitotic index.³⁸ Connexin 43 is the predominant gap junction protein of the testis that plays a role in phenotypic differentiation, cell pattern formation, and morphogenesis, and altered expression patterns may contribute to tumorigenesis and progression.⁴⁵⁻⁴⁹ Similar to other work, differential alterations in connexin 34 expression occur in canine testicular tumors, and its expression may aid in differentiating neoplastic Sertoli cells from seminomas.⁵⁰

Mutations of the p53 tumor suppressor gene are a common genetic alteration in both human and canine malignancies, and increased p53 expression has been associated with tumor progression.⁵¹⁻⁵⁵ A recent evaluation of testicular tumors indicated that nuclear p53 immunoreactivity was detected in 15 of 20 seminomas (75%), 6 of 12 Sertoli cell tumors, and all 3 interstitial cell tumors evaluated.⁴⁰ Interestingly, expression intensity was stronger in diffuse type Sertoli cell tumors and seminomas.^{40,54} Results suggest that p53 may be an indicator of tumor aggression; however, further studies should be done to corroborate this.

Similar to p53 and proliferation indices, angiogenesis plays an important role in cancer progression and metastasis. Vascular endothelial growth factor (VEGF) expression and microvessel density (MVD) were higher in seminomas compared to normal testes in one study.⁵⁶ Additionally, both VEGF expression and MVD were higher in diffuse seminomas compared to more well-differentiated intratubular seminomas, potentially providing a histologic indicator of malignant behavior.⁵⁶

The KIT protein or CD117 is a transmembrane protein for a tyrosine kinase receptor encoded by the proto-oncogene *c-kit*, which, when bound to its ligand stem cell factor (SCF), is essential to the development, proliferation, and maturation of several cell types, including germ cells.⁵⁷⁻⁵⁹ Primordial germinal cells express KIT and migrate to interact with Sertoli cells that express SCF to guide the differentiation of the primordial cells into gonocytes.⁶⁰ Interstitial cells of Leydig also express KIT and, when stimulated by SCF, are stimulated by Sertoli cells to produce testosterone.^{57,60,61} The expression of KIT is maintained by spermatogonia until differentiation into spermatocytes, making it a useful marker to define primordial germinal cells and early germinal cells.^{60,62} In human seminomas, immunohistochemical labeling for KIT and placental alkaline phosphatase (PLAP) is used to distinguish SE and SS because SE should express both and SS should be negative.^{63,64} Normal and neoplastic canine testes were recently characterized for KIT expression, and results were consistent with humans and rodents in that spermatogonia and Leydig cells were KIT positive, whereas Sertoli cells were negative.⁶² Interestingly, canine testicular tumors in this study maintained the same KIT expression as their cell of origin, with interstitial tumors consistently expressing KIT, similar to human tumors. Similar to human seminomas, canine seminomas appeared to be differentiated into SE and SS on the basis of KIT and PLAP staining.^{22,62} Further studies investigating the behavior of SE and SS may support the dog as a relevant model for human disease, permitting investigation into additional roles of KIT-inhibitors.⁶⁵⁻⁶⁷

Natural Behavior

Most primary testicular tumors in the dog are characterized by local invasion and rarely metastasize. Regional or distant metastasis

occurs in less than 15% of dogs diagnosed with Sertoli cell tumors or seminomas.^{6,32,68-74} Due to the malignant histologic appearance but low malignant behavior, canine seminoma has been compared to human spermatocytic seminoma, thereby spawning interest in using canine seminoma as a relevant comparative model.²¹ Recent work has tried to further classify canine seminoma into classic and spermatocytic seminomas in an attempt to help determine metastatic potential, but no clinical conclusions may be drawn as yet.^{19,21,22} Interstitial cell tumors very rarely metastasize.⁶ Sites of metastasis may include regional lymph nodes, eyes, brain, lungs, kidney, spleen, liver, adrenal glands, pancreas, skin, and peritoneum.^{6,32,68-74}

Primary testicular tumors can also cause imbalances in hormone levels, regardless of the degree of local invasion and presence or absence of metastasis. Sertoli cell tumors can cause signs of feminization, and over 50% of affected dogs display signs of estrogen production.^{14,25,32,69} Seminomas and interstitial cell tumors are rarely associated with feminization.⁷⁵⁻⁷⁷ Excess estrogen can cause signs such as bilateral symmetric alopecia, cutaneous hyperpigmentation, epidermal thinning, squamous metaplasia of the prostatic epithelium, gynecomastia, galactorrhea, attraction of other males, preputial atrophy, atrophy of the nonneoplastic testicle, and bone marrow suppression.³² Sertoli cell tumors that develop in retained testicles are more likely to produce signs of hyperestrogenism; however, 17% of dogs with scrotal Sertoli cell tumors developed feminization.^{14,25,32,69} Plasma hormone concentrations from dogs with primary testicular tumors have been investigated in order to better understand their contribution to tumor type and clinical signs.⁷⁷⁻⁸⁰ Estradiol-17 β concentrations were higher in dogs with Sertoli cell tumors compared to normal and were significantly higher in dogs with feminization syndrome secondary to Sertoli cell tumors. Testosterone and testosterone/estradiol ratios are lower in dogs with Sertoli cell tumors when compared to healthy control dogs.⁷⁶ Plasma estradiol concentrations were lower in seminomas compared to normal dogs in one study but were not significantly altered from normal in another study.^{76,77} It has been suggested that clinical signs of feminization due to Sertoli cell tumors best correlated to testosterone/estradiol ratio reductions rather than to absolute increases in estradiol.⁷⁶ Expression of inhibins (inhibins α , β , $\beta\alpha$), 3 β -hydroxysteroid dehydrogenases, and insulin-like growth factors (IGF-1 and IGF-2) has also been assessed, and further study may shed light on their utility as diagnostic or prognostic markers.⁷⁷⁻⁸⁰ A recent study suggested IGF gene expression was altered in canine testicular tumors compared to normal testicular tissue. A unique pattern of expression, as determined by reverse-transcriptase polymerase chain reaction (RT-PCR) of IGFs, their receptors, and their binding proteins, was observed in interstitial cell tumors compared to Sertoli cell tumors and seminomas.⁸⁰ The overall changes in gene expression were small, however, and it remains unclear how significant the IGF signaling system is in canine testicular neoplasia.

History and Clinical Signs

Most dogs with testicular tumors are asymptomatic, and a testicular mass is discovered as an incidental finding. However, clinical signs may be attributable to the primary tumor, to the presence of metastasis, or to paraneoplastic syndromes such as hyperestrogenism. Additionally, breeding dogs may present with fertility problems. Diagnosis is usually made via palpation of an enlarged testicle or a testicular mass during routine physical examination, abdominal ultrasound, or necropsy. Atrophy of the remaining normal testicle is common (Figure 28-3). Tumors in cryptorchid dogs may cause

• **FIGURE 28-3** Large left seminoma with mild atrophy of the right normal testicle identified as an incidental finding on physical examination.

• **FIGURE 28-4** Large mixed echogenic and cavitated testicle within the left midabdomen on abdominal ultrasound in a cryptorchid dog. (Courtesy Dr. T. Schwarz, University of Edinburgh.)

a regional mass effect within the caudal abdominal cavity or inguinal region (Figure 28-4).

Excess estrogen may cause signs of feminization and is the most common paraneoplastic syndrome associated with canine testicular tumors. As stated previously, seminomas and interstitial cell tumors are rarely associated with feminization, whereas over 50% of dogs with Sertoli cell tumors show signs of hyperestrogenism.^{14,32,69,75-77} Common clinical signs include bilateral symmetric alopecia and hyperpigmentation, pendulous prepuce, gynecomastia, galactorrhea, atrophy of the penis, and squamous metaplasia of the prostate.³² The most deleterious effect of hyperestrogenism is bone marrow suppression, which may be irreversible and life threatening. Early effects of estrogen on the bone marrow include a transient increase in granulopoiesis with peripheral neutrophilia followed by progressive neutropenia, thrombocytopenia, and nonregenerative anemia.^{75,81} Severe pancytopenia from bone marrow hypoplasia and blood dyscrasias can be fatal, and clinical signs can range from hemorrhage secondary to thrombocytopenia, anemia, and febrile neutropenia.^{75,81} Less common reported signs associated with testicular neoplasia include lethargy (Sertoli cell tumors), presence of concurrent prostatic cyst or abscess, hematuria, hemoperitoneum, spermatic cord torsion, hypertrophic osteopathy, and perianal

• **FIGURE 28-5** Sagittal ultrasound image of the testicle of a dog demonstrating a mixed echogenic neoplastic nodule. (Courtesy Dr. D. Jimenez, University of Georgia.)

gland hyperplasia/adenomas (interstitial cell tumors).^{3,32,69,82-85} There are several reports of a syndrome in middle-aged miniature Schnauzers of Sertoli cell tumors occurring in cryptorchid male pseudohermaphrodites.⁸⁶⁻⁸⁸ A recent report also described the presence of both a Sertoli cell tumor and an interstitial cell tumor in a mixed breed male pseudohermaphrodite dog.⁸⁹

Diagnostic Techniques and Staging

Physical examination of intact male dogs, particularly older dogs, should always include palpation of the testicles for masses and/or asymmetry. A thorough rectal palpation should be performed to evaluate the prostate gland, regional lymph nodes, and perianal region. In dogs with clinical signs of hormone imbalance, serum testosterone and estradiol-17 β can be measured along with testosterone:estradiol ratio.^{76,77} It is important to note that not all dogs with signs of feminization have absolute increases in estradiol-17 β , and clinical signs may be more closely linked to altered androgen:estrogen ratios.⁷⁶

Definitive diagnosis is achieved by histopathologic evaluation, although the presence of a testicular mass and cytology may be supportive of testicular neoplasia. Because most dogs with testicular tumors are older and therefore have a high likelihood of another primary tumor (up to 50%) or concurrent diseases, complete staging prior to surgery is generally recommended. Preoperative staging typically includes a complete blood count (CBC) to evaluate for hematologic abnormalities, chemistry profile, urinalysis, abdominal ultrasound, and three-view thoracic radiographs. A coagulation profile may be warranted in dogs with anemia and signs of hemorrhage. Abdominal ultrasound may serve multiple purposes: it can aid in identification of undescended testicles in the abdominal cavity or inguinal canal, assessment of regional lymph nodes, assessment of prostatic changes, and evaluation of common sites of metastasis such as spleen and liver (Figure 28-5). Testicular ultrasonography may aid in differentiating neoplastic processes from orchitis, testicular torsion, and epididymitis; however, changes are not specific enough to identify tumor type.⁹⁰⁻⁹² Ultrasound-guided fine-needle aspiration (FNA) may support a suspicion of

neoplasia prior to orchiectomy, particularly in breeding animals.^{90,93} For owners with financial constraints, minimum staging should consist of a CBC, chemistry profile, and urinalysis. Castration may be performed prior to full staging for some cases, with the decision to do a full work-up following histopathologic evaluation because it is appropriate therapy for most testicular tumors. Histopathologic diagnosis is generally straightforward; however, occasionally, immunohistochemistry (IHC) using vimentin, cytokeratin, desmin, and possibly KIT and inhibin may be indicated to identify the underlying cell of origin.^{26,78,94-97}

Treatment and Prognosis

As most primary canine testicular tumors are characterized by local infiltration with low potential for metastasis, orchiectomy with scrotal ablation is the treatment of choice and is often curative. Bilateral orchiectomy is the treatment of choice for testicular tumors, given that up to 50% of dogs have bilateral tumors and only 12% are clinically detectable in the contralateral testicle.¹⁵ In valuable breeding dogs, unilateral orchiectomy can be considered with continued monitoring afterward.^{98,99} Exploratory laparotomy is indicated in cryptorchid dogs, in which case the regional lymph nodes can be visually assessed and biopsied if indicated. In dogs with signs of hyperestrogenism secondary to the primary tumor, clinical signs typically resolve within 1 to 3 months following castration, unless metastatic lesions provide persistent estrogen release.^{68,69,74} Recurrence of feminization following castration may be associated with the presence of metastasis.⁶⁹ Serum hormone levels may be monitored following castration and may correlate to resolution of clinical signs.^{76,100} Dogs with bone marrow hypoplasia secondary to estrogen toxicity require close monitoring perioperatively and postoperatively for complications requiring medical intervention with blood products and/or antibiotics. These dogs carry a guarded prognosis due to the high morbidity and mortality associated with neutropenia and hemorrhage.^{75,81} Dogs with aplastic anemia warrant a poor prognosis.⁷⁵

Primary testicular tumors occasionally metastasize to regional lymph nodes and other distant sites, and therapy other than surgery may be warranted in these dogs. Optimal management employing chemotherapy, radiation therapy (RT), and novel targeted therapies is currently unknown. Cisplatin, actinomycin-D, chlorambucil, mithramycin, and bleomycin have been used; however, too few dogs were treated and evaluated to formulate conclusions regarding efficacy.^{70,71,73,101} Cisplatin was evaluated in three dogs with aggressive testicular tumors, with survival ranging from 5 months to greater than 31 months.⁷⁰ RT was successfully used in four dogs with metastatic seminoma confined to the regional lymph nodes using total doses ranging from 17 to 40 Gy with ¹³⁷Cesium teletherapy.¹⁰² In all four cases, tumors regressed and survival times ranged from 6 to 37 months; importantly, none of the dogs died of seminoma. Numbers were small, and further studies are warranted to evaluate the role of external-beam RT in managing metastatic seminomas because seminomas are considered extremely radioresponsive.¹⁰³

Comparative Aspects

In the United States, testicular cancer is the most common cancer in men 15 to 44 years old but is one of the most curable cancers with early diagnosis.¹⁰⁴ Recent studies have shown an increase in testicular cancer over the past 40 years, suggesting that an individual's risk is a function of the era in which he was born.^{104,105} Causal factors such as genetic predisposition, maternal estrogen exposure, occupational hazards, dietary factors, smoking habits,

and birthplace have been evaluated, but, to date, the most established risk factor remains cryptorchidism.^{23,104,106-114} Most cancers in men are germ cell tumors and are divided into seminomas and nonseminomas, with the former comprising 50% of tumors in this group.^{13,20,23} Seminomas are further classified into classical, atypical, or spermatocytic seminoma, although management does not vary considerably between types.²⁰ Standard staging in human seminomas consists of physical examination, radiographic studies, determination of serum markers, including alpha-fetoprotein (AFP), human chorionic gonadotropin (hCG), and lactate dehydrogenase; and histopathologic assessment. Spermatocytic seminoma is a rare variant of germ cell neoplasia that is most commonly seen in older men and carries a low risk of metastasis, suggesting similar behavior to most canine seminomas.^{21,23} Treatment generally includes surgery for stage I seminomas, and/or RT and chemotherapy for individuals with advanced stage disease.^{23,103,115-117} Cisplatin-based chemotherapy protocols are generally employed for patients with greater than stage I disease, with cure rates in the range of 70% to 80% despite advanced tumor burdens.^{23,103,118} The dog has been proposed as a model for studies evaluating the development of testicular tumors.^{18,21,22} Further interrogation of the molecular pathogenesis, classification system, and behavior of canine tumors may yield further support for use of spontaneously occurring testicular tumors as good comparative models for human disease.

Feline Testicular Tumors

Feline testicular tumors are rare, although Sertoli cell tumor, seminoma, interstitial cell tumor, and teratoma have been reported.^{34,119-125} The biologic behavior of testicular neoplasia in the cat is unclear due to the sparse literature available. Metastasis of a Sertoli cell tumor to the liver and spleen has been reported, and teratoma metastasis to the omentum was observed in another report.^{122,125} Optimal therapy other than orchiectomy is not known.

Canine Prostate Tumors

Incidence/Prevalence

Prostatic tumors are relatively uncommon in dogs and have a low prevalence at less than 1% (0.2% to 0.6%).¹²⁶⁻¹³⁰ In a collection of over 17,000 confirmed neoplasms of the dog collected from veterinary schools in North America, only 11 prostate carcinomas were identified (0.06%).³³ In a separate study that evaluated lifetime occurrence of neoplasia in predominantly intact German shepherd and Belgian Malinois working dogs, over 30% developed at least one cancer; however, only 2 of the 104 primary tumors were prostatic adenocarcinomas.¹⁷ Despite this low incidence, the dog is one of the few domestic species to develop spontaneous prostate cancer, thus sparking interest in the dog as a comparative model for prostate cancer in men.^{129,131,132} In three retrospective reviews of dogs with prostatic disease, between 7% and 16% were diagnosed with prostatic adenocarcinoma.¹³³⁻¹³⁵ One study of 177 dogs found that prostatic adenocarcinoma was the most common disease in neutered dogs, whereas bacterial prostatitis and prostatic cysts were more common in intact male dogs.¹³⁴ Elderly dogs are more commonly diagnosed with prostatic carcinoma, with a median age at diagnosis of 10 years.^{129,135,136} The underlying etiology of canine prostatic cancer is unknown; however, high-grade prostatic intraepithelial neoplasia (PIN or HGPIN), which is believed to be a precursor of human prostate carcinoma, has been detected in dogs without evidence of prostatic disease and in those with existing prostatic carcinoma.¹³⁷⁻¹³⁹ The occurrence of PIN in dogs with concurrent

carcinoma varies from 7% to 72%, although in two large studies of dogs without histologic evidence of prostatic carcinoma, the occurrence was low at 0% to 3%.^{128,137-139}

Most tumors of the canine prostate are carcinomas, and the majority are adenocarcinomas. It is believed that prostate tumors in the dog arise from a urothelial or ductular origin rather than acinar because most canine tumors are androgen independent.¹⁴⁰⁻¹⁴⁵ Other types of carcinomas, including transitional cell carcinoma (TCC) arising from the prostatic ducts, mixed carcinomas, and squamous cell carcinomas, can occur. Classifying carcinomas on the basis of subtype is somewhat subjective, and there is no standard for definitive diagnosis of canine prostate tumors as there is with humans.^{139,146,147} Fibrosarcoma, leiomyosarcoma, osteosarcoma, lymphoma, and hemangiosarcoma have also been reported to affect the prostate.^{128,148-153} Benign tumors of the prostate are rare, although there is a single case report of a dog with a benign prostatic adenoma or nodular hyperplasia.¹⁵⁴ TCC of the prostatic urethra will frequently invade the prostate, and it may be difficult to distinguish primary TCC from secondary invasion of a urethral tumor.

Risk Factors

Both intact and castrated dogs develop prostate carcinomas, although multiple studies have suggested there is an increased risk of prostatic adenocarcinoma in castrated male dogs compared to intact male dogs with an odds ratio of approximately 2.3:4.3.^{126,135,136,140,143} More aggressive tumors may develop in castrated males with a higher risk of metastasis.¹³⁶ The reason for this difference is unclear, although it is possible that castrated dogs live longer than intact dogs and are thus predisposed to developing age-related cancers.^{135,143} It is also possible that androgens provide a protective effect on prostatic tissue or that, on castration, the relative estrogen effect aids in neoplastic transformation.^{143,155-157} A recent study observed that prostatic adenocarcinoma may occur relatively more frequently in intact male dogs, further complicating this issue.^{128,139,143} Although several studies have suggested that androgens may not be required for initiation or progression of adenocarcinoma of the canine prostate, further controlled studies should be done to definitively determine the role of androgens and the impact of early or late castration.^{140,142-145,158}

Breeds that may be at increased risk of developing prostate carcinomas include the Bouvier des Flandres, Doberman Pinscher, Shetland sheepdog, Scottish terrier, beagle, miniature poodle, German shorthaired pointer, Airedale terrier, and Norwegian elkhound.^{135,143} The Shetland sheepdog and Scottish terrier remained at increased risk even when TCC was excluded in one study.¹⁴³ Mixed breed dogs have also been reported as at increased risk for prostate carcinoma, regardless of neutering status, suggesting environmental influences may play a significant role in tumor development.¹⁴³ The American cocker spaniel, miniature poodle, and dachshund may be at decreased risk for developing prostate cancer.¹⁴³

Natural Behavior

At the time of diagnosis, most canine prostatic tumors are characterized by local invasion with a high propensity for regional and distant metastasis. In one postmortem study that retrospectively evaluated 76 dogs, 80% of those with prostate carcinoma had evidence of measurable metastatic disease, with lung and lymph node being the most common sites.¹²⁸ Importantly, similar to high-grade prostatic carcinoma in men, canine prostatic carcinomas have a tendency to metastasize to bone and 22% to 42% of canine patients

develop skeletal metastasis, predominantly to the lumbar vertebrae and pelvis.^{128,144,159,160} Younger dogs may be at increased risk for metastasis, although the role of castration status in this group is unclear.^{128,161} Longitudinal studies in dogs with evidence of PIN are not available, and it is unclear if prostate carcinoma can behave in a slowly progressive fashion in early phases of development. It is presumed that most dogs are diagnosed at an advanced stage of disease due to the high metastatic rate; however, the true behavior from time of onset is not definitively known and prostate carcinoma may behave differently in intact and castrated dogs.^{135,136}

Pathology/Pathogenesis

The underlying cause of prostate tumors is unknown, and it is possible that both genetic and environmental factors contribute to tumor development. As previously mentioned, HGPIN is considered a precursor of human prostate carcinoma and occurs under the influence of androgenic stimulation in those patients at risk for carcinoma.¹⁶² Although PIN has been detected in dogs with existing prostatic carcinoma, it has also been detected in dogs without evidence of prostatic disease, making its role in the dog less clear.¹³⁷⁻¹³⁹ HGPIN as a predictor of carcinoma occurrence is likely not as reliable in the dog as it is in men.^{138,155} It is not known with certainty if low- and intermediate-grade PIN occurs in dogs, although a recent immunohistochemical study suggested the presence of low-grade PIN.¹⁶³ Investigators evaluated five prostates from middle-aged to older intact dogs containing lesions of PIN and compared nuclear protein p63 (marker of prostatic basal cells), androgen receptor expression, and PCNA to normal prostatic tissue from intact dogs. PIN foci had higher p63 expression, higher PCNA index, and heterogeneous androgen receptor expression, suggesting similarities to human low grade PIN.¹⁶³

The role of hormones in prostate development and tumor progression is also unclear in the dog. Castration does not provide a protective effect and, in fact, may contribute to tumor development and/or progression, although prostatic carcinoma may behave differently in the intact male compared to the neutered male.^{135,136} Normal prostate development and regulation is androgen dependent in both humans and dogs; however, neoplastic human prostate remains androgen dependent unlike in the dog. Androgen receptor expression within the nuclei can be identified in 90% to 95% of normal noncastrated prostatic secretory epithelial cells and in the majority of acinar basal cells.^{144,145,164,165} In neutered dogs and dogs with prostatic carcinoma, nuclear androgen expression decreases and is usually lost.^{144,145} The role of estrogen and progesterone has yet to be fully defined, although nuclear estrogen receptor expression appears to be decreased in prostatic carcinoma tissue compared to normal and hyperplastic prostate tissue.^{141,165}

Chromosomal abnormalities of the neoplastic prostate have only recently been studied, and preliminary data suggest abnormalities such as aneuploidy, centromeric fusions, polysomy of chromosome 13, and hyperdiploidy may occur in the dog.¹⁶⁶⁻¹⁶⁸

Because of its aggressive behavior at the time of diagnosis, some investigators have considered mechanisms that may contribute to prostate carcinoma progression and metastasis. The role of cyclooxygenase (COX) has received considerable attention in the human and veterinary literature and inhibition of COX-2 may play a role in the management of prostate tumors. Expression of COX-2 was noted in 75% of prostate carcinomas in one study, whereas none of the normal prostate tissue had expression.¹⁶⁹ Two other studies support the notion that COX-2 and its downstream prostaglandin E2 production play a role in prostate carcinomas.^{170,171} Indeed, a clinical study identified COX-2 protein expression in 88% of 16

prostate carcinomas examined and further showed a survival benefit in dogs treated with either piroxicam or carprofen.¹⁷² As stated earlier, prostatic carcinoma has a predilection for bone, which may be mediated in part by transforming growth factor- β (TGF- β), parathyroid hormone-related protein (PTHrP), and endothelin.¹⁷³⁻¹⁷⁵ PTHrP mediates pathologic bone resorption in many different tumors, including prostate carcinomas, which may encourage release of TGF- β into the microenvironment. In a positive feedback loop, canine prostatic carcinoma cells can increase gene transcription for PTHrP in response to exogenous TGF- β .¹⁷⁴ Although PTHrP and TGF- β may be important in establishing skeletal metastases, it is interesting to note that prostate metastases are more commonly osteoblastic in nature. In a rat model, osteoblast activation was increased following incubation with normal canine prostate protein homogenates through an endothelin-dependent pathway, suggesting a possible contribution to bone metastasis formation.¹⁷⁵

History and Clinical Signs

Clinical signs in dogs with prostate cancer are variable and may be reflective of local and/or metastatic disease. Common historic and clinical examination signs include hematuria, dysuria, stranguria, dyschezia, tenesmus, bacteriuria, and altered stool shape (flattened or ribbonlike stools).^{128,136,160,176,177} If complete obstruction of urinary outflow results from prostatic compression or direct tumor extension into the urethra, hydronephrosis, and renal failure may occur. Local invasion into the lumbar vertebrae or nerve roots may cause signs of pain, gait abnormalities, lameness, and/or constipation. Nonspecific systemic illness, including lethargy, exercise intolerance, tachypnea or dyspnea, inappetence, and weight loss, can occur with advanced disease. Dogs with skeletal metastasis may present with signs of severe bone pain, pathologic fracture, or rarely with a palpable mass.^{128,160,178} Dogs may present with a history of clinical signs that partially improved with empiric therapy for prostatitis.

Diagnostic Techniques and Staging

Dogs with suspected prostatic carcinoma should be fully staged in order to determine extent of disease and to rule out other causes of prostatic disease, such as benign prostatic hypertrophy (BPH), prostatitis, and prostatic cysts or abscesses.^{177,179,180} Physical examination, including a thorough rectal examination, should be performed on every patient. Rectal palpation often reveals a large, firm, and asymmetric or irregular prostate that may be painful. Sublumbar lymphadenopathy may be detected on rectal or abdominal palpation. A normal-sized prostate on rectal examination in a castrated dog is considered abnormal, even if symmetric and nonpainful. CBC and serum chemistry profile may demonstrate anemia, leukocytosis, hypercalcemia, elevated bone alkaline phosphatase activity, or signs of concurrent disease. Urinalysis and culture may show pyuria, bacteriuria, dysplastic urinary epithelial cells, and secondary urinary bacterial infection. Three-view thoracic radiographs may show evidence of pulmonary metastatic disease, sternal lymphadenopathy, or rarely metastasis to the extrathoracic skeletal structures (ribs, scapula).¹⁶⁰ Abdominal radiographs may reveal evidence of an enlarged prostate, with or without evidence of mineralization; periosteal reactions on the vertebrae, femur, or pelvic bones; or sublumbar or retroperitoneal lymphadenopathy (Figure 28-6).^{136,160,181,182} It is important to note that the presence of mineralization, particularly in intact dogs, is not pathognomonic for neoplasia and can occur in dogs with prostatitis, BPH, or prostatic cysts.¹⁸²⁻¹⁸⁴ However, neutered dogs with prostatic mineralization

FIGURE 28-6 **A**, Right lateral abdominal radiograph demonstrating prostatic mineralization, which may be a feature of benign and malignant disease in intact dogs. **B**, Right lateral abdominal radiograph of a dog with prostatic carcinoma with metastasis to the sublumbar lymph nodes and local invasion along the sacrum and ventral aspect of the seventh lumbar vertebral body. (**A** courtesy Dr. S. Holmes, University of Georgia; **B** courtesy Dr. D. Jimenez, University of Georgia.)

are highly likely to have prostatic neoplasia and should undergo further diagnostics.¹⁸² If a clinical suspicion of skeletal metastasis exists, survey radiographs or bone scintigraphy may be useful for localization.¹⁷⁸ Prostate carcinoma metastases to bone most commonly have an osteoproliferative component but may be osteolytic, osteoproliferative, or mixed. Contrast studies such as retrograde urethrography may be useful to evaluate irregularities in the prostatic urethra or reflux of contrast into a prostatic mass; however, they are not specific enough to differentiate neoplasia from inflammatory or infectious processes.^{181,185} Abdominal ultrasound can be useful to further evaluate the prostate, urethra, bladder, locoregional lymph nodes, and cranial abdominal organs. Lymphadenopathy, echogenicity changes, and mineralization may be visualized on ultrasound, although they can also be features of nonneoplastic diseases (Figure 28-7).^{181,182}

Obtaining tissue samples is considered the gold standard of diagnosis of canine prostatic neoplasia; however, a definitive diagnosis of prostatic neoplasia may be garnered from cytology samples as well.^{177,186} A number of methods may provide adequate samples for diagnosis, including ejaculation, traumatic catheterization, prostatic massage, prostatic wash, ultrasound-guided FNA cytology, impression smears during surgery, or biopsy via percutaneous, perineal transrectal, or surgical routes. Risks of percutaneous biopsies, ultrasound-guided aspirates or biopsies, and transrectal

aspirates may include hemorrhage, urethral trauma, and tumor seeding.^{179,187-190} Cytology or histology of suspected metastatic lesions (e.g., lymph node) may also aid with diagnosis and offer an easier approach at diagnosis (Figure 28-8). Histologic grading of prostate cancers is not routinely performed because there is no support for its impact on prognostication.^{128,191} Cytologic evaluation of samples collected via traumatic catheterization or prostatic wash may prove challenging as it can be difficult to differentiate dysplastic epithelial cells from neoplasia.^{186,192} In one study, discordant results between cytology and histology in prostatic disorders occurred in 20% of cases but were not considered a flaw of aspiration techniques but rather of the pathologic process.¹⁸⁶ Multiple techniques were employed, including ultrasound-guided FNA,

• **FIGURE 28-7** Ultrasound image of a symmetrically but severely enlarged prostate of heterogeneous echogenicity in a dog diagnosed with Rocky Mountain spotted fever and bacterial prostatitis. (Courtesy Dr. D. Jimenez, University of Georgia.)

prostatic massage and wash, and impression smears of biopsies. Other factors such as serum and seminal plasma concentrations of acid phosphatase (AP), prostate-specific antigen (PSA), and canine prostate-specific esterase have not been useful in the definitive diagnosis of prostate carcinoma in the dog.^{127,193} Although significantly higher serum total AP, prostatic AP, and nonprostatic AP concentrations were noted in dogs with prostatic carcinoma compared to healthy dogs or dogs with BPH, they were neither sensitive nor specific enough to warrant definitive diagnosis.¹⁹³

Treatment and Prognosis

Because prostate cancer in dogs is characterized by insidious local progression and a high rate of metastasis, most dogs are diagnosed with advanced disease and the overall prognosis is poor. Median survival times (MSTs) for dogs without therapy are often less than 30 days, and in one report of 76 dogs, most dogs were euthanized at the time of diagnosis.^{128,172} If therapy is attempted, effort is generally made to control local disease, as well as locoregional and distant metastases, although therapy is considered largely palliative. There is currently no standard-of-care consensus therapy for canine prostate tumors, although use of nonsteroidal antiinflammatory drugs (NSAIDs) is often recommended as minimal therapy.

Therapeutic options for managing local disease include prostatectomy, electrosurgical transurethral resection (TUR), photodynamic therapy (PDT), RT, laser therapy, and medical management. Surgery is generally considered to be a palliative procedure; surgical goals are to minimize clinical signs secondary to the primary tumor while maintaining normal urethral function. Prostatectomy is generally recommended for dogs with early stage disease that is still confined within the capsule (intracapsular disease). Total prostatectomy can be performed, although it is associated with a high rate of postoperative morbidity and a survival benefit has not been definitively demonstrated.¹⁹⁴⁻¹⁹⁹ Subtotal intracapsular prostatectomy may be a useful alternative in dogs. In one study that compared 10 dogs that underwent total prostatectomy to 11 dogs that underwent subtotal intracapsular prostatectomy, the latter

• **FIGURE 28-8** **A**, Prostatic carcinoma showing a cluster of variably sized polygonal epithelial cells with a moderate amount of basophilic cytoplasm, which often contains clear, nonstaining vacuoles. These cells have round-to-ovoid nuclei with coarsely granular chromatin pattern and occasional distinct nucleoli. A single binucleated cell is seen. Nuclear to cytoplasmic (N:C) ratios are moderate, and there is mild-to-moderate anisocytosis and anisokaryosis. **B**, Normal prostate composed of loosely cohesive clusters of polygonal to columnar epithelial cells with a moderate amount of basophilic cytoplasm that often appears stippled with both eosinophilic granules and tiny, crisp, nonstaining vacuoles. Nuclei are round to ovoid and are often eccentrically located. Chromatin is condensed, and there is minimal anisocytosis and anisokaryosis. (Courtesy Dr. M. Camus, University of Georgia.)

procedure was associated with longer mean survival time (112 days versus 20 days) and a decreased rate of postoperative complications.¹⁹⁶ Importantly, 7 of the 10 dogs that underwent total prostatectomy were euthanized within 2 weeks of surgery compared to only 2 dogs in the subtotal intracapsular group.¹⁹⁶ Urinary incontinence is a common sequela to prostatectomy and attempts have been made to reduce trauma to the prostatic urethra, including use of a neodymium:yttrium-aluminum-garnet (Nd:YAG) laser; however, there is still a risk of significant postoperative complications.^{195,198,199} In one recent report, TUR using an electrocautery cutting loop was performed with or without intraoperative RT in three dogs with prostatic TCC or undifferentiated carcinoma.²⁰⁰ All dogs experienced rapid palliation of dysuria but complications, including urinary tract infection, tumor seeding, and urethral perforation, occurred and survival for all dogs was short.²⁰⁰ Although dogs with prostatic carcinomas may be palliated early with surgical intervention, TUR and total prostatectomy are associated with a high risk of complications and cases should be selected carefully.

In dogs with urethral obstruction due to a prostatic tumor, palliative measures may be attempted to alleviate the obstruction. Placement of a cystostomy tube permits urinary diversion and bladder emptying, but owners should be aware that it generally does not resolve incontinence and stranguria and secondary urinary tract infections are common.²⁰¹⁻²⁰³ Palliative stenting of the urethra in the obstructed area is a reasonable alternative to cystostomy tubes. The extent and location of the obstruction is determined using fluoroscopy, and stents are typically selected to extend approximately 1 cm proximal and distal to the obstruction.¹⁴⁸ Stents can be ordered in various diameters and are recommended to be 10% greater than the diameter of healthy appearing urethra. Of eight dogs with prostatic tumors stented in one study, the severe complication rate was low (two dogs) and the procedure immediately alleviated the obstruction in all dogs.¹⁴⁸ Median survival time in this study involving 12 dogs with bladder TCC or prostate tumors was short (20 days) despite stenting and therapy with a COX-2 inhibitor; however, further experience and evaluation of this technique may demonstrate improved quality of life. PDT may be an option, particularly for dogs with minimally invasive prostate cancer. There is one case report describing the resolution of macroscopic hematuria and sanguineous preputial discharge with stable disease for at least 6 months in a dog with prostatic carcinoma.²⁰⁴ PDT remains predominantly investigational, although several recent reports have suggested that the dog provides a good model to investigate novel treatments for prostatic carcinoma that may benefit both dogs and humans.²⁰⁵⁻²⁰⁸ Challenges in delivering a homogenous dose may limit the utility of PDT in advanced tumors; however, further evaluation may indicate a role in the management of prostatic carcinomas.

RT may be useful in the palliation of clinical signs related to local prostatic carcinoma as well as to palliate painful skeletal metastases, although optimal dose and fractionation are unknown. In one study, 10 dogs with prostatic carcinoma were treated with intraoperative orthovoltage therapy.²⁰⁹ Nine were prescribed 20 to 30 Gy to the prostate, with an MST of 114 days, although the range extended to 750 days.²⁰⁹ It is probable that with advances in 3-dimensional (3D) imaging and intensity-modulated RT (IMRT) planning and delivery, local disease may be better targeted and controlled. However, metastatic disease will remain a challenge unless early prostatic carcinoma can be detected.

The benefit of systemic therapy to manage canine prostatic tumors is unclear, although a pivotal study demonstrated a clear survival benefit in dogs with prostate carcinomas treated with

piroxicam or carprofen compared to those untreated (6.9 months versus 0.7 month).¹⁷² The role of chemotherapy is less clear, although prospective studies are warranted for further investigation of NSAIDs alone and in combination with chemotherapy.

For dogs with skeletal metastasis, palliative options include systemic analgesics, RT, aminobisphosphonate administration, and ¹⁵³samarium ethylenediamine-tetramethylene phosphonate (¹⁵³SM-EDTMP).^{210,211} Standardized protocols have not been determined, although RT and pamidronate are both widely available options and relatively easy to administer.^{210,212,213}

Comparative Aspects

Prostate cancer is the second most frequently diagnosed cancer and the sixth most common fatal cancer among men worldwide, and its incidence is increasing.^{214,215} The only well-established and consistent risk factors for prostate cancer in men are race/ethnicity, family history, and age, although other factors such as diet and lifestyle may contribute as well.²¹⁴⁻²²¹ As in dogs, most prostatic tumors in men are carcinomas; however, the incidence of disease is considerably higher in men. Geriatric men have a high rate of asymptomatic prostate cancer, in part due to the increased occurrence of PSA-driven biopsies. Serum PSA is a readily detectable serine protease produced by both malignant and benign prostate tissues. The dog is one of the few domestic species to develop spontaneous prostate cancer, resulting in considerable interest in the dog as a model for prostatic carcinoma in men.^{129,131,132} A similar canine PSA is not detectable with commercially available human antibodies, thus limiting comparisons made between diagnosis of human PSA-driven and canine prostate cancer.^{127,222} Another important challenge in using the dog as a model is that most early-stage prostate carcinomas in men are highly androgen dependent and disease progression can be manipulated through androgen deprivation.^{214,223} Prostate carcinoma in men typically initiates as PIN, which is often seen as multifocal premalignant lesions that progress to neoplasia; the role of PIN in the development of canine prostatic diseases in either the intact or castrated dog is unclear. High-grade prostate cancer in men behaves similarly to the disease in dogs, with significant local invasion and a propensity to metastasize to the skeleton. While high-grade aggressive prostate carcinoma is less common in the elderly man, the dog may serve as a model for interventional strategies in this setting. Therapy in humans varies from active surveillance to prostatectomy to RT (external beam and brachytherapy) and is highly dependent on the stage of disease at presentation and partially on risks versus benefits of intervention.^{214,215,223} Treatment strategies, including chemotherapy, vascular targeting, RT approaches, and management of skeletal metastasis, may be investigated in canine models and ultimately benefit both species.

Feline Prostate Tumors

Prostate tumors in the cat are rare and reports in the veterinary literature are sparse.²²⁴⁻²²⁹ Of the few case reports, most tumors are adenocarcinomas and affect older castrated cats. Definitive risk factors have not been identified due to the lack of frequent cases and epidemiologic data. Clinical signs often include lower urinary tract signs, as well as obstipation or constipation, tenesmus, and dyschezia. Rectal palpation can reveal the presence of a mass, which may be further characterized with abdominal ultrasound. There is no standard-of-care therapy, and it is difficult to state overall prognosis. Metastasis appears common, and sites of spread include pancreas, lung, and lymph nodes; most cats died within 3 months of

diagnosis.²²⁴⁻²²⁸ A recent report described the use of prostatectomy for a low-grade prostatic sarcomatoid carcinoma, with no evidence of local or metastatic disease at 2 years.²²⁹ One report described the use of prostatectomy followed by doxorubicin and cyclophosphamide to yield a survival time of 10 months.²²⁵

Canine Penile, Preputial, and Scrotal Tumors

Multiple tumor types can affect the soft tissues of the canine penis, prepuce, and scrotum, including transmissible venereal tumor (TVT), squamous cell carcinoma, sebaceous gland adenoma, mesothelioma, papilloma, lymphoma, plasma cell tumor, mast cell tumor, hemangioma, melanoma, and fibrosarcoma.^{37,230-237} Overall, TVT and squamous cell carcinomas are the most common neoplasms of the canine penis. Ossifying fibroma, benign mesenchymoma, multilobular osteochondrosarcoma, and osteosarcoma can arise from the penile bone (os penis).²³⁸⁻²⁴³ Osteosarcoma of the os penis may behave similarly to other axial skeleton sites, with a potential to develop local recurrence following narrow excision and distant metastasis.^{238,240}

Clinical signs are often associated with local disease, and many dogs present with hematuria, stranguria, or dysuria. Occasionally, dogs may present with a visible mass and the absence of urinary signs; this is likely more common in scrotal tumors compared to other tumor sites. It is also possible for clinical signs to be secondary to locoregional or distant metastasis. It is recommended to fully stage dogs with penile tumors prior to definitive therapy. Surgical excision is generally recommended and often involves partial or complete penile amputation and perineal urethrostomy. TVT is an obvious exception because it is a chemoresponsive and radiation-responsive tumor, although surgery may be used for refractory cases.^{244,245} For dogs with scrotal tumors, castration (if intact) with scrotal ablation is recommended. Depending on the underlying tumor type, adjuvant therapy such as RT or chemotherapy may be indicated. Prognosis is heavily dependent on underlying histology, as well as the ability to obtain adequate local control.

Feline Penile, Preputial, and Scrotal Tumors

Little information exists on tumors that affect the feline penis, prepuce, and scrotum. There is a report of fibroma affecting the scrotum of a cat; however, it is probable that clinical signs would be similar to those in dogs.²⁴⁶

Comparative Aspects

Penile tumors in the United States are rare, although they remain a problem in a number of countries in Asia, Africa, and South America, where up to 10% of cancer may arise in the penis.²⁴⁷ The incidence of penile cancer has been declining in part due to increased personal hygiene and circumcision.²⁴⁸⁻²⁵⁰ Indeed, neonatal circumcision, as practiced by a number of groups, virtually eliminates penile carcinoma from the population.²⁴⁹ Poor local hygiene, phimosis, tobacco, chronic inflammation, lack of circumcision, infection with human papilloma virus, and having multiple sexual partners are associated with the development of malignant penile lesions.^{249,251-253} Most penile tumors are carcinomas and over 95% of carcinomas are squamous cell in origin. Clinical signs in men are varied and range from a subtle erythematous local lesion

to an ulcerated, infected mass lesion. Full staging is important in men who present with penile cancer because nodal status is one of the most significant prognostic variables for survival.²⁴⁷ The prognosis is generally excellent for patients with early stage disease and treatment typically consists of surgery. Occasionally, RT is used for primary treatment of early stage disease, but local recurrence rates are higher than with surgery.^{247,254-256} In advanced cases, aggressive surgery may include emasculation procedures or hemipelvectomy followed by RT. The role of chemotherapy is still evolving in human penile carcinoma management, but agents such as cisplatin, methotrexate, and bleomycin appear to have modest activity.

Tumors of the Urinary System

DEBORAH W. KNAPP AND SARAH K. McMILLAN

Canine Urinary Bladder Tumors

Urinary bladder cancer accounts for approximately 2% of all reported malignancies in the dog.¹⁻⁴ With more than 70 million dogs in the United States, even uncommon forms of cancer affect thousands of dogs each year.^{2,3} The hospital prevalence or proportionate morbidity of bladder cancer at university-based veterinary hospitals is increasing.² Invasive transitional cell carcinoma (TCC) is the most common form of canine urinary bladder cancer.¹⁻⁴ Most TCCs are intermediate- to high-grade papillary infiltrative tumors.²⁻⁴ Other types of bladder tumors reported less frequently include squamous cell carcinoma, adenocarcinoma, undifferentiated carcinoma, rhabdomyosarcoma, lymphoma, hemangiosarcoma, fibroma, and other mesenchymal tumors.⁴⁻¹⁰

TCC is most often located in the trigone region of the bladder. Papillary lesions and a thickened bladder wall (Figure 29-1) are common features and can lead to partial or complete urinary tract obstruction. In a series of 102 dogs with TCC of the bladder, the cancer also involved the urethra in 56% of dogs and involved the prostate in 29% of male dogs.² Nodal and distant metastases were present in 16% and 14% of dogs, respectively, at diagnosis.² At the time of death, distant metastases were detected in 50% of the dogs.² Following World Health Organization (WHO) criteria for staging canine bladder tumors¹¹ (Box 29-1), 78% of dogs had T2 tumors and 20% had T3 tumors.²

Etiology and Prevention

The etiology of canine bladder cancer is multifactorial. Risk factors include exposure to older-generation flea control products and lawn chemicals, obesity, possibly cyclophosphamide exposure, female sex, and a very strong breed-associated risk (Table 29-1).^{1,2,12-15} The female:male ratio of dogs with TCC has been reported to range from 1.71:1 to 1.95:1.¹⁻³ TCC risk is higher in neutered dogs than in intact dogs of both sexes, although the reason for this has not been determined.^{2,13}

Two case control studies have implicated chemical exposure in TCC risk in dogs. In a case control study of dogs of several breeds, an association between TCC and exposure to topical flea and tick dips was noted.¹² In the highest risk group (overweight female dogs), the risk of TCC was 28 times that of normal-weight male dogs not exposed to the insecticides.¹² The authors speculated that the “inert” ingredients (solvents and petroleum distillates), which accounted for more than 95% of the product, were the probable carcinogens. Newer, spot-on type flea control products appear safer. In a case control study in Scottish terriers, spot-on products containing fipronil were not associated with increased risk of TCC.¹⁴

In a case control study in Scottish terriers (STs), exposure to lawn herbicides and pesticides was compared between STs with TCC (n = 83) and a control group of STs (n = 83, ≥6 years of age,

no history of urinary tract disease in the previous 2 years).¹⁵ TCC risk was significantly higher in STs that had been exposed to lawn herbicides alone (odds ratio [OR], 3.62; 95% confidence interval [CI] 1.17 to 11.19; $p < 0.03$) or herbicides and insecticides (OR, 7.19; 95% CI 2.15 to 24.07; $p < 0.001$) than in dogs not exposed.¹⁵

A positive finding in the STs study was that dogs that ate vegetables at least three times a week, along with their normal diet, had a reduced risk of TCC (OR, 0.30; 95% CI 0.01 to 0.97; $p < 0.001$).¹⁶ The specific type of vegetable with the most benefit could not be determined, but carrots, given as treats, were the most frequently fed vegetable in the study.

Although prospective prevention studies have not yet been performed, it would appear appropriate to limit exposure to lawn chemicals and older types of flea control products and to feed vegetables at least three times per week, especially in dogs in breeds with high risk for TCC. The owners of dogs in high-risk breeds should be informed of the TCC risk and encouraged to take note of urinary tract signs should they occur and to pursue veterinary care in a timely fashion. Prospective studies to determine the value of TCC screening and early detection have not yet been reported.

Diagnosis and Differential Diagnoses

Many conditions can mimic TCC in regards to clinical signs, abnormal epithelial cells in urine, and mass lesions within the urinary tract (Figures 29-2 and 29-3; Table 29-2). Differential diagnoses include other neoplasia, chronic cystitis, polypoid cystitis, fibroepithelial polyps, granulomatous cystitis/urethritis, gossypiboma, calculi, and inflammatory pseudotumor.^{4-10,17-21} It is important to distinguish non-TCC conditions from TCC because the treatment and prognosis differ considerably and depend on the condition present.

A diagnosis of TCC requires histopathologic confirmation. Although neoplastic cells may be present in the urine of 30% of dogs with TCC,⁴ neoplastic cells often are indistinguishable from reactive epithelial cells associated with inflammation. Urine antigen tests for TCC have been found to be sensitive,²² but a high number of false-positive results limits the value of these tests. A bladder or urethral mass may raise suspicion for TCC, but as discussed previously, other conditions can cause bladder and urethral masses (see Figures 29-2 and 29-3 and Table 29-2). Therefore histopathologic examination of the abnormal tissues is essential to determine whether TCC is present. In addition, different pathologic types of TCC can be identified with histopathology.^{4,21}

Methods for obtaining tissue for histopathologic diagnosis include cystotomy, cystoscopy (see Figure 29-2), and traumatic catheterization.^{2,23-25} Cystoscopy provides the opportunity to visually inspect the urethra and bladder and to obtain biopsies in a noninvasive method. With the small size of cystoscopic biopsies, the operator must be diligent to collect sufficient tissue for

Box 29-1 TNM Clinical Staging System for Canine Bladder Cancer

T—Primary Tumor

- Tis Carcinoma in situ
- T0 No evidence of a primary tumor
- T1 Superficial papillary tumor
- T2 Tumor invading the bladder wall, with induration
- T3 Tumor invading neighboring organs (prostate, uterus, vagina, and pelvic canal)

N—Regional Lymph Node (Internal and External Iliac Lymph Node)

- N0 No regional lymph node involvement
- N1 Regional lymph node involved
- N2 Regional lymph node and juxtaregional lymph node involved

M—Distant Metastases

- M0 No evidence of metastasis
- M1 Distant metastasis present

Modified from Owen LN: *TNM classification of tumours in domestic animals*, Geneva, 1980, World Health Organization.

diagnosis. Placing tissue samples in a histology cassette prior to processing helps prevent loss of small samples (see Figure 29-2, F). In a recent report of 92 dogs, diagnostic samples were obtained by cystoscopy in 96% of female dogs and 65% of male dogs that ultimately had histopathologically diagnosed TCC.²⁵ The more recent use of a wire basket designed to capture stones during cystoscopy (see Figure 29-2, D and E) allows collection of larger samples and is expected to increase the yield of diagnostic biopsy samples. Traumatic catheterization to collect tissues for diagnosis can also be

*This table represents a summary of data from 1290 dogs with TCC and 1290 institution and age-matched control dogs without TCC in the Veterinary Medical Data Base.

[†]Reference category.

performed, although samples collected by this method are usually small and the diagnostic quality varies considerably from case to case. Percutaneous biopsy methods can lead to tumor seeding and are best avoided.^{26,27}

In poorly differentiated carcinomas, immunohistochemistry for uroplakin III (UPIII) can be helpful in distinguishing TCC from other carcinomas. UPIII, a transmembrane protein expressed in superficial transitional epithelial cells in the urinary tract, is expressed in more than 90% of canine TCC and has been considered a specific marker for TCC.²⁸ Recently, UPIII expression has also been reported in canine prostate cancer,²⁹ although it is not known if the immunoreactive cells originated from the transitional epithelium of the prostatic ducts or elsewhere in the gland.

Presentation and Clinical Staging

Common clinical signs in dogs with TCC include hematuria, dysuria, pollakiuria, and, less commonly, lameness caused by bone metastasis or hypertrophic osteopathy.¹ Urinary tract signs may be present for weeks to months and may resolve temporarily with antibiotic therapy.

In dogs with TCC, a physical examination, which includes a rectal examination, may reveal thickening of the urethra and trigone region of the bladder, enlargement of iliac lymph nodes, and sometimes a mass in the bladder or a distended bladder. However, normal findings on a physical examination do not rule out TCC.

In dogs with confirmed or suspected TCC, evaluation should include an assessment of overall health (complete blood count [CBC], serum biochemistry profile, urinalysis, \pm urine culture) and staging of the cancer (thoracic radiography, abdominal ultrasonography, and urinary tract imaging). To avoid the risk of seeding TCC through cystocentesis, urine may be collected by free catch or

• **FIGURE 29-2** **A to E**, Images from cystoscopy of dogs with transitional cell carcinoma (TCC) and biopsy material obtained (**F**), and images of dogs with polypoid cystitis (**G to I**). TCC can appear as a ruffled frond-like mass or less commonly as polyp-like lesions. The images obtained with rigid cystoscopes typically used in female dogs (**A** and **C** to **E**) are usually better than those obtained with smaller diameter flexible scopes used in male dogs (**B**, image from a male Scottish terrier), although both types of cystoscopes allow adequate visualization for biopsy. The use of a cystoscopic wire stone basket (**D** and **E**) allows collection of larger biopsies. Regardless of the biopsy instrument used, however, cystoscopic biopsies are relatively small, and placing the samples in a tissue cassette (**F**) may facilitate processing. Polypoid cystitis (**G to I**) appears very similar to TCC, but it is treated differently and has a better prognosis than TCC. Dog with polypoid cystitis before (**H**) and after (**I**) a month of clavomox treatment alone with no other therapy. The polyps had regressed by >80% (**I**) at the time of rescoping. Cases such as this one emphasize the importance of histopathology in the diagnosis of urinary tract masses, especially when selecting therapy, and even more so when dogs are participating in clinical trials. (Courtesy L.G. Adams, Purdue University.)

catheterization. If a catheter is to be passed, care must be taken to avoid penetrating the diseased bladder or urethral wall. Common sites of metastases detected with thoracic radiography and abdominal ultrasonography include lymph nodes, liver, and lungs, although metastases can occur in other areas as well.¹⁻³ TCC infrequently

metastasizes to bone. Side-by-side comparison of radiographs and a nuclear bone scan may help detect possible bone metastases in dogs with unexplained lameness or bone pain.

Urinary tract imaging is used to assess the TCC location for potential surgical intervention and to map and measure TCC

• **FIGURE 29-3** Cystosonography images from dogs with bladder masses. Note images made in the sagittal (**A**) and transverse (**B**) planes (5 mL/kg fluid distension of the bladder) of an 11-year-old neutered male Shih Tzu with transitional cell carcinoma (TCC). To measure bladder masses over multiple time points, it is important to follow a consistent protocol in regards to level of bladder distension, and patient and probe positioning; and to have the same operator perform the ultrasonography on each visit. Polypoid cystitis (**C** and **D**), which can appear very similar to TCC, can occur in any part of the bladder, including the mid/apex (**C**) and trigone (**D**). The dog imaged in **D** was a 13-year-old spayed female Bichon Frise with history of previous urinary tract infection, current hematuria, stranguria, atypical epithelial cells in urine, and masses in the mid/apex and trigone areas of the bladder. Surgical biopsies of the masses confirmed polyps. (Courtesy J.F. Naughton, Purdue University.)

masses in order to subsequently determine response to medical therapy. Mapping TCC in the bladder, proximal urethra, and prostate can be accomplished by cystosonography (see [Figure 29-3](#)), cystography, or computed tomography (CT).^{30,31} Regardless of the imaging technique used, to accurately track response to therapy, it is important to follow a consistent protocol from visit to visit for bladder distension and patient positioning. In addition, when using cystosonography to monitor therapy response, it is critical to have the same operator perform the examinations over multiple visits.

Treatment

Surgery and Nonsurgical Procedures

In dogs with TCC, surgery may be indicated for one or more of the following reasons: (1) to obtain tissue for a diagnosis, (2) to attempt to remove the TCC within the bladder if lesions are away from the trigone, and (3) to maintain or restore urine flow. The potential value of cytoreductive surgery to enhance the activity of adjuvant therapy requires further study. If surgery is performed, it is crucial to take measures to avoid seeding the cancer.

Complete surgical excision of TCC is not usually possible because of the typical trigonal location, urethral involvement, and metastases in some cases. Although techniques for trigone

resection³² or cystectomy^{33,34} and the use of grafting materials to replace bladder tissues^{35,36} have been reported in the dog, these approaches are associated with substantial morbidity and expense and in most cases are not feasible. In addition, many dogs develop multifocal TCC in the bladder, consistent with the “field effect” proposed in humans in which the entire bladder lining is thought to undergo malignant change in response to carcinogens in the urine. In a series of 67 dogs with TCC that underwent surgery for biopsy or for therapeutic intent, complete surgical excision of the tumor with tumor-free margins was possible in only two dogs.² One of the two dogs had a relapse in the bladder 8 months later, and the second dog developed metastatic disease.

Although surgery is rarely curative in dogs with TCC, surgery can be important in restoring or maintaining urine flow. Ureteral stents, when indicated, have traditionally been placed surgically, although less invasive techniques to place stents have recently been described.³⁷ Previously described ureterocolonic anastomosis is not recommended due to the high complication rate and limited survival.³⁸ Prepubic cystostomy catheters that bypass urethral obstruction can be very effective.^{39,40} More recently, the placement of urethral stents has gained favor over cystostomy tubes in some cases because external tubes are avoided and the pet owner does not have to drain the bladder.⁴¹ The survival following stent placement can

• **TABLE 29-2** Characteristics of 21 Dogs Presented to the Purdue University Veterinary Teaching Hospital (PUVTH) in Recent Years With Bladder/Urethral Masses Caused by Conditions Other Than Transitional Cell Carcinoma (TCC)*

HISTOPATHOLOGIC DIAGNOSIS	DOGS (NO.)	AGE (YEARS)	SEX	BREED	LOCATION OF BLADDER LESIONS
Polypoid cystitis	7	Median 10, range 5-13	4 FS, 3 MN	6 pure bred [†] and 1 mixed breed	Multiple masses; involved trigone area in 4 cases

*Excludes dogs with prostatic carcinoma or other prostatic disease and dogs with cystic calculi.

[†]One each of the following: Australian shepherd, Jack Russell terrier, Bichon Frise, Swiss mountain dog, golden retriever, Rhodesian ridgeback.

[‡]One each of the following: German shepherd, Great Dane, Cocker spaniel, English Springer spaniel, West Highland white terrier, Chesapeake Bay retriever.

[§]One dog had surgical biopsies. The other dog had cystoscopic biopsies and no evidence of progression to TCC >2 years later.

^{||}The dog was presented for urinary obstruction and bladder mass. Prior to presentation at the PUVTH, surgery had been performed to remove a testicle from the abdomen. The testicle and spermatic cord were noted to be wrapped around the urethra. The mesenchymal changes were thought to be due to the bladder response to chronic urethral obstruction.

[¶]The dog was referred to the PUVTH for inappropriate urination and abdominal mass. Based on signalment and history, TCC was included on the differential list. Ultrasonography and computed tomography (CT) demonstrated a large cystic mass associated with the right kidney. A 15 × 10 × 10 cm mass containing 500 mL of fluid was removed surgically. Histopathology of the mass revealed renal atrophy, fibrosis, and moderate hydronephrosis, most likely due to a urinary obstruction event. No cause for urinary obstruction was found, and the dog was normal at last follow-up 7 months post op.

vary considerably from dog to dog. In preliminary findings from Purdue University, survival following stent placement in dogs ranged from a few days to a year.⁴² Urethral stents can be placed nonsurgically with fluoroscopic guidance. Although there has been interest in the potential use of laser ablation of tumor tissue to relieve urethral obstruction, in published work to date this has not been successful due to advanced local disease, complications of the procedure, and local disease recurrence.⁴³ One of the challenges in transurethral resection is the difficulty in judging the deeper tumor margin and the risk of cutting too deep and perforating the urinary tract.

Radiation Therapy

Information on the use of radiation therapy (RT) in TCC and other bladder tumors is limited.^{44,45} In one report, one of seven dogs treated with intraoperative radiation was alive at 1 year.⁴⁵ In another report of 13 dogs, the 1- and 2-year survival rates following intraoperative RT were 69% and 23%, respectively, but complications of therapy (i.e., urinary incontinence and cystitis with accompanying pollakiuria and stranguria) detracted from the dogs' quality of life.⁴⁴ Other studies have confirmed complications associated with pelvic irradiation.⁴⁶ A laparoscopically implanted tissue expander to reduce exposure to surrounding organs during RT of the bladder has been described, but this approach requires more study before routine use.⁴⁷ In a report of 10 dogs, weekly coarse fraction external-beam RT combined with mitoxantrone and piroxicam was tolerated, but results were no better than those with medical therapy alone.⁴⁸ Studies of intensity-modulated RT (IMRT) for TCC are ongoing.

Medical Therapy

Systemic Medical Therapy Systemic medical therapy is the mainstay of TCC treatment in dogs and usually consists of chemotherapy, cyclooxygenase (COX) inhibitors (nonselective COX inhibitors and COX-2 inhibitors), and combinations of these (Table 29-3).^{*} Although medical therapy is not usually curative, several different drugs can lead to remission or stable disease of TCC, and most therapies are well tolerated. Resistance to one drug does not necessarily imply resistance to other drugs. Some of the best results are seen in dogs that sequentially receive multiple different treatment protocols over the course of their disease. The approach used at the Purdue University Veterinary Teaching Hospital (PUVTH) is to obtain baseline measurements of the TCC masses, to initiate a starting treatment, to monitor the response to that treatment at 4- to 8-week intervals, and to continue that treatment as long as the TCC is controlled, side effects are acceptable, and quality of life is good. If cancer progression or unacceptable toxicity occurs, then a different treatment is instituted. Subsequent treatment changes are based on tumor response and treatment tolerability. By following this approach, TCC growth can be controlled in approximately 75% of dogs, the dogs' quality of life is usually very good, and median survival times (MSTs) can extend well beyond a year. Although it could be tempting to simultaneously combine multiple chemotherapy agents in dogs with TCC, the benefit of this has not been determined and the potential development of resistance to multiple drugs at the same time could limit the options for subsequent therapy.

*More advanced TNM stage is associated with a poorer prognosis; the percentages of dogs with metastasis for each study are included.

[†]Total/evaluable for tumor response.

[‡]Diagnosis based on histopathology.

[§]Study included dogs with cytologic evidence of TCC and dogs with biopsy-proved TCC.

^{||}The majority of dogs had failed prior therapy before receiving vinblastine. The dosage of vinblastine used in this trial was 3 mg/m² every 2 weeks. In most dogs in the trial, however, subsequent dose reduction was necessary because of myelosuppression. Currently, at our institution, the starting dosage of vinblastine for dogs with TCC is 2.5 mg/m² every 2 weeks for medium to large dogs and 2.25 mg/m² every 2 weeks for small dogs.

[‡]Dogs that initially received cisplatin alone and had tumor progression were then treated with piroxicam alone; two dogs had PR, and five dogs had SD with piroxicam treatment. This may have contributed to the favorable survival in that treatment arm.

^{***}Despite favorable tumor response, the combination of cisplatin and piroxicam is not recommended for routine use due to frequent renal toxicity.

Two treatment approaches that have been used most commonly in dogs with TCC are (1) a single-agent COX inhibitor and (2) mitoxantrone combined with a COX inhibitor. As a single agent, the nonselective COX inhibitor, piroxicam, is a useful palliative treatment for dogs with TCC.^{1-3,49} The quality of life in dogs that receive piroxicam has been excellent. Responses in 62 dogs with TCC that received piroxicam as a single agent included two complete remissions (CR), nine partial remissions (PR, ≥50% decrease in tumor volume), 35 stable diseases (SD, <50% change in tumor volume), and 16 progressive diseases (PD, ≥50% increase in tumor volume or new tumor masses). The two dogs that had CR died of non-tumor-related causes more than 2 years after beginning piroxicam therapy and were free of tumor at necropsy. The survival time (median 195 days) compared favorably to that of 55 dogs in the Purdue Comparative Oncology Program Tumor Registry that were treated with cytoreductive surgery alone (median survival 109 days).² Piroxicam is administered at a dosage of 0.3 mg/kg PO once daily in dogs. Although most dogs tolerate the drug well, care must be taken to watch for gastrointestinal (GI) toxicity, particularly ulceration. If vomiting, melena, and anorexia occur, the drug must be withdrawn and supportive care provided as needed until the

toxicity resolves. In these cases, it may be safest to switch to a COX-2 inhibitor if further COX inhibitor treatment is indicated.

A COX-2 inhibitor, deracoxib (Deracoxib, Novartis), has been evaluated as a single agent at a dosage of 3 mg/kg PO daily in 26 dogs with TCC.⁵⁰ Tumor responses included four (17%) PR, 17 (71%) SD, and three (12%) PD. The median survival following deracoxib and subsequent therapies was 323 days. Mild GI toxicity occurred in 20% of dogs, and 4% of dogs had renal or hepatic side effects. The 17% remission rate with deracoxib appears comparable to the remission rate with piroxicam; however, occasional CRs occur in dogs receiving piroxicam, whereas CR was not noted in dogs treated with deracoxib.

In a pilot study at the PUVTH, adjuvant deracoxib was given to nine dogs (four spayed female, three neutered male, and two intact male dogs) following surgical removal of TCC.⁶¹ Three dogs had tumor-free margins, and six dogs had microscopic TCC present in surgical margins. Deracoxib (3 mg/kg PO daily) was instituted postoperatively. Of three dogs with tumor-free margins, recurrence (consistent with the field effect) was noted in two dogs at 210 and 332 days, respectively. The third dog died with no relapse detected at 1437 days. Of six dogs with microscopic residual TCC after

surgery, recurrence was noted in two dogs at 140 and 231 days, respectively. One of the six dogs is alive, tumor free, and still receiving deracoxib at 2057 days. Three dogs with microscopic residual TCC have died with no relapse detected at 345, 749, and 963 days. The median survival of the nine dogs was 749 days (range 231 to 2581 days). Without a randomized trial comparing deracoxib to placebo, it is not possible to know the extent to which deracoxib may have prolonged the disease-free interval in these dogs. The findings, however, of no relapse in four dogs with residual microscopic TCC following surgery at 345, 749, 963, and 2057 days are encouraging.

In unpublished work, another COX-2 inhibitor, firocoxib (Previcox, Merial) has also had antitumor activity against canine TCC.⁶² It is not yet known if nonselective COX inhibitors and COX-2 inhibitors are equally effective in treating TCC. COX-2 inhibitors, however, offer an advantage of less GI toxicity.

The most commonly used chemotherapy protocol in dogs with TCC is mitoxantrone combined with piroxicam.⁵¹ In a study of 55 dogs, 35% of dogs had remission with minimal toxicity, and the median survival was 291 days ($n = 55$).⁵¹ Although a higher remission rate (50% to 70%) has been noted with cisplatin combined with piroxicam, this protocol is limited by frequent renal damage.^{55,59,60} Lowering the cisplatin dose did not reduce the renal toxicity of this combination.⁵⁵ Carboplatin, a platinum drug with less renal toxicity, was combined with piroxicam. Remission occurred in 38% of dogs with TCC, but the median remission duration and survival were relatively short.⁵⁶

In a recent study, gemcitabine (800 mg/m²) and piroxicam were given to dogs with cytologic evidence of TCC or biopsy-confirmed TCC.⁵⁸ The reported tumor responses included two (5%) CR, eight (21%) PR, and 19 (50%) SD. The median survival was 230 days. Other emerging therapies that have shown promise include single-agent vinblastine⁵² and metronomic chlorambucil.⁶³ Thirty-six percent of dogs with TCC receiving vinblastine had partial remission.⁵²

Localized Therapy Localized therapies studied in dogs with TCC include intravesical mitomycin C (MMC) and photodynamic therapy (PDT). Intravesical therapy is commonly used in humans with superficial TCC, and there has been interest in this approach to potentially treat the higher grade invasive TCC that occurs in dogs. A phase I clinical trial and pharmacokinetic (PK) study of intravesical MMC (1-hour dwell time/day, 2 consecutive days each month, escalating concentrations) was performed in dogs with TCC.⁵⁷ Tumor response was assessed in 12 of 13 dogs, and responses included five PR and seven SD. The treatment was well tolerated in most dogs, and the maximum tolerated dose based on local toxicity (bladder irritation of 1 to 2 days duration) was 700 µg/mL (1-hour dwell time/day, 2 consecutive days/month). It was noted that care should be taken to prevent the drug from pooling in the prepuce as this could cause more severe irritation. Unfortunately, a much more serious toxicosis emerged. Marked myelosuppression and severe GI upset were noted in two dogs, suggesting that the drug had been absorbed systemically. This occurred after the first treatment cycle in one dog and the fourth cycle in another dog. Serum MMC concentrations were minimal in dogs that provided samples for PK analyses, but neither of the two dogs with severe toxicity had blood sampled for PK analyses. Although both dogs with severe toxicity recovered with supportive care, systemic exposure is of great concern. The amount of drug being instilled in the bladder is great enough that, if a substantial proportion of the drug were to be systemically absorbed, it could be lethal. Therefore intravesical

therapy is not recommended for initial management in dogs with TCC. If other drugs have failed and a given patient does not have other options, then the clinician and pet owner would need to carefully consider the risk versus potential benefit before deciding to use intravesical therapy. In the future, other intravesical therapies may emerge. Experimentally, paclitaxel gelatin nanoparticles have been delivered intravesically to dogs with TCC, but this approach is not in routine use.⁶⁴

Another localized therapy studied in dogs with TCC is PDT.⁶⁵⁻⁶⁷ PDT with 5-aminolevulinic acid (ALA) had potent antiproliferative effects in canine TCC cells in vitro.⁶⁵ ALA was given to healthy dogs, and induction of the photoactive metabolite, protoporphyrin IX (Pp IX), was confined to the bladder mucosa.⁶⁶ In five dogs with TCC treated with ALA-based PDT, the progression-free interval ranged from 4 to 34 weeks (median was 6 weeks). ALA-based PDT was used in a male dog with urethral TCC, and this dog was still disease free 1 year after treatment.⁶⁷

Supportive Care

Dogs with TCC are at high risk for secondary bacterial infections. Urine samples collected by free catch or catheter (to avoid potential seeding from cystocentesis) should be submitted for urinalyses and culture regularly and antibiotics prescribed as indicated. Urination should be monitored closely. If urinary tract obstruction occurs, catheterization, definitive anticancer therapy, antibiotics to reduce inflammation associated with secondary bacterial infection, or placement of stents or prepubic cystostomy tube may be pursued.

Prognosis

The progress being made to help dogs with TCC is encouraging. Multiple different treatments have been identified that result in remission or SD for several months, and the quality of life can be excellent. Unfortunately, most dogs with TCC still ultimately die of the disease. Survival has been strongly associated with the TNM stage at the time of diagnosis (Table 29-4). Factors associated with a more advanced TNM stage at diagnosis include younger age (increased risk of nodal metastasis), prostate involvement (increased risk of distant metastasis), and higher T stage (increased risk of nodal and distant metastasis).² Information on the treatment and prognosis of other types of bladder cancer has been limited. Remission has been reported in a dog with bladder lymphoma treated with radiation and chemotherapy.⁶

• **TABLE 29-4** TNM Stage at Diagnosis and Survival of 102 Dogs with Urinary Bladder Transitional Cell Carcinoma (TCC)

TUMOR STAGE	DOGS (NO.)	MEDIAN SURVIVAL (DAYS)	WILCOXON 2-SAMPLE TEST (P VALUE)
T1 or T2	82	218	0.0167
T3	20	118

M0	88	203	0.0163
M1	14	105	

Modified from previous report by Knapp DW, Glickman NW, DeNicola DB, et al: Naturally-occurring canine transitional cell carcinoma of the urinary bladder: a relevant model of human invasive bladder cancer, *Urol Oncol* 5:47-59, 2000.

Feline Urinary Bladder Tumors

Bladder cancer is rarely reported in cats. A series of 27 feline bladder tumors included 15 carcinomas, 5 benign mesenchymal tumors, 5 malignant mesenchymal tumors, and 2 lymphomas.⁶⁸ There were 20 male and 7 female cats, and most were elderly. Partial cystectomy was performed in 9 cats, and 4 cats (2 with leiomyoma, 1 with hemangiosarcoma, and 1 with leiomyosarcoma) survived longer than 6 months.⁶⁸

A series of 20 cats with TCC has been reported, including 13 neutered male and 7 spayed female cats (median age 15.2 years).⁶⁹ A series of 15 cats with TCC examined at the PUVTH in recent years included 6 neutered male and 9 spayed female cats (median age 13 years, range 4 to 18 years).⁷⁰ Clinical signs in cats with TCC include hematuria, stranguria, and pollakiuria. Concurrent urinary tract infection is common, being reported in 75% of cats in the published study⁶⁹ and 67% of cats at the PUVTH.⁷⁰ Regional and distant metastasis of feline TCC is clearly possible, but the metastatic rate has not been defined.

Of 20 cats with TCC in the published series, treatment was given to 14 cats and included surgery alone (2), surgery plus other therapy (8), piroxicam (3), and chemotherapy (1).⁶⁹ The MST was 261 days.⁶⁹ Due to the limited number of cats receiving each treatment, the value of specific treatments cannot be determined. In a case report, one cat with urethral TCC had surgical debulking, and recurrence was noted 316 days postoperative.⁷¹ This cat subsequently was treated with RT and died 70 days later.

Urethral Tumors

Most urethral tumors are malignant epithelial tumors (TCC or squamous cell carcinoma), with smooth muscle tumors reported less frequently. It is important to distinguish urethral tumors from granulomatous urethritis because the treatment and prognosis differ. Although most urethral tumors are not resectable, long-term survival has been reported in a dog with multiple chondrosarcomas in the urethra following surgery.⁷² Urinary diversion techniques described under “surgery and nonsurgical procedures” of urinary bladder TCC could be considered. The response of urethral TCC to chemotherapy or piroxicam appears similar to that of TCC of the urinary bladder.^{49,59}

Renal Tumors

Tumors that have metastasized to the kidneys from other locations are more common than primary renal tumors, which comprise fewer than 2% of all canine cancers.⁷³ Most primary renal tumors are malignant, and more than half of these are epithelial in origin. The most common renal tumor in dogs is renal cell carcinoma (RCC), accounting for 49% to 65% of primary tumors. Other tumors that can occur in the kidney include TCC, nephroblastoma, hemangiosarcoma, other sarcomas, and lymphomas (see Chapter 32, Section A).⁷³⁻⁷⁵ Lymphoma and RCC often occur bilaterally. RCC can be highly invasive into adjacent structures and may invade the vena cava.

An unusual syndrome in German shepherd dogs consists of slow-growing dermal fibrosis and fibromas, concomitant renal cystadenocarcinoma, and uterine tumors in affected females.⁷⁶ This syndrome results from a dominantly inherited missense mutation in *folliculin*, a putative tumor suppressor gene.^{77,78} This condition in dogs is thought to be similar to Birt-Hogg-Dubé syndrome in humans.^{77,78}

Diagnosis and Clinical Staging

Most RCCs and sarcomas occur in older dogs (mean age 8 years), but nephroblastoma may occur at any age. The male:female ratio of dogs with epithelial renal tumors has been reported to be 1.2:1 to 1.6:1.^{73,74} Clinical signs in dogs with renal tumors are often nonspecific and may include anorexia, weight loss, polyuria, lethargy, or hematuria. Gross hematuria is not a consistent finding. Physical examination may reveal a palpable abdominal mass or, in some cases, pain in the region of the kidneys. Bone metastases or hypertrophic osteopathy is uncommon.

Laboratory findings in dogs with renal tumors may include mild-to-moderate anemia or polycythemia from a suspected increased production of erythropoietin. Serum biochemical changes are nonspecific and can include azotemia, elevation in alkaline phosphatase, or hypoalbuminemia.

Clinical staging of renal cancer should include radiography of the thorax and abdominal ultrasonography. Excretory urography, CT, and evaluation of glomerular filtration rate (GFR) via scintigraphy may also be useful, especially for surgical planning. Evaluation of possible tumor extension into the vena cava is important if surgery is considered. Histopathologic examination is required for diagnosis. Tumor tissue can be obtained by ultrasound-guided percutaneous biopsy or at surgery. Immunoreactivity to uromodulin, c-Kit, and vimentin has been reported in canine RCC.⁷⁹ Immunohistochemical findings vary across subtypes of RCC. Papillary and tubulopapillary RCCs appear to express cytokeratins more often than solid RCCs.⁷⁹

Treatment and Prognosis

Nephrectomy is the treatment of choice for dogs with unilateral renal tumors that have not metastasized. Surgery should include removal of the ureter and possibly retroperitoneal muscle and tissue if the tumor has extended through the capsule and invaded surrounding tissues. In 68 dogs with various renal tumors that underwent nephrectomy, the MST was 16 months.⁷⁴ Renal lymphoma is generally treated with chemotherapy (see the section on Lymphoma in Chapter 32, Section A). Successful chemotherapy protocols for other forms of renal cancer have not been identified, and surgery remains the mainstay of treatment.

Pulmonary metastases have been detected radiographically in 16% to 34% of dogs with primary renal tumors at the time of diagnosis.^{73,74} At death, metastases were detected in 69% of dogs with carcinomas, 88% of dogs with sarcomas, and 75% of dogs with nephroblastomas. Although the survival time for dogs with malignant renal tumors can be short, long-term survival (up to 5 years) in individual dogs has been observed. The median survival in a series of dogs with renal hemangiosarcoma was 278 days.⁸⁰

Feline Renal Tumors

Primary renal tumors in cats are rare.⁸¹ Of 19 cats with primary renal tumors, excluding lymphoma, the median age at diagnosis was 11 years, with similar numbers of male and female cats.⁸¹ The tumors were typically unilateral and included 11 tubular renal carcinoma, 2 tubulopapillary renal carcinomas, 3 TCCs, and 1 each of nephroblastoma, hemangiosarcoma, and adenoma. One cat had polycythemia. The majority of cats had metastases. In a case report involving two cats with renal adenocarcinoma and secondary polycythemia, the polycythemia resolved in both cats following nephrectomy.⁸²

Comparative Aspects

Transitional Cell Carcinoma

Urinary bladder cancer is newly diagnosed in more than 65,000 humans each year in the United States.⁸³ Cigarette smoking is by far the most common known cause of human bladder cancer. In humans, more than two-thirds of bladder tumors are superficial low-grade tumors in the bladder mucosa.⁸³ These tumors generally respond well to transurethral resection and intravesical therapy, although recurrence is common, and progression to invasive TCC is a risk. Approximately 20% of human bladder cancers are higher grade invasive TCC at the time of diagnosis. Metastasis to the regional lymph nodes, lungs, and other organs occurs in approximately 50% of cases of invasive TCC.⁸³ More than 14,000 people die of bladder cancer each year in the United States, and most deaths are due to invasive, metastatic TCC.⁸³ TCC in dogs is extremely similar to invasive TCC in humans in histopathologic characteristics; cellular and molecular features studied to date; biologic behavior, including metastasis; and response to therapy.^{1-3,21,84-90} Canine TCC has emerged as a highly relevant model for human invasive bladder cancer.^{2,3} Successful therapies in dogs have been translated into human clinical trials, and similar effects have been observed between both species.⁹¹

Renal Cancer

Major types of renal cancer in humans include RCC, TCC of the renal pelvis, and Wilms' tumor (nephroblastoma), which is most commonly diagnosed in children.^{92,93} Renal cancer is newly diagnosed in 58,000 people and results in approximately 13,000 deaths each year in the United States. RCC accounts for 90% of adult renal carcinomas. Risk factors for RCC include cigarette smoking, obesity, and hypertension.⁹² Multiple subtypes of RCC exist, including clear cell, papillary, and chromophobe types. The clear cell type is associated with von Hippel-Lindau (VHL) disease in which mutations occur in the VHL gene. A small number of canine RCC samples have been studied for VHL gene mutations.⁹⁴ Mutations were not identified, but this does not rule out mutations in other dogs.⁹⁴ Metastases (lymph nodes, lung, bone, liver, others) are present at diagnosis in 30% of people with RCC. RCC in humans has been treated with surgery, radiation, chemotherapy, and biologic therapy (interferon and interleukin-2). Further study would be indicated to more fully examine the similarities and differences between canine and human RCC.

Tumors of the Nervous System

30

MARGARET C. McENTEE AND CURTIS W. DEWEY

Brain Tumors

Incidence and Risk Factors

Brain tumors are frequently encountered in dogs and cats, with reported incidence rates of 14.5 dogs and 3.5 cats per 100,000 pets at risk, respectively.^{1,2} In addition to being more common in dogs than in cats, there is a wider variety of canine brain tumors than reported in cats; in addition, there is a wider range of histologic subtypes of canine meningioma reported compared with feline meningiomas.^{3,4}

Most brain tumors encountered in clinical practice are primary tumors originating from brain parenchyma (e.g., glial cells and neurons, cells that line the interior and exterior brain surfaces [such as meningeal and ependymal cells]) or cells from vascular structures (e.g., choroid plexus). Meningioma is the most frequently reported primary brain tumor in dogs and cats, although gliomas are also frequently encountered in dogs.^{2,5-7} More than 50% of reported feline brain tumors are meningiomas.^{2,5,6} Gliomas are occasionally reported in cats.^{2,5} Other primary brain tumors less commonly reported in dogs include choroid plexus tumors; primary central nervous system (CNS) lymphosarcomas; primitive neuroectodermal tumors (PNETs), which typically includes neuroblastoma; primary CNS histiocytic sarcomas (also termed *malignant histiocytosis*); ependymomas; and vascular hamartomas. Other primary brain tumors occasionally encountered in cats include (in addition to gliomas): ependymomas, olfactory neuroblastomas, and choroid plexus tumors.^{2,5,7} In both dogs and cats, there are case reports of medulloblastomas, usually involving the cerebellum. Microglial tumors are considered rare in dogs and cats.¹⁻³ Primary brain tumors in dogs and cats are typically solitary. Approximately 17% of cats with intracranial meningioma have more than one tumor.^{8,9} Multiple masses of the same primary brain tumor type in dogs are typically associated with choroid plexus tumors; in this scenario, tumor cells are disseminated or “dropped” via cerebrospinal fluid (CSF) flow in the ventricular system (“drop” metastases).⁵ The authors have encountered a number of Boxers with multiple intracranial gliomas. In one study, 10% of cats were found to have two different types of intracranial neoplasia concurrently.² The occurrence of more than one histologic tumor type in dogs is considered rare.

Secondary brain tumors include metastatic neoplasia, as well as tumors that affect the brain by local extension. Examples of metastatic neoplasia include mammary, pulmonary, and prostatic carcinoma; hemangiosarcoma; malignant melanoma; and lymphosarcoma. Tumors that may extend into the brain from the periphery include nasal and frontal sinus carcinoma (adenocarcinoma, squamous cell carcinoma), calvarial tumors (e.g., osteosarcoma, chondrosarcoma, multilobular osteochondrosarcoma), pituitary tumors (e.g., pituitary macroadenomas in hyperadrenocorticism),

and nerve sheath tumors (e.g., cranial nerve [CN] V tumors). In one large retrospective study of secondary brain tumors in dogs,¹⁰ the most common secondary brain tumor was hemangiosarcoma (29%), followed by pituitary tumors (25%), lymphosarcoma (12%), metastatic carcinoma (11%), and invasive nasal tumors (6%). In one report,² secondary (multicentric) lymphoma and pituitary tumors were the second and third most common intracranial neoplasms found in cats. Lymphoma/lymphosarcoma is considered the most common secondary brain tumor type encountered in cats.

Brain tumors in dogs and cats can occur at any age, in either sex, and in any breed. However, brain tumors occur most commonly in older patients, with a median age of 9 years for dogs and older than 10 years for cats.^{2,5,6} Compared with other tumor types, dogs and cats with meningioma tend to be diagnosed at older ages.^{2,5-7} Male cats are more likely to develop intracranial meningioma than female cats.^{5,6} Golden retrievers and Boxers are considered to be predisposed to developing primary brain tumors.⁵⁻⁷ In general, dolichocephalic dog breeds are prone to develop meningiomas, whereas brachycephalic dog breeds are more likely to be afflicted with gliomas.⁵⁻⁷ There is no known breed predilection for cats to develop primary brain tumors.^{2,5,6} Cerebral tumors are more commonly encountered than tumors in the brainstem or cerebellum. Gliomas have a tendency to occur in the diencephalon and cerebellum, however.^{5,6}

Pathology

As mentioned previously, brain tumors are broadly classified as primary (neoplastic cells originating from tissues intrinsic to the brain, its vasculature, and meninges/ependyma) or secondary (neoplastic cells originating from tissues extrinsic to those comprising primary brain tumors).⁵ Brain tumors exert their pathologic effects both by directly encroaching on and/or invading brain tissue and by secondary effects, such as peritumoral edema, inflammation, obstructive hydrocephalus, and hemorrhage.

The terms *benign* and *malignant* have different connotations when used in the context of intracranial neoplasia compared with tumors in other locations. Even slow-growing, readily removable brain tumors are not benign when considering the potential effect on the patient if therapy is not aggressively pursued in a timely fashion. Cytologic features of tumors are used to assess potential benignity or malignancy and include invasiveness, number of mitotic figures, and nuclear pleomorphism. Meningiomas are often regarded as benign. Considering the aggressive cytologic nature of many canine meningiomas (in comparison with human and feline meningiomas), this is probably an overstatement for this tumor type—especially in dogs.^{6,11}

There are multiple histologic subtypes of meningiomas frequently encountered in dogs, including meningothelial, transitional, fibroblastic, psammomatous, angiomatous, microcystic,

papillary, granular cell, myxoid, and anaplastic.^{3,4,6,11} In addition to these histologic subtypes, a grading system used in humans to predict the biologic behavior of intracranial meningiomas has recently been adapted to dogs; this grading system includes grade I (benign), grade II (atypical), and grade III (malignant).¹¹ The repertoire of feline meningioma histologic subtypes is comparatively limited; the majority of feline meningiomas are meningothelial or psammomatous.^{2-4,6}

Gliomas in dogs and cats include astrocytomas, oligodendrogliomas, and glioblastoma multiforme, in addition to undifferentiated gliomas. Gliomas as a group are considered to be malignant because these tumors tend to invade tissue and are typically resistant to all forms of definitive therapy.^{2,4,5,7,12}

Clinicopathologic features of choroid plexus tumors in dogs have recently been reviewed.¹³ Choroid plexus tumors comprise choroid plexus papillomas (CPP) and choroid plexus carcinomas (CPC). Choroid plexus tumors in general tended to occur in the fourth ventricle in one report, and only CPCs occurred in the lateral ventricles.¹⁴ The two tumor subtypes are differentiated based on the presence or absence of local or distant metastases, as well as on histopathologic features.

In one large study,⁷ it was found that half of canine primary brain tumors occupy more than one anatomic region of the brain; this could lead to the false conclusion based on neurologic examination that a patient with a solitary brain mass has multifocal disease. Also in that study, it was found that 23% of dogs with primary brain tumors had concurrent, unrelated neoplasia (e.g., pulmonary carcinoma, hemangiosarcoma), most of which involved the thoracic or abdominal cavity; this finding underscores the importance of screening for concurrent unrelated neoplasia (via thoracic radiography and abdominal ultrasonography) prior to pursuing advanced diagnostics and definitive therapy for the brain tumor.

History and Clinical Signs

The diagnosis of brain tumor should be highly suspected in an elderly dog or cat with slowly progressive signs of brain dysfunction. A brain tumor should also be suspected in animals that experience a recent onset of seizure activity after 5 years of age, especially in certain breeds (e.g., golden retrievers, Boxers). Depending on the location and size of the tumor, such patients may appear neurologically normal interictally. Historic and presenting clinical signs for dogs and cats with brain tumors are variable and reflect both the location and the secondary effects (e.g., edema, hemorrhage) of the tumor. Seizures represent the most common presenting clinical sign of neurologic dysfunction in dogs with brain tumors, occurring in approximately half of the patients.^{5,6,15} In one study of feline brain tumors, the overall incidence of seizure activity was 23%, occurring more commonly with glioma (26.7%) and lymphoma (26.3%), in comparison with meningioma (15%).¹⁶ Cats with brain tumors are commonly presented to the veterinarian with a complaint of behavior change. In cats with primary brain tumors, non-specific presenting clinical signs (i.e., signs not obviously referable to neurologic dysfunction) are fairly common, occurring in over 20% of cats in one large study.² These clinical signs included lethargy, inappetence, and anorexia. Also in that study, it was found that approximately 19% of feline brain tumors were considered an incidental finding. Cerebral tumors are more common than tumors of the brainstem or cerebellum. Cerebral and diencephalic tumors tend to cause clinical signs of dysfunction such as seizure activity, behavior changes, circling, head-pressing, visual deficits, and hemi-inattention (hemineglect) syndrome (ignoring environmental cues

from the side opposite the tumor). Proprioceptive placing deficits and neck pain are often appreciable on neurologic examination. Tumors of the brainstem from midbrain through medulla often cause alterations of consciousness, dysfunction of cranial nerves (other than CN I and CN II), and obvious gait/proprioceptive abnormalities. Cerebellar tumors may result in clinical signs of dysfunction such as ataxia, dysmetria, intention tremors, vestibular abnormalities, and menace reaction deficits with normal vision.^{5,6}

In most cases, clinical signs of neurologic dysfunction occur slowly and insidiously over time, especially with meningiomas. Owners of pets with meningiomas will often retrospectively realize that their pet had a behavior change for months to over a year prior to diagnosis. The subtle behavior changes are often attributed to “old age.” However, brain tumor patients can have subacute to acute development of neurologic dysfunction. These patients may experience sudden exhaustion of brain compensatory mechanisms or may suffer hemorrhage or acute obstructive hydrocephalus due to the tumor.^{5,6}

Diagnostic Techniques and Work-Up

Signalment, history, and neurologic examination findings often provide a strong index of suspicion of a brain tumor as the cause of neurologic dysfunction in a dog or cat. However, there are a number of disorders (e.g., inflammatory/infectious, congenital, degenerative) that can produce similar signs of neurologic dysfunction in patients at risk for developing brain tumors. It is imperative therefore to follow an ordered diagnostic work-up in patients suspected of having brain tumors.

Minimum Database

Before pursuing advanced imaging, basic blood work (complete blood count [CBC] and chemistry profile) and a urinalysis should be performed. Thoracic radiographs should be taken to help rule out the possibility of metastatic cancer or a second unrelated neoplastic process. Considering the likelihood of concurrent neoplasia in dogs with brain tumors, performing abdominal ultrasound examination is also often advisable.

Imaging

Radiographs of the skull typically do not provide useful clinical information in cases of brain tumor. Computed tomography (CT) and magnetic resonance imaging (MRI) are commonly used in the diagnosis of brain tumors, with MRI being the preferred imaging modality. Although specific types of brain tumors can vary in their appearance with these imaging modalities, there are some characteristic features that help distinguish meningiomas from gliomas. Meningiomas tend to have a broad-based, extraaxial attachment (they arise from the periphery of the brain and move inward, or axially), exhibit distinct tumor margins, and uniformly contrast enhance (Figure 30-1). Meningiomas tend to displace, rather than invade, parenchymal tissue; as discussed previously, however, many canine meningiomas do display some degree of invasiveness. Some meningiomas will calcify, which can be appreciated on a noncontrast CT image (Figure 30-2). The “dural tail” sign is an MRI feature typically associated with meningiomas, in which a contrast-enhancing meningeal-associated “tail” is seen extending from the main tumor mass (Figure 30-3). Meningiomas also may occasionally have a cystic component (cystic meningioma) extending from the main tumor mass (Figure 30-4). Gliomas tend to arise from an intraaxial location (from within the substance of the brain, moving outward), often lack distinct tumor margins (they tend to infiltrate, rather than displace normal tissue), and typically contrast enhance

• **FIGURE 30-1** Postcontrast MRI of a cerebellar meningioma.

• **FIGURE 30-2** Precontrast CT image of feline meningioma with calcification.

• **FIGURE 30-3** Postcontrast MRI of canine meningioma at the cerebellomedullary angle demonstrating a meningeal tail.

• **FIGURE 30-4** Feline meningioma with cystic component.

• **FIGURE 30-5** Postcontrast CT of canine glioma.

poorly and nonuniformly (Figure 30-5). Choroid plexus tumors and ependymomas tend to be intraventricular in location and often uniformly contrast enhance (Figure 30-6). The phenomenon of “ring enhancement,” in which a circular ring of contrast enhancement surrounds nonenhancing tissue, is nonspecific and has been associated with several neoplastic and nonneoplastic brain diseases. However, ring enhancement is often associated with gliomas (see Chapter 6). Meningeal contrast enhancement evident on MR images of the brain has been described but is not specific for brain tumors. These typical imaging features are guidelines only. Meningiomas can arise from the falx cerebri or the choroid plexus and appear intraaxial. Gliomas can be peripherally located and contrast enhancing. In a recent study, the accuracy of predicting primary brain tumor type based on MR images of 40 dogs was 70%.¹⁷ Stereotactic biopsy of brain tumors using MRI or CT images is now

• **FIGURE 30-6** Postcontrast MRI of a canine choroid plexus tumor.

available at several veterinary referral centers.⁵ With this new technology, a definitive diagnosis can be obtained at the time of imaging without the need for major intracranial surgery.

Cerebrospinal Fluid Analysis

The utility of CSF evaluation for the suspected brain tumor patient is controversial. CSF is often abnormal in patients with brain tumors, but the white blood cell (WBC) counts and protein levels are variable and nonspecific for neoplasia. In fact, dogs and cats with meningiomas tend to have CSF with predominantly polymorphonuclear (neutrophilic) WBC counts. The authors often do not pursue CSF analysis if the CT or MR image strongly suggests a brain neoplasm. Although the risk of CSF procurement in the face of elevated intracranial pressure (ICP) in a brain tumor patient is often not great, the potential benefit of a nonspecific CSF result may not outweigh even a small danger of harming the patient with the procedure. Although CSF analysis tends to yield fairly nonspecific information in brain tumor cases, it may be helpful in distinguishing whether a choroid plexus tumor is a CPP or CPC. In one study,¹³ the more malignant CPC was significantly more likely to be associated with a CSF protein concentration greater than 100 mg/dL than the less malignant CPP tumor subtype. Regardless of whether CSF analysis is performed, imaging should always precede CSF analysis when a focal neoplasm is highly suspected. Anesthetizing a patient who is most likely to have a brain tumor solely for the purpose of obtaining CSF is generally contraindicated because the resultant information is unlikely to assist in either planning treatment or estimating prognosis.

Therapy

Surgery

In addition to removing neoplastic tissue, surgical debulking/removal allows for a histologic diagnosis, as well as potentially providing an immediate decompressive effect (decreasing ICP). Feline meningiomas are typically located over the cerebral convexities and tend to “peel away” from normal brain tissue at surgery. In most cases, feline meningiomas can be relatively easily removed en masse. The authors have had considerable experience dealing with recurrent or repeat feline intracranial meningiomas; overall, these tumors are also typically readily removable. Surgical removal is the

• **FIGURE 30-7** Surgical removal of cerebral cortical meningioma.

primary mode of definitive therapy for feline intracranial meningiomas.^{2,5,6,9} Canine meningiomas are also often located over the cerebral cortical surface and are thus surgically accessible (Figure 30-7). However, meningiomas in the cerebellar and brainstem regions are frequently encountered in dogs. Cerebellar meningiomas are often surgically accessible; meningiomas in the brainstem may not be accessible. Meningiomas in dogs are much less predictable than those in cats in terms of ease of surgical removal. Unlike cats, there are multiple histologic subtypes of canine meningiomas, and nearly one-third of these tumors are invasive.^{3-6,11} The authors have successfully used intraoperative ultrasound to assist in locating brain tumors and in judging completeness of removal (Figure 30-8). The authors do not recommend pursuing surgical removal of canine meningiomas if adjunctive therapy (e.g., radiation) is not planned to be used following removal. Some gliomas are surgically accessible, but surgical removal/debulking of gliomas is considerably more difficult than meningiomas. Gliomas tend to infiltrate normal brain parenchyma, and it is often difficult to discern tumor margin from brain tissue at surgery. Surgical removal of intracranial glioma is seldom attempted in dogs and cats because of the invasive nature of these neoplasms. Removal of other brain tumor types (e.g., choroid plexus tumor, ependymoma) is also uncommonly performed because of the intraaxial location of these masses. Surgical removal of secondary brain tumors is also not commonly performed because many of these tumors are invasive as are their extraneural source neoplasms. However, some calvarial tumors (e.g., multilobular osteochondrosarcoma [MLO]) are surgically resectable with good outcomes (see Chapter 24).^{5,18} On rare occasions, metastatic brain tumors are removed surgically.

Radiation Therapy

Radiation therapy (RT) is used in the treatment of primary brain tumors, as well as secondary brain tumors that arise by local extension or from metastasis from a distant site. Treatment options have advanced from early reports of the use of orthovoltage RT to

• **FIGURE 30-8** Intraoperative ultrasound evaluation of canine meningioma.

current options, including intensity-modulated RT (IMRT) and stereotactic RT (SRT).^{19,20} Fractionated radiation protocols have largely transitioned from alternate day treatments to daily therapy (Monday through Friday), although there are reports on the application of hypofractionated protocols.²¹⁻²³ Radiation dose per fraction, total dose of radiation, and the volume of the brain irradiated are important considerations when irradiating brain tumors.^{24,25} In one report of hypofractionated brain irradiation, 14.5% (12/83) of dogs died or were euthanized due to suspected delayed radiation side effects caused by delivery of a high dose per fraction.²² There are reports on the results of RT alone or in combination with surgery for canine primary brain tumors.^{19,24,26-29} RT improves survival over surgery alone or medical management alone.^{26,28} Median overall survival for 29 dogs (presumptive diagnosis of meningioma in 22 dogs, glioma in 4 dogs, and choroid plexus tumor in 3 dogs) that were treated with RT alone was 250 days, with 76% dying of presumptive recurrence or tumor progression.²⁷ In another report of 46 dogs irradiated only for a range of different tumor types the median survival time (MST) was 699 days.²⁴ It is a well-accepted principle that postoperative RT in the microscopic disease setting is generally more efficacious than treating macroscopic disease, including brain tumors. However, it may be difficult to determine if there are postoperative changes versus residual macroscopic disease when CT imaging is done for radiation treatment planning postoperatively.³⁰ With no therapy or only supportive therapy, survival is reported to be 0.2 months in comparison to dogs irradiated with Cobalt-60 external-beam RT alone or in combination with other modalities with a median survival of 4.9 months.²⁶ In another report comparing surgery alone to surgery plus RT, the median survival was 7 months (surgery alone and survival >1 week) compared to 16.5 months (combination therapy).²⁸ In a report of 20 dogs with meningioma that had RT after incomplete resection, the median progression-free survival time was 35 months.²⁹ In a retrospective study of endoscopic-assisted tumor removal in dogs (n = 33) and cats (n = 6), 44% were alive after more than 2 years,

only 4 were irradiated postoperatively, and the MST for dogs with meningiomas was 2104 days.³¹

An alternative to conventional fractionated RT is stereotactic radiosurgery for the management of CNS tumors, which entails the precise delivery of a larger dose per fraction to the tumor in 1 to a few fractions for a total dose of 10 to 15 Gy.²⁰ Limited information is available in the literature, but there are a number of veterinary facilities that now have equipment with this capability.

RT has also been used successfully to irradiate a calvarial allograft used in the repair of a calvarial defect in a cat with an intracranial meningioma.³² It is important to consider the potential impact on radiation dose distribution in patients that have undergone surgery and require reconstruction that may include the use of metal implants.³³⁻³⁶ This is potentially of more concern when larger metal implants (e.g., plates, rods, screws) are used to stabilize the spine.³⁷

Chemotherapy

There are a limited number of reports on the use and efficacy of chemotherapy in the management of brain tumors in companion animals, including individual case reports and small case series.^{21,38-44} Lomustine, carmustine, and hydroxyurea have been utilized in the treatment of canine brain tumors, but there are limited data to provide validation of the utility of chemotherapy. Based on a retrospective study of oral hydroxyurea in combination with glucocorticoids, 33 dogs with MRI-diagnosed meningioma had a significantly longer survival time than observed in 10 dogs treated with glucocorticoids alone.⁴⁵ The MST for the combination therapy group was 28 weeks versus 14 weeks for dogs treated with glucocorticoids alone.⁴⁵ A report on the use of 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU) in 206 dogs with a number of different tumor types, including 11 dogs with brain tumors, documented toxicity of this chemotherapeutic agent but did not provide response data.³⁸ Chemotherapy (carmustine, lomustine) alone or in combination with RT or cytoreductive surgery in dogs with astrocytomas has resulted in survival times of 3 to 8 months.^{21,40}

Other Therapies

There is limited information on other therapeutic approaches to the management of canine brain tumors, including the use of whole body hyperthermia in conjunction with RT and/or chemotherapy, radioactive iodine-125 implants in combination with other therapeutic approaches, gene therapy, and convection-enhanced delivery of liposomal nanoparticles containing topoisomerase inhibitor CPT-11, which is still being developed.^{26,46-52} The use of whole body hyperthermia in conjunction with external-beam irradiation did not alter survival.⁴⁶ Dogs with meningiomas that were irradiated had a mean survival of 314 days versus 288 days for dogs treated with RT plus whole body hyperthermia.⁴⁶ Gene therapy strategies in dogs have included the delivery of an adeno-associated viral vector containing prodrug activating genes that confer sensitivity to toxic metabolites and cytokine-based gene therapy using an intravenously delivered cationic DNA lipid complex containing murine endostatin gene in a DNA plasmid to perturb tumor angiogenesis.^{47,48} There is limited information on the application of brachytherapy in conjunction with excisional biopsy, but it may represent another potential avenue of treatment.^{26,53}

Based on the association between vascular endothelial growth factor (VEGF) expression and survival in dogs with intracranial meningiomas, administration of antiangiogenic agents may have future therapeutic potential.^{54,55}

There is information available that indicates that dynamic contrast-enhanced CT may have utility in evaluating and classifying intracranial lesions and for determining response to therapy.⁵⁶

Prognosis

Prognosis is poor with no therapy or only supportive therapy or palliative therapy in dogs with a MST of 0.2, or less than 2 months.^{23,26} Results of RT based on a subset of the reports in the literature are difficult to interpret because a definitive histopathologic diagnosis is not always obtained and tumor types are grouped together (including pituitary tumors).^{19,24,26,27} A presumptive diagnosis may be made based on either CT or MRI findings.^{27,57} However, this may not be a reliable means of arriving at a presumptive diagnosis.⁵⁸ The interpretation of results is improving with the advent of minimally invasive techniques for brain tumor biopsies or cytology, as well as advancements in surgical techniques and tumor extirpation for histopathologic analysis, including endoscopic-assisted intracranial tumor removal.^{31,59-64} The ability to definitively diagnose the specific histopathologic type of brain tumor prior to surgery may aid both clinicians and clients in deciding on a course of treatment and in understanding the potential prognosis.⁴⁸ Additional potential positive prognostic factors that have been identified include solitary versus multiple lesions, limited neurologic dysfunction, and treatment with RT or a combination of surgery and RT.^{26,28} Tumor location may also impact survival; MST for forebrain versus caudal brain meningiomas was 2104 days and 702 days, respectively.³¹ Pneumonia can develop due to aspiration postoperatively and may have a negative impact on survival.⁶⁵

Meningiomas are the most common intracranial tumor in dogs, but attempts to correlate tumor grade or histologic subtype and MRI features largely have not identified any significant associations that would allow preoperative prognostication.¹¹ In a study of 112 dogs with intracranial meningiomas using criteria of the human WHO international histologic classification system 56% were classified as benign, 43% were atypical, and 1% were malignant meningiomas; the atypical and malignant meningiomas were noted to behave more aggressively with a higher potential for recurrence.¹¹ In one report of 17 dogs treated surgically for meningioma, survival was correlated with histologic tumor type: anaplastic 0 days, fibroblastic 10 days, psammomatous more than 313 days, meningothelial more than 523 days, and transitional 1254 days.⁴⁴ Of interest is that use of a surgical aspirator to resect intracranial meningiomas resulted in a MST of 1254 days.⁴⁴ None of the dogs were irradiated, and only 2 of 17 received postoperative chemotherapy (hydroxyurea) when there were MRI findings suggestive of recurrence.⁴⁴ In a study of 17 dogs with benign meningiomas treated with surgery and postoperative hypofractionated RT, significantly shorter survival times were associated with greater VEGF expression.⁵⁴ The MST was 748 days for dogs with tumors with 75% or fewer cells staining for VEGF compared with 442.5 days for dogs with tumors with more than 75% of cell staining for VEGF.⁵⁴ Furthermore, dogs with more intense staining had a significantly shorter survival time.⁵⁴ In a more recent study, tumor proliferation defined by reactivity of the monoclonal antibody MIB-1 to the Ki67 antigen was not associated with survival, and there was no association between VEGF and tumor proliferation.⁶⁶ In this study, 70 dogs underwent surgery and postoperative hypofractionated RT, and the overall MST from the date of diagnosis was 514 days.⁶⁶ Progesterone and estrogen receptor expression has been evaluated in meningiomas in dogs and cats; further investigation will be necessary to determine if there is prognostic significance or a role for targeted

intervention.^{29,67} In one study, progesterone receptor expression was inversely related to tumor proliferative fraction measured by immunohistochemical detection of proliferating cell nuclear antigen (PF_{PCNA} index), which was predictive of survival in dogs with meningiomas after surgery and postoperative RT.²⁹ The 2-year progression-free survival was 43% for tumors with a high PF_{PCNA} index and 91% for tumors with a low PF_{PCNA} index. Furthermore, tumors with a high PF_{PCNA} index were 9.1 times more likely to recur.²⁹ Cyclooxygenase-2 (COX-2) expression has been demonstrated in the majority of intracranial meningiomas (21/24 or 87%), but the role in tumorigenesis and the potential for therapeutic intervention with COX-2 inhibitors have not been elucidated.⁶⁸ Conversely, in a study of 20 canine gliomas, none of the tumors expressed COX-2.⁶⁹ In this same study that also evaluated c-kit overexpression, the authors speculated that c-kit inhibitors may have an antiangiogenic effect in high-grade tumors due to presence of intramural vascular expression.⁶⁹

Stereotactic radiosurgery may provide comparable or improved tumor control with a fewer number of anesthetic episodes but is limited in its application due to a limited number of facilities with this capability.²⁰ Two dogs with meningiomas survived 227 and 56 weeks after radiosurgery; a dog with an oligodendroglioma survived 66 weeks.²⁰ Additional information should be forthcoming with increased availability of RT units with advanced capability to deliver radiation.

In dogs with choroid plexus tumors, it should be noted that local spread of the tumor within the ventricular system can occur and distant metastasis via the subarachnoid space occurs in approximately 50% of dogs.¹³ Additionally, at necropsy in one study of 56 dogs with choroid plexus tumors, 19% had evidence of gross and/or microscopic spinal cord metastases that should impact considerations of diagnostics, approaches to treatment, and prognosis.¹³

There are descriptive reports but limited prognostic information available for other specific tumor types, such as for astrocytomas.^{12,70,71} In a report of 86 dogs treated for brain tumors that included 27 meningiomas, 7 astrocytomas, and 6 choroid plexus tumors, survival based on tumor type was evaluated as meningioma versus other; dogs with meningiomas lived significantly longer.²⁶ In a study of dogs irradiated with a hypofractionated protocol, the MST for 34 dogs with intraaxial tumors (presumably gliomas) was 40.4 weeks versus 49.7 weeks for 41 dogs with extraaxial tumors (presumably meningioma, including schwannoma and choroid plexus tumor).²²

Histiocytic sarcoma can affect the CNS in dogs with systemic disease, but there are a limited number of reports of localized CNS histiocytic sarcoma, with one report with necropsy information that confirmed the localized nature.⁷²⁻⁷⁶ Rapid disease progression and euthanasia was the outcome for two dogs: one with primary spinal cord involvement and the other with brain involvement.⁷⁶ Surgical intervention has been reported in 12 dogs with subdural histiocytic sarcomas, although no follow-up information was provided.⁷⁵

There are a number of studies that have been conducted to further elucidate the mechanisms of tumorigenesis and determination of the immunohistochemical profiles of brain tumors.⁷⁷⁻⁸³ Such efforts may ultimately lead to a better understanding and ability to prognosticate for individual patients based on identification of specific markers and for determination of appropriate targeted therapy. However, to date, targeted therapies in humans with meningiomas have only realized modest success and are associated with toxicity.⁸⁴

It should be noted that multiple meningiomas, multifocal oligodendroglioma, and synchronous brain tumors (oligodendroglioma and meningioma) have been reported, as well as synchronous primary and metastatic tumors in dogs.^{43,85-89} Based on one small case series, survival may be comparable for dogs with multiple meningiomas as seen for dogs treated for a solitary meningioma.⁴³ Additionally, dogs with a primary brain tumor may have another primary tumor that may affect prognosis.⁷ In a report of 170 dogs with primary intracranial neoplasia, 38/170 (23%) had another tumor unrelated to the brain tumor.⁷ In a study of 28 dogs with meningiomas 7 (25%) had another tumor in addition to the meningioma.⁸⁷ Although rare, pulmonary metastasis in three dogs with intracranial meningioma has been reported.⁹⁰ Cats are also reported to have multiple or two different types of intracranial tumors and, in fact, more commonly have multiple meningiomas (17%) than dogs.^{2,8,91,92} It has been questioned whether multiple meningiomas represent multicentric disease or metastasis. Dogs with metastatic intracranial neoplasms most commonly have metastatic hemangiosarcoma or carcinomas, representing 50% and 20% of metastatic tumors, respectively, with an anticipated poor prognosis.^{10,93} Meningeal carcinomatosis results from spread of a solid tumor that can be an intracranial primary tumor or of distant origin (e.g., mammary gland carcinoma) and is associated with a very poor prognosis.⁹⁴⁻⁹⁶ Metastatic disease is usually recognized as multiple mass lesions, but a solitary lesion may represent metastasis. Full staging is necessary to rule out other disease because secondary intracranial neoplasia may be more common than primary intracranial neoplasia.¹⁰

Cats respond well to surgery alone for intracranial meningiomas, which is the most common primary intracranial tumor in cats, and have a MST of approximately 2 years.^{2,9,97,98} In one report, the MST for cats treated surgically was 685 days compared to 18 days for cats that did not have surgery.² Recurrence is documented to occur; 20.6% in one report had a median postoperative time to recurrence of 285 days (range 123 to 683 days; $n = 6$ cats); second surgeries are feasible in cats.^{2,9} Cats with multiple meningiomas based on one report have long-term survival when treated surgically with follow-up chemotherapy (hydroxyurea) for 2 ($n = 3$ cats) or 4 ($n = 1$ cat) meningiomas.⁹¹

Cats with intracranial lymphoma more commonly have multicentric disease; fewer cats have primary intracranial lymphoma.² In cats treated palliatively with systemic corticosteroids, the MST was 21 days (range 9 to 270 days in nine cats).²

Two cats with oligodendrogliomas were euthanized at the time of diagnosis or 6 weeks after diagnosis due to their poor neurologic status.⁹⁹ Of six cats with oligodendrogliomas, three had surgery ($n = 2$) and/or received corticosteroids ($n = 1$), with survival times of 1 day, 5 days, and one cat that had surgery was lost to follow-up at 1 month.² Four cats with cerebral astrocytomas (three of which were managed medically) lived for 1 to 3 years with anticonvulsant therapy.¹⁰⁰ Two of six cats with astrocytomas had surgery, followed by RT in one cat with survival times of 1 day and 179 days; a third cat treated with only corticosteroids survived 35 days.² One cat with an ependymoma that had two surgeries ultimately survived for 667 days; another cat treated with corticosteroids was euthanized at 685 days.²

Comparative Aspects

Humans are afflicted with the same overall cadre of brain tumor types that are reported in dogs and cats. Overall, the incidence of brain tumors in people is approximately 19 per 100,000 person-years, with about 60% of these being benign tumors; the most

common benign brain tumor in people is meningioma and the most common malignant brain tumor in people is glioblastoma multiforme (also called grade IV astrocytoma).^{101,102} Intracranial meningiomas in humans are often classified based on three histologic grades (benign, atypical, malignant) that predict biologic behavior. Approximately 80% of human meningiomas are considered benign according to this scheme, with atypical and malignant grades accounting for 8% and less than 3%, respectively. Although the specific histologic subtypes (e.g., transitional, psammomatous) of canine and human meningiomas are very similar, the percentage of atypical tumors is much higher in dogs at 43%.^{11,103} Treatment modalities used for human brain tumors are similar to those used for canine and feline brain tumors. Surgical removal is the primary treatment method used for human meningiomas, and survival is linked to the completeness of surgical removal. Adjunctive RT improves survival rates in people for incompletely resected meningiomas.^{11,101,102,104} Oral hydroxyurea therapy may be an effective treatment for human meningioma as well, although this is not as well established as RT.¹⁰⁴ The prognosis for long-term control or cure of human intracranial meningioma is good.^{11,104} The morbidity and mortality for human gliomas is poor overall, with survival times often ranging from 7 to 24 months, even with combination (surgery, radiation, chemotherapy) therapy.¹⁰²

Spinal Tumors

Incidence and Risk Factors

The actual incidence of spinal tumors in dogs and cats is unknown but appears to be considerably less than that of brain tumors. As with brain tumors, spinal tumors are broadly classified as primary or secondary. Spinal tumors are usually also classified in terms of their anatomic location: extradural, intradural/extramedullary, intramedullary, or mixed compartment. The most common primary spinal cord tumor in dogs is meningioma, and in cats the most common primary spinal cord tumor is lymphoma.^{6,105-109} Hemangiosarcoma is the most commonly reported secondary spinal cord tumor in dogs, and osteosarcoma is the most commonly reported secondary spinal cord tumor in cats.^{105,106} In one large retrospective study of 399 histopathologically confirmed spinal cord tumors in dogs, 48% were extradural, 13% were intradural/extramedullary, 6% were intramedullary, and 33% were mixed compartment.¹¹⁰

Canine spinal tumors tend to occur in large breeds, typically at an older age (e.g., 9 to 10 years).^{105,106} Meningiomas and malignant nerve sheath tumors (MNSTs) arise most frequently in the cervical spinal cord, and MNSTs are especially prominent in the cervical intumescence area.^{105,106} Boxers may be predisposed to spinal meningiomas.¹⁰⁹ More aggressive meningiomas (grade II versus grade I) are likely to occur in the thoracolumbar region and in younger dogs.¹⁰⁹ Spinal nephroblastoma typically occurs in young dogs (between 6 months and 3 years of age); this tumor also has a predilection for golden retrievers and German shepherd dogs and is usually located between the T10 and L2 spinal cord segments.^{105,106,111,112} Spinal lymphoma often affects young cats, is often associated with the feline leukemia virus (FeLV), tends to occur in the thoracic and lumbar spine, and is usually present in multiple extraneural locations.¹⁰⁵⁻¹⁰⁸ Vertebral osteosarcoma in cats is usually reported in older patients (e.g., >8 years).^{107,108}

Pathology

The category of extradural tumors includes primary and secondary (metastatic or local invasion) vertebral and soft tissue tumors. Primary vertebral tumors such as osteosarcoma, chondrosarcoma,

myeloma (plasma cell tumor), fibrosarcoma, and hemangiosarcoma are common extradural tumors encountered in dogs.^{105,106} In one study, vertebral tumors were slightly less prevalent than lymphosarcoma in cats, with osteosarcoma being the most common.¹⁰⁷ Other vertebral tumors reported in cats include fibrosarcoma, undifferentiated sarcoma, and plasma cell tumors. The most common primary vertebral body tumor in dogs is also osteosarcoma.^{105,110} It may be difficult in some cases to ascertain whether a vertebral tumor is primary or metastatic. Other tumors may occur in the epidural space, without directly involving the vertebrae. Common among these are sarcomas—most frequently osteosarcoma and hemangiosarcoma. Lymphosarcoma can be primary or metastatic and is often located in the extradural space, particularly in cats. Meningioma and MNSTs usually are typically located intradurally but occasionally will exhibit an extradural pattern on imaging. Metastatic carcinomas (e.g., mammary carcinoma, prostatic carcinoma) may localize to the extradural space. A number of fatty tumors have been reported to affect the spinal cord in dogs, including lipoma, myelolipoma, infiltrative lipoma, and liposarcoma. These all generally occur in an extradural location.^{105,106,110,113-115}

Meningiomas and MNSTs are the two most common neoplasms in the intradural/extramedullary location category, with meningiomas predominating. An uncommon blast cell tumor of young dogs called *nephroblastoma* also typically displays an intradural/extramedullary pattern on spinal imaging.*

Intramedullary tumors are infrequently encountered and include primary spinal parenchymal tumors (e.g., astrocytoma, oligodendroglioma, ependymoma) and intramedullary metastases. The most common intramedullary metastases in dogs are thought to be hemangiosarcoma and lymphosarcoma.^{105,106} In one study, hemangiosarcoma was the most common tumor type in the intramedullary category.¹¹⁰

History and Clinical Signs

Spinal tumors typically cause progressive signs of a myelopathy, but acute or subacute development of spinal cord dysfunction often occurs, especially with feline lymphosarcoma and intramedullary neoplasms. Rapid onset of clinical signs may be due to factors such as pathologic fracture of a cancerous vertebra, acute hemorrhage or necrosis of a tumor, or rapid growth of a neoplasm with subsequent damage to spinal cord parenchyma (more likely with intramedullary tumors). Spinal cord tumors are typically solitary and can occur anywhere along the length of the spine. As with brain tumors, the specific neurologic deficits associated with a spinal tumor will depend on the specific neuroanatomic location of that tumor.

A prominent feature of extradural and intradural/extramedullary spinal neoplasia is spinal hyperesthesia, which often precedes the onset of proprioceptive and voluntary motor deficits. Spinal hyperesthesia is often not a prominent early clinical feature in patients with intramedullary spinal tumors, probably due to the lack of meningeal involvement. In MNSTs of the cervical intumescence, a history of unilateral thoracic limb lameness (on the side of the tumor) preceding the development of clinical signs of myelopathy is common.^{6,105,106}

Diagnostic Techniques and Work-Up

Minimum Database

The minimum database for a patient with a suspected spinal neoplasm is similar to that for a patient with a suspected brain tumor.

Blood work (CBC and chemistry profile) and urinalysis should be performed, and survey radiographs should be procured to help rule out metastatic disease or a secondary neoplastic process.

Imaging

Survey spinal radiographs are generally recommended to identify the presence or absence of any obvious bony lesions (e.g., bone lysis and/or proliferation). In the majority of soft tissue spinal neoplasms, plain radiographs of the spine are normal. In some cases, however, the expanding neoplasm leads to expansion of either the vertebral canal or the intervertebral foramen, with or without obvious thinning of the surrounding bone. As with brain tumors, the preferred imaging modality for investigation of suspected spinal neoplasia is MRI (Figure 30-9). CT, alone or in combination with myelography, can also be used to diagnose spinal cord tumors but is considered to be inferior to MRI in most cases. Lesions that are difficult to distinguish as being either intradural/extramedullary or intramedullary on myelographic images may be better delineated on MRI or CT/myelography; however, some spinal tumors have enough associated spinal cord swelling that this distinction may be difficult to make, even on MR images. Also, intradural/extramedullary spinal tumors will occasionally infiltrate the spinal cord parenchyma (mixed compartment mass), which may contribute to the development of an intramedullary imaging pattern (Figure 30-10).^{105,106,110}

Cerebrospinal Fluid Analysis

CSF analysis is often pursued in combination with spinal imaging. As with brain tumors, CSF analysis is likely to be abnormal but usually does not provide specific information about the disease process. With the possible exception of spinal lymphosarcoma, CSF evaluation rarely reveals neoplastic cells and may reveal increased protein levels, with or without elevated cell counts (more likely with tumors with meningeal involvement).^{6,105,106}

• **FIGURE 30-10** Postcontrast MRI of cervical axial nerve sheath tumor.

Therapy

Therapeutic options for spinal cord tumors are similar to those available for brain tumor management. Surgical removal may be advisable for those neoplasms that have not infiltrated spinal cord parenchyma.

Meningioma is reported to be the most common intraspinal tumor in dogs and can be treated effectively with surgery with or without postoperative external-beam RT.^{109,116-118} RT results in an improved outcome and can contribute to prevention of or delay in local recurrence.^{109,116} With surgery alone for intraspinal meningioma, the mean survival time has been reported to be 19 months for 8 of 10 dogs that had evidence of postoperative recurrence.¹⁰⁹ In a report of the results of surgery in nine dogs with spinal meningioma, five were alive longer than 6 months postoperatively.¹¹⁹ In two dogs treated surgically for spinal meningiomas, the survival time was 1410 and 1440 days.¹¹⁸ In seven dogs that underwent a combination of surgery and postoperative RT, survival times ranged from 18 to 78 months.¹⁰⁹ Six dogs that had postoperative RT for spinal meningioma had a MST of 13.5 months (range 8 to 25 months).¹¹⁶ One dog that had recurrence of an intraspinal meningioma 15 months postoperatively was irradiated with almost complete resolution of neurologic deficits and was ultimately euthanized for recurrence 19 months after RT.¹¹⁷ As with RT for intracranial tumors, the trend has been to reduce the dose per fraction and increase the total dose. The goal is to maximize the dose of radiation that can be delivered while minimizing the risk of radiation myelopathy. Also, there is a dose-volume relationship, and the length of the spinal cord irradiated has to be considered when prescribing the dose.¹²⁰

Dogs with spinal neuroblastomas can be treated effectively with a combination of surgery and RT.^{111,112,121} The results reported for surgery alone are widely variable with MSTs of 70.5 days and 380.5 days.^{111,112,122} It should be noted that since this is a tumor that develops in young dogs, RT carries the risk for the development of radiation-induced tumors.¹²¹ There is one report of possible intraspinal metastasis of a canine spinal cord neuroblastoma, which alternatively may have represented multifocal disease.¹²³

A report of two dogs with intramedullary spinal cord hemangioma included information on one dog treated with lomustine (no

specific details); this dog was euthanized 15 months after the initial diagnosis.¹²⁴

Three dogs treated for spinal lymphoma had a MST of 560 days (range = 560 to 1030 days).¹¹⁸ Two of the dogs were treated with RT and chemotherapy in addition to surgery.

There is limited information on results of treatment of spinal meningiomas in cats.^{107,125} In one report, a cat that underwent decompressive surgery for a spinal meningioma was doing well but was lost to follow-up 7 months postoperatively.¹⁰⁷ The MST for 16 cats that underwent surgery for spinal meningiomas was 518 days.¹²⁵

There are reports on spinal lymphoma in cats, although there is limited information on the results of treatment.^{107,126,127} Lymphoma is the most common tumor affecting the spinal cord in cats and often affects multiple regions of the spinal cord and brain.^{107,128} Treatment options include surgery, RT, and/or chemotherapy.

Spinal nerve sheath tumors treated surgically in seven dogs (with one dog also treated with radiation and chemotherapy) had a MST of 180 days (range of 21 to 300 days).¹¹⁸ One dog irradiated postoperatively for a spinal nerve sheath tumor was alive but lost to follow-up at 25 months.¹¹⁶ Spinal nerve sheath tumors in three cats treated surgically resulted in survival times of 67 days (failed to improve), 112 days, and 275 days (both had local recurrence).¹²⁵

Outcomes for other types of spinal cord tumors in cats are relatively unknown because of the limited number of cases, the tendency to euthanize due to a presumed poor prognosis, or a poor neurologic condition. A tetraparetic cat with a spinal cord glioma at cervical spinal cord segments C3-C4 was euthanized at the time of diagnosis.¹²⁹

Prognosis

The majority of dogs (17/21, 81%) with intraspinal meningiomas improve neurologically postoperatively.¹⁰⁹ Some reports provide histopathologic grade for meningiomas, although this is not done consistently.^{109,116,130} Based on relatively small numbers of dogs, there does not appear to be a correlation between grade and long-term outcome.¹⁰⁹ Perioperative complications are more commonly encountered for lesions in the cranial cervical region. It should be noted that outcome in dogs that decline neurologically after RT may represent either local tumor recurrence or late radiation damage to the spinal cord, and without necropsy examination it is difficult to discern the cause of neurologic impairment.¹¹⁶ Nine dogs (meningioma in six dogs, and one each nerve sheath tumor, ependymoma, and neuroepithelioma) treated postoperatively with RT had MSTs of 17 months (range 6.5 to 70 months).¹¹⁶ There is overall limited information on the results of treatment of spinal cord tumors in dogs or cats.

In cats with lymphoma of the spinal cord, it is important to note that in one study of 26 cats that had necropsy examination, lymphoma was identified in extraneural locations in 22 (84.6%), with the most common locations bone marrow, kidneys, liver, skeletal muscle, and spleen.¹⁰⁷ This is important in considering treatment options, as well as prognosis, in cats with spinal lymphoma. Six cats treated with a combination of vincristine, cyclophosphamide, and prednisone had a complete remission rate of 50%; median duration of remission was 14 weeks.¹²⁷ Another cat treated with decompressive surgery in combination with chemotherapy had a remission of 62 weeks.¹²⁷ In another report of four cats with spinal lymphoma, three were treated with L-asparaginase, vincristine, and prednisone after RT and one cat had surgery; three cats were euthanized or died within 20 weeks and one cat was alive at 13 months.¹²⁶

There are limited reports on the outcome of surgery in cats with spinal meningioma.^{125,131} Of five cats with spinal cord meningioma, one cat was alive 1400 days postoperatively, and the MST for the other four cats was 180 days (range = 30 to 600 days).¹³¹ A MST of 426 days (range 211 to 842 days) was reported for 16 cats treated surgically for spinal cord meningioma.¹²⁵ One cat with a spinal cord nerve sheath tumor treated surgically was alive 2190 days postoperatively.¹³¹

Comparative Aspects

In humans, primary spinal cord tumors are approximately 10 to 15 times less common than primary brain tumors, comprising 2% to 4% of all primary tumors of the CNS.¹³² Primary spinal tumors are typically intradural (intradural extramedullary and intramedullary); extradural spinal tumors in humans are most often metastatic.¹³²⁻¹³⁴ The most common intramedullary spinal tumors in people are ependymoma and low-grade astrocytoma. Ependymomas are typically readily resectable as are some astrocytomas. These tumors carry a fair-to-good prognosis, with surgical resection often combined with radiation and chemotherapy.¹³² The most common intradural extramedullary spinal tumors in people are meningiomas and nerve sheath tumors (schwannoma, neurofibroma, and malignant peripheral nerve sheath tumor [MPNST]); with the exception of MPNST, the prognosis for patients with these tumors is favorable with surgical removal.¹³²

Extradural spinal metastases generally portend a poor prognosis in humans. In addition to histologic features of the specific tumor, neurologic status at the time of diagnosis influences the likelihood of treatment response. Treatment of metastatic extradural spinal metastases in people typically involves RT and chemotherapy, with or without surgical intervention.^{133,134}

Peripheral Nerve Tumors

Incidence and Risk Factors

In general, peripheral nerve tumors (also called *peripheral nerve sheath tumors* [PNSTs]) are infrequently reported in dogs and rarely in cats. Peripheral nerve tumors arise in the cranial nerves, spinal nerve roots, and peripheral nerves. These tumors occur most commonly in middle-aged to older dogs of medium and large breeds. The most common cranial nerve affected is the trigeminal (CN V), and the most common spinal nerve roots affected are in the region of the brachial plexus (C6-T2).^{106,135-137} Tumors of the thoracic and lumbar spinal nerve roots also occur with some frequency and tend to cause signs of spinal cord compression as an early clinical sign of disease. Secondary peripheral nerve tumors (lymphoma, malignant sarcomas, hamartomas) can occasionally involve peripheral nerves as well.^{106,135}

Pathology

Peripheral nerve tumors occur mainly in the cranial, spinal, and associated peripheral nerves and less commonly in the autonomic nervous system (e.g., sympathetic nerves and ganglia). These tumors arise from Schwann cells, perineurial fibroblasts, or a combination of these two cell types.¹³⁵⁻¹³⁸ The traditional nomenclature for these neoplasms is confusing and of limited clinical use. These neoplasms have been classified as schwannomas, neurofibromas and neurofibrosarcomas. They have also been more broadly classified as benign peripheral nerve sheath tumors (BPNSTs) and malignant peripheral nerve sheath tumors (MPNSTs).¹³⁵⁻¹³⁸ This latter terminology is more useful from a clinical standpoint, especially considering that the majority of reported PNSTs in dogs are

histologically and biologically aggressive masses.^{138,139} PNSTs in cats are uncommon, but the proportion of benign tumor types may be higher than that reported for dogs.¹⁴⁰

History and Clinical Signs

As with brain and spinal tumors, the clinical signs of peripheral nerve tumors reflect the anatomic location of the tumor. The majority of reported canine peripheral nerve tumors involve the nerve roots and/or nerves of the brachial plexus region; in such cases, the typical scenario is a chronic progressive unilateral thoracic limb lameness that often eludes diagnosis for months. These dogs are often evaluated for possible orthopedic conditions prior to evaluation for a potential peripheral nerve tumor. A palpable mass may be found in the axillary region in some of these dogs (37% in one report),¹³⁷ and pain is usually easily elicited when palpating this region on the lame side. If the mass invades the vertebral canal and causes spinal cord compression, clinical signs of an asymmetric C6-T2 myelopathy may be apparent.^{106,135-138} Less commonly, a peripheral nerve tumor will involve the thoracolumbar region of the spine; in these cases, a more rapidly progressive development of a T3-L3 myelopathy is common.^{106,135} Peripheral nerve tumors also will occasionally affect nerve roots of the cauda equina, leading to clinical signs of progressive unilateral pelvic limb lameness (similar to the situation described for brachial plexus tumors).^{106,135}

As mentioned previously, the cranial nerve typically affected by peripheral nerve tumor is the trigeminal nerve (CN V). Dogs afflicted by CN V nerve sheath tumors typically develop unilateral atrophy of the muscles of mastication (e.g., temporalis and masseter muscles) over weeks to months. Other clinical features associated with CN V involvement may include decreased-to-absent facial sensation and Horner's syndrome. If the intracranial portion of CN V becomes compressive, clinical signs of brainstem compression (e.g., hemiparesis, dysphagia) may develop.^{135,141,142}

Diagnostic Techniques and Work-Up

Peripheral nerve tumors, especially those involving the brachial plexus region, can be challenging to diagnose. There should be a high index of suspicion for dogs with chronic thoracic limb lameness for which an obvious musculoskeletal cause cannot be found. The most useful imaging tool for diagnosing peripheral nerve tumors is MRI, whether the tumor involves a plexus, the spinal cord, or a cranial nerve. It is important in cases of brachial plexus nerve sheath tumors to image the axillary region, as well as the cervical spinal cord. Small brachial plexus tumors may be difficult to impossible to see on MR images; in some cases, subtle asymmetry in the suspected abnormal region is appreciated without an obvious mass being apparent.^{106,135,141-143} Some dogs may have axillary masses that are visible via ultrasonography, in which case a needle aspirate may be obtained.^{144,145} In the authors' opinion, CT is a poor second choice for imaging patients with suspected nerve sheath tumors. Myelography is unlikely to provide adequate information in such cases and should be avoided if possible. Electrodagnostic studies may be useful in cases of suspected nerve sheath tumor. Abnormal electromyographic (EMG) findings may distinguish atrophied muscles from a primary neurogenic or myopathic disorder from atrophy due to musculoskeletal disease. Nerve conduction studies performed on peripheral nerves of limbs may also indicate abnormalities. In cases for which a peripheral nerve tumor is highly suspected but diagnostic tests are all negative or equivocal, exploratory surgery (e.g., brachial plexus exploratory) may be an option.^{106,135,146}

Therapy

Surgery is the reported approach for the treatment of PNSTs in dogs and cats, although complete resection is difficult to achieve.^{137,140,141,147} Amputation may be necessary alone or in conjunction with laminectomy to accomplish tumor resection as high up as possible for nerve root tumors.^{137,147} Adjunctive RT is a postoperative option for residual microscopic disease, but there are only anecdotal reports regarding the success of treatment. Historically, dogs have been reportedly euthanized intraoperatively due to the recognition of the extent of disease during surgical exploration.¹⁴⁷ Preoperative cross-sectional imaging is recommended to define the extent of disease and for preplanning, particularly when considering combination therapy. Chemotherapy and/or RT is an option for lymphoma involving peripheral nerves.

Prognosis

The prognosis for PNSTs in dogs depends in part on tumor location and whether or not the tumor is amenable to surgery (amputation, laminectomy, or combination), with very limited information available on the results of adjunctive therapy.^{137,141,147,148} The prognosis for dogs treated surgically has been reported to be guarded to poor, although earlier detection after the onset of clinical signs may improve outcome.¹³⁷ Long-term survival has been reported (>18 months, >27 months, >42 months).^{141,147,148} Of seven dogs with trigeminal nerve sheath tumors that were not treated, the survival time was up to 21 months after onset of clinical signs, although several died or were euthanized at the time of presentation.¹⁴¹ Postoperative RT is feasible, but there is limited information on results of treatment. There is no information available on the use of chemotherapy for the treatment of PNSTs. Failure is typically due to neurologic signs associated with local recurrence. Although usually solitary, multicentric disease involving multiple cranial nerve roots has been reported.¹⁴⁹ Additionally, metastasis of PNSTs can occur but is relatively rare.¹⁴¹ The prognosis for cats is more favorable than what has been reported for dogs. In a report of 53 cats with 59 PNSTs, follow-up information was available for 45 cats that had surgical excision and/or amputation.¹⁴⁰ Of the 45 cats, 9 (20%) had local recurrence with histologically malignant tumors more likely to recur than histologically benign tumors, and 3 recurred locally twice. The median follow-up period was 21 months; 13 cats were euthanized at 2 weeks to 52 months (median 21.5 months; mean 22.6 months) after surgery.¹⁴⁰ Although PNSTs in cats can recur postoperatively, metastasis has not been documented to occur; euthanasia when disease related is due to local disease.¹⁴⁰

Comparative Aspects

People are affected by peripheral nerve tumors of the same cellular origins as those that affect dogs. However, the vast majority of peripheral nerve tumors in humans are biologically benign (most are schwannomas and neurofibromas). These tumors are usually readily excised and rarely recur.^{150,151} In comparison, most peripheral nerve tumors in dogs are aggressive and tend to recur following surgical excision.¹³⁵⁻¹³⁸

Ocular Tumors

31

PAUL E. MILLER AND RICHARD R. DUBIELZIG

Tumors of the eye, orbit, or adnexa can have devastating consequences for an animal's vision, appearance, and comfort and may be harbingers of potentially life-threatening disease elsewhere in the body. By virtue of their location, even benign ocular tumors may cause blindness and loss of the eye. Although these tumors reportedly affected only 0.87% of all dogs and 0.34% of all cats recorded in the Veterinary Medical Data Base (VMDB) over a 10-year period, their actual frequency is undoubtedly greater because many presumably benign ocular tumors are not histologically examined. Additional insights into the relative frequency of ocular tumors can also be gained by reviewing submissions over several decades to the large ophthalmic pathology database compiled by the Comparative Ocular Pathology Laboratory of Wisconsin (COPLOW) (Figure 31-1). This chapter describes the more common ocular tumors in small animals and also uses the database of the COPLOW laboratory to estimate the relative frequency of various ocular tumors.

Tumors of the Eyelids, Third Eyelid, Conjunctiva, and Ocular Surface

Incidence and Risk Factors

Benign adenomas and melanomas of the haired skin or eyelid margin make up 81% of eyelid tumors in the COPLOW database and tend to affect old dogs. One study suggests Boxers, collies, Weimaraners, cocker spaniels, and springer spaniels are at greater risk for eyelid neoplasia than the general hospital population,¹ and another study suggests that beagles, Siberian huskies, and English setters are at greater risk than mixed-breed dogs.² Canine juvenile histiocytomas affect the eyelid skin of young to middle-aged dogs^{1,2} but are relatively uncommon, comprising only 2% of eyelid biopsy samples submitted to COPLOW. Squamous cell carcinoma (SCC) comprises up to two-thirds of feline eyelid and third eyelid tumors and has a predilection for the lower eyelid and medial canthus of white cats.³ Ocular SCC is less frequent in dogs, but in both cats and dogs increased exposure to solar radiation, lack of adnexal pigmentation, and possibly chronic ocular surface irritation are believed to be predisposing factors (Figure 31-2).^{1,4,5}

Vascular endothelial cell tumors of the lateral limbus or the leading edge of the third eyelid constitute 27% of conjunctival tumors in dogs and tend to occur in the nonpigmented conjunctiva in Bassett hounds, springer spaniels and beagles. Melanomas often occur in dogs with a pigmented conjunctiva and are the most common malignant tumor of the canine conjunctiva, making up 17% of conjunctival tumor biopsies. Older (mean = 11 years), female, Weimaraner, and possibly German shepherd/large-breed

dogs may be predisposed to conjunctival melanomas.⁶ Melanomas also have a propensity for the nictitating membrane and superior palpebral conjunctiva.^{6,7} Ocular viral papillomas compose about 3% of conjunctival tumors and tend to occur in young dogs and are believed to have a papillomavirus etiology (perhaps canine oral papillomavirus).⁸ Canine squamous papilloma is a benign papillary tumor of unknown etiology and makes up 9% of conjunctival tumor biopsies. Reactive papilloma is seen secondary to other conditions such as meibomian tumors, but they make up 18% of conjunctival tumor biopsies. Corneal tumors have a predilection for the limbus.

Pathology and Natural Behavior

Sebaceous or meibomian gland adenomas and epitheliomas, papillomas, and melanomas comprise more than 85% of canine eyelid and conjunctival neoplasms, and a substantial majority of these tumors are histologically benign.^{1,2} Even histologically malignant eyelid tumors in dogs rarely metastasize, although they are more likely to be locally invasive and recur following surgery.^{1,2} In contrast, most feline eyelid and ocular surface tumors such as SCC are malignant.³

Viral papillomas tend to be well demarcated and superficial, minimally altering deeper tissues. Surgical manipulation has occasionally been associated with dispersal of papillomas throughout the ocular surface.^{9,10} Papillomas, like histiocytomas, often spontaneously resolve in young dogs, although they may persist in the older dog. SCC may also develop superficially, but following malignant transformation the preinvasive actinic plaque can invade deeper tissues. SCC may spread to regional lymph nodes late in the course of the disease and uncommonly distantly metastasize. SCC of the third eyelid may more readily invade the orbit than corneal or eyelid SCC.

Adenocarcinomas of the gland of the third eyelid constitute 13% of conjunctival tumors in dogs. They are variable in morphology and often show moderate infiltrative growth.¹¹ They may mimic prolapse of the gland of the nictitans ("cherry eye") by appearing as localized, firm, smooth, pink swellings on the posterior surface of the nictitans, but a key differentiating feature is their occurrence in much older dogs (10 to 16 years). Although excision of the grossly visible tumor may initially appear adequate, recurrence is common if the entire gland is not removed, and metastasis, especially to the regional lymph nodes and orbit, is possible.^{11,12}

The natural behavior of conjunctival vascular, melanocytic, and mast cell tumors is poorly understood, in part because they are uncommon. Conjunctival hemangiomas and hemangiosarcomas tend to remain relatively superficial but may recur following simple excision.¹³⁻¹⁷ Hemangiosarcomas may exhibit a more aggressive course and a primary ocular hemangiosarcoma must be differentiated from a metastatic lesion. However, metastasis of primary

conjunctival vascular tumors, even when classified as hemangiosarcomas, appears to be rare.¹³⁻¹⁷

Feline conjunctival melanomas originate on the bulbar conjunctiva and invade the eyelid.^{18,19} Melanoma of the conjunctiva in dogs is most often morphologically malignant, but metastatic disease is not common. As in cats, canine conjunctival melanomas have been reported to recur locally following surgical excision in 55% of cases,

Anatomic Distribution of Canine Primary Ocular Neoplasms (n = 6112)

• **FIGURE 31-1** The distribution of canine (A) and feline (B) ocular tumors submitted to the Comparative Ocular Pathology Laboratory of Wisconsin.

and at least 17% of the dogs experienced orbital invasion or spread to the regional lymph nodes or lungs.⁶ Melanomas originating from the palpebral conjunctiva may have greater metastatic potential.⁶ Mitotic index, cell type, and degree of pigmentation are not useful predictors of malignancy for canine conjunctival melanomas.⁶ Subconjunctival mast cell tumors make up 4% of conjunctival tumors, but their natural history is poorly understood in part because they are uncommon. Nevertheless, they have been suggested to have a relatively benign course in dogs.²⁰

History and Clinical Signs

Vascular tumors are often focal, raised, soft, red masses with visible feeder vessels arising from the surface of the conjunctiva or third eyelid.¹³⁻¹⁷ SCC of the eyelid, third eyelid, or ocular surface may appear as a focally thickened, roughened, and usually pink-to-red lesion in older animals or, more commonly, as an ulcerated lesion with a protracted course.³⁻⁵ In contrast, papillomas in young dogs appear verrucous and usually progress rapidly over weeks to a few months. Nonneoplastic conditions such as nodular granulomatous episcleritis can be mistaken for neoplasia.

In addition to a mass lesion, other clinical signs of eyelid or ocular surface tumors may include epiphora, conjunctival vascular injection, mucopurulent ocular discharge, protrusion of the third eyelid, conjunctival/corneal roughening or ulceration, and corneal neovascularization or pigmentation. Occasionally, palpebral conjunctival masses protrude only when their bulk no longer can be accommodated by the space between the eyelid and globe, and very advanced tumors may create exophthalmia or enophthalmia if the orbit is invaded. Large tumors and sebaceous adenomas often have a substantial inflammatory component and may be secondarily infected. Mesenchymal hamartoma appears to have a predisposition for the skin of lateral canthus.²¹

Diagnostic Techniques and Work-Up

In addition to fluorescein staining and examination of the ocular surface with a cobalt filter or black light, the extent of involvement of the bulbar and palpebral conjunctiva should be determined by everting the eyelid (and third eyelid if affected). Careful palpation of the lesion by inserting a lubricated finger in the conjunctival cul-de-sac can be invaluable for determining the full extent of the tumor and whether bony involvement has occurred. Nasolacrimal

• **FIGURE 31-2** A, Squamous cell carcinoma affecting the lower eyelids of a Boxer. B, Same dog after cryosurgical ablation of the tumor. Lid function is spared.

lavage and possibly positive contrast dacryocystorhinography may help characterize medial canthal masses. In general, small eyelid and ocular surface tumors are best diagnosed and treated by excisional biopsy. Fine-needle aspiration (FNA) or incisional biopsies of larger tumors aid in determining prognosis and planning definitive therapy. Occasionally, orbital ultrasound, skull radiographs, computed tomography (CT), magnetic resonance imaging (MRI), regional lymph node cytology, and thoracic radiographs are required to localize or clinically stage potentially malignant tumors such as SCC, mast cell tumors, adenocarcinomas of the third eyelid, and conjunctival melanomas.

Therapy

Specific therapy varies with the type of tumor; its location, size, and extent; whether the eye still has useful vision; the animal's expected lifespan; the degree of discomfort the mass is creating; and the owner's financial limitations. All eyelid tumors, whether benign or malignant, have the potential to affect vision or ocular comfort. Indications for tumor removal include any eyelid tumor in a cat, rapid growth, ocular surface irritation, impaired eyelid function, owner concern, or an unappealing appearance. In young dogs, observation of nonirritating papillomas or histiocytomas, even if quite large, may be appropriate as spontaneous regression is common.

Tumors involving less than one-fourth to one-third of the length of the eyelid are best treated by a V-plasty (wedge) or four-sided excision.²² The latter technique affords superior apposition of the eyelid margins and wound stability, especially in tumors approaching the one-fourth to one-third limit, because the initial incision is made perpendicular to the eyelid margin rather than obliquely. In general, only one-third to one-fourth of the eyelid in dogs and one-fourth of the eyelid in cats can be removed with these techniques. Antibiotic or antiinflammatory therapy may reduce the size of large tumors that are infected or inflamed so that a wedge or four-sided excision becomes possible. Electrosurgical excision should be avoided because it may result in substantial scarring of the eyelids. Carbon dioxide (CO₂) laser ablation may be appropriate for some tumors.

Tumors greater than one-fourth to one-third of the eyelid typically require more advanced reconstructive blepharoplasty or utilization of other therapeutic modalities. Some tumors may be responsive to systemic chemotherapy (e.g., lymphoma, mast cell tumors), local infiltration with chemotherapeutic agents such as cisplatin (e.g., SCC),²³ and/or local radiation therapy (RT; e.g., SCC). In some cases, these modalities will completely eliminate the tumor or shrink it to the point in which a less extensive surgical procedure can be performed. Reconstructive blepharoplasty, however, is the procedure of choice if surgical cure is a possibility and these other modalities have failed or are unlikely to substantially impact the tumor or if the nature of the tumor indicates extensive margins are required.

Cryosurgery is an attractive alternative to extensive blepharoplasty and has been reported to be effective in several canine eyelid tumor types (see Figure 31-2, see also Chapter 10).²⁴ It is quick, less technically demanding than reconstructive blepharoplasty, and usually permits preservation of the nasolacrimal puncta and canaliculus. In many old or debilitated patients, cryosurgery can be accomplished with only sedation or local/topical anesthesia. Following pretreatment with dexamethasone (0.1 mg/kg intravenous [IV]), the mass is isolated with a chalazion forceps (if possible) and debulked flush with the lid margin. Using liquid nitrogen and a closed probe that approximates the diameter of the mass as much

as possible, a double freeze-thaw is performed so that the iceball extends 3 to 5 mm beyond the visible margins of the mass. Iceballs should overlap in large tumors. Freezing may be repeated a second or third time if complete regression is not achieved following the first session. Substantial postoperative swelling and usually transient depigmentation of the frozen tissue are to be expected.

Tumors involving the conjunctiva and third eyelid (especially conjunctival hemangiosarcomas, melanomas, and nictitans adenocarcinomas) are most effectively treated by wide surgical excision—perhaps to the point of exenterating the orbit. If the globe is to be spared, however, excision of the entire nictitans should not be taken lightly because undesirable sequelae such as ocular drying and chronic keratitis frequently result. Bulbar conjunctival tumors move freely and, if small, are generally amenable to excision under only topical anesthesia and perhaps sedation. Cryosurgery may permit the nictitans to be spared in the cases of papillomas and early SCC, or it can be used as an adjunct to excision in advanced canine conjunctival melanomas and SCC.^{6,24}

Superficial keratectomy/sclerectomy is preferred for many corneal and scleral tumors, although some tumors require a full-thickness resection of the cornea or sclera. In the latter case, corneal or scleral allografts or autologous tissue grafts should be used to maintain ocular structural integrity. Limbal SCC and epibulbar melanoma may also be amenable to cryosurgery, although the iceball should be carefully monitored to avoid unnecessary freezing of intraocular structures.

Prognosis

The prognosis for most canine primary eyelid tumors is excellent, whether treated by excision or cryosurgery. Metastasis is rare, even in histologically malignant primary lid tumors, and recurrence rates are low (approximately 10% to 15%).² New primary eyelid tumors are not uncommon and must be distinguished from recurrence. Because most eyelid tumors in cats are malignant, the prognosis is not as good as that for dogs, but it is unclear how prognosis correlates with the histologic features. Conjunctival melanomas and nictitans adenocarcinomas frequently recur following partial excision of the nictitans, even if all of the clinically visible tumor was removed.⁶ Conjunctival hemangiosarcomas appear to have a good prognosis because total excision may be curative, although recurrence and loss of the eye is still possible.¹³⁻¹⁷

Limbal (Epibulbar) Melanomas

Limbal melanomas are typically benign, slightly raised, heavily pigmented masses originating from melanocytes in the sclera or subconjunctival connective tissue (Figure 31-3).²⁵⁻³⁰ They comprise 3.5% of all canine ocular tumors and 1% of feline ocular tumor submissions to COPLOW. The majority of these slow-growing tumors originate in the superior limbal region, suggesting exposure to solar radiation may be a risk factor.¹³ Affected dogs average 5 to 6 years old (cats 8+ years), and a female sex and German shepherd, golden retriever and Labrador retriever breed predilection has been inconsistently reported.²⁵⁻²⁹ Confirmed metastasis has not been reported in dogs or cats and mitotic figures are rarely encountered; although in one study, two of four cats also had feline leukemia virus (FeLV)-associated lymphoma or leukemia, and a third cat had a second intraocular pigmented mass unassociated with the limbal tumor.²⁹ Lightly pigmented spindle cells capable of division are seen histologically, but the dominant cell is presumably a hypermature spindle cell that is large, round, pigment laden, and benign.²⁶ These masses are often only incidentally noted and the clinical signs

• **FIGURE 31-3** Epibulbar melanomas typically originate from the superior limbal region of the globe.

are typically minimal, although local corneal invasion, epiphora, and mild conjunctival irritation may be seen.^{27,28} Differential diagnoses include conjunctival melanoma, invasive uveal melanoma, metastatic melanoma, and staphyloma or coloboma. Gonioscopy aids in differentiating invasive intraocular tumors from limbal melanomas.

Therapy should be considered if the tumor has invaded the eye or if growth is rapid. Given its benign nature and usually slow growth rate (imperceptible growth over 18 months has been described), observation alone may be appropriate in older dogs. If intervention is required, lamellar keratectomy/sclerectomy with graft placement is often curative.³¹ Beta-irradiation and cryosurgery have been used as adjuncts to surgery.^{31,32} Cryosurgery alone or laser photocoagulation³⁰ has also been described as effective means of treatment. Regrowth following local surgical excision occurs in approximately 30% of patients, but 2 to 3 years may pass before the anterior chamber is invaded and enucleation is required.²⁶⁻²⁸ The addition of adjunctive therapy such as cryotherapy or beta-irradiation substantially reduces the risk of recurrence following local excision.^{31,32} Enucleation is curative and indicated if painful intraocular disease is present.²⁶

Primary Ocular Tumors

Canine Anterior Uveal Melanomas

Incidence and Risk Factors

In the Armed Forces Institute of Pathology collection of tumors from the canine eye, orbit, and adnexa, intraocular melanomas constitute 12%, other primary intraocular tumors 14%, and metastatic intraocular neoplasms 9%.³³ In the COPLOW archive, uveal melanocytic tumors make up 27% of all ocular tumor submissions. Any age is at risk, but most affected dogs are older than 7 years of age, and breed or sex predilections are inconsistent.²⁶

Pathology and Natural Behavior

Approximately 78% of canine intraocular melanomas are benign, and 93% arise from the iris or ciliary body (Figure 31-4).^{26,27,34} The most clinically useful classification scheme classifies these tumors simply as melanocytoma (benign) and melanoma (potentially malignant) based on nuclear features of the tumor cells—with

• **FIGURE 31-4** Most anterior uveal melanomas originate from the iris or ciliary body and are benign.

mitotic rate being the most important.²⁶ Benign tumors have fewer than 2 mitotic figures/10 HPF (mitotic index), and malignant tumors demonstrate nuclear pleomorphism and a mitotic index of at least 4 and often more than 30. Destruction of the eye is not by itself sufficient for a diagnosis of malignancy.²⁶ The overall rate of metastasis of intraocular melanomas is approximately 4%³⁴ and usually occurs via the hematogenous route. Local spread along ocular vessels and nerves or via direct penetration of the sclera or cornea also occurs. Benign tumors tend to be more darkly pigmented than malignant tumors.²⁶

Circumscribed, nevus-like pigmented iridal growths have been described in young dogs (7 months to 2 years old).²⁷ The natural history of these lesions is variable because enlargement may not occur over several years.^{27,33} Some, however, are capable of rapid growth, but to date all are clinically and histologically benign.

Ocular melanosis of Cairn terriers resembles feline diffuse iris melanoma in some respects.³⁵ This disorder is probably an autosomal-dominant condition with a variable age of onset and rate of progression. It results in a thickening and pigmentation of the iris, release of pigment into the aqueous, pigment deposition in the sclera/episclera, and to a lesser extent posterior segment pigment deposition. Secondary glaucoma is common, and overt uveal melanocytic neoplasia occurs in a small percentage of dogs.³⁵

History and Clinical Signs

Common presentations of intraocular tumors include a visible intraocular or scleral mass, glaucoma, hyphema, anterior uveitis, or extrabulbar spread, or they can be an incidental finding during an ophthalmic examination.^{26,34} Because glaucoma or hyphema are often the only overtly visible clinical signs,^{26,34} intraocular neoplasia should always be considered in animals with hyphema, glaucoma, or both when there is no history of trauma or coagulopathy. Small masses frequently create few symptoms other than pupillary distortion. Pigmentation is variable and not a reliable indicator of tumor type.

Diagnostic Techniques and Work-Up

Usually, the clinical or ultrasonographic appearance (if the media are opaque) is strongly suggestive of intraocular neoplasia, although it may be difficult to arrive at a definitive diagnosis without

invading the eye or removing it because organizing blood clots are not always distinguishable from neoplastic mass lesions. Because most anterior uveal brown or black masses are cystic and not neoplastic, transillumination should be attempted before more invasive procedures. Uveal cysts typically permit bright light to pass through them, are roughly spherical, and may be attached to the ciliary body or free-floating in the anterior chamber. Once suspected, most primary canine intraocular tumors are observed for progression, although occasionally FNA (with its risks of inflammation, infection, and hemorrhage) or attempts at intraocular resection or enucleation are used for diagnostic purposes. The possibility of metastasis from another primary site (i.e., oral cavity or nail bed) to the eye or from the eye to other organs should be eliminated.

Therapy

Canine primary intraocular tumors are generally carefully observed. Digital photographs are a valuable aid in assessing progression. Enucleation is advised if there is concern about malignancy or if complications such as intractable uveitis or secondary glaucoma occur.³⁶ In the COPLOW collection, 14% of canine globes with glaucoma that are removed also had melanoma. The low risk of metastasis and unproved efficacy of enucleation at preventing metastasis in the few malignant tumors that have been reported, however, make it difficult to automatically advise enucleation of normotensive, noninflamed, visual eyes.²⁶ Isolated primary masses involving only the iris or a portion of the ciliary body may be amenable to local resection by sector iridectomy/cyclectomy in order to preserve the eye and vision.^{27,33} These intraocular procedures, however, require an accomplished ophthalmic surgeon and often have unsatisfactory long-term results. Transscleral and transcorneal Nd:YAG or diode laser therapy has induced remission in some small- to moderate-sized primary intraocular tumors.^{36,37} Specialized goniolens may also allow laser treatment of masses that have invaded into the iridocorneal angle. Although the results were variable, perhaps because these tumors varied histologically in nature, laser therapy holds promise for the palliation or potential cure of a number of intraocular tumor types while also preserving vision. Metastasis was not observed following this procedure, although this obviously remains a risk when the tumor is malignant.³⁶

Prognosis

Although the data in most studies are heavily “censored,” the prognosis for histologically benign melanomas appears to be excellent. Enucleation is curative, but attempts at local excision or laser photocoagulation may be only palliative, especially if the ciliary body or trabecular meshwork is involved. The presence of black, nonsolid material within the orbit following the enucleation of benign melanomas with scleral invasion apparently does not affect prognosis because these cells appear incapable of continued growth.²⁷ In one study, approximately 25% of histologically malignant melanomas demonstrated metastasis, typically within 3 months of enucleation, and most dogs with metastasis are euthanatized within 6 months of enucleation.²⁶ This surprisingly poor prognosis has not been the experience of cases followed recently in the COPLOW data set, and in a larger study, dogs with tumors classified as malignant were reported to have only a somewhat decreased survival time compared to dogs with melanocytoma and dogs from a control population.³⁸

Choroidal Melanomas

Choroidal melanomas are rare intraocular melanocytic tumors, comprising only 4% to 7% of canine uveal melanomas, with no clear

breed or sex predisposition.³⁹ Middle-aged (6 to 7 years), medium- to large-breed dogs predominate.³⁹ Generally, these tumors are well-delineated, raised subretinal pigmented masses with tapering margins, bulging centers, and a propensity for the peripapillary region and optic nerve.^{39,40} In some cases, the tumor may remain virtually static for many years, whereas others exhibit infiltration into the overlying retina, through the sclera, up the optic nerve, and into the orbit.³⁹ Nuclear anaplasia is minimal and generally mitotic figures are absent.⁴⁰ Despite these benign cytologic features, metastasis has been described in one dog 21 months after exenteration, and follow-up in most studies is incomplete.⁴¹ In general, however, these tumors appear to be benign in the vast majority of dogs. Most dogs with tumors involving a limited portion of the choroid are asymptomatic, and the mass is noted incidentally on ophthalmoscopy. Larger tumors frequently present with chronic uveitis, secondary glaucoma, retinal detachment, intraocular hemorrhage, or blindness.^{39,40} Extension into the orbit can occur, and documentation of this is important in planning for enucleation surgery. Ocular ultrasonography may demonstrate mass lesions if anterior segment changes or retinal detachment obscures an underlying mass. Therapy usually consists of enucleation once progression has been documented or if the eye is painful. Diode laser ablation may offer an alternative to enucleation if the lesion is small and does not involve the optic nerve. Optic nerve or scleral invasion may warrant a more cautious prognosis.

Feline Primary Intraocular Melanomas (Feline Diffuse Iris Melanoma)

Incidence and Risk Factors

Anterior uveal melanomas are the most common primary intraocular tumor in cats (Figure 31-5).⁴² They account for 49% of all neoplastic submissions to the COPLOW in cats. There appears to be no breed or sex predisposition, and most cats are more than 9 years of age at the time of diagnosis,^{42,43} although the prodromal period for many of these tumors may be quite long.

Pathology and Natural Behavior

In the malignant form of uveal melanoma, the rate of metastasis (frequently to the liver and lungs) has been reported to vary from

• **FIGURE 31-5** Diffuse iris melanomas may first appear as multifocal to diffuse pigmentary changes, as seen in the coalescing darker regions of the iris in this cat.

55% to 66% or higher.⁴²⁻⁴⁵ Iridal hyperpigmentation, however, frequently takes months to years to progress to the extent to which the eye must be enucleated, and an additional 1 to 3 years after enucleation are required before metastatic disease may become evident.^{42,43,45,46} No single morphologic feature is predictive of outcome, but metastasis has been linked to a greater mitotic index, larger tumors, and extension through the iris into the ciliary body stroma and involvement of the scleral venous plexus.^{42,43}

Most ophthalmologists have noted unilateral or occasionally bilateral slowly progressive iridal pigmentary changes (especially in older orange cats) over many years to a decade or more that apparently do not lead to disease beyond the pigmentation, although eventual removal of these eyes can show melanoma. It is possible in some cats that these initially benign-appearing accumulations of small, angular pigmented cells on the anterior iridal surface undergo transformation to the larger, rounded cells typical of the potentially malignant diffuse iris melanoma. Of concern to the clinician waiting to document progression before advising treatment, however, is that malignant transformation is not readily observable clinically and that these cells, once transformed, appear to be capable of quickly dropping off into the anterior chamber and entering the drainage apparatus and vasculature.⁴³

History, Clinical Signs, Diagnostic Techniques, and Work-Up

Slowly progressive, diffuse iridal hyperpigmentation is the most common clinical sign, although occasionally a pigmented iridal nodule or amelanotic mass is seen. Secondary glaucoma will eventually occur, and the diffuse form may be mistaken for chronic anterior uveitis with iridal hyperpigmentation.

The diagnosis of melanoma, generally made clinically, requires demonstration of progression and iridal thickening or irregularity of the iris surface or pupil. The prognostic and diagnostic value of fine-needle aspirates of the iridal surface or iridal biopsies is unclear and worthy of further study.

Therapy

The treatment of feline uveal melanomas is controversial. Ideally, enucleation would be delayed until just *prior* to malignant transformation, invasion into other ocular structures, secondary glaucoma, or metastasis. Such precise timing, however, is seldom attainable in a clinical setting, and enucleation is commonly performed if iridal pigment changes have been demonstrated to progressively increase to the point that virtually the entire iridal surface is involved, pigmented cells are present in the trabecular meshwork, the pupil is distorted (indicating iridal invasion), ciliary body or scleral invasion is threatened, uveitis is present, or glaucoma is impending. Although it would seem logical that early enucleation would optimize survival, this is unproved. In one study, enucleation has been shown to markedly enhance the rate of metastasis in cats with feline sarcoma virus–induced uveal melanomas.⁴⁷ The applicability of this experimental model to spontaneous disease, however, is unclear and neither feline sarcoma virus nor FeLV were found in a study of 10 eyes with spontaneous diffuse iris melanoma.⁴⁸ Recently, some ophthalmologists have attempted to ablate small, focal, hyperpigmented foci on the iris of cats with a diode laser, thereby preserving vision and the eye. The long-term success rate and side effects of this procedure, however, are not known. Finally, most slowly progressing lesions are simply monitored, ideally by comparison to baseline photographs. This option is particularly suitable for older cats with other diseases that limit their expected lifespan. In many cats, progression may be so slow as to permit the patient to be

followed for many years to a decade or more without apparent metastasis.

Prognosis

In one study, the metastatic potential of feline uveal melanomas has been correlated with the extent of ocular involvement seen histologically.⁴³ Because the tumor is relatively slow-growing, however, the period until metastatic disease becomes apparent may be measured in years, and even then substantial additional time may be required before the metastasis is life threatening. Cats with tumors confined to iris stroma and trabecular meshwork at the time of enucleation have survival times comparable to those of age-matched controls. Enucleation after the tumor has invaded into the ciliary body but not the sclera warrants a poorer prognosis, but median survival time (MST) is still approximately 5 years.⁴³ Enucleation after the tumor has invaded into the ciliary body and the sclera merits an even poorer prognosis, with a MST of approximately 1.5 years.⁴³ MST is also reduced if secondary glaucoma has occurred.⁴³

Feline Ocular Posttraumatic Sarcoma

Sarcomas following ocular trauma, although uncommon, are second only to melanomas in frequency as a primary ocular tumor of cats.⁴⁹⁻⁵² In the COPLOW collection, 8% of feline ocular tumors are posttraumatic sarcoma. These tumors are subdivided into three morphologic subtypes: spindle cell sarcoma (the most common), round cell sarcoma, and osteosarcoma/chondrosarcoma. All three have similar histories leading up to tumor presentation. Cats that are 7 to 15 years of age are most commonly affected, the latency period following trauma averages 5 years,⁵⁰ and 67% of affected cats are males or neutered males. Damage to the lens and chronic uveitis may be risk factors.⁴⁹⁻⁵¹ Because of the risk of posttraumatic sarcoma, many clinicians are cautious about cataract surgery or the use of an intrascleral prosthesis in cats. The cell of origin in the three subtypes is not definitively known, but it is likely that the released lens epithelial cell is the cell of origin in the spindle cell variant and the round cell variant likely represents a form of lymphoma.⁵³ Chronic inflammation may support neoplastic transformation of a pluripotent cell.⁴⁹⁻⁵¹ These tumors, often within the same eye, exhibit a spectrum of changes ranging from granulation tissue to fibrosarcoma, osteosarcoma, and anaplastic spindle cell sarcoma.^{50,51} All of these tumors tend to circumferentially line the choroid and quickly infiltrate the retina and optic nerve.^{50,51} The round cell variant tends to infiltrate the retina early.^{53,54} White or pinkish discoloration of the affected eye or change in the shape or consistency of the globe are the most common presenting signs. Skull radiographs may demonstrate bone involvement or metallic foreign bodies.⁵²

Because this tumor is uncommon, many ophthalmologists will not remove a comfortable phthisical feline eye unless it changes appearance. The advanced stage at which many of these tumors are first identified, however, and the propensity for early optic nerve involvement indicate that enucleation at this point may be only palliative and not prolong life. This has led some authors to advocate prophylactic enucleation of phthisical feline eyes or of feline eyes that are blind and have been severely traumatized or are chronically inflamed.^{49,52} Further support for this approach comes from the observation that approximately 8% of globes removed prophylactically in the COPLOW collection already have tumors. Extension beyond the sclera or into the optic nerve may occur and are poor prognostic indicators, further supporting the concept of early enucleation. As much of the optic nerve as possible should be

removed during enucleation for confirmed or suspected ocular sarcoma so that the extent of infiltrative disease and prognosis may be accurately determined. There is reason to believe that the prognosis is considerably better if enucleation is performed before the tumor invades the optic nerve or extends beyond the sclera.⁵⁵ To date, there have been no reports of treatment by radiation or chemotherapy.

Extraocular extension is common, as is recurrence following orbital exenteration.^{49,52} Continued growth up the remainder of the optic nerve into the chiasm and brain, with vision loss or other neurologic signs, involvement of regional lymph nodes, and distant metastasis, has been reported.^{40,50} The vast majority of animals die from local invasion and recurrence, typically within several months of enucleation.^{49,52}

Spindle Cell Tumors of Blue-Eyed Dogs

Dogs with a blue, or partially blue, iris appear to be at risk of developing a spindle cell sarcoma in the uvea.⁵⁶ These tumors usually involve the iris but can originate or extend into the ciliary body, choroid, and even the vitreous. Breeds that commonly have blue irides are more likely to develop an iridal spindle cell sarcoma, but any dog with any blue in its iris appears to be at risk. The origin of these tumors is thought to be Schwann cells of nonmyelinated peripheral nerves.⁵⁷ The cells stain positive with glial fibrillary acidic protein (GFAP), as do the Schwann cells of nonmyelinating nerves. In a case series involving 11 dogs, more than half of the tumors were not clinically recognized and the diagnosis of neoplasia was not made until histopathology was performed. Metastatic disease has not been seen; however, local recurrence within the scleral shell was seen in a dog that had been treated by evisceration and placement of an intrascleral prosthesis.⁵⁶

Iridociliary Epithelial Tumors

Primary iridociliary epithelial tumors (ciliary body adenomas, adenocarcinomas, pleomorphic adenocarcinoma, and less commonly, medulloepitheliomas) are infrequent in dogs and rare in cats.⁵⁸ The two main histologic forms that have been described are papillary (57% of cases in one study) and solid tumors (43%).⁵⁸ In the authors' experience, these tumors often appear nonpigmented clinically, but histologically at least some pigmented cells are present in approximately one-half of cases. Pigmented tumors of the ciliary body may be grossly indistinguishable from anterior uveal melanomas. Middle-aged to older dogs are the most commonly affected and golden and Labrador retrievers may be predisposed, for they comprised 27% of dogs with iridociliary epithelial tumors in one survey.⁵⁸ Most of these tumors appear to be benign, fairly well-delineated, sometimes pedunculated, slow-growing masses that originate in the pars plicata of the ciliary body or the iris epithelium.^{58,59} Although approximately 60% invade the uveal tract, only 21% invade the sclera.⁵⁸ Tumors that invade the sclera are typically classified as adenocarcinomas and have anaplastic features, but metastasis is uncommon and occurs late in the course of the disease, if at all.⁵⁸⁻⁶¹ A small series of truly malignant pleomorphic adenocarcinomas with potentially fatal metastasis has been described in dogs.⁶² Dogs affected with this rare form usually have long-standing disease thought to be inflammatory or traumatic, and 4 of 25 cases have a prior history of an intravitreal gentamicin injection for the treatment of glaucoma.⁶²

Clinical signs include a retro-iridal mass that may displace the iris or lens by expansive growth, and if the tumor is large, secondary glaucoma, ocular pain, and intraocular hemorrhage may be noted.⁶⁰ The diagnostic work-up and differential diagnosis are similar to

that of anterior uveal melanomas. Given the high frequency of ciliary body cysts in some predisposed breeds (especially the golden retriever), it is essential to differentiate ciliary body tumors from a benign cystic lesion prior to enucleation. Cystic lesions, which rarely require any intervention, are usually seen as lightly pigmented, ovoid, retro-iridal masses that can be shown to be hollow by transillumination or hypoechoic by ultrasonography. Early enucleation of ciliary body tumors has been recommended, although benign adenomas may remain static for years, making enucleation controversial for small tumors unassociated with secondary ocular disease. Local intraocular resection or laser photocoagulation may permit vision and ocular comfort to be maintained.³⁶ Systemic administration of 5-fluorouracil (5-FU) has been described as an adjunct to local resection of ciliary body tumors, but the efficacy of this therapy is unknown.⁶¹

Secondary Uveal Neoplasms

Numerous malignant tumors, especially adenocarcinomas, have been reported to metastasize to the highly vascular uveal tract. Lymphoma is the most common secondary intraocular tumor in the dog and cat, and ocular lesions are present in approximately one-third of dogs with the disease.^{60,63-65} Common presentations include severe uveitis, glaucoma, retinal hemorrhages, hyphema, conjunctivitis, and keratitis characterized by corneal infiltrates, edema, vascularization, and intrastromal hemorrhage.^{60,63-65} Exophthalmia resulting from orbital invasion by the tumor and vision loss due to optic nerve or central nervous system (CNS) disease may also be present. Posterior segment lesions may include retinal vascular tortuosity, papilledema, multiple intraretinal hemorrhages, and retinal detachment. In one study, the lifespan of dogs with intraocular lymphoma was only 60% to 70% as long as dogs without ocular involvement when treated with cyclophosphamide, vincristine, and prednisolone (COP), or with doxorubicin.⁶⁴ Topical or systemic corticosteroid therapy or enucleation is palliative. (See Chapter 32 for the definitive therapy of lymphoma.) Ophthalmic disease, especially intraocular or retinal hemorrhage, may also be the presenting complaint in animals with multiple myeloma.⁶⁶

Tumors of the Orbit and Optic Nerve

Incidence and Risk Factors

Risk factors other than middle to old age, possibly large-breed dogs,⁶⁷ and possibly sex (female dogs, male cats) have not been described.⁶⁷⁻⁷⁵ Tumors involving the optic nerve are rare, although secondary invasion occurs in feline posttraumatic sarcomas, feline SCC, and canine choroidal melanomas. Canine orbital meningioma is the most common tumor of the optic nerve but comprises only 3% of all meningiomas in dogs (Figure 31-6).^{71,73} Lobular adenomas of unspecified glandular origin have been recently reported to involve the anterior orbit in dogs.⁷²

Pathology and Natural Behavior

Orbital neoplasia may be primary (most common in dogs), secondary to extension of adjacent tumors into the orbit (most common in cats), or the result of distant metastasis. In cats and dogs, more than 90% of orbital tumors are malignant, and regional infiltration (including into the CNS) or distant metastasis is common.⁶⁷⁻⁷⁰ At least 26 types of orbital tumors, roughly equally divided among connective tissue, bone, epithelial, and hemolymphatic origins, have been reported in dogs.⁷⁰ Osteosarcomas, mast cell tumors, reticulum cell sarcomas, fibrosarcomas, and neurofibrosarcomas are the most common canine primary orbital tumors.⁷⁰ More than two-thirds of feline orbital tumors are epithelial in origin, with SCC

• **FIGURE 31-6** Orbital meningioma in a dog.

being the most common,⁶⁹ but at least 15 other tumor types have been described in cats.

Canine orbital meningiomas exhibit predictable biologic behavior. They are slowly progressive and rarely metastasize; they may be osteolytic and invade surrounding tissues, including the CNS via the optic foramen.^{70,72,73} Primary optic nerve tumors in dogs include glioma and meningioma.^{70,71,73,74} Retinal and optic nerve gliomas may be considered as differential diagnoses of intraocular and orbital masses. The metastatic potential of gliomas appears to be low, but ascending invasion into the ventral aspect of the brain is possible.⁷⁵ Lobular orbital adenomas are made up of multiple friable lobules in the anterior orbit, making complete surgical excision difficult.⁷²

History and Clinical Signs

Slowly progressive exophthalmia, absent to minimal pain on opening the mouth, difficulty in retropulsing the eye, and deviation of the globe typify orbital neoplasia. Sudden erosion of nasal or sinus tumors into the orbit occasionally results in acute exophthalmia and substantial orbital pain. Enophthalmia may occur if the mass is anterior to the equator of the globe. Lobular adenomas may present as soft, raised, subconjunctival masses and create either enophthalmia or exophthalmia. Chronic epiphora secondary to obstruction of the nasolacrimal duct, exposure keratoconjunctivitis, palpable orbital masses following enucleation, or unexplained orbital pain also suggests orbital neoplasia.⁶⁷⁻⁷⁰ Measurement of corneal diameters and intraocular pressure (IOP) aids in differentiating glaucomatous ocular enlargement (large corneal diameter, high IOP) from exophthalmia (normal corneal diameter and IOP).

Optic nerve lesions may result in unilateral or bilateral blindness (the latter if the optic chiasm is affected), optic nerve head pallor, papilledema, or marked protrusion and congestion of the optic disc on ophthalmoscopy. A relatively mild degree of exophthalmia with vision loss suggests optic nerve neoplasia because tumors of other orbital tissues typically cause profound exophthalmos before visual loss. Tumors affecting the retrobulbar, intracanalicular, or chiasmal

• **FIGURE 31-7** CT (dorsal view) provides detailed information about the location and extent of orbital tumors, as in this 17-year-old cat with orbital osteosarcoma.

portions of the optic nerve may not result in exophthalmia or a visible change in the optic nerve head.

Diagnostic Techniques and Work-Up

It is essential to differentiate nonneoplastic orbital inflammatory diseases (granulomas, cellulitis, abscesses, myositis of the extraocular and masticatory muscles) from neoplasia. Animals with inflammatory disease typically exhibit significant pain on opening the mouth. The location of an orbital mass can usually be determined by careful physical examination, including retropulsion of the globe, oral examination caudal to the last molar, and determination of the direction of malposition of the eye.

In addition to physical examination, cytology of regional lymph nodes, orbital ultrasound, and skull and thoracic radiographs should be performed. In one study of cats with orbital neoplasia, 59% had radiographic signs of orbital bone lesions and 15% had evidence of metastasis on thoracic radiographs.⁶⁹ CT or MRI offer superior depictions of the orbit and facilitate planning of either radiation or surgical therapy (Figure 31-7). Histologic characterization by FNA or needle core biopsies (performed via the mouth or through the orbital skin), with ultrasound guidance if necessary, are helpful in arriving at a definitive diagnosis. The globe, major orbital blood vessels, and optic nerve should be avoided. Because 50% of orbital tumors may have a nondiagnostic FNA, especially in cases of SCC,⁶⁹ exploratory orbitotomy via a number of approaches⁷⁶⁻⁸⁰ or exenteration may be required to characterize the mass and resect it if possible. Cerebrospinal fluid taps may aid in distinguishing optic nerve neoplasia from optic neuritis.

Therapy

Primary orbital and optic nerve tumors that lack metastasis or regional lymph node involvement may be amenable to surgical excision. If bony involvement is not present, orbital exenteration by widely dissecting around the mass (stripping periorbital if necessary) is usually the preferred procedure, as the advanced stage of

the tumor at the time of diagnosis typically makes it impossible to excise the mass completely and preserve a functional or comfortable eye. If periorbital bones are involved, radical “orbitectomy,” which resects the affected orbital tissues and surrounding bones, should be considered.⁷⁸ When treating optic nerve tumors, as much of the ipsilateral optic nerve as possible should be removed in an attempt to obtain complete excision.⁷⁰

If preservation of a comfortable eye and vision appears possible, a variety of orbitotomy techniques, ranging from small incisions through the eyelid or mouth to reflection of the zygomatic arch, temporalis muscle elevation, and zygomatic process osteotomy, have been described.⁷⁶⁻⁸⁰ Postoperative complications are common and may include secondary enophthalmia with entropion and possibly diplopia (double vision). Surgical debulking can be palliative, and some dogs may survive a year or more with minimal therapy.

The role of chemotherapy and RT, either alone or as an adjunct to surgery, is yet to be defined in the treatment of orbital tumors, although chemotherapy for orbital lymphoma may be effective. Systemic corticosteroids may permit some patients with optic nerve meningioma to maintain vision for several weeks to months. RT may be helpful in the case of nasal tumors with orbital extension, in subtotally excised or recurrent meningiomas, and in other select cases.

Prognosis

With conservative treatment the prognosis for most tumors involving the orbit and optic nerve is poor,^{69,70} especially if there is bony involvement on skull radiographs. Recurrence at the primary site and involvement of adjacent or distant sites are common, often occurring within weeks to a few months. Even benign-appearing tumors such as lobular orbital adenomas and orbital meningiomas may be locally invasive and have a propensity for recurrence following wide excision.^{67-73,78} In one study, however, radical orbitectomy (with or without chemotherapy or RT) provided a local disease-free interval of more than 1 year in more than 50% of patients and a 70% survival rate for the first year.⁷⁸ In another study, the mean survival time for cats with orbital tumors treated by RT, chemotherapy, or surgery that included resection of affected orbital bones was only 4.3 months.⁶⁹ In a study of 23 dogs with orbital tumors, most of whom were treated by exenteration with or without adjunct therapy, only 3 survived 3 years or longer.⁷⁰ The majority of these animals died as a direct result of the tumor or were euthanized at the time of diagnosis.⁶⁷⁻⁷⁰

Ocular Effects of Cancer Therapeutic Modalities

The ocular effect of external-beam RT for nasal and periocular tumors can have a substantial impact on an animal's quality of life. Common complications include chronic keratoconjunctivitis, corneal ulceration, “dry eye,” enophthalmia, entropion, cataracts, retinal hemorrhages, retinal detachments, and blindness.^{81,82} Many of these conditions respond poorly to treatment, and vigorous attempts at prevention should be made in order to avoid chronic ocular pain and blindness. Recently, intensity-modulated RT (IMRT), which uses conformal avoidance, has been shown to significantly decrease the ocular toxicity seen in dogs treated by RT for spontaneous sinonasal tumors (Figure 31-8).^{83,84}

In humans, blurred vision, partial visual field defects, loss of color vision, and diplopia have been associated with several antineoplastic drugs.⁸⁵ Similar effects probably occur in animals but

• **FIGURE 31-8** Intensity-modulated radiation therapy (IMRT), which uses conformal avoidance, can spare the eyes (green and blue circles) and has been shown to significantly decrease the ocular toxicity of radiation therapy for sinonasal tumors.

would be difficult to detect. Additionally, in humans, the bacillus Calmette-Guérin (BCG) has been associated with uveitis; cyclophosphamide has been associated with dry eye; cisplatin has been associated with neuroretinal toxicity; doxorubicin has been associated with excessive lacrimation and conjunctivitis; 5-FU has been associated with blurred vision, excessive lacrimation, blepharitis, conjunctivitis, and keratitis; and vincristine has been associated with cranial nerve palsies, optic neuropathy, and cortical and night blindness.⁸⁵ Monoclonal antibodies directed at the vasculature supporting the tumor also have been associated with uveitis.⁸⁶

Comparative Aspects

Malignant melanoma of the choroid is the most common primary ocular malignancy in adult humans. Initially, it was believed that enucleation of these patients may enhance the risk of metastasis; thus a large, randomized clinical trial (the Collaborative Ocular Melanoma Study) was conducted comparing enucleation to iodine-125 brachytherapy, which left the globe intact.^{87,88} Both treatment modalities were found to yield similar results, although many patients still died from metastatic melanoma, and it appears that significant improvement in survival rates will depend on developing effective systemic therapeutic modalities for melanoma.^{87,88} Retinoblastoma is the most common malignant intraocular tumor of children and has a genetic basis. No cases of retinoblastoma have been described in nonhuman primates, and only one case of retinoblastoma has been described in a dog.⁸⁹ With therapy, long-term survival in children is over 85%, but many patients develop second tumors, especially osteosarcoma.⁹⁰ Cancer-associated retinopathy is an uncommon, immune-mediated paraneoplastic phenomenon in humans in which antibodies are directed against specific retinal autoantigens, such as recoverin.⁹¹⁻⁹³ In this condition, patients with small-cell lung carcinoma and other tumors may develop blurred vision, impaired color vision, substantial visual field defects, or complete blindness as tumor antigens cross-react with specific retinal components.⁹¹⁻⁹³ Treatment with IV immunoglobulin has

been reported to return vision to some patients.⁹¹ Although cancer-associated retinopathy has been suggested to occur in dogs, especially those with sudden acquired retinal degeneration syndrome (SARDS), definitive proof is lacking and one study did not identify antibody activity against retinal proteins or evidence of neoplasia in dogs with SARDS.⁹⁴

■ SECTION A

Canine Lymphoma and Lymphoid Leukemias

DAVID M. VAIL, MARIE E. PINKERTON,
AND KAREN M. YOUNG

Lymphoma

The lymphomas (malignant lymphoma or lymphosarcoma) are a diverse group of neoplasms that have in common their origin from lymphoreticular cells. They usually arise in lymphoid tissues such as lymph nodes, spleen, and bone marrow; however, they may arise in almost any tissue in the body. Although the annual incidence of lymphoma is difficult to predict in the absence of a national canine tumor registry, it is clear that it represents one of the most common neoplasms seen in the dog. The annual incidence has been estimated to range between 13 to 24 per 100,000 dogs at risk.¹⁻³ The annual incidence rates at specific ages are estimated to be 1.5 per 100,000 for dogs less than 1.0 year of age and 84 per 100,000 in the 10- to 11-year-old group. Lymphoma comprises approximately 7% to 24% of all canine neoplasia and 83% of all canine hematopoietic malignancies.^{4,5} In a review of the Veterinary Medical Data Base Program (VMDP) at Purdue University from 1987 to 1997, the frequency of canine lymphoma patients presented to 20 veterinary institutions increased from 0.75% of total case load to 2.0%, and it appears the frequency is continuing to increase. A similar trend is present in physician-based oncology; non-Hodgkin's lymphoma (NHL) represents 5% of all new cancer cases, the fifth leading cause of cancer death, and the second fastest growing cancer in terms of mortality in humans.⁶ Middle-aged to older (median age of 6 to 9 years) dogs are primarily affected. A decreased risk for lymphoma is reported for intact females.⁷ Breeds reported to have a higher incidence include Boxers, bull mastiffs, basset hounds, St. Bernards, Scottish terriers, Airedales, and bulldogs; breeds at lower risk include dachshunds and Pomeranians.^{8,9}

Etiology

The etiology of canine lymphoma is likely multifactorial and largely unknown; however, investigations are currently shedding significant light on the subject.

Genetic and Molecular Factors

Recent advances in molecular cytogenetics (see Chapter 1, Section A), including gene microarray techniques, have been and are currently being applied to investigations of chromosomal aberrations in dogs with lymphoma.¹⁰⁻¹⁶ The publication of the canine genome and the commercial availability of canine gene microarrays

(GeneChip Canine Genome 2.0 Array, Affymetrix, Inc.) have led to advances in our understanding of genetic events occurring in lymphoma.¹⁷ Breen's group has documented gain of dog chromosomes 13 and 31 and loss of chromosome 14 as the most common aberrations in a group of 25 cases analyzed.¹¹ Chromosomal aberrations have also been associated with prognosis in dogs with lymphoma. A study of 61 dogs with lymphoma demonstrated a prognostic advantage in dogs with trisomy of chromosome 13 (25% of the dogs studied) as evidenced by increase in duration of first remission and overall survival time.¹⁸ Germline and somatic genetic mutations and altered oncogene/tumor suppressor gene expression, epigenetic changes (e.g., DNA hypomethylation), signal transduction, and death-pathway alterations (e.g., *Bcl-2* family) are common in human lymphomas and have been reported in the dog as well (see Chapter 1, Section A, and Chapter 14, Section B). These include *N-ras*, *p53*, *Rb*, and p16 cyclin-dependent kinase aberrations.¹⁹⁻²⁴ Additionally, differences in the prevalence of immunophenotypic subtypes of lymphoma among different breeds indicate heritable risks.²⁵ Additionally, telomerase activity (see Chapter 2) has been documented in canine lymphoma tissues.²⁶⁻²⁸

Infectious Factors

The hypothesis that a retrovirus may be involved in the pathogenesis of canine lymphoma has not been confirmed. However, serologic detection of Epstein-Barr virus infection, linked to some forms of lymphoma in humans, has been documented in dogs with lymphoma and is currently being investigated.²⁹

In humans, a direct association between *Helicobacter* sp. infections and development of gastric lymphoma has been made.³⁰ Although this has not been definitively shown in dogs, there is evidence of *Helicobacter* sp. infection in laboratory beagle dogs resulting in gastric lymphoid follicle formation that is considered a precursor of mucosa-associated lymphoid tissue (MALT) lymphoma in humans.³¹

Environmental Factors

In humans, evidence has accumulated implicating phenoxyacetic acid herbicides, in particular 2, 4-dichlorophenoxyacetic acid (2, 4-D), in the development of NHL. A published hospital-based case-control study of dogs indicated that owners in households with dogs that develop malignant lymphoma applied 2, 4-D herbicides to their lawn and/or employed commercial lawn care companies to treat their yard more frequently than owners of dogs without lymphoma.³² The risk of canine lymphoma was reported to rise twofold (odds ratio [OR] = 1.3) with four or more yearly owner applications of 2, 4-D. The results of this study have come under criticism, and three additional follow-up investigations have not validated assertions of increased risk.³³⁻³⁵ In another study, dogs exposed to lawn treatment within 7 days of application were greater than 50 times

more likely to have urine levels of 2, 4-D at 50 µg/L or higher.³⁶ The highest concentration was noted 2 days after application. In an environmental case-control study performed in Europe, two variables, residency in industrial areas and use of chemicals (defined as paints or solvents) by owners, modestly increased the risk of developing lymphoma; however, no link was found with pesticide use.³⁷

A weak association between lymphoma in dogs and exposure to strong magnetic fields was observed in a preliminary epidemiologic study.³⁸ In this hospital-based case-control study, the risk of developing lymphoma categorized into high or very high exposure was increased (odds ratio = 1.8). More thorough studies are necessary to evaluate this association further. Proximity to environmental waste was implicated in two European studies; however, it was felt to be a risk indicator rather than a risk factor and would require further case-control investigations.^{39,40}

Immunologic Factors

Impaired immune function has also been implicated in dogs with lymphoma. Immune system alterations in the dog such as immune-mediated thrombocytopenia, independent of age and sex, have been associated with a higher risk of subsequently developing lymphoma when compared to the normal population.^{41,42} Additional evidence comes from observations in human and feline transplantation patients. In a case-control study of cats undergoing renal transplant, 24% of cases developed cancer (36% of those were lymphoma) while on cyclosporine immunosuppressive therapy compared to 5.1% of control cats, none of which developed lymphoma (OR, 6.1; $p = 0.001$).⁴³ A case of lymphoma developing in a dog following treatment with cyclosporine also exists.⁴⁴ One report suggests an association between the immunodysregulation observed in dogs with atopic dermatitis and the risk of developing epitheliotropic T-cell lymphoma; whether this is associated with the disease or the immunomodulatory treatments commonly applied is unknown.⁴⁵

Classification and Pathology

Classification of malignant lymphoma in dogs is based on anatomic location, histologic criteria, and immunophenotypic characteristics. The most common anatomic forms of lymphoma, in order of decreasing prevalence, are multicentric, gastrointestinal (GI), mediastinal, and cutaneous forms.⁴⁶ Primary extranodal forms, which can occur in any location outside the lymphatic system, include the eyes, central nervous system (CNS), bone marrow, bladder, heart, and nasal cavity. The pathologic characteristics of the various anatomic classifications will be discussed in this section and clinical characteristics will be described in subsequent sections.

Eighty-four percent of dogs with lymphoma develop the multicentric form, which is usually characterized by the presence of superficial lymphadenopathy (Figure 32-1).⁴⁶ The alimentary form of lymphoma is much less common, accounting for 5% to 7% of all canine lymphomas. This form is reported to be more common in male dogs than female dogs.⁶ Primary GI lymphoma in dogs may occur focally but more often affects multiple segments, with thickening of the wall, narrowing of the lumen, and frequently mucosal ulceration.^{47,48} Histologically, there is infiltration of neoplastic lymphocytes throughout the mucosa and submucosa, with occasional transmural infiltration. Liver and local lymph nodes are often secondarily involved. Lymphocytic-plasmacytic enteritis (LPE) can be seen adjacent to or distant from the primary tumor. Pathologically, some of these neoplasms may resemble plasma cell tumors, and aberrant production of immunoglobulins may occur.

• **FIGURE 32-1** A dog with obvious mandibular lymphadenopathy resulting from multicentric lymphoma.

Histopathologically, distinguishing between GI lymphoma and LPE can be difficult. Some have suggested that LPE may be a prelymphomatous change in the GI tract. A syndrome of immunoproliferative intestinal disease characterized by LPE has been described in Basenjis, which subsequently develop GI lymphoma.⁴⁹ In addition, plasma cell-rich areas with heterogeneous lymphomatous infiltration may resemble lesions of LPE. Only a few reports specifically identify the immunophenotype of the lymphocyte subpopulations in alimentary lymphoma in dogs. Historically, it was presumed that they most likely originate from B cells; however, recent evidence suggests that most GI lymphomas in dogs arise from T cells and often exhibit epitheliotropism.^{48,50} The Boxer and Shar-pei breeds may be overrepresented in cases of alimentary lymphoma.^{50,51}

The mediastinal form of the disease occurs in approximately 5% of cases.⁴⁶ This form is characterized by enlargement of the cranial mediastinal lymph nodes, thymus, or both (Figure 32-2). Hypercalcemia is reported to occur in 10% to 40% of dogs with lymphoma and is most common with the mediastinal form. In a study of 37 dogs with lymphoma and hypercalcemia, 16 (43%) had mediastinal lymphoma.⁵² The mediastinal form in dogs is most commonly associated with a T-cell phenotype.^{53,54}

Cutaneous lymphoma can be solitary or more generalized and usually is classified as epitheliotropic (mycosis fungoides) or non-epitheliotropic.⁵⁵ Canine epitheliotropic cutaneous lymphoma originates from T-cells,⁵⁵⁻⁶⁰ similar to its development in humans. In dogs, these more commonly represent CD8⁺ cells, whereas in humans they are typically CD4⁺ cells. A rare form of cutaneous T-cell lymphoma, characterized by skin involvement with evidence of peripherally circulating large (15 to 20 µm in diameter) malignant T-cells with folded, grooved nuclei, has been described. In humans, this is referred to as Sézary syndrome and has been reported in both dogs and cats.⁶¹⁻⁶³ Nonepitheliotropic cutaneous lymphomas form single or multiple dermal or subcutaneous nodules or plaques; histologically, they spare the epidermis and papillary dermis and affect the middle and deep portions of the dermis and subcutis.⁵⁵

• **FIGURE 32-2** A, Lateral radiographic projection of a dog with mediastinal lymphoma. B, Ventrodorsal projection of the same dog.

Atypical Anatomic Forms of Lymphoma

Hepatosplenic lymphoma is a relatively uncommon, distinct presentation in the dog marked by a lack of significant peripheral lymphadenopathy in the face of hepatic, splenic, and bone marrow infiltration with malignant lymphocytes, usually of T-cell origin.^{64,65} Biologically, this form of lymphoma is extremely aggressive and poorly responsive to therapy. In humans the tumor usually is composed of $\gamma\delta$ T-cells (i.e., T-cells that express the $\gamma\delta$ T-cell receptor), and this immunophenotype has been confirmed in at least one dog in the veterinary literature.⁶⁵

Intravascular (angiotropic, angioendotheliomatosis) lymphoma is a distinct form of lymphoma defined as proliferations of neoplastic lymphocytes within the lumen and wall of blood vessels in the absence of a primary extravascular mass or leukemia. It has been reported several times in the veterinary literature, and in most cases it involves the CNS and peripheral nervous system (PNS), including the eye.⁶⁶⁻⁷¹ The B-cell immunophenotype is most common in humans; however, in most reported cases in dogs, the origin is either T-cell or null cell (neither B- nor T-cell), although one case of a B-cell phenotype has been reported.

Pulmonary lymphomatoid granulomatosis (PLG) is a rare pulmonary infiltrative and/or nodular disorder characterized by a heterogeneous accumulation of lymphocytes (both B and T, although some evidence suggests primarily a T-cell origin), neutrophils, plasma cells, and macrophages, often arranged angiocentrically.⁷²⁻⁷⁵ Whether this syndrome is a true lymphoma or a prelymphoma state is debatable. Clinical signs are related to respiratory compromise, and various chemotherapeutic protocols have been used with reported results varying from rapid progression to long-term clinical remissions.

Histologic Classification Systems

Lymphomas arise from clonal expansion of lymphoid cells with distinctive morphologic and immunophenotypic features. Many histologic systems have been used to classify NHL in humans, and some of these have been applied to lymphoma in the dog and other

species. The National Cancer Institute (NCI) Working Formulation⁷⁶ and the updated Kiel system⁷⁷ have been adapted to canine tumors with some success. The World Health Organization (WHO) also publishes a histologic classification scheme, which uses the revised European American lymphoma (REAL) system as a basis for defining histologic categories of hematopoietic and lymphoid tumors in domestic animals.⁷⁸ This system incorporates anatomic, histologic, and immunophenotypic criteria (B- and T-cell immunophenotype), with the goal of enabling accurate and reproducible diagnosis of specific neoplastic disease entities. This theoretically should assist in better tailoring of treatment protocols, better correlation of prognosis, and better comparative capabilities. [Table 32-1](#) shows some of the WHO categories in three different surveys, including a 2-year survey (2008-2009) of canine necropsy and biopsy cases at the University of Wisconsin-Madison Veterinary Medical Teaching Hospital pathology service^{79,80}; some of the less common categories in the WHO system were not represented and are not listed. The WHO system provides accurate and consistent reproducible diagnostic results similar to the system used in human pathology; accuracy among a group of pathologists examining 300 cases was at 83% agreement, and accuracy in evaluating the six most common diagnoses (80% of the cases) was 87%.⁸¹ Clinical studies are needed to correlate the various categories of disease with biologic behavior, response to treatment, and prognosis. Preliminary results indicate dogs with indolent lymphoma (e.g., marginal zone lymphoma, follicular lymphoma, B- or T-cell small cell lymphoma, T-cell-rich B-cell lymphoma, and T zone lymphoma) maintain normal activity and appetite levels even during advanced stages of disease and experience long-term survival even with limited or no therapy.⁸¹⁻⁸⁴

The Working Formulation (WF) was developed to allow investigators to “translate” among the numerous classification systems so that clinical trials could be compared in humans. Most of the larger compilations agree that most canine lymphomas are intermediate or high grade; however, diffuse immunoblastic forms appear to predominate in the United States, whereas the follicular

Modified from Sueiro FAR, Alessi AC, Vassallo J: Canine lymphomas: A morphological and immunohistochemical study of 55 cases, with observations on p53 immunorexpression, *J Comp Pathol* 131:207–213, 2004; and Vezzali E, Parodi AL, Marcato PS, et al: Histopathological classification of 171 cases of canine and feline non-Hodgkin lymphoma according to the WHO, *Vet Comp Oncol* 8:36–49, 2009.

large cell variations predominate in Europe. A comparison of European and American classifications is warranted based on this discrepancy. The WF categorizes tumors according to pattern (diffuse or follicular) and cell type (e.g., small cleaved cell, large cell, immunoblastic), but it does not include information about the immunophenotype of the tumor.⁷⁶ The WF subtypes are related to the biology of the tumor and patient survival. The updated Kiel classification includes the architectural pattern, morphology (centroblastic, centrocytic, or immunoblastic), and immunophenotype (B-cell or T-cell) of the tumor cells.⁷⁷ In both systems, the tumors can then be categorized as low-grade, intermediate grade, or high-grade malignancies. Low-grade lymphomas composed of small cells with a low mitotic rate typically progress slowly and are associated with long survival times but are ultimately incurable. High-grade lymphomas with a high mitotic rate progress rapidly but are more likely to respond initially to chemotherapy and, in humans, are potentially curable.

Several features of canine lymphomas become apparent when these classification systems are applied. The most striking difference between canine and human lymphomas is the scarcity of follicular lymphomas in the dog.^{79,80} Some diffuse lymphomas in the dog may initially be follicular, but these may progress to the more aggressive, diffuse form by the time of diagnostic biopsy. The most common form of canine lymphoma is diffuse large-cell lymphoma, a high-grade tumor most commonly of B-cell origin.^{80,81,85} Only a small

percentage of canine lymphomas (5.3% to 29%) are considered low-grade tumors.

High-grade lymphomas occur frequently if diffuse large-cell lymphomas, classified as intermediate grade in the WF, are considered high-grade, as in the updated Kiel classification (in which they are labeled as diffuse centroblastic lymphomas). A documented difference exists in the prevalence of the various immunophenotypes based on breed.²⁵ For example, cocker spaniels and Doberman pinschers are more likely to develop B-cell lymphoma, Boxers are more likely to have T-cell lymphoma, and golden retrievers appear to have an equal likelihood of B- and T-cell tumors.

To be clinically useful, these classification systems in the end must yield information about response to therapy, maintenance of remission, and survival. Some studies suggest that the subtypes in the WF can be correlated with survival, and the Kiel system may be useful for predicting relapse.^{86,87} In most studies, high-grade lymphomas achieve a complete response (CR) to chemotherapy significantly more often than low-grade tumors. However, dogs with low-grade tumors may live a long time without aggressive chemotherapy.^{83,84} Dogs with T-cell lymphomas have shown a lower rate of CR to chemotherapy and shorter remission and survival times than dogs with B-cell tumors (with the exception of low-grade T-cell subtypes).^{53,54,86,88} Furthermore, T-cell lymphomas tend to be associated with hypercalcemia.^{89,90}

In the veterinary literature, 60% to 80% of canine lymphomas are of B-cell origin; T-cell lymphomas account for 10% to 38%; mixed B- and T-cell lymphomas account for as many as 22%; and null cell tumors (i.e., neither B-cell nor T-cell immunoreactive) represent fewer than 5%.^{53,54,91-93} The development of monoclonal antibodies to detect specific markers on canine lymphocytes has made immunophenotyping of tumors in dogs routinely available in many commercial laboratories. Such techniques can be performed on paraffin-embedded samples, from tissue microarrays, on cytologic specimens obtained by fine-needle aspiration (FNA) of lesions, or by flow cytometric analysis of cellular fluid samples (e.g., peripheral blood, effusions) and lesion aspirates.

The Rappaport classification system, proposed in 1956 for human NHL, describes the architectural pattern (follicular or diffuse) and the cytologic features (well differentiated, poorly differentiated, or histiocytic) of lymphoma.^{94,95} This system has not proved useful in providing prognostic information or in guiding therapy in dogs with lymphoma because of the low number of follicular lymphomas in dogs, the problematic “histiocytic” subgroup, and the failure to account for different morphologic and immunologic cell types.

One criticism of the Rappaport, Kiel, and WF classification systems is that they fail to include extranodal lymphomas as a separate category. The WHO system does include anatomic location as a factor in determining certain categories. Although differences between nodal and extranodal tumors in biologic behavior and prognosis are well recognized, comparative information about the histogenesis of these tumors is lacking. For example, in humans small-cell lymphomas arising from MALT are composed of cells with a different immunophenotype than that of other small-cell lymphomas (i.e., MALT lymphomas typically are negative for both CD5 and CD10). Except for cutaneous lymphoid neoplasms, detailed characterization of extranodal lymphomas in dogs has not been done. Although cutaneous lymphoma is a heterogeneous group of neoplasms that includes an epitheliotropic form resembling mycosis fungoides and a nonepitheliotropic form, most cutaneous lymphomas have a T-cell phenotype.^{64,96}

To summarize, it is important to determine the histologic grade of canine lymphomas as low (small lymphocytic or centrocytic lymphomas) or intermediate to high (diffuse large cell, centroblastic, and immunoblastic lymphomas) and the architecture as diffuse or follicular. Furthermore, determining the immunophenotype of the tumor provides useful information. Response rates to chemotherapy are, in general, better in animals with B-cell tumors and intermediate- to high-grade lymphomas. Dogs with low-grade lymphomas can have long survival times without aggressive therapy.

History and Clinical Signs

The clinical signs associated with canine lymphoma are variable and depend on the extent and location of the tumor. Multicentric lymphoma, the most common form, is usually distinguished by the presence of generalized painless lymphadenopathy (see Figure 32-1). Enlarged lymph nodes are usually painless, rubbery, and discrete and may initially include the mandibular and prescapular nodes. In addition, hepatosplenomegaly and bone marrow involvement occur commonly. Most dogs with multicentric lymphoma present without dramatic signs of systemic illness (WHO substage *a*) (Box 32-1); however, a large array of nonspecific signs such as anorexia, weight loss, vomiting, diarrhea, emaciation, ascites, dyspnea, polydipsia, polyuria, and fever can occur (WHO substage *b*). Dogs presented with T-cell lymphoma are more likely to have constitutional (i.e., substage *b*) signs. Polydipsia and polyuria are

Box 32-1 World Health Organization's Clinical Staging System for Lymphoma in Domestic Animals

Anatomic Site

- A Generalized
- B Alimentary
- C Thymic
- D Skin
- E Leukemia (true)*
- F Others (including solitary renal)

Stage (to include anatomic site)

- I Involvement limited to a single node or lymphoid tissue in a single organ.[†]
- II Involvement of many lymph nodes in a regional area (\pm tonsils).
- III Generalized lymph node involvement.
- IV Liver and/or spleen involvement (\pm stage III).
- V Manifestation in the blood and involvement of bone marrow and/or other organ systems (\pm stage I-IV).

Each stage is subclassified into:

- a Without systemic signs
- b With systemic signs

*Only blood and bone marrow involved.

[†]Excluding bone marrow.

• **FIGURE 32-3** Lateral projection of a thoracic radiograph of a dog with diffuse interstitial infiltration with lymphoma secondary to multicentric lymphoma.

particularly evident in dogs with hypercalcemia of malignancy. Dogs may also be presented with clinical signs related to blood dyscrasias secondary to marked tumor infiltration of bone marrow (myelophthisis) or paraneoplastic anemia, thrombocytopenia, or neutropenia. These could include fever, sepsis, anemia, and hemorrhage. Diffuse pulmonary infiltration is seen in 27% to 34% of dogs with the multicentric form, as detected by radiographic changes (Figure 32-3).^{97,98} Based on bronchoalveolar lavage, the actual incidence of lung involvement may be higher.^{99,100}

• **FIGURE 32-4** **A**, Facial edema in a dog with precaval syndrome secondary to mediastinal lymphoma. **B**, Forelimb edema in a dog with precaval syndrome secondary to mediastinal lymphoma. **C**, The dog in **B** 24 hours after radiation therapy to the cranial mediastinal mass, showing resolution of pitting edema.

Dogs with GI or alimentary lymphoma are usually presented with nonspecific GI signs, such as vomiting, diarrhea, weight loss, and malabsorption.^{47,101,102} Mesenteric lymph nodes, spleen, and liver may be involved.

The mediastinal form of lymphoma is characterized by enlargement of the cranial mediastinal structures and/or thymus (see [Figure 32-2](#)), and clinical signs are associated with the extent of disease with resulting respiratory compromise or polydipsia/polyuria from hypercalcemia. Commonly, dogs are presented with respiratory distress caused by a space-occupying mass and pleural effusion, exercise intolerance, and possibly regurgitation. Additionally, dogs with mediastinal lymphoma may present with precaval

syndrome, characterized by pitting edema of the head, neck, and forelimbs secondary to tumor compression or invasion of the cranial vena cava ([Figure 32-4](#)).

Signs in dogs with extranodal lymphoma depend on the specific organ involved. Cutaneous lymphoma is usually generalized or multifocal.⁵⁵⁻⁵⁷ Tumors occur as nodules, plaques, ulcers, and erythemic or exfoliative dermatitis with focal hypopigmentation and alopecia. Epitheliotropic T-cell lymphoma (e.g., mycosis fungoides) typically has a clinical course with three apparent clinical stages. Initially, there will be scaling, alopecia, and pruritus ([Figure 32-5, A](#)), which can mimic a variety of other skin conditions. As the disease progresses, the skin becomes more erythematous,

• **FIGURE 32-5** **A**, Early epitheliotropic cutaneous lymphoma in the scaly, plaque stage in a dog. **B**, Advanced epitheliotropic cutaneous lymphoma in the nodular stage in a dog. **C**, Oral mucosal epitheliotropic cutaneous lymphoma in a dog.

thickened, ulcerated, and exudative. The final stage is characterized by proliferative plaques and nodules with progressive ulceration (Figure 32-5, *B*). Oral involvement may also occur and this can appear as multicentric erythematous plaque-like lesions or nodules associated with the gum and lips (Figure 32-5, *C*). Extracutaneous involvement can also occur, most often in the lymph nodes, spleen, liver, and bone marrow. Nonepitheliotropic cutaneous lymphomas form single or multiple dermal or subcutaneous nodules or plaques; histologically, they spare the epidermis and papillary dermis and affect the middle and deep portions of the dermis and subcutis.⁵⁵

Dogs with primary CNS lymphoma may be presented with either multifocal or solitary involvement.¹⁰³⁻¹⁰⁵ Seizures, paralysis, and paresis may be noted. Ocular lymphoma is characterized by infiltration and thickening of the iris, uveitis, hypopyon, hyphema, posterior synechia, and glaucoma.^{106,107} In one study of 94 cases of canine multicentric lymphoma, 37% had ocular changes consistent with lymphoma, and in a series of 102 cases of uveitis in dogs, 17% were secondary to lymphoma.¹⁰⁷ Anterior uveitis was most commonly seen in advanced stage of disease (stage V). Dogs with

intravascular lymphoma usually present with signs relative to CNS, PNS, or ocular involvement.⁶⁶⁻⁷¹ These include paraparesis, ataxia, hyperesthesia, seizures, blindness, lethargy, anorexia, weight loss, diarrhea, polyuria, polydipsia, and intermittent fever. Finally, dogs with pure hepatosplenic lymphoma usually are presented with non-specific signs of lethargy, inappetence, and weakness and often are icteric.^{64,65}

The differential diagnosis of lymphadenopathy depends on the dog's travel history (i.e., relative to infectious disease) and the size, consistency, and location of affected lymph nodes. Other causes of lymphadenopathy include infections caused by bacteria, viruses, parasites (*Toxoplasma* sp., *Leishmania* sp.), rickettsial organisms (Salmon-poisoning, *Ehrlichia* sp.), and fungal agents (*Blastomyces* and *Histoplasma* sp.). The potential for hypercalcemia to accompany systemic fungal diseases may further complicate differentiation from lymphoma. Discrete, hard, asymmetric lymph nodes, particularly if they are fixed to underlying tissues, may indicate metastatic tumors such as mast cell tumor or carcinoma. Immune-mediated diseases (e.g., pemphigus, systemic lupus erythematosus) also may result in mild-to-moderately enlarged lymph nodes. The

• **TABLE 32-2** Differential Diseases or Conditions That Can Resemble Canine Lymphoma

FORM OF LYMPHOMA	OTHER DISORDERS
Multicentric	Disseminated infections: Bacterial, viral, rickettsial, parasitic, fungal Immune-mediated disorders: Dermatopathies, vasculitis, polyarthritis, lupus erythematosus Tumors metastatic to nodes Other hematopoietic tumors: Leukemia, multiple myeloma, malignant or systemic histiocytosis
Mediastinal	Other tumors: Thymoma, chemodectoma, ultimobranchial cyst, ectopic thyroid carcinoma, pleural carcinomatosis, pulmonary lymphomatoid granulomatosis* Infectious disease: Granulomatous disease, pyothorax Miscellaneous: Congestive heart failure, chylothorax, hemothorax
Alimentary	Other gastrointestinal tumors, foreign body, lymphangiectasia, lymphocytic-plasmacytic enteritis, systemic mycosis, gastroduodenal ulceration
Cutaneous	Infectious dermatitis: Advanced pyoderma Immune-mediated dermatitis: Pemphigus Other cutaneous neoplasms (in particular histiocytic disorders)
Extranodal	Variable, depending on organ/system involved

*The existence of this disease is controversial; in most cases, the disease has been reclassified as a lymphoid neoplasm.

various differential diseases or conditions that can resemble canine lymphoma are listed in Table 32-2.

Canine lymphoma also may be associated with paraneoplastic syndromes (see Chapter 5). Anemia is the most common lymphoma-related paraneoplastic syndrome.¹⁰⁸ Paraneoplastic hypercalcemia is also common and is characterized clinically by anorexia, weight loss, muscle weakness, lethargy, polyuria, polydipsia, and rarely CNS depression and coma. Lymphoma-induced hypercalcemia in most cases results from parathyroid hormone-related peptide (PTHrP), elaborated by neoplastic cells; however, it can also be related to the production of several other humoral factors, including interleukin-1 (IL-1), tumor necrosis factor- α (TNF- α), transforming growth factor- β (TGF- β), and vitamin D analogs (e.g., 1,25-dihydroxyvitamin D).^{89,109,110} As previously discussed, hypercalcemia is most commonly associated with the T-cell immunophenotype. Other paraneoplastic syndromes that may be encountered include monoclonal gammopathies, neuropathies, and cancer cachexia.

Diagnostics and Clinical Staging

For dogs suspected of having lymphoma, the diagnostic evaluation should include a thorough physical examination; complete blood

count (CBC), with a differential cell count, including a platelet count; a serum biochemical profile; and urinalysis. Optimally, ionized calcium should be measured. Ultimately, obtaining tissue or cytologic specimens for a definitive diagnosis is essential.

Physical Examination

A thorough physical examination should include palpation of all assessable lymph nodes, including a rectal examination; in the authors' experience, a significant proportion of dogs will have rectal polyps consisting of aggregates of neoplastic lymphocytes. Inspection of mucous membranes for pallor, icterus, petechiae, and ulceration should be undertaken as these signs may indicate anemia or thrombocytopenia secondary to myelophthisis or immune-mediated disease or may be evidence of major organ failure or uremia. Abdominal palpation may reveal organomegaly, intestinal wall thickening, or mesenteric lymphadenopathy. The presence of a mediastinal mass and/or pleural effusion can be suspected following thoracic auscultation. An ocular examination, including fundoscopic assessment, may reveal abnormalities (e.g., uveitis, retinal hemorrhage, ocular infiltration) in approximately one-third to one-half of dogs with lymphoma.^{107,111}

Complete Blood Count, Biochemistry Profile, and Urinalysis

Anemia, the most common lymphoma-related hematologic abnormality, is usually normochromic and normocytic (nonregenerative), consistent with anemia of chronic disease.¹⁰⁸ However, hemorrhagic and hemolytic anemias may also occur, and regenerative anemias may reflect concomitant blood loss or hemolysis. Additionally, if significant myelophthisis is present, anemia may be accompanied by thrombocytopenia and leukopenia.^{112,113} In animals with anemia or evidence of bleeding, in addition to a platelet count, a reticulocyte count and coagulation testing may be indicated. Thrombocytopenia may be seen in 30% to 50% of cases, but bleeding is seldom a clinical problem. Neutrophilia can be seen in 25% to 40% of dogs and lymphocytosis occurs in approximately 20% of affected dogs.¹⁰⁸ Circulating atypical lymphocytes may be indicative of bone marrow involvement and leukemia. It is important to differentiate multicentric lymphoma with bone marrow involvement (i.e., stage V disease) from primary lymphoblastic leukemia (see later), as the prognosis for each is entirely different. Hypoproteinemia is observed more frequently in animals with alimentary lymphoma. In dogs with a high total protein or evidence of an increased globulin fraction on a chemistry profile, serum proteins may be evaluated by serum electrophoresis. Monoclonal gammopathies have been reported to occur in approximately 6% of dogs with lymphoma.¹¹⁴

Serum biochemical abnormalities often reflect the anatomic site involved, as well as paraneoplastic syndromes such as hypercalcemia. In cases of hypercalcemia of unknown origin, lymphoma should always be considered high on the differential disease list, and diagnostic testing directed at this possibility should be undertaken (see Chapter 5). In addition, the presence of hypercalcemia can serve as a biomarker for response to therapy and early recurrence. Increased urea nitrogen and creatinine concentrations can occur secondary to renal infiltration with tumor, hypercalcemic nephrosis, or prerenal azotemia from dehydration. Increases in liver-specific enzyme activities or bilirubin concentrations may result from hepatic parenchymal infiltration. Increased serum globulin concentrations, usually monoclonal, occur infrequently with B-cell lymphoma.

Urinalysis is part of the minimum database used to assess renal function and the urinary tract. For example, isosthenuria and

proteinuria in the absence of an active sediment may indicate renal disease, and hematuria may result from a hemostatic abnormality. It is important to remember that isosthenuria in azotemic dogs with hypercalcemia is not necessarily indicative of renal disease as the high calcium levels interfere with tubular concentration capabilities through disruption of antidiuretic hormone (ADH) control.

Several abnormalities in serum have been explored as biomarkers of lymphoma in the dog. Examples include alpha-fetoprotein, alpha-1 glycoprotein levels, zinc, chromium, iron, endostatin, vascular endothelial growth factor (VEGF), lactate dehydrogenase, C-reactive protein haptoglobin, and antioxidants/oxidative stress markers.¹¹⁵⁻¹²² The clinical, biologic, and prognostic significance of these alterations is yet to be definitively characterized.

Histologic and Cytologic Evaluation of Lymph Nodes

Morphologic examination of the tissue and cells that constitute the tumor is essential to the diagnosis of lymphoma. Care should be taken to avoid lymph nodes from reactive areas (e.g., mandibular lymph nodes), unless those nodes are the only ones enlarged; the

prescapular or popliteal lymph nodes are preferable if also involved. Also, lymphoid cells are fragile, and in preparing smears of aspirated material only gentle pressure should be applied in spreading material on the slides. In most cases, a diagnosis of lymphoma can be made on evaluation of fine-needle aspirates of affected lymph nodes or other tissues. Typically, most of the cells are large lymphoid cells (>2 times the diameter of a red blood cell [RBC] or larger than neutrophils), and they may have visible nucleoli and basophilic cytoplasm (Figure 32-6, A) or fine chromatin with indistinct nucleoli. Because tissue architecture is not maintained in cytologic specimens, effacement of the node or capsular disruption cannot be detected. Therefore marked reactive hyperplasia characterized by increased numbers of large lymphoid cells may be difficult to distinguish from lymphoma, and small cell lymphomas may have few cytologic clues that point to malignancy. Also, classification of lymphoma, which has been attempted using cytologic appearance and immunophenotypic analysis,¹²³ into subcategories that make up the low-, intermediate-, and high-grade forms is performed most accurately on histologic sections (discussed previously).

FIGURE 32-6 Lymph nodes from dogs with lymphoma. **A**, Fine-needle aspirate. Note the homogenous population of large lymphoid cells with prominent nucleoli and basophilic cytoplasm. These cells are larger than the neutrophil (*black arrow*) in the field. Mitotic figures (*thin white arrows*) and tingible body macrophages (*thick white arrows*) also are present. (Wright's stain, $\times 60$ objective.) **B**, Fine-needle aspirate stained for immunoreactivity for CD79a. Note that nearly all of the lymphocytes express CD79a. The diagnosis was B-cell lymphoma. (Alkaline phosphatase/fast red, $\times 60$ objective.) **C**, Histologic section. Note effacement of normal architecture. The white spaces are macrophages, giving a "starry sky" appearance to the lymph node. (H&E, $\times 20$ objective.) **D**, Histologic section. Note the presence of tumor cells outside the capsule of the lymph node. (H&E, $\times 20$ objective.)

For accurate histopathologic evaluation, an entire lymph node, including the capsule, should be removed, placed in buffered formalin, and submitted to a pathologist. Although needle core biopsies may be satisfactory, it is important to avoid crush artifact or inadequate sample size. Most pathologists prefer whole node biopsies because they provide the maximal amount of information. Effacement of normal nodal architecture by neoplastic lymphocytes and capsular disruption are characteristic findings (Figure 32-6, C and D). Diagnostic ultrasonography and ultrasound-guided FNA or needle biopsy have been useful for evaluation of involvement of the liver, spleen, or abdominal lymph nodes.¹²⁴⁻¹²⁶ Aspiration of ultrasonographically normal splenic tissue is rarely contributory to a diagnosis.¹²⁴ If possible, the diagnosis should be made by sampling peripheral nodes, avoiding percutaneous biopsies of the liver and spleen. However, if there is no peripheral node involvement, it is appropriate to biopsy affected tissues in the abdominal cavity.

Histologic and Cytologic Evaluation of Extranodal Sites

When GI lymphoma is suspected, an open surgical wedge biopsy of the intestine is preferred in most cases to differentiate lymphoma from lymphocytic enteritis. If associated abdominal lymph nodes also appear involved, image-guided biopsies may be associated with less morbidity than intestinal biopsies. Multiple samples may be necessary to accurately diagnose segmental disease. Endoscopic biopsies may be inadequate as only a superficial specimen is obtained; however, more aggressive endoscopic biopsy techniques combined with more accurate histopathologic, immunophenotypic, and molecular assessments are improving the diagnostic yield of these less invasive techniques.¹²⁷⁻¹³⁰ In many dogs with primary GI lymphoma, an inflammatory nonneoplastic infiltrate (i.e., LPE) may be misdiagnosed on biopsy specimens that are too superficial. The application of assays for clonal expansion (e.g., PARR—see next section on [molecular diagnostic techniques](#)) does not appear as yet to be as accurate for endoscopically derived intestinal biopsies as with other solid lymphoid tumors in dogs.

Cytologic examination of cerebrospinal fluid (CSF), thoracic fluid, or mass aspirates is indicated in animals with CNS disease, pleural effusion, or an intrathoracic mass, respectively. In one study of dogs with CNS involvement, CSF analysis was diagnostic in seven of eight dogs.¹⁰³ Characteristics of the CSF included an increased nucleated cell count in the seven dogs, and 95% to 100% of the cells were atypical lymphocytes. The CSF protein concentration was increased in five of the dogs, ranging from 34 to 310 mg/dL (reference interval: <25 mg/dL).

For cutaneous lymphoma, punch biopsies (4 to 8 mm) should be taken from the most representative and infiltrative, but not secondarily infected, skin lesions. Application of immunophenotypic and clonality assessments of cutaneous biopsies can aid in differentiating lymphoma from benign lymphocytic lesions.^{58,131,132}

Molecular Diagnostic Techniques

Molecular techniques can be used to establish a diagnosis of lymphoma or to further characterize the tumor after the initial diagnosis is made. Tissues and cells from peripheral blood, lymph nodes, nonlymphoid sites, and effusions can be analyzed by various molecular means to aid in cases that represent a more difficult diagnostic challenge, particularly in cases where reactive lymphocytosis and lymphoma are both possible based on standard histologic or cytologic assessment. These include histochemical and cytochemical, immunohistochemical and immunocytochemical, flow cytometric, and polymerase chain reaction (PCR) techniques. For example,

the immunophenotype (B-cell versus T-cell),^{93,133-140} proliferation rate (e.g., expression of Ki67, proliferating cell nuclear antigen [PCNA] expression, argyrophilic nucleolar organizer regions [AgNOR]),^{53,133,141-145} and clonality (PCR for antigen receptor gene rearrangement [PARR])¹⁴⁶⁻¹⁵⁴ of the tumor can be determined. The availability of such analyses is increasing; however, at present, only immunophenotype and PARR clonality assays are routinely used in dogs to inform clinical decision making.

Immunophenotyping

Immunophenotyping is used to determine the type of cells that comprise the tumor, but this technique also can be helpful for making the initial diagnosis.^{133-140,155} When a heterogeneous population of lymphocytes is expected in a tissue, documentation of a homogeneous population of the same immunophenotype is supportive of a neoplastic process. The immunophenotype of a lymphocyte is identified by determining the expression of molecules specific for B-cells (e.g., CD79a, CD20) and T-cells (e.g., CD3). Although tumor cells sometimes have morphologic characteristics that typify a particular immunophenotype, exceptions occur, and morphologic appearance cannot be used as the sole determinant of immunophenotype. For example, in a series of nine high-grade T-cell lymphomas and leukemias in dogs, the cells had a plasmacytoid appearance, typically associated with B-cell lymphoma.¹⁵⁶ Similarly, anatomic location does not always predict the immunophenotype.

For accurate determination of immunophenotype, antibodies against lymphocyte markers are applied to tissue sections (immunohistochemistry), cytologic specimens (immunocytochemistry), or individual cells in a fluid medium (flow cytometry). Flow cytometric evaluation of cells obtained by needle aspiration is also feasible. For T-cells, markers include CD3 (pan T), CD4 (helper T), and CD8 (cytotoxic T); for B-cells, the markers are CD79a (Figure 32-6, B), CD20, and CD21. Increasingly, aberrant expression of CD molecules has been reported in canine lymphoma. In a study of 59 dogs with lymphoma, tumor cells from six dogs were positive for both T- and B-cell markers; however, a clonality assay (see later) revealed clonality either of the T-cell or the immunoglobulin receptor but not both. This indicates that in some cases, the malignant cells may co-express B- and T-cell markers.⁹³ Antibodies against these molecules are used to determine the immunophenotype; however, they also have potential utility as a therapeutic modality if tumor cells could be targeted using these antibodies.

Other Immunohistochemical and Immunocytochemical Assessments

Assessments of markers of multidrug resistance and apoptotic pathways (e.g., P-glycoprotein, p53, Bcl-2 proteins) have been evaluated in dogs with lymphoma.^{19,79,142,156a,156b} However, their clinical significance and utility await further evaluation.

Clonality Assays

Occasionally, diagnosis of lymphoma and differentiation of malignant versus benign proliferation of lymphocytes are not possible based on standard histologic and cytologic criteria. In these cases, advanced molecular analyses may be helpful to confirm a diagnosis. Clonality is the hallmark of malignancy; that is, the malignant cell population theoretically should be derived from expansion of a single malignant clone characterized by a particular DNA region unique to that tumor. For example, in a dog with T-cell lymphoma, all the malignant cells theoretically should have the same DNA sequence for the variable region of the T-cell receptor gene.

Likewise, in a dog with B-cell lymphoma, the tumor cells should have identical DNA sequences in the variable region of the immunoglobulin (Ig) receptor gene. Conversely, in reactive lymphocytosis, the cells are polyclonal for their antigen receptors. Using this knowledge, investigators have used PCR technology to amplify the variable regions of the T-cell and immunoglobulin receptor genes to detect the presence of clonal lymphocyte populations in dogs (see Figure 8-4 of Chapter 8). These techniques are reviewed in Chapter 8 and elsewhere.¹⁵⁰ In physician-based medicine, such assays of clonality are approximately 70% to 90% sensitive and have a false-positive rate of approximately 5%, and recent studies report similar rates in dogs. False-negative and false-positive results can occur with clonality assays. For example, cells from a dog with lymphoma may be negative for clonality if the clonal segment of DNA is not detected with the primers used, if the malignant cells are natural killer (NK) cells (rare), or if the malignant cells are present in too low a frequency to be detected. False positives occur rarely in some infectious diseases (e.g., ehrlichiosis and Lyme disease). In these cases, a diagnosis should be made only after considering the results of all the diagnostic tests, including histologic/cytologic evaluation, immunophenotyping, and clonality studies in conjunction with signalment and physical examination findings. These molecular techniques, although helpful for diagnosis, could also have utility in detecting early recurrence and in determining more accurate clinical stage and so-called “molecular remission rates” because they are more sensitive than standard cytologic assessment of peripheral blood, bone marrow, or lymph nodes (covered subsequently in section on treatment response).

Proteomics

Proteomics comprises, simplistically, methodologies that analyze the entire protein component or protein signature of cells (the proteome). Protein components of a cell (normal or malignant) change over time with upregulation and downregulation of gene expression in response to varied stimuli (e.g., growth factors, environmental cues). It may therefore be possible to use the field of proteomics to identify serum biomarkers of malignancy (i.e., cancer-specific protein markers) and to further analyze response to therapy or even to predict which therapies are appropriate for an individual patient's tumor. Although in its infancy in veterinary oncology, preliminary investigations of the proteome of dogs with lymphoma have been reported¹⁵⁷⁻¹⁶⁰; however, they have yet to reach the level of sophistication in which useful output would have an impact on clinical decision making.

Staging

After a diagnosis has been established, the extent of disease should be determined and categorized by the clinical stage of disease. The WHO staging system routinely used to stage dogs with lymphoma is presented in Box 32-1. Most dogs (>80%) are presented in advanced stages (III to IV). Diagnostic imaging and assessment of bone marrow involvement may be indicated for staging. The degree to which thorough staging is implemented depends on whether the result will alter the treatment plan, whether relevant prognostic information is gleaned, and whether the clients need to know the stage prior to initiating (or declining) a treatment plan. Additionally, when comparing different treatment protocols with respect to efficacy, consistent and similar staging diagnostics should be used to avoid so-called “stage migration,” which results when one staging methodology is more accurate than another.¹⁶¹ The impact of stage migration on prognosis should be considered when comparing different published outcomes.

Bone Marrow Evaluation

A bone marrow aspirate or biopsy (from proximal humerus or iliac crest) is recommended for complete staging and prognostication and is indicated in dogs with anemia, lymphocytosis, peripheral lymphocyte atypia, or other peripheral cytopenias. In one study of 53 dogs with lymphoma, 28% had circulating malignant cells and were considered leukemic, whereas bone marrow examination indicated involvement in 57% of the dogs.¹⁶² The presence of a few prolymphocytes and large lymphocytes with nucleoli in the circulation of dogs with lymphoma may indicate bone marrow involvement. It is important to remember these cells also can be seen with GI parasitism, immune-mediated hemolytic anemia, and other immune-mediated and infectious diseases. As discussed previously, tumor cells within the peripheral and bone marrow compartments can also be identified using clonality assays (PARR) that are more sensitive than routine microscopic examination in detecting malignant cells; however, the prognostic significance of the knowledge gained with more sensitive staging methodologies is yet to be determined. Although bone marrow evaluation may offer prognostically valuable information, it is not necessary to perform the procedure if the client is committed to treat regardless of stage.

Imaging

Evaluation of thoracic and abdominal radiographs may be important in determining the extent of internal involvement (Figure 32-7). Approximately 60% to 75% of dogs with multicentric lymphoma have abnormalities on thoracic radiographs, with one-third having evidence of pulmonary infiltrates (see Figure 32-3) and two-thirds having thoracic lymphadenopathy (sternal and tracheobronchial lymph nodes [see Figure 32-2]).^{97,98} Pulmonary infiltrates usually are represented by an interstitial and/or alveolar pattern; however, nodules (rarely) and bronchial infiltrates can also occur.¹⁶³ Pleural effusion may also be present. Cranial mediastinal lymphadenopathy is detected in 20% of dogs with lymphoma.^{97,163} Abdominal radiographs reveal evidence of involvement of medial iliac (sublumbar) and/or mesenteric lymph node, spleen, or liver in approximately 50% of cases. In the authors' practice, for the typical cases of canine multicentric lymphoma, imaging is limited to thoracic

• **FIGURE 32-7** Lateral radiographic projection of a dog with sternal and hilar lymphadenopathy due to lymphoma.

FIGURE 32-8 **A**, FLT-PET/CT image of a 3-year-old MN Hound cross illustrating FLT uptake in the peripheral nodes, bone marrow, kidneys, bladder, and spleen. **B**, FLT-PET/CT image of the same dog 3 weeks after his final dose of chemotherapy. The lymph nodes were small on CT with minimal FLT uptake on PET images. Note the persistent uptake in the bone marrow, kidneys, and bladder. (Reprinted with permission from Lawrence J, Vanderhoek M, Barbee D, et al: Use of 3'-deoxy-3'-[18F]fluorothymidine PET/CT for evaluating response to cytotoxic chemotherapy in dogs with non-Hodgkin's lymphoma, *Vet Radiol Ultrasound* 50:660–668, 2009.)

radiographs as there is no prognostic difference between dogs with stage III and IV disease (i.e., liver/spleen involvement), whereas the presence of cranial mediastinal lymphadenopathy is of prognostic significance (see [prognosis](#) section). However, if there are clinical signs attributable to abdominal disease or if complete staging is necessary (e.g., for clinical trial inclusion), further imaging of the abdomen is warranted. Abdominal ultrasonography can be important for obtaining ultrasound-guided intraabdominal samples for diagnosis. It may also be useful for the diagnosis of GI, abdominal nodal, and hepatosplenic lymphoma.¹²⁵ Ultrasonographic (including Doppler ultrasound) assessment of peripheral lymph nodes has also been explored¹²⁶; however, its clinical applicability is questionable because cytologic assessment of peripheral nodes is easy, inexpensive, and of higher diagnostic utility.

Advanced imaging modalities, including computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), or PET/CT imaging, are becoming more commonplace in veterinary practice and their utility is only now being determined.^{164–169} PET/CT imaging is the current standard of care for following and indeed predicting durability of treatment response in human patients with lymphoma, and both [18F]fluorothymidine (18FLT) PET/CT and [18F]fluoro-D-glucose (18FDG) PET imaging have been reported in dogs with lymphoma.^{164–166} 18FLT-PET/CT functional and anatomic imaging shows promise for the evaluation of response to cytotoxic chemotherapy in dogs with lymphoma and for predicting relapse before standard clinical and clinicopathologic confirmation (Figure 32-8).

Treatment of Multicentric Lymphoma

The therapeutic approach to a particular patient with lymphoma is determined by the stage and substage of disease, the presence or

absence of paraneoplastic disease, the overall physiologic status of the patient, financial and time commitment of the clients, and their level of comfort with respect to likelihood of treatment-related success and/or side effects.

Without treatment, most dogs with lymphoma will die of their disease in 4 to 6 weeks after diagnosis, although significant variability exists.¹¹⁴ With few exceptions, canine lymphoma is considered a systemic disease and therefore requires systemic therapy in order to achieve remission and prolong survival. The majority of canine multicentric lymphomas are intermediate to high grade, and, currently, histopathologic and immunophenotypic characterization has not played a significant role in determining the initial treatment protocol. It is hoped that in the near future, sufficient data will emerge to better tailor treatment protocols chosen for dogs with lymphoma based on these and other yet to be characterized parameters. That being said, systemic multiagent chemotherapy continues to be the therapy of choice for canine lymphoma. In general, combination chemotherapy protocols are superior in efficacy to single-agent protocols. Single-agent protocols result in lower response rates that are not as durable as combination chemotherapy, which is summarized in Table 11-2 in Chapter 11. In rare cases in which lymphoma is limited to one site (especially an extra-nodal site), the animal can be treated with a local modality such as surgery or radiation therapy (RT) as long as the client and clinician are committed to diligent reevaluation to document subsequent progression to systemic involvement, should it occur.

Multidrug Combination Protocols

Many chemotherapeutic protocols for dogs with lymphoma have been developed over the past 15 to 20 years (Table 32-3).^{91,170–190} Significant limitations arise when comparing efficacy studies in the

veterinary literature for the various published protocols. Few of these studies include sufficient numbers for adequate statistical power and even fewer compare treatment protocols in a randomized prospective fashion. In addition, staging, inclusion, and response criteria vary considerably between reports. Therefore evaluations of efficacy among various protocols are subject to substantial bias, making direct comparisons difficult and indeed precarious. A recurring theme in the concluding statement in most of these published protocols is some variation of “prospective randomized trials will be required to confirm these suggestive findings.” In an attempt to better standardize response criteria and outcome reporting of future trials, the Veterinary Cooperative Oncology Group (VCOG) has recently published response evaluation criteria (v1.0)¹⁶⁹ (see subsequent response evaluation section). The greatest obstacle to the performance of prospective randomized comparative lymphoma trials in veterinary oncology is financial;

that is, clinical trials are inherently costly, and because most of the known effective drugs are unregistered off-label human generic (i.e., off patent) drugs, the incentive for pharmaceutical-funded, sufficiently powered, randomized field trials is low, resulting in a general lack of comparative data.

Despite the plethora of available combination protocols, most are modifications of CHOP protocols initially designed for human oncologic use, and currently randomized prospective evidence does not exist to clearly recommend one over the other as long as the basic “CHOP” components are present. CHOP represents combinations of cyclophosphamide (C), doxorubicin (H, hydroxydaunorubicin), vincristine (O, Oncovin), and prednisone (P). Conventional CHOP-based chemotherapy induces remission in approximately 80% to 95% of dogs, with overall median survival times (MSTs) of 10 to 12 months. Approximately 20% to 25% of treated dogs will be alive 2 years after initiation of these protocols (Figure 32-9).

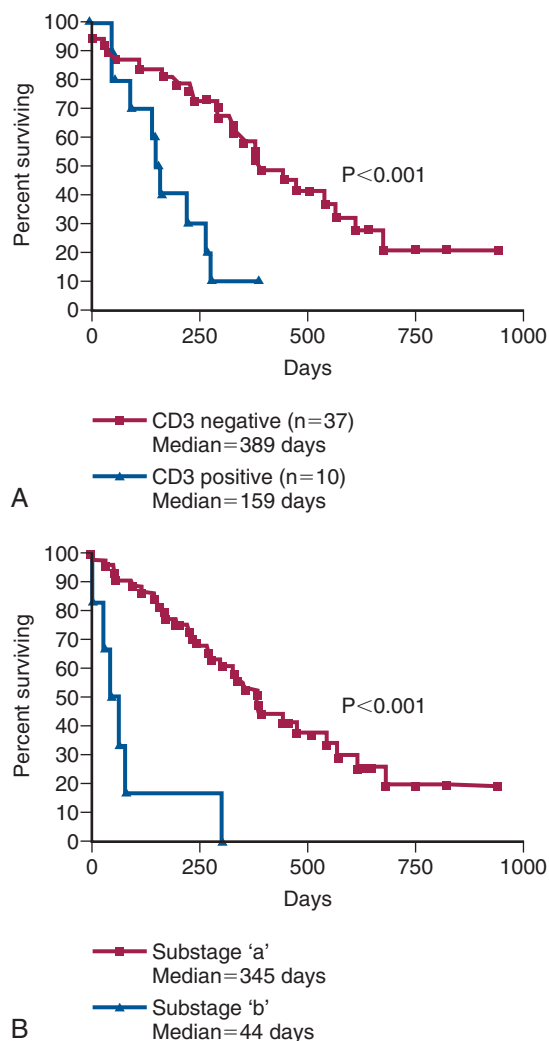

FIGURE 32-9 **A**, Kaplan-Meier survival duration estimates for a group of 55 dogs with lymphoma treated with an identical CHOP-based combination chemotherapy protocol. Dogs with CD3 immunoreactive (T-cell) lymphoma had significantly shorter survival durations. **B**, Kaplan-Meier survival duration estimates for a group of 55 dogs with lymphoma treated with an identical CHOP-based combination chemotherapy protocol at the University of Wisconsin. Dogs with substage *b* disease (i.e., clinically ill) had significantly shorter survival durations. (From Vail DM: *Hematopoietic tumors*. In Ettinger SJ, Feldman EC, editors: *Textbook of veterinary internal medicine*, ed 6, St. Louis, 2005, Elsevier.)

Response rates and duration of response vary according to the presence or absence of prognostic factors discussed subsequently in the section on prognosis in this chapter. The relative cost of the various protocols to the client depends on the drug(s) selected, the size of the animal, the frequency of administration, and the laboratory tests required to monitor adverse events and response.

Dogs responding to chemotherapy and undergoing complete remission are usually free of clinical signs associated with lymphoma and subsequently return to a very good quality of life. Treating dogs with lymphoma is initially gratifying because a high percentage enjoy a complete response. Most dogs tolerate chemotherapy well, and although dose reductions and treatment breaks

(“treatment holidays”) are not uncommonly required in individual cases, only a minority of dogs develop significant adverse events requiring hospitalization.^{191,192} Studies assessing client perceptions of medical treatment for cancer in general and lymphoma in particular report a positive experience; most owners feel treatment was worthwhile, that it resulted in improvement in the well-being of their pet, and that quality of life during treatment was good.^{193,194} Very few clients express regret about treating lymphoma using a multidrug protocol.

With lymphoma, the fundamental goals of chemotherapy are to induce a complete durable (>6 months) first remission (termed *induction*), to reinduce a remission when the tumor recrudesces (or the patient relapses) following achievement of a remission (termed *reinduction*), and, finally, to induce remissions when the cancer fails to respond to induction or reinduction using drugs not present in the initial protocols (termed *rescue*).

An unanswered question in the treatment of lymphoma has been whether long-term maintenance chemotherapy is useful following an initial course of aggressive induction chemotherapy lasting 6 months or less. Long-term maintenance chemotherapy has not been shown to be of significant value in humans with most forms of NHL; however, in humans, the initial induction course of chemotherapy is much more aggressive than that used in veterinary patients. Although no randomized prospective studies have been performed to address the therapeutic benefit of long-term maintenance chemotherapy in dogs, most comparisons of dogs treated with CHOP-based protocols do not show any clear advantage for a maintenance or consolidation phase after induction therapy.* Indeed, in most reports, dogs receiving shorter, less costly protocols that do not include a prolonged maintenance phase have comparable remission and progression-free survival (PFS) durations and appear to more readily achieve second remissions when they relapse following completion of chemotherapy than their counterparts receiving long-term maintenance. These data, taken together, suggest that maintenance therapy is not beneficial for most dogs with lymphoma. Until well-designed randomized prospective trials indicate otherwise, the author (DMV) prefers protocols that utilize an aggressive induction without maintenance.

Single-Agent Chemotherapy with Known Activity for Dogs with Lymphoma

The most effective, currently available chemotherapeutic agents for canine lymphoma include doxorubicin, L-asparaginase, vincristine, cyclophosphamide, and prednisone—most of which are represented to one degree or another in most first-line multiagent chemotherapy protocols. Other drugs that have documented activity are often considered second-line agents and include lomustine, vinblastine, actinomycin-D, mitoxantrone, mustargen, chlorambucil, methotrexate, dacarbazine (DTIC), 9-aminocamptothecin, ifosfamide, cytosine arabinoside, and gemcitabine. Of these, cytosine arabinoside,¹⁹⁹ ifosfamide,²⁰⁰ and gemcitabine²⁰¹ appear to have only minimal activity. With the exception of doxorubicin, induction therapy with single-agent chemotherapy does not typically result in durable remission durations when compared with standard combination protocols (see Table 11-2, Chapter 11). Incorporation of other standard cytotoxic drugs with single-agent activity into standard CHOP-based protocols has not resulted in significant gains, and most are reserved for subsequent rescue settings.

*References 53, 177, 180, 182-186, 188, 190, 195-198.

Overall Chemotherapy Recommendations for Multicentric Lymphoma (Author Preference)

Several factors should be considered and discussed with caregivers on a case-by-case basis when choosing the protocol to be used. These factors include cost, time commitment involved, efficacy, adverse event profiles, and experience of the clinician with the protocols under consideration.

Induction in Treatment-Naïve Patients

It is now clearly established that “standard of care” combination protocols used in dogs with lymphoma are essentially variations of “CHOP” protocols (see Table 32-3). Specific details regarding dose and timing of the CHOP protocol currently preferred by the author (DMV) are outlined in Box 32-2. This protocol does not have a maintenance therapy arm, and all treatments cease at 19 weeks, provided the animal is in complete remission. Although several other CHOP-based protocols include L-asparaginase either at

initiation or at varying times throughout the protocol, several studies suggest this does not result in clinically relevant increases in remission rate, speed of attaining remission, or first-remission duration, and therefore the author reserves its use for rescue situations.^{172,195,202,203}

If client or other considerations preclude a CHOP-based protocol, single-agent doxorubicin (30 mg/m², intravenous [IV], every 3 weeks for 5 total treatments) is offered along with a 4-week tapering oral prednisone regimen (same prednisone regimen in Box 32-2) as a less aggressive and less costly approach. The expected CR rate will range from 50% to 75%, with an anticipated median survival of 6 to 8 months.^{171,172,204,205} The addition of oral cyclophosphamide (50 mg/m² daily for 3 days starting on the same day as doxorubicin) to single-agent doxorubicin resulted in a numerically but not statistically superior outcome in a recent randomized trial²⁰⁵ comparing doxorubicin/prednisone with doxorubicin/cyclophosphamide/prednisone (PFS of 5.6 months versus 8.2 months, respectively). This trial was only powered to detect a threefold difference in PFS; therefore larger trials should be undertaken to confirm any benefit.

If clients are reticent to include IV medications, the author often recommends a protocol of oral lomustine (CCNU; 70 mg/m² by mouth [PO] every 3 weeks for 5 treatments) and prednisone. This protocol has been associated with short median remissions (40 days) in only one small case series²⁰⁶; however, in the author's experience, a subset of dogs have remained in remission for several months on this protocol when clients decline IV medication.

If financial or other client concerns preclude the use of systemic chemotherapy, prednisone alone (2 mg/kg PO, daily) will often result in short-lived remissions of approximately 1 to 2 months. In these cases, it is important to educate clients that, should they decide to pursue more aggressive therapy at a later date, dogs receiving single-agent prednisone therapy are more likely to develop multidrug resistance (MDR) and experience shorter remission and survival durations with subsequent combination protocols.²⁰⁷⁻²⁰⁹ This is especially true following long-term prednisone use or in dogs that have experienced a recurrence while receiving prednisone. Therefore the earlier that clients opt for more aggressive therapy, the more likely a durable response will result.

A CBC should be performed prior to each chemotherapy treatment. A minimum of 1500 neutrophils/μL (some oncologists use a cut-off of 2000 neutrophils/μL) and 50,000 platelets/μL should be present prior to the administration of myelosuppressive chemotherapy. If the neutrophil count is lower than 1500/μL, it is best to wait 5 to 7 days and repeat the CBC; if the neutrophil count has increased to more than 1500 cells/μL, the drug can be safely administered. A caveat to these restrictions is that for dogs presented prior to initiation of chemotherapy with low neutrophil and platelet counts due to bone marrow effacement, myelosuppressive chemotherapy is instituted in the face of cytopenias in order to clear the bone marrow of neoplastic cells and allow hematopoiesis to normalize.

In those breeds likely to have *MDR1* gene mutations (e.g., collies; see Chapter 11) and therefore to be at risk for serious chemotherapeutic toxicity,²¹⁰ the author will initiate a CHOP protocol out of sequence, beginning with non-*MDR1*-associated drugs, such as cyclophosphamide. This ensures treatment of the lymphoma while allowing sufficient time for analysis of *MDR1* gene mutations prior to initiating *MDR1* substrate drugs. No specific protocols have been scrutinized for treating dogs that are double-mutant for *MDR1*; however, if using *MDR1* substrate drugs, the author initiates at a 40% dose reduction. Subsequent dose modifications (increased or decreased dosage) can be implemented,

Box 32-2 Current Canine Lymphoma Protocol (UW-Madison-Short)

Week 1: Vincristine 0.7 mg/m² IV
Prednisone 2 mg/kg PO, q24hr
Week 2: Cyclophosphamide* 250 mg/m² IV
Prednisone 1.5 mg/kg PO, q24hr
Week 3: Vincristine 0.7 mg/m² IV
Prednisone 1.0 mg/kg PO, q24hr
Week 4: Doxorubicin[†] 30 mg/m² IV
Prednisone 0.5 mg/kg PO, q24hr
Week 6: Vincristine 0.7 mg/m² IV
Week 7: Cyclophosphamide* 250 mg/m² IV
Week 8: Vincristine 0.7 mg/m² IV

Week 19: Doxorubicin[†] 30 mg/m² IV

IV, Intravenous; PO, by mouth.

*Furosemide (1 mg/kg) is given IV, concurrent with cyclophosphamide to reduce incidence of sterile hemorrhagic cystitis.

[†]In dogs <15 kg in body weight, a doxorubicin dose of 1 mg/kg is substituted for 30 mg/m².

1. All treatments discontinued after week 19 if in complete remission (CR).
2. A complete blood count (CBC) should be performed prior to each chemotherapy. If neutrophil count <1500 (some use 2000), wait 5-7 days and repeat CBC.
3. If sterile hemorrhagic cystitis occurs on cyclophosphamide, discontinue and substitute chlorambucil (1.4 mg/kg PO) for subsequently scheduled cyclophosphamide injections.
4. For acute lymphoblastic leukemia (ALL): Administer L-asparaginase 400 IU/kg subcutaneously (SQ) with each vincristine injection, until a CR is achieved.

depending on adverse event levels observed, particularly neutrophil counts at nadir.

The Case for Treating T-Cell Lymphoma Differently

With some exceptions, multicentric T-cell lymphoma, when compared with multicentric B-cell lymphoma, is associated with similar initial response rates, but significantly lower response durability (e.g., PFS) following chemotherapy (including CHOP-based protocols).^{*} Additionally, the effectiveness of a single treatment of doxorubicin in the treatment of naïve dogs with lymphoma in one retrospective case series suggested a lower initial response rate for T-cell, compared with B-cell, immunophenotypes.²¹³ This has led many to question whether dogs diagnosed with T-cell lymphoma should be treated with standard CHOP-based protocols or with alternative protocols. This is a valid question; however, the answer remains elusive because adequately powered randomized controlled trials do not currently exist in the literature to show superiority for an alternate protocol in this scenario. A retrospective study of an L-asparaginase and MOPP (*M*, mechlorethamine; *O*, Oncovin; *P*, procarbazine; *P*, prednisone) protocol suggested improvement in PFS in dogs with either confirmed T-cell lymphoma or lymphoma with hypercalcemia and no immunophenotypic classification.²¹⁴ However, differences in determining PFS, response evaluation, and study population in this retrospective study did not definitively confirm superiority.²¹¹ Further, some have advocated early inclusion of lomustine (CCNU) into protocols for treating multicentric T-cell lymphoma based on moderate success of lomustine-based rescue protocols in dogs failing CHOP. As yet, no randomized trials have documented superiority with this approach. Ultimately, superior protocol development for T-cell lymphoma awaits careful, randomized, prospective trial assessment. Until such time, the author prefers to initiate CHOP-based induction and switch to lomustine-based rescue at the first sign of progression.

Treatment Response Evaluation for Lymphoma

VCOG has recently published response evaluation criteria (v1.0)¹⁶⁹ to standardize reporting of outcome results and comparisons among protocols for peripheral nodal disease. The most important of these outcome measures and the preferred temporal outcome criterion for assessing protocol activity is now considered to be PFS, which is defined as being from the time of treatment initiation until tumor progression or death from any cause. This brings veterinary outcome reporting more in line with human standards. Because the majority of dogs with lymphoma eventually experience recurrence following chemotherapy-induced remissions and because methodology for differentiating complete and partial responses is analysis dependent, PFS removes many sources of bias. Further, overall survival in published reports invariably includes patients who go on to receive varied rescue protocols that bias the overall result, making it a less comparable outcome. Widespread application of these standardized criteria should allow more suitable comparisons in the future.

Superior methods of detection of minimal residual disease (MRD) or early recurrence have been investigated in dogs with lymphoma and include advanced imaging and detection of

molecular and biologic markers of minimal disease. Advanced functional and anatomic imaging (i.e., PET/CT) are the current standard for assessing treatment response and early relapse of lymphoma in humans and have also been investigated in dogs (see Figure 32-8).^{164-166,168} As this technology becomes available to a broader veterinary population, its clinical application will surely increase. Molecular detection of MRD applies clonality and PCR techniques previously discussed in this chapter. Beyond diagnostic applications, these techniques have been applied to determine cytoreductive efficacy of various chemotherapeutic drugs and to document and predict early relapse in patients prior to more conventional methods.²¹⁵⁻²¹⁹ Regarding biomarkers of MRD, preliminary investigations have suggested serum lactate dehydrogenase activity,¹²⁰ thymidine kinase 1 activity,²²⁰ and serum C-reactive protein²²¹ may be candidates in the dog.

As we become more proficient at defining MRD, the pressing clinical question becomes how we use this information. Theoretically, such information could suggest when more aggressive therapy or alternative therapy should be instituted in patients who have not achieved a “molecular remission” or who are undergoing early relapse; however, until we determine what these interventions should be, their clinical utility remains theoretical.

Reinduction and Rescue Chemotherapy

Eventually, the majority of dogs that achieve a remission will relapse or experience recrudescence of lymphoma. This usually represents the emergence of tumor clones or tumor stem cells²²² (see Chapter 2) that are inherently more resistant to chemotherapy than the original tumor, the so-called MDR clones that either were initially drug resistant or became so following exposure to selected chemotherapy agents. Evidence suggests that in dogs with recurrent lymphoma, tumor cells are more likely to express the *MDR1* gene that encodes the protein transmembrane drug pump often associated with MDR.^{156a,156b,225} *MDR1* represents only one of the plethora of mechanisms that lead to drug-resistant disease (see Chapter 11). Other causes for relapse following chemotherapy include inadequate dosing and frequency of administration of chemotherapy, failure to achieve high concentrations of chemotherapeutic drugs in certain sites such as the CNS, and initial treatment with prednisone alone.

At the first recurrence of lymphoma, it is recommended that reinduction be attempted first by reintroducing the induction protocol that was initially successful, provided the recurrence occurred temporally far enough from the conclusion of the initial protocol (e.g., ≥ 2 months) to make reinduction likely. Attention must be given to the cumulative dose of doxorubicin that will result from reinduction, and baseline cardiac assessment, the use of cardioprotectants, alternative drug choices, and client education should all be considered. In general, the length of the reinduction will be half that encountered in the initial therapy; however, a subset of animals will enjoy long-term reinductions, especially if the dog completed the initial induction treatment protocol and was currently not receiving chemotherapy for several months when relapse occurred. Nearly 80% to 90% reinduction rates can be expected in dogs that have completed CHOP-based protocols and then relapse while not receiving therapy.^{185,226} The duration of a second CHOP-based remission in one report was predicted by the duration of the interval between protocols and the duration of the first remission.²²⁶

If reinduction fails or the dog does not respond to the initial induction, the use of so-called “rescue” agents or “rescue” protocols may be attempted. These are single drugs or drug combinations that are typically not found in standard CHOP protocols and are

NR, Not reported.

*Few of these protocols include sufficient numbers for adequate statistical power and fewer compare treatment protocols in a randomized prospective fashion. In addition, staging, inclusion, and response criteria vary considerably between protocols presented. Therefore evaluations of efficacy between the various protocols are subject to bias, making direct comparisons difficult and indeed precarious.

[†]Various temporal response endpoints were used, including disease-free interval, time to progression, and progression-free survival.

[‡]Prednisone often used concurrently.

withheld for use in the drug-resistant setting. The most common rescue protocols used in dogs include single-agent use or a combination of actinomycin D, mitoxantrone, doxorubicin (if doxorubicin was not part of the original induction protocol), dacarbazine (DTIC), temozolomide, lomustine (CCNU), L-asparaginase, mechlorethamine, vincristine, vinblastine, procarbazine, prednisone, and etoposide. Some rescue protocols are easy and convenient single-agent treatments, whereas others are more complicated (and expensive) multiagent protocols, such as MOPP. Overall rescue response rates of 40% to 90% are reported; however, responses are usually not durable, with median responses of 1.5 to 2.5 months being typical, regardless of the complexity of the protocol. A small (<20%) subset of animals will enjoy longer rescue durations. Table 32-4 provides a summary of canine rescue protocols and published results.²²⁷⁻²³⁸ Current published data from rescue protocols do not include sufficient numbers for adequate statistical power nor do they compare protocols in a randomized prospective fashion. Therefore evaluations of efficacy among various protocols are subject to substantial bias, making direct comparisons difficult and indeed precarious. Choice of a particular rescue protocol should depend on several factors, including cost, time commitment required, efficacy, toxicity, and experience of the clinician with the protocols in question. As the complexity of rescue protocols does not yet appear to be associated with significant gains in rescue durability, the author tends to choose simpler and less costly protocols (e.g., CCNU/L-asparaginase/prednisone) (Table 32-5). However, the use of multiple varied rescue protocols, switching as needed based on response, continues as long as clients are

comfortable with their dog's quality of life. This sequential application of several different rescue protocols can result in several months of extended survival with acceptable quality of life.

Strategies to Enhance Effectiveness of Therapy in Lymphoma

Despite the plethora of published chemotherapeutic protocols for dogs with lymphoma, it appears we have achieved as much as we can from currently available chemotherapeutics in standard settings. The 12-month median survival "wall" and the 20% to 25% 2-year survival rates have not improved dramatically. Further advances in remission and survival durations await the development of new methods of delivering or targeting traditional chemotherapeutic drugs, new generations of chemotherapeutic drugs, or novel nonchemotherapeutic treatment modalities. Mechanisms of avoiding or abrogating MDR, enhancing tumor apoptosis (programmed cell death), tumor ablation, and immune-system reconstitution, as well as novel immunomodulatory therapies for lymphoma, are all active areas of investigation in both human and veterinary medicine.

Mechanisms of Drug Resistance

Drug resistance can be inherent in cancer cells or develop following exposure to selected chemotherapeutic agents and often is associated with increased expression of members of the adenosine triphosphate (ATP)-binding cassette (ABC) transporter superfamily (e.g., P-glycoprotein pump), many of which efflux various

chemotherapeutic compounds from cells (see Chapter 11).²³⁹ P-glycoprotein is under the control of the *MDR1* gene. MDR has been reported in canine lymphoma following exposure to chemotherapy.^{156a,225,240} Expression levels of mRNA encoding the canine *MDR1* gene have been characterized in canine cell lines and lymphomas. Although expression of *MDR1* mRNA correlated with in vitro drug sensitivity, it did not correlate with in vivo doxorubicin sensitivity in dogs with lymphoma in this study. Additionally, quantitative analysis of mRNA for 10 different drug-resistance factors was performed in 23 dogs with lymphoma.²⁴¹ These dogs were divided into drug “sensitive” and “resistant” categories based on response to a CHOP-based protocol; however, significant differences in expression were not observed in this small study.

Altering Drug Pharmacokinetics

Methods of increasing the time that tumor cells are exposed to chemotherapeutics should theoretically enhance tumor killing. These methods could include long-term continuous infusions (impractical in many veterinary situations), increasing the frequency of treatments, or enhancing the circulation time of drugs used. In one study, dogs with lymphoma received lower dose doxorubicin weekly rather than a higher dose every 3 weeks (thereby decreasing C_{max} , which is associated with cardiotoxicity) in order to potentially increase the time of drug exposure.²⁴² No benefit was noted, and, in fact, remission rates were inferior. Studies evaluating pegylated long-circulating doxorubicin-containing liposome drug delivery systems in dogs with lymphoma have also been

performed.^{243,244} Although efficacy was established, enhancement of remission or survival durations over equivalent doses of native doxorubicin was not observed.

Treatment Approaches Using Immunologic or Biologic Agents

Monoclonal Antibody Approaches

In the past decade, enhanced durability of first remissions in humans with non-Hodgkin's B-cell lymphoma has been achieved primarily through the institution of monoclonal antibody (MAb)-based therapies (so-called R-CHOP protocols); the “R” refers to rituximab, a recombinant chimeric murine/human antibody directed against the CD20 antigen, a hydrophobic transmembrane protein located on normal pre-B and mature B lymphocytes. Following binding, rituximab triggers a host cytotoxic immune response against CD20-positive cells. Unfortunately, rituximab does not have therapeutic activity in dogs due to a lack of external recognition of a similar antigen on canine lymphoma cells and the inherent antigenicity of human-derived antibodies in dogs.^{245,246} Another immunotherapy approach involved MAb-231, a murine-derived anticancer MAb (IgG2a). It mediates antibody-dependent cellular cytotoxicity (ADCC) and complement-mediated cellular cytotoxicity (CMCC).²⁴⁷⁻²⁴⁹ It also prevented outgrowth of canine lymphoma xenografts in nude mice. In a noncontrolled clinical study of 215 dogs treated with CHOP-based chemotherapy and MAb-231, enhanced overall survival was observed; however, the antibody was removed from the commercial market in the mid-1990s without definitive randomized trials being performed. Several laboratories throughout the world are currently working to characterize and develop effective MAb therapies for use in dogs.

Antitumor Vaccine Approaches

Several antitumor vaccine approaches have been applied in dogs with lymphoma. A tumor vaccine extract using killed lymphoma cells combined with Freund's adjuvant was administered to a small number of dogs after remission induction with combination chemotherapy.²⁵⁰ Prolongation of median survival was noted in the treatment group; however, a subsequent study revealed that prolongation was likely due to the Freund's adjuvant.²⁵¹ An autologous killed lymphoma tumor cell vaccine has been intralymphatically administered to dogs placed in remission using a combination chemotherapy protocol, and, although modest gains were reported in remission times, no survival advantage was found.²⁵² An exploratory vaccine study targeting telomerase²⁵³ (see Chapter 14, Section D) and one using RNA-loaded CD40-activated B cells²⁵⁴ in dogs with lymphoma have also been conducted. These studies involved small numbers of nonrandomized patients and lacked controlled populations for comparison. In a randomized study of 60 dogs with lymphoma comparing CHOP-based chemotherapy with CHOP-based chemotherapy and a human granulocyte-macrophage colony-stimulating factor (GM-CSF) DNA cationic-lipid complexed autologous whole tumor cell vaccine, a small measure of immunomodulation was documented by delayed-type hypersensitivity; however, significant improvement in clinical outcome was not noted.²⁵⁵ Although little well-supported activity is reported to date with these immunomodulatory approaches, our basic understanding of methodologies is expanding.

Surgery

Most dogs with lymphoma have multicentric disease and therefore require systemic chemotherapy to effectively treat their disease.

However, surgery has been used to treat solitary lymphoma (early stage I) or solitary extranodal disease. Careful staging is necessary in such cases to rule out multicentric involvement prior to treating local disease.

The benefit of surgical removal of the spleen in dogs with massive splenomegaly remains unclear.^{82,83,256} In an older report, 16 dogs with lymphoma underwent splenectomy to remove a massively enlarged spleen and were subsequently treated with chemotherapy.²⁵⁶ Within 6 weeks of splenectomy, 5 of the 16 dogs died of disseminated intravascular coagulation (DIC) and sepsis. The remaining 11 dogs (66%) had a CR, and 7 dogs had a MST of 14 months. No staging or histologic information was provided, so the information appears of limited usefulness, although those with follow-up lived approximately 1 year. In two reports of indolent nodular lymphoma of the spleen (marginal zone lymphoma [MZL] and mantle cell lymphoma [MCL]), outcome was available on seven MZL cases, including three cases that did not receive adjuvant chemotherapy after surgery,^{82,83} and only one died of lymphoma following splenectomy. In a recent report of indolent lymphomas, four splenic lymphomas (three MZL and one MCL) underwent splenectomy alone and all survived greater than 1 year with none dying of their primary disease.⁸⁴ Splenectomy should be considered if the lymphoma is not documented in other sites following thorough staging, if lymphoma is an indolent form histologically, or if splenic rupture has occurred. Of note, no control population consisting of dogs that did not undergo splenectomy exists, so the natural history of indolent splenic lymphoma remains uncertain.

Radiation Therapy

Radiation therapy, although its use is limited in the treatment of lymphoma, may be indicated in selected cases.²⁵⁷ Indications are as follows:

1. Curative intent therapy for stage I lymph node and solitary extranodal disease (i.e., nasal, cutaneous, spinal lymphoma).
2. Palliation for local disease (e.g., mandibular lymphadenopathy, rectal lymphoma, mediastinal lymphoma where precaval syndrome is present, localized bone involvement).
3. Total body radiation combined with bone marrow or stem cell transplantation.
4. Whole or staged half-body RT following chemotherapy-induced remissions.

In the latter case, staged half-body irradiation sandwiched between chemotherapy cycles or following the attainment of remission by induction chemotherapy has been preliminarily investigated as a form of consolidation or maintenance.^{198,258-262} Radiation therapy was delivered to either the cranial or the caudal half of the dog's body in 4 to 8 Gy fractions, and following a 2- or 4-week rest the other half of the body was irradiated in a similar fashion. Although these preliminary investigations were not randomized, they suggest that RT applied when dogs are in either complete or partial remission is safe and warrants further investigation to determine if a significant therapeutic gain can be realized. A pilot study of low-dose (1 Gy) single-fraction total body irradiation in seven dogs with relapsed drug-resistant lymphoma, although safely applied, resulted in only partial nondurable (1 to 4 week) remissions.²⁶³

Total body irradiation (and/or ablative chemotherapy) for complete or partial bone marrow ablation followed by reconstitution with bone marrow or stem-cell transplant in dogs, although a recognized model in comparative research settings,^{264,265} is still in its early phases of development and application in clinical veterinary

practice.^{266,267} Because of the high cost, limited accessibility to relatively sophisticated equipment, and management requirements, these types of procedures are limited to preliminary investigations at a few centers. Currently, long-term results in significant numbers of treated cases have yet to be presented.

Treatment of Extranodal Lymphoma

In general, the veterinary literature suffers from a paucity of information on treating various extranodal forms of lymphoma in dogs, and our ability to predict outcome is thus limited. In general, it is recommended that, following extensive staging, in those cases where disease is shown to be localized to a solitary site, local therapies (e.g., surgery, local RT) can be used. In contrast, if multiple extranodal sites are involved or they are part of a more generalized process, systemic chemotherapy should be chosen.

Alimentary Lymphoma

Most dogs with alimentary lymphoma are presented with diffuse involvement of the intestinal tract, and involvement of local lymph nodes and liver is common. Chemotherapy in dogs with diffuse disease has been reported to be unrewarding for the most part^{47,268,269}; however, more aggressive CHOP-based protocols used extensively for multicentric lymphoma in dogs have resulted in durable remissions in a small subset of cases. Solitary alimentary lymphoma is rare in the dog; however, if the tumor is localized and can be surgically removed, results (with or without follow-up chemotherapy) can be encouraging.

Primary Central Nervous System Lymphoma

CNS lymphoma in dogs usually results from extension of multicentric lymphoma. However, primary CNS lymphoma (PCNSL) has been reported.¹⁰³⁻¹⁰⁵ If tumors are localized, local RT should be considered. Few studies have reported the use of chemotherapy. In one study, cytosine arabinoside (Ara-C) at a dosage of 20 mg/m² was given intrathecally; this treatment was combined with systemic chemotherapy and CNS radiation.¹⁰³ Overall, the response rates are low and of short duration (several weeks to months).

Cutaneous Lymphoma

Treatment of cutaneous lymphoma depends on the extent of disease. Solitary lesions may be treated with surgical excision or RT. Fractionated RT (to a total dose of 30 to 45 Gy) has been associated with long-term control.²⁷⁰ Diffuse cutaneous lymphoma is best managed with combination chemotherapy, although the rate and durability of response is generally less than in multicentric lymphoma. The most widely used protocols for epitheliotropic cutaneous T-cell lymphoma include CCNU (60 to 70 mg/m² PO, every 3 weeks) along with prednisone.^{271,272} Although response rates approach 80%, median remission is approximately 3 months; occasionally, durable remissions are encountered. The author has added L-asparaginase to this protocol (see Table 32-5), and although anecdotally it appears to improve response, comparative data are not available. Sporadic reports of other therapies for cutaneous lymphoma in small numbers of cases include the use of COAP (cyclophosphamide, vincristine [Oncovin], Ara-C, and prednisone),²⁷³ retinoic acid analogs (e.g., Accutane, etretinate),²⁷⁴ L-asparaginase and pegylated L-asparaginase,²⁷⁵ topical mechlorethamine (Mustargen),²⁷⁶ and recombinant human α -interferon.²⁷⁷ All of these reports involved small numbers of cases and resulted in limited response rates with short durations.

A form of cutaneous lymphocytic infiltration has recently been characterized as an indolent T-cell lymphoma based on clonality.¹³¹

It is associated with slow progression and long-term survival following corticosteroid management; however, it does have the potential to progress to high-grade lymphoma.

Prognosis

The prognosis for dogs with lymphoma is highly variable and depends on a wide variety of factors documented or presumed to affect response to therapy. Although rarely curable (<10% of cases), CRs and a good quality of life during extended remissions and survival are typical. Factors that have been shown to influence treatment response and survival are summarized in Tables 32-6* and 32-7.[†] The two prognostic factors most consistently identified are immunophenotype and WHO substage (see Figure 32-9). Many reports have confirmed that dogs with CD3-immunoreactive tumors (i.e., T-cell derivation) are associated with significantly shorter remission and survival durations.[‡] This holds true primarily for dogs with multicentric lymphoma because the immunophenotype of solitary or extranodal forms of lymphoma has not been thoroughly investigated with respect to prognosis. Additionally, it has been shown that dogs with B-cell lymphomas that express lower than normal levels of B5 antigen (expressed in 95% of nonneoplastic lymphocytes) also experience shorter remission and survival durations.⁵⁴ Recently, low levels of class II MHC expression on B-cell lymphoma predicted poor outcomes.²⁷⁹ Dogs presented with WHO substage *b* disease (i.e., clinically ill) also do poorly when compared with dogs with substage *a* disease.^{53,86,91,181,278} Dogs with stage I and II disease have a better prognosis than those dogs in more advanced stages (stage III, IV, and V).

Histologic grade (subtype) has been found to influence prognosis in some studies; however, our ability to predict outcome based on subtype is still quite limited. Dogs with lymphoma classified as intermediate or high grade (large cell, centroblastic, and immunoblastic) tend to respond to chemotherapy but can relapse early. Dogs with low-grade lymphomas (small lymphocytic or centrocytic) have a poorer response rate to chemotherapy, yet have a survival advantage over dogs with intermediate- and high-grade lymphomas (Figure 32-10) in that the disease may be more indolent. Several case compilations have documented that dogs with indolent lymphoma (e.g., MZL, MCL, T-zone) experience prolonged survivals, often in the absence of any or aggressive chemotherapy.⁸²⁻⁸⁴ Proliferative assays such as analysis of bromodeoxyuridine (BrdU) uptake, Ki67 antibody reactivity, and argyrophilic nucleolar organizer region (AgNOR) indices to measure proliferative activity of tumor cells have been shown to provide prognostic information in dogs treated with combination chemotherapy. Results of different studies are contradictory, however. In two trials, dogs having tumors with short doubling times, high AgNOR frequencies, or high Ki67 immunoreactivity had a better prognosis than those with tumors with long doubling times or low AgNOR frequencies.^{53,142} In other trials, the low-proliferating tumor groups were associated with a better prognosis.^{283,284} Additionally, in one trial, the proportion of tumor cells undergoing apoptosis was mostly predictive of remission duration.¹⁴²

The anatomic site of disease is also of considerable prognostic importance. Primary diffuse cutaneous, diffuse GI, hepatosplenic, and primary CNS lymphomas tend to be associated with a poor

(From Teske E, van Heerde P, Rutteman GR, et al: *Prognostic factors for treatment of malignant lymphoma in dogs*, J Am Vet Med Assoc 205:1722–1728, 1994.)

prognosis. Dogs with indolent cutaneous T-cell lymphocytic infiltration experience long-term survivals.¹³¹ Sex has been shown to influence prognosis in some studies.^{175, 181} Neutered females tend to have a better prognosis; male dogs may have a higher incidence of the T-cell phenotype, which may account for the poorer prognosis.

Reported biomarkers of prognosis, summarized in Table 32-7, include circulating levels of glutathione-S-transferase, thymidine kinase, lactate dehydrogenase, serum C-reactive proteins, and VEGF. Finally, one report suggests that a history of chronic inflammatory disease of several types predicts likelihood of early relapse.²⁹¹ These putative prognostic indicators require further confirmation in larger trials.

Lymphocytic Leukemia

Lymphocytic leukemia is typically defined as proliferation of neoplastic lymphocytes in bone marrow. Neoplastic cells usually originate in the bone marrow, but occasionally in the spleen, and may or may not be circulating in the peripheral blood. Although our ability to diagnose lymphocytic leukemias using flow cytometric and molecular diagnostic techniques has increased significantly in the past decade, little information on treatment and prognosis is available except for chronic lymphocytic leukemia (CLL). Differentiating between true leukemia and stage V lymphoma can be difficult and arbitrary and is often based on lack of significant lymphadenopathy, degree of blood and bone marrow involvement, and immunophenotypic characteristics.

Incidence, Risk Factors, and Etiology

Lymphocytic leukemia is more common than acute myeloid leukemia and myeloproliferative disorders (MPD), but the true incidence is unknown. German shepherd dogs and golden retrievers may be overrepresented.^{137,292} Lymphocytic leukemia can occur in dogs of any age but typically occurs in middle-aged to older dogs (mean of 7 to 10 years); CLL usually occurs in older dogs (mean of 10 years).^{137,280,292,293} A significant sex predilection is not reported. As with lymphoma, the etiology of lymphocytic leukemia is for the

• **TABLE 32-6** Prognostic Factors for Lymphoma in Dogs

FACTOR	STRONG ASSOCIATION	MODEST ASSOCIATION REQUIRING FURTHER INVESTIGATION	COMMENTS	REFERENCES
WHO clinical stage		X	Stage I/II—favorable. Stage V with significant bone marrow involvement—unfavorable.	170, 204, 278
WHO clinical substage	X		Substage b (clinically ill)—associated with decreased survival.	53, 86, 91, 181, 278
Histopathology	X		High-grade/medium-grade—associated with high response rate but reduced survival. The indolent lymphomas generally experience prolonged survivals, often in the absence of systemic therapy.	82-84, 86, 87, 209
Immunophenotype	X		T-cell phenotype associated with reduced survival. Low MHC II expression on B-cell associated with reduced survival.	53, 54, 86, 88, 91, 209, 279
Flow cytometric characteristics of peripheral blood	X		Includes combined size and immunophenotypic analysis.	280
Sex		X	Some studies suggest females have a favorable prognosis.	175, 181
Anemia	X		Presence of anemia diminishes prognosis.	209, 281, 282
Molecular assessment of minimal residual disease (e.g., PARR)		X	Likely to become much more important when more “curative” therapeutic approaches are developed and instituted.	217-219
Measures of proliferation		X	Contradictory reports exist.	53, 142, 283, 284
Prolonged steroid pretreatment	X		Most reports suggest previous steroid use shortens response durations; however, length of exposure necessary is unknown.	207, 208
P-glycoprotein expression (drug resistance factors add)		X	May be associated with poor response rates and shortened remissions	223-225
Cranial mediastinal lymphadenopathy	X		Large compilation of cases reports shorter remission and survival durations.	97
Anatomic location	X		Leukemia, diffuse cutaneous and alimentary, hepatosplenic forms associated with unfavorable prognosis	See text for extra nodal sites
Chemotherapy-induced hematologic toxicity		X	Dogs experiencing grade III/IV neutropenia have prolonged first remission durations.	285

PARR, PCR for antigen receptor gene rearrangement.

• **TABLE 32-7** Circulating (Serum/Plasma) Biomarkers as Prognostic Indices in Dogs with Lymphoma

BIOMARKER	COMMENTS	REFERENCES
Lactate dehydrogenase activity	Increased activity predicted early recurrence.	120
Thymidine kinase activity	Increases associated with diminished prognosis.	220, 286
Serum VEGF levels	Small study suggests pretreatment levels predictive of remission duration.	119, 287
Glutathione-S-transferase	Increases associated with diminished prognosis.	288
Hypercalcemia	Negative factor if associated with T-cell subtype and reduced renal function.	91, 289, 290
Serum cobalamine	Hypocobalaminemia associated with poor outcome.	290
Serum C-reactive protein	Although it may be used to characterize remission status, variable levels preclude utility.	221

(Wright's stain, $\times 60$ objective.)

most part unknown. Genetic factors likely play a role and have been compared between dogs and humans.¹⁶ Retroviruses have been implicated in diverse animal species such as cats, cattle, fish, snakes, birds, rodents, nonhuman primates, and humans; however, there is no proven evidence implicating a retroviral cause in dogs. In humans, acute lymphocytic leukemia (ALL) has been associated with genetic factors and exposure to radiation, benzene, phenylbutazone, and antineoplastic agents. Extrapolation of predisposing factors across species is not warranted; in fact, etiologic factors in dogs may be quite different from those for humans given the difference in the predominant immunophenotype of the neoplastic cells (see later).

Pathology and Classification

Lymphocytic leukemias can be subdivided based on cell size, maturity, genetic aberrations, microRNA expression, and immunophenotype.* The simplest classification divides leukemia into two groups: chronic (small cells with a mature cytologic phenotype) and

acute (large cells with an immature cytologic phenotype). Immunophenotypic assessment using flow cytometric and molecular assays can further characterize these two major subtypes; however, some discordance exists in the veterinary literature.

Three primary subtypes of CLL are reported in dogs, based primarily on immunophenotyping^{137,280,293}: (1) T-CLL, which is the most common form, with cells in the majority of cases being CD8⁺ granular lymphocytes; (2) B-CLL, which is the next most common subtype; and (3) atypical CLL, which represents a combination of immunophenotypes (CD3⁺, CD8⁺; CD3⁺, CD4⁺, CD8⁺; CD3⁺, CD4⁺, CD8⁺; and CD3⁺ + CD21⁺). This is in contrast to CLL in humans, which is primarily a disease of B-cells. In CLL, lymphocytes often are indistinguishable morphologically from normal small lymphocytes (Figure 32-11) and have a low rate of proliferation; accumulation of lymphocytes likely results from their prolonged lifespan.

The immunophenotype of ALL typically is B-cell (CD21⁺, CD3⁺, CD4⁺, CD8⁺), although a smaller percentage (<10%) are of T-cell

*References 16, 137, 150, 280, 292-294.

*Note that either CD21 or CD79 can be used for assessing B-cell lineage in this context.

origin (CD3⁺, CD4⁻, CD8⁻, CD21⁻).¹³⁷ In general, these cells tend to be intermediate-sized or large cells with moderate amounts of basophilic cytoplasm. Perhaps the most distinguishing feature of lymphoblasts is the nuclear chromatin pattern, which typically is more condensed than the chromatin in myeloblasts. Lymphoblasts are larger than neutrophils, have a high nuclear:cytoplasmic ratio, and contain blue cytoplasm that in some cases is intensely basophilic (see Figure 32-11). Nucleoli, although present, are less prominent in lymphoblasts than in myeloblasts. Nevertheless, these cells cannot be distinguished easily from blast cells of other hematopoietic lineages, and identification of lineage-specific markers by immunocytochemical or flow cytometric analysis is required to ascertain the lineage. If the cells express CD34, a stem cell marker, an acute phenotype is implied^{137,280}; however, both myeloid and lymphoid lineages express CD34, and our ability to differentiate ALL from acute myeloid leukemia (AML) relies on detection of other markers, including T- and B-cell markers and myeloperoxidase, a myeloid marker.

History and Clinical Signs

Dogs with CLL are often asymptomatic, but some owners report lethargy and decreased appetite. Mild lymphadenopathy and splenomegaly may be present, although late in the disease splenomegaly may be marked.²⁹⁵ The white blood cell (WBC) count is usually greater than 30,000 cells/ μ L but can vary from normal to greater than 100,000 cells/ μ L because of an increase in circulating mature lymphocytes. Lymphocytosis is persistent and granulocytes are usually present in normal numbers. Other than lymphocytosis, hemograms of dogs with CLL tend to have few abnormalities when lymphocytes are less than 30,000/ μ L.^{137,280,293} In some dogs, the disease is identified incidentally when the animal is undergoing evaluation for an unrelated problem. Mild anemia, neutropenia, and thrombocytopenia are common but may become marked as the disease progresses and lymphocyte counts increase above 30,000/ μ L. Despite the well-differentiated appearance of the lymphocytes in CLL, these cells may function abnormally. Paraneoplastic syndromes include monoclonal gammopathies, immune-mediated hemolytic anemia, pure red cell aplasia, and, rarely, hypercalcemia.^{296,297} In one report of 22 dogs with CLL, 68% had monoclonal gammopathies (usually IgM or IgA).²⁹⁶ The immunophenotypes were not reported, but a monoclonal gammopathy would be more likely to occur in B-CLL.

Dogs with ALL usually are presented with clinical signs of anorexia, weight loss, and lethargy. Splenomegaly is typical and other physical abnormalities may include hemorrhage, lymphadenopathy, and hepatomegaly.²⁹⁸ Infiltration of bone marrow by neoplastic lymphoblasts may be extensive, resulting in significant depression of normal hematopoietic elements or myelophthisis.^{137,280,292,298,299} Anemia, neutropenia, and thrombocytopenia are typically much more severe than with CLL and may become life threatening. Infiltration of extramedullary sites such as the CNS, bone, and GI tract may also occur and can result in neuropathies, bone pain, and GI signs, respectively.

Diagnostics and Clinical Staging

Consideration of signalment, history, physical findings, and morphologic appearance and immunophenotype of cells is essential in making an accurate diagnosis. It is helpful to know the profile of lymphocyte subsets in the peripheral blood of normal dogs to determine if a particular subset has expanded. Approximately 80% of circulating lymphocytes in normal dogs are T-cells, and about 15% are B-cells. NK cells and double-negative (CD4⁻, CD8⁻) T-cells

constitute the remaining fraction. In the T-cell fraction, helper T-cells (CD4⁺) outnumber cytotoxic T-cells (CD8⁺).²⁹⁶ Lymphocytic leukemia should be a consideration if atypical lymphocytes are in circulation, the immunophenotype of the lymphocytes in circulation is homogenous as determined by flow cytometric analysis, a phenotype typically present in low frequency has increased, or if clonality is documented (e.g., by PARR analysis). Other differential diagnoses for lymphocytosis include infectious diseases, such as chronic ehrlichiosis, postvaccinal responses in young dogs, IL-2 administration, and transient physiologic or epinephrine-induced lymphocytosis. In some cases, reactive and neoplastic lymphocytosis are difficult to distinguish.

Expansion of neoplastic lymphocytes in bone marrow is the hallmark of ALL and, in most cases, CLL. Careful examination of peripheral blood and bone marrow by an experienced cytopathologist is important in establishing a diagnosis of lymphoid leukemia; in cases of marked lymphocytosis with atypia, peripheral blood can be used for analysis of immunophenotype and clonality, and examination of bone marrow is not essential. If diagnostic bone marrow cannot be adequately obtained by aspiration, bone marrow core biopsy should be performed. In ALL, lymphoblasts predominate in the bone marrow and are also present in peripheral blood, and other lineages are decreased. In B- and T-cell CLL, the lymphocytes are small mature cells that occur in excessive numbers in bone marrow ($\geq 30\%$ of all nucleated cells) early in the disease.²⁹⁵ In T-CLL, lymphocytes may contain pink granules. Infiltration becomes more extensive as the disease slowly progresses, and eventually the neoplastic cells replace normal marrow.

A separate clinical staging system has not been developed for lymphoid leukemia. Currently, all dogs with leukemia are classified as stage V based on the WHO Staging System for lymphoma as presented in Table 32-2.

Treatment of Chronic Lymphocytic Leukemia

Because of the indolent and often asymptomatic nature of CLL, the decision to treat is often based on the clinical and laboratory findings in the individual dog. Most oncologists recommend active surveillance (monthly or bimonthly physical examination and CBC) over active therapy for patients when CLL is identified incidentally, there are no accompanying clinical signs, and other significant hematologic abnormalities are not identified. If the animal is significantly anemic or thrombocytopenic, is showing evidence of significant lymphadenopathy or hepatosplenomegaly, or has an excessively high lymphocyte count (e.g., $>60,000/\mu$ L), therapy should be instituted. The definition of "excessively high" varies among oncologists, and a standard has not been established in veterinary medicine. The author (DMV) prefers to base treatment decisions on the presence of significant constitutional signs and peripheral cytopenias. Currently, the most effective drug available for treatment of CLL is chlorambucil.²⁹⁵ Chlorambucil is given orally at a dose of 0.2 mg/kg or 6 mg/m² PO once daily for 7 to 14 days; the dose can then be reduced to 0.1 mg/kg or 3 mg/m² PO daily. For long-term maintenance, a dose of 2.0 mg/m² every other day can be used. The dose is adjusted based on clinical response and bone marrow tolerance. Oral prednisone is used concurrently with chlorambucil at doses of 1 mg/kg daily for 1 to 2 weeks, then 0.5 mg/kg every other day thereafter. The addition of vincristine or the substitution of cyclophosphamide for chlorambucil has been advocated in animals that do not respond to chlorambucil.

Treatment of CLL is primarily palliative with rare complete remissions. Owing to the indolent nature of this disease, however, survival times have been in the range of 1 to 3 years with a good quality of life.^{295,300} The phenotypic expression of CLL is usually stable over months to years. However, the disease may evolve into an acute phase, and some dogs will develop a form of lymphoma that is rapidly progressive and characterized by the presence of pleomorphic immunoblasts; in humans, this is termed *Richter's syndrome*.³⁰¹ The prognosis for response to treatment is poor for this form of lymphoma.

Treatment of Acute Lymphoblastic Leukemia

Much of the morbidity in dogs with ALL results from effacement of bone marrow (myelophthisis) and subsequent life-threatening peripheral cytopenias. Neutropenia, thrombocytopenia, and anemia may be severe. Patients often require supportive therapy, such as fresh whole-blood transfusions, broad-spectrum antibiotics, fluid therapy, and nutritional support. Careful monitoring for sepsis, hemorrhage, and DIC is important. Specific treatment of ALL requires aggressive chemotherapy. Consistently efficacious protocols for ALL have not been developed in veterinary medicine, and there are few published reports. CHOP-based protocols, similar to those used for lymphoma (see Table 32-4), have been used by the author (DMV) for dogs with ALL; however, responses and durability of response are generally disappointing. The standard of care in humans with acute leukemia generally involves bone marrow ablative treatments with stem cell or marrow replacement, a protocol not generally available in veterinary oncology.

Prognosis

In general, CLL is a slowly progressive disease, and some animals will not require therapy for some time after diagnosis; one dog was reported to survive almost 2 years without treatment.³⁰² For those dogs that are treated, normalization of lymphocyte counts can be expected in 70% of cases. In one report of 17 dogs treated with vincristine, chlorambucil, and prednisone, MST was approximately 12 months with an expected 30% survival at 2 years.²⁹⁵ In larger compilations of cases that include immunophenotypic analysis, treatment protocols were poorly documented, although most received chlorambucil and prednisone; in 43 dogs with follow-up, for dogs with T-CLL, B-CLL, and atypical CLL, median survival was 930, 480, and only 22 days, respectively.²⁹³ In this group of dogs, young age and anemia were also associated with a poor prognosis. In another series with limited treatment information, dogs with CLL of a CD8⁺ immunophenotype that presented with less than 30,000 lymphocytes/ μ L or greater than 30,000 lymphocytes/ μ L had median survivals of 1098 and 131 days, respectively.

Prognosis for dogs with ALL is generally very poor. In a study of 21 dogs treated with vincristine and prednisone, the dogs achieving complete or partial remission (29%) had a MST of 120 days, and few dogs survived longer than 8 months with that protocol.²⁹⁸ In one report of 46 cases of ALL with a CD34⁺ phenotype, dogs had a median survival of 16 days (ranged from 3 to 128 days), even though the majority received a CHOP-based treatment protocol.²⁸⁰ Additionally, dogs with B-cell ALL (CD21⁺) in which the lymphocytes were large cells (forward scatter lymphocyte/forward scatter neutrophil ratio of >0.58 by flow cytometric analysis) had a median survival of only 129 days, independent of treatment protocol.²⁸⁰

■ SECTION B

Feline Lymphoma and Leukemia

DAVID M. VAIL

Lymphoma

The lymphomas (malignant lymphoma or lymphosarcoma) are a diverse group of neoplasms that have in common their origin from lymphoreticular cells. They usually arise in lymphoid tissues such as lymph nodes, spleen, and bone marrow; however, they may arise in almost any tissue in the body. Lymphoma is one of the most common neoplasms seen in the cat.

Incidence

Epidemiologic reports prior to 1990 suggested that lymphoma accounted for 50% to 90% of all hematopoietic tumors in the cat,^{1,2} and since hematopoietic tumors (lymphoid and myeloid) represent approximately one-third of all feline tumors, it was estimated lymphoid neoplasia accounted for an incidence of 200 per 100,000 cats at risk.³ In one series of 400 cats with hematopoietic tumors, 61% had lymphoma and 39% had leukemias and MPDs, of which 21% were categorized as undifferentiated leukemias, most likely myeloid in origin.⁴ However, a significant change in the epidemiology and characteristics of lymphoma in cats coincides with the widespread integration of clinically relevant feline leukemia virus (FeLV) diagnostic assays and affected animal elimination regimens of the late 1970s and 1980s and was further enhanced by the commercially

available FeLV vaccines appearing in the late 1980s (see the later section on viral etiology). The decline in FeLV-associated lymphoma was mirrored by a decline in the overall prevalence per year of FeLV positivity in cats tested as characterized by reports, including the Tufts Veterinary Diagnostic Laboratory from 1989 to 1997,^{5,6} and by the Louwerens group, who reported a decline in FeLV association in over 500 cases of lymphoma in cats presenting to the University of California at Davis veterinary teaching hospital.⁷ In these reports, FeLV antigenicity declined to represent only 14% to 25% of cats presenting with lymphoma. Importantly, Louwerens' study revealed that despite a sharp drop in FeLV-associated lymphoma, the overall prevalence of lymphoma in cats is increasing. The increased prevalence appears due to an increase in the number and relative frequency of the alimentary (and in particular the intestinal) anatomic form of lymphoma in the species. This is supported by an epidemiologic survey of 619 cases of feline intestinal lymphoma; 534 (86%) were from the 20 years following 1985 and only 14% were from cases diagnosed in the 20 years prior to 1985.⁸ The true annual incidence rate for lymphoma in cats is currently unknown. With respect to feline pediatric tumors, a study in the United Kingdom ($n = 233$ pathology specimens) found that 73 (31%) represented hematopoietic tumors, of which 51 (70%) were lymphoma—note that FeLV status was unavailable for this compilation of cases.⁹

The typical signalment for cats with lymphoma cannot be uniformly stated as it varies widely based on anatomic site and FeLV status and therefore will be discussed individually under site-specific discussions. In general, based on two large compilations ($n = 700$) of cases in North America,^{5,7} Siamese cats appear overrepresented and although a 1.5:1 male to female ratio was observed in one, no association with sex or neutering status was observed in the other. In a large compilation of Australian cases, male cats and the Siamese/oriental breeds were overrepresented,¹⁰ and similar breed findings have been observed in North America, although similar sex predilections have not been found. Within the Siamese/oriental breeds, there appears to be a predisposition for a

mediastinal form that is not FeLV associated and represents a younger population (median of 2 years).

Etiology

Viral Factors

FeLV was the most common cause of hematopoietic tumors in the cat in the so-called “FeLV era” of the 1960s through the 1980s when approximately two-thirds of lymphoma cases were associated with FeLV antigenemia. Several studies have documented the potential molecular means by which FeLV can result in lymphoid neoplasia (see Chapter 1, Section C). As one would predict, along with a shift away from FeLV-associated tumors came a shift away from traditional signalment and relative frequency of anatomic sites. This is also supported outside of North America by similar signalment and anatomic frequency data observed in Australia where FeLV infection is quite rare.^{10,11} The median age of approximately 11 years now reported in North America is considerably higher than the median ages of 4 to 6 years reported in the FeLV era.^{1,2,5-7} The median age of cats within various anatomic tumor groupings has not changed, and anatomic forms traditionally associated with FeLV such as the mediastinal form still occur in younger, FeLV antigenemic cats. Similarly, the alimentary form occurs most often in older, FeLV-negative cats. Table 32-8 presents an overview of the characteristics, including FeLV antigenemic status, of the various anatomic sites of lymphoma in cats. As our ability to interrogate FeLV associations on a molecular basis has improved (e.g., PCR amplification and fluorescent in-situ hybridization), several reports exist defining the role or potential role of FeLV in cats with and without FeLV antigenemia.¹²⁻¹⁷ Collectively, these studies indicate FeLV proviral insertion exists in a significant proportion of feline lymphoma tissues and is more common in those of T-cell origin, particularly the thymic and peripheral lymph node anatomic forms. They also suggest that several common FeLV integration sites exist.

There is also evidence that feline immunodeficiency virus (FIV) infection can increase the incidence of lymphoma in cats.¹⁸⁻²⁷ In contrast to the direct role of FeLV in tumorigenesis, most evidence

• **TABLE 32-8** General Characteristics of the Most Commonly Encountered Anatomic Forms of Lymphoma in Cats*

ANATOMIC FORM [†]	RELATIVE FREQUENCY	MEDIAN AGE (YEARS)	FeLV ANTIGENEMIC	B-CELL	T-CELL	GENERAL PROGNOSIS
Alimentary/Gastrointestinal [‡]						
Small cell/low grade	Common	13	Rare	Rare	Common	Good
Large cell/intermediate grade	Moderate	10	Rare	Common	Rare	Poor
Nasal	Uncommon	9.5	Rare	Common	Uncommon	Good
Mediastinal	Uncommon	2-4	Common	Uncommon	Common	Poor to fair
Peripheral nodal	Uncommon	7	Uncommon	Moderate	Moderate	Fair to poor
Laryngeal/tracheal	Rare	9	Rare	ID	ID	Good to fair
Renal	Rare	9	Rare	Common	Uncommon	Poor to fair
CNS	Rare	4-10	Rare	ID	ID	Poor
Cutaneous	Rare	10-13	Rare	Rare	Common	Fair
Hepatic (pure)	Rare	12	Rare	Uncommon	Common	Poor

FeLV, Feline leukemia virus; ID, insufficient data; CNS, central nervous system.

Common = >50% of clinical presentations; moderate = 20%-50% of clinical presentations; uncommon = 5%-20% of clinical presentation; rare = <5% of clinical presentations.

*Data may include overlap or mixing of sites and represents the post-FeLV era.

[†]As the primary site of presentation, rather than extension or progression.

[‡]Includes those reported as “intraabdominal” in which intestinal is a documented component.

points toward an indirect role for FIV secondary to the immunosuppressive effects of the virus. Shelton¹⁸ determined that FIV infection alone in cats was associated with a fivefold increased risk for development of lymphoma. Coinfection with FeLV will further potentiate the development of lymphoproliferative disorders. Experimentally, cats infected with FIV have developed lymphoma in the kidney, alimentary tract, liver, and multicentric sites. FIV-associated lymphoma is more likely that of the B-cell immunophenotype rather than the T-cell predominance associated with FeLV. It has been suggested that FIV infection may be associated more commonly with alimentary lymphoma of B-cell origin,^{28,29} and this may be related to chronic dysregulation of the immune system or the activation of oncogenic pathways; however, FIV antigenemia was only rarely associated with alimentary lymphoma in other large compilations of cases.^{5,30-33}

Genetic and Molecular Factors

As discussed earlier in Section A, recent advances in molecular cytogenetics (see Chapter 1, Section A, and Chapter 8), including gene microarray techniques, have and are currently being applied to investigations of chromosomal aberrations in veterinary species with lymphoma. Indeed a predisposition of the oriental cat breeds to develop lymphoma suggests a genetic predisposition and indicates heritable risk.^{7,10} Altered oncogene/tumor suppressor gene expression, epigenetic changes, signal transduction, and cell death-pathway alterations are common in lymphomas of humans and are likely also involved in the cat. Several genetic factors have already been discussed as they relate to FeLV associations. Additionally, *N-ras* aberrations have been implicated, although they are rare in cats.³⁴ Furthermore, telomerase activity (see Chapter 2) has been documented in feline lymphoma tissues.^{35,36} Alterations in cellular proliferation and in cell-cycle and death (apoptosis) pathways, in particular the cyclin-dependent kinase cell-cycle regulators and the Bcl-2 family of proapoptotic and antiapoptotic governing molecules, have also been implicated in feline lymphoma.³⁷⁻³⁹

Environmental Factors

Evidence for exposure to environmental tobacco smoke (ETS) as a risk factor for lymphoma in humans has prompted investigations in cats. In one report, the relative risk of developing lymphoma in cats with any exposure to ETS and with 5 or more years of exposure to ETS was 2.4 and 3.2, respectively.⁴⁰ A large European study documenting an association between proximity of waste management and cancer in dogs failed to show increased risk in cats.⁴¹

Immunosuppression

Immune system alterations in the cat such as those accompanying FIV infection has been implicated in the development of lymphoma.^{18-20,25} As is the case in immunosuppressed human organ transplantation patients, two reports of immunosuppressed feline renal transplant recipients document increased risk of lymphoma following transplant and associated immunosuppressive therapy.^{42,43} In both studies, nearly 10% of transplanted cats developed *de novo* malignant lymphoma.

Chronic Inflammation

Although definitive proof is lacking, there is a growing body of indirect evidence to suggest that lymphoma can be associated with the presence of chronic inflammation, which theoretically could be the case with intestinal and nasal lymphoma. In particular, an association has been suggested between intestinal lymphoma and inflammatory bowel disease^{7,44-46}; however, others have not found

support for this concept.⁴⁷ Additionally, an association between gastric *Helicobacter* infection and gastric MALT lymphoma in cats is suggested in one study, and because this is a recognized syndrome in humans, it warrants further investigation.^{47a}

Diet and Intestinal Lymphoma

Although no direct evidence exists, a link between diet and the development of intestinal lymphoma in cats has been suggested.⁷ Support is offered by the relative and absolute increase in the alimentary form of lymphoma in the past 20 years and the fact that several dietary modifications in cat food have occurred in a similar timeframe in response to diseases, such as urinary tract disease. Further investigation is warranted to prove or disprove such assertions.

Pathology and Natural Behavior

Lymphoma can be classified based on anatomic location and histologic and immunophenotypic criteria; often, the two are intimately associated because certain histologic and immunophenotypic types are commonly associated with specific anatomic locations necessitating discussions within the individual anatomic categories that follow. The largest compilation of feline cases subjected to rigorous histologic classification was reported by Valli and others⁴⁸ using the NCI WF. WHO has also published a histologic classification system that uses the REAL system as a basis for defining histologic categories of hematopoietic tumors of domestic animals.⁴⁹ This system incorporates both histologic criteria and immunohistologic criteria (e.g., B- and T-cell immunophenotype). Regarding anatomic location, as discussed previously, a profound change in presentation, signalment, FeLV antigenemia, immunophenotype, and frequency of anatomic sites has occurred in cats with lymphoma in the “post-FeLV” era (see Table 32-8). Because of this shift, characteristics of feline lymphoma discussed in this chapter will be primarily limited to reports collected from cases presenting after 1995.

Several anatomic classifications exist for lymphoma in the cat, and some categorize the disease as mediastinal, alimentary, multicentric, nodal, leukemic, and individual extranodal forms. Others have combined various nodal and extranodal forms into categories of atypical, unclassified, and mixed, and others have combined intestinal, splenic, hepatic, and mesenteric nodal forms into one category termed *intraabdominal*. Some discrepancies in the discussion of frequency will inevitably result from the variations in classification used in the literature. The relative frequency of anatomic forms and their associated immunophenotype may also vary with geographic distribution and may be related to genetic and FeLV strain differences, as well as prevalence of FeLV vaccine use.

Alimentary/Gastrointestinal Lymphoma

Alimentary/GI lymphoma can present as a purely intestinal infiltration or a combination of intestinal, mesenteric lymph nodes and liver involvement. The tumors can be solitary but more commonly diffuse throughout the intestines. Some reports limit the alimentary form to GI involvement with or without extension to the liver. Lymphoma is the most common tumor type found in the intestines of cats, representing 55% of cases in an epidemiologic survey of 1129 intestinal tumors in the species.⁸ The Siamese breed is reported at increased risk.^{7,8} While lymphoma may occur in cats of any age, it is primarily a disease of aged cats with a mean age of approximately 13 years for T-cell alimentary lymphoma and 12 years for B-cell lymphoma.^{7,8,50-52} No consistent sex bias is noted. Anatomically, alimentary lymphoma is nearly 4 times more likely to occur in the small intestine than the large intestine.⁵² In a series of colonic

neoplasia in cats, lymphoma was the second most common malignancy (41%), second only to adenocarcinoma.³³

There is some discordance in the literature regarding the histologic type (primarily cell size: small versus large), immunophenotype, and architecture involved with GI lymphoma. While studies (often older or smaller reports) suggest a majority of B-cell immunophenotypes,^{5,53} larger, more recent reports^{51,54,55} indicate the majority represent mucosal low-grade T-cell immunophenotypes. Conversely, the vast majority of B-cell GI lymphomas in cats are large cells and intermediate or high grade.^{51,53} The largest compilation to date (n = 120), by Moore and others,⁵¹ classified GI lymphomas based on immunophenotype, then as either mucosal (infiltrate confined to mucosa and lamina propria with minimal submucosal extension) or transmural (significant extension into submucosa and muscularis propria). They then compared infiltration patterns with the WHO classification scheme,⁵⁶ as well as documenting anatomic location, cell size, presence of epitheliotropism, clonality, and outcome data. This information is summarized in Table 32-9. Of the 120 cases, none tested serologically positive for FeLV and only 3 for FIV. Four cats had concurrent large B-cell lymphoma (stomach, cecum, or colon) and small T-cell lymphoma of the small intestine. Topographically, T-cell variants are much more likely to occur in the small intestine (94%) and rarely in the stomach or large intestine. Conversely, B-cell variants were often multiple and often occurred simultaneously within the stomach, small intestine, and ileocecolic junction. The vast majority of T-cell variants were mucosal (equivalent to WHO enteropathy-associated T-cell lymphoma [WHO EATCL] type II), and the vast majority of B-cell tumors were transmural (equivalent to WHO EATCL type I classification). Regarding cell size, nearly all mucosal T-cell tumors were composed of small lymphocytes, and slightly more than half of transmural T-cell and all B-cell variants were composed of larger cells. Epitheliotropism is present in approximately 40% of T-cell tumors but is rare in B-cell tumors. Other abdominal organ involvement is common, and in one report of 29 cases of low-grade T-cell intestinal lymphoma, liver and mesenteric involvement was documented in 53% and 33% of cases, respectively.⁵⁷ Hepatic lymphoma can occur concurrently with GI lymphoma or be confined solely to the liver.^{52,58} Most are T-cell and clonal or oligoclonal based on PCR analysis.

A less common, distinct form of alimentary lymphoma, large granular lymphoma (LGL), also occurs in older (median age 9 to 10 years) cats.^{51,53,59-61} These granulated round cell tumors have been termed *globule leukocyte tumors*, although they are likely variations of the same disease. LGL is characterized by lymphoblasts described as 12 to 20 μ m in diameter with a round, clefted, or cerebriform nucleus; variably distinct nucleoli; finely granular to lacey chromatin; and a moderate amount of basophilic granular cytoplasm that was occasionally vacuolated.⁵⁹ Prominent magenta or azurophilic granules are characteristic (see Figure 7-34, Chapter 7). They are granzyme B positive by immunohistochemistry.⁵¹ This population of cells includes cytotoxic T-cells and occasionally NK cell immunophenotypes—most are CD3⁺, CD8⁺, and CD20⁻ and have T-cell receptor gene rearrangement.^{51,60} In one report, nearly 60% expressed CD103 (integrin).⁶⁰ Approximately 10% express neither B- or T-cell markers and are thus classified as NK cells. These NK tumors commonly originate in the small intestine, especially the jejunum, are transmural, often exhibit epitheliotropism, and at least two-thirds present with other organs involved—most with mesenteric lymph node involvement and many with liver, spleen, kidney, peritoneal malignant effusions, and bone marrow infiltration. Also, thoracic involvement may occur

with malignant pleural effusion and a mediastinal mass present. Peripheral blood involvement was present in 10% of cases in one report⁵⁹ and 86% in another.⁶⁰ Affected cats are generally FeLV/FIV negative.

Mediastinal Form

The mediastinal form can involve the thymus, mediastinal, and sternal lymph nodes. Pleural effusion is common. In two large compilations, 63% of cats with thymic disease and 17% of cats with pleural effusion were documented as having lymphoma.^{62,63} Hypercalcemia occurs frequently with mediastinal lymphoma in dogs but is rare in cats. The majority of cats with mediastinal lymphoma are young (median age 2 to 4 years), FeLV positive, and the T-cell immunophenotype.^{5,7,9-11} The disease is confined to the mediastinum in most cases.⁷ There also exists a form of mediastinal lymphoma occurring primarily in young, FeLV-negative Siamese cats that appears to be less biologically aggressive and more responsive to chemotherapy than FeLV-associated forms.⁶⁴

Nodal Lymphoma

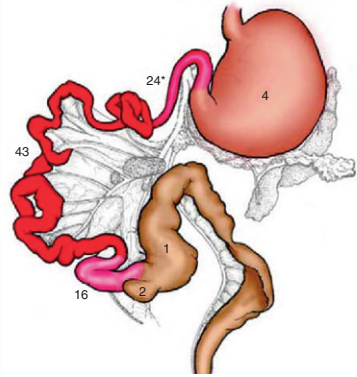

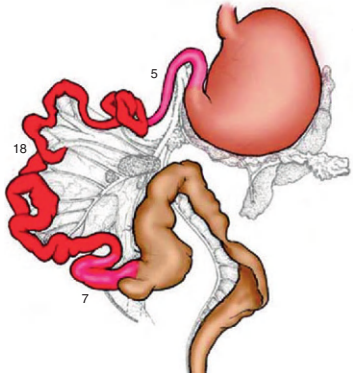

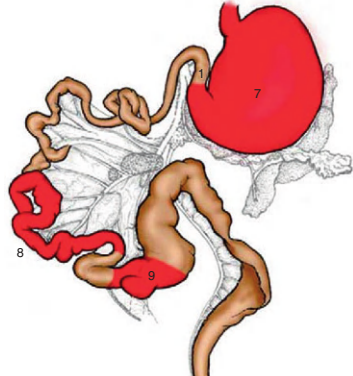

Involvement limited to peripheral lymph nodes is unusual in cats with lymphoma, representing approximately 4% to 10% of cases.^{5,7} In contrast, approximately one-quarter of all other anatomic forms of lymphoma have some component of lymph node involvement. One-third of cats with nodal lymphoma are T-cell immunophenotype and FeLV antigenemic; however, complete categorizations have not occurred in the post-FeLV era and this may no longer be true.^{5,7,11,55} Peripheral nodal lymphoma was the most common anatomic form of lymphoma reported in a recent compilation of cases in cats under the age of 1 year, representing a full third of cases in this age group.⁹ As lymphoma progresses, bone marrow and hepatic infiltration may develop.

An uncommon and distinct form of nodal lymphoma in cats referred to as “Hodgkin’s-like” lymphoma has been reported.^{65,66} This form typically involves solitary or regional nodes of the head and neck (Figure 32-12) and histologically resembles Hodgkin’s lymphoma in humans. Affected cats generally present with enlargement of one or two mandibular or cervical nodes initially, and tumors are immunophenotypically classified as T-cell-rich, B-cell lymphoma. One case each of inguinal node, multicentric nodal, and

• **FIGURE 32-12** A cat presented with mandibular lymphadenopathy that was confirmed to be Hodgkin’s-like lymphoma following histologic assessment.

conjunctival involvement have been reported.^{66,67} Histologically, lymph nodes can be effaced by either nodular or diffuse small to blastic lymphocytes with characteristic bizarre or multinucleated cells (Reed-Sternberg-like cells) (Figure 32-13). No association with FeLV or FIV has been documented.

Extranodal Lymphoma

The most common extranodal sites for lymphoma in cats include nasal (including nasopharyngeal and sinonasal), kidney, CNS, laryngeal and tracheal, ocular, retrobulbar, and skin.

Nasal lymphoma is the most common extranodal lymphoma in cats.⁶⁸ It is usually a localized disease; however, 20% have local extension or distant metastasis at necropsy.⁶⁹ The majority of non-viral nasal/paranasal disease in cats are neoplasias, and lymphoma represents nearly one-third to half of these cases.^{70,72} It occurs primarily in older (median age 9 to 10 years; range 3 to 17 years) FeLV/FIV-negative cats and at least three-quarters are B-cell in origin, although T-cell and mixed B-cell/T-cell immunophenotypes can be seen in approximately 10% to 15% of cases.^{5,68,69,73} Siamese cats appear overrepresented, and one report⁷³ observed a 2:1 male-to-female ratio. Most are of intermediate- or high-grade histology.^{69,73} Epitheliotropism is common if the epithelium is present in the biopsy.

Renal lymphoma is the second most common form of extranodal lymphoma after the nasal form, occurring in approximately one-third of cases.⁶⁸ It can present as primary to kidney lymphoma or occur concurrent with alimentary lymphoma. In more contemporary reports, the median age at presentation is 9 years, although 6% occurred in cats under 1 year of age.^{68,69} The vast majority of cases are not associated with either FeLV or FIV. The greater median age and lack of FeLV/FIV association are in contrast to reports compiled prior to the post-FeLV era; in earlier studies, the median age was approximately 7.5 years, 25% of cases were FeLV antigenemic, and the majority constituted a B-cell immunophenotype. Little contemporary information exists on the immunohistologic classification of renal lymphoma; however, in Australia where FeLV is not a significant problem, most renal lymphoma is B-cell and intermediate to high grade.¹¹ Extension to the CNS is a

frequent sequela to renal lymphoma and occurs in 40% to 50% of treated cats.⁷⁴

CNS lymphoma can be intracranial, spinal, or both. CNS lymphoma made up 14% of 110 reported cases of extranodal lymphoma,⁶⁸ 15% to 31% of intracranial tumors,^{75,76} and 39% of spinal cord tumors,⁷⁷ making it one of the most common malignancies encountered in the CNS in cats. Although some discordance exists in the literature, cats with CNS lymphoma are younger (median ages of 4 to 10.5 years reported), and 17% to 50% of cases are FeLV antigenemic.^{76,78} Approximately two-thirds of intracranial cases are part of a multicentric, extracranial process, and approximately 40% of spinal lymphoma cases occur in multiple spinal cord sites with one-third also involving intracranial locations.⁷⁶⁻⁷⁸ In a compilation of 160 cases of intracranial tumors in cats, diffuse cerebral and diffuse brainstem involvement was most common for lymphoid malignancies.⁷⁶ Spinal lesions are usually both extradural and intradural, although they can be limited to one or the other compartment.⁷⁷ Feline CNS lymphoma may be primary but more commonly (approximately 80%) represents a multicentric process (especially renal or bone marrow).^{76,78} A paucity of information exists on the immunophenotype of CNS lymphoma.

Laryngeal lymphoma made up 10% of 110 cases of extranodal forms in one report and represented 11% of all laryngeal disease in the species.^{68,79} It occurs in older cats (median age 9 years), is not associated with FeLV, and may be a solitary lesion or occur in the presence of other multicentric sites. No information on immunophenotype is available.

Cutaneous lymphoma is a rarely encountered anatomic form in the cat. It is usually seen in older cats (median age 10 to 13.5 years), with no sex or breed predominance, and is not associated with FeLV/FIV.^{80,81} It can be solitary or generalized, often affecting the head and face and is generally a slow chronic disease. Two forms of cutaneous lymphoma have been distinguished histologically and immunohistochemically. Most reports in the cat are epitheliotropic and consist of T-cells, although unlike the disease in dogs, adnexal structures are often spared. A report of nonepitheliotropic cutaneous lymphoma in cats also found five of six cases to be of T-cell derivation.⁸² Cutaneous "lymphocytosis," an uncommon disease histologically resembling well-differentiated lymphoma, was characterized in 23 cats.⁸³ Solitary lesions were most common, and all were composed primarily of T-cells, with two-thirds having some B-cell aggregates. Cutaneous lymphocytosis was characterized as a slowly progressive disorder; however, a few cases went on to develop internal organ infiltration. Two case reports exist of cats with cutaneous T-cell lymphoma and circulating atypical lymphocytes.^{84,85} The circulating cells were lymphocytes with large, hyperchromatic, grooved nuclei, and one case was immunophenotyped as a CD3/CD8 population. In humans, cutaneous T-cell lymphoma with circulating malignant cells is termed *Sézary syndrome*.

Ocular lymphoma was identified in 5 of 110 cases of extranodal lymphoma in one report.⁶⁸ In a compilation of 75 cases of intraocular tumors, 15 (20%) were lymphoma (7 B-cell and 4 T-cell).⁸⁶ It was presumed but not proved that the majority were part of a systemic multicentric process.

History, Clinical Signs, and Physical Examination Findings

The clinical signs associated with feline lymphoma are variable and depend on anatomic location and extent of disease.

The alimentary form is most commonly associated with non-specific signs associated with the intestinal tract. In the more

FIGURE 32-14 **A**, Ventrodorsal projection of a cat with renal lymphoma. Massive, bilateral renomegaly is observed. **B**, Necropsy specimens of a cat with bilateral renal lymphoma illustrating the diffuse cortical nature of the disease that is most common.

common low-grade small cell forms, weight loss (83% to 100%), vomiting and/or diarrhea (73% to 88%), and anorexia (66%) are the most common findings, and icterus is uncommon (7%).^{50,52,87} Abdominal palpation is abnormal in approximately 70% of cases, with half consisting of intestinal wall thickening and one-third having a palpable mass. Clinical signs are usually present for several months (median: 6 months).⁸⁷ In contrast, although the lymphoblastic high-grade forms tend to cause similar clinical signs, they progress more rapidly with signs present for days or weeks and are more likely to present with a palpable abdominal mass originating from the GI tract, enlarged mesenteric lymph nodes, or liver.^{31,50,88} Icterus is also more common in large cell forms. Hematochezia and tenesmus may also be present if the colon is involved.³³ Rarely, cats may present with signs consistent with an acute abdomen due to intestinal obstruction or perforation and concurrent peritonitis. Cats with intestinal LGL are presented with anorexia, weight loss, lethargy, and vomiting.^{59,60} A palpable abdominal mass is present in approximately half of LGL cases, and hepatomegaly, splenomegaly, and renomegaly are common. Abdominal effusions, pleural effusions, and icterus are observed in less than 10% of cases.

The clinical signs associated with the mediastinal form of lymphoma include dyspnea, tachypnea, and a noncompressible anterior mediastinum with dull heart and lung sounds.⁸⁹ Rarely, a Horner's syndrome and precaval syndrome may be observed. Pleural effusion is common and characterized by serohemorrhagic to chylous effusion, and in most cases, neoplastic cells (lymphoblasts) are identified.^{63,90}

Cats with the nodal form of lymphoma present with variable clinical signs depending on the extent of disease; however, they are often depressed and lethargic. Peripheral lymphadenopathy, as the only physical finding, is an uncommon presentation. Cats with

Hodgkin's-like nodal lymphoma usually present without overt clinical signs.^{65,66}

Cats with nasal lymphoma are typically presented with nasal discharge (60% to 85%), sneezing (20% to 70%), upper respiratory noise (stridor, stertor, wheezing; 20% to 60%), facial deformity (0% to 20%), anorexia (10% to 60%), epiphora (10% to 30%), and occasionally increased respiratory effort and coughing.^{68,69,73} The nasal discharge is usually mucopurulent, although epistaxis is present in up to one-third of cases. Regional lymphadenopathy can also occur. The median duration of clinical signs prior to diagnosis is 2 months (range of 1 to 1800 days).

Cats with renal lymphoma present with signs consistent with renal insufficiency: inappetence, weight loss, and polyuria/polydipsia.^{68,74} On physical examination, renomegaly (usually bilateral, lumpy, and irregular) is palpated in the majority of cases (Figure 32-14).

Cats with CNS lymphoma can present with constitutional signs (anorexia, lethargy) and signs referring to intracranial lesions, spinal lesions, or both.^{68,75-77,91,92} Intracranial signs may include ataxia, altered consciousness, aggression, central blindness, and vestibular abnormalities. In a study of cats with seizures, of those diagnosed with intracranial lesions, 8% were due to lymphoma.⁷⁵ Clinical signs referring to spinal cord involvement may include paresis or paraplegia (>80%; tetraparesis in 20%), ataxia, pain, and constipation, and nonspecific constitutional signs (e.g., anorexia, lethargy, weight loss) are also common.^{77,92} In cats with spinal cord involvement, neurologic examination may further reveal tetraparesis, lower or upper motor neuron bladder, tail flaccidity, and absent deep pain; approximately one-third of signs will be asymmetric and most refer to thoracolumbar involvement. The neurologic dysfunction may be insidious or progress rapidly.

Signs associated with laryngeal lymphoma in cats most commonly include dyspnea, dysphonia, stridor, gagging or retching, and rarely, coughing.^{68,79}

Cutaneous lymphoma may be solitary or diffuse with a varied presentation.^{80,83} In decreasing order of likelihood, lesions may include erythematous patches, alopecia, scaling, dermal nodules, or ulcerative plaques. Nasal hypopigmentation, miliary dermatitis, and mucosal lesions are rarely observed. Peripheral lymphadenopathy may also be present. In most cats, the duration of signs will be prolonged, lasting several months.

Cats with ocular lymphoma are presented with uveitis or iridial masses, as well as signs related to systemic involvement of disease.⁶⁸

Nonspecific Signs

All cats with lymphoma, regardless of site, may be presented with nonspecific constitutional signs that may include anorexia, weight loss, lethargy, or depression. Secondary bone marrow infiltration may lead to anemia—at least 50% of affected cats have moderate-to-severe nonregenerative anemia. Signs related to paraneoplastic hypercalcemia (PU/PD) can occur in cats, however, much less commonly than in the dog. In one survey of hypercalcemia in cats, approximately 10% were diagnosed with lymphoma of various anatomic types.⁹³

Diagnosis and Clinical Staging

For most cats with suspect lymphoma, the diagnostic evaluation should include a baseline assessment consisting of a CBC with differential cell count, platelet count, serum chemistry profile, urinalysis, and retroviral (FeLV/FIV) screen. Serum chemistry profiles can help establish the overall health of the animal, as well as, in some cases, suggest site-specific tumor involvement; for example, increased activities of liver enzymes may indicate hepatic infiltration and increased blood urea nitrogen (BUN) and creatinine may indicate renal lymphoma. For cats with alimentary lymphoma, hypoproteinemia and anemia are reported to occur in up to 23% and 76% of cases, respectively.^{31,52,94} Hypercalcemia is rarely seen in cats but has been reported in cats with lymphoma at various anatomic sites. Hypoglycemia was reported in approximately one-third of cats with lymphoma in one Australian study.⁹⁴ In a series of cats with various anatomic forms of lymphoma, serum albumin concentrations were significantly lower and β -globulin concentrations (as measured by protein electrophoresis) were significantly higher than a healthy control population.⁹⁵

The use of various imaging modalities in cats with lymphoma depends on the anatomic site and will be discussed in site-specific discussions to follow.

Cytopathologic or histopathologic evaluation of lymph node or involved organ tissue, procured via needle aspirate cytology (see Chapter 7), surgical, endoscopic, or needle-core biopsy (see Chapter 9) is required for a definitive diagnosis. FNA cytology alone may not be sufficient in some cases, owing to difficulties encountered in distinguishing lymphoma from benign hyperplastic or reactive lymphoid conditions. In such cases, whole lymph node excision and/or involved organ biopsy is preferred because orientation and information regarding invasiveness and architectural abnormalities may be necessary for diagnosis. Additionally, involved tissue, needle aspirate, and fluid samples can be further interrogated by various histochemical, immunohistochemical, flow cytometric analysis (e.g., size and immunophenotypic assessment), and molecular techniques (e.g., PARR to assess clonality) to further characterize the disease process and refine the diagnosis in equivocal cases.

The reader is referred to Chapter 8 for a general discussion of flow cytometric analysis and molecular diagnostic techniques, as well as the molecular diagnostic techniques section in [Section A](#) of this chapter for specific applications to lymphoma. PARR applications in cats have been described as being approximately 80% sensitive for the diagnosis of feline lymphoma⁹⁶; however, assessment of specificity has not been clearly established. Clonality assessment tools (e.g., primers) for both Ig and T-cell receptor variable region genes have been developed in cats.⁹⁷⁻¹⁰⁰

Assessments of tumor proliferation rates (e.g., Ki67, PCNA, AgNOR), telomerase activity, and serum protein electrophoresis can also be performed on involved tissues in cats; however, consistent prognostic value across the anatomic, histopathologic, and immunophenotypic variants of lymphoma in cats is not well characterized. If these ancillary assays are helpful with respect to prognosis or diagnosis, they will be discussed in site-specific discussions to follow.

Thorough staging, including a bone marrow aspiration or biopsy, peripheral lymph node assessment (clinically normal or abnormal nodes), and thoracic and/or abdominal imaging, is indicated when (1) solitary site disease is suspected (in particular, extranodal sites) and a decision between locoregional therapy (i.e., surgery and/or RT) versus systemic therapy (i.e., chemotherapy) is being considered; (2) it provides prognostic information that will help a caregiver make treatment decisions; and (3) complete staging of the extent of disease is required as part of a clinical trial. Bone marrow evaluation may be of particular interest if anemia, cellular atypia, and leukopenia are present. A WHO staging system exists for the cat that is similar to that used in the dog (see [Box 32-1](#)); however, because of the high incidence of visceral/extranodal involvement in the feline species, a separate staging system has been evaluated and is often used ([Box 32-3](#)).¹⁰¹ Because lymphoma in cats is more varied with respect to anatomic locations, staging systems are generally less helpful for predicting response.

Anatomic Site-Specific Diagnostics

Alimentary/Gastrointestinal Lymphoma The diagnosis of large cell, high-grade alimentary/GI lymphoma is generally less complicated than for the more common low-grade GI type. The former (including LGL) is often diagnosed with physical examination, abdominal imaging (e.g., ultrasound), and cytologic or histologic assessment of needle aspirate or needle biopsy samples from intestinal masses, enlarged mesenteric lymph nodes, or liver because mass lesions and gross lymphadenopathy are more commonly present. If obvious abdominal masses are present on physical examination, transabdominal needle aspiration may be possible without the aid of abdominal imaging. Less commonly, abdominal exploration is necessary if lesions are more subtle or not amenable to transabdominal sampling. Further staging via thoracic imaging, peripheral lymph node aspiration, and bone marrow assessment may be performed, but rarely contributes prognostic information or alters treatment decisions because the disease is already widespread and systemic therapy is required.

In contrast, low-grade, small cell GI lymphoma is more commonly associated with modest (or palpably absent) intestinal thickening without mass effect and is clinically similar if not identical in presentation to benign inflammatory bowel disease (IBD). Cytologic assessment alone is often not sufficient for diagnosis; in one study, eight of nine cases in which mesenteric lymph nodes were confirmed histologically as lymphoma, cytologic assessment incorrectly indicated benign lymphoid hyperplasia.⁵² The key elements necessary for the diagnosis of low-grade, small cell GI lymphoma

Box 32-3 Clinical Staging System for Feline Lymphoma

Stage 1

- A single tumor (extranodal) or single anatomic area (nodal)
- Includes primary intrathoracic tumors

Stage 2

- A single tumor (extranodal) with regional lymph node involvement
- Two or more nodal areas on the same side of the diaphragm
- Two single (extranodal) tumors with or without regional lymph node involvement on the same side of the diaphragm
- A resectable primary gastrointestinal tract tumor, usually in the ileocecal area, with or without involvement of associated mesenteric nodes only

Stage 3

- Two single tumors (extranodal) on opposite sides of the diaphragm
- Two or more nodal areas above and below the diaphragm
- All extensive primary unresectable intraabdominal disease
- All paraspinal or epidural tumors, regardless of other tumor site or sites

Stage 4

- Stages 1-3 with liver and/or spleen involvement

Stage 5

- Stages 1-4 with initial involvement of CNS or bone marrow or both

Data from Terry A, Callanan JJ, Fulton R, et al: Molecular analysis of tumours from feline immunodeficiency virus (FIV)-infected cats: An indirect role for FIV, *Int J Cancer* 61:227–232, 1995.

(and differentiation from IBD) include abdominal imaging (usually ultrasound), procurement of tissue for histopathology, and if necessary, assessment of immunophenotype and clonality.

Abdominal ultrasound will be abnormal in approximately 60% to 90% of cats with low-grade, small cell GI lymphoma.^{31,52,102,103} Diffuse small intestinal wall thickening is the most common finding; 50% to 70% of cats with lymphoma will have ultrasonic evidence of wall thickening, which predominantly involves the muscularis propria, and submucosa, although mucosal thickening can also occur. Focal mural masses are uncommon. Mesenteric lymphadenopathy is also common and reported in 45% to 80% of affected cats. These ultrasonographic findings are by no means pathognomonic for lymphoma, however, because 10% to 50% and 15% to 20% of cats with IBD also have ultrasonographic evidence of intestinal wall thickening and lymphadenopathy, respectively.^{102,103} Mucosal thickening is more common, and muscularis propria thickening is less common in IBD than lymphoma. Less commonly, cats with low-grade intestinal lymphoma will have ultrasonographic abnormalities in other abdominal organs such as

the stomach, liver, spleen, colon, and pancreas, and occasionally, mild effusions are observed.

As mentioned previously, although aspirate cytology may be sufficient for diagnosis of large cell intermediate- or high-grade alimentary lymphoma in cats, it is rarely diagnostic for low-grade, small cell intestinal lymphoma, and tissue procurement for histologic and ancillary assessment is required for diagnosis (and differentiation from IBD). The debate still rages as to whether endoscopically obtained tissue is sufficient for diagnosis or if full-thickness tissue procured during laparotomy or laparoscopy is necessary in light of similarities with IBD.^{51,54,103,104} As previously discussed, histologic features that help differentiate intestinal lymphoma from IBD include lymphoid infiltration of the intestinal wall beyond the mucosa, epitheliotropism (especially intraepithelial nests and plaques), heterogeneity, and nuclear size of lymphocytes.^{51,54} Although the presence of transmural involvement is highly suggestive of lymphoma, the lack of transmural infiltration is not pathognomonic for IBD; transmural infiltration is common with B-cell and large T-cell (including LGL) intestinal lymphoma but is observed in the minority of low-grade T-cell intestinal lymphomas that represent the largest group in cats (see Table 32-9).⁵¹ For these reasons, if the differentiation of lymphoma and IBD is equivocal after standard histopathologic assessment, the addition of immunophenotypic and PARR analysis in a stepwise fashion, as proposed by Kiupel and others,⁵⁴ may be ultimately necessary for a definitive diagnosis. Their study of 63 cats with either lymphoma or IBD found that, although standard histopathology was highly specific for diagnosis of lymphoma (99% specific, 72% sensitive), sensitivity was enhanced by the addition of immunophenotypic analysis (99% specific, 78% sensitive) and further enhanced by PARR analysis (99% specific, 83% sensitive).

Mediastinal Lymphoma For cats with mediastinal lymphoma, diagnostic suspicion may begin with a noncompressible cranial thorax on physical examination and confirmation of a mediastinal mass/pleural effusion on thoracic radiograph. FNA of the mass or cytologic evaluation of pleural fluid may be sufficient to establish a diagnosis. In most cats, the finding of a monotonous population of intermediate- or high-grade cells will establish a diagnosis. However, definitive diagnosis of lymphoma in cats with a mediastinal mass and concurrent chylothorax can be challenging. CT appearance may be helpful but generally does not contribute to a definitive diagnosis. If lymphoblasts are not identified in the pleural chylous effusion, then cholesterol and triglyceride concentrations can be measured.¹⁰⁵ In chylous effusions, the pleural fluid triglyceride concentration will be greater than in the serum; however, anorectic cats will have lower triglyceride levels in the pleural fluid. A major differential for mediastinal lymphoma is thymoma. The cytologic features of thymoma can be distinct from lymphoma in many cases, but the diagnosis can be challenging because of a preponderance of small lymphocytes in thymoma. Mast cells can also be seen in up to 50% of aspirations from thymomas. The addition of immunophenotypic and clonality assessment may be helpful in equivocal cases.

Nasal Lymphoma If nasal lymphoma is suspected, advanced imaging (CT, MRI), rhinoscopy, and biopsy are usually necessary for diagnosis (see Chapter 23, Section B). CT or MRI is useful to determine the extent of involvement and to help plan biopsy procurement and RT if that treatment option is pursued. CT characteristics associated with sinonasal tumors in cats include the presence of a unilateral or bilateral nasal/sinus mass or fluid, bulla

• **FIGURE 32-15** Flush biopsy of nasal lymphoma. Note the large sample (arrow) procured by retrograde flushing of saline through one nares while occluding the contralateral nares. The sample is flushed through the pharynx and out the mouth.

effusion, and lysis of associated bony structures.^{106,107} A biopsy can be procured either by intranasal procurement (with or without rhinoscopy) or by flushing one hemicavity with a bulb syringe and saline while occluding the contralateral cavity and collecting samples flushed out of the nasopharynx (Figure 32-15). Thorough staging (i.e., regional node assessment, thoracic and abdominal staging, and bone marrow assessment) to ensure the disease is confined to the nasal passages is recommended, if local RT without systemic chemotherapy is being considered.

Renal Lymphoma In the case of renal lymphoma, physical examination findings of massive and often bilateral renomegaly will raise the index of suspicion. Radiographic appearance is smooth-to-irregular renomegaly (see Figure 32-14, A). Ultrasonographic imaging usually reveals bilateral (>80%), irregular renomegaly with hypoechoic subcapsular thickening.¹⁰⁸ Approximately one-third of cases will have ultrasonographic evidence of other abdominal organ involvement. The disease is usually diffuse throughout the renal cortex (see Figure 32-14, B) and transabdominal needle aspirate or core biopsy is diagnostic in most cases.

Central Nervous System Lymphoma In cats with suspected spinal lymphoma, survey radiographs of the spine will rarely reveal osseous lesions. Myelograms, CT, or MRI are indicated, and in approximately 75% of the cases, an extradural or intradural mass will be detected.^{76,77,91,92} Most lesions occur at a thoracolumbar or lumbosacral location, and they are often found in more than one location. Image-guided needle aspiration of epidural lesions may

yield enough tissue for a cytologic diagnosis. CT or MR also reveals multifocal disease in the majority of cats with intracranial lymphoma.^{75,76} CSF analysis may be helpful but is rarely definitive for lymphoma. One of 11 cats with confirmed spinal lymphoma in one study⁷⁷ and 6 of 17 with confirmed intracranial lymphoma in another⁷⁶ had evidence of lymphoblasts in the CNS, and an increased protein content was commonly found. In cats suspected of CNS lymphoma, bone marrow and renal involvement are often present, and cytologic assessment of these or other more accessible organs is generally more easily attainable than from spinal sites.

For cats suspected of cutaneous lymphoma, punch biopsies (4 to 8 mm) should be taken from the most representative and infiltrative sites, while avoiding overtly infected skin lesions. Immunophenotypic and PARR analysis often are helpful in definitive diagnosis. Complete staging to rule out systemic disease is also recommended for cats with cutaneous lymphoma because local therapies can be applied in cases of solitary disease.

Treatment and Prognosis

Our knowledge base for treating cats with lymphoma is less well established, and outcomes are less predictable than that in dogs, primarily due to the greater variation in histologic type and anatomic location observed in the species. This is further complicated by the plethora of papers that “lump” very small numbers of cases representing multiple anatomic/immunophenotypic and histologic subtypes (e.g., small cell versus large cell variants) together when reporting survival analysis following chemotherapy. This provides only general observations rather than important specific outcome information (i.e., response rate and durability of response) that can vary significantly with respect to anatomic and histologic subtype. In general, canine lymphoma is most commonly intermediate-high grade and nodal, whereas cats more commonly present with GI or extranodal (±nodal extension), small cell, low-grade, and/or indolent forms. As will be discussed subsequently, the author bases most treatment decisions on assessment of whether the individual case represents a low-grade (e.g., indolent, small cell variants) versus an intermediate- or high-grade (e.g., large cell) lymphoma. Finally, much of the early work on chemotherapy protocol development for cats with lymphoma occurred during the FeLV era, and care should be exercised when applying this information in the post-FeLV era.

In general, cats tolerate chemotherapy for lymphoma quite well, most clients are happy with their choice to initiate treatment, and quality of life generally improves following commencement of therapy.^{109,110} The chemotherapeutic agents used most commonly to treat intermediate- or high-grade lymphoma in cats are similar to those used for dogs and humans with lymphoma (see Section A in this chapter) and include doxorubicin, vincristine, cyclophosphamide, methotrexate, L-asparaginase, CCNU (lomustine), and prednisone. Most combination induction protocols currently employed in cats are modifications of CHOP protocols initially designed for human oncologic use.^{5,110-116} CHOP represents combinations of cyclophosphamide (C), doxorubicin (H, hydroxydaunorubicin), vincristine (O, Oncovin) and prednisone (P). In general, CHOP-based protocols are appropriate for cats with large cell, intermediate- and high-grade lymphoma involving any anatomic site (e.g., peripheral nodal, mediastinal, and renal forms) but should not be first-line therapy for small cell, low-grade variants. As in the dog (see Section A in this chapter), a plethora of modifications are used with CHOP-based protocols, although virtually no quality comparative data exist to compare outcomes, and as such, the protocol used should be based on cost, ease, client/veterinarian preference, and level of comfort. The current CHOP-based protocol in use by

• **TABLE 32-10** The CHOP-Based Chemotherapy Protocol for Cats with Lymphoma Employed by the Author

TREATMENT WEEK	DRUG, DOSAGE, AND ROUTE
1	Vincristine 0.5-0.7 mg/m ² IV L-Asparaginase 400 Units/kg SQ Prednisone 2.0 mg/kg PO, q24hr

IV, Intravenous; SQ, subcutaneous; PO, by mouth.

*Prednisone is continued (1 mg/kg PO) every other day from this point on.

[†]If renal lymphoma or central nervous system (CNS) lymphoma is present, substitute cytosine arabinoside (Ara-C) at 600 mg/m² divided SQ twice a day (BID) over 2 days at these treatments.

[‡]If in complete remission at week 9, continue to week 11.

[§]If in complete remission at week 25, therapy is discontinued and cat is rechecked monthly for recurrence.

NOTE: A complete blood count (CBC) should be performed prior to each chemotherapy. If neutrophils are <1500 cells/UL, wait 5 to 7 days, repeat CBC, then administer the drug if neutrophils have risen above the 1500 cell/UL cutoff.

the author is presented in Table 32-10. This protocol has been used in many cats with various forms of intermediate- and high-grade lymphoma and is generally well tolerated. At present, most canine lymphoma protocols (see Section A in this chapter) discontinue chemotherapy by the 25th week, and we have sufficient data to show shorter, maintenance-free protocols are as good if not superior to longer maintenance protocols; however, similar comparative data do not exist in the cat. Until such time as evidence to the contrary exists, the author presently recommends discontinuation of chemotherapy at week 25 in cats who have attained a complete remission. Doxorubicin alone (25 mg/m², every 3 weeks for 5 total treatments) or palliative prednisone therapy is offered if clients decline more aggressive CHOP-based therapy. Cats are generally less tolerant of doxorubicin than are dogs; therefore a lower dosage (25 mg/m² IV or 1 mg/kg IV) is used (see Chapter 11). Cardiac toxicity does not appear to be a clinically significant problem in cats, although renal toxicity is more commonly encountered in the species¹¹⁷ and renal function should be monitored (i.e., serial BUN, creatinine, and urine specific gravity) closely prior to and during therapy. The use of COP (i.e., CHOP without the addition of doxorubicin) is often

• **TABLE 32-11** COP Protocol for Lymphoma in Cats

DRUG	FREQUENCY OF DRUG DELIVERY
Cyclophosphamide 300 mg/m ² IV	Given every 3 weeks on the day after vincristine. Discontinued if animal is in complete remission at 1 year.
Vincristine (Oncovin) 0.75 mg/m ² IV	Given weekly on weeks 1, 2, 3, and 4, then given every 3 weeks thereafter on the day before cyclophosphamide, Discontinued if animal is in complete remission at 1 year.
Prednisone/ prednisolone 50 mg/m ² orally	Given daily for 1 year.

NOTE: A complete blood count (CBC) should be performed prior to each treatment. If neutrophils are <1.5 × 10⁹/L, wait 5 to 7 days and repeat the CBC. Treat if neutrophils are ≥1.5 × 10⁹/L.

used in cats in Europe, and one compilation reported similar results to CHOP.⁶⁴ A COP protocol commonly employed in cats is presented in Table 32-11. Some studies with relatively few case entries have reported limited activity for doxorubicin as a single agent in cats with lymphoma^{118,119}; however, larger studies using combination protocols have more consistently reported the addition of doxorubicin as necessary for the attainment of more durable responses.^{5,114} Interestingly, in a report of 23 cats having relapsed following COP-based protocols (without doxorubicin), only 22% responded subsequently to doxorubicin-containing rescue therapy.¹²⁰ A small number of cats with lymphoma have been treated with single-agent oral CCNU (lomustine) at a dosage range of 30 to 60 mg/m² every 3 to 6 weeks.^{121,122} Whereas activity was noted, only partial responses were reported. L-asparaginase, which is often included in protocols for lymphoma in cats, has a much shorter asparagine-depleting effect in cats (lost by 7 days) than in dogs and in one study in 13 cats with lymphoma resulted in only a 30% response rate.¹²³

In general, cats with intermediate- and high-grade lymphoma treated with CHOP-based or COP protocols do not enjoy the same level of success as dogs. Bearing in mind that these reports group together a wide variety of subtypes having dissimilar prognoses (see subsequent site-specific treatment sections), the overall response rates tend to be in the 50% to 80% range with median remission and survival durations of 4 and 6 months, respectively.^{5,64,110-116,124}

Anatomic Site-Specific Treatment

Alimentary/Gastrointestinal Lymphoma Representing the most common presentation for cats with lymphoma, the large majority have the small cell, mucosal, T-cell variant that carries a good prognosis, often with less aggressive chemotherapy protocols (e.g., oral chlorambucil and prednisone).^{51,52,87,125} Chlorambucil (20 mg/m² PO, every 2 weeks [preferred by the author] or 2 mg PO every other day) and prednisone or prednisolone (initially 1 to 2 mg/kg PO daily, reduced to 0.5 to 1.0 mg/kg every other day over several weeks) results in response rates (i.e., resolution of clinical signs) of greater than 90% and median survivals of approximately 2 years or longer.^{52,87,125} Cats who relapse with this protocol often will subsequently respond to alternative alkylators, such as cyclophosphamide or lomustine.¹²⁵ Anecdotally, many will also respond

to vinblastine chemotherapy if they no longer are responsive to alkylators.

In contrast, cats with B-cell or large T-cell (including LGL) or small T-cell lymphoma that is transmural typically do not enjoy a durable response to therapy and survivals are much shorter.^{31,51,59,60} Median survivals range from 45 to 100 days, even in cats treated with more aggressive COP-based protocols. In the author's experience, these variants are more likely to respond to CHOP-based protocols than chlorambucil/prednisone; however, durable responses occur only in a minority of cases. In particular, LGL appears to carry a grave prognosis^{59,60}; in 2 compilations of 66 cats with LGL, median survivals of approximately 2 months were reported, including 23 cats receiving either COP or CHOP-based protocols, which resulted in only a 30% response rate.

Nutritional support is especially important for cats with GI lymphomas. It may be necessary to place a feeding tube in cats undergoing chemotherapy, particularly if prolonged anorexia is present (see Chapter 15, Section B).

Recently, two preliminary studies evaluated RT, either as rescue following recurrence or in addition to chemotherapy for the treatment of intestinal lymphoma in cats.^{126,127} Eleven cats (6 small cell, 4 large cell, and 1 LGL) that progressed following chemotherapy received abdominal radiation (8 Gy in 2 fractions over 2 days) and resulted in a median survival of 7 months, although numbers were small and 40% were lost to follow-up.¹²⁷ A second report of eight cats (seven with large cell lymphoma) underwent 6 weeks of CHOP-based combination chemotherapy, followed 2 weeks later by whole abdomen radiation consisting of 10 daily 1.5 Gy fractions.¹²⁶ Although three cats died within 3 weeks of RT, five enjoyed durable remissions. These preliminary promising outcomes warrant further investigation.

Mediastinal Lymphoma Mediastinal lymphoma in young FeLV-positive cats is generally associated with a poor prognosis, and survival times of approximately 2 to 3 months are expected following CHOP- or COP-based protocols.^{5,116} In contrast, young FeLV-negative Siamese cats with mediastinal lymphoma experience remission rates approaching 90%, and responses tend to be more durable (median \approx 9 months).⁶⁴

Nodal Lymphoma The treatment choice for peripheral nodal lymphoma in cats depends on whether the individual case represents a low-grade (e.g., indolent, small cell variants) versus an intermediate- or high-grade (e.g., large cell) lymphoma; the latter are best treated with CHOP- or COP-based protocols and carry a less favorable prognosis, whereas the former generally respond to less aggressive chlorambucil/corticosteroid protocols and enjoy durable responses. Less is known regarding the treatment of Hodgkin's-like lymphoma involving solitary or regional nodes of the head and neck.^{65,66} Clinical outcome following surgical extirpation of the affected node (or nodes if a reasonable number) is often associated with long-term, disease-free intervals and survivals of approximately 1 year, suggesting it is a more indolent form of lymphoma. Eventual recurrence in distal nodes following surgical excision is common, and the author currently offers clients the option of adjuvant chlorambucil/corticosteroids following surgery—this theoretically may have benefit; however, insufficient data exist to document a survival advantage with this approach.

Nasal Lymphoma Cats with nasal lymphoma generally enjoy durable remissions following therapy and lengthy overall survival durations.^{5,68,73,128,129} If disease is documented as confined to the

nasal cavity following thorough staging (node cytology, thoracic and abdominal imaging, bone marrow aspiration), then RT is the treatment of choice. CRs in the order of 75% to 95% are reported, with reports of median survivals following RT of 1.5 to 3 years.^{73,129} Cats that do not achieve a CR with RT have a median survival of approximately 4.5 months. Total radiation dosage does affect survival durations, and a total dose greater than 32 Gy is recommended.⁷³ The addition of chemotherapy has not been shown to enhance survival for cats with locally confined disease; combinations of RT and chemotherapy result in similar response rates and survival times.^{73,128,129} Chemotherapy (COP- or CHOP-based protocols) used in the absence of RT is a reasonable alternative, with complete response rates of approximately 75% and median survivals of approximately 2 years reported for cats achieving CR.⁶⁸ The author's preference is to initiate systemic chemotherapy only for (1) cases that have confirmed disease beyond the nasal passage, (2) cases that relapsed following RT, or (3) cases in which RT is unavailable or declined.

Central Nervous System Lymphoma Very few cases involving treatment for CNS lymphoma exist, and although an occasional case experienced durable response to systemic chemotherapy, generally less than 50% will respond and median survivals of 1 to 2 months can be expected.^{68,76,77}

Laryngeal/Tracheal Lymphoma The vast majority of cats with laryngeal or tracheal lymphoma respond to either RT (if localized) or systemic chemotherapy (90% CR to COP- or CHOP-based protocols) (Figure 32-16).⁶⁸ Whereas the authors experience is that most have durable responses and survival durations typically approach or exceed 1 year, the only case series (n = 8) reported a median survival of 5.5 months following achievement of a CR.

Cutaneous Lymphoma Very little has been published regarding the treatment of cutaneous lymphoma or mycosis fungoides in cats⁸⁰; however, a report of a CR to lomustine exists.¹³⁰ Cats with a solitary disease could theoretically be treated with surgical excision

FIGURE 32-16 **A**, Lateral radiographic projection of a cat with tracheal lymphoma prior to treatment. **B**, The same cat 6 weeks following initiation of CHOP-based chemotherapy protocol.

or RT, although clinical staging is necessary to rule out possible further systemic involvement. For multiple sites, combination chemotherapy may be considered.

General Summary of Prognosis for Cats with Lymphoma

As previously discussed, the prediction of outcomes in cats with lymphoma is not generalizable due to the wide spectrum of histologic and anatomic subtypes encountered. Much has been mentioned in the previous treatment sections, and Tables 32-8 and Table 32-9 summarize prognostic parameters for lymphoma in cats.

Feline Leukemias, Myeloproliferative Disorders, and Myelodysplasia

For a complete discussion of leukemias and MPDs, including a general discussion of hematopoiesis, etiologies, lineage classification and descriptions, see Section C of this chapter. The classification of leukemias in cats is difficult because of the similarity of clinical and pathologic features and the transition, overlap, or mixture of cell types involved.¹³¹⁻¹³⁵ Most case-series reports are from the FeLV era and generally only single case reports exist from the more contemporary post-FeLV era, which further confuses our understanding of the biology and outcome. For this reason, only a simplistic discussion, primarily relating to the lymphoid leukemias will be presented here and the interested reader is again referred to Section C for a general discussion of nonlymphoid leukemia.

For cats with suspected leukemia, peripheral blood assessment (e.g., CBC with differential, flow cytometric analysis for size and immunophenotype, and PARR [for lymphoid leukemias]), and bone marrow aspiration or biopsy may contribute to a diagnosis. The preferred sites for bone marrow aspiration are the proximal humerus or iliac crest. Cats with acute leukemia are likely to have malignant cellular infiltrates in organs other than bone marrow.¹³⁴ A bone marrow aspirate with greater than 30% abnormal blast cells is sufficient to make a diagnosis of an acute leukemia. In cats with suspected CLL, infiltration of the bone marrow with more than 20% mature lymphocytes helps confirm the diagnosis. All cats with leukemia should be tested for FeLV/FIV. Determining the lineage of some leukemias can be challenging; most can be distinguished from one another by histologic appearance, histochemical stains, or immunohistochemical or flow cytometric analysis of the leukemic cells for cellular antigens that identify their lineage (see Chapter 8 and Section C in this chapter).^{131,133,136} In addition, examination of blast cells by electron microscopy may reveal characteristic ultrastructural features. The French-American-British (FAB) classification system is considered useful in cats with myelodysplastic syndromes and almost all will be FeLV antigenemic.^{136,137}

Lymphoid Leukemia

ALL was the most commonly encountered type of leukemia in cats in the FeLV era; however, it is much less common today. ALL is characterized by poorly differentiated lymphoblasts and prolymphocytes in blood and bone marrow. Approximately 60% to 80% of cats with ALL were FeLV positive, and most malignant cells have T-cell immunophenotypes¹³⁸; however, little information is available in the contemporary literature.

CLL is rarely reported in cats and is characterized by well-differentiated, small, mature lymphocytes in peripheral blood and

bone marrow. Whereas most are of the T-cell lineage, B-cell CLL has also been reported.^{136,139,140} Most cats have increased WBC counts greater than 50,000/ μ L, and most are FeLV negative.

Treatment of Leukemias

The use of chemotherapy to treat ALL has been disappointing. Using COP-based protocols, Cotter¹²⁴ reported a 27% CR rate. CLL can be treated with chlorambucil (0.2 mg/kg PO or 2 mg/cat QOD) and prednisone (1 mg/kg PO daily); however, little information exists regarding outcome. As in humans and dogs, if significant clinical signs or profound cytopenias are not present, treatment can be withheld—one cat with CLL remained stable without chemotherapy for over a year.¹⁴⁰ The prognoses for acute nonlymphoblastic leukemias are generally very poor, although some exceptions exist in case report form in the historic literature.

■ SECTION C

Canine Acute Myeloid Leukemia, Myeloproliferative Neoplasms, and Myelodysplasia

KAREN M. YOUNG AND DAVID M. VAIL

Myeloproliferative disorders (MPDs) are a group of neoplastic diseases of bone marrow in which there are clonal disorders of hematopoietic stem cells.¹ Aberrant proliferation of cells with defective maturation and function leads to reduction of normal hematopoiesis and invasion of other tissues. These disorders have been classified based on biologic behavior, degree of cellular differentiation, and lineage of the neoplastic cells (granulocytic, monocytic, erythroid, megakaryocytic, or mixed). Newer classification systems in humans have incorporated genetics and molecular genetic analysis; these are currently areas of active investigation in the study of animal leukemias.² In 1991 the Animal Leukemia Study Group made recommendations for classifying nonlymphoid leukemias in dogs and cats.³ More recently, the Oncology Committee of the American College of Veterinary Pathologists (ACVP) has been reexamining criteria for a classification system and spearheading large multiinstitutional studies to validate the criteria. Long-term

objectives of these studies are to define molecular lesions, establish prognostic markers, and target effective therapeutic approaches.⁴

Incidence and Risk Factors

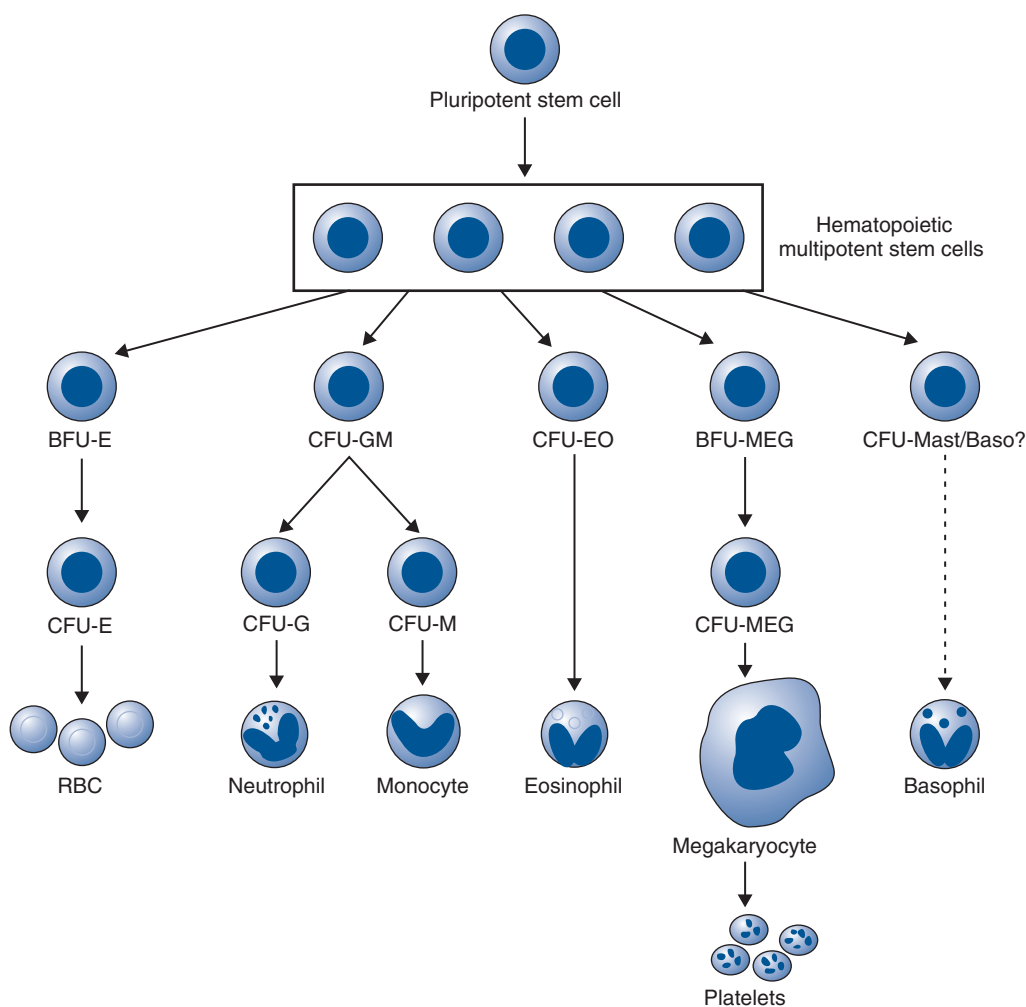

Myeloid neoplasms are uncommon or rare in the dog and occur 10 times less frequently than lymphoproliferative disorders.⁵ Accurate information about incidence and other epidemiologic information await consistent use of a uniform classification system (see later discussion). There is no known age, breed, or sex predisposition, although in some retrospective studies, large-breed dogs have been overrepresented.⁶⁻¹⁴ In dogs, the etiology of spontaneously occurring leukemia is unknown. It is likely that genetic and environmental factors (including exposure to radiation, drugs, or toxic chemicals) play a role. In humans, acquired chromosomal derangements lead to clonal overgrowth with arrested development.¹⁵ At the end of the last century, chromosomal abnormalities were reported in dogs with AML, chronic myelogenous leukemia (CML), and lymphoid leukemia.^{16,17} However, because karyotyping is difficult to perform in dogs because of the large number and morphologic similarity of their chromosomes and their resistance to banding, defining genetic factors in canine myeloid neoplasms has awaited application of molecular technologies and use of the canine genome map.^{2,18-21} Certain forms of leukemia in dogs have been

produced experimentally following irradiation.²²⁻²⁴ In contrast to MPDs in cats, no causative viral agent has been demonstrated in dogs, although retrovirus-like budding particles were observed in the neoplastic cells of a dog with granulocytic leukemia.²⁵

Pathology and Natural Behavior

A review of normal hematopoiesis will aid in understanding the various manifestations of MPDs. Hematopoiesis is the process of proliferation, differentiation, and maturation of stem cells into terminally differentiated blood cells. A simplified scheme is presented in Figure 32-17. Pluripotent stem cells differentiate into either lymphopoietic or hematopoietic multipotent stem cells.²⁶ Under the influence of specific regulatory and microenvironmental factors, multipotent stem cells in bone marrow differentiate into progenitor cells committed to a specific hematopoietic cell line, for example, erythroid, granulocytic-monocytic, or megakaryocytic. Maturation results in the production of terminally differentiated blood cells—erythrocytes, granulocytes, monocytes, and platelets—that are delivered to the circulation. In some cases, as in the maturation of reticulocytes to erythrocytes, final development may occur in the spleen.

Proliferation and differentiation of hematopoietic cells are controlled by a group of regulatory growth factors.^{26,27} Of these,

• **FIGURE 32-17** A simplified scheme of hematopoiesis. *BFU*, Blast-forming units; *CFU*, colony-forming units; *E*, erythroid; *GM*, granulocytic-monocytic; *EO*, eosinophil; *MEG*, megakaryocyte.

erythropoietin is the best characterized; it regulates erythroid proliferation and differentiation and is produced in the kidney, where changes in oxygen tension are detected. The myeloid compartment depends on a group of factors, collectively referred to as *colony-stimulating factors* (CSFs). These factors act at the level of the committed progenitor cells but also influence the functional capabilities of mature cells. Some of these factors have a broad spectrum of activity; others are more restricted in their target cells and actions. CSFs are produced in vitro by a multitude of cell types, including monocytes, macrophages, lymphocytes, and endothelial cells, and these cells likely play a role in the production and regulation of these factors in vivo. The gene for thrombopoietin also has been cloned, and it appears that this hormone alone can induce differentiation of megakaryocytes and platelet production.²⁸ Recombinant forms of many of these hormones are increasingly available.

Clonal disorders of bone marrow include myeloaplasia (usually referred to as *aplastic anemia*), myelodysplasia, and myeloproliferation. A preleukemic syndrome, characterized by peripheral pancytopenia and bone marrow hyperplasia with maturation arrest, is more correctly termed *myelodysplasia* because the syndrome does not always progress to overt leukemia. This syndrome has been described in cats, usually in association with FeLV infection but has only rarely been recognized in dogs.²⁹⁻³² These clonal disorders may be manifested by abnormalities in any or all lineages because hematopoietic cells share a common stem cell. In addition, transformation from one form to another may occur.³³

Myeloid neoplasms are classified in several ways. The terms *acute* and *chronic* refer to the degree of cellular differentiation of the leukemic cells, but these terms also correlate with the biologic behavior of the neoplasm.³⁴ Disorders resulting from uncontrolled proliferation or decreased apoptosis of cells incapable of maturation lead to the accumulation of poorly differentiated or “blast” cells. These disorders are included under the umbrella term, *acute myeloid leukemia* (AML). Disorders resulting from unregulated proliferation of cells that exhibit progressive, albeit incomplete and defective, maturation lead to the accumulation of differentiated cells. These disorders are termed *myeloproliferative neoplasms* (MPN) and include polycythemia vera, CML and its variants, essential thrombocythemia, and possibly primary myelofibrosis. Myeloid neoplasms are further classified by the lineage of the dominant cell type(s), defined by Romanowsky stains, special cytochemical stains, ultrastructural features, flow cytometric analysis, and immunologic cell markers, and they have been classified into subtypes (see later discussion).

AML has a more sudden onset and is more aggressive. In both acute and chronic disorders, however, abnormalities in proliferation, maturation, and functional characteristics can occur in any hematopoietic cell line.¹ In addition, normal hematopoiesis is adversely affected. Animals with leukemia usually have decreased numbers of circulating normal cells. The pathogenesis of the cytopenias is complex and may result in part from production of inhibitory factors. Eventually, neoplastic cells displace normal hematopoietic cells, and this is termed *myelophthisis*. Anemia and thrombocytopenia are particularly common. Neutropenia and thrombocytopenia result in infection and hemorrhage, which may be more deleterious to the animal than the primary disease process.

Acute Myeloid Leukemia

AML is rare and is characterized by aberrant proliferation and/or decreased apoptosis of a clone of cells without maturation. This results in accumulation of immature blast cells in bone marrow and

peripheral blood (Figure 32-18, A to E). The WBC count is variable and ranges from leukopenia to counts up to 150,000/μL. Spleen, liver, and lymph nodes are frequently involved, and other tissues, including tonsils, kidney, heart, and the CNS, may be infiltrated as well. There is no characteristic age, and even very young dogs may be affected.³⁵ The clinical course of these disorders tends to be rapid. Production of normal peripheral blood cells is usually diminished or absent, and anemia, neutropenia, and thrombocytopenia are common with infection and hemorrhage occurring as frequent sequelae. Occasionally, neoplastic blasts are present in bone marrow but not in peripheral blood. This is termed *aleukemic* leukemia, whereas *subleukemic* suggests a normal or decreased WBC count with some neoplastic cells in circulation.

In 1985 the Animal Leukemia Study Group was formed under the auspices of the American Society for Veterinary Clinical Pathology to develop specific morphologic and cytochemical criteria for classifying acute nonlymphocytic leukemias. Recognition of specific subtypes of leukemia is required to compile accurate and useful information about prognosis and response to treatment, as well as to compare studies from different sites. In 1991, this group proposed a classification system following adaptation of the French-American-British (FAB) system and criteria established by the NCI Workshop.³ Group members examined blood and bone marrow from 49 dogs and cats with myeloid neoplasms. Romanowsky-stained specimens were examined first to identify blast cells and their percentages. Lineage specificity was then determined using cytochemical markers. The percentage of blasts and the information about lineage specificity were used in combination to classify disorders as acute undifferentiated leukemia (AUL), acute myeloid leukemia (AML, subtypes M1 to M5 and M7), and erythroleukemia with or without erythroid predominance (M6 and M6Er). A description of these subtypes is presented in Table 32-12.

Canine karyotyping is difficult, but with advancements in molecular cytogenetic analysis, chromosome painting, and genomic hybridization, AML in dogs can now be analyzed at the base-pair level,^{18,19} and missense mutations in *FLT3*, *C-KIT*, and *RAS* sequences have been identified in dogs with AML, similar to what has been found for human AML.³⁶ In addition to serving as diagnostic and prognostic markers, cytogenetic lesions may be therapeutic targets. As cytogenetic abnormalities continue to be identified, this information will need to be incorporated into classification schemes.

With the exception of acute promyelocytic leukemia or M3, all of these subtypes have been described in dogs. However, because this modified FAB system has been adopted only recently, the names given to these disorders in the literature vary considerably. In addition, in the absence of cytochemical staining, immunophenotyping, or electron microscopic evaluation, the specific subtype of leukemia has often been uncertain, making retrospective analysis of epidemiologic information, prognosis, and response to therapy confusing at best. Although defining specific subtypes may seem to be an academic exercise owing to the uniformly poor prognosis of acute leukemias, this information is critical to improving the management of these diseases. Because of the low incidence of AML, national and international cooperative efforts will be required to accumulate information on the pathogenesis and response to different treatment modalities of specific subtypes. Utilization of a uniform classification system is an essential first step.

Different forms of AML are demonstrated in Figure 32-18, A to E. The most frequently reported forms of AML in the dog are acute myeloblastic leukemia (M1 and M2) and acute myelomonocytic

• **FIGURE 32-18** Peripheral blood from dogs with myeloid neoplasms. All diagnoses were confirmed by cytochemical staining. Note how similar the blast cells appear in **A** to **C**. **A**, Acute myeloblastic leukemia (M1). (Wright's stain, $\times 100$ objective.) **B**, Acute myelomonocytic leukemia (M4). • **TABLE 32-12** Subtypes of Leukemias and Dysplasias Adapting the FAB System

SUBTYPE	DESCRIPTION
Acute Leukemias	
AUL	Acute undifferentiated leukemia (formerly called <i>reticuloendotheliosis</i>)
M1	Myeloblastic leukemia, without differentiation
M2	Myeloblastic leukemia, with some neutrophilic differentiation
M3	Promyelocytic leukemia (not recognized in animals)
M4	Myelomonocytic leukemia
M5a	Monocytic leukemia, without differentiation
M5b	Monocytic leukemia, with some monocytic differentiation
M6	Erythroleukemia
M6Er	Variant of M6, with erythroblasts constituting the erythroid component
M7	Megakaryoblastic leukemia
Chronic Myeloid Leukemias	
CML	Chronic myelogenous leukemia
CMML	Chronic myelomonocytic leukemia
CMoL	Chronic monocytic leukemia
Hematopoietic Dysplasia	
MDS	Myelodysplastic syndrome
MDS-Er	Myelodysplastic syndrome with erythroid predominance

leukemia (M4).^{*} Megakaryoblastic leukemia (M7) also is well recognized in dogs^{10,47-58} and may be associated with platelet dysfunction.⁵¹ Monocytic leukemias have likely included those with and without monocytic differentiation (M5a and M5b),^{11,59} but in some cases the diagnosis may have been chronic myelomonocytic or chronic monocytic leukemia (see later discussion). There are few reports in dogs of spontaneously occurring erythroleukemia (M6) in which the leukemic cells include myeloblasts, monoblasts, and erythroid elements.⁶⁰⁻⁶² AULs have uncertain lineages because they are negative for all cytochemical markers. These leukemias should be distinguished from lymphoid leukemias by flow cytometric analysis of the leukemic cells for cellular antigens that identify their lineage.⁶³ In addition, examination of blast cells by electron microscopy may reveal characteristic ultrastructural features.

Myeloproliferative Neoplasms

MPNs, previously termed *chronic myeloproliferative disorders*, are characterized by excessive production of differentiated bone marrow cells, resulting in the accumulation of erythrocytes (polycythemia vera), granulocytes and/or monocytes (CML and its variants), or platelets (essential thrombocythemia). Primary myelofibrosis as a clonal disorder of marrow stromal cells, characterized by proliferation of megakaryocytes and granulocytic precursors with accumulation of collagen in bone marrow, has been

recognized only rarely in animals. Myelofibrosis is considered a response to injury and may occur secondary to other neoplasms, systemic inflammation, drug exposure, or FeLV infection in cats.

Polycythemia Vera

Polycythemia vera (PV) is a clonal disorder of stem cells, although whether the defect is in the pluripotent stem cell or the hematopoietic multipotent stem cell is still not clear. In humans, progenitor cells have an increased sensitivity to insulin-like growth factor 1, which stimulates hematopoiesis.⁶⁴ It is not known whether this hypersensitivity is the primary defect or is secondary to another gene mutation. In any case, the result is overproduction of red blood cells (RBCs). The disease is rare and must be distinguished from more common causes of polycythemia, including relative and secondary absolute polycythemia (see later discussion). In PV, there is neoplastic proliferation of the erythroid series with terminal differentiation to RBCs. The disease has been reported in dogs that tend to be middle-aged with no breed or sex predilection⁶⁵⁻⁷³ and is characterized by an increased RBC mass evidenced by an increased packed cell volume (PCV), RBC count, and hemoglobin concentration. The PCV is typically in the range of 65% to 85%. The bone marrow is hyperplastic, although the myeloid:erythroid (M:E) ratio tends to be normal. In contrast to the disease in humans, other cell lines do not appear to be involved, and transformation to other MPNs has not been reported. The disease in dogs may be more appropriately termed *primary erythrocytosis*. In humans, acquired *JAK2* gene mutations are identified in 90% of patients with primary polycythemia, and recently an identical mutation in the *JAK2* gene of one of five dogs with primary polycythemia was reported.⁷⁴

Chronic Myelogenous Leukemia

In dogs, CML is more similar to chronic neutrophilic leukemia, a rare form of MPN in humans, than to CML in humans because it is a neoplastic proliferation of the neutrophil series, although concurrent eosinophilic and basophilic differentiation can occur. CML can occur in dogs of any age.^{35,75-79} Neutrophils and neutrophilic precursors accumulate in bone marrow and peripheral blood as well as in other organs. The peripheral WBC count is usually, but not always, greater than 100,000/ μ L. Both immature and mature neutrophils are present, as demonstrated in Figure 32-18, F. Mature forms are usually more numerous, but sometimes an “uneven” left shift is present. Signs of dysplasia may be evident, including hypersegmentation, ringed nuclei, and giant forms. Eosinophils and basophils may also be increased. The bone marrow is characterized by granulocytic hyperplasia, and morphologic abnormalities may not be present. Erythroid and megakaryocytic lines may be affected, resulting in anemia, thrombocytopenia, or less commonly, thrombocytosis. This disorder must be distinguished from severe neutrophilic leukocytosis and “leukemoid reactions” caused by inflammation or immune-mediated diseases. Leukemoid reactions can also occur as a paraneoplastic syndrome. In humans with CML, characteristic cytogenetic abnormalities are present in all bone marrow cells, signifying a lesion at the level of an early multipotent stem cell. Typically, these individuals have a chromosomal translocation, resulting in the Philadelphia chromosome or BCR-ABL translocation between chromosomes 9 and 22.⁸⁰ The analogous chromosomes in dogs are chromosomes 9 and 26, and BCR-ABL mutations have now been reported in three cases of CML in dogs.² Variants of CML are chronic myelomonocytic leukemia (CMML) and chronic monocytic leukemia (CMoL).⁸¹⁻⁸³ These diagnoses are made based on the percentage of monocytes in the leukemic cell

*References 5-9, 23-34, 37-46.

population. BCR-ABL translocation has also been reported in a dog with CMoL.⁴⁵

In addition to accumulating in bone marrow and peripheral blood, leukemic cells also are found in the red pulp of the spleen, the periportal and sinusoidal areas of the liver, and sometimes lymph nodes. Other organs such as the kidney, heart, and lung are less commonly affected. In addition, extramedullary hematopoiesis may be present in the liver and spleen. Death is usually due to complications of infection or hemorrhage secondary to neutrophil dysfunction and thrombocytopenia. In some cases, CML may terminate in “blast crisis,” in which there is a transformation from a predominance of well-differentiated granulocytes to excessive numbers of poorly differentiated blast cells in peripheral blood and bone marrow. This phenomenon is well documented in the dog.^{75,76,78}

Basophilic and Eosinophilic Leukemia

Basophilic leukemia, although rare, has been reported in dogs and is characterized by an increased WBC count with a high proportion of basophils in peripheral blood and bone marrow.⁸⁴⁻⁸⁶ Hepatosplenomegaly, lymphadenopathy, and thrombocytosis may be present. All the dogs have been anemic. Basophilic leukemia should be distinguished from mast cell leukemia (mastocytosis). Whether dogs develop eosinophilic leukemia remains in question. Reported cases have had high blood eosinophil counts and eosinophilic infiltrates in organs.^{87,88} One dog responded well to treatment with corticosteroids. The distinction between neoplastic proliferation of eosinophils and idiopathic hypereosinophilic syndrome remains elusive. Disorders associated with eosinophilia such as parasitism, skin diseases, or diseases of the respiratory and GI tracts should be considered first in an animal with eosinophilia. One distinguishing feature should be clonality, with reactive eosinophilia comprising polyclonal cells and the neoplastic condition arising from a single clone. As clonality assays become more available, this discrepancy may be resolved.

Essential Thrombocythemia

In humans, essential thrombocythemia, or primary thrombocythemia, is characterized by platelet counts that are persistently greater than 600,000/ μ L. There are no blast cells in circulation, and marked megakaryocytic hyperplasia of the bone marrow without myelofibrosis is present. Thrombosis and bleeding are the most common sequelae, and most patients have splenomegaly. Other MPDs, especially PV, should be ruled out, and importantly, there should be no primary disorders associated with reactive thrombocytosis.⁸⁹ These include inflammation, hemolytic anemia, iron deficiency anemia, malignancies, recovery from severe hemorrhage, rebound from immune-mediated thrombocytopenia, and splenectomy. In addition, certain drugs such as vincristine can induce thrombocytosis. Essential thrombocythemia has been recognized in dogs.^{33,90-93} In one dog, the platelet count exceeded 4 million/ μ L and bizarre giant forms with abnormal granulation were present. The bone marrow contained increased numbers of megakaryocytes and megakaryoblasts, but circulating blast cells were not seen. Other findings included splenomegaly, GI bleeding, and increased numbers of circulating basophils. Causes of secondary or reactive thrombocytosis were ruled out.⁹⁰ Basophilia was also reported in a more recent case.⁹² In another dog, primary thrombocytosis was diagnosed and then progressed to CML.³³ In some cases reported in the literature as essential thrombocythemia, the dogs had microcytic hypochromic anemias. Because iron deficiency anemia is associated with reactive or secondary thrombocytosis, care must be taken to rule

out this disorder. However, spurious microcytosis may be reported if a dog has many giant platelets that are counted by an analyzer as small RBCs.⁹³ Microscopic review of the blood film may be helpful in these cases.

Other Bone Marrow Disorders

Myelofibrosis

Primary myelofibrosis has been reported only rarely in dogs and is usually a secondary, or reactive, process.^{94,95} In humans, myelofibrosis is characterized by collagen deposition in bone marrow and increased numbers of megakaryocytes and granulocytic precursors, many of which exhibit morphologic abnormalities. In fact, breakdown of intramedullary megakaryocytes and subsequent release of factors that promote fibroblast proliferation or inhibit collagen breakdown may be the underlying pathogenesis of the fibrosis.⁹⁶ Focal osteosclerosis is sometimes present. Anemia, thrombocytopenia, splenomegaly, and myeloid metaplasia (production of hematopoietic cells outside the bone marrow) are consistent features.

In dogs, myelofibrosis occurs secondary to MPDs, radiation damage, and congenital hemolytic anemias.⁹⁷⁻¹⁰⁰ In some cases, the inciting cause is unknown (idiopathic myelofibrosis). There may be concurrent marrow necrosis in cases of ehrlichiosis, septicemia, or drug toxicity (estrogens, cephalosporins), and there is speculation that fibroblasts proliferate in response to release of inflammatory mediators associated with the necrosis.⁹⁴ Myeloid metaplasia has been reported to occur in the liver, spleen, and lung.¹⁰⁰ Extramedullary hematopoiesis is ineffective in preventing or correcting the pancytopenia that eventually develops.

Myelodysplastic Syndrome

Dysfunction of the hematopoietic system can be manifested by a variety of abnormalities that constitute myelodysplastic syndrome (MDS). In dogs, in which the syndrome is rare, there usually are cytopenias in two or three lines in the peripheral blood (anemia, neutropenia, and/or thrombocytopenia). Other blood abnormalities can include macrocytic erythrocytes and metarubricytosis. The bone marrow is typically normocellular or hypercellular, and dysplastic changes are evident in several cell lines. If blast cells are present, they make up less than 30% of all nucleated cells,² although this threshold is being changed to less than 20%.^{4,20} Myelodysplasia is sometimes referred to as *preleukemia* because, in some cases, it may progress to acute leukemia.²⁹⁻³¹ Based on reported cases, poor prognostic indices include increased percentage of blast cells, cytopenias involving more than one lineage, and cellular atypia. Primary MDSs are clonal disorders and are considered neoplastic. Complex classification schemes for human MDS, based on percentages of blasts in bone marrow, cytogenetic analysis, cytopenias, need for transfusions, and other variables, comprise at least nine subtypes; their applicability to veterinary medicine is unknown.⁵ Three subtypes are proposed for dogs and cats and include MDS with excessive blasts (MDS-EB), in which blast percentages are greater than 5% and less than 20%, and progression to AML may occur; MDS with refractory cytopenia (MDS-RC) with blast percentages less than 5% and cytopenias in one or more lineages; and MDS with erythroid predominance (MDS-ER) in which the M:E ratio is less than 1 and prognosis is poor.⁴ Larger studies are needed to determine the utility of this classification scheme and other potential prognostic indices, such as sex, age, and FeLV positivity. In addition to accumulating enough cases, another confounding factor to studying and classifying MDS is the presence of reversible MDSs

that occur secondary to immune-mediated, infectious, and other diseases in both dogs and cats.

History and Clinical Signs

Dogs with myeloid neoplasms have similar presentations regardless of the specific disease entity, although animals with AML have a more acute onset of illness and a more rapid clinical course. A history of lethargy, inappetence, and weight loss is common. Clinical signs include emaciation, persistent fever, pallor, petechiation, hepatosplenomegaly, and, less commonly, lymphadenopathy and enlarged tonsils. Shifting leg lameness, ocular lesions, and recurrent infections are also seen. Vomiting, diarrhea, dyspnea, and neurologic signs are variable features. Serum biochemical analytes may be within the reference intervals but can change if significant organ infiltration occurs. Animals with MDS may be lethargic and anorectic and have pallor, fever, and hepatosplenomegaly. In PV, dogs often have erythema of mucous membranes owing to the increase in RBC mass. Some dogs are polydipsic. In addition, neurologic signs such as disorientation, ataxia, or seizures may be present and are thought to be the result of hyperviscosity or hypervolemia.⁶⁹ Hepatosplenomegaly is usually absent.

Peripheral blood abnormalities are consistently found. In addition to the presence of neoplastic cells, other abnormalities, including cytopenias of any lineage, may be present. Low numbers of nucleated RBCs are present in the blood of about half the dogs with acute nonlymphocytic leukemia.³ Nonregenerative anemia and thrombocytopenia are present in most cases. Anemia is usually normocytic and normochromic, although macrocytic anemia is sometimes present. Pathogenic mechanisms include effects of inhibitory factors leading to ineffective hematopoiesis, myelophthisis, immune-mediated anemia secondary to neoplasia, and hemorrhage secondary to thrombocytopenia, platelet dysfunction, or DIC. Anemia is most severe in AML, although both anemia and thrombocytopenia may be milder in animals with the M5 subtype (acute monocytic leukemia). In myelofibrosis, the anemia is characterized by anisocytosis and poikilocytosis. In addition, pancytopenia and leukoerythroblastosis, in which immature erythroid and myeloid cells are in circulation, may be present. These phenomena probably result from replacement of marrow by fibrous tissue with resultant shearing of red cells and escape of immature cells normally confined to bone marrow. In PV, the PCV is increased, usually in the range of 65% to 85%. The bone marrow is hyperplastic, and the M:E ratio is usually in the normal range.

Neoplastic cells are often defective functionally. Platelet dysfunction has been reported in a dog with acute megakaryoblastic leukemia (M7),⁵¹ and in CML, neutrophils have decreased phagocytic capacity and other abnormalities. One exception to this was a report of CML in a dog in which the neutrophils had enhanced phagocytic capacity and superoxide production.¹⁰¹ The authors hypothesized that increased synthesis of GM-CSF resulted from a lactoferrin deficiency in the neoplastic neutrophils and mediated the enhanced function of these cells.

Diagnostic Techniques and Work-Up

In all cases of myeloid neoplasms, diagnosis depends on examination of peripheral blood and bone marrow. AML is diagnosed on the basis of finding blast cells with clearly visible nucleoli in blood and bone marrow. Most dogs with acute leukemia have circulating blasts. These cells may be present in low numbers in peripheral blood, and a careful search of the smear, especially at the feathered edge, should be made. Even if blasts are not detected in circulation, indications of bone marrow disease such as nonregenerative anemia

or thrombocytopenia are usually present. Occasionally, neoplastic cells can be found in cerebrospinal fluid in animals with invasion of the CNS. Smears of aspirates from tissues such as the lymph nodes, spleen, or liver may contain blasts but usually contribute little to the diagnostic work-up.

Examination of blasts stained with standard Romanowsky stains may give clues as to the lineage of the cells (Figure 32-18, A to C and E). In myelomonocytic leukemia, the nuclei of the blasts are usually pleomorphic, with round to lobulated forms. In some cells, the cytoplasm may contain large azurophilic granules or vacuoles. Blasts in megakaryocytic leukemia may contain vacuoles and have cytoplasmic blebs. In addition, bizarre macroplatelets may be present. Although these distinguishing morphologic features may suggest a definitive diagnosis, cytochemical staining or immunophenotyping are usually required to define the lineage of the blasts. Several investigators have reported modification of diagnoses following cytochemical staining.^{102,103} It is especially important to distinguish AML from lymphocytic leukemia in order to provide accurate prognostic information to the owner and institute appropriate therapy.

The Animal Leukemia Group has recommended the following diagnostic criteria, summarized in Figure 32-19.³ Using well-prepared Romanowsky-stained blood and bone marrow films, a minimum of 200 cells are counted to determine the leukocyte differential in blood and the percentage of blast cells in bone marrow and/or blood. In bone marrow, blast cells are calculated both as a percentage of all nucleated cells (ANC) and nonerythroid cells (NEC) and are further characterized using cytochemical markers.¹⁰²⁻¹⁰⁴ Neutrophil differentiation is identified by positive staining of blasts for peroxidase, Sudan Black B, and chloracetate esterase. Nonspecific esterases (alpha-naphthyl acetate esterase or alpha-naphthyl butyrate esterase), especially if they are inhibited by sodium fluoride, mark monocytes. Canine monocytes may also contain a few peroxidase-positive granules. Acetylcholinesterase is a marker for megakaryocytes in dogs and cats. In addition, positive immunostaining for von Willebrand's factor (factor VIII-related antigen) and platelet glycoproteins on the surface of blasts identifies them as megakaryocyte precursors.^{10,49-53} Alkaline phosphatase (AP) only rarely marks normal cells in dogs and cats but is present in blast cells in acute myeloblastic and myelomonocytic leukemias. However, owing to reports of AP activity in lymphoid leukemias in dogs, its specificity as a marker for myeloid cells is not certain. Omega exonuclease is a specific marker for basophils, which are also positive for chloracetate esterase activity.⁸⁶

Blood and bone marrow differential counts and cytochemical staining should be performed and interpreted by experienced veterinary cytopathologists. If erythroid cells are less than 50% of ANC and the blast cells are greater than 30%, a diagnosis of AML or AUL is made. If erythroid cells are greater than 50% of ANC and the blast cells are greater than 30%, a diagnosis of erythroleukemia (M6) is made. If rubriblasts are a significant proportion of the blast cells, a diagnosis of M6Er, or erythroleukemia with erythroid predominance, can be made. It should be noted that in the human AML classification system, the blast threshold has been lowered to 20% and similar recommendations are being made for AML in dogs and cats.

In some cases, electron microscopy is required to identify the lineage of the blast cells. For example, megakaryocyte precursors are positive for platelet peroxidase activity and contain demarcation membranes and alpha granules.^{49,53} Both of these features are detected at the ultrastructural level. Immunophenotyping, used to identify cell lineages in human patients, awaits development of

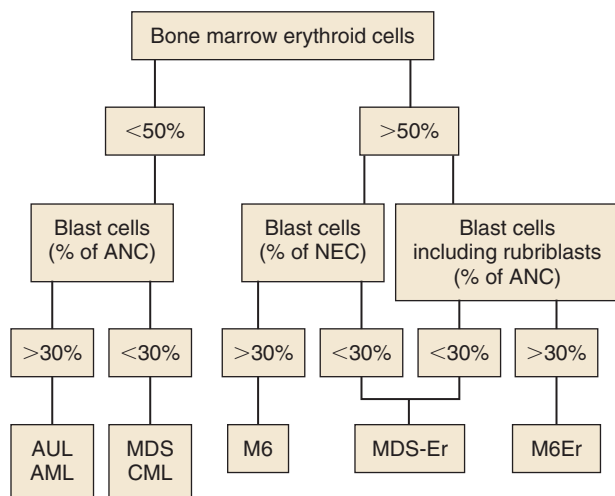

FIGURE 32-19 A scheme to classify myeloid neoplasms and myelodysplastic syndromes in dogs and cats. (*Blast cells*, Myeloblasts, monoblasts, and megakaryoblasts; *ANC*, all nucleated cells in bone marrow, including lymphocytes, plasma cells, macrophages, and mast cells; *NEC*, nonerythroid cells in bone marrow; *AUL*, acute undifferentiated leukemia; *AML*, acute myeloid leukemias M1 to M5 and M7; *CML*, chronic myeloid leukemias, including chronic myelogenous, chronic myelomonocytic, and chronic monocytic leukemias; *MDS*, myelodysplastic syndrome; *MDS-Er*, myelodysplastic syndrome with erythroid predominance; *M6*, erythroleukemia; *M6Er*, erythroleukemia with erythroid predominance.) (From Jain NC, Blue JT, Grindem CB, et al: Proposed criteria for classification of acute myeloid leukemia in dogs and cats, Vet Clin Pathol 20(3):63–82, 1991.)

appropriate markers for animal species (see later). Increasingly, cytogenetic abnormalities are being identified in animal leukemias; cytogenetic analysis may yield important diagnostic and prognostic information and become a valuable tool for identifying targeted therapeutic approaches.

Although morphologic and cytochemical analyses have formed the mainstay of cell identification, newer technologies now are routinely used to classify leukemias by using monoclonal antibodies to detect antigens associated with certain cell types. Cells can be immunophenotyped using flow cytometric analysis or immunocytochemistry.^{20,63,105–108} Cells from both acute lymphoid leukemia and AML are positive for CD34. Many lymphocyte markers, including CD3, CD4, CD8, CD18, CD21, CD45, CD79, and IgG, are available for dogs and can be used to rule out lymphoblastic leukemia in dogs with acute leukemias.^{63,105} Other markers include myeloperoxidase (MPO) and CD11b for myeloid cells and CD41 for megakaryoblasts. There is some overlap in expression of these cellular antigens. For example, canine (but not human) granulocytes express CD4. It is best to use a panel of antibodies (similar to using a battery of cytochemical stains) because antigens are often expressed on multiple lineages, and lineage infidelity can occur. These tests have become more valuable with the availability of canine reagents. Currently, the ACVP Oncology Committee recommends that the following immunophenotyping panel be done on bone marrow and/or blood smears to characterize animal leukemias: for B lymphocytes, CD79a; for T lymphocytes, CD3; for myeloid cells, MPO and CD11b; for megakaryoblasts, CD41; for dendritic cells, CD1c; and for acute leukemias, CD34.²⁰

Because of the degree of differentiation of cells in MPN, these disorders must be distinguished from nonneoplastic causes of

increases in these cell types. In order to make a diagnosis of PV, it must first be established that the polycythemia is absolute rather than relative. In relative polycythemias, plasma volume is decreased from hemoconcentration, dehydration, or hypovolemia, and the absolute RBC mass is not increased. Splenic contraction can also result in relative polycythemia. Absolute polycythemia, in which RBC mass is increased, is usually secondary to tissue hypoxia, causing appropriate increased production of erythropoietin. Rarely, erythropoietin may be produced inappropriately by a tumor (e.g., renal cell carcinoma) or in renal disease (pyelonephritis) or localized renal hypoxia.^{109–111} These causes of polycythemia should be eliminated by appropriate laboratory work, thoracic radiographs, arterial blood gas analysis, and renal ultrasonography. In humans with PV, plasma erythropoietin (EPO) levels are low. EPO levels in dogs with PV tend to be low or low-normal, whereas in animals with secondary absolute polycythemia, the levels are high.^{112,113} Samples for determination of EPO concentrations should be taken prior to therapeutic phlebotomy used to treat hyperviscosity and, owing to fluctuations in EPO levels, should be repeated if results are incongruous with other information.

There are no pathognomonic features of CML in dogs, and other common causes for marked leukocytosis with a left shift (“leukemoid reaction”) and granulocytic hyperplasia of bone marrow must be eliminated. These include infections, especially pyogenic ones; immune-mediated diseases; and other malignant neoplasms. In CML, maturation sometimes appears disorderly, and there may be variation in the size and shape of neutrophils at the same level of maturation. In addition, neoplastic leukocytes may disintegrate more rapidly and appear vacuolated.³⁵ Because of the invasive nature of CML, biopsy of liver or spleen may also help to distinguish true leukemia from a leukemoid reaction, assuming the animal can tolerate the procedure. If characteristic cytogenetic abnormalities can be found in dogs with CML, this analysis may be helpful.

Basophilic leukemia is diagnosed by finding excessive numbers of basophils in circulation and in bone marrow. Basophilic leukemia must be differentiated from mastocytosis based on the morphology of the cell type present. Basophils have a segmented nucleus and variably sized granules, whereas mast cells have a round-to-oval nucleus that may be partially or totally obscured by small, round, metachromatic-staining granules. This distinction is usually easy to make; however, in basophilic leukemia, changes in the morphology of the nucleus and granules make the distinction less clear.⁸⁵

Essential thrombocythemia has been diagnosed based on finding persistent and excessive thrombocytosis (>600,000/ μ L) without circulating blast cells and in the absence of another MPD (e.g., PV), myelofibrosis, or disorders known to cause secondary thrombocytosis.⁸⁹ These include iron deficiency anemia, chronic inflammatory diseases, recovery from severe hemorrhage, rebound from immune-mediated thrombocytopenia, and absence of a spleen. Thrombocytosis is transient in these disorders or abates with resolution of the primary disease. In essential thrombocythemia, platelet morphology may be abnormal, with bizarre giant forms and abnormal granulation.⁹⁰ In the bone marrow, megakaryocytic hyperplasia is a consistent feature, and dysplastic changes may be evident in megakaryocytes.⁹³ Spurious hyperkalemia may be present in serum samples from dogs with thrombocytosis from any cause due to the release of potassium from platelets during clot formation.¹¹⁴ Measuring potassium in plasma is recommended in these cases and usually demonstrates a potassium concentration within reference interval. Platelet aggregability has been

variably reported as impaired⁹⁰ or enhanced.⁹³ In the one dog in which it was measured, the plasma thrombopoietin (TPO) concentration was normal.⁹² It is unclear whether TPO plays a role in essential thrombocythemia or is suppressed by the high platelet mass. Elucidation of the pathogenesis of this disorder should be aided by the recent cloning of the genes for thrombopoietin and its receptor, the proto-oncogene *mpl*.¹¹⁵

In MDS, abnormalities in two or three cell lines are usually manifested in peripheral blood as neutropenia with or without a left shift, nonregenerative anemia, or thrombocytopenia. Other changes include macrocytosis and metarubricytosis. The bone marrow is typically normocellular or hypercellular with an increased M:E ratio, and blasts cells, although increased, constitute less than 20% of nucleated cells; in a report of 13 dogs with primary or secondary MDS, in all but one dog the blast cell percentage was less than 20%.¹¹⁶ Dysplastic changes can be detected in any cell line. Dyserythropoiesis is characterized by asynchronous maturation of erythroid cells typified by large hemoglobinized cells with immature nuclei (megaloblastic change). If the erythroid component is dominant, the MDS is called *MDS-Er* (see Table 32-12).^{3,32} In dysgranulopoiesis, giant neutrophil precursors and abnormalities in nuclear segmentation and cytoplasmic granulation can be seen. Finally, dysthrombopoiesis is characterized by giant platelets and micromegakaryocytes.

Myelofibrosis should be suspected in animals with nonregenerative anemia or pancytopenia, abnormalities in erythrocyte morphology (especially shape), and leukoerythroblastosis. Bone marrow aspiration is usually unsuccessful, resulting in a “dry tap.” This necessitates a bone marrow biopsy taken with a Jamshidi needle.¹¹⁷ The specimen is processed for routine histopathologic examination, and if necessary, special stains for fibrous tissue can be used. Because myelofibrosis occurs secondary to other diseases of bone marrow such as chronic hemolytic anemia or bone marrow necrosis, the clinician should look for a primary disease process.

Treatment

Acute Myeloid Leukemia

Treatment of acute nonlymphocytic leukemias has been unrewarding to date. However, we have little information on the response of specific subtypes of leukemia to uniform chemotherapeutic protocols, in part due to the rarity of these disease processes and the paucity of cases in the literature. The veterinarian is advised to contact a veterinary oncologist for advice on new protocols and appropriate management of these cases.

The therapeutic goal is to eradicate leukemic cells and reestablish normal hematopoiesis. Currently, this is best accomplished by cytoreductive chemotherapy, and the agents most commonly utilized include a combination of Ara-C plus an anthracycline, such as doxorubicin or cyclophosphamide, vincristine, and prednisone.* In humans, the introduction of cytosine arabinoside has been the single most important development in the therapy of acute nonlymphocytic leukemia.¹²⁰ In dogs, Ara-C, 100 to 200 mg/m², given by slow infusion (12 to 24 hrs) daily for 3 days and repeated weekly, has been used, as well as several other variations using subcutaneous injections of cytosine (see Chapter 11). Doxorubicin, 30 mg/m² IV every 2 to 3 weeks, can be administered at intervals alternating with Ara-C. If remission is achieved, as evidenced by normalization of the hemogram, the COAP protocol (cyclophosphamide, vincristine (Oncovin), Ara-C, and prednisone), as described for canine

• **TABLE 32-13** Protocol for the Treatment of Acute Myeloproliferative Disorders

DRUG	DOSAGE	ROUTE
Remission Induction		
Cytosine arabinoside (Ara-C)	100 mg/m ² /day	IV over 60 minutes every 12 hours
6-Thioguanine	40 mg/m ²	PO for 4 days
Doxorubicin	10-15 mg/m ²	IV daily for 3 days
Maintenance		
Ara-C	100 mg/m ² /day	SQ or IV once or twice/week
6-Thioguanine	40 mg/m ²	PO twice weekly
Doxorubicin	30 mg/m ²	IV every 3 weeks

Data from Mears EA, Raskin RE, Legendre AM: Basophilic leukemia in a dog, *J Vet Intern Med* 11(2):92-94, 1997.

IV, Intravenous; PO, by mouth; SQ, subcutaneous.

lymphoma, could be used as maintenance therapy.^{9,118} Another protocol that has been used in treating acute myeloblastic leukemia is presented in Table 32-13.

Regardless of the chemotherapy protocol used, significant bone marrow suppression will develop, and intensive supportive care will be necessary. Transfusions of whole blood or platelet-rich plasma may be required to treat anemia and thrombocytopenia, and infection should be managed with aggressive antibiotic therapy. Because of the generally poor response, the major thrust of therapy may be to provide palliative supportive care.

Polycythemia Vera

In treating PV, therapy is directed at reducing RBC mass. The PCV should be reduced to 50% to 60% or by one-sixth of its starting value; phlebotomies should be performed as needed, administering appropriate colloid and crystalloid solutions to replace lost electrolytes; 20 mL of whole blood/kg of body weight can be removed at regular intervals.⁶⁷ In humans, phlebotomy continues to be the therapeutic approach used most frequently.

Radiophosphorus (³²P) has been shown to provide long-term control but can only be used in specialized centers.¹²¹ The chemotherapeutic drug of choice is hydroxyurea, an inhibitor of DNA synthesis. This drug should be administered at an initial dose of 30 mg/kg for 10 days and then reduced to 15 mg/kg PO daily.⁶⁹ The major goal of treatment is to maintain the PCV as close to normal as possible.

Chronic Myelogenous Leukemia

CML is best managed with chemotherapy to control the proliferation of the abnormal cell line and improve the quality of life. Hydroxyurea is the most effective agent for treating CML during the chronic phase.^{75,122} The initial dosage is 20 to 25 mg/kg twice daily. Treatment with hydroxyurea should continue until the leukocyte count falls to 15,000 to 20,000 cells/ μ L.^{75,79,84} Then the dosage of hydroxyurea can be reduced by 50% on a daily basis or to 50 mg/kg given biweekly or triweekly. In humans, the alkylating agent busulfan can be used as an alternative.¹²³ An effective dosage has not been established in the dog, but following human protocols, 0.1 mg/kg/day PO is given until the leukocyte count is reduced to 15,000 to 20,000 cells/ μ L.

*References 9, 12, 29, 39, 118, 119.

Despite response to chemotherapy and control for many months, most dogs with CML will eventually enter a terminal phase of their disease. In one study of seven dogs with CML, four underwent terminal phase blast crisis.⁷⁵ In humans, blast crisis may be lymphoid or myeloid.¹²⁴ In dogs, it is usually difficult to determine the cell of origin. These dogs have a poor prognosis, and the best treatment to consider, if any, would be that listed in Table 32-13.

It has now been documented that a subset of CML in dogs may be associated with a BCR-ABL chromosomal abnormality (the so-called “Raleigh chromosome”) similar to the “Philadelphia chromosome” translocation responsible for a large majority of CML in humans.² While imatinib mesylate (Gleevec) is known to be an effective therapy for CML in humans, BCR-ABL kinase inhibitors have, as yet, not been investigated for this subset of CML in dogs.

Essential Thrombocythemia

Few cases have been reported, but one dog was treated successfully with a combination chemotherapy protocol that included vincristine, Ara-C, cyclophosphamide, and prednisone.⁹¹ Treatment is controversial in humans because of the lack of evidence that asymptomatic patients benefit from chemotherapy. Patients with thrombosis or bleeding are given cytoreductive therapy. Hydroxyurea is the drug of choice for initially controlling the thrombocytosis.⁸⁹

Myelodysplastic Syndrome

There is no standard therapeutic regime for MDS. Often, humans receive no treatment if the cytopenias do not cause clinical signs. Transfusions are given when necessary, and patients with fever are evaluated aggressively to detect infections. Growth factors, such as EPO, GM-CSF, G-CSF, and IL-3, are sometimes used in patients who require frequent transfusions to increase their blood cell counts and enhance neutrophil function.^{125,126} In one case report, human EPO was administered (100 U/kg SQ, every 48 hours) to a dog with MDS because of profound anemia. The rationale for use of EPO was to promote terminal differentiation of dysplastic erythrocytes. The PCV increased from 12% to 34% by day 19 of EPO treatment. This dog remained in remission for more than 30 months.³² Other factors that induce differentiation of hematopoietic cells include retinoic acid analogs,¹²⁷ 1,25 dihydroxyvitamin D₃,¹²⁸ interferon- α , and conventional chemotherapeutic agents, such as 6-thioguanine and Ara-C.¹²⁹ The propensity of these factors to enhance progression to leukemia is not known in many cases, but the potential risk exists.

Prognosis

In general, the prognosis for animals with MPN is better than for dogs with AML, in which it is grave. The prognosis for PV and CML is guarded, but significant remissions have been achieved with certain therapeutic regimes and careful monitoring. Animals commonly survive a year or more.^{75,84} Development of blast crisis portends a grave prognosis.

Comparative Aspects

The pathophysiology and therapy of nonlymphocytic leukemia in humans are being studied intensively. Myeloid neoplasms have been demonstrated to be clonal, with abnormalities evident in all hematopoietic cell lines. Leukemogenesis is likely caused by mutation or amplification of proto-oncogenes in a two-step process that initially involves a single cell and is followed by additional chromosomal alterations that may involve oncogenes.^{1,15} These alterations are manifested as cytogenetic abnormalities. Environmental factors known to cause leukemia are exposure to high-dose radiation,

benzene (chronic exposure), and alkylating agents.¹³⁰ New classification systems have incorporated genetic mutations, more accurately reflect prognoses, and facilitate use of consistent categorization among institutions.¹³¹

Therapeutic modalities under investigation or development include combination chemotherapy, immunotherapy, cytokine therapy, drug-resistance modulators, proapoptotic agents, antiangiogenic factors, signal transduction-active agents, and bone marrow transplantation. The prognosis for MPN is better than for AML. For acute nonlymphocytic leukemias, the prognosis is better for children than adults, with only 10% of adults receiving chemotherapy maintaining remissions for more than 5 years.¹³⁰ The spontaneous canine diseases probably occur too infrequently to serve as useful models. Myeloid neoplasms have been induced experimentally in the dog by irradiation and transplantation in an attempt to create models for study. Many similarities between human and canine myeloid neoplasms exist, and veterinary medicine may benefit from any therapeutic advances made in the human field.

SECTION D

Myeloma-Related Disorders

DAVID M. VAIL

Myeloma-related disorders (MRDs) arise when a cell of the plasma cell or immunoglobulin-producing B-lymphocyte precursor lineage transforms and proliferates to form a neoplastic population of similar cells. This population is believed in most instances to be monoclonal (i.e., derived from a single cell) because they typically produce homogenous immunoglobulin, although some examples of biclonal and polyclonal MRD neoplasms exist. A wide variety of clinical syndromes are represented by MRDs, including multiple myeloma (MM), extramedullary plasmacytoma (EMP [both cutaneous and noncutaneous]), IgM (Waldenström's) macroglobulinemia, solitary osseous plasmacytoma (SOP), and Ig-secreting lymphomas and leukemias (including plasma cell leukemia). MM is the most important MRD based on clinical incidence and severity. There appears to be some discordance and

blurring of the distinction between MM and multicentric noncutaneous EMP in cats and these two MRDs will be discussed together in this species.

Multiple Myeloma

Incidence and Etiology

Although MM represents less than 1% of all malignant tumors in animals, it is responsible for approximately 8% of all hematopoietic tumors and 3.6% of all primary and secondary tumors affecting bone in dogs.^{1,2} In a compilation of bone marrow disorders in dogs (n = 717), MM represented 4.4% and 19.8% of all abnormal samples and neoplastic processes, respectively.³ Further, in a compilation of serum protein electrophoretic samples (n = 147 dogs), MM accounted for 4.3% of abnormal and 28.5% of neoplastic processes encountered, respectively.⁴ Early studies suggested a male predisposition,⁵ although subsequent reports have not supported this.^{1,6} Older dogs are affected with an average age of between 8 and 9 years.^{1,5,6} In one large case series, German shepherd dogs were over-represented based on the hospital population.¹ The true incidence of MM in the cat is unknown; however, it is a more rare diagnosis than in the dog, representing only 1 of 395 and 4 of 3248 tumors in two large compilations of feline malignancies and 0.9% of all malignancies and 1.9% of hematologic malignancies in another report.^{7–9} MM represented 1.4% and 14% of abnormal and malignant serum protein electrophoretic samples, respectively, in a compilation of 155 feline samples.¹⁰ MM occurs in aged cats (median age 12 to 14 years), most commonly in domestic short hairs and no sex predilection has been consistently reported, although a male preponderance may exist.^{6,9,11,12} MM has not been associated with corona virus or FeLV or FIV infections.

The etiology of MM is for the most part unknown. Genetic predispositions, molecular aberrations (e.g., c-Kit), viral infections, chronic immune stimulation, and exposure to carcinogen stimulation have all been suggested as contributing factors.^{6,13–18} Suggestion of a familial association in cats follows cases reported among siblings.¹² Evidence exists that molecular mechanisms of cellular control, including overexpression of cell cycle control components like cyclin D1 (see Chapter 2) and receptor tyrosine kinase dysregulation may be involved in canine myeloma and plasma cell tumors.^{17,18} In rodent models, chronic immune stimulation and exposure to implanted silicone gel have been associated with development of MM,^{13,14} as have chronic infections and prolonged hyposensitization therapy in humans.¹⁵ Viral Aleutian disease of mink results in monoclonal gammopathies in a small percentage of cases.¹⁶ Exposure to the agricultural industry, petroleum products, and irradiation are known risk factors for development in humans.^{19–21} Additionally, progression of solitary plasma cell tumors to MM has been reported in both dogs and cats, and a single case of a B-cell lymphoma progressing to MM exists in the dog.^{22,23}

Pathology and Natural Behavior

Multiple myeloma is a systemic proliferation of malignant plasma cells or their precursors arising as a clone of a single cell that usually involves multiple bone marrow sites in dogs. In cats, as previously stated, a blurring of the distinction of MM and multicentric noncutaneous EMP within the MRD occurs because widespread abdominal organ involvement without significant bone marrow infiltration has been described in a significant proportion of cases in European compilations.^{11,24} Because both MM and multicentric noncutaneous EMP have a similar clinical course and widespread systemic involvement with hyperglobulinemia in cats, they will be

• **FIGURE 32-20** Bone marrow aspirate from a dog with multiple myeloma showing an overabundance of large neoplastic plasma cells with characteristic paranuclear clear zone representing the Golgi apparatus (arrow). (Dif-quick stain, $\times 100$ objective.)

discussed as MM in this chapter. Malignant plasma cells can have a varied appearance on histologic sections and cytologic preparations. The degree of differentiation ranges from those resembling normal plasma cells in late stages of differentiation (Figure 32-20) to very large anaplastic round cells (often referred to as *plasmablasts*), with a high mitotic index representing early stages of differentiation.^{5,6,9,24,25} Binucleate and multinucleate cells are often present (see Figure 7-32, Chapter 7). In 16 cats with MM in a North American case series, the majority (83%) of plasma cells were immature and had marked atypia, including increased size, multiple nuclei, clefted nuclei, anisocytosis, anisokaryosis, variable N:C ratios, decreased chromatin density, and variable nucleoli; nearly one-quarter had “flame cell” morphology characterized by peripheral eosinophilic cytoplasmic processes.⁹ However, in a European compilation of feline multicentric noncutaneous MRD cases ($n = 17$), 78% had well-differentiated morphologies.²⁴ The authors of this latter case series developed a grading system dependent on the percentage of plasmablasts within the neoplastic cells in which well-differentiated, intermediate-grade, and poorly differentiated have less than 15%, 15% to 49%, and 50% or more plasmablasts, respectively. Malignant plasma cells typically produce an overabundance of a single type of or component of immunoglobulin, which is referred to as the *M component* (Figure 32-21). The M component can be represented by any class of the entire immunoglobulin or only a portion of the molecule, such as the light chain (Bence Jones protein) or heavy chain (heavy chain disease) of the molecule. In the dog, the M component is usually represented by either IgA or IgG immunoglobulin types in nearly equal incidence, whereas the ratio of IgG:IgA in cats is approximately 5:1 in some reports and approximately 1:1 in others.^{1,5-9,24,26} That being said, in the author’s (DMV) experience, the vast majority of canine cases are of the IgA type. If the M component is the IgM type, the term *macroglobulinemia* (Waldenström’s) is often applied. Several cases of biclonal gammopathy in dogs and cats have been reported.^{9,11,12,27-32} Several cases of nonsecretory MM have been reported in dogs.^{33,34} Rarely, cryoglobulinemia occurs in dogs with MM and IgM macroglobulinemia and has been reported in a cat with IgG myeloma.^{6,35-37} Cryoglobulins are paraproteins that are insoluble at temperatures

below 37° C and require blood collection and clotting to be performed at 37° C prior to serum separation. If whole blood is allowed to clot at temperatures below this, the protein precipitates in the clot and is lost. Pure light-chain M component is rare but has been reported in both dogs and cats.^{38,39}

The pathology associated with MM is a result of either high levels of circulating M component, organ or bone infiltration with neoplastic cells, or both. Associated pathologic conditions include bone disease, bleeding diathesis, hyperviscosity syndrome, renal disease, hypercalcemia, immunodeficiency (and subsequent susceptibility to infections), cytopenias secondary to myelophthisis, and cardiac failure.

Bone lesions can be isolated, discrete osteolytic lesions (including pathologic fractures) (Figure 32-22, A) or diffuse osteopenias, or both (Figure 32-23). Approximately one-quarter to two-thirds of dogs with MM have radiographic evidence of bony lysis or diffuse osteoporosis.^{1,5,6} The incidence of radiographic skeletal lesions in cats varies tremendously within reports, from as few as 8% in European case series to as high as 65% in North American case series.^{8,9,11,12,26} Those bones engaged in active hematopoiesis are more commonly affected and include the vertebrae, ribs, pelvis, skull, and proximal or distal long bones. Skeletal lesions are rare with IgM (Waldenström’s) macrogammaglobulinemia, in which malignant cells often infiltrate the spleen, liver, and lymph tissue rather than bone.^{6,40-42}

Bleeding diathesis can result from one or a combination of events. M components may interfere with coagulation by (1) inhibiting platelet aggregation and the release of platelet factor-3; (2) causing adsorption of minor clotting proteins; (3) generating abnormal fibrin polymerization; and (4) producing a functional decrease in calcium.^{6,43,44} Approximately one-third of dogs and

• **FIGURE 32-22** **A**, Radiograph of a distal femur in a dog demonstrating severe osteolysis and a pathologic fracture secondary to a plasma cell tumor. **B**, Radiograph of the same pathologic fracture after surgical repair with Rush rods and bone cement. Local site was treated with adjuvant radiation. The dog was continued on chemotherapy for 2 more years and did well.

• **FIGURE 32-23** **A**, Lateral thoracic radiographs of a dog showing multiple expansile lytic lesions and pathologic fractures of the dorsal spinous processes and collapse fracture (*arrow*) of the third thoracic vertebral body. **B**, Lateral thoracic radiographs of a dog with diffuse osteopenia secondary to multiple myeloma. Note the overall decreased opacity of the lumbar vertebrae and dorsal spinous processes secondary to diffuse marrow involvement causing loss of bone trabeculae and thinning of the cortices.

• **FIGURE 32-24** Multiple retinal hemorrhages on the fundus in a cat with hyperviscosity syndrome secondary to multiple myeloma.

one-quarter of cats have clinical evidence of hemorrhage.^{1,9,11,12} In dogs, nearly half have abnormal prothrombin (PT) and partial thromboplastin (PTT) times. Thrombocytopenia may also play a role if bone marrow infiltration is significant (i.e., myelophthisis).

Hyperviscosity syndrome (HVS) represents one of a constellation of clinicopathologic abnormalities resulting from greatly increased serum viscosity. The magnitude of viscosity changes is related to the type, size, shape, and concentration of the M component in the blood. HVS is more common with IgM macroglobulinemias due to the high molecular weight of this class of immunoglobulin. IgA-secreting myelomas (usually present as a dimer in the dog), may undergo polymerization resulting in increased serum viscosity.^{1,6,45} IgG-associated HVS can also occur, albeit less frequently. High serum viscosity occurs in approximately 20% of dogs with MM and can result in bleeding diathesis, neurologic signs (e.g., dementia, depression, seizure activity, coma), ophthalmic abnormalities (e.g., dilated and tortuous retinal vessels, retinal hemorrhage [Figure 32-24], retinal detachment), and increased cardiac workload with the potential for subsequent development of cardiomyopathy.* These consequences are thought to be a result of sludging of blood in small vessels, ineffective delivery of oxygen and nutrients, and coagulation abnormalities. HVS has been reported in cats with IgG-, IgA-, and IgM-secreting tumors.^{6,8,49-53} In several of these cases, relative serum viscosity was increased above control ranges.

Renal disease is present in approximately one-third to one-half of dogs with MM, and azotemia was observed in one-third of cats in one report.^{1,5,9,11} The pathogenesis of renal failure is often multifactorial and can ensue as a result of Bence Jones (light-chain) proteinuria, tumor infiltration into renal tissue, hypercalcemia, amyloidosis, diminished perfusion secondary to hyperviscosity syndrome, dehydration, or ascending urinary tract infections.^{1,6,43,44} Normally, heavy- and light-chain synthesis is well balanced in

nonneoplastic immunoglobulin production. In the case of MM, an unbalanced excess of light-chain products may be produced. Light chains are of low molecular weight and are normally filtered by the renal glomerulus, and their presence in urine can result in protein precipitates and subsequent renal tubular injury. The presence of light chains in urine without a concomitant monoclonal spike in serum, although rare, is indicative of pure light-chain disease.³⁸ Tubules become obstructed by large laminated casts containing albumin, immunoglobulin, and light chains.^{6,38,43,44} Bence Jones proteinuria occurs in approximately 25% to 40% of dogs with MM.^{1,5,6} Bence Jones proteinuria is reported to occur in approximately 40% of cats with MM/MRD.^{9,11} Hypercalcemia is reported in 15% to 20% of dogs with MM and is thought to result primarily from the production of osteoclast-activating factor by neoplastic cells.^{1,6,54} Other factors, including increased levels of various cytokines, TNF, IL-1, and IL-6 have been implicated in human MM. In two dogs with MM and hypercalcemia, serum elevations in circulating N-terminal PTHrP were noted.⁵⁵ Hypercalcemia may also be exacerbated by associated renal disease. Hypercalcemia, initially thought to be a rare event in cats with MM, occurred in 10% to 25% of recently reported cases.^{9,11,12,56}

Susceptibility to infection and immunodeficiency have long been associated with MM and are often the ultimate cause of death in affected animals.^{1,6,26} Infection rates in humans with MM are fifteen times higher than normal and usually represent pneumonia or urinary tract infections.⁵⁷ Response to vaccination has also been shown to be suppressed in humans with MM.⁵⁷ Immunoglobulin levels are often severely depressed in affected animals.⁶ In addition, leukopenias may be present secondary to myelophthisis.

Variable cytopenias may be observed in association with MM. A normocytic, normochromic, nonregenerative anemia is encountered in approximately two-thirds of dogs with MM.^{1,5,6} This can result from marrow infiltration (myelophthisis), blood loss from coagulation disorders, anemia of chronic disease, or increased erythrocyte destruction secondary to high serum viscosity. Rare erythrophagocytic forms of MM have also been reported in both dogs and cats and may contribute to anemia.^{58,59} Similar factors lead to thrombocytopenia and leukopenia in nearly one-third and one-quarter of dogs with MM, respectively. In cats, approximately two-thirds, half, and one-third will be anemic, thrombocytopenic, and neutropenic, respectively.^{9,11,12}

Cardiac disease if present is usually a result of excessive cardiac workload and myocardial hypoxia secondary to hyperviscosity.^{43,45,53} Myocardial infiltration with amyloid and anemia may be complicating factors. Nearly half of cats with MM in one report presented with a cardiac murmur, the etiology of which was not established.⁹ Three cats with HVS presented with congestive heart failure, murmurs, and echocardiographic signs consistent with hypertrophic cardiomyopathy.⁵³

History and Clinical Signs

Clinical signs of MM may be present up to a year prior to diagnosis with a median duration of one month reported in dogs.^{1,9} In one cat, M-component elevations were detected 9 years prior to clinical presentation. In this latter case, the M-component elevation was consistent with monoclonal gammopathy of unknown significance (MGUS). MGUS (i.e., benign, essential, or idiopathic monoclonal gammopathy) is a benign monoclonal gammopathy that is not associated with osteolysis, bone marrow infiltration, or Bence Jones proteinuria. MGUS has also been reported in dogs.^{60,61} Signs of MM can be variable based on the wide range of pathologic effects

possible. Tables 32-14 and 32-15 list the relative frequencies of clinical signs observed in the dog and cat, respectively, based on a compilation of several reports.* Bleeding diathesis is usually represented by epistaxis and gingival bleeding. Funduscopy abnormalities may include retinal hemorrhage (see Figure 32-24), venous dilatation with sacculation and tortuosity, retinal detachment, and blindness.† CNS signs may include dementia, seizure activity, tremors, and deficiencies in midbrain or brain-stem localizing reflexes secondary to HVS or extreme hypercalcemia. Signs reflective of transverse myelopathies secondary to vertebral column infiltration, pathologic fracture, or extradural mass compression can also occur.^{1,6,35,62,63} One case of ataxia and seizure activity in a dog with EMP secondary to tumor-associated hypoglycemia has been reported.⁶⁴ Additionally, paraneoplastic polyneuropathy has been reported in a dog with MM.⁶⁵ A history of chronic respiratory infections and persistent fever may also be present in cats. Hepatosplenomegaly and renomegaly can occur due to organ infiltration. Bleeding diathesis due to HVS is less common in the cat; however, epistaxis, pleural and peritoneal hemorrhagic effusions, retinal hemorrhage, and central neurologic signs have been reported.^{6,8,49-53} Polydipsia and polyuria can occur secondary to renal disease or hypercalcemia, and dehydration may develop. Hindlimb paresis secondary to osteolysis of lumbar vertebral bodies or extradural compression has been reported in cats.^{12,66}

Diagnosis and Staging

The diagnosis of MM in dogs usually follows the demonstration of bone marrow plasmacytosis (see Figure 32-20), the presence of osteolytic bone lesions (see Figures 32-22 and 32-23), and the demonstration of serum or urine myeloma proteins (M component) (see Figure 32-21). In the absence of osteolytic bone lesions, a diagnosis can also be made if marrow plasmacytosis is associated with a progressive increase in the M component. In the cat, because the degree of bone marrow infiltration may not be as marked, it has been suggested that consideration of plasma cell morphology and visceral organ infiltration (Figure 32-25) be given in cases with demonstrable M-component disease in the absence of marked (<20%) marrow plasmacytosis.^{9,11,24}

All animals suspected of plasma cell tumors should receive a minimal diagnostic evaluation including a CBC, platelet count,

serum biochemistry profile, and urinalysis. Particular attention should be paid to renal function and serum calcium levels. If clinical hemorrhage is present, a coagulation assessment (e.g., platelet count, PT, PTT) and serum viscosity measurements are indicated. All animals should undergo a careful funduscopy examination. Serum electrophoresis and immunoelectrophoresis are performed to determine the presence of a monoclonal M component (see Figure 32-21) and to categorize the immunoglobulin class involved. Heat precipitation and electrophoresis of urine may be performed to determine presence of Bence Jones proteinuria

*References 1, 6, 9, 11, 12, 26.

†References 1, 6, 11, 45, 46-48.

because commercial urine dipstick methods are not capable of this determination. Definitive diagnosis usually follows the performance of a bone marrow aspiration in the dog. A bone marrow core biopsy or multiple aspirations may be necessary due to the possibility of uneven clustering or infiltration of plasma cells in the bone marrow. Normal marrow contains less than 5% plasma cells, whereas myelomatous marrow often greatly exceeds this level. Current recommendations require more than 20% marrow plasmacytosis to be present, although a 10% cutoff in cats has been recently recommended with special attention to cellular atypia.⁹ Even the 10% threshold is problematic in cats, and cellular atypia and visceral organ involvement (assessed through needle aspiration cytology or tissue biopsy) should be considered equally important in the species.^{9,11,24} Rarely, biopsy of osteolytic lesions (i.e., Jamshidi core biopsy; see Chapter 24) is necessary for diagnosis in the dog. In one case of MM in a dog, splenic aspirates were diagnostically helpful.⁶⁷ Overall frequencies of clinical diagnostic abnormalities for dogs and cats with MM are compiled from published series having at least five cases each and are listed in Table 32-16.

Immunohistochemical and Molecular Diagnostics

Histochemical and immunohistochemical analyses of cells or tissues suspected of MRD are more often applied in the case of solitary plasmacytomas or where EMP is suspected in the absence of marrow involvement and will be discussed in subsequent sections; however, they have been occasionally useful in the diagnosis of MM. Molecular diagnostic techniques for MM have received limited use thus far in veterinary oncology; however, determining clonality of the immunoglobulin heavy chain variable region gene has been performed in feline plasmacytoma and myeloma using PARR techniques (see Chapter 8),⁶⁸ and use of this technology in cases where diagnosis is not straightforward awaits further investigation. The author has used PARR analysis both before treatment and after clinical remission in a small number of dogs with MM involved in clinical trials and documented its utility (1) for initial diagnosis and (2) to characterize molecular remission.

Imaging

Routine thoracic and abdominal radiographs are recommended in suspected cases. Occasionally, bony lesions can be observed in skeletal areas on these standard films, and organomegaly (liver, spleen, kidney) is observed in the majority of cats.^{9,11} Abdominal ultrasound is recommended in all cats suspected of MM because this modality reveals involvement of one or more abdominal organs in the majority of cases.^{9,11} These include splenomegaly with or without nodules, diffuse hyperechoic hepatomegaly with or without nodules, renomegaly, and iliac lymph node enlargement. In one case series in cats, 85% of organs with ultrasonographic abnormalities were subsequently confirmed to have plasma cell infiltration.¹¹ Skeletal survey radiographs are recommended to determine presence and extent of osteolytic lesions, which may have diagnostic, prognostic, and therapeutic implications. Although nuclear scintigraphy (bone scan) for clinical staging of dogs with MM has been performed, due to the predominant osteolytic activity with osteoblastic inactivity present, scans seldom give positive results and are therefore not useful for routine diagnosis.⁶⁹ In physician-based oncology, bone mineral density analysis (dual-energy x-ray absorptiometry [DEXA] scan) to document osteoporosis, MRI scan of bone marrow, and PET/CT are commonly used for staging; however, these modalities have not been applied consistently in the veterinary literature. A clinical staging system for canine MM has been suggested¹; however, at present, no prognostic significance has been attributed to it.

Differential Diagnosis of MM

Disease syndromes other than plasma cell tumors can be associated with monoclonal gammopathies and should be considered in any list of differentials. These include other lymphoreticular tumors (B-cell lymphoma, extramedullary plasmacytoma, chronic and acute B-lymphocytic leukemia), chronic infections (e.g., ehrlichiosis, leishmaniasis, FIP), and MGUS.*

*References 5, 9, 60, 61, 70-73.

Treatment

Initial Therapy of Multiple Myeloma

Therapy for MM is directed at both the tumor cell mass and the secondary systemic effects they elicit. All diagnostic procedures should be completed before initiating primary therapy to ensure a diagnosis is complete and baseline values are procured for monitoring response. Chemotherapy is effective at reducing myeloma cell burden, relieving bone pain, allowing for skeletal healing, and reducing levels of serum immunoglobulins in the majority of dogs with MM and will greatly extend both the quality and quantity of most patients' lives. MM in dogs is initially a gratifying disease to treat for both the clinician and the companion animal owner, although complete elimination of neoplastic myeloma cells is rarely achieved and eventual relapse is to be expected. Unlike dogs, only one-half of cats with MM will respond to chemotherapy and most responses will be short-lived; however, several long-term responses (i.e., >1 year) have been reported and treatment should be attempted when educated clients decide on a therapeutic option.*

Melphalan, an alkylating agent, is the chemotherapeutic of choice for the treatment of multiple myeloma.^{1,6} In the dog, an initial starting dose of 0.1 mg/kg PO, once daily for 10 days, is then reduced to 0.05 mg/kg PO, once daily continuously. The addition of prednisone therapy is thought to increase the efficacy of melphalan therapy. Prednisone is initiated at a dosage of 0.5 mg/kg PO, once daily for 10 days, then reduced to 0.5 mg/kg every other day prior to discontinuation after 60 days of therapy. Melphalan, however, is continued at 0.05 mg/kg/day until clinical relapse occurs or myelosuppression necessitates a dose reduction. The vast majority of dogs on melphalan and prednisone combination therapy tolerate the regimen well. The most clinically significant toxicity of melphalan is myelosuppression, in particular a delayed thrombocytopenia. CBCs, including platelet counts, should be performed biweekly for 2 months of therapy and monthly thereafter. If significant myelosuppression occurs (usually thrombocytopenia or neutropenia), reduction of the dosage or treatment frequency may be necessary. An alternative pulse-dosing regimen for melphalan (7 mg/m² PO, daily for 5 consecutive days every 3 weeks) has been used successfully by the author in a small number of cases in which myelosuppression was limiting more conventional continuous low-dose therapy. This pulse-dose regimen is now being used first-line by the author with the caveat that long-term response data are currently lacking.

Melphalan and prednisone therapy can also be used in cats with multiple myeloma; however, it appears this protocol is more myelosuppressive than in the dog and careful monitoring is required. In the cat, a dosing schedule similar to the dog has been reported^{12,26}; 0.1 mg/kg (approximately 0.5 mg, or one-quarter of a 2 mg tablet) once daily for 10 to 14 days, then every other day until clinical improvement or leukopenia develop. Long-term continuous maintenance (0.1 mg/kg, once every 7 days) has been advocated.¹² An alternative protocol advocated in the cat uses melphalan at 2 mg/m², once every 4 days continuously, and appears to be well tolerated.¹¹

Cyclophosphamide has been used as an alternative alkylating agent or in combination with melphalan in dogs and cats with MM.^{1,6,11} There is no evidence to suggest it is superior to melphalan therapy. In the author's practice, cyclophosphamide is limited to those cases presenting with severe hypercalcemia or with widespread systemic involvement in which a faster acting alkylating

agent may more quickly alleviate systemic effects of the disease. Cyclophosphamide is initiated at a dosage of 200 mg/m² IV, once, at the same time oral melphalan therapy is started. Because cyclophosphamide is less likely to affect thrombocytes, it may be substituted in those patients in which thrombocytopenia has developed secondary to long-term melphalan use.

Chlorambucil, another alkylating agent, has been used successfully for the treatment of IgM macroglobulinemia in dogs at a dosage of 0.2 mg/kg PO, once daily.^{6,40} Little or no clinical signs of toxicity result from this dosing schedule. Chlorambucil has also been used in cats with MRD.¹¹

Lomustine (CCNU), yet another alkylating agent, has been used in a limited number of cats with MM and a partial response has been reported following dosing at 50 mg/m² PO, every 21 days.⁷⁴

Evaluation of Response to Therapy

Evaluation of response to systemic therapy for multiple myeloma is based on improvement in clinical signs, clinicopathologic parameters, and radiographic improvement of skeletal lesions or ultrasonographic improvement of organ involvement.^{1,6,11} Subjective improvement in clinical signs of bone pain, lameness, lethargy, and anorexia should be evident within 3 to 4 weeks following initiation of therapy. Objective laboratory improvement, including reduction in serum globulin, immunoglobulin, and calcium, along with normalization of the hemogram, is usually noted within 3 to 6 weeks (Figure 32-26). Radiographic improvement in osteolytic bone lesions may take months and resolution may only be partial. Ophthalmic complications (including long-standing retinal detachments) and paraneoplastic neuropathies can be expected to resolve along with tumor mass.^{48,65} In cats responding to chemotherapy, clinical improvement is noted in 2 to 4 weeks and serum protein and radiographic bone abnormalities were greatly improved by 8 weeks.^{11,12}

As previously discussed, complete resolution of MM does not generally occur and a good response is defined as a reduction in measured M component (i.e., immunoglobulin or Bence Jones proteins) of at least 50% of pretreatment values.⁶ Reduction in serum immunoglobulin levels may lag behind reductions in Bence Jones proteinuria because the half-lives are 15 to 20 days and 8 to 12 hours, respectively.⁷⁵ For routine follow-up, quantification of the increased serum globulin, immunoglobulin, or urine Bence Jones protein is performed monthly until a good response is noted and then every 2 to 3 months thereafter. Repeat bone marrow aspiration or imaging (in the case of visceral disease) for evaluation of plasma cell infiltration may be occasionally necessary. Bone marrow reevaluation is particularly prudent when cytopenias develop during chemotherapy, and drug-induced myelosuppression must be differentiated from myelophthisis due to neoplastic marrow recurrence.

Therapy Directed at Complications of Multiple Myeloma

The long-term control of complications, including hypercalcemia, HVS, bleeding diathesis, renal disease, immunosuppression, ophthalmic complications, and pathologic skeletal fractures, depend on controlling the primary tumor mass. Therapy directed more specifically at these complications may, however, be indicated in the short term.

If hypercalcemia is marked and significant clinical signs exist, standard therapies, including fluid diureses, with or without pharmacologic agents (e.g., calcitonin), may be indicated (see Chapter 5). Moderate hypercalcemia will typically resolve within 2 to 3 days following initiation of melphalan/prednisone chemotherapy.

*References 6, 9, 11, 12, 31, 26.

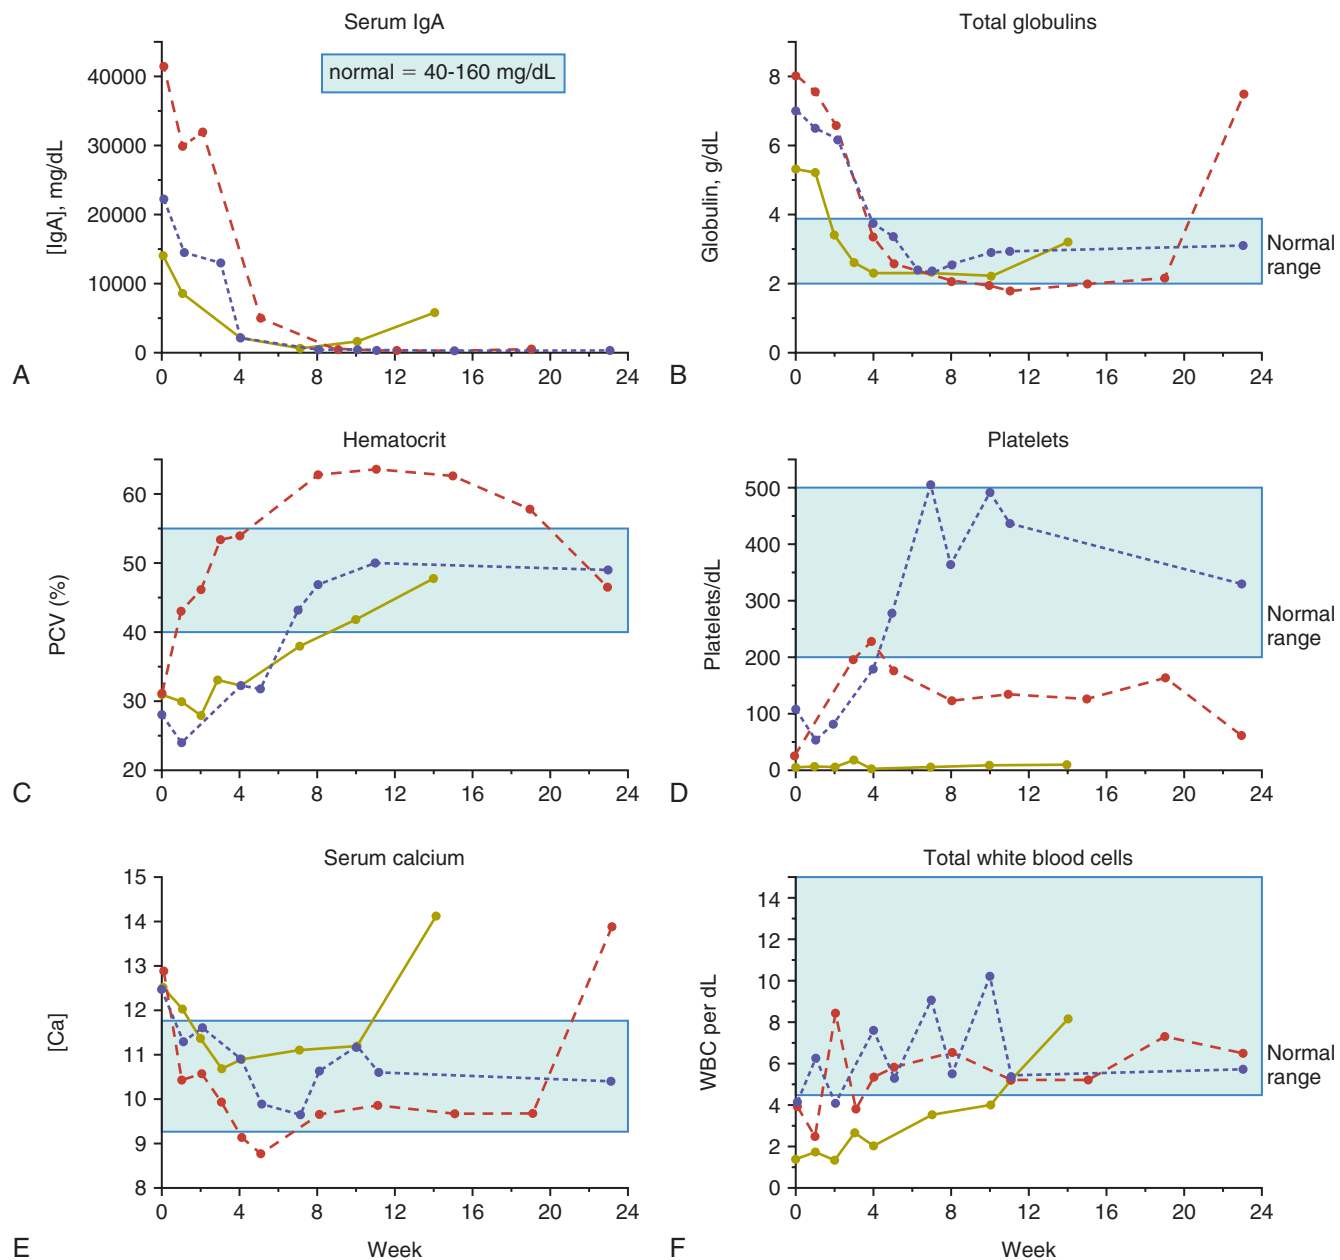

FIGURE 32-26 Clinicopathologic data changes over time (weeks) after initiation of cytotoxic chemotherapy in three dogs with IgA multiple myeloma. Light blue area, Normal reference range. **A**, Serum IgA (mg/dL); **B**, total globulins (g/dL); **C**, hematocrit (%); **D**, platelets/dL; **E**, serum calcium (mg/dL); **F**, total white blood cells/dL.

HVS is best treated in the short term by plasmapheresis.* Whole blood is collected from the patient and centrifuged to separate plasma from packed cells. Packed red cells are resuspended in normal saline or other crystalloid and reinfused into the patient. Bleeding diathesis will usually resolve along with HVS; however, platelet-rich plasma transfusions may be necessary in the face of thrombocytopenia.

Renal impairment may necessitate aggressive fluid therapy in the short term and maintenance of adequate hydration in the long term. Careful attention to secondary urinary tract infections and appropriate antimicrobial therapy is indicated. Ensuring adequate

water intake at home is important, and occasionally, educating owners in subcutaneous fluid administration is indicated. Continued monitoring of renal function is recommended along with follow-up directed at tumor response.

Patients with MM can be thought of as immunologically impaired. Some have recommended prophylactic antibiotic therapy in dogs with MM⁶; however, in humans, no benefit for this approach over diligent monitoring and aggressive antimicrobial management when indicated has been observed.⁴³ Cidal antimicrobials are preferred over static drugs, and avoidance of nephrotoxic antimicrobials is recommended.

Pathologic fractures of weight-bearing long bones and vertebrae resulting in spinal cord compression may require immediate surgical intervention in conjunction with systemic chemotherapy.

• **FIGURE 32-27** Survival curve of 37 dogs with multiple myeloma treated with chemotherapy. The median survival time (MST) is 540 days. (From Matus RE, Leifer CE, MacEwen EG, et al: *Prognostic factors for multiple myeloma in the dog*, J Am Vet Med Assoc 188:1288–1292, 1986.)

Orthopedic stabilization of fractures should be undertaken and may be followed with external-beam RT (see Figure 32-22). Recently, inhibition of osteoclast activity by bisphosphonate drugs has been shown to reduce the incidence and severity of skeletal complications of MM in humans.⁶⁹ This class of drugs may hold promise for use in dogs and cats with various skeletal tumors; however, they have not been adequately evaluated in MRD.⁷⁸

Rescue Therapy

When MM eventually relapses in dogs and cats undergoing melphalan therapy or in the uncommon case that is initially resistant to alkylating agents, rescue therapy may be attempted. The author has had success with VAD, which is a combination of doxorubicin (30 mg/m² IV, every 21 days), vincristine (0.7 mg/m² IV, days 8 and 15), and dexamethasone sodium phosphate (1.0 mg/kg IV, once a week on days 1, 8, and 15), given in 21-day cycles. Whereas most dogs initially respond to this rescue protocol, the duration of response tends to be short, lasting only a few months. High-dose cyclophosphamide (300 mg/m² IV, every 7 days) has also been used with limited success as a rescue agent. Liposomal doxorubicin has produced a long-term remission in a dog with MM previously resistant to native doxorubicin.⁷⁹

Investigational Therapies

MM is ultimately a uniformly fatal disease in most species, including humans, and thus significant effort is being placed on investigational therapies for this disease. Currently, bone marrow ablative therapy and marrow or stem cell rescue, thalidomide (and other antiangiogenic therapies), bortezomib (a proteasome inhibitor), arsenic trioxide, the bisphosphonates, and several molecular targeting therapies are under investigation; however, their use in veterinary species is limited or completely absent at present. The promise of molecular targeted therapies is, however, foreshadowed by a case of a dog with MM that was resistant to melphalan, prednisone, and doxorubicin that subsequently achieved a partial response to tyrosine kinase inhibitor therapy (toceranib; see Chapter 14, Section B) that was maintained for 6 months.¹⁸

Prognosis

The prognosis for dogs with MM is good for initial control of tumor and a return to good quality of life. In a group of 60 dogs with MM, approximately 43% achieved a complete remission (i.e., serum immunoglobulins normalized), 49% achieved a partial remission (i.e., immunoglobulins <50% pretreatment values), and only 8% did not respond to melphalan and prednisone chemotherapy.¹ Long-term survival is the norm, with a median of 540 days reported (Figure 32-27). The presence of hypercalcemia, Bence Jones proteinuria, and extensive bony lysis are known negative prognostic indices in the dog.¹ The long-term prognosis for dogs with MM is poor because recurrence of tumor mass and associated clinical signs is expected. Eventually, the tumor is no longer responsive to available chemotherapeutics and death follows from renal failure, sepsis, or euthanasia for intractable bone or spinal pain.^{1,6}

The prognosis for MM in the cat is not as favorable in the short term as it is in the dog.^{6,9,11,12,26} Whereas most cats (approximately 60%) transiently respond to melphalan/prednisone or COP-based protocols, most responses are partial and not durable. Typically, cats with MM succumb to their disease within 4 months.^{8,9,12,26} However, long-term survivors (>1 year) have been occasionally reported.* In one European case series, seven cats undergoing melphalan or COP-based therapy had a median survival of 9.5 months.¹¹ One investigator grouped MM in cats into two prognostic categories (Table 32-17) based on criteria known to predict behavior in dogs.¹² Although no rigorous statistical analysis was performed on this small group of nine cats, the median survival for cats in “aggressive” and “nonaggressive” categories was 5 days and 387 days, respectively.

Experience in dogs with IgM macroglobulinemia is limited.^{6,40-42} Response to chlorambucil is to be expected, and in nine treated dogs, 77% achieved remission with a median survival of 11 months.⁶

*References 9, 11, 12, 26, 31, 56.

• **TABLE 32-17** Classification of Multiple Myeloma in Cats Based on Clinical and Diagnostic Criteria Suspected of Predicting Prognosis

BEHAVIOR CATEGORY	CRITERIA
Aggressive	Hypocalcemia, presence of bony lesions with pathological fracture, low packed cell volume (PCV), presence of light-chain Bence Jones protein in urine, azotemia, hypercreatinemia, persistence of high serum protein level after 8 weeks of treatment, little or no clinical improvement.
Less aggressive	Normal serum calcium, normal creatinine, blood urea nitrogen (BUN), PCV levels, presence of bony lesions without pathologic fractures, absence of light-chain Bence Jones protein, normalization of serum protein level after 8 weeks of treatment.

Data from Hanna F: Multiple myelomas in cats, *J Feline Med Surg* 7:275–287, 2005.

Solitary and Extramedullary Plasmacytic Tumors

Solitary collections of monoclonal plasmacytic tumors can originate in soft tissues or bone and are referred to as *extramedullary plasmacytoma* (EMP) and *solitary osseous plasmacytoma* (SOP), respectively. The systemic, multicentric, biologically aggressive EMP syndrome encountered in cats^{11,24} has been discussed in the MM section and will not be included in this discussion. A number of large case compilations of cutaneous plasmacytoma have been reported in the dog.^{17,80–86} The most common locations for EMP in the dog are cutaneous (86%; **Figure 32-28**), the mucous membranes of the oral cavity and lips (9%; **Figure 32-29**), and the rectum and colon (4%). The skin of the limbs and head (including the ears) are most frequently reported cutaneous sites. Other sites accounted for only 1% of the remaining cases and can include stomach, spleen, genitalia, eye, uterus, liver, larynx, trachea, third eyelid, sinonasal cavity, and intracranial sites.^{87–94} The American cocker spaniel, English cocker spaniel, and West Highland white terrier (and perhaps Yorkshire terriers, Boxers, German shepherds, and Airedale terriers) are at increased risk for developing plasmacytomas and the median age of affected dogs is 9 to 10 years of age.⁸⁶

Cutaneous and oral EMP in dogs are typically benign tumors that are highly amenable to local therapy. There exists, however, a rare form of multiple cutaneous plasmacytomas in dogs that is part of a more generalized biologically aggressive MM process.^{95,96} The natural behavior of noncutaneous/nonoral EMP appears to be somewhat more aggressive in the dog. GI EMP have been reported on a number of occasions in the veterinary literature, including the esophagus,⁹¹ stomach,^{97,98} and small⁹⁹ and large intestine.^{98–101} Metastasis to associated lymph nodes is more common in these cases; however, bone marrow involvement and monoclonal gammopathies are less commonly encountered. Colorectal EMPs tend

• **FIGURE 32-28** A cutaneous plasmacytoma on the limb of a dog.

to be of low biologic aggressiveness, and most do not recur following surgical excision.¹⁰⁰ Conversely, the majority of SOPs eventually progress to systemic MM; however, the time course from local tumor development to systemic MM may be many months to years.^{33,102} SOPs have been reported in the dog involving the appendicular skeleton, as well as the zygomatic arch, and ribs.³³

SOPs are less common in cats, and fewer reports exist in the literature.^{11,22,103–107} They occur in older cats (mean ages 9 to 14 years), with no significant sex predilection. The skin is the most common site; however, other sites include the oral cavity, eye, GI tract, liver, subcutaneous tissues, and brain. Reports exist of cutaneous EMP in cats that progressed to systemic MRD.^{11,22,105}

Clinical Signs

Clinical signs associated with SOPs relate to the location of involvement, or in those rare cases with high levels of M component, HVS may occur. Most cutaneous plasmacytomas are solitary, smooth, raised pink nodules from 1 to 2 cm in diameter (see **Figure 32-28**), although tumors as large as 10 cm have been reported. Combining large series, greater than 95% occur as solitary masses and less than 1% occur as part of a systemic MM process.^{17,80–86,95,96} Cutaneous and oral EMPs usually have a benign course with no related clinical signs. GI EMP, however, typically presents with relatively nonspecific signs, which may suggest alimentary involvement. Colorectal plasmacytomas usually present with rectal bleeding, hematochezia, tenesmus, and rectal prolapse.¹⁰⁰ One case of ataxia and seizure activity in a dog with EMP secondary to tumor-associated hypoglycemia has been reported.⁶⁴ SOP is usually associated with pain and lameness if the appendicular skeleton is affected or neurologic signs if vertebral bodies are involved.

Diagnosis for Solitary Plasmacytic Tumors

The diagnosis of SOP and EMP usually requires tissue biopsy or FNA for diagnosis. Cells making up solitary plasmacytic tumors in both cats and dogs have been histologically classified into mature, hyaline, cleaved, asynchronous, monomorphous blastic and

• **FIGURE 32-29** Examples of oral solitary plasmacytoma in dogs; one involving the maxilla (**A**), the other involving the underside of the tongue (**B**). Both dogs were cured following surgical excision.

polymorphous blastic cell types; however, no prognostic significance has been observed following classification, although it has been suggested that the polymorphous-blastic type may act more aggressively in the dog.^{17,86,103} A different classification was proposed for EMP in cats based on percentage of plasmablasts (see previous section), and some prognostic importance has been documented.²⁴ In the case of poorly differentiated plasmacytic tumors, immunohistochemical studies, directed at detecting immunoglobulin, light- and heavy-chains, MM-1/interferon regulatory factor-4 (MUM1/IRF4), and thioflavin T, may be helpful in differentiation from other round cell tumors.^{33,85,86,106-110} Immunoreactivity has been demonstrated for canine IgG F(ab)₂ and vimentin.⁸² A variant characterized by an IgG-reactive amyloid interspersed with the neoplastic cells has also been described.⁸³ A panel of MABs (recognizing tryptase, chymase, serotonin, CD1a, CD3, CD79a, CD18, MHC class II) in association with a histochemical stain (naphthol AS-D chloroacetate) has been advocated for use on formalin-fixed, paraffin-embedded sections of cutaneous round cell tumors to help classify poorly differentiated round cell tumors (mast cell tumors, histiocytomas, lymphomas, and plasmacytomas).¹⁰⁹ Additionally, clonality of the immunoglobulin heavy chain variable region gene can be performed in plasmacytomas and myelomas using PCR technology, and this may have some diagnostic utility in difficult cases.

It is important to thoroughly stage dogs and cats with plasmacytomas that are at higher risk for systemic spread if contemplating local or locoregional therapy without systemic therapy. This should include bone marrow aspiration, serum electrophoresis, abdominal ultrasound, and skeletal survey radiographs to ensure the disease is confined to a local site prior to initiation of therapy. This is most important in cases of SOP and GI EMP due to their relatively high metastatic rate and less important for cutaneous, oral, and colorectal plasmacytomas because of their more typical benign behavior.

For GI EMP (including colorectal EMP), endoscopic evaluation of the entire GI tract is recommended. A single case report of the use of PET/CT imaging for extramedullary splenic plasmacytoma in a dog exists; however, its utility remains unknown.¹¹¹

Therapy for Solitary Plasmacytic Tumors

Cutaneous and oral plasma cell tumors in the dog are almost always benign and carry an excellent prognosis following conservative surgical excision.^{17,81-86,100,112} EMPs of the trachea, liver, and uterus have also been reported in dogs, and all had a benign course following local resection.⁹²⁻⁹⁴ Successful therapy with melphalan and prednisone has been rarely applied for a local recurrence or incomplete margins in dogs and cats. RT has been used infrequently for cases that are nonsurgical, including the application of strontium-90 plesiotherapy for lingual plasmacytoma in a dog.¹¹³ Surgery is recommended in combination with radiotherapy for those cases of SOP in which the lesion results in an unstable, long bone fracture (see Figure 32-22), or the patient is nonambulatory from neurologic compromise resulting from a vertebral body SOP. In the latter case, spinal cord decompression, mass excision, and possibly spinal stabilization may be necessary.⁶³ Radiotherapy can be used alone (i.e., without surgery) in those cases where fractures are stable, as a palliative measure for bone pain, or in the case of vertebral SOP if the patient is ambulatory and stable. Good local control is usually achieved; however, most go on to develop systemic multiple myeloma.^{33,63,102} SOP of the axial skeleton can be managed by excision or radiotherapy alone. There is controversy as to whether systemic chemotherapy should be initiated at the time of local therapy for SOP when systemic involvement is not documented. Systemic spread may not occur for many months to even years beyond primary SOP diagnosis in humans and dogs, and studies in humans reveal no benefit derived from initiation of systemic chemotherapy prior to documentation of subsequent systemic spread.^{44,63} Two

cases of SOP in cats were recently reported; one was treated with external-beam RT and one managed with melphalan chemotherapy and both enjoyed durable remissions of greater than 4 years.¹¹⁴ Similarly, EMP of the GI tract in humans are treated most commonly by surgical excision and thorough staging of disease. Systemic therapy is not initiated unless systemic involvement is documented. Systemic chemotherapy has been used following gastric EMP in a cat; however, the utility of adjuvant therapy in the species is unknown.¹¹⁵

Long-term follow-up of patients with SOP is indicated in order to recognize both recurrence of disease and systemic spread. Careful attention is given to serum globulin levels, bone pain, and radiographic appearance of bone healing in cases of SOP. Restaging of disease, including bone marrow evaluation, is indicated if systemic spread is suspected.

Prognosis for solitary plasma cell tumors is generally good. Cutaneous and mucocutaneous plasmacytomas are usually cured following surgical excision.^{17,86,112} In large compilations of cases in dogs, the local recurrence rate was approximately 5%, and nodal or distant metastasis occurred in only 7 of 349 cases (2%).^{17,80-82,86} New cutaneous plasmacytomas at sites distant from the primary developed in less than 2% of cases. Neither tumor cell proliferation rate (as measured by Ki67 immunohistochemistry) in the dog nor histopathologic grading in dogs and cats were prognostic in large compilations of cases, although it has been suggested that the polymorphous-blastic and plasmablastic type may act more aggressively in the dog and cat.^{17,24,86} The presence of amyloid and overexpression of cyclin D1 (prognostic in human plasmacytomas) were not shown to be of prognostic value in dogs.¹⁷ Dogs with EMP of the alimentary tract and other abdominal organs (e.g., liver, uterus) treated by surgical excision alone or in combination with systemic chemotherapy (if metastasis is present) can enjoy long-term survival in the majority of cases.* In a compilation of nine dogs with colorectal plasmacytoma, two dogs had local recurrence at 5 and 8 months following surgery, and the overall median survival was 15 months following surgery alone.¹⁰⁰ DNA ploidy and c-myc oncoprotein expression in biopsy samples were determined to be prognostic for EMPs in dogs; however, those that were malignant were all from noncutaneous sites (i.e., lymph node, colon, spleen). Therefore location appears to be as predictive.¹¹⁶ As previously discussed, the majority of cases of SOP will eventually develop systemic disease; however, long disease-free periods usually precede the event.

The prognosis in cats is less well-defined because of the paucity of reported cases. If disease is confined to a local site and/or regional nodes, surgical excision and chemotherapy can result in long-term control; however, early, widespread metastasis and progression to MM is also reported in cats.[†]

SECTION A

Hemangiosarcoma

DOUGLAS H. THAMM

Incidence and Risk Factors

Hemangiosarcoma (HSA), also known as *malignant hemangioendothelioma* or *angiosarcoma*, is a malignant neoplasm of vascular endothelial origin. HSA occurs more frequently in dogs than in any other species.^{1,2} It represents about 5% of all noncutaneous primary malignant neoplasms and 12% to 21% of all mesenchymal neoplasms in the dog.³⁻⁵ HSA accounts for 2.3% to 3.6% of skin tumors in dogs^{1,6} and 45% to 51% of splenic malignancies.^{2,7,8} It is less common in the cat, occurring in approximately 0.5% of cats examined at necropsy in one study and accounting for 2% of all neoplasms in another.^{9,10}

HSA is seen mostly in middle-aged to older animals, although there are reports in dogs less than 3 years of age.^{7,10-14} German shepherds, golden retrievers, and Labrador retrievers are overrepresented in many case series.^{7,11,14-16} There may be a slight male predisposition in dogs.^{11,12,14,15,17}

Although the etiology is unknown, reports in humans have been related to exposure to thorium dioxide, arsenicals, vinyl chloride, and androgens.¹⁸ It is reported as a rare late sequela to breast-conserving irradiation in humans with breast cancer.¹⁹ The human vascular neoplasm Kaposi's sarcoma is causally associated with human herpesvirus 8, and although some studies have demonstrated herpesviral elements in human angiosarcoma as well, the majority have not.²⁰⁻²³ There is a documented increase in HSA development in dogs exposed to ionizing radiation prenatally or postnatally.²⁴ Cutaneous HSAs are found more frequently in dogs with minimal pigmentation and thin hair coats²⁵ and have been associated with ultraviolet light exposure in laboratory dogs.²⁶

There is increasing evidence that dysregulation of molecular pathways governing angiogenesis may be important in the pathogenesis of HSA. Studies in humans and dogs have demonstrated abundant expression of angiogenic growth factors such as vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and angiopoietins-1 and -2 (Ang-1 and -2) in HSA cells and tissues and concomitant expression of the cellular receptors for VEGF, bFGF, and Ang-1.²⁷⁻³⁶ This suggests the potential for autocrine stimulation of one or more of these receptors leading to dysregulated proliferation and survival. Indeed, enforced overexpression of VEGF is sufficient to transform immortalized murine endothelial cells into HSA,³⁷ and in vivo overexpression of VEGF has led to vascular tumor formation in mice.³⁸

Mutations in tumor suppressor genes such as *p53*,^{39,40} *Ras*,⁴¹⁻⁴³ and *Tsc2*⁴⁴ have likewise been implicated in the pathogenesis of HSA, based on murine or human studies. Recent studies suggest that *p53* and *Ras* mutations are infrequent in canine HSA⁴⁵⁻⁴⁷; however, *PTEN* inactivation was demonstrated in greater than 50% of evaluated canine HSA samples in one study.⁴⁸ Key growth- and apoptosis-regulating proteins such as pRB, cyclin D1, BCL2, and survivin appear overexpressed in HSA when compared with hemangiomas or normal tissues.^{46,49} Gene expression profiling studies indicate an enrichment for genes involved in inflammation and angiogenesis.⁴⁷

Pathology and Natural Behavior

In the dog, the most common primary site for HSA is the spleen.^{1,11,12,14,15} Other frequent sites include the right atrium, skin and subcutis, and liver.^{11,14,25,50-53} Occurrence has also been reported in the lung, kidney, oral cavity, muscle, bone, urinary bladder, left ventricle, uterus, tongue, digit, and retroperitoneum.^{12,14,54-60} In the cat, cutaneous and visceral (e.g., spleen, liver, intestine) locations are evenly distributed.^{10,61} Other reported sites in the cat include the heart, thoracic cavity, eyelid, and nasal cavity.^{10,53,61-64} HSA is the most common splenic neoplasm encountered but is by no means the only differential for splenomegaly or splenic masses in dogs. The "double two-thirds rule" has been applied to canine splenic masses: approximately two-thirds of dogs with splenic masses will have a malignant tumor, and approximately two-thirds of those malignancies will be HSA.^{2,8,17,65}; however, recent studies have found that 63% to 70% of dogs with splenic masses presenting with non-traumatic hemoabdomen were HSA.⁶⁶⁻⁶⁸ Several splenic mass lesions (e.g., HSA, hematoma, hemangioma) can have a similar gross and ultrasonographic appearance, and large masses do not necessarily denote malignancy.⁶⁹ Histopathology is necessary to establish a definitive diagnosis in these cases.

HSA may be solitary, multifocal within an organ, or widely disseminated at presentation. Grossly, they are of variable size, pale gray to dark red or purple, and soft or gelatinous, often containing blood-filled or necrotic areas on cut surface (Figure 33-1). They are poorly circumscribed, nonencapsulated, and often adhered to adjacent organs. They are extremely friable, and complications associated with rupture and hemorrhage are frequent presenting complaints. Histologically, HSA consists of immature, pleomorphic endothelial cells forming vascular spaces containing variable amounts of blood and/or thrombi.^{70,71} When such features are minimal but HSA is suspected, immunohistochemistry for von Willebrand's factor (factor VIII-related antigen) or CD31/platelet endothelial cell-adhesion molecule (PECAM) can be used to demonstrate endothelial derivation and support the diagnosis of

• **FIGURE 33-1** Intraoperative image of multifocal hemangiosarcoma (HAS) within the spleen of a dog. (Courtesy M.G. O'Brien, Madison, Wisconsin.)

HSA.⁷¹⁻⁷⁴ Recently, claudin-5 and CD117 (KIT) have also been identified as potentially useful immunohistochemical markers for distinguishing canine tumors of vascular endothelial origin.^{75,76}

Perhaps owing to its intimate association with the vasculature, facilitating extravasation and angiogenesis of metastatic clones, canine HSA is typified by very aggressive biologic behavior, with rapid and wide metastasis occurring frequently. An exception to this rule is pure cutaneous or dermal HSA, without any clinical or histologic evidence of subdermal infiltration.⁵¹ Metastasis is typically hematogenous or through transabdominal implantation following rupture. The most frequent metastatic sites are the liver, omentum, mesentery, and lungs.^{14,77} One study suggested that approximately, 25% of dogs with splenic HSA will also have right atrial involvement.⁷⁷ However, the experience of the author suggests that this percentage at initial presentation is significantly lower (5% or less). Other reported sites of metastasis are the kidney, muscle, peritoneum, lymph nodes, adrenal gland, brain, and diaphragm. In dogs, HSA is considered the most common metastatic tumor to the brain.^{78,79}

HSA in cats is considered to be a less aggressive disease. Cutaneous or subcutaneous HSA often behaves in a fashion similar to other soft tissue sarcomas, and local recurrence is the major concern.^{72,80,81} Reports do exist of more aggressive biologic behavior in a subset of cats with cutaneous HSA, however.⁸⁰⁻⁸² Visceral HSAs have a higher metastatic rate, similar to that in dogs, and the common sites include the liver, omentum, diaphragm, pancreas, and lung.^{10,61,81,83,84}

History and Clinical Signs

Presenting complaints vary, depending on the location of the primary tumor, and can range from vague, nonspecific signs of illness, to asymptomatic abdominal swelling, to acute collapse and death secondary to hemorrhagic/hypotensive shock. Common presenting complaints for visceral HSA are acute weakness or collapse. This may have been preceded by similar transient episodes occurring over a period of weeks or days, which resolved spontaneously in 12 to 36 hours. In such cases, it is theorized that HSA rupture leads to hemoperitoneum, followed by subsequent reabsorption (i.e., autotransfusion) of red blood cells. For those dogs that present asymptotically or with vague signs (lethargy, inappetence, weight loss, abdominal distension), an abdominal mass may be

palpated during examination. Dogs with cardiac HSA typically present with signs related to pericardial tamponade and associated right-sided heart failure, such as exercise intolerance, dyspnea, and ascites.

Common physical examination findings for visceral HSA include pale mucous membranes with delayed capillary refill, tachycardia with poor pulse quality, and a palpable fluid wave in the abdomen, with or without a palpable abdominal mass. Dogs with cardiac HSA may display ascites, muffled heart sounds, and/or pulsus paradoxus (variation in pulse quality associated with respiration).

In the cat, signs will depend on location and extent of tumor. Cats with visceral tumors usually have a history of lethargy, anorexia, vomiting, sudden collapse, dyspnea, or a distended abdomen.^{61,81,83} On physical examination, pallor, pleural or peritoneal fluid, and a palpable abdominal mass may be detected.

Diagnostic Techniques and Work-Up

Complete staging for an HSA suspect typically includes hematology and serum biochemistry, coagulation testing, thoracoabdominal imaging, ±abdominocentesis, and/or echocardiography.

In both dogs and cats, anemia is often seen, usually characterized by the presence of schistocytes (associated with microangiopathic hemolysis) and acanthocytes in the peripheral blood.* Anemia may be regenerative or nonregenerative, depending on duration. Blood typing and/or crossmatching may be indicated if surgery is planned in a severely anemic patient. In addition, a neutrophilic leukocytosis may be seen.^{61,66} Thrombocytopenia is observed in 75% to 97% of cases, ranging from mild to severe.^{66,67,86,87} Serum biochemistry changes are typically nonspecific and can include hypoalbuminemia, hypoglobulinemia, and mild elevations in liver enzymes.^{66,83}

A coagulogram is very useful in animals with suspected HSA. Perturbations in some aspect of the coagulation cascade (prothrombin time [PT], activated partial thromboplastin time [APTT], platelet count, activated clotting time, fibrinogen concentration, fibrin degradation products) are seen in the majority of patients (Table 33-1)^{66,86-91} and approximately 50% have coagulation abnormalities that meet the criteria for disseminated intravascular coagulation (DIC).^{86,88} Tumor vasculature, especially in the case of HSA, differs significantly from normal vasculature, commonly containing blind-ended or irregular tortuous vessels, incomplete endothelial lining, arteriovenous shunts, exposed subendothelial collagen, and platelet-tumor aggregates.⁹² HSA-derived endothelial cells may also have an “activated” phenotype, further promoting initiation of the coagulation cascade.

HSA effusions are serosanguineous (or frank blood) and usually do not clot. Cytology of effusions is rarely diagnostic; although tumor cells are likely present, they are heavily diluted with peripheral blood.

Screening for metastasis is mandatory prior to definitive surgery for HSA. Dogs with gross evidence of metastasis have a grave prognosis, and surgery is purely palliative. Thoracic radiographs should be obtained in all cases. One study reported a 78% sensitivity and 74% negative predictive value for detecting pulmonary manifestations of HSA, and obtaining three views significantly decreased the

*References 12, 14, 61, 66, 83, 85.

false-negative rate.⁹³ Dogs with hemopericardium secondary to cardiac HSA will typically have a globoid cardiac silhouette, with or without distension of the caudal vena cava.⁹⁴ Abdominal radiographs may reveal a cranial abdominal mass in many cases; however, abdominal ultrasound is a superior modality for imaging the abdomen. Many animals with visceral HSA will have ascites, which diminishes abdominal detail with radiographs but not ultrasound. Ultrasound also allows for the more thorough evaluation of the rest

of the abdomen for evidence of metastatic disease. HSA typically has a heteroechoic appearance, ranging from anechoic/cavitated to hyperechoic, or a targetoid appearance (Figure 33-2).^{95,96}

Typical electrocardiographic signs consistent with pericardial effusion (decreased amplitude QRS complex, electrical alternans) can be seen in dogs with cardiac HSA and hemopericardium. Echocardiography can be useful in dogs with suspected pericardial effusion, and a right atrial mass may be visible in 65% to 90% of cases (Figure 33-3)⁹⁷⁻¹⁰⁰; however, some dogs may develop blood clots within the pericardium that can have a mass effect. Thus the absence of a mass does not rule out HSA, and the presence of a mass is not pathognomonic. Despite this, detection of a mass on echocardiography is strongly associated with a worse prognosis in dogs with pericardial effusion.^{94,99} Other negative prognostic factors include

III	T2 or T3, N0, N1 or N2, M1

history of collapse and presence of ascites.⁹⁴ Routine evaluation of the heart for metastatic disease in a dog with subcutaneous or visceral HSA without evidence of other metastasis is rarely rewarding.

A clinical staging system for HSA is given in Table 33-2.

Ultimately, a definitive diagnosis of HSA usually requires a surgical biopsy. Needle aspiration cytology of suspicious masses, although simple and cost-effective, is of low diagnostic utility due to the hemodilution that usually accompanies sampling.¹⁰¹ Needle core biopsies can be obtained of cutaneous or subcutaneous lesions but should not be performed on suspect visceral lesions due to the risk of induction of hemorrhage and subsequent seeding of the peritoneum. If only small samples of suspected HSA are submitted, histopathology may only reveal blood clots or other nonspecific findings. Submission of large samples of suspected HSA is preferred to maximize the likelihood of capturing a true tumor if present. This includes submission of entire spleens whenever possible or, at the very least, numerous parts of the mass.

Several investigators are evaluating additional tests, which may allow more accurate presurgical diagnosis. Pericardial fluid pH was suggested to correlate with presence or absence of neoplasia in one study¹⁰²; however, subsequent studies have shown pericardial fluid analysis to be of little diagnostic benefit.^{103,104} Recent studies have found a significant difference in concentrations of troponin I, an indicator of myocardial damage, between dogs with cardiac HSA and dogs with idiopathic pericardial effusions.^{105,106} Plasma concentrations of VEGF and urine concentrations of bFGF are elevated in dogs with HSA versus normal controls^{27,28}; however, neither was found to correlate with remission status, disease stage, or outcome. Advanced imaging techniques such as contrast-enhanced ultrasound,¹⁰⁷⁻¹¹³ contrast-enhanced computed tomography (CT),¹¹⁴ and magnetic resonance imaging (MRI)¹¹⁵ have been useful in discriminating malignant versus benign lesions in preliminary studies. Additional blood-based biomarkers showing early promise include measurement of serum alpha-1 acid glycoprotein,¹¹⁶ lipocalin region of collagen XXVII alpha 1,¹¹⁷ and thymidine kinase

activity,^{118,119} as well as multiparameter flow cytometry of peripheral blood utilizing a variety of endothelial and primitive hematopoietic cell markers.¹²⁰

Treatment

Surgery

Surgery remains the primary method of treatment for almost all dogs and cats with HSA. Prior to surgery, appropriate treatment for shock (e.g., crystalloids, colloids) and correction of severe hematology or coagulation abnormalities should be addressed with blood products as necessary. Surgery should be as aggressive as possible to remove all locally affected tissue.

For cutaneous or subcutaneous HSA, surgical considerations are similar to those for other soft-tissue sarcomas (see Chapter 21). Dermal HSA is usually discrete, and surgical margins of 1 to 2 cm are often adequate. Intramuscular HSA will often present with a large blood clot admixed with actual tumor. Wide margins can be difficult to achieve, short of limb amputation when possible. Debulking may provide short-term relief.

For splenic HSA, splenectomy is required and can be performed with sutures, staples, or electrothermal vessel sealant devices (e.g., LigaSure Force Triad, Covidien, Mansfield, MA).¹²¹ The spleen should be carefully delivered from the abdomen to avoid iatrogenic rupture. Attached omentum should be removed en bloc. Intraoperative autotransfusion of blood has been described but requires specialized equipment and personnel and still remains controversial.¹²² At the time of splenectomy, the abdomen should be thoroughly explored and any suspicious lesions in the liver or omentum, especially if actively bleeding, should be excised and submitted for histopathology. Biopsy of grossly normal livers is probably not useful. The abdomen should be thoroughly lavaged and instruments changed prior to closure to minimize the risk of abdominal/wound bed or suture line seeding. Dogs undergoing splenectomy are prone to develop ventricular arrhythmias following surgery. In one study of 59 dogs, 24% developed arrhythmias.¹²³ Poor myocardial perfusion secondary to hypoxia, hypovolemia, or anemia or a neurohormonal response associated with manipulation of the spleen are all potential causes. An electrocardiogram should be monitored intraoperatively and in the postoperative period, and arrhythmias treated as they arise. Arrhythmias usually resolve within 24 to 48 hours.

Surgery can be performed for primary cardiac HSA. An open or thoracoscopic pericardiectomy can be used as a palliative procedure, allowing effusion to escape into the thorax rather than accumulating in the pericardium, where a small volume can readily restrict function. Right atrial appendage masses can be resected with a stapling device or hand stitching,^{124,125} and reconstructive procedures have been described in cases where extensive resection is required.^{126,127} A recent retrospective study suggests that dogs surviving the perioperative period have a prognosis similar to dogs with HSA of other visceral sites.¹²⁵

Chemotherapy

Given the very high metastatic rate of most canine HSA and the poor outcome associated with surgery alone (see later), adjuvant chemotherapy is indicated in all cases, with the exception of pure cutaneous tumors. Single-agent and combination doxorubicin (DOX)-based chemotherapy protocols are most frequently used (Box 33-1).¹²⁸⁻¹³⁴ Other combinations such as vincristine, cyclophosphamide, and methotrexate (VCM) have yielded only modest improvements in survival time.¹⁴ Recently, ifosfamide was shown

Box 33-1 Doxorubicin-Based Chemotherapy Protocols for Canine Hemangiosarcoma

1. VAC*

Day 1 Doxorubicin† 30 mg/m² IV
Cyclophosphamide 100-150 mg/m² IV
OR
Cyclophosphamide 150-200 mg/m² PO,
divided over 3-4 days
Days 8 and 15 Vincristine 0.75 mg/m² IV
Day 22 Repeat cycle for a total of 4-6 cycles

2. AC*

Day 1 Doxorubicin† 30 mg/m² IV
Cyclophosphamide 100-150 mg/m² IV
OR
Cyclophosphamide 150-200 mg/m² PO,
divided over 3-4 days
Day 22 Repeat cycle for a total of 4-6 cycles

3. DOX*

Doxorubicin† 30 mg/m² IV
Repeat every 2-3 weeks for 5 treatments

VAC, Vincristine, doxorubicin, cyclophosphamide; IV, Intravenous; PO, by mouth; AC, doxorubicin, cyclophosphamide; DOX, doxorubicin.

*Perform complete blood count (CBC) prior to each chemotherapy treatment—delay treatment for 5-7 days if neutrophils <2000/uL or platelets <75,000/uL.

†Doxorubicin is given at 25 mg/m² or 1 mg/kg in dogs weighing less than 10 kg.

to also have some modest antitumor activity in canine HSA.^{134,135} Both epirubicin and liposome-encapsulated DOX appear to have roughly equivalent activity to conventional DOX.^{136,137} In cats, similar DOX-based protocols are employed, although reports of systematic evaluations are lacking. For cases in which surgery is declined or impossible due to size/location or presence of metastasis, DOX-based chemotherapy induces meaningful tumor regression in a large minority of animals¹³⁸⁻¹⁴⁰; however, remissions are typically incomplete and brief in duration. Isolated reports of antitumor activity have been reported with carboplatin as well.¹⁴¹

Immunotherapy

Very few studies have been conducted to evaluate biologic therapy for HSA (see Chapter 13). One study used a mixed killed bacterial vaccine following surgery and showed some improvement in survival time in dogs with splenic HSA.¹⁴ More recently, a surgical adjuvant study was conducted in dogs with splenic HSA to compare chemotherapy (DOX and cyclophosphamide) to the same chemotherapy combined with immunotherapy using liposome-encapsulated muramyl tripeptide-phosphatidylethanolamine (L-MTP-PE). The median survival time (MST) for those dogs treated with chemotherapy alone was 5.7 months versus 9.1 months ($p = 0.03$) for those treated with L-MTP-PE and chemotherapy, with 40% of dogs in the L-MTP-PE group experiencing long-term survival.¹³³ L-MTP-PE is currently unavailable in the United States but has been granted orphan drug status for the treatment of pediatric osteosarcoma in the European Union. Investigations of allogeneic tumor cell vaccine approaches in combination with chemotherapy have shown initial promise in small numbers of dogs.¹⁴²

Radiation Therapy

Radiation therapy (RT) is rarely utilized for HSA due to the anatomic sites involved and high metastatic rate. Coarsely fractionated (palliative) RT for peripheral masses (e.g., cutaneous and subcutaneous lesions) may dramatically decrease local disease but may not significantly impact overall survival.¹⁴³⁻¹⁴⁵ It is conceivable that a combination of palliative RT and chemotherapy may provide better control, but this awaits further investigation. Full-course (definitive) RT may be reasonable for dogs with incompletely resected, solitary dermal HSA or feline nonvisceral HSA due to their reduced potential for metastasis.

Novel Therapies

Given the endothelial derivation of HSA, therapy directed against angiogenesis is a logical avenue of exploration, and murine HSA has been used as a model for the evaluation of novel antiangiogenic strategies. Antitumor activity has been seen in a murine HSA model to a variety of antiangiogenic treatments, such as VEGF receptor kinase inhibitors,¹⁴⁶ TNP-470,¹⁴⁷ and several others,¹⁴⁸⁻¹⁵⁰ and objective responses have been observed with several angiogenic receptor tyrosine kinase inhibitors in human reports.^{151,152} Interleukin-12 (IL-12) has been shown to retard tumor growth in a canine HSA xenograft as well.³³

A small pilot study recently reported the outcome following treatment of dogs with splenic HSA with a combination of splenectomy, a nonsteroidal antiinflammatory drug (NSAID), and low-dose continuous (metronomic) chemotherapy with alternating courses of cyclophosphamide and etoposide. Outcome was similar to what has been reported following DOX-based injectable chemotherapy.¹⁵³

Current studies are focusing on whether combinations of conventional DOX-based chemotherapy followed by “maintenance” therapy with low-dose continuous chemotherapy or VEGF receptor kinase inhibitors such as toceranib may improve postsurgical outcome in patients with HSA; the results of these studies are eagerly anticipated.

In humans with various vascular tumors, antitumor activity has been observed following the local administration of IL-2,^{154,155} and the local or systemic administration of interferon- α (IFN α) in combination with traditional cytotoxics.¹⁵⁶⁻¹⁵⁹ Additionally, paclitaxel, docetaxel, and gemcitabine appear to have activity against human HSA.^{157,160-162}

Prognosis

Canine

A summary of the results of several reports on the treatment of splenic HSA is presented in Table 33-3. Overall, the prognosis for dogs with splenic HSA treated by surgery alone is extremely poor. MSTs for splenic HSA range from 19 to 86 days, and less than 10% survive to 12 months.^{2,8,14,163,164} Primary hepatic HSA is thought to carry an equally poor prognosis. In contrast, one study suggests that dogs with primary renal HSA may have a more favorable outcome than those with HSA of other visceral sites.⁶⁰

Surgery plus anthracycline-based chemotherapy following surgery will increase median survival times to 141 to 179 days.* Even without the addition of chemotherapy, the 12-month survival percentage is 10% or less. In one report, the addition of immunotherapy (L-MTP-PE) to standard chemotherapy increased median

survival time to 273 days.¹³³ In splenic HSA, stage I (nonruptured) tumors may have a more favorable outcome than stage II (ruptured) tumors when postoperative chemotherapy is used.^{14,130,133} One study employed a histologic grading scheme, and demonstrated that dogs with low-grade tumors had a better prognosis than dogs with intermediate- or high-grade tumors.¹²⁹

In a study of surgically treated cutaneous HSA, tumors involving the dermis (without subdermal invasion) had a MST of 780 days (n = 10).⁵¹ Tumors with invasion into the subcutaneous tissues or muscle generally have worse outcomes than those confined to the dermis.^{11,51,165,166} Therefore adjuvant medical therapy should be offered for subcutaneous or intramuscular HSA, although reports regarding efficacy are divergent.^{165,166}

Overall, the prognosis is poor for cardiac HSA. In dogs undergoing surgery for right atrial HSA, the average survival time ranges from 1 to 4 months.^{99,124} A recent study reported an outcome following surgery and chemotherapy roughly equivalent to that reported for HSA of the spleen.¹²⁵

Feline

In cats, the prognosis for visceral HSA is poor. Most cats die from recurrence of the primary tumor or metastasis, and MSTs are generally short, owing to metastasis.^{61,84} HSAs located in cutaneous and subcutaneous sites have recurrence rates of 60% to 80%,^{61,72} although one recent case series reported a favorable outcome following aggressive surgery, and complete excision is associated with improvement in outcome.^{80,81} Metastasis can develop following surgical resection in some cases, although the frequency is unknown.⁸²

In summary, surgery still offers the best approach to diagnose and treat HSA even though it is generally only palliative. Novel avenues for adjuvant chemotherapy need evaluation. New approaches to treatment such as immunotherapy or antiangiogenic therapy may provide alternatives, and additional investigation into the biology of canine HSA, hopefully leading to clinical trials, is desperately needed.

Comparative Aspects

In humans, a spectrum of endothelial tumors, including hemangioma, hemangioblastoma, Kaposi's sarcoma, hemangioendothelioma, and angiosarcoma, is seen. Angiosarcoma is extremely rare in humans and can be a late sequela to RT in women treated for breast cancer.¹⁶⁷ With this exception, it has a lesion distribution and behavior similar to canine HSA. As in dogs, metastasis is frequent and adjuvant chemotherapy provides minimal benefit.

SECTION B

Thymoma

CARLOS HENRIQUE DE MELLO SOUZA

Incidence and Risk Factors

Thymomas are one of the most common tumors of the cranial mediastinum, second only to lymphoma, yet they are uncommon in both dogs and cats. Thymomas can occur at any age but usually

affect older patients. The reported peak age for presentation is 9 and 10 years in dogs and cats, respectively.^{1,2} Breed predisposition has not been reported, and most studies do not show a sex predisposition.^{1,2} Risk factors predisposing animals to thymoma have not been identified.

Pathology and Natural Behavior

Thymomas are neoplasms of thymic epithelial cells.¹ Different histologic types of thymoma have been described and include differentiated epithelial, lymphocyte-rich, and clear-cell type. The degree of lymphocyte infiltration within thymomas in dogs and cats has been shown to correlate positively with survival.^{1,3} In cats, cystic thymomas seem to be the most common form, although squamous cell carcinoma variants and a thymolipoma have been reported.^{1,4-8} The terms *benign* or *malignant thymoma* are commonly used and are based on clinical criteria of invasiveness and resectability rather than on histologic features of malignancy. Distant metastasis has been rarely reported in dogs.^{5,9-11} The same is probably true in cats, although one study revealed a 20% metastatic rate in cystic thymomas in the species.⁶ The differential diagnoses for mediastinal masses should include lymphoma, ectopic thyroid tumor, branchial cysts, rare sarcomas, and metastatic neoplasms. Tumors extending from the ribs or sternum into the mediastinum may sometimes resemble a mediastinal mass.¹²

History and Clinical Signs

Clinical signs are usually related to organ displacement due to the presence of a mediastinal mass and include lethargy, coughing, tachypnea, and dyspnea. Less commonly, cranial vena cava syndrome (edema of the head, neck, and front limbs) may occur and is related to obstruction of vessels draining the cranial part of the body.^{3-7,10-12} Paraneoplastic syndromes are common in dogs and cats and may occur in as many as 67% of dogs with thymoma.^{3,4} Reported paraneoplastic syndromes include myasthenia gravis (MG), exfoliative dermatitis, erythema multiforme, hypercalcemia, T-cell lymphocytosis, anemia, and polymyositis. Myasthenia gravis may occur in up to 40% of dogs with thymoma and has also been reported in cats.^{3,10,11} Concurrent megaesophagus and aspiration pneumonia has been reported in as many as 40% of canine patients.³ Paraneoplastic syndromes may occur at presentation, later in the course of the disease, or after tumor removal.*

Diagnostic Techniques and Work-Up

Physical examination findings may include edema of the head, cervical area, or front limbs, secondary to cranial vena cava syndrome. The jugular veins may be dilated and tortuous. Auscultation of the thoracic cavity may reveal decreased or absent lung sounds in the cranial mediastinum related to displacement by the mass or pleural effusion. Cardiac displacement may also occur, and the heart sounds may be heard either more dorsally, caudally, or both. In small dogs and cats, decreased compressibility of the anterior thorax may also be detected.^{3-6,10-11,22}

Complete blood count (CBC) is usually normal, but anemia, thrombocytopenia (secondary to immune-mediated destruction),

*References 3, 5, 10, 11, 13–21.

• **FIGURE 33-4** **A**, Ventrodorsal thoracic radiograph of a large left-sided cranial mediastinal mass that severely displaces the trachea and the heart. **B**, Lateral view of the same mass showing dorsal displacement of the trachea and caudal displacement of the heart. A small amount of pleural effusion can also be observed. (Courtesy Dr. Christine Warzee, College of Veterinary Medicine, Michigan State University.)

and lymphocytosis may occur. Hypercalcemia, although uncommon, has been reported in association with thymomas but is much more common in cases of mediastinal lymphoma.^{5,11,23} In both tumors, hypercalcemia is usually the result of excessive production of parathyroid hormone–related peptide (PTHrP). The presence of hypercalcemia in an animal with a mediastinal mass should not be used as the sole means to differentiate thymoma from lymphoma.²²⁻²⁶

Thoracic radiographs may reveal the presence of a cranial mediastinal mass, pleural effusion, and cardiac displacement (Figure 33-4). Dilatation of the esophagus in the presence of megaesophagus secondary to MG and an increase in alveolar or interstitial lung pattern suggestive of aspiration pneumonia may also be detected. When MG is suspected, demonstration of serum antibodies against acetylcholine receptor is indicated. The Tensilon test (edrophonium chloride, which is an ultrashort anticholinesterase agent) can be used in cases suspected of having MG, in which muscle weakness and fatigue are observed. A marked short-lived improvement in muscle strength is considered a positive response.¹⁸⁻²¹ In cases presenting with pleural effusion, fluid analysis after thoracocentesis usually reveals a modified transudate and numerous small mature lymphocytes or a mixed lymphocyte population.^{3-5,10,22} Thoracic ultrasonography can be used to determine a presumptive diagnosis of thoracic masses, including thymomas. In addition ultrasound can guide biopsy needles for sampling of the mass.^{27,28} More recently, endoscopic thoracic ultrasound has been described in dogs with the reported advantage of a decrease in artifacts caused by the lungs.²⁹ Transthoracic ultrasound-guided fine-needle aspiration (FNA) of the mediastinum can be easily and safely performed after deep sedation and analgesia or general anesthesia. The diagnosis of thymoma is made when the presence of neoplastic epithelial cells interspersed between large numbers of small mature lymphocytes (and occasional mast cells) is observed.^{30,31} Unfortunately, nondiagnostic samples are common due to either a small percentage of epithelial cells, the presence of only small mature lymphocytes in the samples, or the presence of cysts within the mass. The diagnosis is further complicated due to the fact that both

lymphoma and thymoma may be composed primarily of small lymphocytes. In three studies, a presumptive diagnosis of thymoma was achieved in approximately 20%, 40%, and 77% of mediastinal masses after FNA and cytology. In addition, Hassall's corpuscles, cytoplasmic structures present in thymocytes, are not usually visualized in Wright-Giemsa preparations in comparison to hematoxylin-eosin (H&E) used for formalin-fixed samples.^{3,10,30,31}

Flow cytometry has been recently reported to aid in the specific diagnosis of mediastinal tumors. Flow cytometry of the thymus is based on the fact that thymic lymphocytes can be differentiated from peripheral lymphocytes by simultaneous expression of CD4 and CD8. In that study, all cases of thymoma expressed 10% lymphocytes co-expressing CD4 and CD8, whereas six of seven lymphomas contained less than 2% of CD4⁺CD8⁺ lymphocytes. The additional case of lymphoma was readily differentiated from thymoma by flow cytometric scatter plot analysis.³²

Advanced imaging modalities such as CT are now used to help the surgeon evaluate the possibility of resection. Three-dimensional (3D) CT reconstructions can estimate the size and volume of the mass, in addition to identifying neighboring structures and whether invasion of these structures has occurred. If the tumor is deemed inoperable, CT will still be helpful if radiotherapy is to be employed (Figure 33-5). Furthermore, CT-guided biopsies can be obtained during the process. Despite these advantages, nonangiographic CT has been shown to have limitations, which were outlined by a recent study. In that study, nonangiographic CT scanning significantly underestimated vascular invasion when compared to surgical exploration. These limitations can be potentially overcome by the use of CT angiography.³³⁻³⁶

Therapy

A variety of different modalities have been described for the treatment of thymomas in dogs and cats, including surgery, RT, and chemotherapy and multimodality treatments. Unfortunately, there are no available studies comparing outcomes of animals treated

• **FIGURE 33-5** **A**, CT view of the mass. The mass occupies most of the lateral aspect of the thoracic cavity, and despite significant organ displacement, no evidence of vascular invasion is detected. **B**, Surgical specimen of the large mass after sternotomy and complete resection. (Courtesy Dr. Christine Warzee, College of Veterinary Medicine, Michigan State University.)

with these different modalities. In addition, in many studies, animals were treated by a combination of different methods.* In a recent retrospective study that evaluated 11 dogs and 9 cats with invasive and noninvasive thymomas treated by surgery alone, the median survival was 790 days and 1825 days, respectively. The 1- and 3-year survival rates were 64% and 42% for dogs and 89% and 74% for cats, respectively.³ The successful resection of noninvasive thymomas in two dogs by video-assisted thoracoscopy has also been reported.³⁸

In another retrospective study, 17 dogs and 7 cats with thymoma were treated with RT alone or as an adjunctive therapy. Twenty cases were available for follow-up, and a response rate of 75% (11 partial responses [PRs]; 4 complete responses [CRs]) was observed. MSTs for dogs and cats were 248 days and 720 days, respectively. In that study, the total radiation dose (15 to 54 Gy) and treatment interval (from daily to once weekly) varied markedly among animals. To further confound the effects of RT in thymomas, the same study reported that many animals received concurrent chemotherapy.³⁷

The effects of chemotherapy for the treatment of thymomas have not been well evaluated in veterinary patients. Long-term remission and stable disease after treatment of thymomas in humans and dogs have been reported (single-case reports) with the use of high-dose prednisone. In one report a cat with thymoma achieved partial remission after treatment with DOX. Likely, the effects of chemotherapy and RT against thymomas reflect, at least in part, a greater reduction in the nonneoplastic lymphocyte population in the thymus, rather than in the primary carcinoma cells.^{3-5,10,39}

Prognosis

Surgically resectable thymomas in dogs without megaesophagus and aspiration pneumonia are thought to carry a good prognosis.^{3,5,10} The definition of surgical resectability will depend on the

experience and ability of the surgeon. Vascular invasion, which could potentially limit resection in the past, may be managed with a jugular vein autograft for reconstruction of the cranial vena cava in a dog with invasive thymoma.⁴⁰

As mentioned previously, thymomas with a significant lymphocytic infiltrate demonstrate improved survival. Age of the dog or cat, invasiveness of the tumor, and mitotic index had no effect on prognosis.³

In cats, cystic thymomas are commonly reported and they have been associated with better prognosis, although no other possible prognostic factors such as surgical resectability were critically evaluated.^{3,41}

In conclusion, long-term survival should be expected for dogs and cats with thymomas that can be completely resected. Vascular invasion may increase surgical complexity but not necessarily exclude surgery as an option.

Comparative Aspects

Thymic neoplasms in humans constitute 30% of anterior mediastinal masses in adults and less than 15% in children. The majority will occur in elderly patients, 60 years or older, and no sex or race predilection is thought to occur.^{42,43} A clinicopathologic classification has been adopted by the World Health Organization (WHO) and correlates well with behavior. In the WHO system, cells are classified as spindle (predominant in the medullary), oval and epithelioid (predominant in the cortex), or dendritic. The tumors are then further divided into medullary, mixed, predominantly cortical and cortical thymomas, and well-differentiated and high-grade thymic carcinoma. Medullary and mixed thymomas are considered benign tumors even in the face of capsular invasion. Predominantly cortical and cortical thymomas display intermediate aggressiveness and have a low risk of relapse independent of their invasiveness. Well-differentiated and high-grade thymomas are considered to be highly invasive and are associated with a high frequency of relapse and death. A staging system that employs both surgical and

*References 3-6, 10, 14, 21, 37.

histologic signs of invasiveness to describe five different stages correlates well with prognosis.^{42,44}

MG is the most common paraneoplastic syndrome associated with thymomas, occurring in 30% to 50% of patients. Red cell aplasia and hypogammaglobulinemia are reported to occur in 5% to 10% of patients.

Complete surgical resection is considered the best predictor for long-term survival for humans with thymomas and is the standard of care in patients with resectable tumors. RT is indicated most commonly for extensive or recurrent disease. A variety of chemotherapy drugs have been used to treat inoperable thymomas or in cases in which gross residual disease is present after surgery. Cisplatin, ifosfamide, and prednisone are considered the most effective agents. In addition neoadjuvant chemotherapy has been shown to influence long-term survival for thymomas of Masaoka stages III and IVa.⁴⁵

■ SECTION C

Canine Transmissible Venereal Tumor

J. PAUL WOODS

Incidence and Risk factors

Canine transmissible venereal tumor (TVT), also known as transmissible venereal sarcoma and Sticker's sarcoma, is a naturally occurring, horizontally transmitted infectious histiocytic tumor of dogs usually spread by coitus, but it may also be spread by licking, biting, and sniffing tumor-affected areas.¹⁻⁵ It has been observed occasionally in other canids, such as foxes, coyotes, and jackals.^{1,2} It has also been known as infectious sarcoma, venereal granuloma, canine condyloma, transmissible sarcoma, and transmissible lymphosarcoma.^{6,7}

Although TVT has a worldwide distribution, its prevalence is highest in tropical and subtropical areas, particularly in the southern United States, Central and South America, southeast Europe, Ireland, Japan, China, the Far East, the Middle East, and parts of Africa.^{1,2} In enzootic areas, where breeding is poorly controlled and there are high numbers of free-roaming sexually active dogs, TVT is the most common canine tumor.^{1-3,8} In North America, prevalence of TVT is correlated with increased rainfall and mean annual temperature.⁹ Occasional cases occur in regions otherwise free of TVT following travel to endemic areas as a result of tourism.¹⁰ Pets travelling abroad can be exposed to TVT and carry it back home to nonendemic areas; therefore veterinarians may act as the first line of defense against the introduction of TVT as an emerging disease in nonendemic areas.

Because TVT is primarily spread by coitus, free-roaming, sexually intact mature dogs are at greatest risk.² Dogs of any breed, age, or sex are susceptible.^{1,2,6} No heritable breed-related predisposition has been found.^{2,6} In endemic areas, although dogs over 1 year of age are at high risk, TVT is most common in dogs 2 to 5 years of age.² The physical exertions associated with coitus in the dog with extensive abrasions and bleeding make both sexes susceptible to injury to the genital mucosa, which facilitates the exfoliation and implantation of tumor cells.^{2,6} Transmission can occur efficiently in either direction between the dog and the bitch. The most common sites of involvement are the external genitalia, but other sites that can be affected through licking or sniffing include the nasal and oral cavities, subcutaneous tissues, and the eyes.^{1-4,6,11-14} Spontaneous regressions occur and have been associated with immune responses against the tumor. Hence immunosuppression from any cause may be a risk factor for the development and maintenance of TVT and may predispose to widespread dissemination. When spontaneous regressions occurs, it usually starts within 3 months after implantation but rarely after 9 months of tumor.⁶

TVT is a transmissible allograft spread directly from dog to dog across major histocompatibility complex (MHC) barriers through transplantation of viable tumor cells on damaged mucosa through coitus or sniffing and licking.¹⁵ TVT and Tasmanian devil facial tumor disease (DFTD) are the only known naturally occurring clonally transmissible cancers that behave like an infectious parasitic neoplastic tissue graft.¹⁶ These cancers have overcome the limitations of existing within the single host, which gave rise to the tumors by gaining the ability to spread between individuals and thus survive long after the original hosts have died.

Pathology and Natural Behavior

TVT was initially recognized in 1876 and was utilized for the first successful experimental transmission of a tumor.⁶ A number of characteristics of TVT suggest that the tumor originated in inbred wolves or dogs about 10,000 to 15,000 years ago around the time that the dog was domesticated and subsequently the tumor has been spread worldwide.¹⁷ TVT has evolved into a transmissible parasite representing the oldest known colony of cloned somatic mammalian cells in continuous propagation.

Tumor growth generally appears on the external genitalia or nasal or oral mucosa within 2 to 6 months of mating and can either grow slowly and unpredictably for years or grow invasively and eventually become malignant and metastasize.^{1,2,6} Extragenital lesions can occur both alone (in isolation) and in association with genital lesions; however, it has been suggested that in most cases neoplastic foci can be detected on the genitalia.

TVT usually remains localized, but metastasis occurs in up to 5% to 17% of cases to draining regional lymph nodes (i.e., inguinal, iliac, tonsils), subcutaneous tissue, skin, eyes, oral mucosa, liver, spleen, peritoneum, hypophysis, brain, and bone marrow.^{2,11,18-20} Because TVT is also transmitted by licking, sniffing, and biting, many cases of reported metastases may instead actually be spread of the growth by mechanical extension or autotransplantation or heterotransplantation. Spontaneous regression can occur within 3 to 6 months of implantation, but the chance of self-regression is remote if the tumor is present for over 9 months.²

TVT is commonly described as a round (or discrete) cell tumor and suggested to be of histiocytic origin.⁶ This is supported by immunohistochemical (IHC) expression of vimentin, lysozyme, alpha-1-antitrypsin (AAT), and macrophage-specific ACM1, as well as negative IHC staining specific for other cell types.^{4,6,21,22} Immunohistochemistry has been helpful in confirming metastatic TVT in various anatomic locations.¹⁸⁻²⁰ Furthermore, there have been reports describing TVT cells with intracellular *Leishmania* organisms also suggesting a histiocytic origin.^{14,23}

Cytogenetic and genetic analyses have provided robust evidence of clonality. Whereas normal canine cell chromosomes consist of 76 acrocentric autosomes plus submetacentric X and Y sex chromosomes, TVT cells have a vastly rearranged karyotype consisting of 57 to 59 chromosomes, including 15 to 17 submetacentric chromosomes as a result of multiple centric fusions.^{4,17} However, the total number of chromosome arms in TVT is grossly comparable to the normal dog, so it appears the karyotypic rearrangement is not associated with significant change in DNA content.^{15,17} Although TVT cells are aneuploid, they exhibit remarkably stable and similar karyotypes in samples obtained from widely separate geographic regions (i.e., different continents).¹⁵ Likewise, molecular genetic studies of globally distributed TVT tumors provide evidence of a monophyletic origin, which has diverged into two subclades.^{15,24}

In addition, TVT cells all share an insertion of a long interspersed nuclear element (LINE-1) upstream of the *c-myc* oncogene that is not found in normal dog genomes.²⁵⁻²⁹ This insertion has the potential to disrupt transcriptional regulation of downstream genes, possibly initiating oncogenic activity, and may have been causally involved in the origin of the tumor.³⁰ This unique rearranged LINE-*c-myc* gene sequence has been used with polymerase chain reaction (PCR) as a diagnostic marker of TVT to confirm diagnosis.^{31,32} TVT cells have also demonstrated point mutations in the tumor suppressor gene *p53*, which is responsible for protecting the integrity of the DNA.^{29,33,34} Mutations of such a key regulator of

the cell cycle, apoptosis, and senescence may be another factor in the oncogenesis of TVT.

TVT is an immunogenic tumor and the immunologic response of the host appears to play a critical role in determining the natural behavior of the disease. The course of disease is divided into a progressive phase (P) in which the tumor grows for 3 to 6 months, then a short stationary phase (S), which is followed by a regressive phase (R) in most dogs, unless the dog is elderly, in poor general condition, or immunologically compromised.^{6,8,35-44}

Initially, in the P phase, the tumor downregulates its MHC class I β 2-microglobulin and class II expression, which allows it to evade the host's histocompatibility barrier, particularly T-cell cytotoxicity.⁴⁵ Some cell-surface MHC class I expression remains, likely to prevent recognition and killing by natural killer (NK) cells. This immunoevasion is partly due to the high concentration of tumor-secreted transforming growth factor- β 1 (TGF- β 1), which inhibits tumor MHC antigen expression and NK cell activity.⁴⁰ TVT also targets and damages dendritic cells (DCs).⁴⁵ It has been suggested that TVT has evolved under survival pressures to escape host immunosurveillance.⁴⁶

Tumor-infiltrating lymphocytes (TILs) produce IFN γ but fail to promote tumor MHC expression due to inhibition of IFN γ effects by tumor-derived TGF- β 1, which also suppresses the cytotoxicity of the NK cells that migrate to the tumor site because of low tumor-antigen expression.^{36,39,40} However, late in the P phase, TILs produce high concentrations of the proinflammatory cytokine IL-6, which acts synergistically with host-derived IFN γ to antagonize the immunoinhibitory activity of TGF- β 1 and results in MHC expression in up to 40% of tumor cells and restores NK cytotoxicity.^{37,47} A critical threshold level of IL-6 secreted by TILs has to be reached to trigger TVT into R phase.^{40,47} Therefore, after progressive growth for 3 to 4 months, the tumor spontaneously regresses with upregulation of MHC antigen expression possibly under epigenetic control.⁴⁶

In addition to cell-mediated immunity, TVT also elicits a humoral immune response demonstrable by antibodies against TVT antigens.^{35,48} Experimentally, immunocompromised dogs do not demonstrate regression but rather continued progression of TVT and widespread metastatic disease.⁶ Conversely, dogs recovered from TVT have serum-transferable immunity to reinfection and puppies born to bitches exposed to TVT are less susceptible to the disease.⁴⁹ In addition to the host immune response, during TVT regression stromal cells and extracellular matrix (ECM) react comparably to wound repair with collapse of the tumor parenchyma and replacement by fibrous stroma.⁴³

History and Clinical Signs

The archetypical TVT patient is a sexually intact young adult dog either living in or having travelled to an area endemic for TVT, with a history of contact (coitus, sniffing, licking, or biting) with dogs of similar signalment.^{1,2,6,7} The primary lesions are usually on the external genitalia. In the male, the tumor is usually located on the caudal part of the penis, requiring caudal retraction of the penile sheath for visualization (Figure 33-6).^{2,6} Occasionally, it is on the prepuce. In the bitch, the tumor is usually in the posterior vagina or vestibule.^{2,6} Tumors appear initially as small 1 to 3 mm hyperemic papules that progress by fusing together into nodular, papillary, multilobulated cauliflower-like or pedunculated proliferations up to 10 to 15 cm in diameter. The mass is firm but friable, with an ulcerated inflamed surface. The tumor often oozes a serosanguineous or hemorrhagic fluid. Examples of extragenital sites are illustrated in Figure 33-7.

FIGURE 33-6 Typical appearance of a transmissible venereal tumor (TVT) in a male dog. The tumor is located at the base of the penis, has a cauliflower-like appearance, is very friable, and bleeds easily.

Clinical signs vary according to the location of the lesions. Genital lesions often manifest with chronic signs of discomfort or hemorrhagic discharge from the penile sheath or vulva for weeks to months prior to diagnosis, which can result in anemia.^{2,6,7} Lesions can predispose to ascending bacterial urinary tract infections but rarely interfere with micturition.⁵⁰ Extragenital lesions cause a variety of signs, depending on anatomic location, such as sneezing, epistaxis, epiphora, halitosis, tooth loss, exophthalmos, skin masses, facial deformation, and regional lymph node enlargement.

Diagnostic Techniques and Work-Up

A presumptive diagnosis of TVT can be obtained based on history (including travel), signalment, clinical signs, and physical findings in dogs with the classic presentation. Definitive diagnosis is based on cytologic examination of cells obtained by swabs, FNAs, or imprints of the tumors or histologic examination of a biopsy from the mass. TVT is described as a discrete (or round) cell tumor. TVT has a characteristic morphologic appearance on cytopathology and is often diagnosed without need for histopathology (see Figure 7-37). Exfoliative cytology demonstrates uniform discrete round to polyhedral-shaped cells with moderately abundant pale blue cytoplasm and an eccentrically located nucleus, with occasional binucleation and mitotic figures.^{4,6} Single or multiple nucleoli are often observed, surrounded by clumped chromatin. The most characteristic feature is the presence of numerous discrete clear cytoplasmic vacuoles. In R phase, TVTs contain a higher number of infiltrating lymphocytes. Other round cell tumors, including lymphomas, mast cell tumors, plasma cell tumors, histiocytomas, and amelanotic melanomas, are important differential diagnoses but are generally not confused with TVT on cytopathology.

Histopathology of TVT reveals compact masses of round or polyhedral cells with slightly granular, vacuolated, eosinophilic cytoplasm.^{4,6} The neoplastic cells are arranged in a diffuse pattern and supported by a thin trabecula of fibrovascular tissue.

• **FIGURE 33-7** Other primary tumor sites. **A**, Male dog with cutaneous dissemination of transmissible venereal tumor (TVT) on the ventral abdomen. **B**, Mucocutaneous TVT of the anal area in a dog. **C**, Corneal involvement with TVT in a dog. (Courtesy Pr. Noeme S. Rocha.)

Regressing tumors are infiltrated by lymphocytes, plasma cells, and macrophages.⁶ For atypical TVTs, if there is doubt about the diagnosis, specific molecular techniques can be utilized (e.g., in situ PCR of the rearranged LINE-*c-myc* gene sequence).³¹

The incidence of metastatic spread of TVT has been reported as less than 15%. However, in most cases of TVT, tumor staging is not performed. Therefore the metastatic rate might be higher. Regional lymph nodes should always be evaluated for metastasis by palpation and cytopathology. A thorough physical examination is essential to rule out other possible sites of involvement (i.e., skin, subcutis, nasal and oral cavities, the eye, the orbit). Diagnostic imaging is

usually not required except with invasive TVT of the nasal cavity, orbit, or unusual locations. However, abdominal ultrasound may be used to image regional lymph nodes. CBC, serum biochemistry profile, and urinalysis do not reveal specific changes. Dogs bearing a large tumor burden of TVT have been associated with a paraneoplastic erythrocytosis that may require temporary symptomatic therapy.⁶

Therapy

TVTs will respond to many forms of therapy; however, chemotherapy is the most effective. Single-agent vincristine (0.5 to 0.7 mg/m² intravenous [IV], once weekly for 3 to 6 treatments) obtains a complete and durable response in 90% to 95% of treated dogs.* Other single-agent and combination multiagent protocols employing cyclophosphamide, vinblastine, methotrexate, and prednisolone have not demonstrated superiority to vincristine alone.^{52,53,56} Resistant cases can be treated with DOX (25 to 30 mg/m² IV, every 21 days for 3 treatments).¹

RT has demonstrated efficacy against TVT. In a study using orthovoltage radiation at 1000 to 3000 cGy, all 18 dogs treated responded with a complete and durable response.⁵⁷ Seven dogs were cured with a single coarse fraction of 1000 cGy. The other 11 dogs required 2 or 3 fractions to achieve complete response. Three of the 18 dogs were presented after recurrence following chemotherapy. Another study using megavoltage radiation from a Cobalt-60 unit reported all 15 dogs achieved complete and durable responses with 3 fractions administered over 1 week, for an average dose of 1500 cGy.¹¹

Four of the 15 dogs had been resistant to vincristine. Therefore RT can be considered an effective treatment for TVT, particularly for lesions showing resistance to chemotherapy or located in sanctuary sites from chemotherapy (i.e., brain, testicle, eye).

Surgery can be an effective treatment for small localized TVT; however, surgery has an overall recurrence rate of 30% to 75%.^{58,59} Marginal surgical excision is not effective, and it can be difficult to obtain wide surgical margins in the areas in which TVT typically appears.^{58,59} In addition, tumor transplantation into the surgical wound by contamination from instruments or gloves may also cause postoperative tumor recurrence.

Other therapies described in spontaneous and experimentally induced cases include biologic-response modifiers, piroxicam, cryosurgery, radiofrequency ablation, laser ablation, and electrochemotherapy.⁶⁰⁻⁶⁴

Reduction of the incidence of TVT is possible by having dog owners and breeders carefully examine all males and females before mating to avoid breeding from affected animals.² In addition, stray dogs can act as a TVT reservoir; therefore the mingling of breeding dogs with strays should be prevented. In some areas, the control of ownerless, free-roaming dogs can drastically reduce the incidence of TVT. TVT can enter the wild canid population through physical contact (licking, biting, or mating), and it is not known whether TVT could pose a threat to endangered wild canids.⁶⁵

Prognosis

In most cases, TVT remains localized and rarely becomes disseminated in an immunocompetent host. In fact, a number of dogs will have their TVT spontaneously regress. For those dogs requiring

*References 1, 2, 11-13, 42, 51-55.

treatment with vincristine or radiation, the prognosis for complete and durable clinical remission is excellent. Therefore the overall prognosis of canine TVT is generally very good to excellent. In stark contrast, the other naturally occurring transmissible tumor allograft, the Tasmanian DFTD, is highly virulent and kills most affected animals within 6 months by obstructing their ability to feed or breathe. It is speculated that the difference in virulence between the two allografts is due to the loss of MHC diversity in the Tasmanian devils, and perhaps one reason for MHC diversity in vertebrates is to ensure that cancer is not communicable between hosts like an infectious disease.^{15,17,46}

SECTION D

Mesothelioma

LAURA D. GARRETT

Incidence and Risk Factors

Mesothelioma is a rare neoplasm of dogs and cats affecting the cells lining the coelomic cavities of the body. In 1962, Gerb et al cited reports of one case of mesothelioma in 1000 dogs and three cases in 5315 dogs.¹ In dogs, primary mesothelial tumors affecting the thoracic cavity, abdominal cavity, pericardial sac, and vaginal tunics of the scrotum have been reported.^{2–6} In the cat, primary mesotheliomas have been reported in the pericardium, pleura, and peritoneum, as well as throughout the abdomen with lung and mediastinal lymph node metastases.^{7–12} Exposure to asbestos may be an important contributory factor to mesothelioma development in pet dog populations. Affected dogs often live with owners who have occupations or hobbies for which exposure to asbestos is a known risk.¹³ The level of asbestos fibers in lung tissues of affected dogs has been documented to be greater than controls.^{13,14} Asbestos refers to a family of silicate minerals that crystallize into long, flexible fibers. The fibers are categorized into two groups: thin rodlike amphibole and long curly serpentine, the main type being chrysotile. In humans, much greater risk has been related to amphibole asbestos compared to chrysotile exposure.¹⁵ Chrysotile now accounts for 90% of asbestos used worldwide.¹⁵

The underlying mechanisms of the neoplastic transformation of mesothelial cells, despite its association with asbestos, are not completely understood. Asbestos interacts with mesothelial cells via direct and indirect mechanisms and is associated with both phenotypic and genotypic changes in the affected cells. Chromosomal missegregation, aneuploidy, and deletions are reported.^{15,16} Loss of tumor suppressor gene products is thought to contribute to the transformation of mesothelial cells.¹⁶ Also, reactive oxygen and nitrogen species generated by macrophages as the cellular response to asbestos fiber phagocytosis and by the fibers themselves add to the genetic damage in the tumor precursor cells.¹⁵ Numerous growth factors (e.g., insulin-like growth factor-1 [IGF-1], platelet-derived growth factor [PDGF], and VEGF) produced by stimulated macrophages or mesothelial cells, as well as tumor suppressor genes, are likely important in the pathogenesis of mesothelioma.^{16–18} A recent report of five golden retrievers that developed pericardial mesothelioma after a long-term (30 to 54 months) history of idiopathic hemorrhagic pericardial effusion (IHPE) supports the concept that chronic inflammation may lead to neoplastic transformation in canine mesothelial cells.¹⁹

Mesothelial tumors occur most often in older animals; however, in cattle and sheep, newborn or young animals may be affected.²⁰ Juvenile mesothelioma has been reported in two mixed-breed dogs under 1 year of age; no underlying etiology was identified.^{21,22} A

report of a 7-week-old puppy with mesothelioma suggests a congenital form may exist.²³

Pathology and Natural Behavior

The normal mesothelium is a monolayer of flattened mesothelial cells. These cells are distinguished by the presence of microvilli, desmosomes, and evidence of phagocytic potential. Disease conditions associated with inflammation or irritation of the lining of body cavities commonly result in a marked physiologic proliferation of mesothelial cells. Fluid accumulation in a body cavity promotes exfoliation and implantation of mesothelial cells. Mesotheliomas are considered malignant due to their ability to seed the body cavity, resulting in multiple tumor growths. Distant metastasis is rare.

Mesothelial cells appear morphologically as epithelial cells; however, their derivation is from mesoderm. Mesothelioma can appear histologically as epithelial, mesenchymal, or biphasic, which is a combination of the two.²⁴ The epithelial form, which resembles carcinoma or adenocarcinoma, is by far the most common form in small animals. There are also several reports of a variation of the mesenchymal form, which resembles sarcoma and is referred to as *sclerosing mesothelioma*.^{4,25,26} The biphasic form of mesothelioma has been reported in two dogs.^{27,28} A cystic peritoneal mesothelioma has also been reported in the dog. This is a rare, benign, slowly progressive form of mesothelioma in humans, which is treated with surgical excision when the disease is localized.²⁹

History and Clinical Signs

Classic mesotheliomas occur as a diffuse nodular mass or multifocal masses covering the surfaces of the body cavity (Figure 33-8). Extensive effusions occur due to exudation from the tumor surface or from tumor-obstructed lymphatics; therefore the most common presenting sign is dyspnea from pleural effusion or a distended abdomen from peritoneal effusion. Dogs with pericardial or heart-base mesotheliomas can present with acute tamponade and right-sided heart failure.³⁰⁻³²

Sclerosing mesothelioma is a variation of mesothelial tumor seen primarily in male dogs, with German shepherd dogs being overrepresented.^{4,25,26,33} These tumors present as thick fibrous linings in the abdominal and/or pleural cavities. Restriction occurs

around organs in the affected area, and in the abdomen such changes can impinge on organs and lead to vomiting and urinary tract signs.

Diagnostic Techniques and Work-Up

Mesothelioma should be suspected in adult dogs presenting with a history of chronic, nonspecific disease and fluid accumulation in any of the body cavities. Routine echocardiography and abdominal ultrasound are not typically helpful because the tumor cells cling to epithelial surfaces and a mass lesion is rarely noted.³⁴ In a recent study of echocardiography of dogs with pericardial effusion, only 5 of 15 dogs with pericardial effusion due to mesothelioma had a discrete cardiac mass identified.³² Thoracic CT may be of benefit in identification of nodular lesions and in assessment of lung parenchyma in the face of pleural effusion^{35,36} (Figure 33-9).

Cytologic evaluation of fluid can be diagnostic for other disease processes such as infection or lymphoma but will not conclusively diagnose mesothelioma. Mesothelial cells proliferate under any circumstance associated with fluid accumulation in the body cavity, making the distinction between physiologic mesothelial proliferation and neoplasia difficult. Although malignant mesothelial cells easily exfoliate into effusion fluid, they are hard to distinguish from reactive hypertrophic mesothelial cells cytologically. Reactive mesothelial cells display many cytologic features of malignancy, making a definitive diagnosis of neoplasia via cytology impossible in most cases. Although one study found pericardial fluid pH analysis to be a discriminatory test to differentiate benign from malignant effusions, subsequent studies found too much overlap in the pH values for the test to be of benefit.³⁷⁻³⁹ Fibronectin concentrations have also been evaluated in pleural effusions in dogs and cats and were found to differentiate malignant or inflammatory causes from cardiogenic effusions. Elevation in fibronectin levels is a sensitive but nonspecific test for malignant effusions, and mesothelioma can be ruled out if fibronectin levels are not increased.⁴⁰

Establishing a definitive diagnosis of malignant mesothelioma may be difficult, particularly early in the disease. The diagnosis of mesothelioma requires adequate tissue sampling, preferably from an open, visually directed biopsy. Increasing availability of thoracoscopy and laparoscopy for small animals provides a less invasive

• **FIGURE 33-8** **A**, Pleural, parietal, and pericardial surfaces of a dog at necropsy illustrating nodular lesions histologically confirmed as mesothelioma. **B**, Mesothelioma involving the peritoneal surfaces of a cat at necropsy.

• **FIGURE 33-9** Thoracic CT (with contrast) from a dog with histologically confirmed mesothelioma. The effusion resolved following the first of five doxorubicin chemotherapy (30 mg/m² every 3 weeks, IV) treatments.

means to evaluate these cases.⁴¹ In either procedure, the clinician is encouraged to biopsy any body cavity lining when an obvious cause for fluid accumulation is not found. Sclerosing mesothelioma must be distinguished from chronic inflammatory diseases of the body cavity, such as chronic peritonitis, and histologic examination of biopsy material is essential to establish the diagnosis. Additionally, embolized, nonneoplastic mesothelial cells within lymph nodes is a rare finding in humans with cavity effusions and has been reported in dogs affected with idiopathic hemorrhagic pericardial effusion; therefore care must be taken so as not to overinterpret these cells as indicative of a metastatic process.⁴²

The most useful criteria in establishing a diagnosis of mesothelioma is to demonstrate that the tumor is primarily a neoplasm of the coelomic cavity lining and that the method of tumor spread is by transcoelomic implantation. Therefore mesothelioma should be considered when the bulk of the neoplastic tissue exists on the coelomic surface. Histologically, mesotheliomas need to be differentiated from carcinomas, adenocarcinomas, or sarcomas, depending on the morphologic type of the mesothelioma. Unfortunately, there are no cellular markers that conclusively define the mesothelial cell. Recent advances in IHC staining have provided additional ways to examine neoplastic cells to help differentiate mesothelioma from other epithelial or mesenchymal tumors in humans. Podoplanin and D2-40 were found to be highly sensitive IHC markers for sarcomatoid mesotheliomas.⁴³ Differentiation of malignant epithelial mesotheliomas from adenocarcinomas can be aided by application of a panel of different immunohistochemical stains, including calretinin, Wilms' tumor-1, and cytokeratin 5/6 for which mesotheliomas, but not adenocarcinomas, are strongly positive.⁴⁴

Treatment and Prognosis

No satisfactory treatment exists for mesothelioma. Radical excision may benefit some animals, but usually the tumors are too advanced locally and have spread by implantation early in the course of disease. In one case report, a 2-year-old Siberian Husky with a solitary sclerosing mesothelioma affecting the left thoracic diaphragmatic surface with pericardial and mediastinal adhesions was treated with aggressive surgical resection and diaphragmatic reconstruction using the transversus abdominis muscle.⁴⁵ The dog recovered well, but subcutaneous masses at the surgery site, as well as hepatic and renal masses, were noted 54 days postoperatively, leading to euthanasia. Pericardiectomy may palliate mesothelioma patients that present with cardiac tamponade; two dogs treated with surgery alone survived 4 and 9 months in one study.⁴⁶ In another report, the median survival in five dogs treated with pericardiectomy was 13.6 months; three of these dogs received adjuvant IV chemotherapy (two DOX, one mitoxantrone).⁴⁷ A dog treated with pericardiectomy, intrathoracic and IV cisplatin, and IV DOX remained free of disease at 27 months.⁴⁸ In a report of eight dogs with pericardial mesothelioma, the MST was 60 days (range 15 to 300 days) following partial pericardiectomy. The one dog that survived 300 days was treated with DOX and intracavitary cisplatin for the 4 months preceding death.³⁴ Thoracoscopic partial pericardiectomy is a less invasive procedure than open thoracic surgical pericardiectomy and has been successfully performed in dogs with malignant pericardial effusions, including four dogs with mesotheliomas.⁴⁹ Portal site seeding with the mesothelioma is a potential complication of this procedure.⁵⁰ Median survival for animals with untreated mesotheliomas in any location is difficult to assess from reports because the tumors are rare and animals frequently are euthanized at the time of diagnosis.

Intracavitary cisplatin has shown palliative potential in the dog; it was well tolerated and greatly decreased mesothelioma-associated thoracic fluid accumulation in three dogs in one study.⁵¹ The treatments also appeared to arrest tumor growth for a limited time. Two doses of intracavitary carboplatin were safely administered to a cat with suspected pleural mesothelioma and resulted in transient resolution of clinical signs for a total of 54 days, at which point the owners discontinued therapy.⁵² Unfortunately, local penetration of intracavitary chemotherapy only occurs to a limited depth (2 to 3 mm); thus large masses will not be affected significantly, other than from ultimate exposure to the systemically absorbed intracavitary drug. In such cases, combining debulking surgery or systemic chemotherapy such as DOX or mitoxantrone with intracavitary cisplatin may be beneficial. For peritoneal mesothelioma, four doses of intracavitary cisplatin in two dogs and carboplatin in one cat, combined with piroxicam administration, resolved the effusion in all cases.⁵³ One of the dogs had debulking surgery first; this dog was still in remission at 2 years, whereas the other dog and the cat lived 8 and 6 months, respectively. IV chemotherapy may provide benefit in some patients; single-agent IV cisplatin administered every 3 weeks was reported to improve clinical signs in a dog with bicavitary epithelial mesothelioma, until sudden death occurred 5 months after treatment initiation.⁵⁴

Comparative Aspects

In humans, mesothelioma is closely linked to exposure to aerosolized asbestos fibers. Approximately 70% to 80% of cases have a history of occupational exposure, with the type of employment significantly affecting relative risk.^{17,55,56} Occupations such as

construction work, ship building, heating trades, asbestos mining, and insulation work are strong risk factors in the development of mesothelioma in humans.¹⁷ Family members of exposed industrial workers are at risk due to asbestos fiber exposure from the workers' clothing. Affected individuals routinely have greatly increased counts of asbestos fibers in parenchymal lung tissue.⁵⁵ The latency period from time of exposure to tumor development is long, with reports ranging from 12 to 50 years.¹⁷ Other risk factors discussed in the development of mesotheliomas include past radiation, exposure to certain chemicals or nonasbestos fibers, and genetic tendency.^{15,17} In addition, the DNA tumor virus Simian 40 (SV40) is suspected to act as a cocarcinogen with asbestos in causing mesotheliomas.^{16,57,58} SV40 was introduced into a large percentage of humans through contaminated polio vaccines between 1955 and 1963. SV40 can transform cells and experimentally leads to mesothelioma development in laboratory animals. However, there is strong evidence against the proposed connection between SV40 and mesothelioma and data support that the high prevalence of SV40 found in human mesotheliomas in previous studies was likely due to false-positive molecular assays.^{59,60}

In humans, the median survival is approximately 1 year from symptom onset. A prognostic index, based on a combination of prognostic factors and gene expression testing, allows for the determination of high- and low-risk patients with respective median survivals of 6.9 versus 31.9 months.⁵⁶ There is no consensus in the literature regarding surgery and RT for treatment, although recently several chemotherapy options have been shown to improve survival time and quality of life.⁵⁶ The current gold standard drugs are antifolates, specifically pemetrexed and raltitrexed, often combined with cisplatin or carboplatin.⁵⁶ Gemcitabine and vinorelbine have also shown some efficacy in humans with mesothelioma. Several novel therapies are also under investigation. Unfortunately, some therapies (e.g., epidermal growth factor receptor [EGFR] inhibitors) performing well in preclinical models did not show activity in clinical mesothelioma patients.⁶¹ Trials of other novel therapies, including anti-VEGF antibody, cyclin-dependent kinase (CDK) inhibitor, antimesothelin antibody, and proteasome inhibitors, are ongoing. Multimodality therapy, including novel agents, will hopefully improve survival time in the future.^{57,61}

SECTION E

Neoplasia of the Heart

WILLIAM C. KISSEBERTH

Incidence and Risk Factors

Neoplasia of the heart and pericardium is rare in the dog and even less common in the cat. The proportional morbidity of canine heart tumors was 0.19% in a Veterinary Medical Data Base (VMDB) search.¹ In two necropsy series, the overall frequency of primary or metastatic cardiac tumors was 0.12% to 5.73%^{2–9} and 11.74% to 28.3% of neoplasms involving intrapericardial tissues, respectively.^{2,3} Cardiac tumors (excluding lymphoma) occur most frequently in middle-aged to older (7 to 15 years) dogs.¹ Overwhelmingly, HSA is the most common primary cardiac tumor in the dog, followed by aortic body tumors (chemodectoma, paraganglioma) and then miscellaneous other tumors.¹ HSA represented 69% and aortic body tumor 8% of the histologically diagnosed cardiac tumors in the VMDB.¹ Breeds reported to be at increased risk or predisposed for cardiac HSA include the German shepherd dog and golden retriever.^{3,10,11} Aortic body tumors occur most commonly in older brachycephalic dogs,^{3,12–15} including Boxers, Boston terriers, English bulldogs, and also German shepherd dogs.¹ It has been suggested that chronic hypoxia may stimulate development of chemoreceptor tumors in both dogs and humans^{12,13} and that this factor could explain the increased occurrence of aortic body chemodectomas in brachycephalic breeds; however, not all dogs diagnosed with aortic body tumors are brachycephalic nor do all brachycephalic breeds appear to be at increased risk, and thus other factors (e.g., genetic) presumably contribute to pathogenesis. Based on the VMDB study, 12 breeds were identified as having a significantly higher cardiac tumor incidence compared to all other breeds. Many of the breeds previously reported to be at increased risk for cardiac tumors were identified; however, other breeds were also identified with a relatively high incidence. Most notably, the golden retriever had a high incidence of cardiac tumors (primarily HSA) and total number of recorded tumors.¹

A similar VMDB search determined an overall incidence of 0.0275% for feline cardiac tumors.¹⁶ The only primary tumors of the cardiovascular system found in a series of 4933 feline necropsies were one case of mesothelioma of the pericardium and two cases of chemodectoma.¹⁷ Overall, the most common primary or metastatic cardiac tumor in cats is lymphoma.¹⁶

Pathology and Natural Behavior

Neoplasms affecting the heart may occur in intracavitary, intramural, or pericardial locations or at the heart base. Primary tumors may be benign or malignant, with most in the dog occurring in the right atrium and auricle. The most common primary cardiac tumor in the dog is HSA (Figure 33-10, A), followed by aortic body tumor (Figure 33-10, B).^{1–15} Cardiac HSAs often are associated with hemorrhagic pericardial effusion, cardiac tamponade, and metastatic disease.^{10,11,18,19} Aortic body tumors arise from chemoreceptor cells at the heart base. Most frequently, they present as a single mass at the base of the heart; however, occasionally they present as a localized collection of focal masses or are infiltrative into the myocardium. Aortic body tumors are primarily locally invasive but occasionally metastasize. Functional tumors have not been found in domestic animals but have been reported in

FIGURE 33-10 **A**, Gross postmortem specimen from a dog with right auricular HSA. Note the large, hemorrhagic mass effacing the right auricle (*). **B**, Gross postmortem specimen from a dog with an aortic body tumor (chemodectoma). Note the large, multilobulated mass (*) surrounding the aorta and compressing the atria. LV, Left ventricle; AoV, aortic valve; Ao, ascending aorta. (Courtesy Brian A. Scansen, DVM, MS, DACVIM [Cardiology], the Ohio State University, College of Veterinary Medicine.)

humans.²⁰ Other primary cardiac tumors reported in the dog include lymphoma, undifferentiated sarcoma, myxoma, ectopic thyroid carcinoma, fibroma, fibrosarcoma, rhabdomyosarcoma, chondrosarcoma, mesothelioma, granular cell tumor, osteosarcoma, myxosarcoma, leiomyoma, thyroid adenoma, thyroid carcinosarcoma, leiomyosarcoma, lipoma, peripheral nerve sheath tumor, and mixed mesenchymal tumor.²¹⁻⁴⁸ In contrast to humans, primary cardiac tumors are more common than metastatic tumors in the dog.¹ This is due largely to the high incidence of HSA in dogs. HSA accounts for 40% to 69% of cardiac neoplasms in the dog.¹⁻³ In most studies, cardiac HSA is considered a primary site, although dogs often have evidence of disease at other locations at the time of diagnosis, and it usually is impossible to determine which is the primary site and which are the metastatic sites. In a recent necropsy case series, 24 of 66 dogs (36%) with extracardiac malignant tumors had metastases found in the heart (15 carcinomas, 6 lymphomas, 3 HSAs), suggesting that cardiac metastases may be underdiagnosed in dogs with malignant, especially advanced, cancers.⁴⁹ In individual reports, metastatic mammary carcinoma, melanoma, malignant histiocytosis, pheochromocytoma, granulosa cell tumor, gastric adenocarcinoma, lymphoma, and liposarcoma have been reported to occur in the heart of the dog.⁵⁰⁻⁵⁸ Primary cardiac HSA, aortic body tumors, myxoma, and rhabdomyosarcoma have been reported in the cat^{16,59-64}; however, metastatic tumors are more common—lymphoma (Figure 33-11), mammary gland carcinoma, pulmonary carcinoma, salivary gland adenocarcinoma, oral melanoma, rhabdomyosarcoma, sweat gland adenocarcinoma, squamous cell carcinoma, and mast cell tumor have been reported.^{16,17,49,65-70}

History and Clinical Signs

Tumors involving the heart cause varied clinical signs. Cardiac tumors disrupt the normal function of the tissues from which they arise, leading to altered cardiovascular function. In general, signs

result from (1) the physical presence of the mass causing obstruction of blood flow into or out of the heart, (2) external compression of the heart that impedes filling (e.g., pericardial effusion) and resulting cardiac tamponade, and (3) disruption of normal heart rhythm or contractility if myocardial infiltration occurs or ischemia develops. Clinical signs produced by cardiac tumors are more closely related to their precise anatomic location than their histologic type. Specific clinical signs observed in an individual patient are influenced by the tumor's size and location and the presence of pericardial effusion. Acute death from rupture of a tumor with subsequent blood loss, with or without cardiac tamponade, is a common sequela of cardiac HSA. Sudden death due to cardiac arrhythmias may also occur. Cardiac HSAs, as well as the majority of reported primary sarcomas of the right heart in dogs, often produce signs of right heart failure due to the presence of cardiac tamponade and inflow obstruction. These signs include ascites, pleural effusion, jugular venous distension, abnormal jugular pulsations, exercise intolerance, dyspnea, pulse deficits, muffled heart sounds, and syncope. Tumors that cause pericardial effusion and cardiac tamponade have been reported the most often.¹ Cardiac or pericardial tumors are responsible for approximately 60% of cases of pericardial effusion in dogs.⁷¹ The most common tumors to cause pericardial effusion are right atrial HSA, aortic body tumors, and mesothelioma.⁷¹ Associated clinical signs resulting from cardiac tamponade include restricted ventricular filling secondary to external cardiac compression, venous congestion, and poor cardiac output. Heart base tumors are most often associated with pericardial involvement of the tumor and accompanying pericardial effusion.¹⁶ Edema, ascites, cough, dyspnea, weight loss, and vomiting are the signs most commonly reported with aortic body tumors in dogs.^{14,16,72} Heart base masses are a common cause for cranial vena cava syndrome (edema of the head, neck, and forelimbs) due to tumor pressure on the cranial vena cava. Sometimes, these tumors may be present without causing clinical signs or are incidental findings at necropsy. Cardiac tumors that do not cause pericardial

• **FIGURE 33-11** Gross postmortem specimen from a cat with cardiac lymphoma. **A**, The external surface of the heart shows several raised, white masses. **B**, A cross-section of the ventricles shows a large expansile infiltrate determined to be lymphoma by histopathology. (Courtesy Paul C. Stromberg DVM, PhD, DACVP, the Ohio State University, College of Veterinary Medicine.)

effusion can cause signs of congestive heart failure or low cardiac output by obstructing blood flow within the heart or great vessels and by inducing arrhythmias. Syncope and weakness with exertion or excitement are common signs in animals with cardiac tumors. These signs of low cardiac output can result from cardiac tamponade, blood flow obstruction, arrhythmias, impaired myocardial function, and hemorrhage.¹ Clinical signs may be absent if the tumor is small or in a location that does not affect cardiac function.

Diagnostic Techniques and Work-Up

The diagnosis of cardiac neoplasia in the dog and cat is usually based on clinical history, physical examination, and radiographic and echocardiographic findings. Occasionally, tumors, especially aortic body tumors, are an incidental finding at necropsy. In many instances, cytologic or histologic confirmation of neoplasia is not obtained antemortem; however, FNA or tissue biopsy should be obtained when indicated and technically feasible. An electrocardiogram may be normal in patients with cardiac tumors or may show any of a variety of arrhythmias, which may correlate with the underlying site of the primary or metastatic tumor or may be secondary to myocardial ischemia or hypoxia. Low-amplitude QRS complexes and electrical alternans may be seen in animals with pericardial effusion.⁷³ Sinus tachycardia is common with cardiac tamponade. Conduction and rhythm abnormalities are especially common with infiltrative tumors of the myocardium. Animals with a large volume of pericardial effusion may have a rounded (“globoid”) cardiac silhouette (Figure 33-12). Smaller fluid accumulations may allow visualization of atrial and tumor shadows.¹⁶ Thoracic radiographs may reveal cardiomegaly or effusions associated with cardiac tamponade. Mass lesions, if seen, are most common in the areas of the right atrium and heart base. Lung metastases may also be seen.

Echocardiography is the most valuable diagnostic procedure for identifying tumors of the heart in cats and dogs (Figure 33-13).⁷⁴⁻⁷⁶ In a recent study of 107 dogs with pericardial effusion, the sensitivity and specificity of echocardiography were 82% and 100%, respectively, for detection of a cardiac mass; 82% and 99%, respectively, for detection of a right atrial mass; and 74% and 98%, respectively, for detection of a heart base mass.⁷⁷ The positive and negative predictive values of echocardiography were 100% and 75%, respectively, for detection of a cardiac mass; 100% and 87%, respectively, for the detection of a right atrial mass; and 89% and 93%, respectively, for detection of a heart base mass.⁷⁷ In another study of histologically confirmed HSA of the right atrium/auricle, echocardiography had a positive predictive value of 92% (11/12) and a negative predictive value of 64% (9/14) in dogs.⁷⁶ Tumor location (extrapericardial, noncavitary pericardial, and small auricular masses) and size appear to be the most important factors for false-negative results with echocardiography.⁷⁶ Pericardial effusions are a common finding associated with cardiac tumors in both cats and dogs.^{36,76-78} Echocardiographic diagnosis of mesothelioma is difficult. Results of echocardiographic examination may be negative unless there are discrete mass lesions associated with the pericardium. Advanced imaging modalities, including CT, MRI, positron emission tomography (PET), and PET/CT, may be useful for selected cases.⁷⁹⁻⁸²

Other clinical diagnostic methods for the evaluation of cardiac or pericardial masses include pneumopericardiography, selective and nonselective angiography, gated radionuclide imaging, and endomyocardial biopsy in selected patients.^{71,83,84} Cytologic evaluation of pericardial fluid and pericardial fluid pH has proved to be of limited usefulness in diagnosing or discriminating between neoplastic and nonneoplastic causes of pericardial effusion.⁸⁵⁻⁸⁷

Cardiac troponin I (cTnI) appears to be useful for diagnosing cardiac HSA in dogs.^{88,89} cTnI and cardiac troponin T (cTnT) are sensitive and specific markers for myocardial ischemia and necrosis. In one study, dogs with pericardial effusion had

• **Figure 33-12** Thoracic radiographs from an 8-year-old golden retriever with moderate pericardial effusion before **(A)** and 5 days after pericardiocentesis **(B)**. Note the globoid cardiac silhouette prior to pericardiocentesis, compared to the normal cardiac silhouette seen after the pericardial fluid is removed. (Courtesy Brian A Scansen, DVM, MS, DACVIM [Cardiology], the Ohio State University, College of Veterinary Medicine.)

• **FIGURE 33-13** **A**, Echocardiographic image from a 12-year-old golden retriever presented for acute collapse. There is mild pericardial effusion (PE) and a circular mass of mixed echogenicity at the right atrioventricular groove (*) consistent with HSA. RA, Right atrium, RV, right ventricle. **B**, Echocardiographic image from an 8-year-old Boxer. A large mass (*) of mixed echogenicity is seen adjacent to the ascending aorta (Ao) consistent with an aortic body tumor. LV, Left ventricle. significantly higher serum concentrations of cTnI but not cTnT than normal dogs.⁸⁸ Furthermore, dogs with cardiac HSA had significantly higher concentrations of cTnI than did dogs with idiopathic pericardial effusion.⁸⁸ In another study, the median plasma cTnI concentration was higher in dogs with cardiac HSA compared with the median concentration in dogs with HSA at other sites, dogs with other neoplasms, and dogs with pericardial effusion not caused by HSA. Furthermore, dogs with cTnI concentrations higher than 0.25 ng/mL were found likely to have cardiac HSA, and a plasma cTnI higher than 2.45 ng/mL indicated that cardiac involvement is likely in dogs with HSA.⁸⁹

For dogs and cats with a cardiac mass and suspected neoplasia, every effort should be made to determine the extent of disease and the existence of primary or metastatic sites elsewhere in the patient. In addition to echocardiography and possibly other advanced imaging, a minimum database, including a CBC, serum biochemical profile, coagulation profile, thoracic radiographs, and abdominal ultrasound or radiographs, should be obtained. A pathologic diagnosis may be obtained by FNA cytology, endomyocardial biopsy, or open surgical or thoracoscopic biopsy, although many animals are treated based on anatomic location of the mass (e.g., right auricle HSA).

Therapy

Initially, treatment of patients with cardiac tumors consists of treating existing arrhythmias and clinical signs of heart failure, if present. Unfortunately, without effective antitumor treatment, the hemodynamic consequences of the mass often are refractory to medical management. Surgical resection may be indicated for some primary cardiac tumors, especially those of the right auricular appendage.^{10,19,26,90-94} However, surgical resection of right auricular masses in dogs with cardiac HSA must be considered a palliative procedure due to the high probability of metastatic disease, although a pericardiectomy may improve signs. Dogs with aortic body tumors generally benefit from pericardiectomy, independent of the presence or absence of pericardial effusion at the time of surgery.^{14,72} Thoracoscopy has been recommended as an alternative to open thoracotomy for biopsy and pericardiectomy because almost all aortic body tumors and many (≈50%) right auricular masses are unresectable. Thoracoscopy requires advanced training and special instrumentation if it is to attain the goals of tissue diagnosis, decreased operative time, and decreased morbidity.^{93,95-97} DOX-based chemotherapy protocols, including DOX alone, DOX and cyclophosphamide, and DOX-cyclophosphamide-vincristine have been used alone^{98,99} and in combination with surgery¹⁹ for the treatment of cardiac HSA.

Prognosis

The prognosis for primary cardiac tumors generally is poor. Most reported cases responded poorly to medical management. Mean survival of dogs with cardiac HSA treated with surgical resection alone is reported to be 46 days to 5 months.^{10,19,90} Survival time was significantly longer in dogs treated with tumor resection and adjuvant chemotherapy, with a reported mean of 164 days,¹⁹ comparable to dogs with splenic HSA treated with splenectomy and adjuvant chemotherapy.⁹⁹ Complete surgical resection of aortic body tumors usually is not possible; however, dogs that receive a pericardiectomy survive longer (median survival 730 days) than those that do not have a pericardiectomy (median survival 42 days).⁷² Other cardiac tumors found during exploratory thoracotomy commonly are judged to be unresectable; however, a few cases with longer disease-free intervals following resection of tumors other than HSA have been reported.^{26,28} In one study, dogs with HSA involving the pericardium survived a median of 16 days, whereas those with mesothelioma survived a median of 15.3 months following surgery.¹⁰⁰

Comparative Aspects

In humans, primary tumors of the heart and pericardium are rare. The vast majority of such tumors are metastatic.¹⁰¹ Primary cardiac tumors occur with a frequency of approximately 0.02% in pooled autopsy series.¹⁰² Primary tumors are usually cavitary, and 75% are benign.¹⁰³ Familial cardiac myxomas occur and appear to have an autosomal dominant transmission and are caused by mutations in the *PRKAR1alpha* gene that encodes a regulatory subunit of protein kinase A.¹⁰⁴ Myxomas constitute nearly 50% of all histologically benign tumors of the heart in humans. Seventy-five percent of myxomas occur in the left atrium. Systemic tumor embolization occurs with high frequency. Surgical resection of myxoma is the treatment of choice, with recurrence of sporadic atrial myxomas being rare following excision. Rhabdomyoma is the most common cardiac tumor of infants and children.¹⁰³ Other benign primary

cardiac tumors that have been reported in humans include fibroma, papillary fibroelastoma, lipoma, cystic tumors of the atrioventricular node, hemangioma, lymphangioma, and intrapericardial paraganglioma.^{102,103}

Almost all primary malignant cardiac tumors are sarcomas, most frequently angiosarcomas.^{103,105,106} As is the case with HSA in the dog, angiosarcoma of the heart in humans most commonly originates in the right atrium or pericardium.¹⁰³ Rhabdomyosarcoma and mesothelioma rank second and third, respectively, in frequency among primary malignant tumors of the heart and pericardium in humans. Palliative and local control of malignant primary tumors can be achieved with extensive resection. Adjuvant chemotherapy and RT have been used; however, their routine use for primary cardiac sarcomas has been questioned.¹⁰⁷ Cardiac transplantation has been utilized on occasion.

Metastatic tumors involving the heart and pericardium occur up to 100 times more frequently than primary tumors.¹⁰⁸ Incidence rates ranging from 2.3% and 18.3% are reported in autopsy studies of patients who died of cancer.¹⁰⁹ Malignant melanoma metastasizes most frequently to the myocardium, occurring in 46% of autopsies of cancer patients.¹⁰⁸ Cardiac metastasis also frequently occurs with bronchogenic carcinoma and carcinoma of the breast.¹⁰⁹

■ SECTION F Histiocytic Diseases

CRAIG A. CLIFFORD, KATHERINE A. SKORUPSKI,
AND PETER F. MOORE

Background

There are at least four well-defined histiocytic proliferative diseases that have been recognized in dogs. The challenge in some instances is to differentiate them from granulomatous, reactive inflammatory diseases or from lymphoma by examination of routine stains on paraffin sections alone. The clinical presentation and behavior and responsiveness to therapy vary tremendously between the syndromes observed.

• **FIGURE 33-14** Lineage of histiocytic cells and the corresponding histiocytic disease syndromes.

Histiocytic Differentiation and Canine Histiocytosis

The development of canine-specific markers for differentiation molecules of macrophages and dendritic cells (DCs) has enabled the identification of the cell lineages involved in canine histiocytic diseases.¹⁻¹¹ The majority of canine histiocytic diseases involve proliferations of cells of various DC lineages^{1,2} (Figure 33-14).

The term *histiocyte* has been used to generically describe cells of DC or macrophage lineage. Histiocytes differentiate from CD34⁺ stem cell precursors into macrophages and several DC lineages. Intraepithelial DCs are also known as *Langerhans cells* (LC). Interstitial DCs occur in perivascular locations in many organs except the brain, although they do occur in the meninges. Perhaps the most studied interstitial DCs are the dermal DCs. DCs that occur in T-cell domains in peripheral lymphoid organs (lymph node and spleen) are known as interdigitating DCs. Interdigitating DCs in lymph nodes are comprised of resident DCs and migratory DCs. The migratory DCs arrive in lymphatics from tissues and consist of LCs and interstitial DCs.⁶ Cytokines and growth factors that influence DC development include FLT3 ligand, granulocyte-macrophage colony-stimulating factor (GM-CSF), tumor necrosis factor- α (TNF- α), IL-4, and TGF- β .^{6,7} Macrophage development from CD34⁺ precursors is influenced by GM-CSF and M-CSF. Blood monocytes can differentiate either into macrophages under the influence of M-CSF or into DCs under influence of GM-CSF and IL-4.⁶⁻⁹

DCs are the most potent antigen-presenting cells (APCs) for induction of immune responses in naïve T cells. The development of canine-specific monoclonal antibodies (MAbs) for functionally important molecules of DCs and macrophages has enabled their identification in canine tissues, especially skin.^{1,10} DCs occur in two

major locations: within the epidermis (LC) and within the dermis, especially adjacent to postcapillary venules (dermal interstitial DCs).¹¹ Canine DCs abundantly express CD1a molecules, which together with MHC class I and MHC class II molecules, are responsible for presentation of peptides, lipids, and glycolipids to T-cells.^{1,3,12} Hence DCs are best defined by their abundant expression of molecules essential to their function as APCs. Of these, the family of CD1 proteins is largely restricted in expression to DCs in skin, whereas MHC class I and II are more broadly expressed.

The beta-2 integrins (CD11/CD18) are critically important adhesion molecules, which are differentially expressed by all leukocytes. CD11/CD18 expression is highly regulated in normal canine macrophages and DCs. CD11c is expressed by LCs and interstitial DCs, whereas macrophages predominately express CD11b (or CD11d in the splenic red pulp and bone marrow). A subset of dermal interstitial DCs also express CD11b.¹³⁻¹⁵ In diseased tissues, these beta-2 integrin expression patterns may be broadened. LCs and dermal interstitial DCs are also distinguishable by their differential expression of E-cadherin (LC+) and Thy-1 (CD90) (dermal interstitial DC+). LCs localize within epithelia via E-cadherin homotypic adhesion with E-cadherin expressed by epithelial cells.¹

Migration of DCs (as veiled cells) beyond the skin to the paracortex of lymph nodes, where they join forces with interdigitating DCs, occurs following contact with antigen. Successful interaction of DCs and T-cells in response to the antigenic challenge also involves the orderly appearance of co-stimulatory molecules (B7 family—CD80 and CD86) on DCs and their ligands (CD28 and CTLA-4) on T-cells.¹⁶⁻¹⁸ In situ DCs have low expression of MHC II and co-stimulatory molecules and are more receptive to antigen uptake. Migratory DCs upregulate MHC class II and B7 family members and become more adept at antigen presentation to T-cells.^{17,18}

• **TABLE 33-4** Cell Markers of Importance in the Diagnosis of Leukocytic Proliferative Diseases in Dogs

CD3ε	Signaling component of the T-cell antigen receptor. Expressed by αβ T-cells and γδ T-cells. Cytoplasmic expression by natural killer (NK) cells is possible, especially if activated.
CD79a	Signaling component of the B-cell antigen receptor. Expressed by all stages of B-cell differentiation. Expression is less in plasma cells.
CD20	Surface molecule expressed at all stages of B-cell differentiation except for plasma cells. CD20 plays a role in regulation of B-cell activation and proliferation. CD20 is not lineage specific and has been observed uncommonly in T-cell lymphomas. Caution is advised in interpretation of diffuse cytoplasmic expression, which can occur in several cell types.
Pax5	Transcription factor essential for maintenance of B-cell differentiation. Useful B-cell marker.
MUM1/IRF4	Transcription factor essential for plasma cell differentiation. Useful plasma cell marker.
CD11d	αD subunit of beta-2 integrin (CD18) family. Expressed by macrophages and T-cells in hemopoietic environments, especially splenic red pulp. Bone marrow and lymph node medullary sinus macrophages express CD11d. CD11d is consistently expressed in diseases emanating from splenic red pulp (large granulated lymphoma [LGL] form of chronic lymphocytic leukemia [CLL], hepatosplenic lymphoma, and hemophagocytic histiocytic sarcoma).
CD18	β-subunit of the beta-2 integrin family of leukocyte adhesion molecules. Expressed as a heterodimer of CD11a, CD11b, CD11c, or CD11d with CD18. Leukocytes express at least one form of the heterodimer. Hence CD18 is expressed on all leukocytes—the expression level on myeloid cells is especially high compared to normal lymphocytes. CD18 has been used as a marker of histiocytes, but this depends on exclusion of lymphocyte differentiation by the use of other markers (CD3 and CD79a).
CD30	CD30 is an integral membrane glycoprotein and a member of the tumor necrosis factor receptor (TNFR) superfamily. It is not expressed by resting lymphocytes but is expressed by mitogen-activated T- and B-cells.
CD45	Surface molecule expressed by all leukocytes, formerly known as <i>leukocyte common antigen</i> . Antibodies to CD45 bind to the extracellular domain outside of the 3 variably spliced exons (A, B, and C).
CD45RA	Splice variant of CD45 in which the A exon is present. Expressed by B-cells and naïve T-cells. Not typically expressed by histiocytes.
CD90 (Thy-1)	Cell surface molecule with broad cell and tissue distribution. CD90 is expressed by interstitial-type dendritic cells (DC) but not by Langerhans cells (LC).
c-Kit	Surface molecule and member of the receptor tyrosine kinase family (type III). Expressed by most hemopoietic progenitor cells and by mast cells. Expression level is high in high-grade mast cell tumors.
E-cadherin	Adhesion molecule expressed by epithelia and by some leukocytes, especially useful in cutaneous round cell tumors to identify LC indicative of cutaneous histiocytoma.
Granzyme B (GrB)	Serine protease located in the granules of cytotoxic T-cells (CD8 ⁺) and NK cells. GrB is expressed at high levels in activated cells and leads to rapid target cell death by apoptosis.
Myeloperoxidase (MPO)	MPO is a lysosomal protein stored in the azurophilic granules of neutrophils (and monocytes). MPO is an important marker of myeloid differentiation.
Ki67	Cell proliferation marker (nuclear) expressed in all phases of the cell cycle except G0 and early G1. Excellent marker for determining the growth fraction of a cell population.

Aspects of the developmental and migratory program of DCs are recapitulated in canine histiocytic diseases. Defective interaction of DCs and T-cells appears to contribute to the development of reactive histiocytoses (cutaneous and systemic histiocytosis), which are related interstitial DC disorders arising out of disordered immune regulation. The distant migratory potential of DCs is of immense clinical significance in the adverse prognosis of histiocytic sarcomas, which largely originate in interstitial DCs and rapidly disseminate via metastasis.

Immunophenotyping

To classify hematopoietic neoplasia according to the WHO system as applied to the canine, it is important to have access to markers

for IHC analysis.^{19,20} Table 33-4 lists the markers of value for determining cell lineages in leukocytic proliferations in dogs. These markers are suitable for use in formalin-fixed paraffin-embedded tissues with appropriate antigen retrieval protocols. Markers are available for the detection of B- and T-cells. However, markers for the unequivocal detection of NK cells are not available, so the existence of NK cell lymphomas in dogs is not easily assessable. Determination of T-cell receptor usage and major subsets of T-cells (CD4 or CD8), as well as dissecting the lineages of histiocytes (macrophages, interstitial type DCs, and LCs), is best done in unfixed cell smears or snap-frozen tissues or by flow cytometry. Important markers for the dissection of the histiocytic lineage that are only detectable in fresh smears or snap-frozen tissues include CD1a, CD11b, CD11c, MHC class II, CD80, and CD86. However,

it is still possible to presumptively identify histiocytes in formalin-fixed tissues by using combinations of lymphoid markers coupled with CD18 staining (as indicated in Table 33-4) in an appropriate morphologic context.

Once IHC stains are performed, it may also be necessary to run molecular clonality analyses to rule out lymphoma. This is particularly so with inflamed T-cell lymphomas, which are readily mistaken for reactive histiocytoses when they arise in skin.

Cutaneous Histiocytoma

Cutaneous histiocytoma (CH) is a benign tumor that often occurs as a single lesion in young dogs (<3 years of age), although histiocytomas do occur in dogs of all ages. In a retrospective review from the United Kingdom of histopathologic diagnoses of neoplasia in dogs less than 1 year, of 20,280 submissions, CH was the most common diagnosis, representing 89%.²¹ These tumors typically present as a solitary lesion often in the cranial portion of the body. The growth of the lesion can be quite rapid (1 to 4 weeks) and oftentimes will spontaneously regress within 1 to 2 months of presentation.²²⁻³¹ The regression is lymphocyte mediated.

Multiple tumors and metastatic histiocytomas have been reported, and the presence of multiple histiocytomas, especially in aged dogs, can present a diagnostic dilemma. Distinction from epitheliotropic and nonepitheliotropic cutaneous T-cell lymphoma may be challenging unless IHC stains for lymphoid and histiocytic markers are conducted. Definitive diagnosis of histiocytoma depends on IHC, which is best performed on frozen sections of tumor or cytologic preparations. Studies have demonstrated histiocytomas are of epidermal LC origin via expression of CD1a, CD11c, E-cadherin, and MHC class II molecules; inconsistent lysozyme immunoreactivity; and lack of expression of Thy-1 and CD4 (marker of activated DCs).^{1,2,4,23,24} Among skin leukocytes, E-cadherin expression is largely restricted to LCs. LCs utilize E-cadherin to localize in the epidermis via homotypic interaction, with E-cadherin expressed by keratinocytes. E-cadherin expression has only rarely been observed in histiocytic sarcoma (HS) in canine skin and subcutis, although a recent report challenges the specificity of E-cadherin for diagnosis of cutaneous round cell tumors.³² The expression of E-cadherin is unique to histiocytomas, and negative expression of Thy-1 and CD4 helps to differentiate histiocytoma (CH) from reactive histiocytoses—systemic histiocytosis (SH) and cutaneous histiocytosis (CHS).^{2,4} This differentiation can be made based on IHC or flow cytometry.³³ It is interesting to note that CH cells not only have the immunophenotypic characteristics of LCs but also the functional capability of being potent stimulators of the mixed leukocyte reaction.

The factors that determine the onset of regression in canine histiocytomas are unknown. Evidence of regression may be rapid (weeks), although regression can be delayed for many months. Regression is mediated by CD8⁺ $\alpha\beta$ T-cells; only scant numbers of CD4⁺ T-cells are observed in histiocytoma lesions. Migration of tumor histiocytes and/or tumor-infiltrating reactive interstitial DCs to draining lymph nodes likely activate CD4⁺ T-cells, which would assist in CD8⁺ cytotoxic T-cell recruitment. Because massive CD8⁺ T-cell infiltration is observed in all instances of histiocytoma regression, therapeutic intervention with the aim of immunosuppression should be avoided once a definitive diagnosis of histiocytoma has been reached to avoid interference with cytotoxic T-cell function. Recent evidence suggests E-cadherin staining correlates with the stage of regression. In more superficial regions of the tumor, membranous staining was noted versus deeper regions in

which staining was decreased to nonexistent. The decrease in E-cadherin expression is associated with lymphoid infiltration and is linked to its spontaneous regression.

Cutaneous Langerhans Cell Histiocytosis

The presence of multiple histiocytomas is uncommon. Lesions may be limited to skin or involve skin and draining lymph nodes. Rarely, internal organ involvement also occurs. This spectrum of disease best fits under the umbrella of cutaneous Langerhans cell histiocytosis (LCH) because skin is invariably involved.

Cutaneous LCH limited to skin appears to be more common in Shar-Pei dogs (35% of cases) but can occur in any breed. Delayed regression of cutaneous LCH can occur, and lesions can persist for up to 10 months before onset of regression. In about 50% of instances, dogs with cutaneous LCH are euthanized due to lack of regression of lesions and complications in management of the extensive ulcerated lesions that are often present.

Cutaneous LCH with lymph node metastasis has an even poorer prognosis because spontaneous regression has not been encountered, and all of the dogs with this lesion distribution and stage have been euthanized. Cutaneous LCH may spread beyond skin and draining lymph nodes to involve internal organs. This is a more serious and rapidly progressive disease. This spectrum of disease manifestation and diverse clinical behavior is most like LCH of humans.^{34,35} In veterinary medicine, anecdotal responses to this form have been noted with lomustine (CCNU) and the tyrosine kinase inhibitor masitinib (AB Science, Paris).

Reactive Histiocytosis

Reactive histiocytosis can be separated into CHS and SH. CHS represents a benign, diffuse aggregation of histiocytes that grows rapidly into infiltrating nodules, plaques, and crusts within the skin and subcutaneous tissue.^{4,31,36} This disease tends to occur in younger dogs; however, one study noted a range of 2 to 11 years. A breed predisposition has yet to be identified, although, in one study of 32 dogs, golden retrievers, Great Danes, and Bouvier des Flandres were more common.³⁷ A study of 18 dogs with CHS noted a male predilection; however, in a second larger study, no sex predilection was identified.^{4,37} Interestingly, a study of 32 dogs noted a previous history of dermatologic disease, with allergic dermatitis (n = 11) being most common. The duration from appearance of lesions to diagnosis via biopsy in one study was 1.75 months (range 0 to 30 months).³⁷

This disease is limited to the skin and subcutis but can be multifocal. The head, pinna, limb, and scrotum are commonly reported sites.^{4,31,36} Lesions may also be found on the nasal planum and within nasal mucosa, the gross appearance of which has been described as a “clown nose.”³⁸ In a recent study, 10 of 32 dogs had nasal planum/nares involvement, which presented as swelling, erythema, depigmentation, and stertorous respiration. However, extension into the nasal mucosa would classify this disease as SH. Histologically, lesions contain a pleocellular histiocytic infiltrate, often perivascular within the dermis and subcutaneous tissue. Lymphoid infiltrates (T-cell predominance) and some neutrophils are common. Vascular invasion may be present. These histiocytes express CD1a, CD11c, MHC class II molecules, Thy-1, and CD4 but are negative for E-cadherin. The expression of Thy-1 and CD4 aids in differentiation of this disease, which appears to be of

interstitial DC origin from CH, which is of epidermal LC origin.^{4,31,36} Definitive diagnosis of CHS is typically based on history, clinical signs, histopathologic features, and ruling out infectious causes. Immunohistochemistry on fresh, snap-frozen tissue is required to differentiate between macrophages and DCs and to identify dermal DC origin.

CHS follows a benign course and is often responsive to immunosuppressive therapy, although spontaneous regressions have been reported. Surgical excision may be successful in a minority of cases as lesions typically recur in other locations. Antibiotics are generally ineffective in treating CHS. Systemic steroids are a standard of care, and PRs are seen in the majority of dogs.^{4,36,38} However, recent findings and the author's impression are a 50% response rate with steroids. Many of these dogs require continuous therapy to prevent recurrence. A remission was reported in one dog receiving intralésional corticosteroids. Spontaneous regression occurred in 2 of 13 dogs and surgery was curative in another. In another study of 32 dogs, all had complete resolution of lesions within a median number of 45 days (range 10 to 162 days) from initial therapy.³⁷ Initial therapy included prednisone alone or in combination with antibiotics (n = 12), prednisone with tetracycline/doxycycline and niacinamide (n = 4), prednisone and azathioprine (n = 3), and tetracycline/niacinamide either alone or in combination with vitamin E and essential fatty acids (n = 6). Of the 19 dogs receiving prednisone, dosages ranged from 0.5 mg/kg to 2 mg/kg.³⁷

Long-term maintenance therapies may be warranted to prevent recurrence; however, affected dogs may have a prolonged survival. In 32 dogs obtaining complete resolution of lesions, 17 were maintained on a variety of medications, including 12 with tetracycline/niacinamide, either alone (n = 7) or in various combinations with safflower oil, essential fatty acids, or vitamin E.³⁷ Other maintenance therapies included cyclosporine/ketoconazole, azathioprine alone, prednisone and azathioprine, or prednisone alone. Immunosuppressive agents such as leflunomide and cyclosporine A/ketoconazole and azathioprine have demonstrated efficacy in steroid refractory cases.

In a recent study with a median follow-up time of 25 months (mean 32 months, range 6 to 108 months), 26 of 32 dogs were alive with no lesions. Interestingly, 10 dogs were on a maintenance protocol, the majority of which entailed tetracycline/niacinamide alone or in combination with essential fatty acids, azathioprine, or vitamin E.

Systemic Histiocytosis

SH is a nonneoplastic disease of proliferative lymphocytes occurring in Bernese mountain dogs, Rottweilers, golden retrievers, and Irish wolfhounds.^{4,31,38-42} In the Bernese mountain dog, this appears to be a familial disease, suggesting a genetic predisposition.^{4,31,38,40} Earlier work also noted a male predilection in the Bernese breed.^{3,38,40} The age of onset for SH is 3 to 9 years. Dermal lesions manifest in the skin with similar site predilection as CHS; however, other sites, including subcutaneous tissue, lymph node, bone marrow, spleen, liver, lung, and mucous membranes (nasal and ocular tissue), can be involved. Ocular involvement includes the conjunctiva, sclera, ciliary body, extraocular muscles, and retrobulbar tissue.⁴² One distinguishing feature from CH is the presence of palpably enlarged peripheral lymph nodes and the presence of organ involvement.^{4,31} Clinical signs vary, depending on the affected tissue and severity of disease; however, depression, anorexia, weight loss, conjunctivitis, and harsh respiration are common. In one study, 2 of 26 dogs were hypercalcemic at presentation.⁴ This disease appears similar to

some forms of the LC histiocytosis in humans, which are reactive disorders likely secondary to immune system dysregulation. Clinicopathologic features of SH are varied; however, anemia, monocytosis, and lymphopenia are consistently reported.^{31,43}

Cytologically, SH lesions are similar to granulomatous inflammation or CHS, characterized by a predominance of benign histiocytes with occasional multinucleated giant cells.⁴³ Other inflammatory cells including lymphocytes, eosinophils, and neutrophils can be interspersed. Erythrophagia is reported but rare. Histiocytic cells are large, contain voluminous cytoplasm, and have indented nuclei with variable nucleoli.⁴³ Histologically, these lesions are characterized by multicentric, nodular, angiocentric histiocytic infiltrates within the deep dermis and panniculus. To a lesser degree, infiltration of lymphocytes, plasma cells, eosinophils, and neutrophils is present, with small lymphocytes making up the greatest proportion of nonhistiocytic cells.^{1,4,31,38} Blood and lymphatic vessel invasion may also be noted. In some cases, vascular wall degeneration, thrombosis, and ischemic necrosis may be present.^{4,31,38,40} The histologic appearance of lesions within other organs consists of nodular, perivascular accumulation of histiocytes, lymphocytes, and neutrophils.^{4,31,38} With IHC, SH lesions express CD1a, CD11c, MHC class II, Thy-1, and CD4, similar to that of CHS.^{3,4} This expression pattern suggests these cells are of activated interstitial DCs and not epidermal LCs (histiocytoma).^{1,44} The majority of the small lymphocytes present within the lesions have been demonstrated to be of T-cell origin (CD3 and TCR $\alpha\beta$ positive) and 50% were CD8 positive.^{3,4} Unlike cutaneous histiocytomas, the presence of T-cells is not associated with regression but likely secondary to cytokine-induced migration. Interestingly, ocular involvement appears similar to lesions described with fibrous histiocytoma.^{42,43}

Lesions may have a waxing and waning presentation but generally do not spontaneously resolve and thus require long-term therapy. Corticosteroids alone appear ineffective in controlling this disease long term.^{4,31,38,42} Experimentally, bovine thymosin fraction-5 demonstrated some efficacy in two dogs.^{4,40} The use of azathioprine, cyclosporine A, or leflunomide (Hoechst Marion Roussel, Wiesbaden, Germany) has yielded long-term control in some cases.⁴ Cyclosporine and leflunomide both have the ability to inhibit T-cells. The successful treatment with either agent suggests a significant role of T-cell lymphocytes in this disease. Two proposed mechanisms for immune dysregulation include an increase in proinflammatory cytokine (TNF- α , IL-6, IL-12, IFN- γ) production by T-cells due to persistent DC accumulation and inappropriate dendritic and T-cell interaction due to abnormal regulation of accessory ligands on both cell types.^{4,11} These molecules are needed for induction of the immune response and the subsequent down-regulation of the response. Without a proper interaction, the cells may remain within the area.¹¹ Although no infectious cause has been identified, it is important to rule out such etiologies with either a culture or immunohistochemistry of histopathology samples.^{4,11} The clinical course of this disease is often prolonged but rarely results in death. Generally, there are episodic periods of response followed by recrudescence, with most dogs euthanized due to repeated relapses of the clinical condition or failure to respond to therapeutics.^{4,31,40}

Histiocytic Sarcoma

Pathology and Natural Behavior

Malignant proliferations of histiocytic cells were first reported in the dog in the late 1970s. A predisposition in Bernese mountain

dogs was reported in 1986 in a group of 11 dogs affected with the disease, 9 of which were related.⁴⁵ In that study group, a male predisposition was present (10 of 11 dogs) and the majority had pulmonary involvement. Histiocytic sarcoma (HS) has since been identified in a variety of breeds; however, flat-coated retrievers and Rottweilers also appear to be overrepresented.^{46,47} Dogs are commonly middle aged or older, but HS has been reported in dogs as young as 3 years of age. HS may present with either localized organ involvement or disseminated, multiorgan involvement.

HS is the preferred term identifying malignant tumors of histiocytic origin and the older term *malignant histiocytosis* refers to the disseminated form of the disease. Reported anatomic sites include the lungs, lymph nodes, liver, spleen, stomach, pancreas, mediastinum, skin, skeletal muscle, central nervous system (CNS), bone, bone marrow, nasal cavity, and eyes.⁴⁶⁻⁵³ In a clinical population, 5% of primary brain tumors were HS, as were 4.5% of secondary brain tumors in a necropsy population.^{53,54} In a series of 26 dogs with ocular HS, ocular involvement was usually found in association with multisystem disease.⁸ HS also appears to be the most common synovial tumor in dogs, with 18 of 35 tumors previously diagnosed as synovial cell sarcomas reclassified as HS based on IHC staining patterns.⁴⁷ Eleven of these 18 dogs with synovial HS were Rottweilers.

Hemophagocytic HS is a subtype of HS that arises from macrophages rather than DCs. The hemophagocytic HS variant can be definitively differentiated through confirmation of an IHC staining pattern consistent with macrophages.⁵ Clinically, these tumors appear to behave more aggressively due to their cellular ability to phagocytose material, including host red blood cells.

History and Clinical Signs

Presenting complaints and clinical signs vary, depending on site(s) of tumor involvement, but nonspecific symptoms such as lethargy, inappetence, and weight loss are common. Other common signs include a visible mass, lameness, cough, vomiting, and lymphadenopathy.⁵¹ Lymphadenopathy is sometimes the only clinical sign and can appear at a site distant to other tumor lesions. Patients may also present with clinical signs related to severe anemia or thrombocytopenia, especially in dogs with the hemophagocytic variant.^{5,51}

Diagnosis and Staging

A diagnosis of HS can be obtained via cytologic or histologic examination of tumor tissue; however, definitive diagnosis can be challenging in pleomorphic tumors that have morphologic characteristics similar to carcinomas or round cell tumors. HS cells are large, discrete, mononuclear cells that often display marked anisocytosis and anisokaryosis. Nuclei are round, oval, or reniform with prominent nucleoli, and cytoplasm is moderate to abundant, lightly basophilic, and vacuolated. Mitotic figures are common, and some tumor cells may display erythrophagocytosis and/or multinucleated giant cells (Figure 33-15).⁵⁵ Evidence to support a diagnosis of HS may be acquired through immunocytochemistry or immunohistochemistry on formalin-fixed tissues using antibodies to CD18, CD3, and CD79a.² Macrophages and granulocytes express tenfold more CD18 than lymphocytes; thus for differentiation purposes, lymphomas express low or undetectable levels and usually express either CD3 or CD79a.¹ If fresh or frozen tissue is available, further confirmation and subclassification of the cell of origin can be performed using antibody staining for CD1 or the CD11 α subunits.²

Because the disease is multifocal or disseminated in most dogs, complete staging is recommended. CBC and biochemical screens are often abnormal. Anemia is common and usually

FIGURE 33-15 Cytology of histiocytic sarcoma in the liver of a dog. Note individualized and loosely cohesive moderately pleomorphic spindle cells with prominent nucleoli (arrowheads). Some demonstrate phagocytic activity (arrow). (Wright-Giemsa, 100 \times objective.) (Courtesy Elizabeth Little, VMD, DACVP, IDEXX Laboratories, Langhorne, PA.)

regenerative when caused by erythrophagocytosis by neoplastic cells. Leukocytosis, thrombocytopenia, increased liver enzymes, hypoalbuminemia, and hypocholesterolemia are frequent findings, and hypercalcemia occurs occasionally.^{5,51} HS was the second most common cause of pancytopenia in dogs in a retrospective study of 51 dogs at a veterinary teaching hospital.⁵⁶ Hyperferritinemia has also been documented in dogs with HS and is theorized to be the result of ferritin production by tumor cells.^{57,58} Thoracic radiography and abdominal ultrasonography commonly reveal abnormalities. Pulmonary involvement may appear as a diffuse interstitial infiltrate, patchy consolidated areas, or focal or multifocal mass lesions (Figure 33-16). Radiographic evidence of sternal, cranial mediastinal, or tracheobronchial lymphadenopathy may also be noted. Hepatosplenomegaly, splenic or hepatic mottling, or discrete nodules or masses in these organs are the most common abdominal ultrasonographic abnormalities.⁵⁹

Bone marrow aspiration cytology may reveal tumor infiltrate, especially in patients with cytopenias. In addition, flow cytometry has been used to differentiate etiology of hemophagocytosis in bone marrow samples containing over 5% macrophages and cytologic evidence of hemophagocytosis (Figure 33-17).⁶⁰ Results suggested that cellular distribution in scatter plots and the number of histiocytes may help differentiate neoplastic from nonneoplastic causes of hemophagocytosis.

Treatment and Prognosis

The clinical course of disseminated HS, left untreated, is rapid and fatal, whereas the localized form may be more slowly progressive. Few reports documenting survival duration after surgical excision of localized HS exist. However, in a series of 18 synovial or periarticular HSs confirmed with CD18 staining, the MST for dogs undergoing amputation was 6 months and the metastatic rate was 91%.⁴⁷ The periarticular form of HS may be associated with a better prognosis than other locations. In one study, dogs with periarticular HS treated in a variety of ways had a MST of 391 days compared to 128 days in dogs with the nonperiarticular form.⁶¹ Fewer dogs with periarticular HS had distant metastasis; however, it is not clear

• **FIGURE 33-16** **A**, Right lateral radiograph of a 6-year-old female spayed German shepherd dog demonstrating a large, multilobular soft tissue mass and an adjacent yet separate smaller mass in the left caudal thorax. The mass displaces the caudal portion of the left lung bronchus and completely obscures the caudal bronchus. **B**, Ventrodorsal radiograph of the same patient demonstrating a soft tissue density in the left caudal thorax. Histopathology confirmed histiocytic sarcoma. Note phagocytic activity of neoplastic cells. (Wright-Giemsa, 100× objective.) (Courtesy Elizabeth Little, VMD, DACVP, IDEXX Laboratories, Langhorne, PA.)

whether the improved survival may be due to primary tumor location or due to earlier stage of disease at diagnosis.⁶¹

CCNU appears to be the most effective chemotherapy agent against HS in dogs. One study reported a 46% response rate to CCNU in 56 dogs with gross measurable disease.⁵¹ Median remission duration in dogs achieving CR or PR was 85 days, and the MST of responders was 172 days. In this study, anemia, thrombocytopenia, hypoalbuminemia, and splenic involvement, all factors associated with the hemophagocytic subtype of HS, were associated with a grave prognosis. Corticosteroids did not improve response to therapy in this study. In a prospective study of 21 dogs with HS treated with 90 mg/m² of CCNU, the response rate was lower at 29%, although 67% of dogs received only one dose of CCNU.⁶² The median response duration was 96 days. CCNU therapy used as an adjuvant to surgery and/or RT may result in lengthy survival times in dogs with localized HS. One study documented a MST of 19 months in 16 dogs with localized HS treated with aggressive combination therapy.⁶³

There is limited information in the literature regarding alternative chemotherapeutic options to treat HS, but reports of responses to liposomal DOX and paclitaxel chemotherapy exist.^{64,65} In addition, a case report of a dog with cutaneous disseminated HS documented temporary remissions resulting from multiple protocols, including cyclophosphamide, vincristine, prednisone, mitoxantrone, dacarbazine, and etoposide.⁶⁶ The efficacy of the

bisphosphonate, clodronate, has been recently studied in histiocytic cell lines and in five dogs with HS.⁶⁷ Two of the five dogs experienced tumor regression with this therapy, and further study is warranted. The efficacy of DOX against HS has not been published, but preliminary reports suggest that tumor responses can occur.⁶⁸ Additionally, the authors have observed responses to a nanoparticle formulation of paclitaxel in dogs with HS.

The efficacy of RT against HS has not been fully studied; however, preliminary evidence suggests that HS is radiosensitive. In a report of 37 flat-coated retrievers with mostly joint origin HS, dogs undergoing RT lived longer than those not having RT, with a MST of 182 days.⁶⁹ Dogs treated with a set combined protocol of a palliative radiation and CCNU had a MST of 208 days. Further study into the optimal radiation protocol for HS is necessary.

Hemophagocytic Histiocytic Sarcoma

Hemophagocytic HS is a variant of HS that originates from the tissue macrophage, not the DC.⁵ This more aggressive form of HS invariably involves the spleen, but dogs may also have liver, bone marrow, lymph node, and/or lung involvement. Splenic involvement is usually diffuse, resulting in gross enlargement with diffuse infiltrates. In one study, common hematologic findings in dogs with the hemophagocytic variant of HS included a regenerative anemia (94%), thrombocytopenia (88%), hypoalbuminemia (94%), and hypocholesterolemia (69%).⁵ A presumptive diagnosis of hemophagocytic HS may be obtained through splenic cytology, which shows infiltration with atypical to highly pleomorphic macrophages displaying phagocytosis of red blood cells, splenic origin red cell precursors, and white blood cells. However, definitive diagnosis and differentiation from nonhemophagocytic HS requires immunophenotyping. To date, effective treatment of hemophagocytic HS has not been described. Reported survival times are extremely short, ranging from days to 1 to 2 months.^{5,51}

Feline Histiocytic Diseases

Histiocytic neoplasms are much rarer in cats than dogs, but three distinct forms have been documented in the species to date. These include HS, with features similar to the canine disease; feline progressive histiocytosis, a cutaneous form of histiocytic neoplasia with indolent but progressive behavior; and LC histiocytosis, with disease localized primarily to the lungs.

Feline Histiocytic Sarcoma

HS of DC origin and hemophagocytic HS of macrophage origin have both been documented in cats.⁷⁰⁻⁷² With both variants, cats usually present with multifocal or disseminated disease. Spleen, liver, and bone marrow involvement are most common, but lymph node, lung, trachea, mediastinum, kidney, bladder, and CNS involvement are also reported.⁷⁰⁻⁷⁷ Bone marrow involvement appears commonly in cats, and all three cats in a case series were found to have positive bone marrow on postmortem evaluation.⁷¹ Severe anemia and thrombocytopenia are also common findings and may indicate bone marrow involvement and/or hemophagocytic HS, which can be confirmed through immunophenotyping of tumor tissue samples.⁷⁰⁻⁷² The localized form of HS is extremely rare in cats but has been reported in the tarsus of a cat with local lymph node metastasis present at diagnosis.⁷⁸ An aggressive clinical course is typical of HS in cats, particularly in those with anemia and

• **FIGURE 33-18** A cat with advanced feline progressive histiocytosis. The lesions consist of multiple coalescing hairless dermal nodules on the head, some of which have become ulcerated. (Courtesy Emily Rothstein, DVM, DACVD, Animal Allergy and Dermatology Service of Connecticut, Plantsville, CT.)

suspected hemophagocytic HS. Effective treatment options for feline HS have not been studied, although treatment with CCNU chemotherapy has been reported anecdotally.⁷²

Feline Progressive Histiocytosis

Feline progressive histiocytosis is a recently described neoplasm of DCs that occurs initially on the skin and progresses over time to involve multiple organs. Lesions appear on the skin as multiple firm, haired or hairless, dermal papules or nodules with a predilection for the head, feet, and legs. The lesions may enlarge gradually and coalesce into plaques and can become ulcerated and painful over time. An example of a cat with advanced lesions is shown in Figure 33-18. The disease is usually progressive over months or years (median 13.4 months) with involvement of lymph nodes, lungs, and abdominal visceral organs. Females appear to be overrepresented.⁷⁹

A diagnosis of feline progressive histiocytosis is made through biopsy and histopathologic evaluation of skin lesions. Lesions appear histologically as poorly circumscribed multinodular aggregates or masses of round cells with or without epitheliotropism in the dermis and, occasionally, invading subcutis. Cells have mild-to-moderate anisocytosis and anisokaryosis, and mitotic figures are rare. Immunohistochemistry may be necessary to confirm the diagnosis and rule out other round cell tumors.⁷⁹ Staging test results are usually negative for internal organ involvement early in the course of disease, but tumors may be found in lymph nodes, lung, and/or abdominal viscera as the disease progresses. Surgical excision may control solitary, superficial skin lesions early in the course of disease, but development of additional skin lesions is expected. Skin lesions do not appear to respond to corticosteroid therapy, and effective medical treatment of diffuse skin or visceral lesions has not yet been described.⁷⁹

Langerhans Cell Histiocytosis

A single case series exists describing an aggressive neoplasm arising from LCs in three cats.⁸⁰ All three cats presented for respiratory

compromise or distress, with symptom duration ranging from 5 days to 7 months. Thoracic radiographs showed a diffuse, severe bronchointerstitial lung pattern with diffuse miliary to nodular opacities in all lung fields. Symptomatic therapy was unsuccessful in all three cases and the diagnosis of LCH was made on necropsy through the use of extensive immunostaining and electron microscopy confirming the presence of Birbeck's granules. At necropsy, metastasis to pancreas, kidneys, liver, and/or visceral lymph nodes was noted in all three cats.

Malignant Fibrous Histiocytoma

The term *malignant fibrous histiocytoma* (MFH) refers to a group of tumors with histologic characteristics resembling both histiocytes and fibroblasts often displaying a storiform pattern with foam cells and multinucleated tumor giant cells.⁸¹ In some cases, the term may be designated to poorly differentiated or pleomorphic forms of other soft tissue sarcomas.⁸² With the widespread use of IHC techniques to delineate tumor cell lineage, the malignant fibrous histiocytomas have become separated from tumors of true histiocytic origin based on positive vimentin, desmin, and S100 staining but lack of CD18 and CD11 subunit staining.^{82,83} Further discussion on the clinical behavior of soft tissue sarcomas such as MFH are located elsewhere in this text (see Chapter 21).

Preface

The fifth edition of *Small Animal Clinical Oncology* continues to chronicle significant advancement in the field of comparative clinical oncology. Since the first edition in 1989 this text has expanded all segments of the book to keep current with the profound changes in cancer biology and technology; in fact, each edition could be considered a milestone in the development of this specialty. The intent of this text continues to be production of a relevant summary of the field of comparative cancer biology and management for those engaged in all aspects of the veterinary profession. Approximately 20% of this edition has been substantially changed with new authors and both new additions and deletions of entire chapters to reflect an appropriate emphasis on the current state of the profession.

This text, in all its editions, parallels the expansion and maturity of comparative oncology during the last 25 years. The Specialty of Oncology was formalized under the American College of Veterinary Internal Medicine (ACVIM) in 1989 and has grown steadily, particularly in the last 10 to 15 years. Likewise, the European College of Veterinary Internal Medicine (ECVIM)–Oncology Specialty is now a robust and dynamic organization providing important resources to students and practitioners in Europe. The American College of Veterinary Surgeons (ACVS) has formally authorized the Fellowship Training Programs in Veterinary Surgical Oncology, which will promote the expansion of new centers of surgical excellence in this field. Equally important has been the growth of the Veterinary Cancer Society (VCS) and the European Society of Veterinary Oncology (ESVONC), as well as other like-minded associations in Japan (JVCS), Brazil (ABROVET) and others to develop soon. The globalization of the interest and desire for high-quality cancer care for pets is a remarkable and welcome occurrence.

During the last decade and particularly over the last 5 to 7 years, the formalization of clinical trials in companion animals for investigation of animal and human health has matured significantly. The Comparative Oncology Program at the National Cancer Institute (NCI) continues to lead the effort to promote the benefits of companion animals in human cancer control and has currently completed or initiated 18 multicenter trials through the Comparative Oncology Trials Consortium. Other clinical trial organizations and centers, within both the public and private sector, have emerged that have established a more formal infrastructure for cooperative clinical research. No better evidence of this exists than the recent Food and Drug Administration (FDA) and U.S. Department of Agriculture (USDA) approvals for products licensed for use specifically in canine cancer that occurred due to a clinician-animal health industry partnership.

Examples of marked advances in the field of cancer biology, etiology, and staging reflected in this text include a complete rewrite of the role of genetics in cancer development (Chapter 1, Section A), cancer epidemiology (Chapter 4), tumor imaging technology (Chapter 6), and the reliance on more sophisticated molecular

diagnostics (Chapter 8). The rapid change in therapeutic areas include the developing indications for stereotactic radiotherapy in Chapter 12 and the increasing understanding of metronomic and antiangiogenic therapy in Chapter 14, Section C. An entire chapter has been added on clinical trials (Chapter 17) for the interested clinician scientist. All chapters devoted to specific cancer types have been updated; however, due to remarkable changes in the clinical management of certain cancers there has been a large expansion or a complete rewrite of chapters for melanoma, mast cell tumors, tumors of the skeletal system, tumors of the endocrine system, tumors of the mammary gland, urinary cancers, nervous system cancers, lymphoma, and histiocytic diseases.

There is still much to be done and future advances should continue to be a focus for expansion in subsequent editions of this text. Advancing the use and application of evidence-based medicine still remains a challenge in veterinary oncology. The desire to increase evidence-based decision making in clinical practice is being considered throughout the veterinary profession as a whole, and appropriate reporting guidelines for manuscript submission will soon be implemented in the leading veterinary journals. Such guidelines will permit sorting of high or low levels of evidence and an opportunity to engage in formal postpublication data analysis for systematic reviews. We look forward to the next edition of the text that includes therapeutic recommendations based on strong evidence. We also continue to hope that the next edition will see a quantum leap in satisfying several critical needs in the field. We urgently need improved control outcomes for canine lymphoma, hemangiosarcoma, and osteosarcoma and validated biomarkers to assist with prognostic and predictive estimates for all cancers—but in particular, those highly lethal disease processes mentioned above that have frustrated all of us for decades.

It is also important to consider potential operational impacts and solutions to the continued development of comparative oncology. The inconsistent availability of chemotherapy often now rises to levels of serious concern for continuity of care and will require innovative business solutions to ensure robust coverage of the expanding market need. It is obvious that the cost of care for companion animals will continue to rise, and the role that companion animal healthcare insurance will play in this dynamic could have far-reaching effects on the profession in the next decade. Likewise, the potential changes in the profession from increasing liability issues related to emotional pain and suffering litigation could create new operating paradigms.

The authors and editors have created the following text, which both describes the phenomenal strides made during the last 5 to 6 years and sets the standard to measure future growth and understanding of comparative oncology. We hope that it will be a useful resource for those engaged in animal and human oncology and for the ultimate improvement of the quality and length of life for our patients.

*We dedicate this edition to these fine men,
each of whom pioneered his particular branch of
veterinary oncology:*

Dr. E. Gregory MacEwen

1943-2001

The father of veterinary medical oncology,

*Greg was personally responsible for educating and inspiring the current
generation of medical oncologists, both as clinicians and clinician scientists.*

Dr. Robert S. Brodey

1927-1979

The father of veterinary surgical oncology,

*Bob will be remembered for his tireless effort to advance the field of oncology,
to teach principles of surgery, and, most importantly, to preserve nature.*

Dr. Edward L. Gillette

1932-2006

The father of veterinary radiation oncology,

*Ed was a leader in comparative oncology. His vision and leadership
have created a new and contemporary breed of oncologists in all disciplines.*

Why Worry About Cancer in Companion Animals?

Introduction

STEPHEN J. WITHROW, DAVID M. VAIL, AND RODNEY L. PAGE

Why should veterinarians be concerned about cancer in companion animals? Several compelling motivations and opportunities exist for the profession as a whole to continue, and indeed expand on, the significant role we play in the understanding, prevention, and elimination or control of this devastating constellation of disease processes. Although our prime directive is to ensure the health and quality of life of the companions under our care, the needs of our client caregivers during the difficult times of cancer diagnosis, treatment, and outcome (whether optimistic or pessimistic) should be of nearly equal importance. Because cancer is a disease that knows no species boundaries, our profession has considerable opportunity to play a key role in comparative oncologic investigations, with the ultimate goal of effecting cure or, in the absence of cure, transforming cancer from an acute life-threatening disorder into a manageable chronic condition (much like diabetes).

The sheer numbers involved highlight the magnitude of the problem of cancer in companion species. The prevalence of cancer in companion animals continues to rise and is increasing for a variety of reasons, not the least of which is related to animals living longer thanks to the increasing care offered by caregivers and the advanced veterinary care they seek. There are approximately 165 million dogs and cats at risk in the United States,¹ and cancer remains a major cause of companion animal morbidity and mortality (see Chapter 4), with at least 4 million dogs and 4 million cats developing cancer each year.²⁻⁶ Although the true incidence or prevalence of companion animal cancer is currently not known, based on necropsy surveys describing proportional mortality, 45% of dogs that live to 10 years or older die of cancer.⁴ With no age adjustment, 23% of patients presenting for necropsy died of cancer. In a 1998 Morris Animal Foundation Animal Health Survey, more than 2000 respondents stated that cancer was the leading cause of disease-related death in both dogs (47%) and cats (32%).³ Another Morris survey performed in 2005 revealed that cancer was by far the largest health concern among dog owners (41%), with heart disease the number two concern at 7%. Regardless of the exact numbers, both the reality and the perception support the clients' point of view that cancer remains the number one concern in their minds with respect to the health and quality of life of their companions—the so called “Emperor of all maladies.”⁷ Furthermore, breakthroughs in the management of human cancers have received a great deal of exposure through the Internet, news media, and popular press, which further serves to educate companion caregivers and raise the level of expectations as to therapeutic possibilities and promotes an atmosphere of optimism and a demand for similar care for their animals. Increased longevity of companion animals, the increasing prevalence, and enhanced caregiver expectations

require that the veterinary profession be prepared to meet these challenges and opportunities.

Because cancer is a common and serious disease for human beings, many owners have had or will have a personal experience with cancer in themselves, a family member, or a close friend. Realizing the importance of companion animals to our clients, it must be appreciated that they value the veterinarian's ability to care as much as his or her ability to cure. Keeping this in mind, the veterinarian should approach the patient with cancer in a positive, compassionate, and knowledgeable manner. Frequently the veterinary profession has taken a pessimistic approach to cancer. This attitude is not only a detriment to the companion but may also negatively reinforce unfounded fears in the client about the disease in humans. We owe it to our companion animal patients and their caregivers to be well informed and up-to-date on current treatment methods to prevent imparting unnecessary feelings of hopelessness.

Perhaps the greatest opportunity presented to our profession, beyond the immediate care of our patients' and clients' needs, is the more global role (and responsibility) we play in advancing the understanding of cancer biology, prevention, and treatment from a comparative oncology standpoint. Companion animals with spontaneously developing cancer provide an excellent opportunity to investigate many aspects of cancer from etiology to treatment. One of the most exciting achievements in veterinary oncology over the last decade has been the development of successful and collaborative consortia groups that are purposed to perform multicenter clinical trials and prospective tumor biospecimen repository collections. These include the Comparative Oncology Trials Consortium (COTC; <https://ccrod.cancer.gov/confluence/display/CCRCOPWeb/Comparative+Oncology+Trials+Consortium>) and the Canine Comparative Oncology and Genomics Consortium (CCOGC, www.ccohc.net) centrally managed by the National Institutes of Health (NIH)-National Cancer Institute's Comparative Oncology Program (NCI-COP) and discussed in Chapter 17. Their infrastructure allows larger scale clinical trials and provides the voice for collective advocacy in veterinary and comparative oncology. Their success is an example of the growing importance of the study of comparative tumor biology and clinical investigations. Access to novel drugs and biologics will speed clinical applications for both veterinary species and humans. Ultimately, including companion animal populations in clinical trials assessing novel drugs and biologics of interest to the National Cancer Institute, the Food and Drug Administration, and the pharmaceutical industry will both advance veterinary-based practice and inform future human clinical trials that may follow. Some of the aspects of companion animal cancer that enable attractive comparative models include the following:

1. Companion dogs and cats are genetically outbred and immunologically intact animals (like humans) as opposed to many experimental models of rodents and other animals.
2. The cancers seen in practice are spontaneously developing as opposed to experimentally induced and better recapitulate the natural human and veterinary condition.
3. Companion species share the same environment as their caregivers and may serve as epidemiologic or etiologic sentinels for the changing patterns of cancer development seen in humans.
4. Companion species have a higher incidence of some cancers (e.g., osteosarcoma, non-Hodgkin's lymphoma) than humans.
5. Most animal cancers will progress at a more rapid rate than will the human counterpart. This permits more rapid and less costly outcome determinations such as time to metastasis, local recurrence, and survival.
6. Because fewer established "gold standard" treatments exist in veterinary medicine compared to human medicine, it is ethically acceptable to attempt new forms of therapy (especially single-agent trials) on an untreated cancer rather than wait to initiate new treatments until all "known" treatments have failed, as is common in the human condition. It is important to recognize that this latitude in clinical trials can be misused to permit diverse and poorly characterized or even unethical treatments to be attempted as well. We have an obligation to ensure that our patients are not denied known effective treatment while at the same time planning well-designed prospective clinical trials of newer, scientifically sound treatment methods.
7. Companion species' cancers are more akin to human cancers than are rodent tumors in terms of patient size and cell kinetics. Dogs and cats also share similar characteristics of physiology and metabolism for most organ systems and drugs. Such correspondence allows better and safer comparison of treatment modalities such as surgery, radiation, and chemotherapy between animals and humans to be made.
8. Dogs and cats have intact immune systems as opposed to many rodent model systems, which allows immunologic assays and treatment approaches to be explored.
9. Companion animal trials are generally more economical to perform than human trials.
10. Companion animals live long enough to determine the potential late effects of treatment.
11. Regional referral centers exist to concentrate case accrual and facilitate clinical trials.
12. Clients are often willing to allow a necropsy, which is a crucial end point for not only tumor control but also treatment-related toxicity.
13. Dogs and cats are large enough for high-resolution imaging studies and multiple sampling opportunities, as well as for surgical intervention.

14. The recent elucidation of the canine genome and its resemblance and relevance to the human genome open unique and unparalleled opportunities to study comparative oncology from a genetic perspective.⁸

Clients who seek treatment for their companion animals with cancer are a devoted and compassionate subset of the population. Working with these caregivers can be a very satisfying aspect of a frequently frustrating specialty. Clients are almost always satisfied with an honest and aggressive attempt to cure, control, or palliate the disease of their companion, making the experience satisfying for the veterinarian, for the client, and, most important, for the companion.

Oncology also offers the inquisitive veterinarian a complex and challenging area for both clinical and basic research. The challenges and accomplishments in oncology have been and continue to be very impressive. Oncology offers unlimited opportunity for the pursuit of knowledge for the benefit of animals and humankind. "Cancer, unlike politics and religion, is not a topic of controversy. No one is for it. Cancer is not another word for death. Neither is it a single disease for which there is one cure. Instead, it takes many forms, and each form responds differently to treatment."⁹

Clinical and comparative oncology continues to be a rapidly advancing field of study. More training programs are developed each year that allow a wider distribution of experienced veterinarians into practice, research, industry, government, and the academic setting. Through the continued investigation of tumor biology and treatment and the inclusion of veterinary species in well-designed, rigorous, and humane clinical trials, the veterinary profession will play a key role in advancing the diagnosis, treatment, and prevention of cancer for all species.

A

17-AAG, 239-240
 ABC transporter family, 160
 Abdomen, laparoscopic and thoracoscopic
 biopsy of, 145-146
 Abdominal carcinomatosis, 415
 Abl gene, 3
 translocation to bcr gene, 135f
 Ablative technique
 indications/limitations of, 152
 types of
 cryoablation, 153
 radiofrequency, 152-153
 Absorbed dose, 180
 ABT-510, 230
 ABT-526, 230
 Acanthomatous ameloblastoma
 overview of, 384
 prognosis for, 391
 radiation therapy for, 186
 radiography of, 384f, 393f
 rim resection of, 387f
 survival rate of
 after mandibulectomy, 388t
 after maxillectomy, 388t
 Acanthomatous epulis
 diagnosis of, 63-64
 radiation therapy and, 186
 Accelerated fractionation, 181
 Accelerated repopulation, of tumor cells, 181
 Acetaminophen
 dose and effects of
 for cats, 252t-253t
 for dogs, 251t
 for pain management, 249-250
 Acetylcholinesterase, 659
 Acid-base balance, carbonic anhydrase and, 240
 Acidosis, 85
 Aconite, 281-282
 Acrolein, 16
 Acrylic face mask, 184-186, 185f
 ACTH stimulation test, 506
 Actin cytoskeleton, 42
 Actinic keratosis, 310
 Actinomycin D (dactinomycin), 168
 Activating gene, prodrug cancer gene therapy
 and, 218f
 Active immune suppression, 199
 Active vitamin D, 268
 Acupuncture
 benefits of, 281
 description of, 280
 mechanisms of action for, 280-281
 myths about, 281
 for pain management, 256
 scientific approach to, 281

Acute leukemia, 657t
 Acute lymphocytic leukemia (ALL)
 diagnosis of, 630
 immunophenotype of, 629-630
 peripheral blood sample from dog with,
 629f
 prognosis for, 631
 signs of, 630
 treatment of, 631
 Acute lymphoid leukemia, 660
 Acute monocytic leukemia (M5a), 656f
 Acute myeloblastic leukemia (M1), 656f
 Acute myelogenous leukemia (AML)
 cell immunotyping for, 660
 characteristics of, 655
 cytogenetic lesions and, 655
 diagnosis of, 659
 forms of, 655-657
 nucleophosmin gene mutations in, 131
 pathology and behavior of, 655
 PML-RAR fusion transcripts in, 137
 prognosis for, 662
 signs and history of, 659
 tumor-initiating cell hypothesis and, 12
 Acute myeloid leukemia, 655-657
 treatment of, 661
 goal of, 661
 Acute myelomonocytic leukemia (M4), 656f
 Acute myeloproliferative disorder, 661t
 Acute nonlymphocytic leukemia, 661
 Acute undifferentiated leukemia (AUL), 659
 Acutely transforming oncovirus, 35
 Adamantinoma, 186
 Adaptive pain, 248-249
 Adaptive trial design, 299
 Bayesian approach to, 300
 Adeno-associated virus (AAV), 216t
 Adenocarcinoma, 53
 of gastrointestinal system, 120-121
 radiation therapy for, 191-193
 salivary gland cancer as, 398
 as uterine tumor, 535
 Adenoma, 53
 Adenomatous polyp, 413
 Adenosine, 200-202
 Adenosine monophosphate (AMP), 200-202
 Adenosine triphosphate (ATP)-binding cassette
 (ABC) transporter family, 160
 Adenoviral vector, 217f
 Adenovirus, 216t
 conditionally replicating, 219-220, 219f
 Adipose tissue tumor
 cell characteristics in, 124
 infiltrative lipoma as, 359
 intermuscular lipoma as, 358-359
 lipoma as, 358
 liposarcoma as, 359
 Adjuvant therapy. *See also* Canine osteosarcoma
 definition of, 157-158

Adnexal tumor
 identification of, 117
 incidence of, 597
 Adoptive T-cell transfer, 207
 methods for
 lymphodepletion, 208
 lymphokine-activated killer cell transfer,
 207
 tumor-infiltrating lymphocyte transfer,
 207-208
 Adrenal cortical tumor, 121-122
 Adrenal gland neoplasia
 classification of, 510
 imaging modalities for, 510-511
 prevalence of, 510
 Adrenal gland tumor
 right, ultrasonography of, 102f
 surgical management of, 513
 Adrenal hyperplasia, 512
 Adrenal mass, incidental, 513
 Adrenal medullary tumor, 512-513
 Adrenal-dependent hypercortisolism (ADH),
 505
 imaging studies for, 506
 medical therapy for, 511-512
 surgical management of, 511-512
 Adrenalectomy
 for adrenal-dependent hypercortisolism,
 511-512
 for aldosterone-secreting adrenocortical
 tumor, 512
 Adrenocortical tumor
 ADH and surgical management of, 511-512
 aldosterone-secreting, 512
 HC and PDH
 age and weight at onset, 511
 prevalence of, 511
 sex hormone secretion by, 512
 Adrenocorticotrophic hormone (ACTH)
 ectopic production of, 87
 pituitary tumors and, 504
 Adrenocorticotrophic hormone (ACTH)-
 independent HC, 505
 Aerosolization therapy, 487
 Age, tumor-related prognosis and, 149
 Alanine transferase (ALT), 408
 Alcian blue stain, 59
 Aldosterone-secreting adrenocortical tumor,
 512
 Aleukemic leukemia, 655
 Alimentary adenocarcinoma, 413
 Alimentary lymphoma. *See also* Canine
 lymphoma; Lymphoma

 goals of, 294t

- Phase IV trial, 297-298
- Phenoxy acid-containing herbicide, 78
- Pheochromocytoma
- catecholamine and, 512
 - plasma/urinary concentrations for, 512-513
 - cutaneous flushing and, 89
 - diagnostic imaging of, 512
 - prognosis of, 513
 - surgery for, 513
- Philadelphia (Ph) chromosome, 3, 34-35
- CML, ALL, AML and, 133
- Phosphatidyl inositol-3 kinase (PI3K), 223
- Phosphatidyl inositol-3 kinase (PI3K) signal transduction, 224f
- Phosphorylation, 30-31
- Phosphotungstic acid hematoxylin (PTAH), 59
- Photodynamic therapy, 153
- for Bowen's disease, 310
- Photon, 180-181
- Physical carcinogenesis
- asbestos as, 17
 - magnetic fields and, 17
 - radiation as, 17
 - sunlight as, 16
 - trauma/chronic inflammation as, 16-17
- Phytoestrogen, 283
- Phytomedicinal, 281
- PI3K/Akt signaling pathway, 137
- Pilomatricoma, 313
- Piroxicam
- dose and effects of, 252t-253t
 - efficacy of, 230-231
 - for oral melanoma, 329
 - for urinary bladder tumors, 576-577
- Pituitary corticotroph tumor, 505-508
- Pituitary somatotroph tumor. *See* Feline acromegaly
- Pituitary tumor
- classification of, 505
 - radiation therapy for, 189-190
 - considerations for, 189
 - efficacy of, 189
 - toxicities associated with, 189-190
 - signs of, 504
- Pituitary-dependent hypercortisolism (PDH).
- See also* Canine pituitary-dependent hypercortisolism; Feline pituitary-dependent hypercortisolism
 - ACTH secretion in, 505
 - adrenocortical tumor and
 - age and weight at onset, 511
 - prevalence of, 511
 - view of cat with, 508f
- Pivotal/confirming trial. *See* Phase III trial
- Placental alkaline phosphatase (PLAP), 559
- Planning target volume (PTV), 184-186
- Planum nasale SCC, 188
- Plasma cell tumor
- cell characteristics in, 127
 - diagnostic methods for, 669-670
 - immunohistochemical markers/panels for, 60t-62t
 - osteolysis/pathologic fracture secondary to, 667f
- Plasmablast, 665-666
- Plasmacytoma
- cell characteristics in, 127
 - fine-needle aspiration of, 127f
 - staging for, 675
- Plasmapheresis, 672
- Plasmid DNA, 206
- Platelet aggregation, cancer progression and, 89
- Platelet-derived growth factor receptor (PDGFR), 6-7
- expression of, 222
 - toceranib and masitinib, 230
 - vaccine-associated sarcomas and, 369-370
- Platelet-derived growth factor- β (PDGF- β)
- endothelial cells producing, 7f
 - role of, 6-7
- Platinum clearance, 164f
- Platinum compound, 232-233
- Platinum-based chemotherapy, 283
- Platinum-containing antitumor agent, 171
- Pleomorphic cell, 115-116
- Pleomorphism, 117-118
- definition of, 53
 - in salivary gland tumors, 118
- Pluronic lecithin organogel (PLO), 516
- Plutonium-induced osteosarcoma, 463-464
- Pneumonia, brain tumor and, 588
- Pneumopericardiography, 702
- Point mutation, 35, 35f
- cause of, 223-224
- Poly adenosine diphosphate ribose glycohydrolase (PARG), 240
- Poly adenosine diphosphate ribose glycohydrolase (PARG) inhibition, 240
- Poly adenosine diphosphate ribose polymerase (PARP), 240
- Poly adenosine diphosphate ribose polymerase (PARP) inhibition, 240
- Polycythemia vera (PV), 657
- diagnosis of, 660
 - signs of, 659
 - treatment of, 661
- Polymerase chain reaction (PCR), 63
- c-kit mutation detection by, 134f
 - clonality assessments and, 133-135
 - DNA amplification and, 132
 - fusion gene detection by, 133
 - genetic insertions/deletions and, 132-133
 - papillomaviruses and, 306
 - sequencing in, 133
 - single-base mutations and, 133
- Polymerase chain reaction (PCR)-chained assay, 132-133
- Polypoid cystitis, 575f
- Polysulfated glycosaminoglycan, 252t-253t
- Poorly differentiated carcinoma, 59
- Poorly differentiated epithelial tumor, 117
- Poorly differentiated liposarcoma, 59
- Population pharmacokinetic study, 172
- Population studying, 80
- Population-based cancer registry, 70
- Positron-emission tomography (PET)
- glucose uptake and, 11
 - radiation therapy and, 184-186
 - of thymoma, 106f
- Positron-emission tomography/computed tomography (PET/CT), 104-105
- cost/sensitivity/specificity/availability of, 99t
- Postoperative radiation, wound healing and, 153
- Post-registration trial, 297-298
- Posttreatment biopsy, 143
- Power, in clinical trial, 296-297
- Poxvirus, use of, 206
- Prednisone, 171
- CHOP radiation therapy and, 194
 - dose and effects of
 - for cats, 252t-253t
 - for dogs, 251t
 - for hypoglycemia, 520
 - for multiple myeloma, 671
- Preleukemia, 658-659
- Premetastatic niche, 17-18
- Preoperative radiation, surgery and, 153
- Preoperative therapy, assessment of, 58
- Preputial tumor
- canine, 566
 - feline, 566
- Presence of antigen-receptor rearrangement (PARR), 63
- in intestinal tumors, 416
- Preservation, of biopsy sample, 51-52
- Pretreatment biopsy, 143
- contamination and, 146-147
 - contraindications for, 143
 - indications for, 143
- Prevalence, 69t
- Primary aldosteronism, 512
- Primary CNS lymphoma, 614
- prognosis for, 627
 - treatment of, 626
- Primary hyperparathyroidism
- hypercalcemia and, 518
