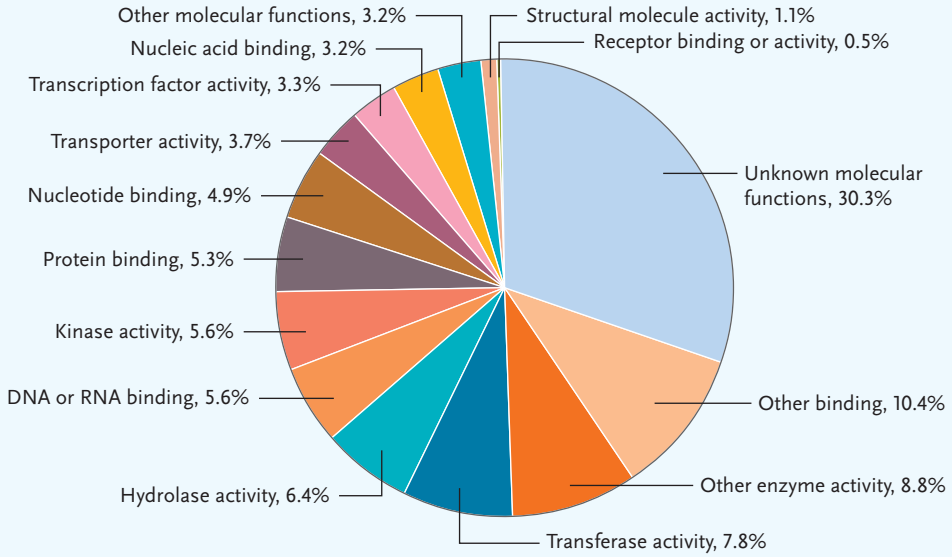
Model Research Organisms: *Arabidopsis thaliana*

For plant geneticists, the little white-flowered thale cress, *A. thaliana* has attributes that make it a prime subject for genetic research. A tiny member of the mustard family Brassicaceae, *A. thaliana,* is revealing answers to some of the biggest questions in plant development and physiology.

Each plant grows only a few centimeters tall, so little laboratory space is required to house a large population. As long as *A. thaliana* is provided with damp soil containing basic nutrients, it grows easily and rapidly in artificial light. Like Mendel's peas, *A. thaliana* is self-compatible and self-fertilizing, and the flowers of a single plant can yield thousands of seeds per mating. Seeds grow to mature plants in just over a month and then flower and reproduce themselves in another 3 to 4 weeks. This permits investigators to perform desired genetic crosses and obtain large numbers of offspring having known, desired genotypes with relative ease. Individual *A. thaliana* cells also grow well in culture.

Arabidopsis thaliana



Elliot Meyerowitz

The *A. thaliana* genome was the first complete plant genome to be sequenced; at this writing researchers have identified approximately 28,000 genes arranged on five pairs of chromosomes. The genome contains relatively little repetitive DNA, so it is fairly easy to isolate *A. thaliana* genes, which can then be cloned using genetic engineering techniques. Cloned genes are inserted into bacterial plasmids and the recombinant plasmids transferred to the bacterial species *Agrobacterium tumefaciens,* which readily infects *A. thaliana* cells. Amplified by the bacteria, the genes and their protein products can be sequenced or studied in other ways.

Typically, researchers use chemical mutagens or recombinant bacteria to introduce changes in the *A. thaliana* genome. These mutants have become powerful tools for exploring molecular and cellular mechanisms that operate in plant development—for example, elucidation of the homeotic genes responsible for flower development described in this chapter. *A. thaliana* mutants are also being used to probe fundamental questions such as how plant cells respond to gravity, and what roles the pigments called phytochromes play in plant responses to light.

Several years ago an ambitious, multinational research effort was launched to determine the functions of all *A. thaliana* genes. This work is providing a comprehensive genetic portrait of a flowering plant—how each gene affects the functioning of not only individual cells but of the plant as a whole. The Arabidopsis Information Resource (TAIR) tallies the percentages of *A. thaliana* genes in different functional categories **(Figure).**

signaling molecule (a hormone of the auxin family, discussed in Chapter 37) to the apical cell, and this sets in motion steps leading to the development of the various embryonic shoot features (Figure 36.19B). Later, gene expression and the flow of chemical signals shift in ways that promote the development of specific structures in the basal cell, including portions of the root apical meristem.

Several of the genes that influence root–shoot polarity have been identified, and when any of them is disrupted, the result can be a serious defect. For example, when an embryo receives two copies of a mutant gene called *gnom,* the embryo doesn't develop distinct root and shoot regions. Instead it remains a lumpy blob.

RADIAL ORGANIZATION OF TISSUE LAYERS A day or so after an *A. thaliana* egg cell is fertilized, the embryo consists of eight cells. Even at this early stage, both the root–shoot axis and the beginnings of tissue systems are present. When an embryo reaches the so-called torpedo stage, cells representing all three basic tissue systems are in place **(Figure 36.19C).** Again working

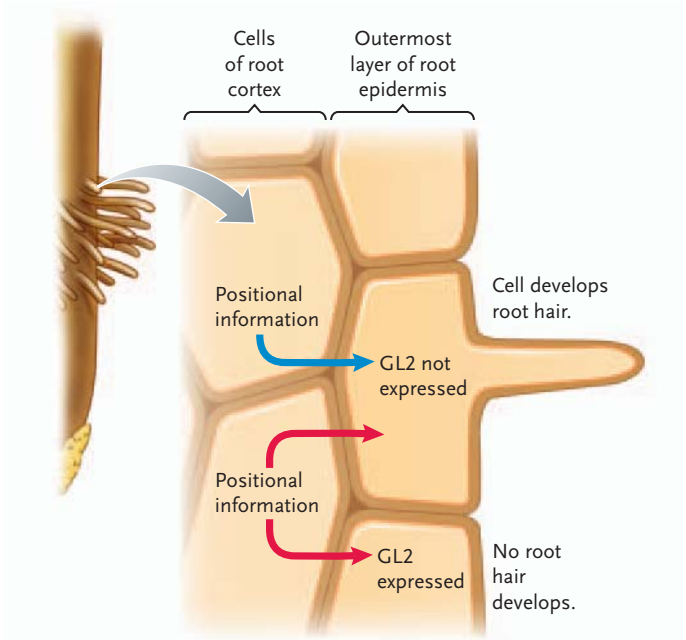
with mutant plants, investigators have identified several *A. thaliana* genes that help govern early development of tissue systems. For example, a gene called *SCR* encodes a protein that apparently regulates mitotic divisions that produce the first cells of a developing root's cortex and endoderm tissue layers (Figure 33.20 shows the locations of these tissues in a mature root). The roots of a mutant *scr* seedling contain cells with jumbled characteristics of both tissue layers.

No matter what the species, nearly all new seed plant embryos have the general body plan we have been discussing. As development proceeds, cells at different sites become specialized in prescribed ways as a particular set of genes is expressed in each type of cell—a process known as *differentiation*. Differentiated cells in turn are the foundation of specialized tissues and organs, which come about through processes we consider next.

Key Developmental Cues Are Based on a Cell's Position

Although many of the specifics of development differ in animals and plants, one fundamental holds true for both: normal development produces ordered spatial arrangements of differentiated tissues. Examples in plants include root and shoot apical meristems at opposite ends of the root–shoot axis, the cotyledons that divide the shoot into an upper epicotyl and a lower hypocotyl, and the nested layers of vascular, ground, and epidermal tissue systems. Developmental biologists call this progressive ordering of parts **pattern formation,** and a wealth of research has shown that it is guided by the position of cells relative to one another. Like the information provided by a hormone gradient mentioned in Section 36.2, this positional information provides cues that "tell" cells where they are in the developing embryo and thus lay the groundwork for an appropriate genetic response.

Numerous researchers have explored how cells in a developing plant or plant part receive and respond to positional information. Experiments have demonstrated, for example, that only certain cells in the epidermis of an embryonic root will



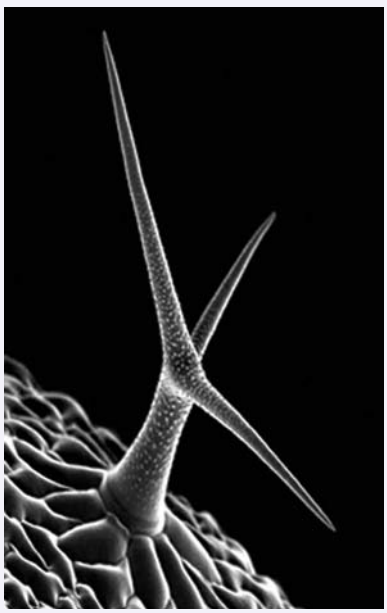


FIGURE 36.20 One model of how positional information influences the development of root hairs. In this model, the only epidermal cells that develop root hairs are those whose inner wall is in contact with two root cortex cells. Such positioning gives rise to signals that block the expression of the GL2 (GLABRA2) gene. When GL2 is expressed, a root epidermal cell will not develop a root hair.

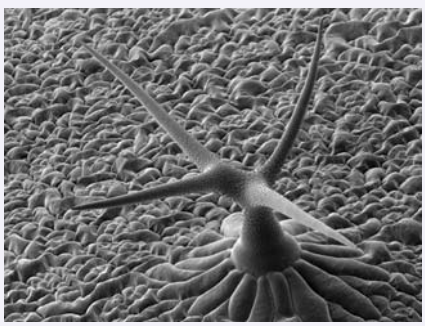
Trichomes: Window on development in a single plant cell

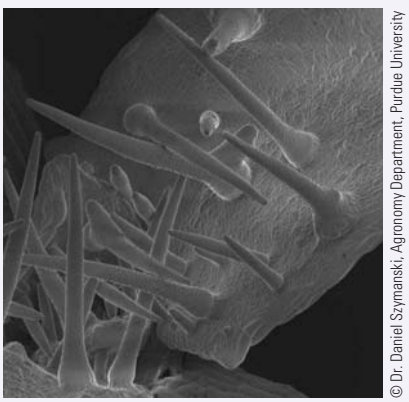


The delicate plant cell extensions called trichomes are helping to illuminate developmental processes that go on in a single plant cell as it differentiates—that is, as it acquires its ultimate specialized structure and function. In *A. thaliana,* each of these minute protuberances consists of a single cell with a branching tripartite pattern **(Figure 1).**

Jonathan Plett and Sharon Regan

FIGURE 1 Normal trichome from the epidermis of a leaf of *Arabidopsis thaliana*.

As a trichome differentiates, increases in size, and extends branches in different directions, its chromosomes—and the cell's DNA—are duplicated several times over without mitosis. As a result of the process, called *endoduplication,* the cell has multiple copies of its chromosomes. Experiments that isolate the effects of different mutants have helped confirm that the overall amount of DNA in the cell strongly influences the cell's structure, and also that several genes interact to determine the structure. One of these genes is called *TRY* (for *TRIPTYCHON*). When it is mutated, the affected plant's trichomes have a double complement of DNA and develop extra branches **(Figure 2).** But genes that influence endoduplication are only part of the story. Experiments with other mutants show that numerous other genes also help produce the characteristic three-pronged trichome branching. For example, when a gene called *STICHEL* is mutated, *sti* mutants don't develop any branches **(Figure 3).** The underlying reason for this phenotype is not yet understood.



Dr. Stanley Flegler/Visuals Unlimited, Inc.

FIGURE 2 Abnormal trichome from a *try* mutant.

These examples underscore how complex molecular interactions that affect multiple aspects of a cell's functioning ultimately determine a cell's form and function. Because the genes that operate in trichomes are also involved in the development of other types of plant cells, studying them promises to shed light on processes that generate differentiated cells throughout the plant body.

THINK LIKE A SCIENTIST In addition to being situated at the surface of leaf and stem epidermis, trichomes are transparent. Given these attributes, what other sorts of cell processes might mutant trichomes be used to study?

give rise to root hairs, the type of trichomes that take up water and minerals from soil (see Section 33.2). These specialized root epidermal cells all share the same position with respect to the underlying root cortex—each abuts two cortical cells. By contrast, no root hair extension will develop from an epidermal cell that lines up against only one cortical cell. **Figure 36.20** diagrams one model of what happens next. In this scenario, one or more chemical signals may cross from cortical to epidermal cells by way of plasmodesmata. When an epidermal cell receives signals from a single cortex cell, a series of genes are expressed in a cascade of effects that culminate in the expression of a gene called GL2 (or GLABRA2). The product of GL2 blocks the formation of root hairs. If, on the other hand, an epidermal cell aligns with two cortex cells, it receives signals from both and the cascade of gene effects blocks expression of GL2—and a root hair develops. *Insights from the Molecular Revolution* gives more examples of ways that trichomes such as root hairs have become popular experimental models for studying the differentiation of plant cells.

Morphogenesis Shapes the Plant Body

As tissues of differentiated cells form in a plant embryo, the stage is set for different body regions to develop characteristic shapes and structures that correlate with their function. This

A. Adding length: Division in a transverse plane parallel to the root–shoot axis produces daughter cells stacked like bricks.

B. Adding girth: Cells may divide so that the daughter cell forms parallel to the plant's nearest surface or so that the new cell wall forms perpendicular to the nearest surface.

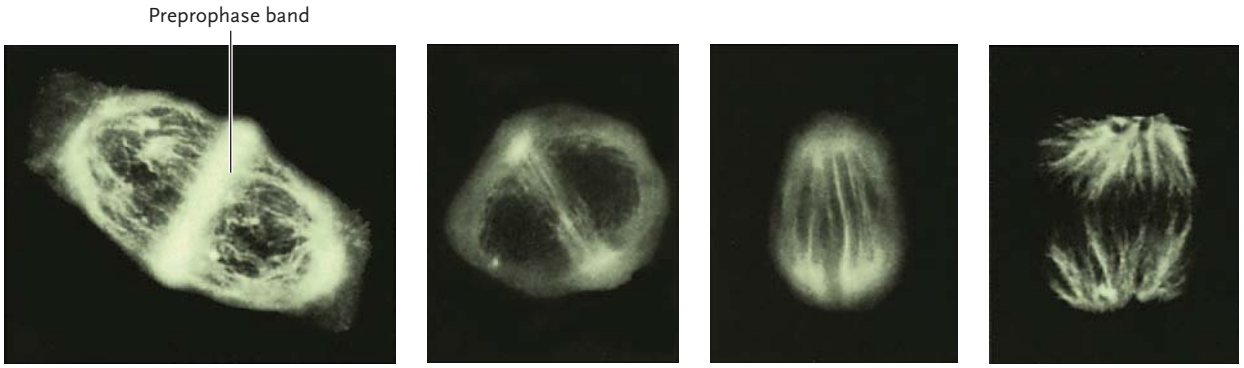
FIGURE 36.21 Plant cell division in different planes. The external surface nearest the dividing cell is the reference point for establishing division planes.

© Cengage Learning 2014

process, called **morphogenesis,** shapes the new shoot and root parts produced by dividing cells in meristems. In animals, morphogenesis involves localized cell division and growth, as well as migration of cells and entire tissues from one site to another (see Chapter 50). Plant cells, however, are enclosed within thick walls and usually cannot move. Thus morphogenesis in plants relies on mechanisms that don't require mobility. One of these mechanisms is **oriented cell division,** which establishes the overall shape of a plant organ, and another is **cell expansion,** which enlarges the cells in specific directions in a developing organ.

ORIENTED CELL DIVISION As described in Chapter 33, roots and stems grow lengthwise as the division and expansion of cells in apical meristems produce columns of cells parallel to the root–shoot axis. The cell divisions occur in a transverse plane—that is, a new cell plate, and then new cell walls, form so that the cells become stacked one atop the other like wooden blocks **(Figure 36.21).** A plant adds girth—increases in circumference—by way of cell divisions in other planes. For instance, new cell walls may form parallel to the nearest plant surface, or perpendicular both to the nearest surface and to the transverse plane **(Figure 36.21B).**

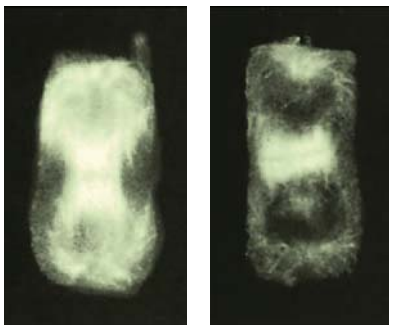
You may remember from Chapter 10 that the cell plate forms during the cytokinesis phase of mitosis. This step establishes the plane of the middle lamella that will eventually separate the parent and daughter cells. The capacity of dividing plant cells to synthesize a new cell plate in a different plane from the old one underlies morphogenesis in nearly all plant groups. In meristematic tissue, changes in the plane of cell division establish the direction in which structures such as lateral roots, branches, and leaf and flower buds will grow, and so gives the plant body its overall form.



The image sequence in **Figure 36.22** shows steps that occur as the plane of a cell plate is established. While a plant cell destined to divide is still in interphase, hours before mitosis begins, the cell nucleus migrates to a particular location in the cell. The nucleus becomes surrounded by a layer of microtubules and microfilaments that radiate outward from it. Where the layer contacts the cell wall, a belt of microtubules and microfilaments called the *preprophase band* forms briefly, encircling the cell cytoplasm. The band usually disappears as mitosis gets underway in the cell, but its position marks the site where the cell plate forms during cytokinesis. Remnants of microfilaments may guide the edges of the developing cell plate into the proper position against the cell wall.

CELL EXPANSION Once a cell has divided, the daughter cells expand to mature size. Yet plant cells are encased in a primary wall of nonliving material. Botanists are beginning to learn how the cell wall expands to accommodate the enlarging cell within.

Primary cell walls consist of a loose mesh of cellulose microfibrils embedded in a gel-like matrix. As plant cells mature, they may elongate to as much as 100 times their embryonic lengths. During this elongation, the cellulose meshwork is first loosened and then stretched. Turgor pressure supplies the force for stretching. The exact mechanism that loosens the wall structure is not known, although experiments indicate that it depends on a dramatic drop in pH. Some researchers suggest that an auxin in the cell cytoplasm may stimulate a plasma membrane proton pump that moves H^+ into the cell wall (see Section 6.4). The acidic wall conditions may activate hydrolytic enzymes that break bonds between wall components, or they may promote loosening in some other way.



During expansion, enzyme complexes in the cell's plasma membrane synthesize new cellulose microfibrils from glucose in the cytoplasm. When each microfibril is fully formed, it is bound in place in the growing wall by pectins and other wall components.

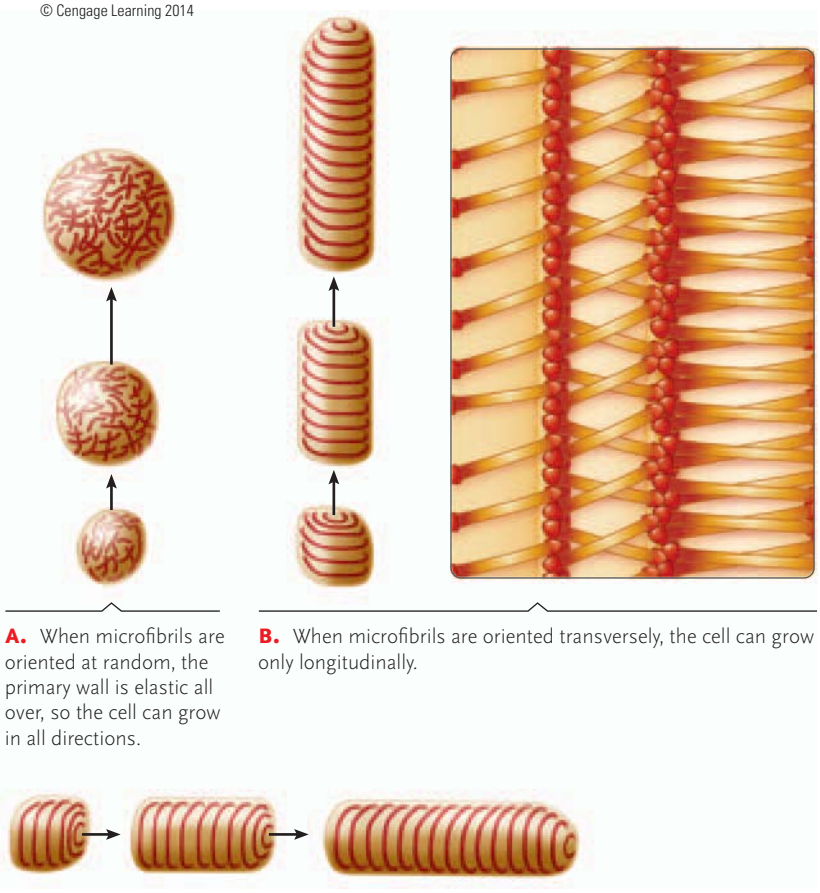
A. In preprophase of mitosis, the microtubules break their links to the plasma membrane and assemble into a thick preprophase band.

B. As cell division begins, the preprophase band disassembles and microtubules organize into a spindle.



All: S. M. Wick, J. Cell Biol. 89:685 (1981), Rockefeller University Press

C. After division is complete, the spindle disassembles, leaving a layer of microtubules in the same plane as the preprophase band. The new cell wall and cell plate form there.

FIGURE 36.22 How the plane of cell division is determined in a plant cell. This series of micrographs shows events in onion *(Allium cepa)* root tip cells, starting with preprophase of mitosis.

FIGURE 36.23 Cell expansion and the orientation of cellulose microfibrils. In each cell, microtubules inherited from the parent cell are already oriented in prescribed patterns that govern how cellulose microfibrils will be oriented in the cell wall. Their orientation in turn governs the direction in which a cell can expand.

© Cengage Learning 2014

A. When microfibrils are oriented at random, the primary wall is elastic all over, so the cell can grow in all directions.

B. When microfibrils are oriented transversely, the cell can grow only longitudinally.

C. When microfibrils are oriented longitudinally, the cell can grow only laterally.

The direction of cell expansion depends on the orientation of the newly formed cellulose microfibrils **(Figure 36.23).** If the microfibrils are randomly oriented, the cell expands equally in all directions. If they are oriented at right angles to the cell's long axis, the cell expands lengthwise. And if new fibrils are deposited parallel to the long axis of the cell, the cell expands laterally.

PATTERNS OF CELL DIVISION DURING EARLY GROWTH Like the first mitotic division in an *A. thaliana* zygote, it's not uncommon for cell divisions in a growing plant to be asymmetrical, so that one daughter cell ends up with more cytoplasm than the other. The unequal distribution of cytoplasm means that the daughter cells differ in their composition and structure, and the differences affect how they interact with their neighbors during growth, even though all cells carry the same genes. Their cytoplasmic differences and interactions with one another trigger selective gene expression. Such events seal the developmental fate of particular cell lineages. Their descendant cells divide in prescribed

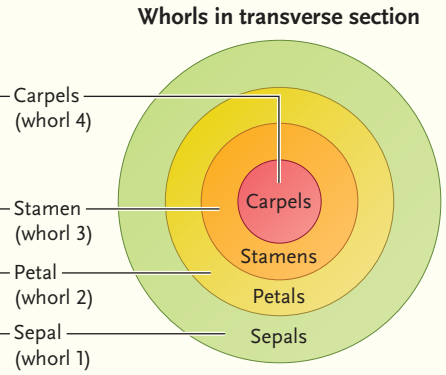
Probing the Roles of Floral Organ Identity Genes



Question: What are the genetic mechanisms that govern the formation of the parts of a flower?

Experiments: Starting in the 1990s, teams of scientists at various research centers grew *A. thaliana* plants having mutated, inactivated versions of the genes that were suspected of controlling the proper development of floral organs. They compared the types and arrangements of floral organs in the test plants with the organs present in normal, wild-type *A. thaliana* flowers.

A. Floral organ whorls in normal *A. thaliana*

B. Overlapping activity fields of floral organ identity genes

		C
	B	C
A	B	
A		
E	E	E

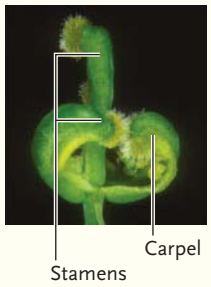
Results: Early experiments showed that at least three classes of homeotic genes—A, B, and C—encoded transcription factors that regulate different aspects of normal floral organ development. Later experiments by others revealed an E class of floral homeotic genes. Various combinations of the different classes of transcription factors produce a normal *A. thaliana* flower's whorls (parts A and B). Particular combinations and dosages of E-class factors, collectively called *SEPALLATA* or *SEP* genes, are required for the normal development of all four whorls. Mutant plants are a window onto this complex system for establishing floral organ identity (Figures C–F).

© Cengage Learning 2014

planes and expand in set directions, producing plant parts with diverse shapes and functions.

Regulatory Genes Guide the Development of Floral Organs

Research with several plant species has shed light on the genetic mechanisms that govern the formation of the parts of a flower. For example, classic experiments with *A. thaliana* carried out by Elliot Meyerowitz and his colleagues at the California Institute of Technology showed that *floral organ homeotic genes* regulate the development of the sepals, petals, stamens, and carpels in flowers.



The Meyerowitz team studied plants with various mutations in floral organs. By observing the effects of specific mutations on the structure of *A. thaliana* flowers, the investigators identified three classes of homeotic gene activity—which they named A, B, and C—that appeared to regulate different aspects of normal flower development in eudicots. The gene products are transcription factors. Subsequent studies by other scientists identified an E class of gene activity that apparently is an essential partner in the functioning of the other floral organ homeotic genes. Today there is widespread acceptance of this **ABCE model of floral organ patterning (Figure 36.24).** Expression of A, B, and C class genes overlaps and the products of E class genes function in all four whorls.

Abnormal floral patterns such as those in Figure 36.24C–F show how deactivation of floral organ homeotic genes can affect the development of flower parts. For example, a mutation that deactivates the A-class gene *APETALA2* produces a flower having both carpels and stamens in whorl 1. An intriguing finding is that the A and C activity classes normally oppose each other. When no A gene is expressed, C activity spreads into whorls where the A usually occurs, and vice versa. Also, the E-class genes are "redundant": the transcription factors they encode have such similar effects that an abnormal phenotype develops only when three or more of the genes are deactivated. Subsequent studies have examined many other floral homeotic genes, as well as the genes that control the various gene classes.

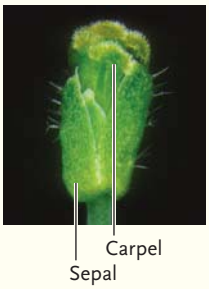
C. When mutation inactivates the *APETALA2* gene, class A genes are not expressed.

Sepals → Carpels
Petals → Stamens

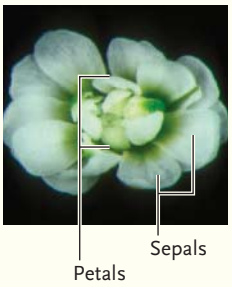


Jose Luis Riechmann

Stamens replace petals and carpels replace sepals. Organ identity in the other whorls does not change.

D. When mutation inactivates the *APETALA3* or *PISTILLATA* gene, class B genes are not expressed.

Petals → Sepals
Stamens → Carpels



Jose Luis Riechmann

Carpels replace stamens and sepals replace petals. Organ identity in the other whorls does not change.

E. When mutation inactivates the *AGAMOUS* gene, class C genes are not expressed.

Stamens → Petals
Carpels → Sepals

Jose Luis Riechmann

No carpels; instead petals develop in whorl 3 and a version of a floral meristem develops where whorl 4 would normally be. It gives rise to extra petals and sepals. Organ identity in other whorls does not change.

F. When mutation inactivates all four known *SEP* genes, class E genes are not expressed.

© blickwinkel/Alamy

Leaflike structures develop but flower parts are poorly defined.

G. SEP4 mutant *A. thaliana* plant

Courtesy of Dr. Martin F. Yanofsky, Distinguished Professor Section of Cell and Developmental Biology, Yanofsky Lab, UCSD

Conclusions: In *A. thaliana,* ABCE activity genes underlie the development of a normal pattern of floral organs. The fields of activity overlap. Further studies have shown that A and C activity apparently counteract each other, and if one is absent the other can spread beyond the whorls where it normally appears. Dosage-dependent activity of E-class *SEP* genes is required for proper expression of all other organ identity genes. The SEP genes are redundant; that is, to some degree their products perform the same or similar functions. As a result, their role in establishing floral organ identity only became apparent when researchers developed mutants lacking functional copies of at least three of the genes.

THINK LIKE A SCIENTIST Do other flowering plants have a comparable system of floral organ identity genes?

Source: This box summarizes experimental studies by several research teams: D. Weigel and E. M. Meyerowitz, 1993. Activation of floral homeotic genes in *Arabidopsis. Science* 261, 1723–1726. J. L. Bowman, J. Alvarez, D. Weigel, E. M. Meyerowitz, and D. R. Smyth, 1993. Control of flower development in *Arabidopsis thaliana* by *APETALA1* and interacting genes. *Development* 119, 721–743. S. Pelaz, G. Ditta, S. Kohlami, E. Baumann and M. Yanofsky, 2000. B and C floral organ identity functions require *SEPALLATA* MADS-box genes. *Nature* 405, 200–203.

As the genes governing flower development are isolated, they can be cloned and their nucleotide sequences defined and manipulated. Such cloned genes already are of keen interest in plant genetic engineering, because food grains such as wheat and many other vital agricultural commodities come directly or indirectly from flowers.

Leaves Arise from Leaf Primordia in a Closely Regulated Sequence

A mature leaf may have many millions of differentiated cells organized into tissues such as epidermis and mesophyll. As described in Chapter 33, leaves develop from leaf primordia that arise just behind the tips of shoot apical meristems **(Figure 36.25).**

Clonal analysis has opened a window on many aspects of plant development, including how leaf primordia originate and give rise to leaves. In this method, the investigator cultures meristematic tissue that contains a mutated embryonic cell having a readily observable trait, such as the absence of normal pigment. (In the laboratory, this kind of mutation can be induced by chemicals or radiation.) The unusual trait then serves as a marker that identifies the mutant cell's clonal descendants, making it possible to map the growing structure. Researchers

© Cengage Learning 2014

have used clonal analysis to study leaf development in garden peas, tomatoes, grasses, and tobacco, among others.

Like flowers, leaves arise through a developmental program that begins with gene-regulated activity in meristematic tissue. Hormones or other signals may arrive at target cells via the stem's vascular tissue, activating genes that regulate development. Studies show that small phloem sieve tubes penetrate a young leaf primordium almost immediately after it begins to bulge out from the underlying meristematic tissue, and xylem soon follows. The early phloem connections are especially vital to the leaf's survival, because the leaf does not begin photosynthesis until it attains one-third of its mature size.

A growing primordium becomes cone-shaped, wider at its base than at its tip. At a certain point, mitosis speeds up in cells along the flanks of the lengthening cone. In eudicots, the rapid cell divisions occur perpendicular to the surface and produce the leaf blade. In monocot grasses, which have long, narrow leaves, vertical "files" of cells develop as cells in the meristem at the base of the cone divide in a plane parallel to the surface. The ultimate shape of a leaf depends in part on variations in the plane and rate of these cell divisions.

Cells at the leaf tip, and those of xylem and phloem that service it, are the oldest in the leaf, and it is here that photosynthesis begins. Commonly, leaf tip cells also are the first to stop dividing. By the time a leaf has expanded to its mature size, all mitosis has ended and the leaf is a fully functional photosynthetic organ.

In nature, genes that govern leaf and flower development switch on or off in response to changing environmental conditions. In many perennials, new leaves begin to develop inside buds in autumn, then become dormant until the following spring, when external conditions favor further growth. Environmental cues stimulate the gene-guided production of hormones that travel through the plant in xylem and phloem, triggering renewed leaf growth and expansion. Leaves and other shoot parts also age, wither, and fall away from the plant as hormonal signals change. The far-reaching effects of plant hormones on growth and development are the subject of Chapter 37.

STUDY BREAK 36.5

1. **What is a homeotic gene? Give at least two examples of plant tissues such genes might govern in a species such as *A. thaliana*.**
2. **What are the two basic mechanisms of morphogenesis in plants? Describe the patterns of cell division by which a plant part (a) grows longer and (b) adds girth.**
3. **Summarize the gene-guided developmental program that gives rise to a leaf.**

UNANSWERED QUESTIONS

What are the chemical cues from female tissues that facilitate compatible pollination?

As you learned in this chapter, if a pollen tube lands on a compatible stigma, chemical cues produced by the female tissue then guide the pollen tube from the stigma to the embryo sac of an ovule. Several lines of evidence point to a role for both sporophytic and gametophytic tissues in proper guidance of pollen tubes to ovules. Recently, it was shown that cysteine-rich polypeptides (LUREs) secreted from synergid cells facilitate pollen tube entry into the ovules of *Torenia fournieri* (wishbone flower). Despite these advances, the identities of the cues released by other pistil tissues remain unknown. What hurdles have hampered the efforts to uncover pollen-tube navigation cues of even the known signaling events described above? First, the pistil tissue within which the pollen tube elongates to the ovule is comprised of several types of tissue, including stigma, style, and transmitting tract, and these tissues are not readily accessible. Second, analyzing the dynamic responses of pollen tubes is difficult given that pollen-tube navigation occurs well within opaque pistils. Third, it appears that multiple, stage-specific, short-range, and readily labile signals produced in minute quantities mediate pollen-tube guidance. However, recent development of highly sensitive global approaches and assays that directly monitor pollen-tube elongation offer hope that guidance cues will be uncovered sooner rather than later.

THINK LIKE A SCIENTIST

1. Do you think pollen-tube guidance signals from different plant species will be similar?
2. What are some of the practical applications of deciphering signals that mediate pollen-tube guidance?

Courtesy of Ravi Palanivelu

Ravi Palanivelu is an assistant professor in the Department of Plant Sciences at the University of Arizona. His current research focuses on the isolation and characterization of pollen-tube guidance signals during *Arabidopsis* reproduction, with the long-term goal of understanding the molecular basis of how cells communicate with each other. To learn more about Palanivelu's research, go to http://ag.arizona.edu/research/ravilab.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

36.1 Overview of Flowering Plant Reproduction

- In most flowering plant species, a multicellular diploid sporophyte (spore-producing plant) stage alternates with a multicellular haploid gametophyte (gamete-producing plant) stage. The sporophyte develops roots, stems, leaves, and, at some point, flowers. This life cycle pattern is called alternation of generations (Figure 36.2).

Animation: Flowering plant life cycle

36.2 The Formation of Flowers and Gametes

- A flower develops at the tip of a floral shoot and has up to four whorls, which are supported by the receptacle. The calyx and corolla consist of the sepals and petals, respectively. The third whorl consists of stamens, and carpels make up the innermost whorl (Figure 36.3).
- The anther of a stamen contains sacs where pollen grains develop. Fertilization occurs if pollen lands on a compatible stigma, which contains an ovary in which eggs develop.
- A complete flower has both male and female reproductive parts. Monoecious species bear both types of flowers on each plant; in dioecious species the "male" and "female" flowers are on different plants (Figure 36.4).
- In pollen sacs, pollen grains (immature male gametophytes) develop inside microspores. In a pollen grain, one cell develops into two sperm cells (male gametes). Another cell produces the pollen tube (Figures 36.5 and 36.6).
- An ovule forms inside a carpel. In the ovule, meiosis produces megaspores, of which one survives and develops further, producing the female gametophyte: the seven-celled embryo sac, one cell of which is the haploid egg. A cell containing polar nuclei helps give rise to endosperm (Figure 36.7).

Animation: Eudicot life cycle

36.3 Pollination, Fertilization, and Germination

- Upon pollination of a compatible stigma, the pollen grain resumes growth, a pollen tube develops, and mitosis of the male gametophyte's sperm-producing cell produces two sperm nuclei. In a double fertilization process, one sperm nucleus fuses with one egg nucleus to form a diploid ($2n$) zygote. The other sperm nucleus and the two polar nuclei formed in the embryo sac also fuse, forming a $3n$ cell that will give rise to triploid ($3n$) endosperm in the seed (Figures 36.8 and 36.9).
- After the endosperm forms, the ovule expands, and the embryonic sporophyte develops. This mature ovule is a seed. Inside it, the embryo has a lengthwise axis with a root apical meristem at one end and a shoot apical meristem at the other (Figure 36.10).
- Eudicot embryos have two cotyledons. The embryonic shoot consists of an upper epicotyl and a lower hypocotyl; also present is an embryonic root, the radicle. The single cotyledon of a monocot forms a scutellum that absorbs nutrients from endosperm (Figure 36.11).
- A fruit is a matured or ripened ovary. Fruits protect seeds and aid in their dispersal by animals, wind, or water. They may be simple, aggregate, or multiple, depending on the number of flowers or ovaries from which they develop. Fruits also vary in the characteristics of the pericarp that surrounds the seed (Figure 36.12).
- The seeds of many plants remain dormant until external conditions such as moisture, temperature, and day length favor the survival of the embryo and the development of a new sporophyte (Figures 36.13–36.15).

Animation: Plant development

Animation: Eudicot seed development

36.4 Asexual Reproduction of Flowering Plants

- Many flowering plants also reproduce asexually, with new plants arising by three general modes: by mitosis at nodes or buds along modified stems, by vegetative propagation (Figures 36.16 and 36.17), or by tissue culture from a parent plant's somatic (nonreproductive) cells (Figure 36.18).

36.5 Early Development of Plant Form and Function

- In plant sexual reproduction, development starts at fertilization. Early on, a new embryo acquires its root–shoot axis, and cells in different regions begin to become specialized for particular functions (Figure 36.19). In morphogenesis, body regions develop characteristic shapes and structures that correlate with their function (Figure 36.20).
- Dividing plant cells can synthesize a new cell plate in a different plane from the old one. Such changes establish the direction in which structures such as lateral roots, branches, and leaf and flower buds grow (Figures 36.21 and 36.22).
- Chemical signals that help guide morphogenesis appear to act on certain cells in meristematic tissue, activating homeotic genes that ultimately regulate cell division and differentiation (Figures 36.23 and 36.24).

UNDERSTAND & APPLY

Test Your Knowledge

1. An angiosperm life cycle includes:
   a. meiosis within the male gametophyte to produce sperm.
   b. meiosis within the female gametophyte to produce eggs.
   c. meiosis within the ovary to produce megaspores.
   d. fertilization leading to development of microspores.
   e. fertilization leading to development of megaspores.
2. In a flower:
   a. the ovary contains the ovule.
   b. the stamens support the petals.
   c. the anther contains the megaspores.
   d. the carpel includes the sepals.
   e. the corolla includes the receptacle.
3. Double fertilization in a flower means:
   a. six sperm fertilize two groups of three eggs each.
   b. one sperm fertilizes the egg; a second sperm fertilizes the mother cell.
   c. one microspore becomes a pollen grain; the other microspore becomes a sperm-producing cell.
   d. one pollen grain can make sperm nuclei and a pollen tube.
   e. one sperm can fertilize two endosperm mother cells.
4. A seed is best described as a (an):
   a. epicotyl.
   b. endosperm.
   c. ovary.
   d. mature spore.
   e. mature ovule.
5. The primary root develops from the embryonic:
   a. epicotyl.
   b. hypocotyl.
   c. coleoptile.
   d. radicle.
   e. plumule.
6. Which of the following is *not* a step in the germination of a monocot seed?
   a. Enzymes secreted into the endosperm digest the endosperm cell wall and macromolecules.
   b. The embryo imbibes water and then produces gibberellin.
   c. The embryo absorbs nutrients released from the endosperm.
   d. Endosperm develops as a food reserve.
   e. Gibberellin acts on the cells of the aleurone and scutellum to encode hydrolytic enzymes.
7. A student cuts off a leaflet from a plant and places it in a glass of water. Within a week roots appear on the base of the cutting. A month later she places the growing cutting into soil and it grows to the full size of the "parent" plant. This is an example of:
   a. parthenocarpy.
   b. fragmentation.
   c. grafting.
   d. vegetative reproduction.
   e. tissue culture propagation.
8. Which of the following is *not* an example of pattern formation in developing plants?
   a. an epidermal cell receiving developmental signals from a cortical cell
   b. the loosening of the cell wall to allow the elongation of selected cells to reach mature size
   c. regulation by homeotic genes of the position of different flower parts
   d. oriented cell division that establishes the shape of an organ
   e. cell expansion that directs specific cells to undergo mitosis at a given time and place
9. During the development of a leaf:
   a. mitotic cell divisions occur on planes specific to different plant groups.
   b. xylem vessels are the first to penetrate the leaf primordium.
   c. the growing leaf primordium becomes wider at its base than at its tip.
   d. the leaf primordium bulges from the region behind the shoot apical meristem.
   e. all of the above occur during leaf development.
10. In spring a lone walnut tree in your backyard develops attractive white flowers, and by the end of summer roughly half the flowers have given rise to the shelled fruits we know as walnuts. Walnut trees are self-pollinating. Assuming that pollination was 100% efficient in the case of your tree, which of the following statements best describes your tree's reproductive parts?
    a. Its flowers are in the botanical category of "perfect" flowers.
    b. The tree is monoecious.
    c. The tree is dioecious.
    d. The tree has imperfect, monoecious flowers.
    e. Answers a and b together provide the best description of the tree's flowers.

Discuss the Concepts

1. A plant physiologist has succeeded in cloning a gene for pest resistance into petunia cells. How can she use tissue culture to propagate a large number of petunia plants that have the gene?
2. A large tree may have tens of thousands of shoot tips, and the cells in each tip can differ genetically from cells in other tips, sometimes substantially. Propose a hypothesis to explain this finding, and speculate about how it might be beneficial to the plant. How might this sort of natural variation be useful to human society?
3. Grocery stores separate displays of fruits and vegetables according to typical uses for these plant foods. For instance, bell peppers, cucumbers, tomatoes, and eggplants are in the vegetable section, while apples, pears, and peaches are displayed with other fruits. How does this practice relate to the biological definition of a fruit?

Design an Experiment

The developmental genetics of flowers are of keen interest in plant biotechnology, especially with regard to food plants such as wheat and rice. Outline a research program for a crop species that would exploit the genetics of flower development, including the effects of homeotic genes, to engineer a more productive variety.

Interpret the Data

As Chapter 37 discusses, the plant hormone ABA (abscisic acid) inhibits seed germination, while any of several GAs (gibberellins) stimulate it. For hundreds of plant species, exposure to a substance in wood smoke—one of a family of plant growth regulators called karrikins, or KARs—markedly improves the germination rate. When flames destroy the existing vegetation at a fire scene, more sunlight reaches the ground. In the presence of ample sunlight, KARs apparently promote germination by enhancing the expression of genes that encode GA.

The **Figure** below summarizes experiments by Australian researchers studying KAR activity in mutant *A. thaliana* plants (called ga1-3), which do not synthesize GA. The graph tracks germination activity after two groups of identical test seeds began imbibing water in a medium that contained the gibberellin GA_3. All seeds were exposed to identical levels of a karrikin called KAR_1. The red symbols designate seeds of mutant ABA-deficient plants that were supplied with supplementary ABA. The white symbols are ABA-deficient seeds that did not receive the supplement.

Apply Evolutionary Thinking

Botanists estimate that half or more of angiosperm species may be polyploids that arose initially through hybridization. *Polyploidy*—having more than a diploid set of the parental chromosomes—can result from nondisjunction of homologous chromosomes during meiosis, or when cytokinesis fails to occur in a dividing cell. *Hybridization* is the successful mating of individuals from two different species. Such an interspecific hybrid is likely to be sterile because it has uneven numbers of parental chromosomes, or because the chromosomes are too different to pair during meiosis. A sterile hybrid may reproduce asexually, however, and if by chance its offspring should become polyploid, that plant will be fertile because the original set of chromosomes will have homologs that can pair normally during meiosis. Explain why both the hybrid parent and fertile polyploid offspring may be considered a new species, and describe at least two ways in which this route to speciation differs from speciation in the animal kingdom.

Sunflower plants *(Helianthus)* with flower heads that orient toward the sun's rays—an example of a plant response to shifting light levels in the environment.

STUDY OUTLINE

37.1 Introduction to Plant Hormones
37.2 Plant Chemical Defenses
37.3 Plant Movements
37.4 Plant Biological Clocks

Plant Signals and Responses to the Environment

Why it matters . . . *Larrea tridentata*—creosote bush—won't win many botanical beauty contests, but it is one tough plant. Native to desert areas of the southwestern United States, this shrubby eudicot can withstand droughts of two years or more **(Figure 37.1).** The species may well be the most drought-tolerant perennial in North America, and individual plants may survive hundreds of years, physiologically "hunkering down" during multi-year dry spells as their fleshy leaves shrivel and reduce photosynthesis to minimal levels. A thick, waxy cuticle helps slow water loss, but the leaves also tend to retain water due to their high internal water potential—a feature related to the plant's adaptations for defense against predation. The leaf tissue is infused with resinous compounds and other chemicals that deter nearly all herbivores as well as pathogenic fungi and most insect predators. Wet leaves exude a tarry odor that gives creosote bush its common name.

FIGURE 37.1 Creosote bush, *Larrea tridentata*, growing in the Mojave Desert. Insert: Flowers, fruits, and the resin-impregnated leaves of *L. tridentata*.

FLPA/AgeFotostock

With adequate rainfall, *L. tridentata* produces small yellow flowers and feathery white fruits packed with seeds (Figure 37.1, inset). However, for a variety of reasons, relatively few *L. tridentata* seeds germinate successfully. Selection pressure related to this high seed mortality may explain another striking *L. tridentata* trait—the formation of large clonal populations by vegetative reproduction. After eight or nine decades, a plant's interior branches may begin to die, eventually leaving what appear to be clusters of separate, widely spaced plants. Carbon dating indicates that some living clusters of these genetically identical *L. tridentata* plants are descended from single seeds that germinated 9,000 to 11,000 years ago—qualifying them as some of the oldest living organisms on Earth.

The drought tolerance, chemical defenses, and reproductive flexibility of the creosote bush are prime examples of adaptations plants have evolved for respond-

ing to both biotic (living) and abiotic (nonliving) shifts and stresses in their environment. Such adaptations are the focus of this chapter, starting with the chemical signaling of hormones that regulate many, if not most, aspects of plant growth and development. Next we survey responses that help protect plants against predation or allow them to make adjustments to abiotic factors that are powerful forces in shaping the physical and chemical environments in which plants live. Collectively these adaptations are the evolutionary solution to a key plant "problem"—the need to respond to changes in the environment despite being rooted in one place.

37.1 Introduction to Plant Hormones

A **hormone** (*hormon* = to stimulate) is a signaling molecule that regulates or helps coordinate some aspect of growth, metabolism, or development. Plant hormones may also be called *phytohormones,* especially in the scientific literature. At a fundamental level, hormones control the plant life cycle. They serve as triggers for seed germination and govern the development of a plant's body form, the shift from a vegetative phase growth to a reproductive phase or vice versa, and the timed death of flowers, leaves, and other parts. Beyond those basic roles, hormones mediate changes in the structure and functioning of plant parts in response to external biotic factors such as predation, and abiotic factors such as the availability of light, moisture, and soil nutrients and effects of air currents, gravity, and physical contact with other objects. Some plant hormones are transported from the tissue that produces them to another plant part, whereas others exert their effects in the tissue where they are synthesized. Often, hormonal effects involve changes in gene expression, although sometimes other mechanisms are at work.

All plant hormones are rather small organic molecules that are active in extremely low concentrations. Hormones that have effects outside the tissue where they are produced typically diffuse to their target site(s) or travel to the site via vascular tissues. Plant hormones vary greatly in their effects, although each one affects a given tissue in a particular way. For instance, some stimulate one or more facets of growth or development, while others have an inhibiting influence. A given hormone also can have different effects in different plant tissues, and the effects can differ depending on a target tissue's stage of development. Adding to the complexity, many physiological responses result from the interaction of two or more hormones. Biologists recognize at least seven major classes of plant hormones **(Table 37.1):** gibberellins, auxins, cytokinins, ethylene, brassinosteroids, abscisic acid (ABA), and jasmonates. Recent discoveries have added other hormonelike signaling agents to this list.

Plant Hormones Exert Their Effects Via Signal Transduction Pathways

In general, the target cells for a particular hormone have receptors that can bind the hormone and cellular pathways that are activated in response. This mechanism unfolds in three basic steps introduced in Section 7.1. We'll briefly review those steps here, and consider current scientific understanding of the signal transduction pathways by which specific hormones exert their effects.

Recall from Chapter 7 that in the first step of a signal transduction pathway, a target cell receptor receives the signal, which may be a molecule or an environmental cue such as sunlight. Next, the signal is transduced—that is, its "message" is changed into a form that can trigger the cellular response. In the third step, the transduced signal causes the cellular response **(Figure 37.2).** Some transduced signals activate or turn off genes and so

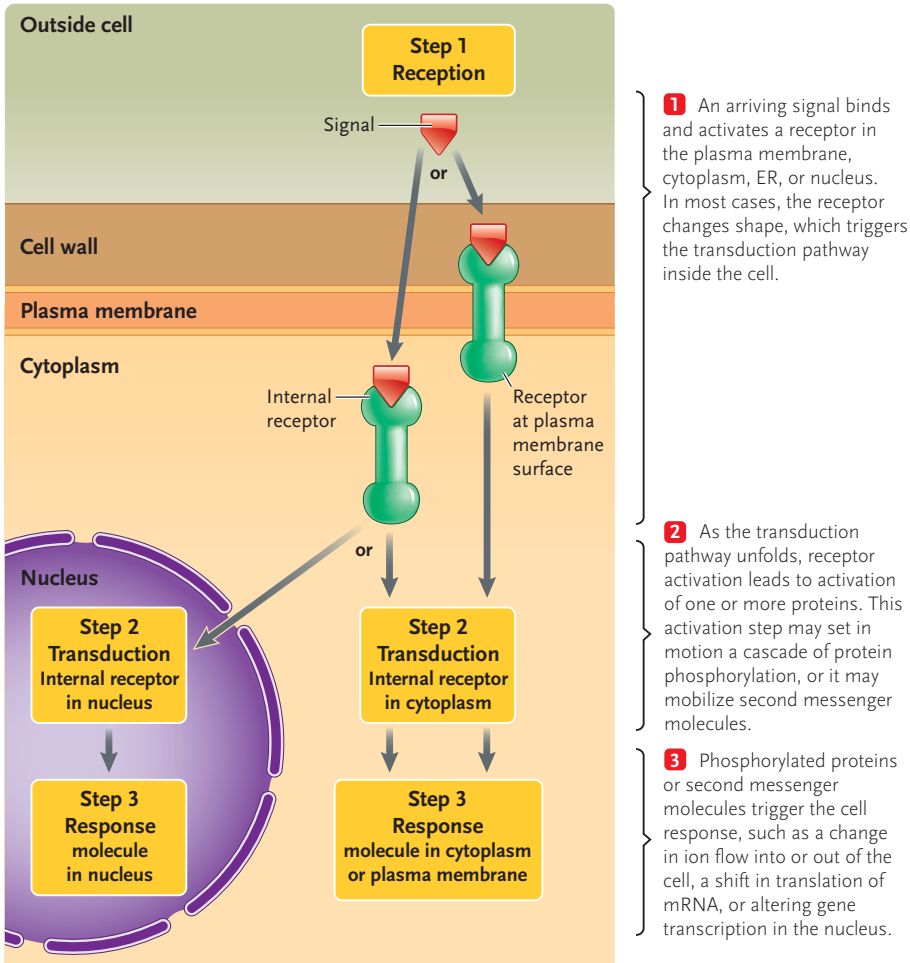

FIGURE 37.2 Overview of signal transduction pathways in plant cells. The three stages of a signal response pathway are reception of the signal, transduction into a form the cell can recognize, and the cell's response. Proteins or second messenger molecules may be the intermediaries in the transduction stage of a signal response pathway (compare Figure 37.6).

TABLE 37.1 Major Plant Hormones and Signaling Molecules

Hormone/ Signaling Compound	Where Synthesized	Tissues Affected	Effects
Auxins	Apical meristems, developing leaves and embryos	Growing tissues, buds, roots, leaves, fruits, vascular tissues	Promote growth and elongation of stems; promote formation of lateral roots and dormancy in lateral buds; promote fruit development; inhibit leaf abscission; orient plants with respect to light, gravity
Gibberellins	Root and shoot tips, young leaves, developing embryos	Stems, developing seeds	Promote cell divisions and growth and elongation of stems; promote seed germination and bolting
Cytokinins	Mainly in root tips	Shoot apical meristems, leaves, buds	Promote cell division; inhibit senescence of leaves; coordinate growth of roots and shoots (with auxin)
Ethylene	Shoot tips, roots, leaf nodes, flowers, fruits	Seeds, buds, seedlings, mature leaves, flowers, fruits	Regulates elongation and division of cells in seedling stems, roots; in mature plants regulates senescence and abscission of leaves, flowers, and fruits
Brassinosteroids	Young seeds; shoots and leaves	Mainly shoot tips, developing embryos	Stimulate cell division and elongation, differentiation of vascular tissue
Abscisic acid	Leaves, chloroplasts, possibly roots in drying soils	Mainly shoot tips, developing embryos, leaves (stomata)	Stimulates cell division and elongation, differentiation of vascular tissue, opening/closing of stomata
Jasmonates	Roots, seeds, probably other tissues	Various tissues, including damaged ones	In defense responses, promote transcription of genes encoding protease inhibitors; possible role in plant responses to nutrient deficiencies
Oligosaccharins	Cell walls	Damaged tissues; possibly active in most plant cells	Promote synthesis of phytoalexins in injured plants; may also have a role in regulating growth
Systemin	Damaged tissues	Damaged tissues	To date known only in tomato; roles in defense, including triggering jasmonate-induced chemical defenses
Salicylic acid	Damaged tissues	Many plant parts	Triggers synthesis of pathogenesis-related (PR) proteins, other general defenses

© Cengage Learning 2014

alter protein synthesis; others set in motion events that modify existing cell proteins. Various plant hormones and growth factors bind to receptors at the target cell's plasma membrane. Others cross the plasma membrane and bind to receptors inside the cell. These receptors may be located on the endoplasmic reticulum (ER), in the cytoplasm, or in the nucleus. In many cases, hormone binding causes the receptor to change shape. Regardless, binding of a hormone or growth factor triggers a complex pathway that leads to the cell response—the opening of ion channels, activation of transport proteins, or some other event. Only cells with the appropriate receptor can respond to a particular signaling molecule. For example, certain cells in developing seeds and maturing fruits have receptors for the "ripening hormone" ethylene, but cells in stems generally do not.

We can think of plant hormones and other signaling molecules as external "first messengers" that deliver the initial physiological signal to a target cell. Often, binding of the signal molecule triggers the synthesis of internal second messengers (introduced in Section 7.4). These go-between molecules diffuse rapidly through the cytoplasm and provide the main chemical signal that alters cell functioning.

Second Messenger Systems Enhance the Plant Cell's Response to a Hormone Signal

Second messengers usually are synthesized in the sequence of chemical reactions that convert an external signal into internal cell activity. For many years the details of plant second-messenger systems were sketchy and hotly debated. Fairly early on, calcium ions were found to play a second messenger role in some hormonal responses. Recent experimental evidence indicates that the hormonal signal from auxins often is conveyed by cAMP (cyclic adenosine monophosphate), a major second messenger in cells of animals and other organisms. Inositol triphosphate (IP_3), a second messenger in plants, fungi, and animals, is involved in the reactions that close plant stomata in response to a signal from abscisic acid, ABA. Other research suggests that a molecule called cGMP (cyclic guanosine monophosphate)

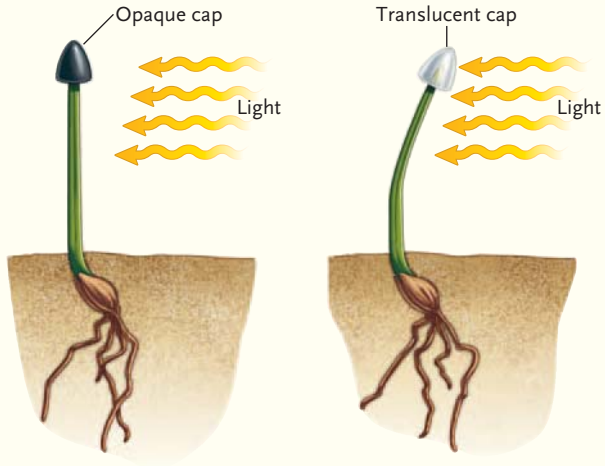
FIGURE 37.3 **Experimental Research**

The Darwins' Experiments on Phototropism



Question: Why does a plant stem bend toward the light?

Experiment 1: The Darwins observed that the first shoot of an emerging grass seedling, which is sheathed by a coleoptile, bends toward sunlight shining through a window. They removed the shoot tip from a grass seedling and illuminated one side of the seedling.

Result: The seedling neither grew nor bent.

Experiment 2: The Darwins divided seedlings into two groups. They covered the shoot tips of one group with an opaque cap and the shoot tips of the other group with a translucent cap. All the seedlings were illuminated from the same side.

Result: The seedlings with opaque caps grew but did not bend. Those with translucent caps both grew *and* bent toward the light.

Conclusion: When seedlings are illuminated from one side, an unknown factor transmitted from a seedling's tip to the tissue below causes it to bend toward the light.

THINK LIKE A SCIENTIST Grasses are monocots. Would the Darwins' results and conclusions have differed if they had done the experiments with eudicot seedlings?

Source: C. R. Darwin. 1880. *The Power of Movement in Plants.* London: John Murray.

serves as a second messenger for auxins, ABA, and a few other plant hormones.

In addition to the basic signal transduction pathways described here, other routes may exist that are unique to plant cells. Light is the driving force for photosynthesis, and researchers are investigating the possibility that plants have evolved other unique light-related biochemical pathways as well. For instance, experiments are extending our knowledge of how plant cells respond to blue light, which, as you will read, triggers some photoperiod responses such as the opening and closing of stomata. Other exciting research suggests that it is probably common for signal response pathways in plant cells to include many steps in which different types of proteins and other molecules are mobilized, not unlike the steps in animal cells.

Auxins were the first plant hormones to be identified, and we start with them as we consider each major class of plant hormones and discuss some newly discovered signaling molecules as well.

Auxins Promote Growth

Auxins are synthesized mainly in the shoot apical meristem and young stems and leaves. They are crucial to plant growth. Among other effects, auxins are essential for the normal progression of the cell cycle, and they stimulate the elongation of cells in growing stems and coleoptiles. Auxins also mediate growth responses to light and gravity. Indoleacetic acid (IAA) is the most important natural auxin. Botanists often use the general term "auxin" to refer to IAA, a practice we follow here.

EXPERIMENTS THAT LEAD TO THE DISCOVERY OF AUXINS

The path to the discovery of auxins began in the late nineteenth century in the library of Charles Darwin's home in the English countryside (see *Focus on Basic Research* in Chapter 20). Among his interests, Darwin was fascinated by plant **tropisms**—movements such as the bending of a houseplant toward light. This growth response, triggered by exposure to a directional light source, is an example of a **phototropism.**

Working with his son Francis, Darwin explored phototropisms by germinating seeds of two species of grasses, oats *(Avena sativa)* and canary grass *(Phalaris canariensis),* in pots on the sill of a sunny window. Recall from Chapter 36 that the shoot apical meristem and plumule of grass seedlings are sheathed by a coleoptile—a protective structure that is extremely sensitive to light. Darwin did not know this detail, but he observed that as the emerging shoots grew, within a few days they bent toward the light. He hypothesized that the tip of the shoot detected light and communicated that information to the coleoptile. Darwin tested this idea in several ways **(Figure 37.3)** and concluded

that when seedlings are illuminated from the side, "some influence is transmitted from the upper to the lower part, causing them to bend."

The Darwins' observations spawned decades of studies that illustrate how scientific understanding typically advances step-by-step, as one set of experimental findings stimulates new research. First, scientists in Denmark and Poland showed that the bending of a shoot toward a light source was caused by something that could move through agar (a jellylike culture material derived from certain red algae) but not through a sheet of the mineral mica. This finding prompted experiments establishing that indeed the stimulus was a chemical produced in the shoot tip. Soon afterward, in 1926, experiments by the Dutch plant physiologist Frits Went confirmed that the growth-promoting chemical diffuses downward from the shoot tip to the stem below **(Figure 37.4).** Using oat seeds, Went first sliced the tips from young shoots that had been grown under normal light conditions. He then placed the tips on agar blocks and left them there long enough for diffusible substances to move into the agar. Meanwhile, the decapitated stems stopped growing, but growth quickly resumed in seedlings that Went "capped" with the agar blocks (see Figure 37.4A). Clearly, a growth-promoting substance in the excised shoot tips had diffused into the agar, and from there into the seedling stems. Went also attached an agar block to one side of a decapitated shoot tip; when the shoot began growing again, it bent away from the agar (see Figure 37.4B). Importantly, Went performed his experiments in total darkness, to avoid any "contamination" of his results by the possible effects of light.

FIGURE 37.4 Two experiments by Frits Went demonstrating the effect of IAA on an oat coleoptile. Went carried out the experiments in darkness to prevent effects of light from skewing the results.

© Cengage Learning 2014

Went did not determine the mechanism—differential elongation of cells on the shaded side of a shoot—by which the growth promoter controlled phototropism. However, he did develop a test that correlated specific amounts of the substance, later named auxin (*auxein* = to increase), with particular growth effects. This careful groundwork culminated several years later when other researchers identified auxin as indoleacetic acid (IAA).

EFFECTS OF AUXIN Auxin is one of the first chemical signals to help shape the plant body. When the zygote first divides, forming an embryo that consists of a basal cell and an apical cell (see Section 36.3), auxin exported by the apical cell to the basal cell helps guide the development of the various features of the embryonic shoot. It plays a key role in when and where leaf primordia form in the apical meristem (as shown in Figure 36.22). As the embryo develops, the leaf primordium of the young shoot becomes the main source of IAA; a secondary signal stimulates the primary growth of the stem and root as long as the embryonic plant is underground. Once an elongating shoot breaks through the soil surface, its tip is exposed to sunlight, and the first leaves unfurl and begin photosynthesis. Shortly thereafter the leaf tip stops producing IAA and that task is assumed first by cells at the leaf edges, then by cells at base of the young leaf. Even so, as described in Section 37.3, IAA continues to influence a plant's responses to light and plays a role in its growth responses to gravity as well. IAA also stimulates cell division in the vascular cambium and promotes the formation of secondary xylem, as well as the formation of new root apical meristems, including lateral meristems. Not all of auxin's effects promote growth, however. IAA also maintains apical dominance, which inhibits growth of lateral meristems on shoots and restricts the formation of branches

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(see Section 33.3). Hence, auxin is a signal that the shoot apical meristem is present and active.

Commercial orchardists spray synthetic IAA on fruit trees because it promotes uniform flowering, helps set the fruit, and also helps prevent fruit from dropping off the plant prematurely. Various synthetic auxins are used as **herbicides** (generally, weed killers), essentially stimulating a target plant to "grow itself to death." The most widely used herbicide in the world is the synthetic auxin 2,4-D (2,4-dichlorophenoxyacetic acid). This chemical kills broadleaf eudicots but spares monocots such as grasses. It is used extensively to prevent broadleaf weeds from growing in fields of cereal crops such as corn (which are monocots).

AUXIN TRANSPORT To exert its far-reaching effects on plant tissues, auxin must travel away from its main synthesis sites in shoot meristems and young leaves. Although IAA moves through plant tissues slowly—roughly 1 cm/hr—this rate is 10 times faster than could be explained by simple diffusion. How, then, is auxin transported?

Researchers adapted the agar block method pioneered by Went to trace the direction and rate of auxin movements in different kinds of tissues. A team led by Winslow Briggs at Stanford University determined that the shaded side of a shoot tip contains more IAA than the illuminated side. Hypothesizing that light causes IAA to move laterally from the illuminated to the shaded side of a shoot tip, the team then inserted a vertical barrier (a thin slice of mica) between the shaded and illuminated sides of a shoot tip. IAA could not cross the barrier, and when the shoot tip was illuminated it did not bend. In addition, the concentrations of IAA in the two sides of the shoot tip remained about the same. When the barrier was shortened so that the separated sides of the tip again touched, the IAA concentration in the shaded area increased significantly, and the tip *did* bend. The study confirmed that IAA initially moves laterally in the shoot tip, from the illuminated side to the shaded side, where it triggers the elongation of cells and curving of the tip toward light. Subsequent research showed that IAA then moves downward in a shoot by way of a top-to-bottom mechanism called **polar transport.** That is, IAA in a coleoptile or shoot tip travels from the apex of the tissue to its base, such as from the tip of a developing leaf to the stem. **Figure 37.5** outlines the experimental method that demonstrated polar transport. When IAA reaches roots, it moves toward the root tip.

In a stem, parenchyma cells next to vascular bundles apparently transport IAA. The hormone moves through and between cells, apparently traveling by polar transport. Figure 37.5D diagrams one widely accepted model for this process. As you can see, the IAA enters at one end by diffusing passively through cell walls, driven by concentration and electrochemical gradients produced by H^+ pumps in the plasma membrane. The hormone exits at the opposite end by active transport across the plasma membrane.

Although auxin typically is not found in xylem, there is increasing evidence that it sometimes moves from parenchyma

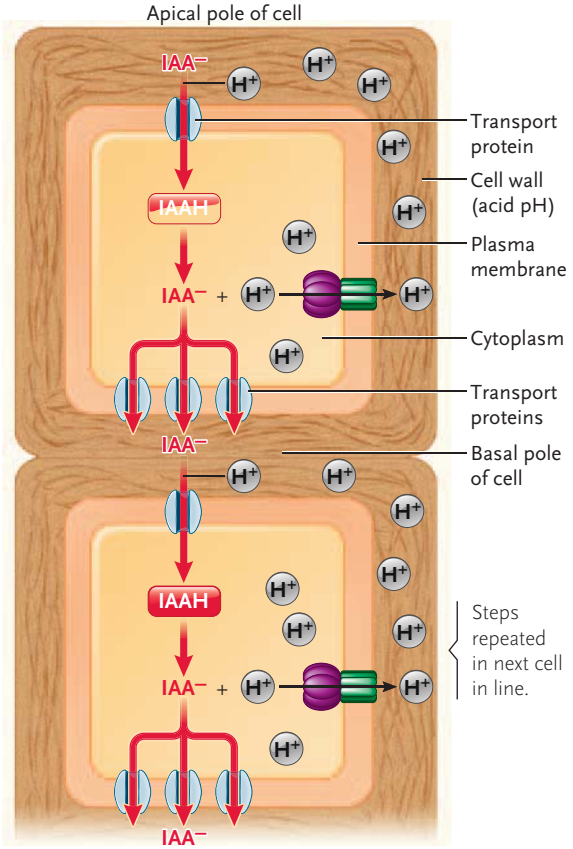

FIGURE 37.5 The polar transport of auxin in plant shoots. Studies of IAA transport in plants have demonstrated that the hormone moves only in one direction, from the shoot tip downward to plant parts below. This diagram shows one model for this polar auxin transport. In this model, a plasma membrane H^+ pump maintains gradients of pH and electrical charge across the membrane, moving H^+ out of the cell using energy from ATP hydrolysis. Following the gradients, at the basal pole of a cell IAA diffuses through the transport proteins into the cell wall, then (as IAAH) into the next cell in line.

cells into phloem and travels rapidly through plants. As this work continues, researchers will undoubtedly gain a clearer understanding of how plants distribute this crucial hormone to their growing parts.

INSIGHTS INTO AUXIN SIGNAL TRANSDUCTION Only in recent years have researchers begun to understand how target cells detect auxins and how subsequent transduction steps unfold. Experiments suggest that auxin binds different receptors, depending on the nature of the ensuing response. Responses that require a change in a gene expression rely on a family of proteins often called simply TIR1, after the original protein discovered. Research in several laboratories confirmed that when IAA in a cell enters the nucleus and binds to TIR1, binding removes an existing inhibition of the transcription of particular genes. As a result, the previously repressed genes are turned on and the cell's activity changes in some way. In responses that don't require a change in gene expression (such as swelling of the protoplast during cell expansion) auxin binds to a receptor called ABP1 (for auxin binding protein 1) at the outer surface

of the plasma membrane. ABP1 binding triggers additional transduction steps within the cell, although the steps are not well understood. **Figure 37.6** sketches these pathways as researchers currently envision them.

POSSIBLE MECHANISMS OF IAA ACTION Ever since auxins were discovered, researchers have sought to understand how IAA stimulates plant cells to elongate. As you may recall from Section 36.5, in an elongating plant cell the cellulose meshwork of the cell wall is first loosened and then stretched by turgor pressure. Several hormones, and auxin especially, apparently increase the plasticity (stretching) of the cell wall. Two major hypotheses have sought to explain this effect, and both may be correct.

Plant cell walls grow much faster in an acidic environment—that is, when the pH is less than 7. The **acid-growth hypothesis** proposes that auxin causes cells to secrete acid (H^+) into the cell wall by stimulating the plasma membrane H^+ pumps to move protons from the cell interior into the cell wall; the increased acidity activates proteins called *expansins*, which penetrate the cell wall and disrupt bonds between cellulose microfibrils in the wall **(Figure 37.7).** Activation of the plasma membrane H^+ pump also produces a membrane potential that pulls K^+ and other cations into the cell; the resulting osmotic gradient draws water into the cell, increasing turgor pressure and helping to stretch the "loosened" cell walls. (Experiments have shown that all these effects occur shortly after ABP1 binds auxin.)

It is also possible that IAA triggers the expression of genes encoding enzymes that play roles in the synthesis of new wall components. Plant cells exposed to IAA do not show increased growth if they are treated with a chemical that inhibits protein synthesis. On the other hand, certain mRNAs rapidly increase in concentration within 10 to 20 min after stem sections are treated with auxin. Expression of mRNAs in response to auxin likely is regulated by the activity of micro RNAs, as described in Chapter 16. It is not yet known exactly which proteins these mRNAs encode.

Gibberellins Also Stimulate Growth, Including the Elongation of Stems

Gibberellins stimulate various aspects of plant growth. Collectively they make up the largest class of plant hormones, with more than 130 recognized chemical variations. Gibberellins have been isolated from fungi and from flowering plants, including eudicots and some monocots. They may also exist in other plant groups as well. Their effects include triggering stem elongation and prompting seeds and buds to break dormancy. Research on barley embryos showed that a gibberellin provides signals during germination that lead to the enzymatic breakdown of endosperm, releasing nutrients that nourish the developing seedling (see Section 36.3).

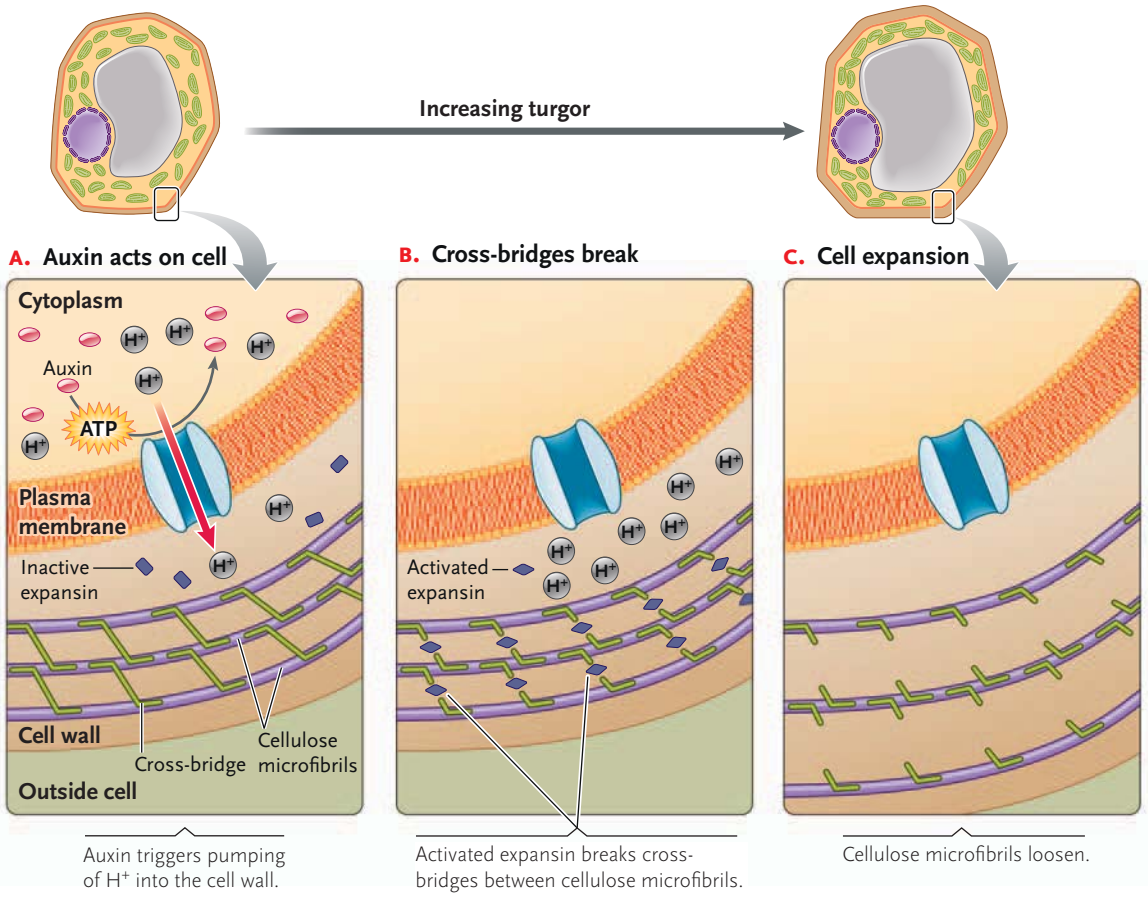

FIGURE 37.7 How auxin may regulate expansion of plant cells. According to the acid-growth hypothesis, plant cells secrete acid (H^+) when auxin stimulates the plasma membrane H^+ pumps to move protons into the cell wall; the increased acidity activates enzymes called *expansins*, which disrupt bonds between cellulose microfibrils in the wall. As a result, the wall becomes extensible and the cell can expand.

© Cengage Learning 2014

Perhaps most apparent to humans is the ability of gibberellins to promote the lengthening of plant stems by stimulating both cell division and cell elongation. Synthesized in shoot and root tips and young leaves, gibberellins, like auxins, modify the properties of plant cell walls in ways that promote expansion (although the gibberellin mechanism does not involve acidification of the cell wall). It may be that the two hormones both affect expansins, or are functionally linked in some other way. Experiments show that the general signal transduction pathway for gibberellins is essentially identical to that for auxins—the target cell's activity is altered when a gene repressor in the cell nucleus is inactivated and the gene begins to be expressed (see Figure 37.6).

In most plant species analyzed to date, the main controller of stem elongation is the gibberellin called GA_1. Normally, GA_1 is synthesized in small amounts in young leaves and transported throughout the plant in the phloem. When GA_1 synthesis goes awry, the outcome is a dramatic change in the plant's stature. For example, experiments with a dwarf variety of peas *(Pisum sativum)* and some other species show that these plants and their taller relatives differ at a single gene locus. Normal plants make an enzyme required for gibberellin synthesis; dwarf plants of the same species lack the enzyme, and their internodes barely elongate at all.

Another stark demonstration of the effect gibberellins can have on internode growth is **bolting,** growth of a floral stalk in plants that form vegetative rosettes, such as cabbages *(Brassica oleracea),* iceberg lettuce *(Lactuca sativa),* and tarweeds such as the silversword *(Argyroxiphium sandwicense).* In a rosette plant, stem internodes are so short that the leaves appear to arise from a single node. When these plants flower, however, the stem elongates rapidly and flowers develop on the new stem parts **(Figure 37.8).** In nature, external cues such as increasing day length or warming after a cold snap stimulate gibberellin synthesis, and bolting occurs soon afterward. This observation supports the hypothesis that in rosette plants and possibly some others, gibberellins switch on internode lengthening

FIGURE 37.8 Bolting. This Haleakala silversword, one of 28 endangered tarweed species that evolved in the isolation of the Hawaiian Islands, grows only along the upper fringe of Maui's volcanic Haleakala Crater. The plants may grow in a compact rosette form for more than half a century before several weeks of bolting produce a tall floral shoot, as shown here. After flowering, the plant dies.

when environmental conditions favor a shift from vegetative growth to reproductive growth.

Beyond the effects just mentioned, in monoecious species (having flowers of both sexual types on the same plant), applications of a gibberellin seems to encourage proportionately more "male" flowers to develop. As a result, there may be more pollen available to pollinate "female" flowers and, eventually, more fruit produced.

Cytokinins Enhance Growth and Retard Aging

Cytokinins play a major role in stimulating cell division (hence the name, which refers to cytokinesis) and many of their effects appear to come about as they interact with auxins. They were first discovered during experiments designed to define the nutrient media required for plant tissue culture. Researchers found that in addition to a carbon source such as sucrose or glucose, minerals, and certain vitamins, cells in culture also required two other substances. One was auxin, which promoted the elongation of plant cells but did not stimulate the cells to divide. The other substance could be coconut milk, which is actually liquid endosperm, or it could be DNA that had been degraded into smaller molecules by boiling. When either was added to a culture medium along with an auxin, the cultured cells would begin dividing and grow normally.

We now know that the active ingredients in both boiled DNA and endosperm are cytokinins, which have a chemical structure similar to that of the nucleic acid base adenine. The most abundant natural cytokinin is zeatin, so-called because it was first isolated from the endosperm of young corn seeds *(Zea mays).* In endosperm, zeatin probably promotes the burst of cell division that takes place as a fruit matures. As you might expect, cytokinins also are abundant in the rapidly dividing meristem tissues of root and shoot tips. Cytokinins occur not only in flowering plants but also in many conifers, mosses, and ferns. They are also synthesized by many soil-dwelling bacteria and fungi and may be crucial to the growth of mycorrhizae, which help nourish thousands of plant species (see Section 35.3). Conversely, *Agrobacterium* and other microbes that cause plant tumors carry genes that regulate the production of cytokinins.

Cytokinins are synthesized mainly in root tips and apparently travel through the plant in xylem sap. Besides promoting cell division generally, they stimulate the growth of lateral buds and have other developmental and metabolic effects. For example, cytokinins promote expansion of young leaves (as leaf cells expand), cause chloroplasts to mature, and retard leaf aging. In concert with auxin they also coordinate the growth of roots and shoots. Investigators culturing tobacco tissues found that the relative amounts of auxin and a cytokinin strongly influenced not only growth, but also development, as illustrated in **Figure 37.9.**

Natural cytokinins can prolong the life of stored vegetables. Similar synthetic compounds are already widely used to prolong the shelf life of lettuces and mushrooms and to keep cut flowers fresh.

Ethylene Regulates Plant Aging and Some Other Responses

Most parts of a plant can produce **ethylene,** which is present in fruits, flowers, seeds, leaves, and roots and helps regulate a wide variety of plant physiological responses. Ethylene also is an unusual hormone, in part because it is structurally simple (see Table 37.1) and in part because it is a gas at normal temperature and pressure.

ETHYLENE AND PLANT SENESCENCE The aging of plant parts is termed **senescence.** Senescence is a closely controlled process of deterioration that leads to the death of plant cells. In autumn the leaves of deciduous trees senesce, often turning yellow or red as chlorophyll and proteins break down, allowing other pigments to become more noticeable. Ethylene triggers the expression of genes leading to the synthesis of chlorophyllases and proteases, enzymes that launch the breakdown process. In many plants, senescence is associated with **abscission,** the dropping of flowers, fruits, and leaves in response to environmental signals.

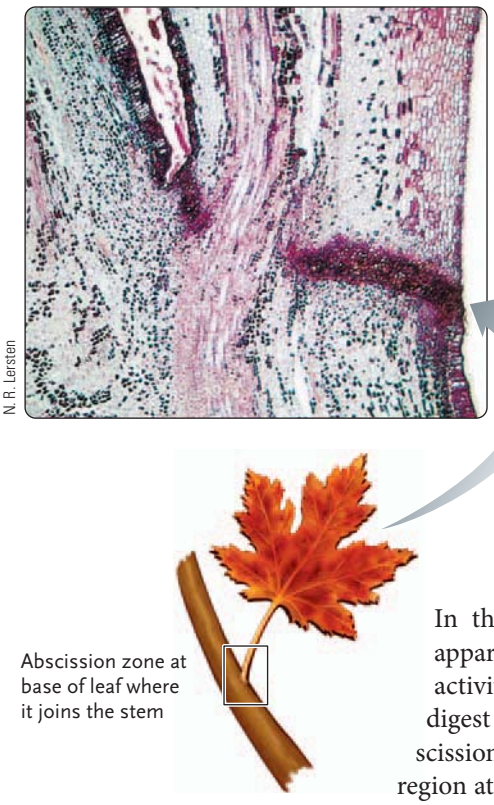

FIGURE 37.10
Abscission zone in a maple *(Acer).* This longitudinal section is through the base of the petiole of a leaf.
© Cengage Learning 2014

In this process, ethylene apparently stimulates the activity of enzymes that digest cell walls in an abscission zone—a localized region at the base of the petiole. The petiole detaches from the stem at that point **(Figure 37.10).**

Senescence appears to require a range of cues. For some species, the funneling of nutrients into reproductive parts may help to trigger senescence of leaves, stems, and roots. When the drain of nutrients is halted by removing each newly emerging flower or seed pod, a plant's leaves and stems stay green and vigorous much longer **(Figure 37.11).** Gardeners routinely remove flower buds from many plants to maintain vegetative growth. Evidence suggests that other cues are important, too. For instance, when a cocklebur is induced to flower under winterlike conditions, its leaves turn yellow regardless of whether the nutrient-demanding young flowers are left on or pinched off. It is as if a "death signal" forms that leads to flowering and senescence when there are fewer hours of daylight (typical of winter days). This observation underscores the general theme that many plant responses to the environment involve the interaction of multiple molecular signals.

FRUIT RIPENING: A FORM OF SENESCENCE Although the precise mechanisms are not well understood, ripening begins when a fruit starts to synthesize ethylene. The ripening process may involve the conversion of starch or organic acids to sugars, the softening of cell walls, or the rupturing of the cell membrane and loss of cell fluid. The same kinds of events occur in wounded plant tissues, which also synthesize ethylene.

Ethylene from an outside source can stimulate senescence responses, including ripening, when it binds to specific protein receptors on plant cells. The ancient Chinese observed that they could induce picked fruit to ripen faster by burning incense; later, it was found that the incense smoke contains ethylene.

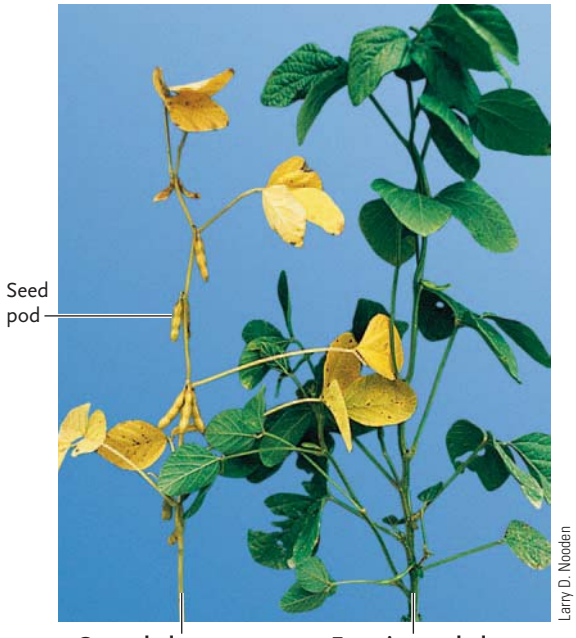

FIGURE 37.11 **Experimental results showing that the removal of seed pods from a soybean plant *(Glycine max)* delays its senescence.**

Today ethylene gas is widely used to ripen tomatoes, pineapples, bananas, honeydew melons, mangoes, papayas, and other fruit that has been picked and shipped while still green. Ripening fruit itself gives off ethylene, which is why placing a ripe banana in a closed sack of unripe peaches (or some other green fruit) often can cause the fruit to ripen. Oranges and other citrus fruits may be exposed to ethylene to brighten their rind. Conversely, limiting fruit exposure to ethylene can delay ripening. Apples will keep for months without rotting if they are exposed to a chemical that inhibits ethylene production or if they are stored in an environment that inhibits the hormone's effects—including low atmospheric pressure and a high concentration of CO_2, which may bind ethylene receptors.

Brassinosteroids Regulate Plant Growth Responses

The dozens of steroid hormones classed as **brassinosteroids** all appear to be vital for normal growth in plants, for they stimulate cell division and elongation in a wide range of plant-cell types. Confirmed as plant hormones in the 1980s, brassinosteroids now are the subject of intense research on their sources and effects. Although brassinosteroids have been detected in a wide variety of plant tissues and organs, the highest concentrations are found in shoot tips and in developing seeds and embryos—all examples of young, actively developing parts. In laboratory studies, the hormones have different effects depending on the tissue where they are active. They have promoted cell elongation, differentiation of vascular tissue, and elongation of a pollen tube after a flower is pollinated. By contrast, they inhibit the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

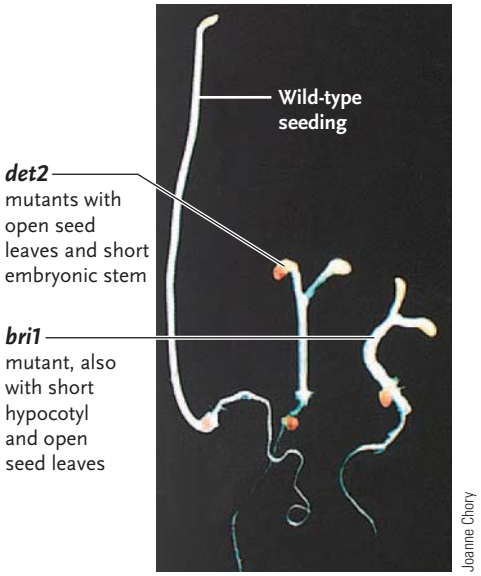

FIGURE 37.12 Experimental evidence that brassinosteroids can mediate a plant's responses to light by regulating gene expression. In *Arabidopsis,* wild-type seedlings synthesize a protein (encoded by the *DET2* gene) that prevents leaves from developing *(seedling at left)* until photosynthesis is possible, after the seedling breaks out of the dark environment of soil. When the gene is defective, a mutant *det2* plant *(center)* will develop a short hypocotyl (embryonic stem) and open seed leaves (cotyledons) even when there is no light for photosynthesis. Experiments with *bri1* mutants, which lack functioning receptors for a brassinosteroid, resulted in a similar phenotype *(right)*. These findings supported the hypothesis that a brassinosteroid is necessary for normal expression of the *DET2* gene.

elongation of roots. First isolated from pollen of a plant in the mustard family, *Brassica napus* (a type of canola), brassinosteroids seem to regulate the expression of genes associated with a plant's growth responses to light. This role was underscored by the outcomes of experiments using mutant *Arabidopsis* plants that were homozygous for a defective gene called *bri1* (for brassinosteroid-insensitive receptor) **(Figure 37.12).** The results provided convincing evidence that brassinosteroids mediate growth responses to light.

Abscisic Acid Suppresses Growth and Influences Responses to Environmental Stress

The hormone **abscisic acid** (ABA) has a variety of effects, many of which represent evolutionary adaptations to environmental challenges. Plants apparently synthesize ABA from carotenoid pigments inside plastids in leaves and possibly other plant parts. Several ABA receptors have been identified, and in general, we can group ABA effects into changes in gene expression that result in long-term inhibition of growth, and rapid, short-term physiological changes that are responses to immediate stresses, such as a lack of water, in a plant's surroundings. As its name suggests, at one time ABA was thought to play a central role in abscission. As already described, however, we now know that ethylene is the major abscission trigger.

FIGURE 37.13 Bud scales, here on the bud of a perennial cornflower *(Centaurea montana)*.

SUPPRESSING GROWTH IN BUDS AND SEEDS Operating as a counterpoint to growth-stimulating hormones like gibberellins, ABA inhibits growth in response to environmental cues, such as seasonal changes in temperature and light. This growth suppression can last for many months or even years. For example, one of ABA's major growth-inhibiting effects is apparent in perennial plants, in which the hormone promotes dormancy in leaf buds—an important adaptive advantage in places where winter cold can damage young leaves. If ABA is applied to a growing leaf bud, the bud's normal development stops, and instead protective *bud scales*—modified, nonphotosynthetic leaves that are small, dry, and tough—form around the apical meristem and insulate it from the elements **(Figure 37.13).** After the scales develop, most cell metabolic activity shuts down and the leaf bud becomes dormant.

In some plants that produce fleshy fruits, such as apples and cherries, abscisic acid is associated with the dormancy of seeds as well. As the seed develops, ABA accumulates in the seed coat, and the embryo does not germinate even if it becomes hydrated. The buildup of ABA in developing seeds does more than simply inhibit development, however. As early development draws to a close, ABA stimulates the transcription of certain genes, and large amounts of their protein products are synthesized. These proteins are thought to store nitrogen and other nutrients that the embryo will use when it eventually does germinate. Before such a seed can germinate, it usually will require a long period of cool, wet conditions, which stimulate the breakdown of ABA. Commercial growers often apply ABA and related growth inhibitors to plants slated to be shipped to plant nurseries. Dormant plants suffer less shipping damage, and the effects of the inhibitors can be reversed by applying a gibberellin.

RESPONSES TO ENVIRONMENTAL STRESS ABA also triggers plant responses to various environmental stresses, including cold snaps, high soil salinity, and drought. A great deal of research has focused on how ABA influences plant responses to a lack of water. When a plant is water-stressed, ABA helps prevent excessive water loss by stimulating stomata to close. As described in Section 33.3, flowering plants depend heavily on the proper

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

functioning of stomata. When a lack of water leads to wilting, mesophyll cells in wilted leaves rapidly synthesize and secrete ABA. The hormone diffuses to guard cells, where an ABA receptor binds it. Binding stimulates the release of K^+ and water from the guard cells, and within minutes the stomata close.

ABA's role in stomatal closure—triggered by water stress or some other environmental cue—begins when the hormone activates a receptor in the plant cell plasma membrane. Experiments have shown that this binding launches a complex sequence of events that transduce the hormone signal. In a first step, binding activates G proteins that in turn activate phospholipase C (see Figure 7.11). This enzyme then stimulates the synthesis of second messengers such as inositol triphosphate (IP_3). The second messenger diffuses through the cytoplasm and binds with calcium channels in structures such as the endoplasmic reticulum and tonoplast. Those channels then open, releasing calcium ions that activate protein kinases in the cytoplasm. In turn, these enzymes activate their target proteins by phosphorylating them. It's likely that the cellular response to ABA also involves cleaving phosphates needed for the phosphorylation step. Experiments have shown that an *Arabidopsis* mutant unable to respond to ABA lacks an enzyme that removes phosphate groups from certain proteins.

As described in Section 7.2, the original hormone signal is greatly amplified by a cascade of activated protein kinases, each one of which can activate a large number of target proteins. *Insights from the Molecular Revolution* highlights research filling in other steps in the ABA-induced response pathway.

Jasmonates and Oligosaccharins Regulate Growth and Function in Defense

In recent years, studies of plant growth and development have helped define the roles—or revealed the existence—of several other hormonelike compounds in plants. Like the well-established plant hormones just described, these substances are organic molecules, and only tiny amounts are required to alter some aspect of a plant's functioning. Some have long been known to exist in plants, but the extent of their signaling roles has only recently become better understood. This group includes **jasmonates** (JA), a family of about 20 compounds derived from fatty acids. Experiments with *Arabidopsis* and other plants have revealed numerous genes that respond to JA, including genes that help regulate root growth and seed germination. JA also appears to help plants "manage" stresses caused by deficiencies of certain nutrients (such as K^+). The JA family is best known, however, as part of the plant arsenal to limit damage by pathogens and predators, the topic of the following section.

Some other substances also are drawing keen interest from plant scientists, but because their signaling roles are still poorly understood they are not widely accepted as confirmed plant hormones. A case in point involves the complex carbohydrates that are structural elements in the cell walls of plants and some fungi. Several years ago, researchers observed that in some plants, some of these oligosaccharides could serve as signaling molecules. Such compounds were named **oligosaccharins,** and one of their known roles is to defend the plant against pathogens. In addition, oligosaccharins have been proposed as growth regulators that adjust the growth and differentiation of plant cells, possibly by modulating the influences of growth-promoting hormones such as auxin. At this writing, researchers in many laboratories are pursuing a deeper understanding of this curious subset of plant signaling molecules.

STUDY BREAK 37.1

1. **Which plant hormones promote growth and which inhibit it?**
2. **Give examples of how some hormones have both promoting and inhibiting effects on growth in different parts of the plant at different times of the life cycle.**
3. **Summarize the various ways that chemical signals reaching plant cells are converted to changes in cell functioning.**

THINK OUTSIDE THE BOOK

This section discussed several target tissues for auxin, including cells just below the apical meristem of a shoot part, young lateral meristems, and vascular cambium. Collaboratively or on your own, write a short explanation of why each of these tissues responds differently to the hormone. You may find it helpful to reread the introduction to Chapter 16, which gives an overview of some early events in development.

37.2 Plant Chemical Defenses

Plants do not have immune systems like those that have evolved in animals (the subject of Chapter 47), but higher plants have evolved an array of means for coping with biotic stressors in the environment. Over the millennia, virtually constant exposure to predation by herbivores and the onslaught of pathogens have resulted in a striking array of chemical defenses that ward off or reduce damage to plant tissues from infectious bacteria, fungi, worms, or plant-eating insects **(Table 37.2).** You will discover in this section that, as with the defensive strategies of animals, plant defenses include both general responses to any type of attack and specific responses to particular threats. Some get underway almost as soon as an attack begins, whereas others help promote the plant's long-term survival. And more often than not, multiple chemicals interact as the response unfolds.

Jasmonates and Other Compounds Interact in a General Response to Wounds

When an insect begins feeding on a leaf or some other plant part, the plant may respond to the resulting wound by launching what in effect is a cascade of chemical responses. These complex signaling pathways often rely on interactions among jasmonates, ethylene, or some other plant hormone. As the pathway unfolds

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Stressing Out in Plants and People

Recent molecular work shows that plant responses to stress imposed by drought and cold involve some of the same chemical steps in plants and humans, indicating an ancient link to a common evolutionary ancestor. The research may also point the way to genetic engineering strategies to modify major crop plants for earlier and better responses to stress, including drought.

Many stress responses in plants are triggered by the hormone abscisic acid (ABA). It has long been known that calcium ions increase in concentration in the cytoplasm when plant cells are exposed to ABA. Soon after the rise in Ca^{2+}, genes are activated that compensate for the stressful situation.

In the 1990s Nam-Hai Chua and his colleagues at the Rockefeller University and the University of Minnesota were interested in piecing together the molecular steps in the plant pathway. One substance they thought might be involved is *cyclic ADP-ribose (cADPR)*, a signaling molecule that was first implicated in calcium release pathways in animal cells.

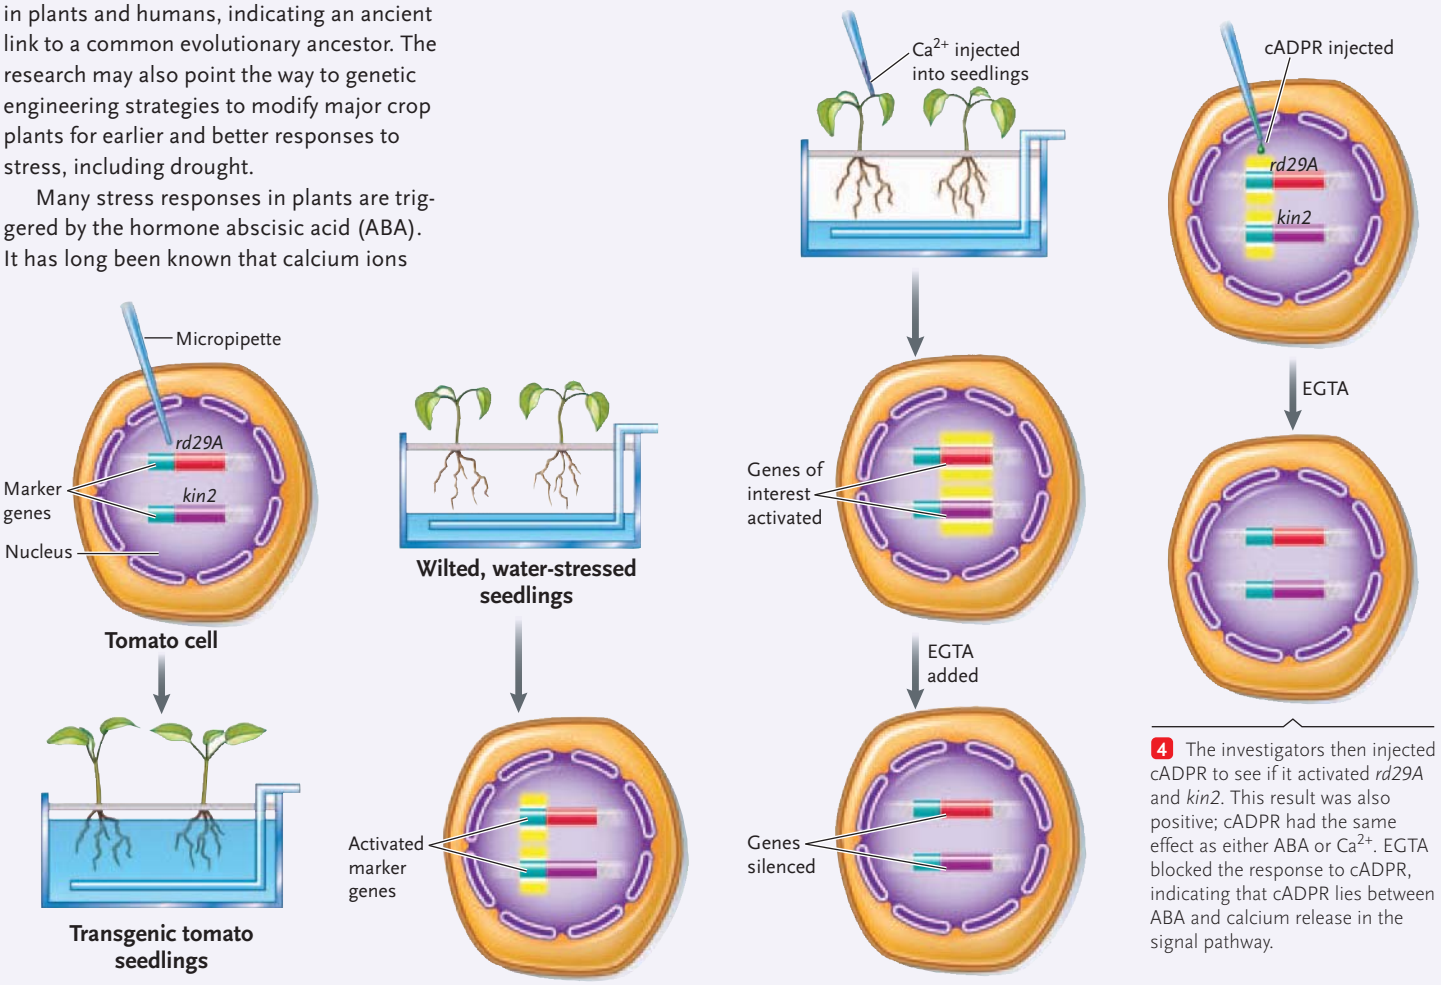

FIGURE Piecing together the role of cADPR in the plant response to water stress.

© Cengage Learning 2014

it triggers expression of genes leading to chemical and physical defenses at the wound site. For example, in some plants jasmonate induces a response leading to the synthesis of protease inhibitors, which disrupt an insect's capacity to digest proteins in the plant tissue. The protein deficiency in turn hampers the insect's growth and functioning.

A plant's capacity to recognize and respond to the physical damage of a wound apparently has been subject to strong selection pressure during plant evolution. When a plant is wounded experimentally, numerous defensive chemicals can soon be detected in its tissues. One of these, **salicylic acid,** or **SA** (a compound similar to aspirin, which is acetylsalicylic acid), seems to

Research Question

Is *cADPR* involved in the plant response to stress?

Experiments

In a series of experiments with tomato plants **(Figure),** the team demonstrated cADPR's role in the pathway.

Another experiment probed whether protein phosphorylation might be part of the pathway. To find out, the investigators injected an inhibitor of protein kinases, the enzymes that phosphorylate proteins as a part of many cellular response pathways. After the inhibitor was added, injecting ABA, cADPR, or Ca^{2+} failed to activate *rd29A* and *kin2,* indicating that protein phosphorylation is a crucial step following these elements in the pathway.

Conclusion

From these results the Chua team was able to reconstruct an important part of the pathway:

$$\text{ABA} \rightarrow ? \rightarrow \text{cADPR} \rightarrow Ca^{2+} \rightarrow \text{protein kinases} \rightarrow ? \rightarrow \text{stress gene activation}$$

The question marks indicate one or more unknowns, including the ABA receptor that carries out the first step in the response pathway. Studies of a recently identified ABA receptor called PYR/PYL/RCAR (after its major components) that is involved in the events that cause stomata to close (among other effects) are shedding further light on this process. Recent experiments showed that ABA binding to the PYR/PYL/RCAR receptor launches at least four responses in the cell: one that induces production of second messenger molecules, two others that regulate the movement of ions into or out of the cell, and a fourth that activates gene expression in the cell nucleus. The elucidation of this complex response marks a major advance in our understanding of ABA signaling.

Since the Chua team's research, we have also learned much more about signal pathways in animals in which cADPR plays a part. For example, a study by researchers in Italy found that certain human white blood cells released ABA as part of an inflammation response. These and other discoveries are helping fill in steps in both plant and animal responses, in pathways inherited from a common ancestor predating both plants and people.

THINK LIKE A SCIENTIST Is it likely that second messengers involved in ABA response pathways also reflect a common evolutionary heritage for plants and animals?

TABLE 37.2 Summary of Plant Chemical Defenses

Type of Defense	Effects
General Defenses	
Jasmonate (JA) responses to wounds/injury by pathogens; pathways often include other hormones such as ethylene	Synthesis of defensive chemicals such as protease inhibitors
Hypersensitive response to infectious pathogens (e.g., fungi, bacteria)	Physically isolates infection site by surrounding it with dead cells
PR (pathogenesis-related) proteins	Enzymes, other proteins that degrade cell walls of pathogens
Salicylic acid (SA)	Mobilized during other responses and independently; induces the synthesis of PR proteins, operates in systemic acquired resistance
Systemin (in tomato)	Triggers JA response
Secondary metabolites	
Phytoalexins	Antibiotic
Oligosaccharins	Trigger synthesis of phytoalexins
Systemic acquired resistance (SAR)	Long-lasting protection against some pathogens; components include SA and PR proteins that accumulate in healthy tissues
Specific Defenses	
Gene-for-gene recognition of chemical features of specific pathogens (by binding with receptors coded by R genes)	Triggers defensive response (e.g., hypersensitive response, PR proteins) against pathogens
Other	
Heat-shock responses (encoded by heat-shock genes)	Synthesis of chaperone proteins that reversibly bind other plant proteins and prevent denaturing caused by heat stress
"Antifreeze" proteins	In some species, stabilize cell proteins under freezing conditions

© Cengage Learning 2014

have multiple roles in plant defenses, including interacting with jasmonates.

Researchers are regularly discovering new variations of hormone-induced wound responses in plants. For example, experiments have elucidated some of the steps in an unusual pathway that thus far is known only in tomato *(Solanum lycopersicum)* and a few other plant species. As diagrammed in **Figure 37.14,** the wounded plant rapidly synthesizes **systemin,** the first peptide hormone to be discovered in plants. (Various animal hormones are peptides, a topic covered in Chapter 44.) Systemin enters the phloem and is transported throughout the plant. Although various details of the signaling pathway have

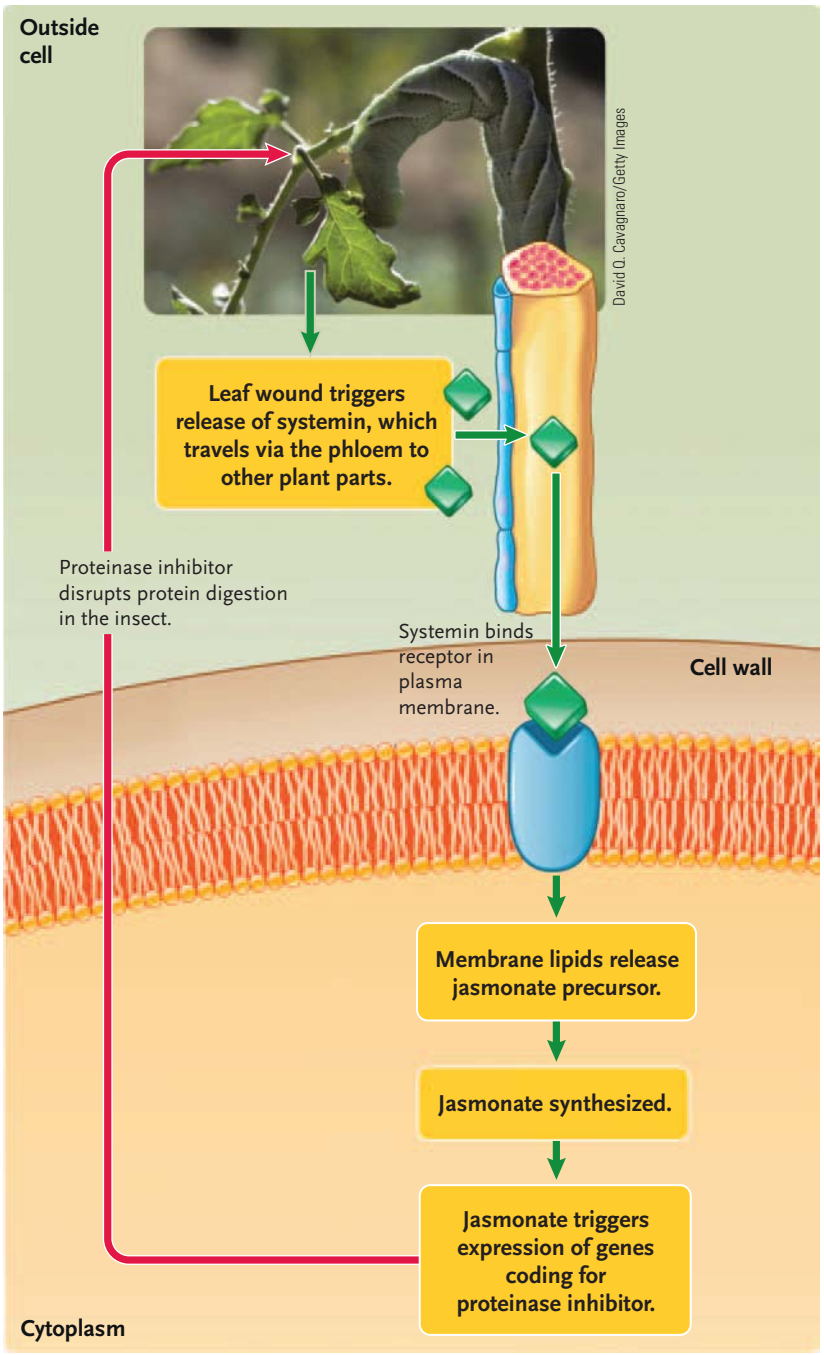

FIGURE 37.14 The systemin response to wounding. When a plant is wounded, it responds by releasing the protein hormone systemin. Transported through the phloem to other plant parts, in receptive cells systemin sets in motion a sequence of reactions that lead to the expression of genes encoding protease inhibitors—substances that can seriously disrupt an insect predator's capacity to digest protein.

© Cengage Learning 2014

yet to be worked out, when receptive cells bind systemin, their plasma membranes release a lipid that is the chemical precursor of jasmonate. Next jasmonate is synthesized, and it in turn sets in motion the expression of genes that encode protease inhibitors, which protect the plant against attack, even in parts remote from the original wound.

FIGURE 37.15 Evidence of the hypersensitive response. The dead brown spots on these leaves of a strawberry plant *(Fragaria)* are sites where a pathogen invaded, triggering the defensive destruction of the surrounding cells.

The Hypersensitive Response and PR Proteins Are Other General Defenses

Often, a plant that becomes infected by pathogenic bacteria or fungi counters the attack by way of a **hypersensitive response**—a defense that physically cordons off an infection site by surrounding it with dead cells. Initially, cells near the site respond by producing a burst of highly reactive oxygen-containing compounds (such as hydrogen peroxide, H_2O_2) that can break down nucleic acids, inactivate enzymes, or have other toxic effects on cells. The burst is catalyzed by enzymes in the plant cell's plasma membrane. It may begin the process of killing cells close to the attack site and, as the response advances, programmed cell death may also come into play. In short order, the "sacrificed" dead cells wall off the infected area from the rest of the plant. Thus denied an ongoing supply of nutrients, the invading pathogen dies. A common sign of a successful hypersensitive response is a dead spot surrounded by healthy tissue **(Figure 37.15).**

While the hypersensitive response is underway, salicylic acid triggers other defensive responses by an infected plant. One of its effects is to induce the synthesis of **pathogenesis-related proteins,** or **PR proteins.** Some PR proteins are hydrolytic enzymes that break down components of a pathogen's cell wall. Examples are chitinases that dismantle the chitin in the cell walls of fungi and so kill the cells. In some cases, plant cell receptors also detect the presence of fragments of the disintegrating wall and set in motion additional defense responses.

Secondary Metabolites Defend against Pathogens and Herbivores

Many plants counter bacteria and fungi by making **phytoalexins,** biochemicals of various types that function as antibiotics. When an infectious agent breaches a plant part, genes encoding phytoalexins begin to be transcribed in the affected tissue. For instance, when a fungus invades plant tissues, the enzymes it secretes may trigger the release of oligosaccharins. In addition to their roles as growth regulators (described in Section 37.1), these substances also can promote the production of phytoalexins, which have toxic effects on a variety of fungi. Plant tissues may also synthesize phytoalexins in response to attacks by viruses.

Phytoalexins are among many *secondary metabolites* produced by plants. Such substances are termed "secondary" because they are not routinely synthesized in all plant cells as part of basic metabolism. A wide range of plant species deploy secondary metabolites as defenses against feeding herbivores. Examples are alkaloids such as caffeine, cocaine, and the poison strychnine (in seeds of the *nux vomica* tree, *Strychnos nux-vomica*), tannins such as those in oak acorns, and various terpenes. The terpene family includes insect-repelling substances in cotton and the resins of conifers and the creosote bush, and essential oils produced by sage and basil plants. Because these terpenes are volatile—they easily diffuse out of the plant into the surrounding air—they also can provide indirect defense to a plant. Released from the wounds created by a munching insect, they attract other insects that prey on the herbivore. Chapter 54 looks in detail at the interactions between plants and herbivores.

Gene-for-Gene Recognition Allows Rapid Responses to Specific Threats

One of the most interesting questions with respect to plant defenses is how plants first sense that an attack is underway. In some instances plants apparently can detect an attack by a specific predator through a mechanism called **gene-for-gene recognition.** This term refers to a matchup between the products of dominant alleles of two types of genes: a so-called *R* **gene** (for "resistance") in a plant, and an *Avr* **gene** (for "avirulence") in a particular pathogen. Thousands of *R* genes have been identified in a wide range of plant species. Dominant *R* alleles confer enhanced resistance to plant pathogens including bacteria, fungi, and nematode worms that attack roots.

The basic mechanism of gene-for-gene recognition is simple: the dominant *R* allele encodes a receptor in plant cell plasma membranes, and the dominant pathogen *Avr* allele encodes a molecule that can bind the receptor. "Avirulence" implies that the pathogen becomes "not virulent" because binding of its Avr gene product triggers an immediate defense response in the plant. Trigger molecules run the gamut from proteins to lipids to carbohydrates that have been secreted by the pathogen or released from its surface **(Figure 37.16).** Experiments have demonstrated a rapid-fire sequence of early biochemical changes that follow binding of the *Avr*-encoded

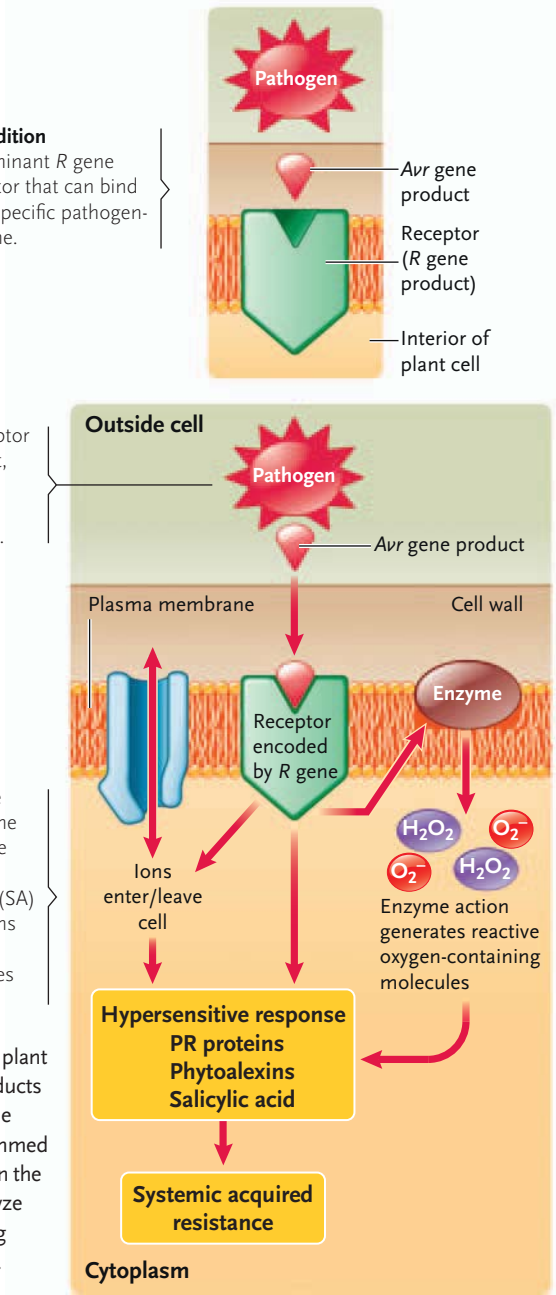

FIGURE 37.16 **Model of how gene-for-gene resistance may operate.** For resistance to develop, the plant must have a dominant *R* gene and the pathogen must have a corresponding dominant *Avr* gene. Products of such "matching" genes can interact physically, rather like the lock-and-key mechanism of an enzyme and its substrate. Most *R* genes encode receptors at the plasma membranes of plant cells. As diagrammed in step 1, when one of these receptors binds an *Avr* gene's product, the initial result may be changes in the movements of specific ions into or out of the cell and the activation of membrane enzymes that catalyze the formation of highly reactive oxygen-containing molecules. Such events help launch other signaling pathways that lead to a variety of defensive responses, including the hypersensitive response (step 2).

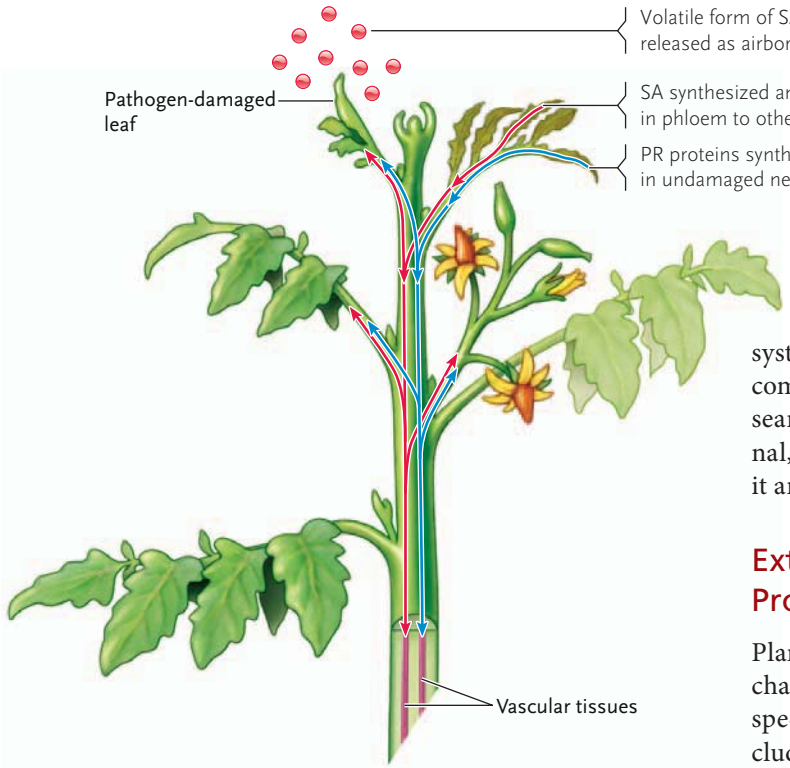

FIGURE 37.17 A proposed mechanism for systemic acquired resistance. When a plant successfully fends off a pathogen, the defensive chemical salicylic acid (SA) is transported in the phloem to other plant parts, where it may help protect against another attack by stimulating the synthesis of PR proteins. In addition, the plant synthesizes and releases a slightly different, more volatile form of SA called methyl salicylate. It may serve as an airborne signal to other parts of the plant as well as to neighboring plants.

© Cengage Learning 2014

molecule; these include changes in ion concentrations inside and outside plant cells and the production of biologically active oxygen compounds that heralds the hypersensitive response. In fact, of the instances of gene-for-gene recognition plant scientists have observed thus far, most trigger the hypersensitive response and the ensuing synthesis of PR proteins, with their antibiotic effects.

Systemic Acquired Resistance Can Provide Long-Term Protection

The defensive response to a microbial invasion may spread throughout a plant, so that the plant's healthy tissues become less vulnerable to infection. This phenomenon is called **systemic acquired resistance,** and experiments using *Arabidopsis* plants have shed light on how it comes about **(Figure 37.17).** In a key early step, salicylic acid builds up in the affected tissues. By some route, probably through the phloem, the SA passes from the infected organ to newly forming organs such as leaves, which begin to synthesize PR proteins—again, providing the plant with a "home-grown" antimicrobial arsenal. How does the SA exert this effect? It seems that when enough SA accumulates in a plant cell's cytoplasm, a regulatory protein called NPR-1 (for *n*onexpressor of *p*athogenesis-*r*elated genes) moves from the cytoplasm into the cell nucleus. There it interacts with factors that promote the transcription of genes encoding PR proteins.

In addition to synthesizing SA that will be transported to other tissues by a plant's vascular system, the damaged leaf also synthesizes a chemically similar compound, methyl salicylate. This substance is volatile, and researchers speculate that it may serve as an airborne "harm" signal, promoting defense responses in the plant that synthesized it and possibly in nearby plants as well.

Extremes of Heat and Cold Also Elicit Protective Chemical Responses

Plant cells also contain **heat-shock proteins (HSPs),** a type of chaperone protein (see Section 3.4) found in cells of many species. In general, HSPs bind and stabilize other proteins, including enzymes, which might otherwise stop functioning if they were to become denatured by rising temperature. Plant cells may rapidly synthesize HSPs in response to various stimuli, including a sudden temperature rise. For example, experiments with cells and seedlings of soybean *(Glycine max)* showed that when the temperature rose 10°C to 15°C, in less than 5 min smRNA transcripts coding for as many as 50 different HSPs were present in cells. When the temperature returns to a normal range, HSPs release bound proteins, which can then resume their usual functions. Further studies have revealed that heat-shock proteins help protect plant cells subjected to other environmental stresses as well, including drought, salinity, and cold.

Like extreme heat, freezing can also be lethal to plants. If ice crystals form in cells they can literally tear the cell apart. In many cold-resistant species, dormancy (discussed in Section 37.4) is the long-term strategy for dealing with cold, but in the short term, such as an unseasonable cold snap, some species also undergo a rapid shift in gene expression that equips cold-stressed cells with so-called antifreeze proteins. Like heat-shock proteins, these molecules are thought to help maintain the structural integrity of other cell proteins.

STUDY BREAK 37.2

1. **Which plant chemical defenses are general responses to attack, and which are specific to a particular pathogen?**
2. **Why is salicylic acid considered to be a general systemic response to damage?**
3. **How is the hypersensitive response integrated with other chemical defenses?**

THINK OUTSIDE THE BOOK

Experiments by a team at Pennsylvania State University in State College have provided evidence that dodder (*Cuscuta* spp.; see Figure 35.10), a parasitic weed, uses airborne chemical cues to locate suitable host plants. The findings have added fuel to an ongoing debate about the extent to which airborne molecules may serve as a "language" that also operates in plant defenses. Research this topic and summarize the various arguments for and against the existence of "chemical crosstalk" among plants.

37.3 Plant Movements

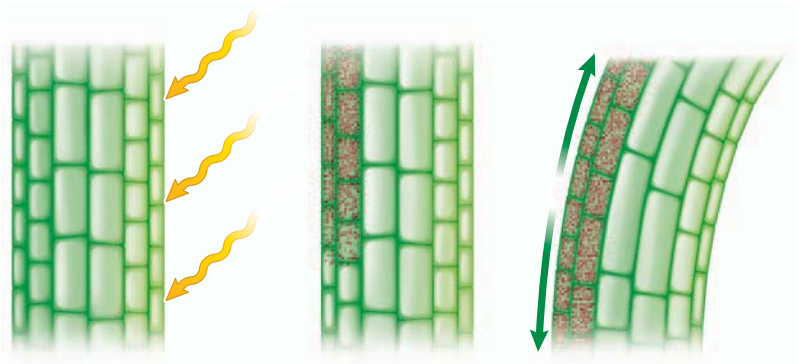
Although a plant cannot move from place to place as external conditions change, plants do alter the orientation of their body parts in response to environmental stimuli. As noted earlier in the chapter, growth toward or away from a unidirectional stimulus, such as light or gravity, is called a tropism. Tropic movement involves permanent changes in the plant body because cells in particular areas or organs grow differentially in response to the stimulus. Plant physiologists do not fully understand how tropisms occur, but they are fascinating examples of the complex abilities of plants to adjust to their environment. This section will also touch on two other kinds of movements—developmental responses to physical contact, and changes in the position of plant parts that are not related to the location of the stimulus.

Phototropisms Are Responses to Light

Light is a key abiotic stimulus for many kinds of organisms. Phototropisms, which we have already discussed in the section on auxins, are growth responses to a directional light source. As the Darwins discovered, if light is more intense on one side of a stem, the stem may curve toward the light **(Figure 37.18A).** Phototropic movements are extremely adaptive for photosynthesizing organisms because they help maximize the exposure of photosynthetic tissues to sunlight.

How do auxins influence phototropic movements? In a coleoptile that is illuminated from one side, IAA moves by polar transport into the cells on the shaded side **(Figure 37.18B–D).** Phototropic bending occurs because cells on the shaded side elongate more rapidly than do cells on the illuminated side.

The main stimulus for phototropism is light of blue wavelengths. Experiments on corn coleoptiles have shown that a large, yellow pigment molecule called phototropin can absorb blue wavelengths, and it may play a role in stimulating the initial lateral transport of IAA to the dark side of a shoot tip. Studies with *Arabidopsis* suggest there is more than one blue-light receptor, however. One is a light-absorbing protein called **cryptochrome,** which is sensitive to blue light and may also be an important early step in the various light-based growth responses. As you will read later, cryptochrome appears to have a role in other plant responses to light as well.



Gravitropism Orients Plant Parts to the Pull of Gravity

Plants show growth responses to Earth's gravitational pull, a phenomenon called **gravitropism.** After a seed germinates, the primary root curves down, toward the "pull" (positive gravitropism), and the shoot curves up (negative gravitropism).

Several hypotheses seek to explain how plants respond to gravity. The most widely accepted hypothesis proposes that plants detect gravity much as animals do—that is, particles called **statoliths** in certain cells move in the direction gravity pulls them. In the semicircular canals of human ears, calcium carbonate crystals serve as statoliths; in most plants the statoliths are amyloplasts, modified plastids that contain starch grains (see Section 5.4). In eudicot angiosperm stems, amyloplasts often are present in one or two layers of cells just outside the vascular bundles. In monocots such as cereal grasses, amy-

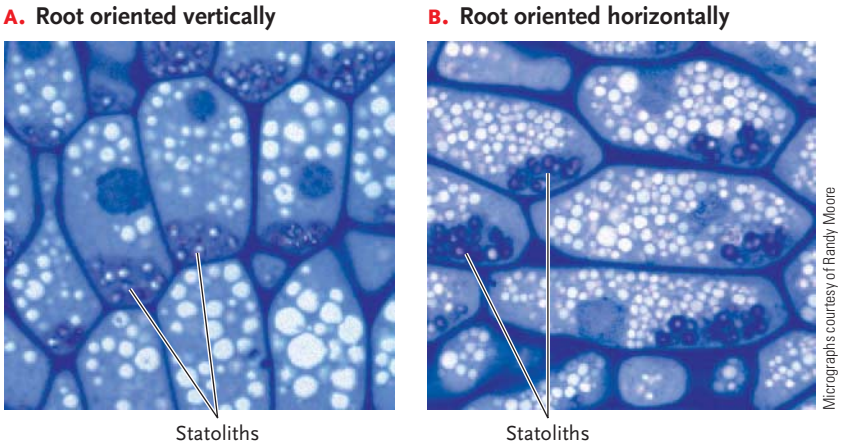

FIGURE 37.19 Evidence that supports the statolith hypothesis. When a corn root was laid on its side, amyloplasts—statoliths—in cells from the root cap settled to the bottom of the cells within 5 to 10 min. Statoliths may be part of a gravity-sensing mechanism that redistributes auxin through a root tip.

FIGURE 37.20 Gravitropism in corn seedlings. The two corn grains shown here were oriented in opposite directions with respect to gravity. Regardless, the primary root of each one grew downward through the soil and each stem grew upward.

loplasts are located in a region of tissue near the base of the leaf sheath. In roots, amyloplasts occur in the root cap. If the spatial orientation of a plant cell is shifted experimentally, its amyloplasts sink through the cytoplasm until they come to rest at the bottom of the cell **(Figure 37.19).**

How do amyloplast movements translate into an altered growth response? The full explanation appears to be complex, and there is evidence that somewhat different mechanisms operate in stems and in roots. In stems, the sinking of amyloplasts may provide a mechanical stimulus that triggers a gene-guided redistribution of IAA. For example, when a potted sunflower seedling is turned on its side in a dark room, within 15 to 20 minutes cell elongation decreases markedly on the upper side of the growing horizontal stem, but increases on the lower side. With the adjusted growth pattern, the stem curves upward, even in the absence of light. Using different types of tests, researchers have been able to document the shifting of IAA from the top to the bottom side of the stem. The changing auxin gradient correlates with the altered pattern of cell elongation.

In roots, a high concentration of auxin has the opposite effect—it inhibits cell elongation. If a root is placed on its side, amyloplasts in the root cap accumulate near the side wall that now is the bottom side of the cap. This shift stimulates cell elongation in the opposite wall, and within a few hours the root once again curves downward. In root tips of many plants, however, especially eudicots, researchers could not detect a change in IAA concentration that correlates with the changing position of amyloplasts. Eventually experiments on gravitropism in soybean *(Glycine max)* root tips suggested that the IAA signal is transduced by way of a signal cascade. The hormone induces the accumulation of nitric oxide (NO) at the downward side of the root tip, where NO in turn appears to induce activity cGMP. This second messenger then delivers the original IAA signal. The sequence inhibits the elongation of cells on the tip's downward side, so the root curves downward.

Along with IAA, calcium ions (Ca^{2+}) appear to play a major role in gravitropism. For example, if Ca^{2+} is added to an otherwise untreated agar block that is then placed on one side of a root cap, the root will bend toward the block. In this way, experimenters have been able to manipulate the direction of growth so that the elongating root forms a loop. Similarly, if an actively bending root is deprived of Ca^{2+}, the gravitropic response abruptly stops. By contrast, the negative gravitropic response of a shoot tip is inhibited when the tissue is exposed to excess calcium.

Just how Ca^{2+} interacts with IAA in gravitropic responses is unknown. One hypothesis posits that calcium functions as an activator. Calcium binds to a small protein called *calmodulin,* activating it in the process. Activated calmodulin in turn can activate a variety of key cell enzymes in many organisms, both plants and animals. One possibility is that calcium-activated calmodulin stimulates cell membrane pumps that enhance the flow of both IAA and calcium through a gravity-stimulated plant tissue.

Some of the most active research in plant biology focuses on the intricate mechanisms of gravitropism **(Figure 37.20).** For example, there is increasing evidence that in many plants, cells in different regions of stem tissue differ in their sensitivity to IAA, and that gravitropism is linked in some fundamental way to these differences. In a few plants, including some cultivated varieties of corn and radish, the direction of the gravitropic response by a seedling's primary root is influenced by light. Clearly there is much more to be learned.

Thigmotropism and Thigmomorphogenesis Are Responses to Physical Contact

Varieties of peas, grapes, and some other plants demonstrate **thigmotropism** (*thigma* = touch), which is growth in response to contact with a solid object. Thigmotropic plants typically have long, slender stems and cannot grow upright without physical support. They often have *tendrils,* modified stems or leaves that can rapidly curl around a fencepost or the sturdier stem of a neighboring plant. If one side of a grape vine stem grows against a trellis, for example, specialized epidermal cells on that side of the stem tendril shorten whereas cells on the other side

of the tendril rapidly elongate. Within minutes the tendril starts to curl around the trellis, forming tight coils that provide strong support for the vine stem. **Figure 37.21** shows thigmotropic twisting in the passionflower *(Passiflora)*. Auxin and ethylene may be involved in thigmotropism, but most details of the mechanism remain elusive.

The rubbing and bending of stems caused by frequent strong winds, rainstorms, grazing animals, and even farm machinery can inhibit the overall growth of plants and can alter their growth patterns. In this phenomenon, called **thigmomorphogenesis,** a stem stops elongating and instead adds girth when it is regularly subjected to mechanical stress. Merely shaking some plants daily for a brief period will inhibit their upward growth, but although such plants may be shorter, their thickened stems will be stronger. Thigmomorphogenesis helps explain why plants growing outdoors are often shorter, have somewhat thicker stems, and are not as easily blown over as plants of the same species grown indoors. Trees growing near the snowline of windswept mountains show an altered growth pattern that reflects this response to wind stress.

Research on the cellular mechanisms of thigmomorphogenesis has begun to yield tantalizing clues. In one study, investigators repeatedly sprayed *Arabidopsis* plants with water and imposed other mechanical stresses, then sampled tissues from the stressed plants. The samples contained as much as double the usual amount of mRNA for at least four genes, which had been activated by the stress. The mRNAs encoded calmodulin and several other proteins that may have roles in altering *Arabidopsis* growth responses. The test plants were also short, generally reaching only half the height of unstressed controls.

Nastic Movements Are Nondirectional

Tropisms are responses to directional stimuli, such as light striking one side of a shoot tip, but many plants also exhibit **nastic movements** (*nastos* = pressed close together)—reversible responses to nondirectional stimuli, such as mechanical pressure or humidity. We see nastic movements in leaves, leaflets, and even flowers. For instance, certain plants exhibit nastic sleep movements, holding their leaves (or flower petals) in roughly horizontal positions during the day but folding them closer to the stem at night **(Figure 37.22).** Tulip flowers "go to sleep" in this way.

Many nastic movements are temporary and result from changes in cell turgor. For example, the daily opening and closing of stomata in response to changing light levels are nastic movements, as is the traplike closing of the lobed leaves of the Venus flytrap when an insect brushes against hairlike sensory structures on the leaves. The leaves of *Mimosa pudica,* the sensitive plant, also close in a nastic response to mechanical pressure. Each *Mimosa* leaf is divided into pairs of leaflets **(Figure 37.23A).** Touching even one leaflet at the leaf tip triggers a chain reaction in which each pair of leaflets closes up within seconds **(Figure 37.23B).**

In many turgor-driven nastic movements, water moves into and out of the cells in **pulvini** (*pulvinus* = cushion), thickened pads of tissue at the base of a leaf or petiole. Stomatal movements depend on changing concentrations of ions within guard cells, and pulvinar cells drive nastic leaf movements in *Mimosa* and numerous other plants by the same mechanism **(Figure 37.23C).**

How is the original stimulus transferred from cells in one part of a leaf to cells elsewhere? The answer lies in the polarity of charge across cell plasma membranes (see Section 6.4). Touching a *Mimosa* leaflet triggers an **action potential**—a brief reversal in the polarity of the membrane charge. When an action potential occurs at the plasma membrane of a pulvinar cell, the change in polarity causes potassium ion (K^+) channels to open, and ions flow out of the cell, setting up an osmotic gradient that draws water out as well. As water leaves by osmosis, turgor pressure falls, pulvinar cells become flaccid, and the leaflets move together. Later, when the process is reversed, the pulvinar cells regain turgor and the leaflets spread apart. Action potentials travel between parenchyma cells in the pulvini via plasmodesmata at the rate of about 2 cm/sec. Animal nerves conduct similar changes in membrane polarity along their plasma membranes (see Chapter 40). These changes in polarity, which are also called action potentials, occur much more rapidly—at velocities between 1 and 100 m/sec.

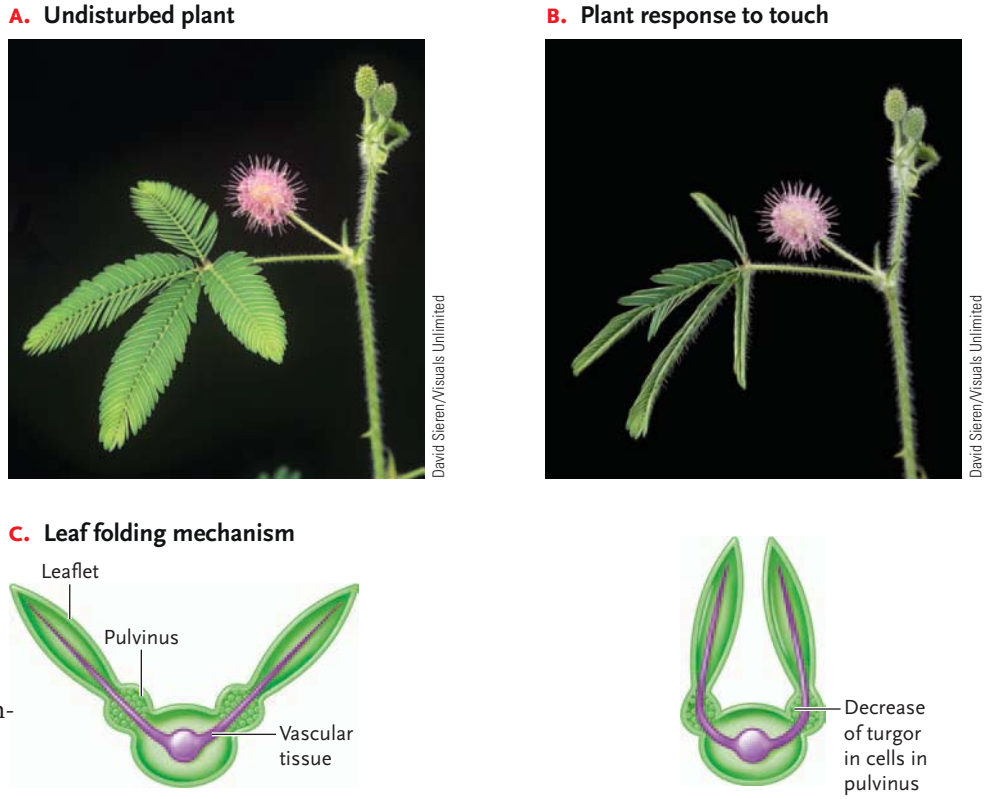

FIGURE 37.23 **Nastic movements in leaflets of *Mimosa pudica*, the sensitive plant. (A)** In an undisturbed plant the leaflets are open. If a leaflet near the leaf tip is touched, changes in turgor pressure in pulvini at the base cause the leaf to fold closed. **(B, C).** The diagram sketches this folding movement in cross section. Other leaflets close in sequence as action potentials transmit the stimulus along the leaf.
© Cengage Learning 2014

Stimuli other than touch also can trigger action potentials leading to nastic movements. Cotton, soybean, sunflower, and some other plants display *solar tracking*, nastic movements in which leaf blades are oriented toward the east in the morning, then steadily change their position during the day, following the sun across the sky. Such movements maximize the amount of time that leaf blades are perpendicular to the sun, which is the angle at which photosynthesis is most efficient.

STUDY BREAK 37.3

1. What is the direct stimulus for phototropism? For gravitropism?
2. Explain how nastic movements differ from tropic movements.

37.4 Plant Biological Clocks

Like all eukaryotic organisms, plants have internal time-measuring mechanisms called **biological clocks** that adapt the organism to recurring environmental changes. In plants biological clocks help adjust both daily and seasonal activities.

Circadian Rhythms Are Based on 24-Hour Cycles

Some plant activities occur regularly in cycles of about 24 hours, even when environmental conditions remain constant. These are **circadian rhythms** (*circa* = around, *dies* = day). In Chapter 33, we noted that stomata open and close on a daily cycle, even when plants are kept in total darkness. Nastic sleep movements, described earlier, are another example of a circadian rhythm. Even when a plant that exhibits such movements is kept in constant light or darkness for a few days, it folds its leaves into the "sleep" position at roughly 24-hour intervals. In some way, the plant measures time without sunrise (light) and sunset (darkness). Such experiments demonstrate that internal controls, rather than external cues, largely govern circadian rhythms.

Circadian rhythms and other activities regulated by a biological clock help ensure that plants of a single species do the same thing, such as flowering, at the same time. For instance, flowers of the aptly named four-o'clock plant *(Mirabilis jalapa)* open predictably every 24 hours—in nature, in the late afternoon. Such coordination can be crucial for successful pollination. Although some circadian rhythms can proceed without direct stimulus from light, many biological clock mechanisms are influenced by the relative lengths of day and night.

Photoperiodism Involves Seasonal Changes in the Relative Length of Night and Day

Obviously, environmental conditions in a 24-hour period are not the same in summer as they are in winter. In North America, for instance, winter temperatures are cooler and winter day length is shorter. Experimenting with tobacco and soybean plants in the early 1900s, two American botanists, Wightman Garner and Henry Allard, elucidated a phenomenon they called **photoperiodism,** in which plants respond to changes in the relative lengths of light and dark periods in their environment during each 24-hour period. Through photoperiodism, the biological clocks of plants (and animals) make seasonal adjustments in their patterns of growth, development, and reproduction.

In plants, we now know that a family of blue-green pigments collectively called **phytochrome** often serves as a switching mechanism in the photoperiodic response, signaling the plant to make seasonal changes. Plants synthesize phytochrome in an in active form, P_r, which absorbs light of shorter wavelengths (about 660 nm) at the "red" end of the spectrum (see Figure 9.4). Sunlight contains relatively more red light than far-red light, which has a longer wavelength (about 730 nm). During

© Cengage Learning 2014

daylight hours when red wavelengths dominate, P_r absorbs red light. Absorption of red light triggers the conversion of phytochrome to an active form designated P_{fr}, which absorbs light of far-red wavelengths. At sunset, at night, or even in shade, where far-red wavelengths predominate, P_{fr} reverts to P_r **(Figure 37.24).**

In nature a high concentration of P_{fr} "tells" a plant that it is exposed to sunlight. The plant's ability to sense sunlight is vital given that over time sunlight provides favorable conditions for leaf growth, photosynthesis, and flowering. The exact mechanism of this crucial transfer of environmental information still is not fully understood. Phytochrome activation may stimulate plant cells to take up Ca^{2+} ions, or it may induce certain plant organelles to release them. Either way, when free calcium ions combine with calcium-binding proteins (such as calmodulin) they may initiate at least some responses to light. Botanists suspect that P_{fr} controls the types of enzymes being produced in particular cells—and different enzymes are required for seed germination, stem elongation and branching, leaf expansion, and the formation of flowers, fruits, and seeds. When plants adapted to full sunlight are grown in darkness, they put more resources into stem elongation and less into leaf expansion or stem branching **(Figure 37.25).**

Cryptochrome—which, recall, is sensitive to blue light and appears to influence light-related growth responses—also interacts with phytochromes in producing circadian responses. Researchers have recently discovered that cryptochrome occurs not only in plants but also in animals such as fruit flies and mice. Does it act as a circadian photoreceptor in both kingdoms? Only further study will provide the answer.

Natural Sciences Image Library/Visuals Unlimited

FIGURE 37.25 Effects of the absence of light on young bean plants *(Phaseolus).* The seedling on the left was grown in darkness for several days. Its leaves are yellow because it could form carotenoids but not chlorophyll in darkness. It also has a larger stem, smaller leaves, and a smaller root system than the seedling on the right, which was grown in the light.

Cycles of Light and Dark Often Influence Flowering

Photoperiodism is especially apparent in the flowering process. Like other plant responses, flowering is often keyed to changes in day length through the year and to the resulting changes in environmental conditions. Corn, soybeans, peas, and other annual plants begin flowering after only a few months of growth. Roses and other perennials typically flower every year or after several years of vegetative growth. Carrots, cabbages, and other biennials typically produce roots, stems, and leaves the first growing season, die back to soil level in autumn, then grow a new flower-forming stem the second season.

In the late 1930s, Karl Hamner and James Bonner grew cocklebur plants *(Xanthium strumarium)* in chambers in which the researchers could carefully control environmental conditions, including photoperiod. And they made an unexpected discovery: flowering occurred only when the test plants were exposed to a single night of 8.5 hours of uninterrupted darkness. The length of the "day" in the growth chamber did not matter, but if light interrupted the dark period for even a minute or two, the plant would not flower at all. Subsequent research confirmed that for most angiosperms, it is the length of darkness, not light, that controls flowering.

KINDS OF FLOWERING RESPONSES The photoperiodic responses of flowering plants are so predictable that botanists have long used them to categorize plants **(Figure 37.26).** The categories, which refer to day length, reflect the fact that scientists recognized the phenomenon of photoperiodic flowering responses long before they understood that darkness, not light, was the cue. **Long-day plants,** such as irises, daffodils, and

corn, usually flower in spring when dark periods become shorter and day length becomes longer than some critical value—usually 9 to 16 hours. **Short-day plants,** including cocklebur, chrysanthemums, and potatoes, flower in late summer or early autumn when dark periods become longer and day length becomes shorter than some critical value. **Intermediate-day plants,** such as sugarcane, flower only when day length falls in between the values for long-day and short-day plants. **Day-neutral plants,** such as dandelions and roses, flower whenever they become mature enough to do so, without regard to photoperiod.

Experiments demonstrate what happens when plants are grown under the "wrong" photoperiod regimes. For instance, spinach, a long-day plant, flowers and produces seeds only if it is exposed to no more than 10 hr of darkness each day for 2 weeks (see Figure 37.26). **Figure 37.27** illustrates the results of an experiment to test the responses of short-day and long-day plants to night length. In this experiment, bearded iris plants (*Iris* species), which are long-day plants, and chrysanthemums, which are short-day plants, were exposed to a range of light conditions. In each case, when the researchers interrupted a critical dark period with a pulse of red light, the light reset the plants' clocks. The experiment provided clear evidence that short-day plants flower only when nights are longer than a critical value—and long-day plants flower only when nights are shorter than a critical value.

CHEMICAL SIGNALS FOR FLOWERING When photoperiod conditions are right, what sort of chemical message stimulates a plant to develop flowers? In the 1930s botanists began postulating the existence of "florigen," a hypothetical hormone that served as the flowering signal. In a somewhat frustrating scientific quest, researchers spent the rest of the twentieth century seeking this substance in vain. Recently, however, molecular studies using *Arabidopsis* plants have defined a sequence of steps that may collectively provide the internal stimulus for flowering. Here again, we see one of the recurring themes in plant development—major developmental changes guided by several interacting genes.

Figure 37.28 traces the steps of the proposed flowering signal. To begin with, a gene called *CONSTANS* is expressed in a plant's leaves in tune with the daily light/dark cycle, with expression peaking at dusk (step 1). The gene encodes a regulatory protein called CO (not to be confused with carbon monoxide). As days lengthen in spring, the concentration of CO rises in leaves, and as a result a second gene is activated (step 2). The product of this gene, a regulatory protein called FT (for Flowering locus T), travels in the phloem to shoot tips (step 3). Once there, FT interacts with a second regulatory protein (step 4) that is synthesized only in shoot apical meristems (step 5). The encounter apparently sparks the development of a flower by promoting the expression of floral organ identity genes in the meristem tissue (see Section 36.5). Key experiments that uncovered this pathway all relied on analysis of DNA microarrays, a technique introduced in Section 19.3 and featured in this chapter's *Focus on Basic Research*.

VERNALIZATION AND FLOWERING Flowering is more than a response to changing night length. Temperatures also change with the seasons in most parts of the world, and they too influence flowering. For instance, unless buds of some biennials and perennials are exposed to low winter temperatures, flowers do not form on stems in spring. Low-temperature stimulation of flowering is called **vernalization** ("making springlike").

In 1915 the plant physiologist Gustav Gassner demonstrated that it was possible to influence the flowering of cereal plants by controlling the temperature of seeds while they were germinating. In one case, he maintained germinating seeds of

winter rye *(Secale cereale)* at just above freezing (1°C) before planting them. In nature, winter rye seeds in soil germinate during the winter, giving rise to a plant that flowers months later, in summer. Plants grown from Gassner's test seeds, however, flowered the same summer even when the seeds were planted in the late spring. Home gardeners can induce flowering of daffodils and tulips by putting the bulbs (technically, *corms*) in a freezer for several weeks before early spring planting. Commercial growers use vernalization to induce millions of plants, such as Easter lilies, to flower just in time for seasonal sales.

Dormancy Is an Adaptation to Seasonal Changes or Stress

As autumn approaches and days grow shorter, growth slows or stops in many plants even if temperatures are still moderate, the sky is bright, and water is plentiful. When a perennial or biennial plant stops growing under conditions that seem (to us) quite suitable for growth, it has entered a state of **dormancy.** Ordinarily, its buds will not resume growth until early spring.

Short days and long nights—conditions typical of winter—are strong cues for dormancy. In one experiment, in which a short period of red light interrupted the long dark period for

R. J. Downs

FIGURE 37.29 **Effect of the relative length of day and night on the growth of Douglas firs *(Pseudotsuga menziesii)*.** The young tree at the left was exposed to alternating periods of 12 hours of light followed by 12 hours of darkness for a year; its buds became dormant because day length was too short. The tree at the right was exposed to a cycle of 20 hours of light and 4 hours of darkness; its buds remained active and growth continued. The middle plant was exposed each day to 12 hours of light and 11 hours of darkness, with a 1-hour light in the middle of the dark period. This light interruption of an otherwise long dark period also prevented buds from going dormant.

Using DNA Microarray Analysis to Track Down "Florigen"

The more plant scientists learn about plant genomes, the more they are relying on DNA microarray assays to elucidate the activity of plant genes.

Recall from Section 19.3 that a DNA microarray, also called a DNA chip, allows an investigator to explore questions such as how the expression of a particular gene differs in different types of cells. This procedure can be manipulated to reveal the relative amounts of expression of more than one of a cell's genes.

Philip A. Wigge and his colleagues used this method to learn more about the signaling pathway that causes a plant's apical meristem to give rise to flowers. Previous research had established that in leaves, lengthening spring days coincided with rising concentrations of CO, a regulatory protein encoded by the *CONSTANS* gene. But what did CO regulate? Working with *Arabidopsis thaliana,* Wigge's group was able to narrow down the field to four genes, and using microarray analysis of DNA from leaf cells they pinpointed one called FT (for flowering locus T). The researchers found that in leaves, CO causes strong expression of FT: when enough CO is present, FT mRNA is rapidly transcribed, then enters the phloem. (The transport of mRNA in phloem is not unusual.) By contrast, when they tested CO's effects in shoot apex cells, they found that it triggers far less gene expression there. Clearly, CO was not directly triggering the development of flowers. However, FT mRNA moves in the phloem to the shoot apex, where it is translated into protein. Was that protein the direct flowering signal? Other studies had implicated a regulatory protein called FD, which microarray analysis had shown was expressed *only*—but very strongly—in the shoot apex.

To sort out this final piece of the puzzle, the Wigge team examined flowering responses in normal *A. thaliana* plants as well as in mutants having a normal FT protein but a defective *fd,* and vice versa. Flowering was abnormal in both types of mutants, possibly because the mutated "partner" suppressed some aspect of the functioning of the normal protein. On the other hand, in wild-type plants, which had a functioning FD protein, expression of FT triggered a marked increase in the expression of the floral organ gene *APETALA1* **(Figure).** These results have two major implications. First, they support the hypothesis that FT and FD interact in a normal flowering response. Second, the study suggests that FT, the CO-induced signal from leaves, conveys the environmental signal that it is time for a plant to flower. In that sense, FT may be the long sought "florigen." However, only by interacting with FD does FT "know" where to deliver its flowering signal—in the apical meristems of shoots.

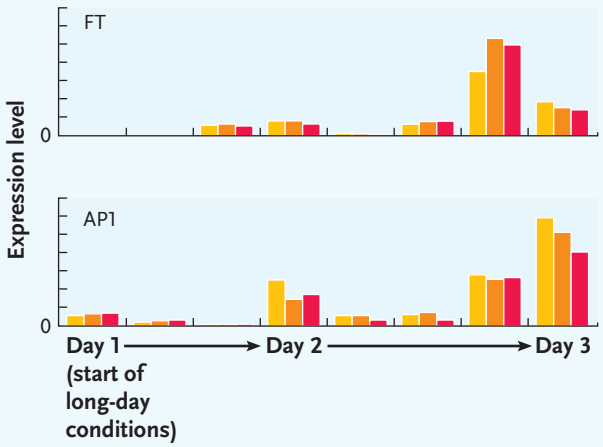

FIGURE Effect of the FT protein on expression of the *APETALA1 (AP1)* floral organ identity gene. In nature, *Arabidopsis thaliana* is a long-day plant, and the experiment was carried out under long-day (that is, short-night) conditions. Three groups of replicates shown here in yellow, orange, and red respectively, were monitored for both AP1 and FT. After a brief delay, the expression of AP1 closely tracked the appearance of the FT regulatory protein, which had been activated by its interaction with the FD protein.

FIGURE 37.30 Effect of cold temperature on dormant buds of a lilac *(Syringa vulgaris).* In this experiment, a lilac plant was grown in winter inside a warm greenhouse with one branch extending through a hole to the outdoors. Only the buds on the branch exposed to low outside temperatures resumed growth in spring. This experiment suggests that low-temperature effects are localized in plants.

Douglas firs, the plants responded as if nights were shorter and days were longer; they continued to grow taller **(Figure 37.29).** Conversion of P_r to P_{fr} by red light during the dark period prevented dormancy. In nature, buds may enter dormancy because less P_{fr} can form when day length shortens in late summer. Other environmental cues are at work also. Cold nights, dry soil, and a deficiency of nitrogen apparently also promote dormancy.

The requirement for multiple dormancy cues has adaptive value. For example, if temperature were the only cue, plants might flower and seeds might germinate in warm autumn weather—only to be killed by winter frost.

A dormancy-breaking process is at work between fall and spring. Depending on the species, breaking dormancy probably involves gibberellins and abscisic acid, and it requires exposure to low winter temperatures for specific periods **(Figure 37.30).** The temperature needed to break dormancy

varies greatly among species. For example, the Delicious variety of apples grown in Utah requires 1,230 hours near 43°F (6°C); apricots grown there require only 720 hours at that temperature. Generally, trees growing in the southern United States or in Italy require less cold exposure than those growing in Canada or in Sweden.

STUDY BREAK 37.4

1. **Summarize the switching mechanism that operates in plant responses to changes in photoperiod.**
2. **Give some examples of how relative lengths of dark and light can influence flowering.**
3. **Explain why dormancy is an adaptive response to a plant's environment.**

UNANSWERED QUESTIONS

How does the plant genome respond to the external environment?

Genome size across the plant kingdom can vary more than 1,000-fold. For instance, the genome of *Arabidopsis thaliana* runs about 125 million base pairs (bp), that of *Pinus taeda,* the loblolly pine, roughly 21 billion bp. Even more remarkably, genome size can vary markedly among individuals of the same species. Among inbred maize *(Zea mays)* plants, for example, the genome size of different individuals may vary by as much as 30%.

What molecular mechanisms underlie these genomic changes? In my laboratory at Case Western Reserve University, my coworkers and I have spent more than three decades investigating this question, examining environmentally induced heritable changes in flax *(Linum)*. Certain flax varieties respond to specific environmental stresses by physically restructuring specific portions of their genome, with the variant genomes being stably transmitted over many generations. Fortunately, the changes occur within a single generation and therefore can be readily tracked. We now know, for example, that the genomic changes occur in the vegetative apical meristem. This tissue is where all new growth occurs, and it also gives rise to the cells (in flowers) that ultimately produce flax gametes. This means that the environment can act as a selective agent to establish advantageous variants that may then be transmitted to the next generation.

We have identified one DNA fragment of interest—*Linum* insertion sequence-1 (LIS-1)—and followed it as responsive flax varieties grow in different environments. LIS-1 is assembled while the plant is growing under inducing conditions and is then (or simultaneously) inserted into a specific genome site with very high frequency. Under the inducing growth conditions, this event occurs in all the test plants, and all their progeny inherit the altered genomic site. Under different conditions, although the insertion occasionally occurs, none of the progeny inherit the altered site. Some other regions of the genome also frequently alter, but in our experiments only insertion of LIS-1 is strongly associated with a specific change in the plant's environment.

The high frequency with which LIS-1 arises and is transmitted to progeny in one environment but not others accords with a hypothesis that the insertion is directly adaptive or is closely linked to an adaptive change. Not all stresses result in the same genomic rearrangements, and the particular genome regions that are restructured under a particular stress are related to the physiological effects of that stress. We are currently investigating the complete genome sequences of the original and induced lines to identify the variable loci and will be using the genome reorganization to point us toward a molecular mechanism. We are also looking at intermediates that may be formed during the induction of the changes. Elucidating these and related mechanisms in flax can help clarify some basic questions—including whether genetic adaptations to stress are an integrated genome-wide reconfiguration rather than single gene mutations. We will also better understand the precise circumstances under which a stressful environment can trigger rapid, limited restructuring of a plant genome. And finally, such studies may also reveal how a stress can then act as the selective force determining which genome variations are transmitted into the next generation.

THINK LIKE A SCIENTIST

1. How does genome reconfiguration differ from mutation systems that normally operate in plants?
2. Given data on environmentally induced heritable changes in flax, how might plant scientists need to modify their thinking about the role of the environment as a mutagen, rather than simply as a selective agent?

Christopher A. Cullis

Christopher A. Cullis is the Frances Hobart Herrick Professor of Biology at Case Western Reserve University. His research focuses on the mechanisms by which DNA within the cell can change rapidly, particularly in response to external stimuli. He uses flax as a model organism and is interested in developing a flax genome project. Learn more about his research at www.case.edu/artsci/biol/people/cullis.html.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

37.1 Introduction to Plant Hormones

- Hormones and environmental stimuli alter the behavior of target cells, which have receptors to which signal molecules can bind. By means of a response pathway that transduces the hormone signal, a signal can induce changes in the cell's shape or internal structure or influence its metabolism or the transport of substances across the plasma membrane (Figures 37.1 and 37.2).
- Some plant hormones and growth factors may bind to receptors at the target cell's plasma membrane, changing the receptor's shape. This binding often triggers the release of internal second messengers that diffuse through the cytoplasm and provide a chemical signal that alters gene expression.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Second messengers usually act by way of a reaction sequence that amplifies the cell's response to a signal. The sequence activates a series of proteins, including G proteins and enzymes that stimulate the synthesis of second messengers (such as IP_3) that bind ion channels on endoplasmic reticulum. Binding releases calcium ions, which enter the cytoplasm and activate protein kinases, enzymes that activate specific proteins that produce the cell response.
- At least seven classes of hormones govern flowering plant development, including germination, growth, flowering, fruit set, and senescence (Table 37.1).
- Auxins, mainly IAA, promote elongation of cells in the coleoptile and stem among other effects (Figures 37.3–37.6).
- Gibberellins promote stem elongation and help seeds and buds break dormancy (Figures 37.7 and 37.8).
- Cytokinins stimulate cell division, promote leaf expansion, and retard leaf aging (Figure 37.9).
- Ethylene promotes senescence, as well as fruit ripening and abscission (Figures 37.10 and 37.11).
- Brassinosteroids stimulate cell division and elongation (Figure 37.12).
- Abscisic acid (ABA) promotes stomatal closure and may trigger seed and bud dormancy (Figure 37.13).
- Jasmonates regulate growth and have roles in defense.

Animation: Auxin's effects

37.2 Plant Chemical Defenses

- Plants have diverse chemical defenses that limit damage from bacteria, fungi, worms, or plant-eating insects (Figure 37.14).
- The hypersensitive response isolates an infection site by surrounding it with dead cells (Figure 37.15).
- Oligosaccharins can trigger the synthesis of phytoalexins, secondary metabolites that function as antibiotics.
- Gene-for-gene recognition enables a plant to chemically recognize a specific pathogen and mount a defense (Figure 37.16).
- Systemic acquired resistance provides long-term protection against some pathogens. Salicylic acid has a central role in this response (Figure 37.17).
- Heat-shock proteins can reversibly bind enzymes and other proteins in plant cells and prevent them from denaturing when the plant is under certain types of stress.
- Some plants can synthesize "antifreeze" proteins that stabilize cell proteins when cells are threatened with freezing.

37.3 Plant Movements

- Plants adjust their growth patterns in response to environmental rhythms and unique environmental circumstances. These responses include tropisms.
- Phototropisms, mainly stimulated by blue light, are growth responses to a directional light source. (Figure 37.18).
- Gravitropism is a growth response to Earth's gravitational pull. Stems exhibit negative gravitropism (growing upward) whereas roots show positive gravitropism (Figures 37.19 and 37.20).
- Some plants or plant parts demonstrate thigmotropism, growth in response to contact with a solid object (Figure 37.21). Mechanical stress can cause thigmomorphogenesis, which causes the stem to add girth.
- Some plant species show nastic leaf movements in response to certain environmental cues. Changes in fluid pressure in cells of a pulvinus, a pad of tissue at the base of a leaf or petiole, cause the movements (Figures 37.22 and 37.23).

Animation: Rhythmic leaf movements

37.4 Plant Biological Clocks

- Plants have biological clocks, internal time-measuring mechanisms with a biochemical basis. Environmental cues can "reset" the clocks, enabling plants to make seasonal adjustments in growth, development, and reproduction.
- In photoperiodism, plants respond to a change in the relative length of daylight and darkness in a 24-hour period. A switching mechanism involving the pigment phytochrome promotes or inhibits germination, growth, and flowering and fruiting (Figure 37.24).
- Long-day plants flower when day length is long relative to night. Short-day plants flower when day length is relatively short, and intermediate-day plants flower when day length falls in between the values for long-day and short-day plants. Flowering of day-neutral plants is not regulated by light. In vernalization, a period of low temperature stimulates flowering (Figures 37.25–37.27).
- The direct trigger for flowering may begin in leaves, when the regulatory protein CO triggers the expression of the FT gene. The resulting mRNA transcripts move in phloem to apical meristems where translation of the mRNAs yields a second regulatory protein, which in turn interacts with a third. This final interaction activates genes that encode the development of flower parts (Figure 37.28).
- Senescence is the sum of processes leading to the death of a plant or plant structure.
- Dormancy is a state in which a perennial or biennial stops growing even though conditions appear to be suitable for continued growth (Figures 37.29 and 37.30).

Animation: Flowering response experiments

UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following plant hormones does *not* stimulate cell division?
   a. auxins
   b. cytokinins
   c. ethylene
   d. gibberellins
   e. abscisic acid

2. Which is the correct pairing of a plant hormone and its function?
   a. salicylic acid: triggers synthesis of general defense proteins
   b. brassinosteroids: promote responses to environmental stress
   c. cytokinins: stimulate stomata to close in water-stressed plants
   d. gibberellins: slow seed germination
   e. ethylene: promotes formation of lateral roots

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

3. A characteristic of auxin (IAA) transport is:
   a. IAA moves by polar transport from the base of a tissue to its apex.
   b. IAA moves laterally from a shaded to an illuminated side of a plant.
   c. IAA enters a plant cell in the form of IAAH, an uncharged molecule that can diffuse across cell membranes.
   d. IAA exits one cell and enters the next by means of transporter proteins clustered at both the apical and basal ends of the cells.
   e. All of the above are characteristics of auxin transport in different types of cells.
4. Hanging wire fruit baskets have many holes or open spaces. The major advantage of these spaces is that they:
   a. prevent gibberellins from causing bolting or the formation of rosettes on the fruit.
   b. allow the evaporation of ethylene and thus slow ripening of the fruit.
   c. allow oxygen in the air to stimulate the production of ethylene, which hastens the abscission of fruits.
   d. allow oxygen to stimulate brassinosteroids, which hasten the maturation of seeds in/on the fruits.
   e. allow carbon dioxide in the air to stimulate the production of cytokinins, which promotes mitosis in the fruit tissue and hastens ripening.
5. Which of the following is *not* an example of a plant chemical defense?
   a. ABA inhibits leaves from budding if conditions favor attacks by sap-sucking insects.
   b. Jasmonate activates plant genes encoding protease inhibitors that prevent insects from digesting plant proteins.
   c. Acting against fungal infections, the hypersensitive response allows plants to produce highly reactive oxygen compounds that kill selected tissue, thus forming a dead tissue barrier that walls off the infected area from healthy tissues.
   d. Chitinase, a PR hydrolytic protein produced by plants, breaks down chitin in the cell walls of fungi and thus halts the fungal infection.
   e. Attack by fungi or viruses triggers the release of oligosaccharins, which in turn stimulate the production of phytoalexins having antibiotic properties.
6. Which of the following statements about plant responses to the environment is true?
   a. The heat-shock response induces a sudden halt to cellular metabolism when an insect begins feeding on plant tissue.
   b. In gravitropism, amyloplasts sink to the bottom of cells in a plant stem, causing the redistribution of IAA.
   c. The curling of tendrils around a twig is an example of thigmotropism.
   d. Phototropism results when IAA moves first laterally, then downward in a shoot tip when one side of the tip is exposed to light.
   e. Nastic movements, such as the sudden closing of the leaves of a Venus flytrap, are examples of a plant's ability to respond to specific directional stimuli.
7. In nature the poinsettia, a plant native to Mexico, blooms only in or around December. This pattern suggests:
   a. The long daily period of darkness (short day) in December stimulates the flowering.
   b. Vernalization stimulates the flowering.
   c. The plant is dormant for the rest of the year.
   d. Phytochrome is not affecting the poinsettia flowering cycle.
   e. A circadian rhythm is in effect.
8. Which of the following steps is *not* part of the sequence that is thought to trigger flowering?
   a. Cycles of light and dark stimulate the expression of the *CONSTANS* gene in a plant's leaves.
   b. CO proteins accumulate in the leaves and trigger expression of a second regulatory gene.
   c. mRNA transcribed during expression of a second regulatory gene moves via the phloem to the shoot apical meristem.
   d. Interactions among regulatory proteins promote the expression of floral organ identity genes in meristem tissue.
   e. CO proteins in the floral meristem interact with florigen, a so-called flowering hormone, which provides the final stimulus for expression of floral organ identity genes.
9. Damage from an infectious bacterium, fungus, or worm may trigger a plant defensive response when the pathogen or a substance it produces binds to:
   a. a receptor encoded by the plant's *avirulence (Avr)* gene.
   b. an *R* gene in the plant cell nucleus.
   c. a receptor encoded by a dominant R gene.
   d. PR proteins embedded in the plant cell plasma membrane.
   e. salicylic acid molecules released from the besieged plant cell.
10. In the sequence that unfolds after molecules of a hormone such as ABA bind to receptors at the surface of a target plant cell:
   a. first messenger molecules in the cytoplasm are mobilized, then G proteins carry the signal to second messengers such as protein kinases, which alter the activity of cell proteins such as IP_3.
   b. binding activates G proteins, which in turn activate second messengers such as IP_3; subsequent steps are thought to involve activation of genes that encode protein kinases.
   c. binding activates phospholipase C, which in turn activates G proteins, which then activate molecules of IP_3, a step that leads to the synthesis of protein kinases.
   d. binding stimulates G proteins to activate protein kinases, which then bind calcium channels in ER; the flux of calcium ions activates second messenger molecules that alter the activity of cell proteins or enter the cell nucleus and alter the expression of target genes.
   e. binding activates G proteins, which in turn activate phospholipase C; this substance then stimulates the synthesis of second messenger molecules, the second messengers bind calcium channels in the cell's ER, and finally protein kinases alter the activity of proteins by phosphorylating them.

Discuss the Concepts

1. You work for a plant nursery and are asked to design a special horticultural regimen for a particular flowering plant. The plant is native to northern Spain, and in the wild it grows a few long, slender stems that produce flowers each July. Your boss wants the nursery plants to be shorter, with thicker stems and more branches, and she wants them to bloom in early December in time for holiday sales. Outline your detailed plan for altering the plant's growth and reproductive characteristics to meet these specifications.
2. Synthetic auxins such as 2,4-D can be weed killers because they cause an abnormal growth burst that kills the plant within a few days. Suggest reasons why such rapid growth might be lethal to a plant.
3. In some plant species, an endodermis is present in both stems and roots. In experiments, the shoots of mutant plants lacking differentiated endodermis in their root and shoot tissue do not respond normally to gravity, but roots of such plants do respond normally. Explain this finding, based on your reading in this chapter.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

4. In *A. thaliana* plants carrying a mutation called *pickle (pkl),* the primary root meristem retains characteristics of embryonic tissue—it spontaneously regenerates new embryos that can grow into mature plants. However, when the mutant root tissue is exposed to a gibberellin (GA), this abnormal developmental condition is suppressed. Explain why this finding suggests that additional research is needed on the fundamental biological role of GA.

Design an Experiment

Tiny, thornlike trichomes on leaves are a common plant adaptation to ward off insects. Those trichomes develop very early on, as outgrowths of a seedling's epidermal cells. Biologists have observed, however, that many mature plants develop more leaf trichomes after the fact, as a *response* to insect damage. Researchers at the University of Chicago decided to study this phenomenon, and specifically wanted to determine the effects, if any, of jasmonate, salicylic acid, and gibberellin in stimulating trichome development. Keeping in mind that plant hormones often interact, how many separate experiments, at a minimum, would the research team have had to carry out to obtain useful initial data? Do you suppose they used mutant plants for some or all of the tests? Why or why not?

Interpret the Data

Jennifer Nemhauser, Todd Mockler, and Joanne Chory at the Plant Biology Laboratory of the Salk Institute for Biological Studies performed experiments to learn more about the interaction of auxin and brassinosteroids (BR) in regulating the growth of *Arabidopsis* seedlings. In a 2004 research report on this work, graphics for displaying experimental data included the Venn diagram shown here **(Figure).** Venn diagrams are useful for giving a snapshot of the interrelationships between sets of data, often using overlapping circles. In this diagram, "up" and "down" refer to hormone effects that stimulate or inhibit gene expression. The numerals in each circle represent numbers of seedlings.

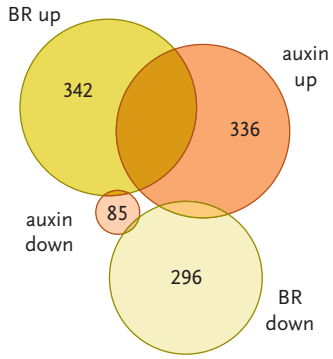

FIGURE Venn diagram showing the overlap between *Yucca* genes responsive to auxin and BR.

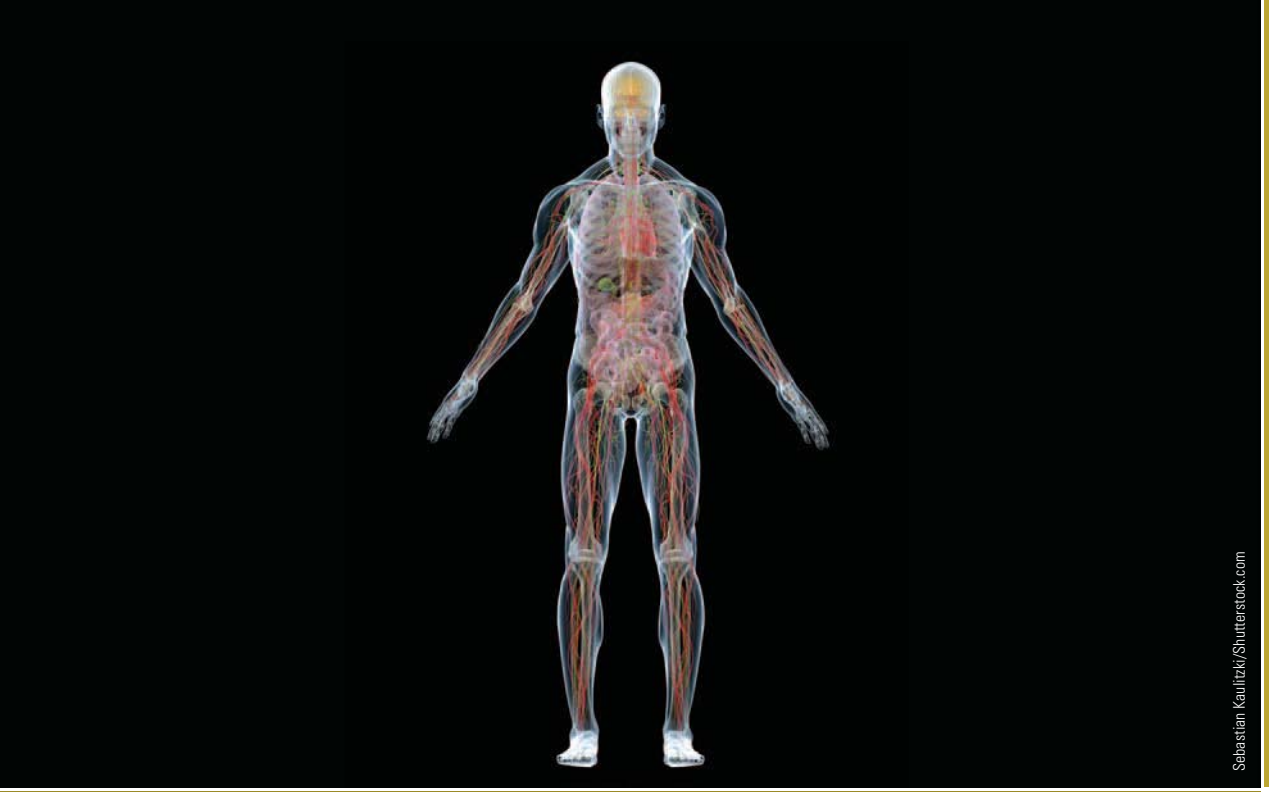
Nemhauser JL, Mockler TC, Chory J (2004) Interdependency of Brassinosteroid and Auxin Signaling in Arabidopsis. PLoS Biol 2(9): e258. Doi:10.1371/journal.pbio.0020258.



1. Considering the two upper overlapping circles, what general finding do the data support?
2. Describe at least two other general findings summarized in the diagram.
3. Why isn't there any overlap between the "up" and "down" bubbles for each hormone?

Source: J. Nemhauser, T. Mockler, and J. Chory. 2004. Interdependency of brassinosteroids and auxin in *Arabidopsis* seedling growth. *PLoS Biology* 2:1460–1471.

Apply Evolutionary Thinking

Cryptochrome occurs in plants and animals. If it was inherited from their shared ancestor, what other major groups of organisms might also have it?

STUDY OUTLINE

38.1 Organization of the Animal Body

38.2 Animal Tissues

38.3 Coordination of Tissues in Organs and Organ Systems

38.4 Homeostasis

Introduction to Animal Organization and Physiology

Why it matters . . . On April 10, 1912, the RMS *Titanic* left Southampton, England, on her maiden voyage, bound for New York. A total of 2,223 people were on board, including 899 crew. Four days out, near midnight, the ship hit an iceberg. Some parts of the hull buckled, and rivets popped out below the waterline. As a result, the *Titanic* began to take on water. The captain ordered passengers and crew to the lifeboats. The ship's lifeboats could hold a maximum of 1,178 people, far fewer than the number of people on board. Two hours and forty minutes after striking the iceberg, the *Titanic* sank. Of the people on board, 1,517 died, most of them succumbing to hypothermia in the −2°C water. At that temperature, death likely occurred within 15 minutes. *Hypothermia* is a condition in which the core temperature of the body falls significantly below normal for a prolonged period. In humans, a drop in core temperature of a few degrees affects brain function and leads to confusion; continued hypothermia, as in the case of the *Titanic,* can lead to death.

Human body temperature is normally regulated within a narrow range so as to provide optimal conditions for cellular life. Body temperature is just one aspect of an animal's internal environment that must be regulated. The maintenance of the internal environment in a relatively stable state is called **homeostasis** (*homeo* = similar; *stasis* = standing or stopping). The processes and activities responsible for homeostasis are called **homeostatic control systems.** These control systems compensate both for the external environmental changes that a human or other animal encounters, such as differences in temperature and humidity, and for changes in their own body systems, such as the availability of nutrients for cells and tissues. As we saw for the unfortunate *Titanic* passengers and crew, the homeostatic control systems for temperature regulation are limited in their ability to maintain the stable state, after which they break down. Not only can animals die from hypothermia after prolonged exposure to the cold, they can also die from hyper-

thermia after prolonged exposure to excessive heat. Similarly, an imbalance between energy input (in the form of nutrients) and energy output can be lethal.

All animals have body systems for acquiring and digesting nutrients to provide energy for life, growth, reproduction, and movement. Other body systems seen in animals include the nervous system, endocrine system, muscular system, integumentary system, circulatory system, lymphatic system, respiratory system, excretory system, and reproductive system. Biologists are interested in the *structures* and *functions* of all of these systems. **Anatomy** is the study of the *structures* of organisms, and **physiology** is the study of their *functions*—the physicochemical processes of organisms.

In this unit, the structures and functions of the body systems of animals are discussed. In this introductory chapter to animal organization and physiology, we describe the organization of individual cells into tissues, organs, and organ systems, the major body structures that carry out animal activities. Our discussion continues with a look at how the functions of organ systems coordinate to accomplish homeostasis. The other chapters in this unit discuss the structures and functions of individual organ systems. Although the unit emphasizes vertebrates, with particular reference to human physiology, comparisons are made with invertebrates, to keep the structural and functional diversity of the animal kingdom in perspective and to understand the evolution of the structures and functions involved.

38.1 Organization of the Animal Body

The individual cells of animals must be surrounded by an aqueous solution that contains ions and molecules in particular concentrations to maintain osmotic balance and to supply energy and maintenance needs. Most animal cells also require oxygen to serve as the final acceptor for electrons removed in oxidative reactions. Also, waste molecules and other by-products of their metabolic activities, such as carbon dioxide, need to be released from the cells.

The evolution of multicellularity (see Section 25.3) made it possible for organisms to create an **internal environment** of fluid that supplies all the needs of individual cells so that multicellular organisms are able to occupy a wider range of **external environments** than is possible for single-celled organisms. For instance, dry terrestrial habitats likely would be lethal to single-celled organisms. Multicellular organisms can also become relatively large because their individual cells remain small enough to exchange ions and molecules with the internal fluid.

The evolution of multicellularity also allowed major life functions to be subdivided among specialized groups of cells. In animals, some groups of cells became specialized for movement, others for functions such as food capture, digestion, internal circulation of nutrients, excretion of wastes, and reproduction. Specialization greatly increases the efficiency by which animals carry out these functions.

In most animals, specialized groups of cells are organized into tissues, the tissues into organs, and the organs into organ systems **(Figure 38.1).** A **tissue** is a group of cells with the same structure and function, working together as a unit to carry out one or more specialized activities; four types of tissues are shown in the figure. An **organ** integrates two or more different tissues into a structure that carries out a specific function. The eye, liver, and stomach are examples of organs. An **organ system** (also called a **body system**) coordinates the activities of two or more organs to carry out a major body function such as movement, digestion, or reproduction. The nervous system, for example, is the main regulatory system of the body and consists of the brain, spinal cord, peripheral nerves, and sensory organs.

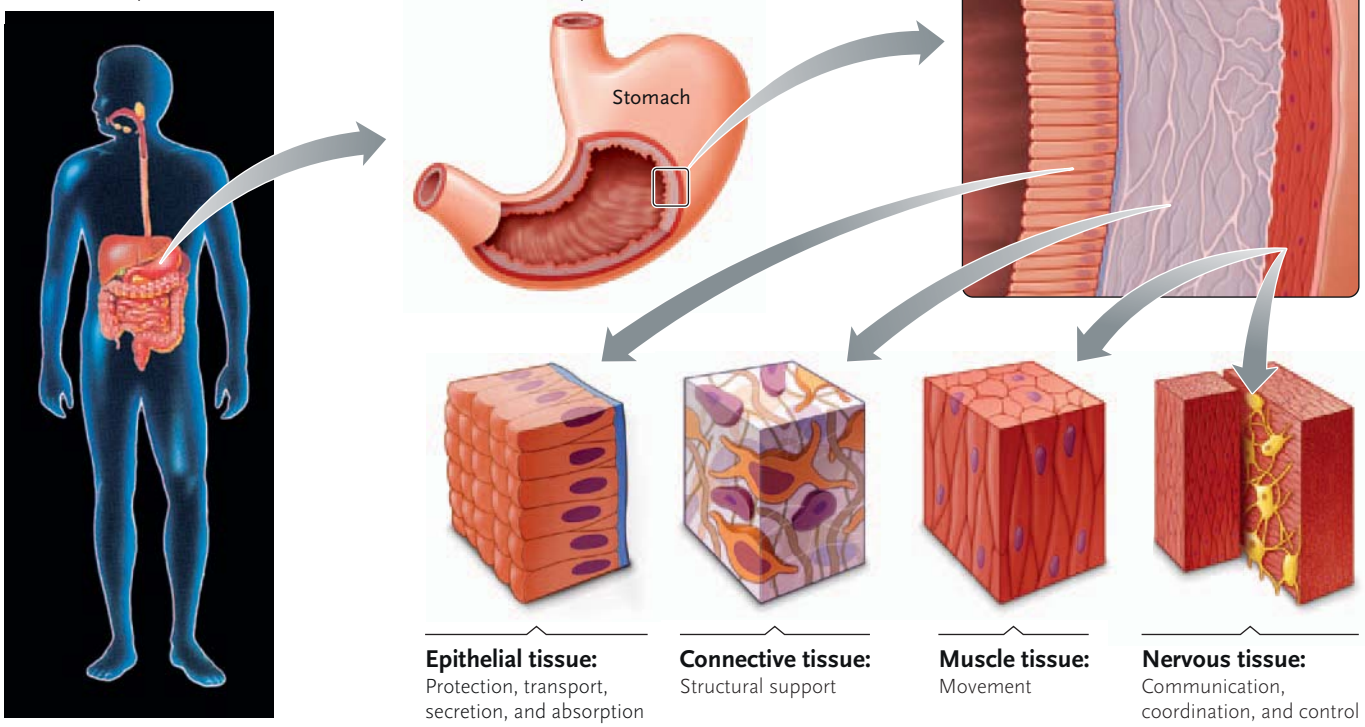
1. **What are some advantages for an organism being multicellular?**
2. **What is the difference between a tissue, an organ, and an organ system?**

38.2 Animal Tissues

Although the most complex animals may contain hundreds of distinct cell types, all can be classified into one of four basic tissue groups: *epithelial, connective, muscle,* and *nervous* (see Figure 38.1). Each tissue type is assembled from individual cells. The properties of those cells determine the structure and, therefore, the function of the tissue. More specifically, the structure and integrity of a tissue depends on the structure and organization of the cytoskeleton within the cell, the type and organization of the extracellular matrix (ECM) surrounding the cell, and the junctions holding cells together (see Section 5.5).

Junctions of various kinds link cells into tissues (see Figure 5.27). *Anchoring junctions* form buttonlike spots or belts that weld cells together. They are most abundant in tissues subject to stretching, such as skin and heart muscle. *Tight junctions* seal the spaces between cells, keeping molecules and even ions from leaking between cells. For example, tight junctions in the tissue lining the urinary bladder prevent waste molecules and ions from leaking out of the bladder into other body tissues. *Gap junctions* open channels between cells in the same tissue, allowing ions and small molecules to flow freely from one to another. For example, gap junctions between muscle cells help muscle tissue function as a unit.



Epithelial Tissue Forms Protective, Secretory, and Absorptive Coverings and Linings of Body Structures

Epithelial tissue (*epi* = over; *thele* = covering) consists of sheetlike layers of cells that are usually connected by tight junctions, with little ECM material between them **(Figure 38.2).** Also called *epithelia* (singular, *epithelium*), these tissues cover body surfaces and the surfaces of internal organs, as well as line cavi-

Organ system:
A set of organs that interacts to carry out a major body function. The digestive system coordinates the activities of organs, including the mouth, esophagus, stomach, small and large intestines, liver, pancreas, rectum, and anus, to convert ingested nutrients into absorbable molecules and ions, eliminate undigested matter, and help regulate water content of the body.

Organ:
Body structure that integrates different tissues and carries out a specific function which, for the stomach, is processing food.

Epithelial tissue:
Protection, transport, secretion, and absorption of nutrients released by digestion of food

Connective tissue:
Structural support

Muscle tissue:
Movement

Nervous tissue:
Communication, coordination, and control

ties and ducts within the body. They protect body surfaces from abrasion or from invasion by bacteria and viruses and secrete or absorb substances. For example, the epithelium covering a fish's gill structures serves as a barrier to bacteria and viruses and exchanges oxygen, carbon dioxide, and ions with the aqueous environment. In the epidermis of vertebrates, some epithelial cells contain a network of keratin, a family of fibrous proteins. Keratin forms protective structures: the fingernails, hair, claws, hooves, and horns of mammals, the feathers of birds, and the scales of reptiles and fish. In arthropods, the surface epithelium secretes a tough cuticle that forms a barrier to the environment and serves as the animal's skeleton.

Some epithelia, such as those lining the capillaries of the circulatory system, act as filters, allowing ions and small molecules to leak from the blood into surrounding tissues while barring the passage of blood cells and large molecules such as proteins.

Because epithelia form coverings and linings, they have an outer surface and an inner surface. The outer, **apical surface** may be exposed to water, air, or fluids within the body. The inner, **basal surface** adheres to a layer of ECM secreted by the epithelial cells called the **basal lamina,** which fixes the epithelium to underlying tissues, often connective tissues.

In internal cavities and ducts, the apical surface is often covered with *cilia* (see Section 5.3), which beat like oars to move fluids through the cavity or duct. The epithelium lining the oviducts in mammals, for example, is covered with cilia that generate fluid currents to move eggs from the ovaries to the uterus. In some epithelia, including the lining of the small intestine, the free surface is crowded with *microvilli,* fingerlike extensions of the plasma membrane that increase the area available for secretion or absorption.

TYPES OF EPITHELIA Epithelia are classified as *simple*—formed by a single layer of cells—or *stratified*—formed by multiple cell layers (see Figure 38.2). The shapes of cells within an epithelium may be *squamous* (mosaic, flattened, and spread out), *cuboidal* (shaped roughly like dice or cubes), or *columnar* (elongated, with the long axis perpendicular to the epithelial layer). Four principal types of epithelia are found in the body (see Figure 38.2).

The cells of some epithelia, such as those forming the skin and the lining of the intestine, divide constantly to replace worn and dying cells. New cells are produced through division of stem cells in the basal layer of the skin. *Stem cells* are undifferentiated cells that divide to produce either more stem cells or

differentiating cells that become specialized into one of the many cell types of the body. Stem cells are found in both adult organisms and embryos. Besides the skin, adult stem cells are found in tissues of the brain, bone marrow, blood vessels, skeletal muscle, and liver. (*Insights from the Molecular Revolution* describes an effort to culture embryonic stem cells as a source of replacements for damaged tissues and organs.)

GLANDS FORMED BY EPITHELIA Epithelia typically contain or give rise to cells that are specialized for secretion. Some of these secretory cells are scattered among nonsecretory cells within the epithelium. Others form structures called **glands,** which are derived from pockets of epithelium during embryonic development.

Some glands, called **exocrine glands** (*exo* = external; *crine* = secretion), remain connected to the epithelium by a duct, which empties their secretions at the epithelial surface. Exocrine secretions include mucus, saliva, digestive enzymes, sweat, earwax, oils,

Culturing Human Embryonic Stem Cells

Embryonic stem (ES) cells—cells derived from embryos—are totipotent, meaning that they have the potential to develop into any tissue. Human ES cells are highly useful for research and hold great promise for biomedical applications. If stem cells can be directed to become any kind of differentiated cells in the test tube, those cells can potentially be used for replacing dead or damaged tissue in the body with healthy cells. The key to the value of human ES cells in biomedical science is the ability to maintain them indefinitely in an undifferentiated state, that is, without becoming specialized.

Research Question

How can human ES cells be cultured?

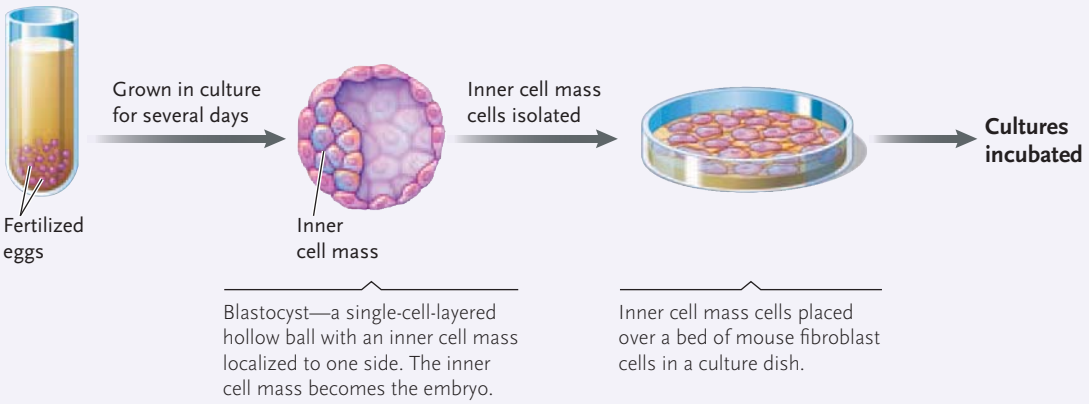
Experiment

A few years ago, James A. Thomson and his coworkers at the University of Wisconsin and a collaborator at the Rambam Medical Center, Haifa, Israel, developed a successful method for culturing stem cells **(Figure).** Their use of mouse fibroblast cells derived from similar experiments in which nonhuman primate ES cells were successfully cultured. It was unknown at the outset if this experimental step would work with human cells.

Results

Inner cell mass cells multiplied on the fibroblasts, producing clumps of cells. As long as the clumps did not contain more than 50 to 100 cells, cells remained undifferentiated. To continue culturing the ES cells, some of the cells were taken and placed over a bed of mouse fibroblast cells in a fresh culture dish. Using this technique, the cell cultures were maintained for as long as 8 months in the laboratory with no signs of differentiation.

Critically, the researchers demonstrated by several tests that the cultured cells retained full stem cell function:



1. The cultured stem cells had characteristic surface molecules that change when the cells begin to differentiate into adult tissues.
2. Cultured stem cells contained fully active telomerase, an enzyme that helps maintain chromosomes at their normal length during rapid cycles of DNA replication and cell division (see Section 14.3). The enzyme becomes inactive in most cells as they differentiate into adult form.
3. Stem cells can differentiate into a wide range of tissues. When mice were injected with samples of cultured cells, the cells grew into balls of tissue that included skin cells, gut epithelium, cartilage, bone, smooth and striated muscle, and nerve cells. The cultured cells seemed to differentiate into adult tissues when stimulated to do so, and thus to have all the characteristics of stem cells.

Conclusions

The researchers demonstrated that human ES cells could be cultured indefinitely while retaining all their stem cell properties. This was pioneering research, the first human ES cell line to be isolated.

THINK LIKE A SCIENTIST The researchers observed that, when the ES cell cultures grew until they covered the culture dish and the cells began to pile up on one another, the cells differentiated spontaneously. Conceptually, what does that observation indicate?

milk, and venom (**Figure 38.3A** shows an exocrine gland in the skin of a poisonous tree frog). Other glands, called **endocrine glands** (*endo* = inside), become suspended in connective tissue underlying the epithelium, with no ducts leading to the epithelial surface. These ductless glands, such as the pituitary gland, adrenal gland, and thyroid gland **(Figure 38.3B),** release their products—hormones (see Chapters 7 and 42)—directly into the interstitial fluid, to be picked up and distributed by the circulatory system.

Some glands act as both exocrine glands and endocrine glands. The pancreas, for instance, has an exocrine function of secreting pancreatic juice through a duct into the small intestine where it plays an important role in food digestion, and an endocrine function of secreting the hormones insulin and glucagon into the bloodstream to help regulate glucose levels in the blood.

Connective Tissue Supports Other Body Tissues

Most animal body structures contain one or more types of **connective tissues.** Connective tissues support other body tissues, transmit mechanical and other forces, and in some cases

act as filters. They consist of cells that form networks or layers in and around body structures and that are separated by nonliving material, specifically the ECM secreted by the cells of the tissue (see Section 5.5). Many forms of connective tissue have more ECM material (both by weight and by volume) than cellular material.

The mechanical properties of a connective tissue depend on the type and quantity of its ECM. The consistency of the ECM ranges from fluid (as in blood and lymph), through soft and firm gels (as in tendons), to hard and crystalline (as in bone).

In most connective tissues, the ECM consists primarily of the fibrous glycoprotein **collagen** embedded in a network of proteoglycans—glycoproteins that are very rich in carbohydrates. Collagen is the most abundant family of proteins in animals; collagens occur in all Eumetazoa.

In bone, the glycoprotein network surrounding the collagen is impregnated with mineral deposits that produce a hard, yet still somewhat elastic, structure. Another family of glycoproteins, **fibronectin,** aids in the attachment of cells to the ECM and helps hold the cells in position.

In some connective tissues another rubbery protein, **elastin,** adds elasticity to the ECM—it is able to return to its original shape after being stretched, bent, or compressed. Elastin fibers, for example, help the skin return to its original shape when pulled or stretched, and give the lungs the elasticity required for their alternating inflation and deflation. Related to elastin, the protein **resilin** is found only in insects and some crustaceans and is the most elastic material known. Resilin is the basis for the jumping of fleas, crickets, and locusts.

Vertebrates have six major types of connective tissues: **loose connective tissue, fibrous connective tissue, cartilage, bone, adipose tissue,** and **blood.** Each type has a characteristic function correlated with its structure **(Figure 38.4).**

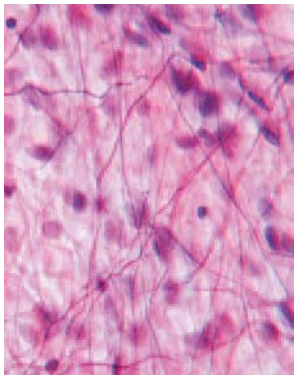
LOOSE CONNECTIVE TISSUE **Loose connective tissue** consists of sparsely distributed **fibroblast** cells surrounded by a more or less open network of collagen and other glycoprotein fibers **(Figure 38.4A);** the fibroblasts secrete most of these proteins. Loose connective tissues support epithelia and form a corset-like band around blood vessels, nerves, and some internal organs; they also reinforce deeper layers of the skin. Sheets of loose connective tissue, covered on both surfaces with epithelial cells, form the **mesenteries,** which hold the abdominal organs in place and provide lubricated, smooth surfaces that prevent chafing or abrasion between adjacent structures as the body moves.

FIBROUS CONNECTIVE TISSUE In **fibrous connective tissue,** fibroblasts are sparsely distributed among dense masses of collagen and elastin fibers that are lined up in highly ordered, parallel bundles **(Figure 38.4B).** The parallel arrangement produces maximum tensile strength and elasticity. Examples include **tendons,** which attach muscles to bones, and **ligaments,** which connect bones to each other at a joint. The cornea of the eye is a transparent fibrous connective tissue formed from highly ordered collagen molecules.

CARTILAGE **Cartilage** consists of sparsely distributed cartilage-producing cells called **chondrocytes,** surrounded by networks of collagen fibers embedded in a tough but elastic matrix of the glycoprotein *chondroitin sulfate* **(Figure 38.4C).** Elastin is also present in some forms of cartilage.

The elasticity of cartilage allows it to resist compression and stay resilient, like a piece of rubber. Bending your ear or pushing the tip of your nose, which are supported by a core of cartilage, shows the flexible nature of this tissue. In humans, cartilage also supports the larynx, trachea, and smaller air passages in the lungs. It forms the disks cushioning the vertebrae in the spinal column and the smooth, slippery capsules around the ends of bones in joints such as the hip and knee. Cartilage also serves as a precursor to bone during embryonic development; in sharks and rays and their relatives, almost the entire skeleton remains as cartilage in adults.

BONE The densest form of connective tissue, **bone,** forms the skeleton, which supports the body, protects softer body structures such as the brain, and contributes to body movements (see Chapter 43).



Mature bone consists primarily of cells called **osteocytes** (*osteon* = bone) embedded in an ECM containing collagen fibers and glycoproteins impregnated with *hydroxyapatite,* a calcium-phosphate mineral **(Figure 38.4D).** The collagen gives bone tensile strength and elasticity; the hydroxyapatite resists compression and allows bones to support body weight. Cells called **osteoblasts** (*blast* = bud or sprout) produce the collagen and mineral of bone—as much as 85% of the weight of bone is mineral deposits. Osteocytes, in fact, are osteoblasts that have become trapped and surrounded by the bone materials they themselves produce. **Osteoclasts** (*clast* = break) are cells that remove the minerals and recycle them through the bloodstream. Bone is not a stable tissue; it is reshaped continuously by the bone-building osteoblasts and the bone-degrading osteoclasts.

Although bones appear superficially to be solid, actually they are porous structures, with microscopic spaces and canals. The structural unit of bone, the **osteon,** consists of a minute central canal surrounded by osteocytes embedded in concentric layers of mineral matter (see Figure 38.4D). A blood vessel and extensions of nerve cells run through the central canal, which is connected to the spaces containing cells by very fine, radiating canals filled with interstitial fluid. The blood vessels supply nutrients to the cells with which the bone is built, and the nerve cells hook up the bone cells to the body's nervous system.

ADIPOSE TISSUE The connective tissue called *adipose tissue* mostly contains large, densely clustered cells called **adipocytes** that are specialized for fat storage **(Figure 38.4E).** It has little ECM. Adipose tissue also cushions the body and, in mammals, forms an especially important insulating layer under the skin.

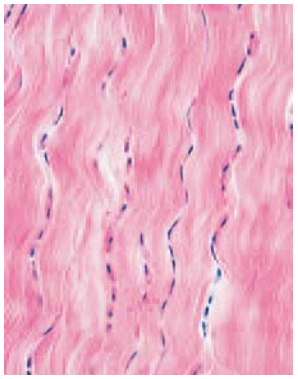
A. Loose connective tissue



Ed Reschke

Description: Fibroblasts and other cells surrounded by collagen and elastin fibers forming a glycoprotein matrix

Common locations: Under the skin and most epithelia; around blood vessels, nerves, and some internal organs

Function: Support, elasticity, diffusion

B. Fibrous connective tissue

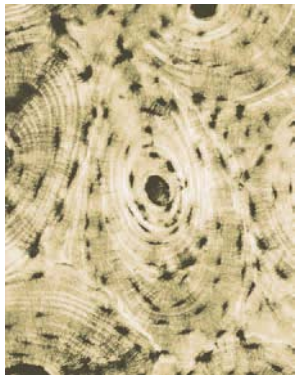
Ed Reschke

Description: Long rows of fibroblasts surrounded by collagen and elastin fibers in parallel bundles with a dense ECM

Common locations: Tendons, ligaments

Function: Strength, elasticity

C. Cartilage



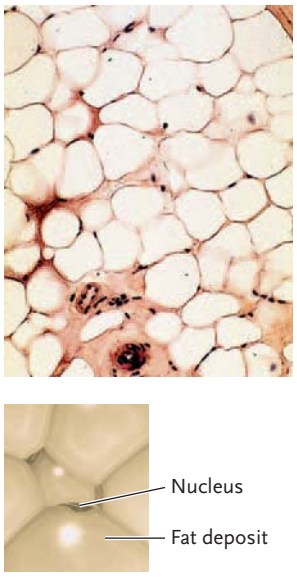
Fred Hossler/Visuals Unlimited

Description: Chondrocytes embedded in a pliable, solid matrix of collagen and chondroitin sulfate

Common locations: Ends of long bones, ears, nose, parts of airways, skeleton of vertebrate embryos

Function: Support, flexibility, low-friction surface for joint movement

D. Bone tissue



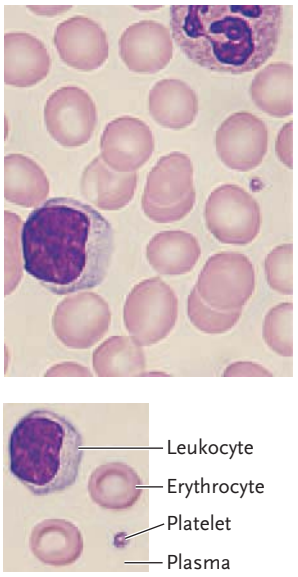
Ed Reschke

Description: Osteocytes in a matrix of collagen and glycoproteins hardened with hydroxyapatite

Common locations: Bones of vertebrate skeleton

Function: Movement, support, protection

E. Adipose tissue



Ed Reschke

Description: Large, tightly packed adipocytes with little ECM

Common locations: Under skin; around heart, kidneys

Function: Energy reserves, insulation, padding

F. Blood

Ed Reschke

Description: Leukocytes, erythrocytes, and platelets suspended in plasma, a fluid ECM

Common locations: Circulatory system

Function: Transport of substances

FIGURE 38.4 Structures and functions of the six major types of connective tissues in vertebrates.

The animal body stores limited amounts of carbohydrates, primarily in muscle and liver cells. Excess carbohydrates are converted into the fats stored in adipocytes. The storage of chemical energy as fats offers animals a weight advantage. For example, the average human would weigh about 45 kg (100 pounds) more if the same amount of chemical energy was stored as carbohydrates instead of fats. Adipose tissue is richly supplied with blood vessels, which move fats or their components to and from adipocytes.

BLOOD **Blood (Figure 38.4F)** is considered a connective tissue because its cells are suspended in a fluid ECM, plasma. The straw-colored **plasma** is a solution of proteins, nutrient molecules, ions, and gases.

Blood contains two primary cell types, **erythrocytes** (red blood cells; *erythros* = red) and **leukocytes** (white blood cells; *leukos* = white). Erythrocytes are packed with hemoglobin, a protein that can bind and transport oxygen. There are several types of leukocytes—all help to protect the body against invading viruses, bacteria, and other disease-causing agents. The blood

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

plasma also contains **platelets,** membrane-bound fragments of specialized blood cells, which take part in the reactions that seal wounds with blood clots.

Blood is the major transport vehicle of the body. It carries oxygen and nutrients to body cells, removes wastes and by-products such as carbon dioxide, and maintains the internal fluid environment, including the osmotic balance between cells and the interstitial fluid. Blood also transports hormones and other signal molecules that coordinate body responses. (The components and roles of blood are described in Chapter 44.)

Muscle Tissue Produces the Force for Body Movements

Muscle tissue consists of cells that have the ability to contract ("shorten"). The contractions, which depend on the interaction of two proteins—**actin** and **myosin**—move body limbs and other structures, pump the blood, and produce a squeezing pressure in organs such as the intestine and uterus. Three types of muscle tissues, *skeletal, cardiac,* and *smooth,* produce body movements in vertebrates **(Figure 38.5).**

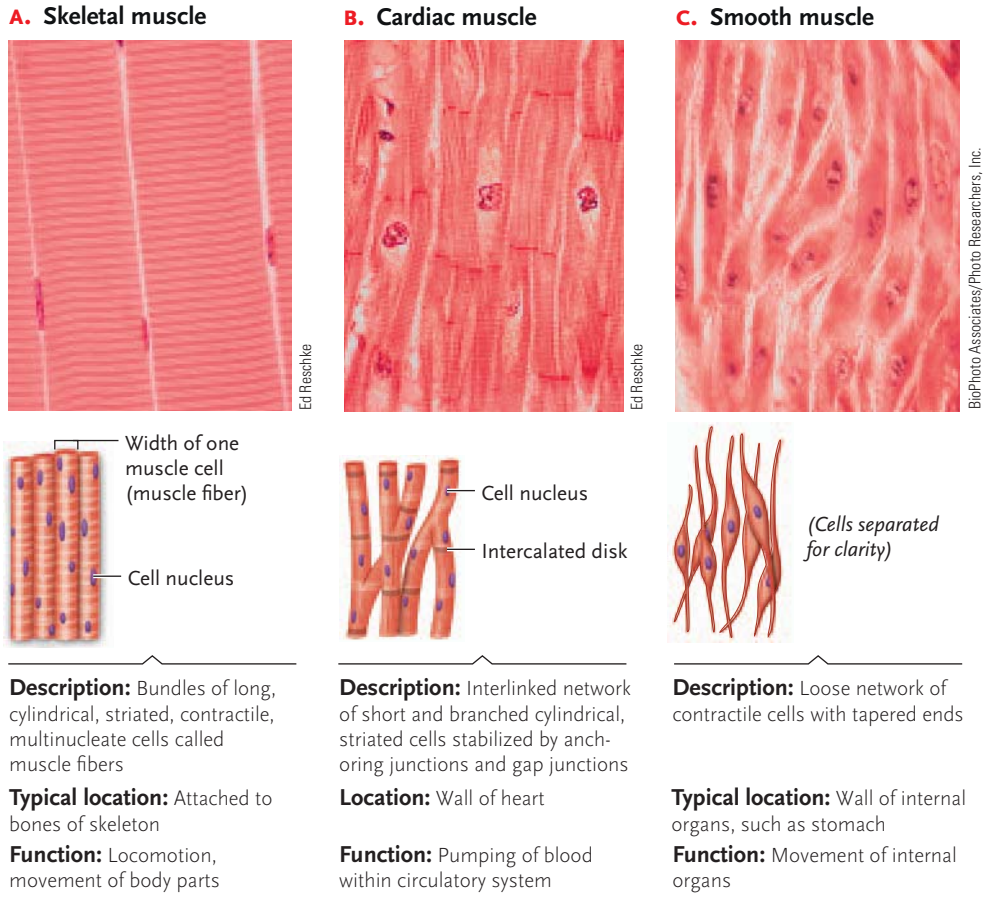

FIGURE 38.5 **Structures and functions of skeletal, cardiac, and smooth muscle.**

© Cengage Learning 2014

SKELETAL MUSCLE **Skeletal muscle** is so called because typically it is attached by tendons to the skeleton. Skeletal muscle cells are also called **muscle fibers (Figure 38.5A).** These cells are multinucleate (contain many nuclei in the same cytoplasm) and are packed with actin and myosin molecules arranged in highly ordered, parallel units that give the tissue a banded or striated appearance when viewed under a microscope. Muscle fibers packed side-by-side into parallel bundles surrounded by sheaths of connective tissue constitute muscles, such as the biceps.

Skeletal muscle contracts in response to signals carried by the nervous system. The contractions of skeletal muscles, characteristically rapid and powerful, move body parts and maintain posture. In some cases disorganized muscle contractions (shivering) are used to release heat as a by-product of cellular metabolism. This heat helps mammals, birds, and some other vertebrates maintain their body temperatures when environmental temperatures fall. (Skeletal muscle is discussed further in Chapter 43.)

CARDIAC MUSCLE **Cardiac muscle** is the contractile tissue of the heart **(Figure 38.5B).** Cardiac muscle has a striated appearance because it contains actin and myosin molecules arranged like those in skeletal muscle. However, cardiac muscle cells are short and branched, with each cell connecting to several neighboring cells; the joining point between two such cells is called an **intercalated disk.** Cardiac muscle cells thus form an interlinked network, which is stabilized by anchoring junctions and gap junctions. This network enables heart muscle to contract in all directions, producing a squeezing or pumping action rather than the lengthwise, unidirectional contraction characteristic of skeletal muscle.

SMOOTH MUSCLE **Smooth muscle** is found in the walls of tubes and cavities in the body, including blood vessels, the stomach and intestine, the bladder, and the uterus. Smooth muscle cells are relatively small and spindle-shaped (pointed at both ends), and their actin and myosin molecules are arranged in a loose network rather than in bundles **(Figure 38.5C).** This loose network makes the cells appear smooth rather than striated when viewed under a microscope. Smooth muscle cells are enclosed by a mesh of connective tissue, and some of them are connected by gap junctions. The gap junctions allow the passage of current that makes smooth muscles contract as a unit, typically producing a squeezing motion. Although smooth muscle contracts more slowly than skeletal and cardiac muscles do, its contractions can be maintained at steady levels for a much longer time. These contractions move and mix the stomach and intestinal contents, constrict blood vessels, and push the infant out of the uterus during childbirth.

Nervous Tissue Receives, Integrates, and Transmits Information

Nervous tissue contains cells called **neurons** (also called *nerve cells*) that serve as lines of communication and control between body parts. Billions of neurons are packed into the human brain; others extend throughout the body. Nervous tissue also contains **glial cells** (*glia* = glue), which physically support and provide nutrients to neurons, provide electrical insulation between them, and scavenge cellular debris and foreign matter.

A neuron consists of a *cell body,* containing the nucleus and organelles, and two types of cell extensions, dendrites and axons **(Figure 38.6).** *Dendrites* are usually highly branched, whereas *axons* are usually unbranched except at their terminals. Depending on the type of neuron and its location in the body, its axon may extend from a few micrometers or millimeters to more than a meter.

The cell body or the dendrites of a neuron receive chemical or electrical signals from other neurons. The signals are converted into an electrical wave that is transmitted along the axons to the axon terminals. Depending on the type of neuron, axons either convert the electrical signal at their terminals to a chemical signal that stimulates a response in nearby muscle cells, gland cells, or other neurons or transfers the electrical signal directly to another neuron through gap junctions. (Neurons and their organization in body structures are discussed further in Chapters 39, 40, and 41.)

All four major tissue types—epithelial, connective, muscle, and nervous—combine to form the organs and organ systems of animals. The next section depicts the major organs and organ systems of vertebrates, and outlines their main functions.

STUDY BREAK 38.2

1. Distinguish between exocrine and endocrine glands. What is the tissue type of each of these glands?
2. What are the six major types of connective tissue in vertebrates?
3. What three types of muscle tissue produce movements in the body?

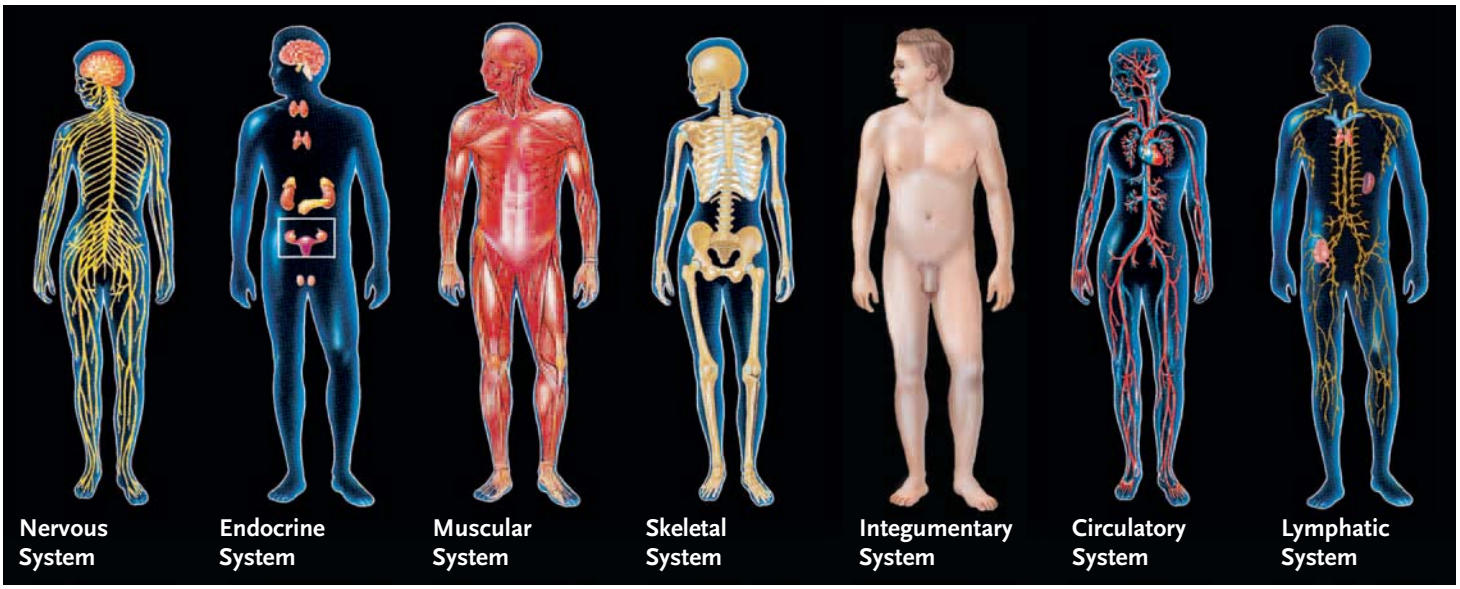
THINK OUTSIDE THE BOOK

Individually or collaboratively, determine the type or types of muscle tissues found in invertebrates and give examples of each type.

38.3 Coordination of Tissues in Organs and Organ Systems

In the tissues, organs, and organ systems of an animal, each cell engages in the basic metabolic activities that ensure its own survival, and performs one or more functions of the system to which it belongs. All vertebrates (and most invertebrates) have eleven major organ systems. **Figure 38.7** summarizes structures and functions of these organ systems, which are discussed in the rest of this unit.

The functions of all these organ systems are coordinated and integrated to accomplish collectively tasks that are vital to all animals, whether a flatworm, a fly, a salmon, a platypus, or a human. These functions include:



1. Acquiring nutrients and other required substances such as oxygen, coordinating their processing, distributing them throughout the body, and disposing of wastes.
2. Synthesizing the protein, carbohydrate, lipid, and nucleic acid molecules required for body structure and function.
3. Sensing and responding to changes in the environment, such as temperature, pH, and ion concentrations.
4. Protecting the body against injury or attack from other animals, and from viruses, bacteria, and other disease-causing agents.
5. Reproducing and, in many instances, nourishing and protecting offspring through their early growth and development.

Together these tasks maintain homeostasis, preserving the internal environment required for survival of the body. Homeostasis is the topic of the next section.

STUDY BREAK 38.3

What are the major functions of each of the eleven organ systems of the vertebrate body?

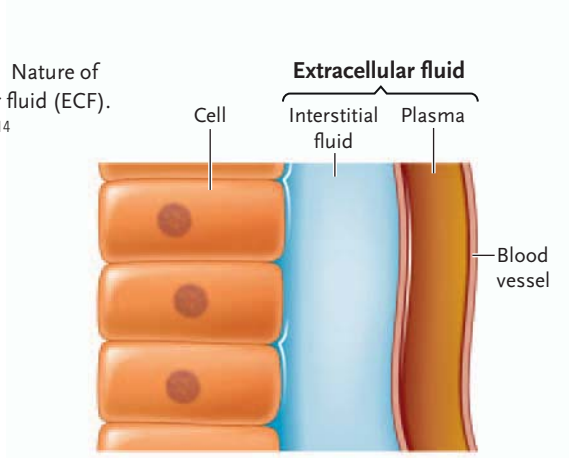
38.4 Homeostasis

To live, cells of all organisms must take in nutrients and O_2 from the external environment and eliminate wastes such as CO_2 and particular chemicals to that external environment. A single-celled organism such as an amoeba is in direct contact with the external environment. Although most cells of a multicellular animal are isolated from direct contact with the external environment, those cells have the same needs of nutrient and O_2 input and waste elimination. Those needs are met by the internal environment, namely the aqueous **extracellular fluid (ECF) (Figure 38.8).** The ECF has two components:

- **Plasma,** the fluid portion of blood.
- **Interstitial fluid** (*inter* = between; *stitial* = that which stands), the fluid that surrounds the cells.

The ECF connects all cells to the external environment. Thus, no matter where a cell is within the body, it can make the exchanges essential to its life with the interstitial fluid. Particular organ systems enable these exchanges between the external and internal environments. The digestive system processes incoming food and transfers the resulting nutrients into the plasma of the blood. The nutrients reach all parts of the body by



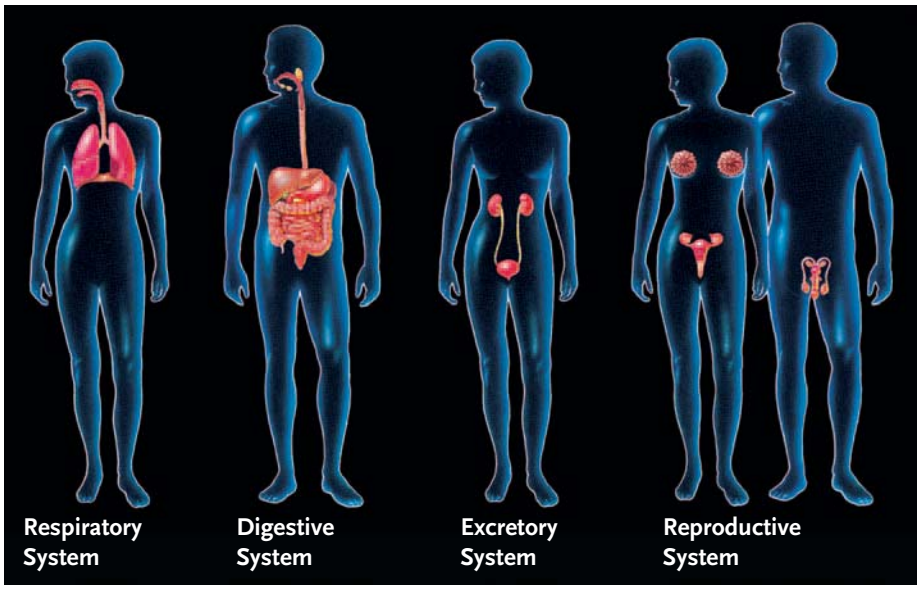


FIGURE 38.8 Nature of the extracellular fluid (ECF).

Respiratory System	Digestive System	Excretory System	Reproductive System
Main structures: Lungs, diaphragm, trachea, and other airways	**Main structures:** Oral cavity, pharynx, esophagus, stomach, intestines, liver, pancreas, rectum, anus	**Main structures:** Kidneys, bladder, ureter, urethra	**Main structures:** *Female*: ovaries, oviducts, uterus, vagina, mammary glands *Male*: testes, sperm ducts, accessory glands, penis
Main functions: Exchanges gases with the environment, including uptake of oxygen and release of carbon dioxide	**Main functions:** Converts ingested matter into molecules and ions that can be absorbed into body; eliminates undigested matter; helps regulate water content	**Main functions:** Removes and eliminates excess water, ions, and metabolic wastes from body; helps regulate internal osmotic balance and pH; helps regulate blood pressure	**Main functions:** Maintains the sexual characteristics and passes on genes to the next generation

the action of the circulatory system, along with O_2 which enters the blood by the action of the respiratory system. The nutrients and O_2 in the plasma reach the interstitial fluid through the capillaries and, from there, they enter the cells as needed. Waste moves in the opposite direction: from the cells into the interstitial fluid, and then to the plasma. The respiratory system handles removal of CO_2, and the excretory system handles the metabolic wastes.

For optimal function of these systems, the composition and state of the ECF must be maintained within a narrow range so that cells have available the necessary nutrients and O_2 and wastes can be eliminated. Further, other aspects of the internal environment that are important for cellular (and therefore organismal) life, such as temperature, must also be regulated within a narrow range (especially in warm-blooded animals).

As introduced in *Why It Matters,* the maintenance of the internal environment in a relatively stable state is **homeostasis.** Note that, although the *stasis* part of homeostasis might suggest a static, unchanging process, homeostasis is actually a *dynamic* process, in which internal adjustments are made continuously to compensate for external changes. For example, internal adjustments are needed for homeostasis during exercise or hibernation. The factors controlled by homeostatic mechanisms all require energy that must be constantly acquired from the external environment.

Homeostatic control systems are found in all organisms. Humans and other mammals maintain a consistent internal environment, but many kinds of multicellular animals show much more variability in their internal environment than mammals do. Animals fall into two major categories in this regard: **regulators** maintain factors of the internal environment in a relatively constant state, and **conformers** have internal environments that match the external environment. For instance, mammals and birds are thermoregulators, meaning that they maintain their body temperature at a relatively constant value regardless of the temperature of the external environment. However, most animals—for example, fishes, reptiles, and insects—are thermoconformers, meaning that their body temperature matches that of the external environment. We will use mammals, and especially humans, as primary examples in the discussions throughout this unit.

Many Factors of the Internal Environment Are Regulated Homeostatically

Factors of the internal environment that are regulated homeostatically include:

1. *Nutrient concentration.* Energy production by cells requires a constant supply of nutrient molecules. The energy generated by catabolizing the nutrients is used for basic cellular processes and any specialized activities of the cell.
2. *Concentration of O_2.* Cellular respiration (see Chapter 8), the process that generates energy from catabolic reactions, requires a constant supply of O_2 for optimal productivity.
3. *Concentration of CO_2.* The CO_2 produced by the catabolic reactions of cellular respiration must be removed as waste or the ECF would become increasingly acidic.
4. *Concentration of waste chemicals.* Particular biochemical reactions in the cell generate products that would be toxic to the cell if not removed as waste.
5. *Concentration of water and NaCl.* The relative concentrations of NaCl and water in the ECF affect how much water enters or leaves a cell and hence the cell's volume (see Chapter 6). These concentrations must be regulated to maintain a cell volume that is optimal for function; swollen or shrunken cells are functionally impaired.
6. *pH.* Changes in pH of the ECF can adversely affect enzymatic activities within cells, as well as nerve cell functions.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

7. *Volume and pressure of plasma.* Both the volume and pressure in the vessels of the plasma component of the ECF must be maintained at levels adequate to distribute the fluid throughout the body. This circulation is vitally important for supplying cells with their needs and removing their wastes.
8. *Temperature.* Body cells (of warm-blooded animals) function optimally within a fairly narrow temperature range. Outside of that range, chemical reactions change their rates and may be completely inhibited. If cells become too cold, the rates of enzymatic reactions decrease too much. If cells become too hot, structural and enzymatic proteins can be denatured and, therefore, become inactive.

Most Homeostatic Control Systems Operate Throughout the Body

Local homeostatic controls operate only within an organ where a change in the internal environment needs to be addressed. For example, when you exercise, a skeletal muscle increases its use of O_2, which reduces the concentration of O_2 in the muscle cells and sets up a requirement for increased O_2 uptake from the interstitial fluid. The local homeostatic control in this instance responds to the decreased O_2 concentration by triggering the relaxation of the smooth muscle in the walls of the blood vessels supplying the exercising muscle. As a result, the blood vessels dilate (expand in diameter), increasing the blood flow to the exercising muscle, which brings more O_2. The end result is maintenance of an optimal O_2 concentration for the exercising skeletal muscle.

Systemic homeostatic controls are initiated outside of an organ or organ system to control that organ's or organ system's activity. The body's two major regulatory systems, the nervous system and the endocrine system, are responsible for most systemic homeostatic control of organs and organ systems. This type of control enables the regulation of several organs or organ systems to be coordinated toward a common goal. For example, if blood pressure drops too low, the nervous system acts on the heart to increase contraction strength and on blood vessels to constrict them so as to increase pressure in the system. Blood pH is controlled by both the nervous and endocrine systems, blood glucose by the endocrine system, internal temperature by the nervous and endocrine systems, and oxygen and carbon dioxide concentrations by the nervous system.

Homeostasis Is Accomplished by Negative Feedback Control Systems

The primary mechanism of homeostasis is **negative feedback (Figure 38.9).** The following presents the components of a negative feedback control system maintaining homeostasis. In parentheses are descriptions of the specific homeostatic control system used by mammals and birds—warm-blooded vertebrates—to maintain body temperature within a relatively narrow range around a set point:

- **Stimulus**—an environmental change that triggers a response. (A change in body temperature beyond the normally controlled range around the normal temperature level.)
- **Sensor**—the body component that detects the environmental change. (Temperature-monitoring nerve cells throughout the body.)
- **Integrator**—a control center that receives information from the sensor and compares it with the **set point,** the normal level at which the condition being controlled is to be maintained. The integrator, typically part of the brain or endocrine system, sends out commands to correct any significant change from the set point detected. (The temperature control center in a region of the brain called the *hypothalamus* (see Chapter 40) detects changes in the temperature of the brain and the rest of the body, and compares it with a set point. For humans, the set point has a relatively narrow range centered at about 37°C.)

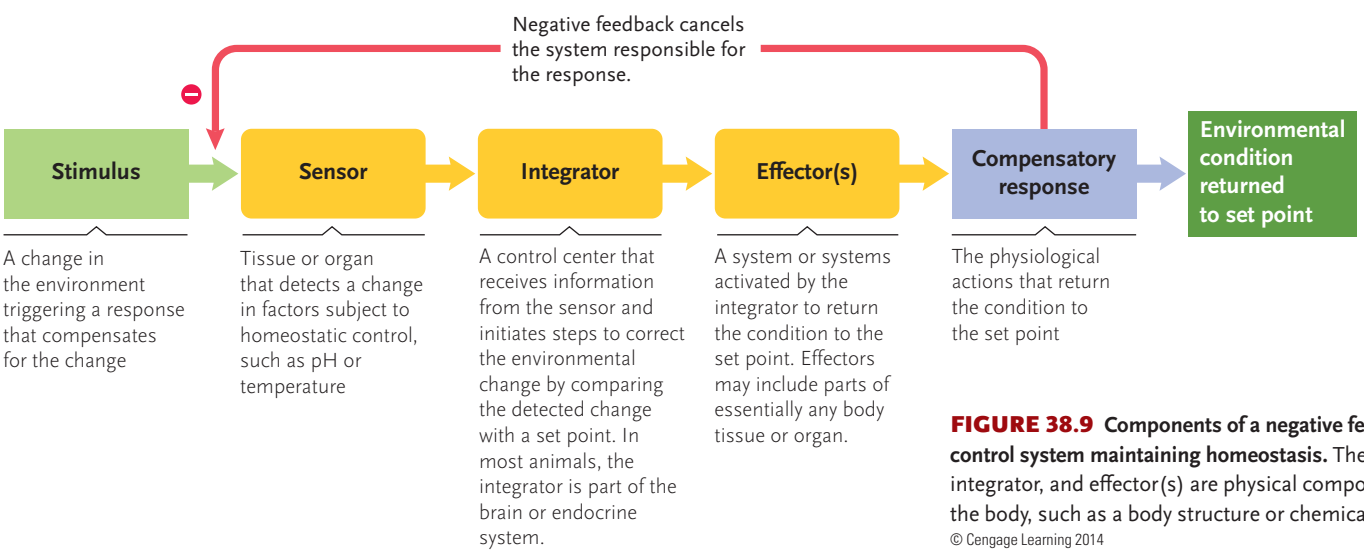

FIGURE 38.9 Components of a negative feedback control system maintaining homeostasis. The sensor, integrator, and effector(s) are physical components in the body, such as a body structure or chemical.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

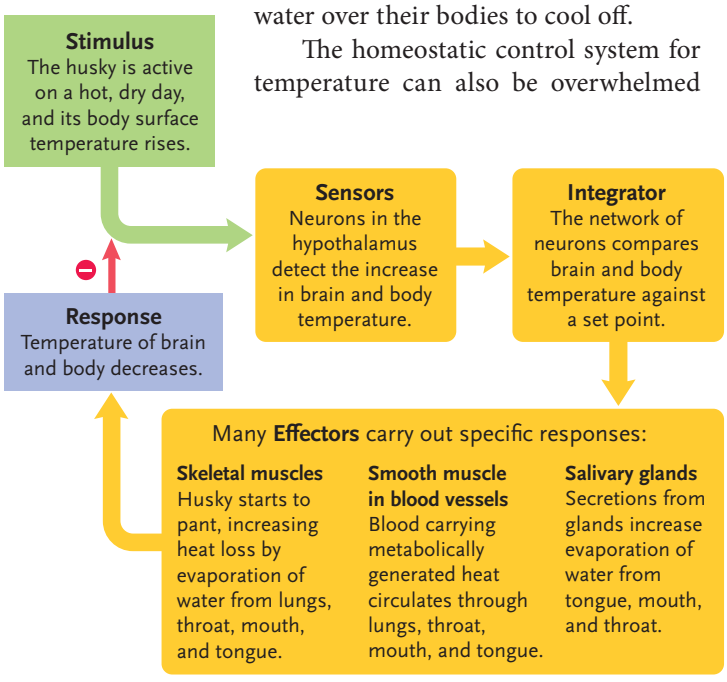
- **Effector**—a system that is activated by the integrator to bring the condition under control back to the set point. Effectors may include parts of essentially any body tissue or organ. (Physiological or behavioral responses that function to return body temperature to the set point.)

Let us consider the effectors for body temperature homeostasis in warm-blooded vertebrates in a little more detail. If the temperature falls below the lower limit, as was the case for the passengers and crew of the *Titanic* who ended up in the water (see *Why It Matters*), the hypothalamus activates effectors that constrict the blood vessels in the skin. The reduction in blood flow means that less heat is conducted from the blood through the skin to the environment, reducing heat loss from the skin. Other effectors may induce shivering, a physical mechanism to generate body heat. Also, integrating neurons in the brain, stimulated by signals from the hypothalamus, make us consciously sense a chill, which we may counteract behaviorally by, if possible, putting on more clothes or moving to a warmer area.

Conversely, if blood temperature rises above the set point by exposure to high external temperature or by vigorous exercise, the hypothalamus triggers effectors that dilate the blood vessels in the skin, increasing blood flow and heat loss from the skin. Other effectors induce sweating, which cools the skin and the blood flowing through it as the sweat evaporates. And again, through integrating neurons in the brain, we may consciously sense being overheated, which we may counteract behaviorally by shedding clothes, moving to a cooler location, stopping exercise, or taking a dip in a pool or a cool shower.

All mammals have similar homeostatic control systems that maintain or adjust body temperature. **Figure 38.10** illustrates how a dog responds to high environmental temperatures by the mechanisms we have discussed and, in addition, by panting. Birds also pant to reduce their body temperatures. Many terrestrial animals enter or splash water over their bodies to cool off.

The homeostatic control system for temperature can also be overwhelmed by prolonged exposure to a particularly high or low temperature. In either case, the end result will be death unless the external temperature returns to a more moderate value. As the *Titanic* story describes, only 15 minutes in about-freezing water can kill a person. Likewise, homeostatic control systems for other regulated factors can also be overwhelmed or be disrupted. For example, the inability to regulate blood glucose concentration homeostatically leads to the disease state of diabetes.



Whereas mammals and birds regulate their internal body temperature within a narrow range around a set point, certain other vertebrates regulate over a broader range. These vertebrates use other, less precise negative feedback mechanisms for their temperature regulation. Snakes and lizards, for example, respond behaviorally to compensate for variations in environmental temperatures. They may absorb heat by basking on sunny rocks in the cool early morning and move to cooler, shaded spots in the heat of the afternoon.

Some invertebrates, such as dragonflies, moths, and butterflies, use muscular contractions equivalent to shivering when their body temperature falls below the level required for flight. The shivering contractions warm the muscles to flying temperature. All of these physiological and behavioral responses depend on negative feedback mechanisms involving sensors, integrators, and effectors.

Animals Also Have Positive Feedback Mechanisms That Do Not Result in Homeostasis

Under certain circumstances, animals respond to a change in internal or external environmental condition by a **positive feedback** mechanism that intensifies or adds to the change. Such mechanisms, with some exceptions, do not result in homeostasis. Positive feedback mechanisms are less common than negative feedback mechanisms.

The birth process in mammals provides an example of positive feedback. During human childbirth, initial contractions

of the uterus push the head of the fetus against the cervix, the opening of the uterus into the vagina, causing the cervix to stretch. Sensors that detect the stretching signal the hypothalamus to stimulate the release of the hormone oxytocin from the pituitary gland. Oxytocin increases the uterine contractions, intensifying the squeezing pressure on the fetus and further stretching the cervix. The stretching results in more oxytocin release and stronger uterine contraction, repeating the positive feedback circuit and increasing the squeezing pressure until the fetus is pushed entirely out of the uterus.

In conclusion, we learned in this chapter about the various tissues and organ systems of the body, and of the involvement of organ systems in homeostasis. Next, we begin a series of chapters describing the organ systems in detail, starting with the nervous system.

STUDY BREAK 38.4

What are the components of a negative feedback control system that results in homeostasis?

UNANSWERED QUESTIONS

As described in the chapter, all animals have homeostatic control systems through which they maintain a consistent internal environment. The physiological processes underlying many of these control systems are shaped by evolution to adapt to daily changes in the external environment. In mammals, many physiological processes display 24-hour rhythms that are generated by an internal gene-based clock called a circadian clock (*circa* = approximately; *dies* = day). Some malfunctions of systems that are normally under homeostatic control also seem to exhibit a circadian cycle.

Why do so many strokes and heart attacks occur in the morning?

Strokes and heart attacks occur most frequently at a particular time of the day—in the morning—exhibiting a 24-hour, or circadian, rhythm. Circadian rhythms are generated through a molecular signaling mechanism called the circadian clock. A "central" circadian clock in the brain acts to control circadian rhythm in sleep-wake cycles. These same proteins are also found throughout the organs and cells of the body, including blood vessels (vascular clock). Recent work has shown that a broken clock also breaks down important physiologic signals, like nitric oxide to worsen heart attack, stroke, and vascular disease in animal models. (The role of nitric oxide on neuron function is discussed in Chapter 39.) Current research is addressing how circadian clock malfunctions contribute to both acute and chronic disease processes. In our laboratory, we are using mice with targeted disruption of circadian clock genes (knockout or mutant mice) and studying their response to cardiovascular stresses, including hypertension and vascular disease.

Location, location, location: Where in the body does the circadian clock malfunction to cause vascular disease?

Though heart attacks and strokes are the culmination of ongoing vascular disease, their onset is acute, often occurring in the morning around 8 A.M. In contrast, the progression to vascular disease is chronic, occurring in a time-span of years. Our laboratory and others have now demonstrated that the genes comprising the circadian clock can contribute to vascular disease. This finding suggests that, in addition to daily cycles, the circadian clock controls aspects of biology that are also important in the long-term. We think of circadian disorders as overt behavioral disorders that include poor sleep, night/shift work, and jet-lag, but there may be more to the picture. Recently, we have demonstrated that dysfunction of the circadian clock within local tissue (blood vessels) is important to confer disease, independent of the central clock. Thus, circadian malfunction in tissues outside the brain may contribute to diseases such as atherosclerosis, hypertension, diabetes, and even cancer. These basic science observations of circadian function in animals may lay the foundation for clinical studies in humans, which ultimately may change the way we understand and treat arteriosclerosis, hypertension, and heart attack.

THINK LIKE A SCIENTIST How might circadian rhythms have been important for survival in early organisms?

R. Daniel Rudic

R. Daniel Rudic is an Associate Professor in the Department of Pharmacology and Toxicology at the Medical College of Georgia. To learn more about his research on circadian rhythms and vascular biology, go to http://www.mcg.edu/som/phmtox/RudicLab/index.asp.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

38.1 Organization of the Animal Body

- In most animals, cells are specialized and organized into tissues, tissues into organs, and organs into organ systems. A tissue is a group of cells with the same structure and function, working as a unit to carry out one or more activities. An organ is an assembly of tissues integrated into a structure that carries out a specific function. An organ system is a group of organs that carry out related steps in a major physiological process (Figure 38.1).

Animation: Soft connective tissues

Animation: Specialized connective tissues

38.2 Animal Tissues

- Animal tissues are classified as epithelial, connective, muscle, or nervous (Figure 38.1). The properties of the cells of these tissues determine the structures and functions of the tissues.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Various kinds of junctions link cells in a tissue. Anchoring junctions "weld" cells together. Tight junctions seal the cells into a leak-proof layer. Gap junctions form direct avenues of communication between the cytoplasm of adjacent cells in the same tissue.
- Epithelial tissue consists of sheetlike layers of cells that cover body surfaces and the surfaces of internal organs and line cavities and ducts within the body (Figure 38.2).
- Glands are secretory structures derived from epithelia. They may be exocrine (connected to an epithelium by a duct that empties on the epithelial surface) or endocrine (ductless, with no direct connection to an epithelium) (Figure 38.3).
- Connective tissue consists of cell networks or layers and an extracellular matrix (ECM). It supports other body tissues, transmits mechanical and other forces, and in some cases acts as a filter (Figure 38.4).
- Loose connective tissue consists of sparsely distributed fibroblasts surrounded by an open network of collagen and other glycoproteins. It supports epithelia and organs of the body and forms a covering around blood vessels, nerves, and some internal organs.
- Fibrous connective tissue contains sparsely distributed fibroblasts in a matrix of densely packed, parallel bundles of collagen and elastin fibers. It forms high tensile-strength structures such as tendons and ligaments.
- Cartilage consists of sparsely distributed chondrocytes surrounded by a network of collagen fibers embedded in a tough but highly elastic matrix of branched glycoproteins. Cartilage provides support, flexibility, and a low-friction surface for joint movement (Figure 38.4).
- In bone, osteocytes are embedded in a collagen matrix hardened by mineral deposits. Osteoblasts secrete collagen and minerals for the ECM; osteoclasts remove the minerals and recycle them into the bloodstream (Figure 38.4).
- Adipose tissue consists of cells specialized for fat storage. It also cushions and rounds out the body and provides an insulating layer under the skin (Figure 38.4).
- Blood consists of a fluid matrix, the plasma, in which erythrocytes and leukocytes are suspended. The erythrocytes carry oxygen to body cells; the leukocytes produce antibodies and initiate the immune response against disease-causing agents (Figure 38.4).
- Muscle tissue contains cells that have the ability to contract forcibly (Figure 38.5). Skeletal muscle, containing long cells called muscle fibers, moves body parts and maintains posture.
- Cardiac muscle, which contains short contractile cells with a branched structure, forms the heart.
- Smooth muscle consists of spindle-shaped contractile cells that form layers surrounding body cavities and ducts.
- Nervous tissue contains neurons and glial cells. Neurons communicate information between body parts in the form of electrical and chemical signals (Figure 38.6). Glial cells support the neurons or provide electrical insulation between them.

Animation: Differences between cell and tissue types

Animation: Structure of an epithelium

Animation: Neuron structure and function

38.3 Coordination of Tissues in Organs and Organ Systems

- Organs and organ systems are coordinated to carry out vital tasks, including maintenance of internal body conditions; nutrient acquisition, processing, and distribution; waste disposal; molecular synthesis; environmental sensing and response; protection against injury and disease; and reproduction.
- In vertebrates and most invertebrates, the major organ systems that accomplish these tasks are the nervous, endocrine, muscular, skeletal, integumentary, circulatory, lymphatic, immune, respiratory, digestive, excretory, and reproductive systems (Figure 38.7).

Animation: Human organ systems

38.4 Homeostasis

- Homeostasis is the process by which animals maintain their internal environment—the extracellular fluid (Figure 38.8)—under conditions their cells can tolerate. It is a dynamic state, in which internal adjustments are made continuously to compensate for environmental changes.
- Multicellular organisms fall into two categories with respect to homeostatic regulation of the internal environment: regulators maintain factors of the internal environment in a relatively constant state, whereas conformers have internal environments that match the external environment.
- Homeostatically regulated factors of the internal environment include nutrient concentration; O_2 and CO_2 concentrations; concentrations of waste chemicals, water and NaCl; pH; and volume and pressure of plasma.
- Most homeostatic control systems operate systemically, whereas only some operate locally.
- Homeostasis is accomplished by negative feedback mechanisms that include a sensor, which detects a change in an external or internal condition; an integrator, which compares the detected change with a set point; and an effector or effectors, which return the condition to the set point if it has varied (Figure 38.9).
- Animals also have positive feedback mechanisms, in which a change in an internal or external condition triggers a response that intensifies the change, and typically does not result in homeostasis.

Animation: Negative feedback system

UNDERSTAND & APPLY

Test Your Knowledge

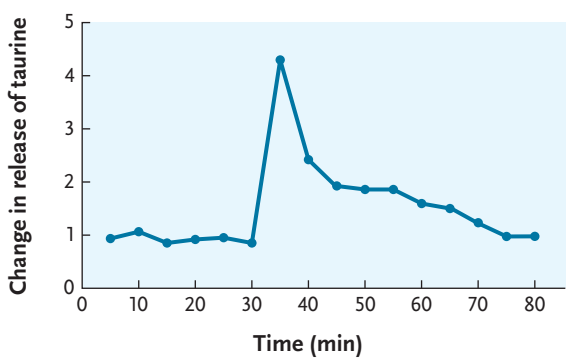
1. Which tissue type consisting of sheetlike layers of cells can both exchange oxygen and act as a barrier to bacteria?
   a. nervous
   b. epithelial
   c. connective
   d. muscle
   e. heart

2. Which of the following is a constant source of adult stem cells in a mammal?
   a. bone marrow
   b. pancreas
   c. basal lamina
   d. heart muscle
   e. kidney

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

3. A flexible, rubbery protein in connective tissue is called ___, whereas a more fibrous, less flexible glycoprotein is called ___.
   a. adipose; cartilage
   b. endocrine; exocrine
   c. sweat; hormones
   d. chondroitin sulfate; hydroxyapatite
   e. elastin; collagen
4. Adipose tissue:
   a. gives elasticity under epithelium.
   b. gives strength to tendons.
   c. insulates and is an energy reserve.
   d. provides movement, support, and protection.
   e. supports the nose and airways.
5. The bones of an elderly woman break more easily than those of a younger person. You would surmise that with aging, the cell type that diminishes in activity is the:
   a. osteocyte.
   b. osteoblast.
   c. osteoclast.
   d. chondrocyte.
   e. fibroblast.
6. Lifting weights will most increase the size of:
   a. skeletal muscle.
   b. smooth muscle.
   c. cardiac muscle.
   d. involuntary muscle.
   e. interlinked, branched muscle.
7. Which muscle types appear striated under a microscope?
   a. skeletal muscles only
   b. cardiac muscles only
   c. skeletal muscles and cardiac muscles
   d. smooth muscles only
   e. skeletal muscles and smooth muscles
8. Which of the following is *not* a homeostatic response?
   a. In a contest, a student eats an entire chocolate cake in 10 minutes, and his blood glucose level does not change dramatically.
   b. A jogger is sweating after a two-mile jog.
   c. The pupils in humans' eyes constrict when looking at a light.
   d. Physical activity increases carbon dioxide blood levels, which lowers blood pH, and increases breathing.
   e. Oxytocin is released by the hypothalamus during human childbirth.
9. When you exercise, a skeletal muscle increases its use of O_2, which reduces the concentration of O_2 in the muscle cells and sets up a requirement for increased O_2 uptake from the interstitial fluid. This is an example of:
   a. osmolarity.
   b. environmental sensing.
   c. integration.
   d. systemic homeostatic control.
   e. local homeostatic control.
10. The system that coordinates other organ systems is the:
   a. skeletal system.
   b. reproductive system.
   c. muscular system.
   d. nervous system.
   e. integumentary system.

Discuss the Concepts



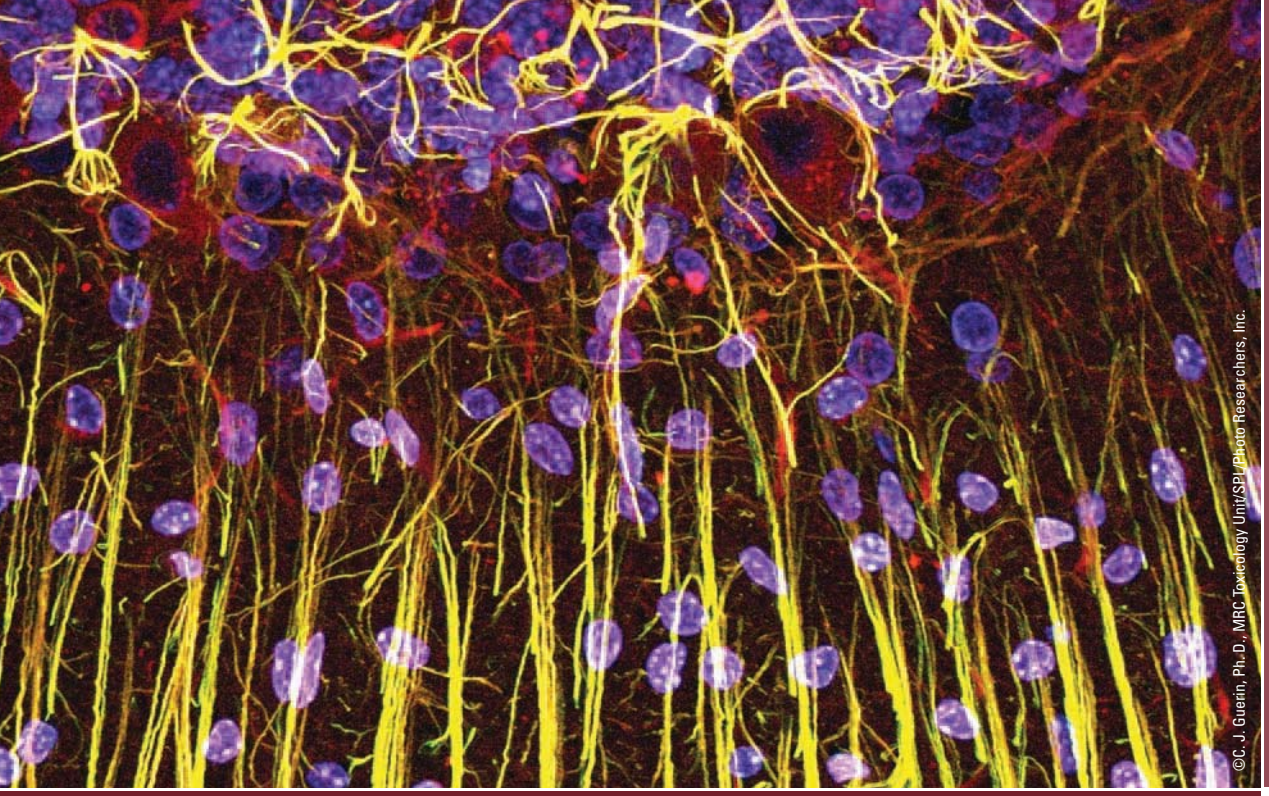
1. Blood is often described as an atypical connective tissue. If you had to argue that blood is a connective tissue, what reasons would you include? What reasons would you include if you had to argue that blood is not a connective tissue?
2. What effect do you think a program of lifting weights would have on the bones of the skeleton? How would you design an experiment to test your prediction?
3. Positive feedback mechanisms are rare in animals compared with negative feedback mechanisms. Why do you think this is so?
4. Near the time of childbirth, collagen fibers in the connective tissue of the cervix break down, and gap junctions between the smooth muscle cells of the uterus increase in number. What do you think is the significance of these tissue changes?
5. Explain how, when driving, you control the car's speed by a typical negative feedback mechanism.

Design an Experiment

The regulation of temperature in mammals and birds is an example of homeostasis. Design an experiment to observe and measure processes involved in temperature homeostasis in sedentary versus athletic humans during exercise.

Interpret the Data

Vasopressin is an important regulator of blood pressure. Taurine has been shown to inhibit vasopressin release. An experiment was done to test the hypothesis that taurine acts as part of a negative feedback system that regulates vasopressin. The experiment measured the release of taurine from rat pituitary cells in the presence of vasopressin (10 nM) **(Figure)**. Are these data consistent with the hypothesis? Why?



L. Rosso et al. 2004. Vasopressin-induced taurine efflux from rat pituicytes: a potential negative feedback for hormone secretion. *The Journal of Physiology* 554:731–742. Reprinted by permission of John Wiley and Sons.

Source: L. Rosso et al. 2004. Vasopressin-induced taurine efflux from rat pituicytes: a potential negative feedback for hormone secretion. *The Journal of Physiology* 554:731–742.

Apply Evolutionary Thinking

Large animals (like many of the vertebrates described in this chapter) often have more types of specialized tissues and organ systems than do small animals (such as flatworms). Why would natural selection favor the evolution of additional tissue types and organ systems in larger organisms?

Section through the cerebellum, a part of the brain that integrates signals coming from particular regions of the body (confocal light micrograph). Neurons, the cells that send and receive signals, are red; glial cells, which provide structural and functional support for neurons, are yellow; and nuclei are purple.

39

Information Flow and the Neuron

STUDY OUTLINE

39.1 Neurons and Their Organization in Nervous Systems

39.2 Signaling by Neurons

39.3 Transmission across Chemical Synapses

39.4 Integration of Incoming Signals by Neurons

Why it matters . . . The dog stands alert, muscles tense, motionless except for a wagging tail. His eyes are turned toward his master, a boy, poised to throw a Frisbee for him to catch. With a snap of the wrist, the boy throws the Frisbee, and the dog springs into action. Legs churning, eyes following the Frisbee, the dog runs beneath its track, closing the distance as the Frisbee reaches the peak of its climb and begins to descend. All this time, parts of the dog's brain have been processing information received through various sensory inputs. The eyes report his travel over the ground and the speed and arc of the Frisbee. Sensors in the inner ears, muscles, and joints detect the position of the dog's body, and his brain sends out signals that keep his movements on track and in balance. Other parts of the brain register inputs from sensors monitoring body temperature and carbon dioxide levels in the blood, and send signals that adjust heart and breathing rates accordingly.

At just the right instant, a burst of signals from the dog's brain causes trunk and leg muscles to contract in a coordinated pattern, and the dog leaps to intercept the Frisbee in midair with an assured snap of his jaws **(Figure 39.1).** Now the animal twists, turning his head and eyes toward the ground as his brain calculates the motions required to land on his feet and in balance. The dog makes a perfect landing and trots happily back to his master, ready to repeat the entire performance.

The functions of the dog's nervous system in the chase and capture are astounding in the amount and variety of sensory inputs, the rate and complexity of the brain's analysis and integration of incoming information, and the flurry of signals the brain sends to make compensating adjustments in body activities. Yet they are ordinary in the sense that the same activities take place countless times each day in the nervous system of all but the simplest animals.

All these activities, no matter how complex, depend on the functions of only two major cell types: *neurons* and *glial cells.* In most animals, these cells are organized into complex networks

FIGURE 39.1 A dog leaps to catch a Frisbee. The coordinated leap involves processing and integration of information by the dog's nervous system.

called *nervous systems.* This chapter describes neuron structure and tells how neurons send and receive signals with the aid and support of glial cells. The next chapter considers the neural networks of the brain and its associated structures. Chapter 41 discusses the sensory receptors that detect environmental changes and convert that information into signals for integration by the nervous system.

39.1 Neurons and Their Organization in Nervous Systems

An animal constantly receives stimuli from both internal and external sources. **Neural signaling,** communication by neurons, is the process by which an animal responds appropriately to a stimulus **(Figure 39.2).** In most animals, the four components of neural signaling are *reception, transmission, integration,* and *response:*

- **Reception,** the detection of a stimulus, is performed by specialized sensory receptors such as those in the eye and skin and directly by **neurons.**
- **Transmission** is the sending of a message along a neuron, and then to another neuron or to a muscle or gland.
- **Integration** is the sorting and interpretation of neural messages and the determination of the appropriate response(s).
- **Response** is the "output" or action resulting from the integration of neural messages.

For a dog catching a Frisbee, for instance, sensors in the eye receive light stimuli from the environment, and internal sensors receive stimuli from all the animal's organ systems. The neural messages generated are transmitted through the nervous system and integrated to determine the appropriate response, in this case stimulating the muscles so the dog jumps into the air and catches the Frisbee.

Neurons Are Cells Specialized for the Reception and Transmission of Informational Signals

Neural signaling involves three functional classes of neurons (the blue boxes in Figure 39.2). **Afferent** (*afferre* = to bring to) **neurons** (also called **sensory neurons**) transmit stimuli collected by their sensory receptors to **interneurons,** which integrate the information to formulate an appropriate response. In humans and some other primates, 99% of neurons are interneurons. **Efferent** (*efferre* = to carry away) **neurons** carry the signals indicating a response away from the interneuron networks to the **effectors,** the muscles and glands. Efferent neurons that carry signals to skeletal muscle are called **motor neurons.** The information-processing steps in the nervous system, therefore, are:

1. Sensory receptors on afferent neurons receive a stimulus.
2. Afferent neurons transmit the information to interneurons.
3. Interneurons integrate the neural messages.

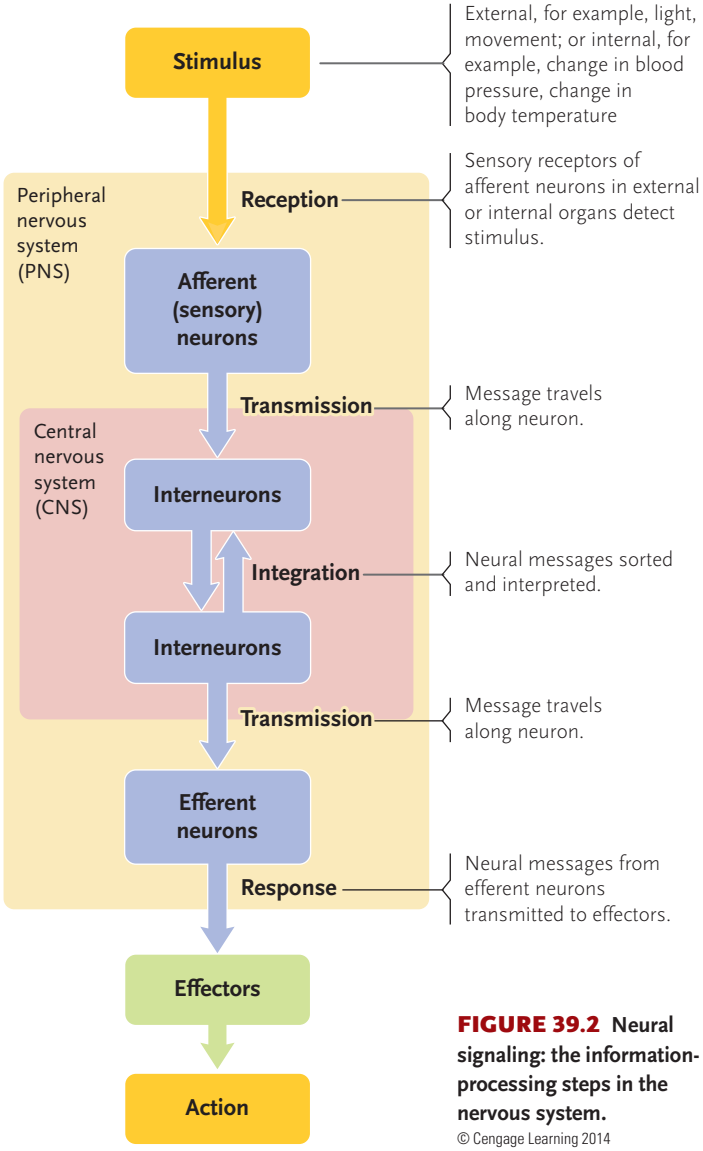

FIGURE 39.2 Neural signaling: the information-processing steps in the nervous system.

© Cengage Learning 2014

4. Efferent neurons transmit the neural messages to effectors, which act in a way appropriate to the stimulus.

Neurons vary widely in shape and size. All have an enlarged cell body and two types of extensions or processes, called dendrites and axons **(Figure 39.3).** The **cell body,** which contains the nucleus and the majority of cell organelles, is the site of synthesis of most of the proteins, carbohydrates, and lipids of the neuron. Dendrites and axons conduct electrical signals, which are produced by ions flowing down concentration gradients through channels in the plasma membrane of the neuron. **Dendrites** (*dendron* = tree) receive the signals and transmit them toward the cell body. Dendrites are generally highly branched, forming a tree-like outgrowth at one end of the neuron. **Axons** conduct signals away from the cell body to another neuron or an effector. Neurons typically have a single axon, which arises from a junction with the cell body called an **axon hillock.** The axon has branches at its tip that end as small, buttonlike swellings called **axon terminals.** The more terminals from different presynaptic cells that contact a neuron, the more incoming information it can integrate.

© Cengage Learning 2014

Connections between axon terminals of one neuron and the dendrites or cell body of a second neuron contribute to the formation of **neural circuits**. A typical neural circuit contains an afferent (sensory) neuron, one or more interneurons, and an efferent neuron. The circuits combine into networks that interconnect the parts of the nervous system. In vertebrates, the afferent neurons and efferent neurons collectively form the **peripheral nervous system (PNS).** The interneurons form the brain and spinal cord, called the **central nervous system (CNS).** The anatomical terms, **ganglia** and **nuclei,** are used to refer to clusters of nerve cells typically having related functions. Generally a **ganglion** is a group of neurons lying outside the CNS and a **nucleus** refers to a comparable concentration of cells within the CNS. As depicted in Figure 39.2, afferent information is ultimately transmitted to the CNS where efferent information is initiated. The nervous systems of most invertebrates are also divided into central and peripheral divisions.

Neurons Are Supported Structurally and Functionally by Glial Cells

Glial cells are nonneuronal cells that provide nutrition and support to neurons. One type, called **astrocytes** because they are star-shaped **(Figure 39.4),** occurs only in the vertebrate CNS, where they closely cover the surfaces of blood vessels. Astrocytes provide physical support to neurons and help maintain the concentrations of ions in the interstitial fluid surrounding them. Two other types of glial cells—**oligodendrocytes** in the CNS and **Schwann cells** in the PNS—wrap around axons in a jelly roll fashion to form myelin sheaths **(Figure 39.5).** Myelin sheaths have a high lipid content because of the many layers of plasma membranes of the myelin-forming cells. Because of their high lipid content, the myelin sheaths act as electrical insulators. The gaps between Schwann cells, called **nodes of Ranvier,** expose the axon membrane directly to extracellular fluids. This structure speeds the rate at which electrical impulses move along the axons covered by glial cells (explained later in the chapter).

Unlike most neurons, glial cells retain the capacity to divide throughout the life of the animal. This capacity allows glial tissues to replace damaged or dead cells, but also makes them the source of almost all brain tumors, produced when regulation of glial cell division is lost.

Neurons Communicate via Synapses

A **synapse** (*synapsis* = juncture) is a site where a neuron makes a communicating connection with another neuron or with an effector such as a muscle fiber or gland. On one side of the synapse is an axon terminal of the **presynaptic cell,** the neuron that transmits the signal. On the other side is a dendrite (in most cases) or a cell body of the **postsynaptic cell,** the neuron or the surface of an effector that receives the signal. There are two types of synapses, *electrical synapses* and *chemical synapses,* which differ in how the signal crosses from the presynaptic cell to the postsynaptic cell.

In **electrical synapses,** the plasma membranes of the presynaptic and postsynaptic cells are in direct contact **(Figure 39.6A),**

and communication across such synapses occurs by the direct flow of an electrical signal. When an electrical impulse arrives at the axon terminal, gap junctions (see Section 5.5) allow ions to flow directly between the two cells, leading to unbroken transmission of the electrical signal. Although electrical synapses allow the most rapid conduction of signals, this type of connection is essentially "on" or "off" and unregulated. In humans and other animals, electrical synapses typically occur as neural circuit elements where synchrony of firing and speed of response are paramount. Electrical synapses are found, for instance, in cardiac muscle, in the retina of the eye, and in the pulp of a tooth.

In **chemical synapses,** the plasma membranes of the presynaptic and postsynaptic cells are separated by a narrow gap, about 25 nm wide, called the **synaptic cleft (Figure 39.6B).** Communication across such synapses occurs by means of a **neurotransmitter,** a chemical released by an axon terminal at the synapse. That is, when an electrical impulse arrives at an

FIGURE 39.6 The two types of synapses by which neurons communicate with other neurons or effectors.

A. Electrical synapse

In an electrical synapse, channel proteins in the plasma membranes of the presynaptic and postsynaptic cells form gap junctions. Ions flow through the gap junctions, allowing impulses to pass directly to the postsynaptic cell.

B. Chemical synapse

In a chemical synapse, the plasma membranes of the presynaptic and postsynaptic cells are separated by a narrow synaptic cleft. Neurotransmitter molecules diffuse across the cleft and bind to receptors in the plasma membrane of the postsynaptic cell. The binding opens channels to ion flow that may generate an impulse in the postsynaptic cell.

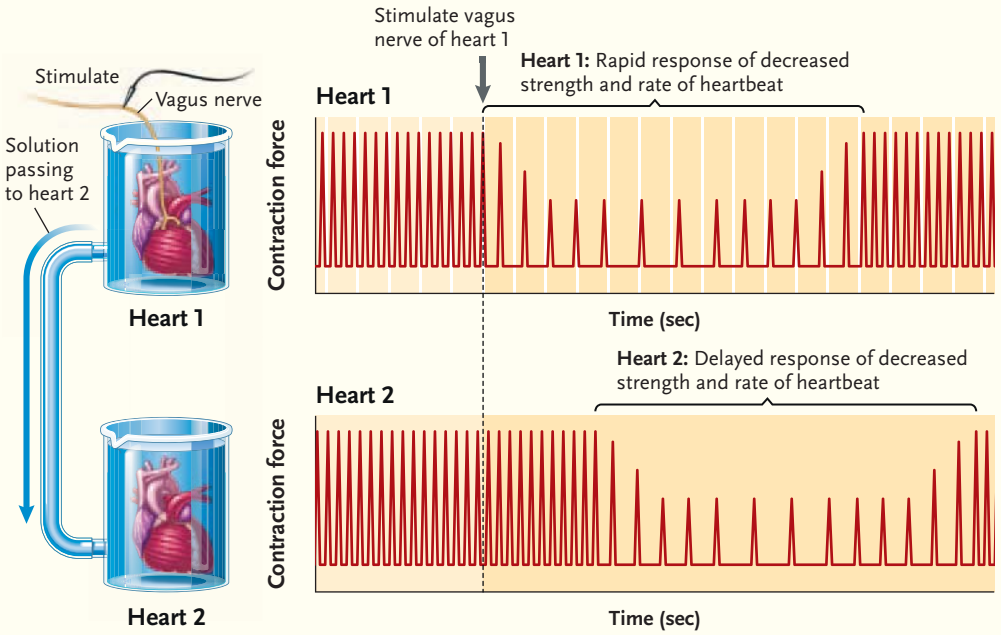

FIGURE 39.7 Experimental Research

Demonstration of Chemical Transmission of Nerve Impulses at Synapses

Question: How do neurons transmit signals across synapses?

Experiment: In the first part of the twentieth century, scientists were divided about how neurons transmit signals across synapses. Many scientists thought the signal was electrical, like the nerve signal itself; others thought that chemicals were involved. In 1921, Otto Loewi of Graz University, Austria, performed a simple, but elegant, experiment demonstrating that chemicals can transmit a signal across the synapse.

Results: Loewi isolated the hearts from two frogs, putting each into a separate container filled with a warm solution that kept the hearts alive. The two containers were linked to allow interchange of solutions. In this set up, the hearts could continue to beat for several hours. Loewi stimulated the vagus nerve of heart 1, which resulted in a rapid decrease in the strength and rate of its beating. Loewi observed that, after a short delay, the strength and rate of beating of heart 2 in the connected container also decreased.

Conclusion: Loewi concluded that, when the nerve was stimulated, some chemical substance was produced at the synapses of heart 1 that could diffuse through the solution and cause the same physiological effect in heart 2. The delayed response of heart 2 was the result of the time it took for the chemical to diffuse through the solution. Loewi called the chemical Vagusstoff (vagal substance), to relate it to the vagus nerve stimulation. Subsequently, Vagusstoff was shown to be acetylcholine.

THINK LIKE A SCIENTIST How could you demonstrate experimentally that acetylcholine is Vagusstoff?

axon terminal, it causes the release of a neurotransmitter into the synaptic cleft. The neurotransmitter diffuses across the synaptic cleft and binds to a receptor in the plasma membrane of the postsynaptic cell. If enough neurotransmitter molecules bind to these receptors, the postsynaptic cell generates a new electrical impulse, which travels along its axon to reach a synapse with the next neuron or effector in the circuit. The vast majority of vertebrate neurons communicate by means of neurotransmitters.

A chemical synapse is more than a simple on–off switch because many factors can influence the generation of a new electrical impulse in the postsynaptic cell, including neurotransmitters that inhibit that cell rather than stimulating it. The balance of stimulatory and inhibitory effects in chemical synapses contributes to the integration of incoming information in a receiving neuron.

Figure 39.7 shows the first experiment to demonstrate the chemical transmission of a nerve impulse across a synapse.

FIGURE 39.8 Research Method

Measuring Membrane Potential

Purpose: To determine the membrane potentials of unstimulated and stimulated neurons and muscle cells.

Protocol: Prepare a microelectrode by drawing out a glass capillary tube to a tip with a diameter much smaller than that of a cell and filling it with a salt solution that can conduct an electric current. Under a microscope, use a micromanipulator (mechanical positioning device) to insert the tip of the microelectrode into an axon. Place a reference electrode in the solution outside the cell. Use an oscilloscope or voltmeter to measure the voltage between the microelectrode tip in the axon and the reference electrode outside the cell.

Interpreting the Results: The oscilloscope or voltmeter indicates the membrane potential in volts. Changes in membrane potential caused by stimuli or chemical treatments can be measured and recorded. For an isolated, unstimulated neuron (shown above), the membrane potential is typically about −70 mV.

© Cengage Learning 2014

Two other aspects of cellular membrane permeability are also crucial to the establishment of the resting membrane potential:

1. The membrane is more permeable to passive diffusion of K^+ than of Na^+, about 50 times more permeable.
2. The cytoplasm is rich in large anionic molecules—amino acids, proteins, nucleic acids—that cannot cross the cell membrane. The distribution and mobility of these various ionic species produce the steady-state resting potential.

Because of its concentration gradient, K^+ attempts to diffuse from the cell. But, when it does, large anion molecules are left behind. These anions are not effectively neutralized by cations because the cell membrane does not permit significant Na^+ movement. At steady state, the cell has a negative internal potential produced by the unpaired organic anions that is just strong enough to prevent further K^+ exit. Thus, this steady state forms a balanced disequilibrium between the concentration gradient for K^+ and the electrical gradient counteracting further K^+ movement.

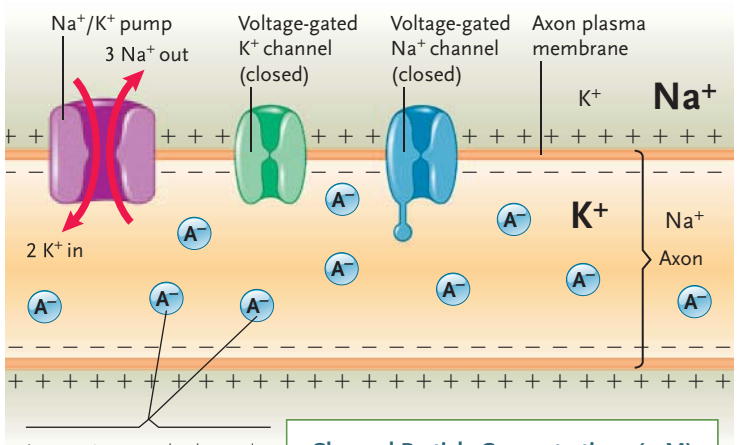
In most cells, the membrane potential does not change. However, neurons and muscle cells use the membrane potential in a specialized way. That is, in response to electrical, chemical, mechanical, and certain other types of stimuli, their membrane potential changes rapidly and transiently. Cells with this property are said to be *excitable cells.* Excitability, produced by a sudden ion flow across the plasma membrane, is the basis for nerve impulse generation.

39.2 Signaling by Neurons

All cells of an animal have a **membrane potential,** a separation of positive and negative charges across the plasma membrane. Outside the cell the net charge is positive, and inside the cell it is negative. This charge separation produces *voltage*—an electrical potential difference—across the plasma membrane.

Selective Permeability of the Plasma Membrane to Ions and Other Charged Molecules Produces the Membrane Potential

Membrane potential is the result of the selective permeability of the plasma membrane to charged atoms (ions) and molecules. Because of the action of the Na^+/K^+ pump in the membrane, Na^+ is removed from the cytoplasm and K^+ is brought into the cytoplasm (see Section 6.4; the ATPase of the pump hydrolyzes ATP to provide the energy for the pump's activity). This results in a concentration gradient of Na^+ strongly favoring its diffusion into the cell and the opposite for K^+.



Resting Potential Is the Unchanging Membrane Potential of an Unstimulated Neuron

The membrane of a neuron (or another excitable cell) that is not conducting an impulse exhibits a steady negative membrane potential, called the **resting potential.** Resting potentials are typically in the −50 to −70 millivolt (mV) range in isolated neurons **(Figure 39.8).** A neuron exhibiting the resting potential is said to be *polarized.*

The distribution of ions inside and outside an axon that produces the resting potential is shown in **Figure 39.9.** As described earlier in this section, the Na^+/K^+ pump is responsible for creating both the imbalance of Na^+ and K^+ inside and outside of the cell and the unpaired charge state between intracellular anions and extracellular positive charges. Voltage-gated ion channels for Na^+ and K^+ open and close when a neuron is stimulated, causing the membrane potential changes.

As noted previously, the tendency for K^+ to diffuse from the cell and leave behind unpaired negative charges is largely responsible for the negative resting potential. The electrical potential necessary to balance this diffusional potential of K^+ can

© Cengage Learning 2014

be calculated and is called the **equilibrium potential** for K^+ (E_K). Similarly, equilibrium potentials can be calculated for other ions distributed unequally across the cell membrane. If K^+ were the only ion moving across the membrane, the E_K would be equal to the resting potential. Typically, the resting potential is a little more positive than E_K, indicating that some positive ion may be leaking into the cell. The obvious candidate is Na^+ because of the strong concentration gradient for this ion between the outside and the inside of the cell. The reason that the positive charge of Na^+ does not swamp the negative charge within the cell is the extremely low permeability of the membrane to Na^+. Indeed, the equilibrium potential for Na^+ (E_{Na}) is around 50 mV; in other words, if Na^+ diffused freely across the membrane, the charge inside of the cell would have to be raised to +50 mV to maintain the disequilibrium of Na^+ concentration between the inside of the cell and the outside.

Equilibrium potentials provide a convenient way to predict ion movement across the cell membrane. If an equilibrium potential is close to the resting potential, there will be little ion movement even if the membrane is freely permeable to the ion. For example, if a K^+ channel opens in a membrane with a resting membrane potential in the −70 mV range, some small amount of K^+ will leave the cell to bring the membrane potential closer to the E_K, which is generally somewhat more negative than −70 mV. By contrast, if a Na^+ channel opens, both the concentration gradient for Na^+ and the attraction of the intracellular anions will act together to promote significant Na^+ entry into the cell. The effect will be to **depolarize** the cell—make it less negative.

The Membrane Potential Changes from Negative to Positive during an Action Potential

When a neuron transmits an electrical impulse, an abrupt and transient change in membrane potential occurs; this is called the **action potential.** An action potential begins as a stimulus that causes positive charges from outside the neuron to flow inward, making the cytoplasmic side of the membrane less negative **(Figure 39.10).** As the membrane potential becomes less negative, the membrane (which was polarized at rest) becomes depolarized. Depolarization proceeds relatively slowly until it reaches a level known as the **threshold potential,** typically 10 to 20 mV more positive than the resting potential. Once the threshold is reached, the action potential fires—and the membrane potential suddenly increases. In less than 1 msec (millisecond, one-thousandth of a second), it rises so high that the inside of the plasma membrane becomes positive due to an influx of positive ions across the cell membrane, momentarily reaching a value of +30 mV or more. The potential then falls again, in many cases dropping to about −80 mV before rising again to the resting potential. When the potential is below the resting value, the membrane is said to be **hyperpolarized.** The entire change, from initiation of the action potential to the return to the resting potential, may take as little as 1 msec in the fastest neurons. Action potentials take the same basic form in neurons of all types, with differences in the values of the resting potential and the peak of the action potential, and in the time required to return to the resting potential.

An action potential is produced only if a stimulus that causes positive charges from outside the neurons to flow inward is strong enough to cause depolarization that reaches the threshold. This is referred to as the **all-or-nothing principle;** once triggered, the changes in membrane potential take place independently of the strength of the stimulus.

Beginning at the peak of an action potential, the membrane enters a **refractory period** that consists of two phases.

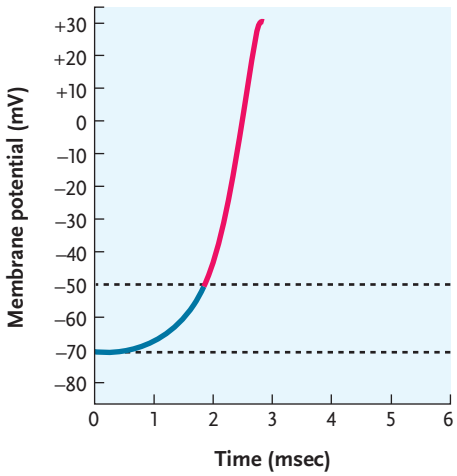
CLOSER LOOK

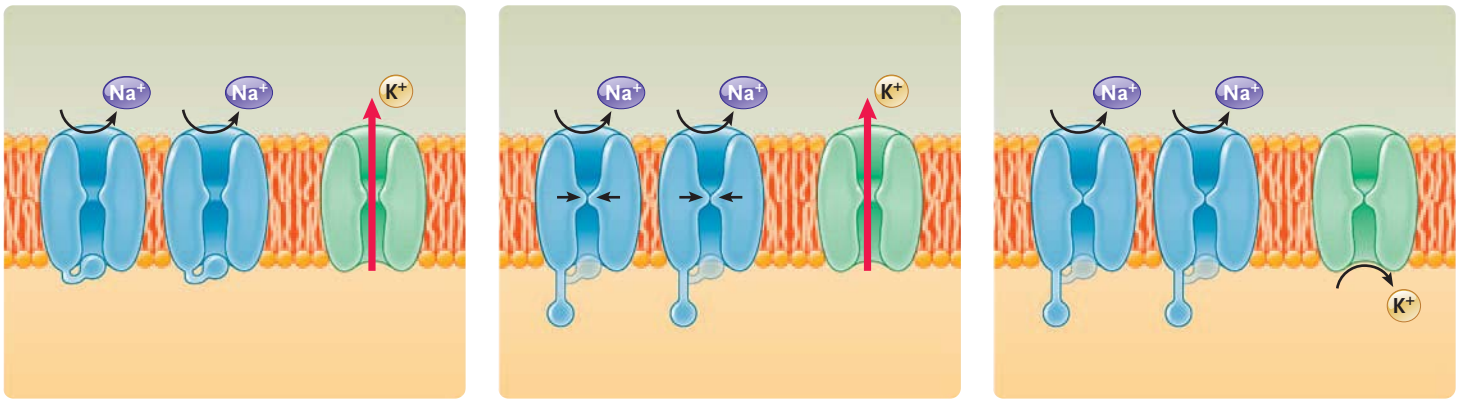
FIGURE 39.11 Changes in voltage-gated Na^+ and K^+ channels that produce the action potential.



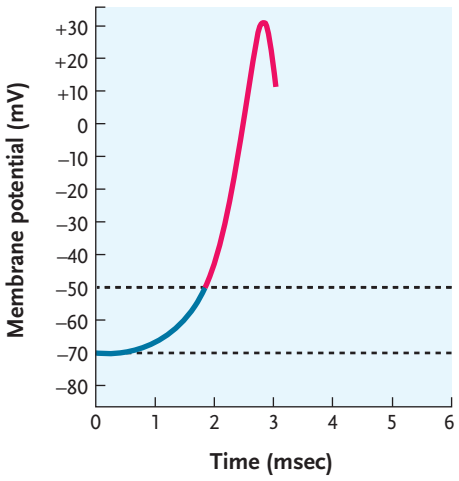
1 When the membrane is at the resting potential, the activation gates of both the Na^+ and K^+ channels are closed. As a depolarizing stimulus raises the membrane potential to threshold, the activation gates of the Na^+ channels open, causing a burst of Na^+ ions to flow into the axon along their concentration gradient.

2 Once above the threshold, more Na^+ channels open, causing a rapid inward flow of positive charges that raises the membrane potential toward the peak of the action potential.

3 The onset of Na^+ channel inactivation (resembling putting a stopper into a sink) stops the inward flow of Na^+ and causes the action potential to peak. At the same time, activated K^+ channels allow K^+ to flow outward in response to their concentration gradient. The refractory period now begins.

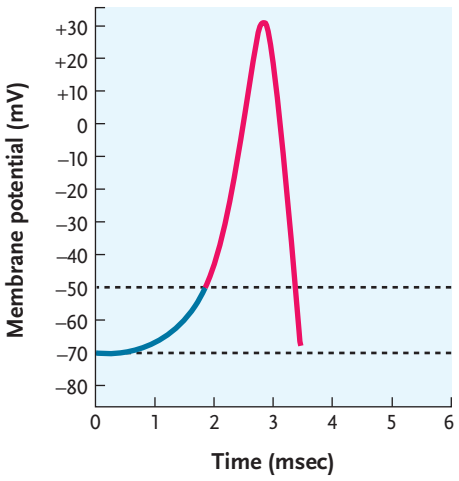


© Cengage Learning 2014



During the initial phase, the cell cannot be restimulated. This is followed by a period during which the threshold required for generation of an action potential is much higher than normal. The refractory period lasts until the membrane has stabilized at the resting potential. As we shall see, the refractory period keeps impulses traveling in a one-way direction in neurons.

The Action Potential Is Produced by Ion Movements through the Plasma Membrane



The action potential is produced by movements of Na^+ and K^+ through the plasma membrane. The movements are controlled by specific **voltage-gated ion channels,** membrane-embedded proteins that open and close as the membrane potential changes (see Figure 39.9). Voltage-gated Na^+ channels have two gates, an

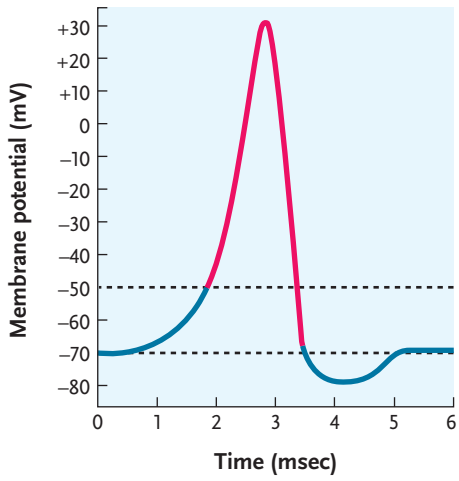
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.



4 The outward flow of K^+ along its concentration gradient compensates for the inward movement of Na^+ ions and causes the membrane potential to begin to fall.

5 As the membrane potential reaches the resting value, the activation gate of the Na^+ channel closes and the inactivation gate opens. In most neurons, the K^+ activation gate remains open and K^+ continues to flow outward for a brief time after the membrane reaches the resting potential. This excess outward flow causes hyperpolarization, in which the membrane potential dips briefly below the resting potential (the dip is seen in step 6).

6 Closure of the K^+ activation gate stabilizes the membrane potential at the resting value. The refractory period has now ended, and the membrane is ready for another action potential.

SUMMARY An action potential is generated when a depolarizing stimulus initiates a specific sequence of opening and closing voltage-gated Na^+ and K^+ channels in the axon's plasma membrane. Na^+ flows into the axon raising the membrane potential until the peak of the action potential, at which point Na^+ channels are blocked and K^+ begins to flow outward through K^+ channels. The outflow of K^+ lowers the membrane potential. When the resting potential is reached, K^+ flow stops.

THINK LIKE A SCIENTIST How might the action potential curve change if you inhibited the voltage-gated K^+ channel significantly?

activation gate and an *inactivation gate,* whereas voltage-gated K^+ channels have one gate, an *activation gate.*

Figure 39.11 shows how the two voltage-gated ion channels operate to generate an action potential. At the end of an action potential, the membrane potential has returned to its resting state, but the ion distribution has changed slightly. That is, some Na^+ ions have entered the cell, and some K^+ ions have left the cell—but not many, relative to the total number of ions, and the distribution is not altered enough to prevent other action potentials from occurring. In the long term, the Na^+/K^+ pumps restore the Na^+ and K^+ ions to their original locations.

Some of what is known about how ions flow through channels can change membrane potential has come from experiments using the *patch-clamp* technique. In the *patch* part of the technique, a micropipette with a tip 1 to 3 μm in diameter is touched to the plasma membrane of a neuron (or other cell type). The con-

© Cengage Learning 2014

tact seals the membrane to the micropipette and, when the micropipette is pulled away, a patch of membrane with one or a few ion channels comes with it. The *clamp* part of the technique refers to a voltage clamp, in which an electronic device holds the membrane potential of the patch at a steady value chosen by the investigator. The investigator can add a stimulus that is expected to open or close ion channels. The amount of current the clamping device needs to keep the voltage constant is directly related to the number and charge of the ions moving through the channels and, hence, measures channel activity.

Neural Impulses Move by Propagation of Action Potentials

Once an action potential is initiated in a neuron, it passes along the surface of the axon as an automatic wave of depolarization traveling away from the stimulation point **(Figure 39.12).** The action potential does not need further trigger events to be propagated along the axon to the terminals. In a segment of an axon that is generating an action potential, the outside of the membrane becomes temporarily negative and the inside positive. Because opposites attract, as the region outside becomes negative, local current flow occurs between the area undergoing an action potential and the adjacent downstream inactive area both inside and outside the membrane (arrows, Figure 39.12). This current flow makes nearby regions of the axon membrane less positive on the outside and more positive on the inside; in other words, they depolarize the membrane.

The depolarization is large enough to push the membrane potential past the threshold, opening the voltage-gated Na^+ and K^+ channels and starting an action potential in the down-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

stream adjacent region. In this way, each segment of the axon stimulates the next segment to fire, and the action potential moves rapidly along the axon as a nerve impulse.

The refractory period keeps an action potential from reversing direction at any point along an axon; only the region in front of the action potential can fire. The refractory period results from the properties of the voltage-gated ion channels. Once they have been opened to their activated state, the upstream voltage-gated ion channels need time to reset to their original positions before they can open again. Therefore, only downstream voltage-gated ion channels are able to open, ensuring the one-way movement of the action potential toward the axon tips. By the time the refractory period ends in a membrane segment that has just fired an action potential, the action potential has moved too far away to cause a second action potential to develop in the same segment.

The magnitude of an action potential stays the same as it travels along an axon, even where the axon branches at its tips. Thus the propagation of an action potential resembles a burning fuse, which, once it is lit at one end, burns with the same intensity along its length and along any branches. Unlike a fuse, however, an axon can fire another action potential of the same intensity within a few milliseconds after an action potential passes through.

Due to the all-or-nothing principle of action potential generation, the intensity of a stimulus is reflected in the *frequency* of action potentials—the greater the stimulus, the more action potentials per second, up to a limit depending on the axon type—rather than by the change in membrane potential. For most neuron types, the limit is about 100 action potentials per second.

Both natural and synthetic substances target specific parts of the mechanism generating action potentials. Local anesthetics, such as procaine and lidocaine, bind to voltage-gated Na^+ channels and block their ability to permit ion flow; thus, sensory nerves in the anesthetized region cannot transmit pain signals. The potent poison of the pufferfish, tetrodotoxin, also blocks voltage-gated Na^+ channels in neurons, potentially causing muscle paralysis and death.

Saltatory Conduction Increases Propagation Rate in Small-Diameter Axons

In the propagation pattern shown in Figure 39.12, an action potential spreads along every segment of the membrane along the length of the axon. For this type of action potential propagation, the rate of conduction increases with the diameter of the axon. Axons with a very large diameter have evolved in invertebrates such as lobsters, earthworms, and squids, as well as a few marine fishes. Giant axons typically carry signals that produce an escape or prey–capture response, such as the sudden flexing of the tail (abdomen) in lobsters that propels the animal backward. The largest known axons, 1.7 mm in diameter, occur in fanworms *(Myxicola)*. The signals they carry contract a muscle that retracts the fanworm's body into a protective tube when the animal is threatened.

Although large-diameter axons can propagate impulses as rapidly as 25 m/sec (over twice the speed of the world record 100-meter dash), they take up a great deal of space. In vertebrate central nervous systems with many more neurons, natural selection has led to a mechanism that allows small-diameter axons to conduct impulses rapidly. The mechanism, called **saltatory conduction** (*saltare* = to hop, leap), allows action potentials to "hop" rapidly along axons instead of burning smoothly like a fuse.

Saltatory conduction depends on the insulating myelin sheath that forms around some axons and on the periodic interruption of the sheath at the nodes of Ranvier, exposing the axon membrane to extracellular fluids. Voltage-gated Na^+ and K^+ channels crowded into the neuronal membrane at the nodes allow action potentials to develop at these positions **(Figure 39.13).** The inward movement of Na^+ ions produces depolarization, and positive ions spread rapidly with little loss, due to the myelin insulation, to the next node where they cause depolarization, inducing an action potential at that node. As this mechanism repeats, the action potential jumps rapidly along the axon from node to node. Saltatory conduction proceeds at rates up to 130 m/sec while an unmyelinated axon of the same diameter conducts action potentials at about 1 m/sec.

In humans, the optic nerve leading from the eye to the brain is only 3 mm in diameter but is packed with more than a million axons. If those axons were unmyelinated, each would have to be about 100 times thicker to conduct impulses at the same velocity, producing an optic nerve about 300 mm (12 inches) in diameter.

The disease *multiple sclerosis* (*sklerosis* = hardening) underscores the importance of myelin sheaths to the operation of the vertebrate nervous system. In this disease, myelin is progressively lost from axons and replaced by hardened scar tissue.

The changes block or slow the transmission of action potentials, producing numbness, muscular weakness, faulty coordination of movements, and paralysis that worsens as the disease progresses.

39.3 Transmission across Chemical Synapses

As described in Section 39.1, there is either an electrical synapse or a chemical synapse between a presynaptic cell and a postsynaptic cell depending on the neuron junction. In this section, we focus on chemical synapses, which constitute the vast majority of synapses in vertebrates.

Whereas action potentials are transmitted directly across electrical synapses, they cannot jump across the cleft in a chemical synapse. Instead, the arrival of an action potential causes neurotransmitter molecules to be released by exocytosis from the plasma membrane of the axon terminal, called the presynaptic membrane **(Figure 39.14).** The neurotransmitter diffuses across the cleft and alters ion conduction by activating receptors in the plasma membrane of the postsynaptic cell. Neurotransmitter communication from presynaptic to postsynaptic cells is a specialized case of cell-to-cell communication and signal transduction, which you learned about in Chapter 7. Neurobiologists study this phenomenon to understand the function of neurons, but some of the details are similar in many other types of cells.

Two types of receptors bind neurotransmitters, with different consequences:

- For **ionotropic neurotransmitter receptors,** a neurotransmitter binds to the receptor in the postsynaptic membrane, causing an associated ion channel gate to open or close, thereby altering the transmembrane flow of a specific ion or ions in the postsynaptic cell. Figure 39.14 illustrates this type of receptor. (This is an example of a *ligand-gated ion channel,* a channel that opens or closes when a specific chemical, here a neurotransmitter, binds to the channel.) The time between arrival of an action potential at an axon terminal and alteration of the membrane potential in the postsynaptic cell may be as little as 0.2 msec.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- For **metabotropic neurotransmitter receptors,** a neurotransmitter works indirectly and, hence, more slowly (on the order of hundreds of milliseconds). For this type of receptor, which is typically of the G-protein–coupled receptor type, the neurotransmitters act as *first messengers.* That is, the neurotransmitters bind to the receptor, which activates it and triggers generation of a second messenger such as cyclic AMP or other processes (see Section 7.4). The cascade of *second-messenger* reactions opens or closes ion-conducting channels in the postsynaptic membrane. Neurotransmitters that bind to metabotropic neurotransmitter receptors typically have effects that may last for minutes or hours.

Some neurotransmitters bind only to one or other of the receptor types, whereas other neurotransmitters bind to both receptor types, bringing about different responses depending on which receptor is involved.

The time required for the release, diffusion, and binding of neurotransmitters across chemical synapses delays transmission as compared with the almost instantaneous transmission of impulses across electrical synapses. However, communication through chemical synapses allows neurons to receive inputs from hundreds to thousands of axon terminals at the same time. Some neurotransmitters have stimulatory effects and others have inhibitory effects. All of the information received at a postsynaptic membrane is integrated to produce a response. Thus, by analogy, communication by electrical synapses resembles the effect of simply touching one wire to another; communication by neurotransmitters through both direct and indirect receptor responses resembles the integration of multiple inputs by a computer chip.

Neurotransmitters Are Released by Exocytosis

Neurotransmitters are stored in synaptic vesicles in the cytoplasm of an axon terminal. The arrival of an action potential at the terminal releases the neurotransmitters by *exocytosis:* the vesicles fuse with the presynaptic membrane and release the neurotransmitter molecules into the synaptic cleft.

The release of neurotransmitters from synaptic vesicles depends on voltage-gated Ca^{2+} channels in the plasma membrane of an axon terminal (see Figure 39.14). Ca^{2+} ions are constantly pumped out of all animal cells by an active transport protein in the plasma membrane, keeping their concentration higher outside than inside. (That is, the equilibrium potential for Ca^{2+}, E_{Ca}, is strongly positive.) As an action potential arrives, the change in membrane potential opens the Ca^{2+} channel gates in

Dissecting Neurotransmitter Receptor Functions

Many ionotropic neurotransmitter receptors are ion channels that are opened or closed by the binding of a neurotransmitter molecule. Each of these receptors has two domains: a hydrophilic portion on the outside surface of the plasma membrane that binds the neurotransmitter, and a hydrophobic transmembrane portion that anchors the receptor in the plasma membrane and forms the ion-conducting channel.

Research Question

Are the two primary activities of these receptors—binding neurotransmitters and conducting ions—dependent on parts of the protein that work independently, or do they each require the entire protein structure?

Experiment

To answer the question, Jean-Luc Eiselé and his coworkers at Institut Pasteur, Paris, and colleagues at Centre Médical Universitaire, Geneva, Switzerland, constructed artificial receptors using regions of the ionotropic receptors for two different neurotransmitters. The two receptors are not closely related in amino acid sequence, bind different neurotransmitters, and react differently to calcium ions. One receptor, the nicotinic acetylcholine receptor (nAChR), is activated by acetylcholine and by nicotine, and ion conduction by the receptor is enhanced by Ca^{2+}. The other receptor, the serotonin receptor ($5HT_3$), is activated by serotonin, and Ca^{2+} ions block its channel and stop ion conduction.

To create the artificial receptors, the investigators used molecular techniques to break each of the genes for the nicotinic acetylcholine and serotonin receptors into two sequences, one encoding the hydrophilic domain and the other encoding the hydrophobic domain. They then reassembled the parts so that in the protein encoded by the chimeric gene, the part of the acetylcholine receptor located on the membrane surface was joined to the transmembrane channel of the serotonin receptor **(Figure).** Five versions of the artificial gene, encoding proteins in which the two parts were joined at different positions in the amino acid sequence, were then cloned to increase their quantity and injected into oocytes of the African clawed frog, *Xenopus laevis.* Once in the oocytes, the genes were expressed to produce the chimeric receptor proteins, which became inserted into the oocyte plasma membranes. The properties of the chimeric receptors were then examined.

Results

Of the five artificial receptors, all bound acetylcholine, but only two conducted ions in response to binding the neurotransmitter. Agents that inhibit the normal acetylcholine receptor, such as curare, also inhibited the artificial receptors. Serotonin, in contrast, did not bind nor did it open the receptor channels, and agents that inhibit the normal serotonin receptor had no effect on the artificial receptors. However, elevated Ca^{2+} concentrations blocked the channel, as in the normal serotonin receptor.

Conclusion

The research by Eiselé and his coworkers showed that the parts of a receptor binding a neurotransmitter and conducting ions function independently. Their work also demonstrated the feasibility of constructing chimeric receptors as a means for dissecting the functions of subregions of the receptors.

THINK LIKE A SCIENTIST As stated in the Results, two of the five artificial receptors conducted ions whereas the other three did not. What is the likely explanation for this result?

the axon terminal, allowing Ca^{2+} to flow back into the cytoplasm. The rise in Ca^{2+} concentration triggers a protein in the membrane of the synaptic vesicle that allows the vesicle to fuse with the plasma membrane, releasing neurotransmitter molecules into the synaptic cleft.

Each action potential arriving at a synapse typically causes approximately the same number of synaptic vesicles to release their neurotransmitter molecules. For example, arrival of an action potential at one type of synapse causes about 300 synaptic vesicles to release a neurotransmitter called acetylcholine. Each vesicle contains about 10,000 molecules of the neurotransmitter, giving a total of some 3 million acetylcholine molecules released into the synaptic cleft by each arriving action potential.

When a stimulus is no longer present, action potentials are no longer generated and a response is no longer needed. In this case, a series of events prevents continued transmission of the signal. When action potentials stop arriving at the axon terminal, the voltage-gated Ca^{2+} channels close and the Ca^{2+} in the axon cytoplasm is quickly pumped to the outside. The drop in cytoplasmic Ca^{2+} stops vesicles from fusing with the presynaptic membrane, and no further neurotransmitter molecules are released. Any free neurotransmitter molecules remaining in

the cleft quickly diffuse away, are broken down by enzymes in the cleft, or are pumped back into the axon terminals or into glial cells by active transport. Transmission of information across the synaptic cleft ceases within milliseconds after action potentials stop arriving at the axon terminal.

Most Neurotransmitters Alter Ion Flow through Na^+ or K^+ Channels

Neurotransmitters work by opening or closing ion channels; most of these channels conduct Na^+ or K^+ across the postsynaptic membrane, although some regulate chloride ions (Cl^-). The altered ion flow in the postsynaptic cell that results from the opening or closing of the gates may stimulate or inhibit the generation of action potentials by that cell. For example, if Na^+ channels are opened, the inward Na^+ flow brings the membrane potential of the postsynaptic cell toward the threshold (the membrane becomes depolarized). If K^+ channels are opened, the outward flow of K^+ has the opposite effect (the membrane becomes hyperpolarized). The combined effects of the various stimulatory and inhibitory neurotransmitters at all the chemical synapses of a postsynaptic neuron or muscle cell determine whether the postsynaptic cell triggers an action potential. (*Insights from the Molecular Revolution* describes experiments that worked out the structure and function of an ion channel gated directly by a neurotransmitter.)

Many Different Molecules Act as Neurotransmitters

In all, nearly 100 different substances are now known or suspected to be neurotransmitters. Most of them are relatively small molecules that diffuse rapidly across the synaptic cleft. Some axon terminals release only one type of neurotransmitter; others release several types. Depending on the type of receptor to which it binds, the same neurotransmitter may depolarize or hyperpolarize potentials in the postsynaptic cell. **Table 39.1** lists a number of neurotransmitters, the types of molecules they represent, their sites and type of action, and some drugs and other molecules that affect neurotransmission.

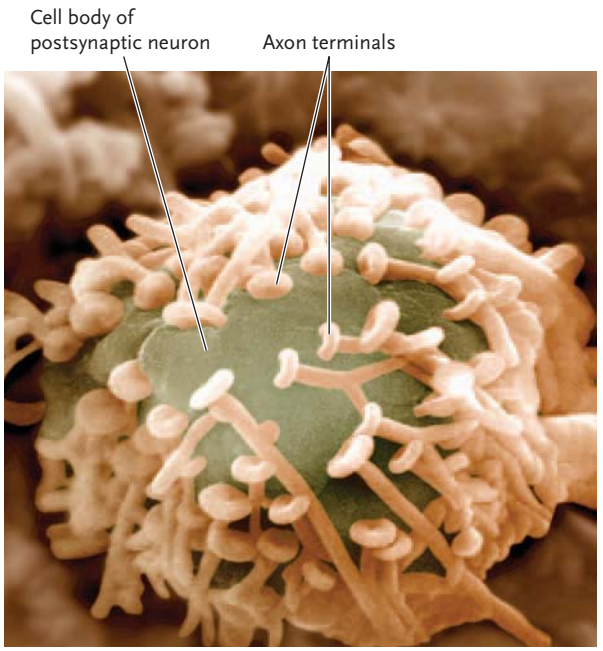
2. **Describe how a neurotransmitter that binds to an ionotropic neurotransmitter receptor in a presynaptic neuron controls action potentials in a postsynaptic neuron.**



39.4 Integration of Incoming Signals by Neurons

Most neurons receive a multitude of stimulatory and inhibitory signals carried by both direct and indirect neurotransmitters. These signals are integrated by the postsynaptic neuron into a response that reflects their combined effects. The integration depends primarily on the patterns, number, types, and activity of the synapses the postsynaptic neuron makes with presynaptic neurons. Inputs from other sources, such as indirect neurotransmitters and other signal molecules, can modify the integration. The response of the postsynaptic neuron is elucidated by the frequency of action potentials it generates.

Integration at Chemical Synapses Occurs by Summation

As mentioned earlier, depending on the type of receptor to which it binds, a neurotransmitter may stimulate or inhibit the generation of action potentials in the postsynaptic neuron. If a neurotransmitter opens a Na^+ channel, Na^+ enters the cell, causing a depolarization. This change in membrane potential pushes the neuron closer to threshold; that is, it is excitatory and is called an **excitatory postsynaptic potential,** or **EPSP.** However, if a neurotransmitter opens an ion channel that allows Cl^- to flow into the cell or K^+ to flow out, hyperpolarization occurs. This change in membrane potential pushes the neuron farther from threshold; that is, it is an **inhibitory postsynaptic potential,** or **IPSP.** In contrast to the all-or-nothing operation of an action potential, EPSPs and IPSPs are **graded potentials,** in which the membrane potential increases or decreases to a greater or lesser degree.

A neuron typically has hundreds to thousands of chemical synapses formed by axon terminals of presynaptic neurons contacting its dendrites and cell body **(Figure 39.15).** The events that occur at a single synapse produce either an EPSP or an IPSP in that postsynaptic neuron. But how is an action poten-

TABLE 39.1 Examples of Neurotransmitters and Drugs and Chemicals That Affect Neurotransmission

Neurotransmitter	Site(s) of Action	Action	Examples of Drugs and Other Molecules That Affect Neurotransmission
Acetylcholine			
Acetylcholine	Between some neurons of CNS and at neuromuscular junctions in PNS	Mostly excitatory; inhibitory at some sites	• Curare—blocks release • Atropine—blocks receptors • Nicotine—activates receptors
Monoamines (biogenic amines)			
Norepinephrine	CNS interneurons involved in diverse brain and body functions, such as memory, mood, sensory perception, muscle movements, maintenance of blood pressure and sleep	Excitatory or inhibitory	• Amphetamines—stimulate release of norepinephrine and dopamine and block their reuptake • Methylphenidate (Ritalin)—increases release • Certain antidepressants—prevent reuptake
Dopamine	CNS interneurons involved in many pathways similar to norepinephrine	Mostly excitatory	• Amphetamines—stimulate release of norepinephrine and dopamine and block their reuptake • Cocaine—stimulates release of norepinephrine and dopamine and blocks dopamine reuptake
Serotonin	CNS interneurons in a number of pathways, including those regulating appetite, reproductive behavior, muscular movement, sleep, and some emotional states	Inhibitory or modulatory	• Fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil)—block serotonin reuptake
Amino Acids			
Glutamate	Many CNS pathways, including those involved in vital brain functions such as memory and learning	Excitatory	• Phencyclidine (PCP or angel dust)—blocks receptor
Gamma-aminobutyric acid (GABA)	Many CNS pathways; often acts in same circuits as glutamate	Inhibitory (main inhibitory neurotransmitter in mammalian CNS)	• Alcohol (ethanol)—stimulates GABA neurotransmission, increases dopamine neurotransmission, and inhibits glutamate neurotransmission • Some antianxiety/sedative drugs such as diazepam (Valium) and flunitrazepam (Rohypnol, the "date rape" drug) increase GABA neurotransmission • Tetanus toxin blocks GABA release in synapses that control muscle contraction
Neuropeptides			
Endorphins ("endogenous morphines")	Most act on CNS and PNS as well as on effectors such as muscle, reducing pain and, in some cases, also inducing euphoria	Inhibitory—modulate pain response	
Enkephalins (subclass of endorphins)	CNS	Inhibitory—modulate pain response	
Substance P	Released by special, unmyelinated sensory neurons in spinal cord	Excitatory—pain perception	
Gaseous neurotransmitters			
Nitrous oxide (NO)	Diffuses across cell membranes in PNS rather than being released at synapses	Modulatory—relaxes smooth muscles in walls of blood vessels	Sildenafil citrate (Viagra, an impotency drug)—aids erection by inhibiting enzyme that normally reduces effects of NO in vascular beds of penis

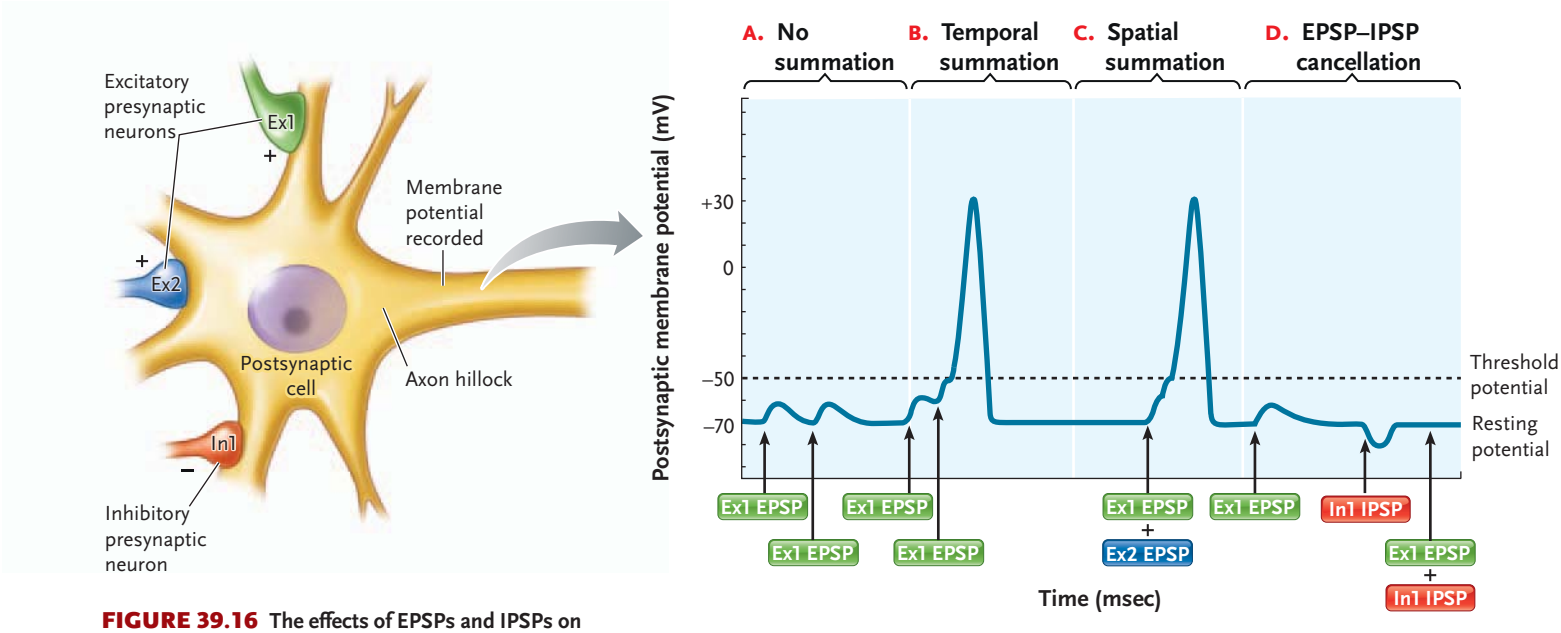

FIGURE 39.16 **The effects of EPSPs and IPSPs on membrane potential, and how summation of inputs over space and time brings a postsynaptic neuron to threshold.**

© Cengage Learning 2014

A. No summation: The axon of Ex1 releases a neurotransmitter, which produces an EPSP in the postsynaptic cell. The membrane depolarizes, but not enough to reach threshold. If Ex1 input causes a new EPSP after the first EPSP has died down, it will be of the same magnitude as the first EPSP and no progression toward threshold has taken place—no summation has occurred.

B. Temporal summation: If instead, Ex1 input causes a new EPSP before the first EPSP has died down, the second EPSP will sum with the first and a greater depolarization will have taken place. This summation of two (or more) EPSPs produced by successive firing of a single presynaptic neuron over a short period of time is temporal summation. If the total depolarization achieved in this way reaches threshold, an action potential is produced in the postsynaptic neuron.

C. Spatial summation: The postsynaptic neuron may be brought to threshold by spatial summation, the summation of EPSPs produced by the simultaneous firing of two different excitatory presynaptic neurons, such as Ex1 and Ex2.

D. Summation resulting in cancellation: EPSPs and IPSPs can sum to cancel each other out. In the example, firing of the excitatory presynaptic neuron Ex1 alone produces an EPSP, firing of presynaptic inhibitory neuron In3 alone produces an IPSP, while firing of Ex1 and In3 simultaneously produces no change in the membrane potential.

tial produced if a single EPSP is not sufficient to push the postsynaptic neuron to threshold? The answer involves summation of the inputs received through those many chemical synapses formed by presynaptic neurons. At any given time, some or many of the presynaptic neurons may be firing, producing EPSPs and/or IPSPs in the postsynaptic neuron. The sum of all the EPSPs and IPSPs at a given time determines the total potential in the postsynaptic neuron and, therefore, how that neuron responds. **Figure 39.16** shows, in a greatly simplified way, the effects of EPSPs and IPSPs on membrane potential, and how summation of inputs over space and time brings a postsynaptic neuron to threshold. The postsynaptic neuron in the figure has three presynaptic neurons forming synapses with its dendrites and cell body; Ex1 and Ex2 are excitatory neurons, and In1 is an inhibitory neuron. The summation point for EPSPs and IPSPs is the axon hillock of the postsynaptic neuron. A high density of voltage-gated Na^+ channels occurs in that region, resulting in the lowest threshold potential in the neuron.

The Patterns of Synaptic Connections Contribute to Integration

The total number of connections made by a neuron may be very large—some single interneurons in the human brain, for example, form as many as 100,000 synapses with other neurons. The number of synapses is not absolutely fixed; they can change through modification, addition, or removal as animals mature and experience changes in their environments. The combined activities of all the neurons in the nervous system, constantly integrating information from sensory receptors and triggering responses by effectors, control the internal activities of animals and regulate their behavior. This behavior ranges from the simple reflexes of a flatworm to the complex behavior of mammals, including consciousness, emotions, reasoning, and creativity in humans.

Although researchers do not yet understand how processes such as ion flow, synaptic connections, and neural networks produce complex mental activities, they continue to find correspondences between them and the types of neuronal communication described in this chapter. In the next chapter we learn about how nervous systems of animals are organized, and how higher functions such as memory, learning, and consciousness are produced.

UNANSWERED QUESTIONS

What is the basic wiring diagram of the brain?

To understand how the brain processes information, we must first understand the wiring that handles this information. There are about 100,000,000,000 (10^{11}) neurons in the human brain. This daunting number can be managed by grouping the neurons into classes or categories. It has been estimated that there are fewer than 10,000 different neuronal classes in the entire brain. Still, each neuron makes and receives synaptic contacts with about 1,000 other neurons on average, making the wiring diagram complex.

Many techniques have been used to unravel the wiring of the brain. Modern techniques have used dyes or retroviruses that transport along axons. Also, electrophysiology has been used to determine which neurons communicate with each other. New molecular techniques are being developed that allow different fluorescent proteins to be expressed in different neuron classes. Because the neurons can glow in all colors of the rainbow, this technique has been called "brainbow."

Despite all of the advances for gathering information about the brain's wiring diagram, we do not have an adequate means to represent this complexity, nor do we have a means of understanding how information flows through such a complex network. Just as modern DNA sequencing technology allowed a revolution in the field of genomics (the categorization of all of the genes in an organism), similar breakthroughs will need to occur in the field of neuromics (the categorization of all of the neurons and their interactions). These breakthroughs will have to be in data management, computational simulations, and multisite recording techniques. I have been collaborating with computer scientists and database specialists to develop tools for cataloging neurons and their synaptic connections. The hope is that one day we will have a way to represent the complex wiring in the brain.

How did the brain evolve?

Given that the brain is so complex, how could it have evolved? If you look at human brains and the brains of other primates, such as monkeys, there is not much difference, except size. Is size all that matters, or are there differences in the way neural circuits function? In my laboratory we have been investigating the evolution of neural circuits in simpler animals: sea slugs. These creatures have just 10,000 neurons in their brains, so it is easier to understand the circuitry. We are examining how the same sets of neurons produce different types of swimming behaviors in different species of sea slug.

How does processing in the brain lead to consciousness?

Even if we figure out how to represent all of the neurons in the brain and all of the ways that they communicate, we still need to answer the ultimate question, "How does neural activity cause the sensation that we all feel of being conscious and alive?" In every age, it is hard to imagine the things that we do not know. For example, imagine trying to understand how the brain worked before electricity was understood; it would have seemed like a magical force.

THINK LIKE A SCIENTIST What would it mean to understand the biological nature of conscious thought?

Paul S. Katz

Paul S. Katz is a professor in the Neuroscience Institute and the director of the Center for Neuromics at Georgia State University. REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

39.1 Neurons and Their Organization in Nervous Systems

- The nervous system of an animal: (1) receives information about conditions in the internal and external environment; (2) transmits the message along neurons; (3) integrates the information to formulate an appropriate response; and (4) sends out signals to muscles or glands that accomplish the response (Figure 39.2).
- Neurons have dendrites, which receive information and conduct signals toward the cell body, and axons, which conduct signals away from the cell body to another neuron or an effector (Figure 39.3).
- Afferent neurons conduct information from sensory receptors to interneurons, which integrate the information into a response. The response signals are passed to efferent neurons, which activate the effectors carrying out the response (Figure 39.2).
- The combination of an afferent neuron, an interneuron, and an efferent neuron makes up a basic neuronal circuit. The circuits combine into networks that interconnect the peripheral and central nervous systems.
- Glial cells help maintain the balance of ions surrounding neurons and form insulating layers around the axons (Figure 39.5).
- Neurons make connections by two types of synapses. In an electrical synapse, impulses pass directly from the sending to the receiving cell. In a chemical synapse, neurotransmitter molecules released by the presynaptic cell diffuse across a narrow synaptic cleft and bind to receptors in the plasma membrane of the postsynaptic cell (Figure 39.6).

Animation: Nerve structure

Animation: Chemical synapse

39.2 Signaling by Neurons

- The membrane potential of a cell depends on the unequal distribution of positive and negative charges on either side of the membrane, which establishes a potential difference across the membrane.
- Three primary conditions contribute to the resting potential of neurons: (1) an Na^+/K^+ active transport pump that sets up concentration gradients of Na^+ ions (higher outside) and K^+ ions (higher inside); (2) an open channel that allows K^+ to flow out freely; and

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(3) negatively charged proteins and other molecules inside the cell that cannot pass through the membrane (Figure 39.9).

- An action potential is generated when a stimulus pushes the resting potential to the threshold value at which voltage-gated Na^+ and K^+ channels open in the plasma membrane. The inward flow of Na^+ changes membrane potential abruptly from negative to a positive peak. The potential falls to the resting value again as the gated K^+ channels allow this ion to flow out (Figure 39.11).
- Action potentials move along an axon as the ion flows generated in one segment depolarize the potential in the next segment (Figure 39.12).
- Action potentials are prevented from reversing direction by a brief refractory period, during which a segment of membrane that has just generated an action potential cannot be stimulated to produce another for a few milliseconds.
- In myelinated axons, ions can flow across the plasma membrane only at nodes where the myelin sheath is interrupted. As a result, action potentials skip rapidly from node to node by saltatory conduction (Figure 39.13).

Animation: Measuring membrane potential

Animation: Resting Potential

Animation: Action Potential

Animation: Traveling Action Potentials

Animation: Ion flow in myelinated axons

39.3 Transmission across Chemical Synapses

- Neurotransmitters released into the synaptic cleft bind to receptors in the plasma membrane of the postsynaptic cell, altering the flow of ions across the plasma membrane of the postsynaptic cell and pushing its membrane potential toward or away from the threshold potential (Figure 39.14).
- Neurotransmitters that bind to ionotropic neurotransmitter receptors act directly. Binding to a receptor in the postsynaptic membrane activates it, leading to opening or closing of the channel in the associated ion channel.
- Neurotransmitters that bind to metabotropic neurotransmitter receptors act indirectly. Binding to a receptor in the postsynaptic membrane triggers generation of a second messenger, which causes an ion-conducting channel to open or close.
- Neurotransmitters are released from synaptic vesicles into the synaptic cleft by exocytosis, which is triggered by entry of Ca^{2+} ions into the cytoplasm of the axon terminal through voltage-gated Ca^{2+} channels opened by the arrival of an action potential.
- Neurotransmitter release stops when action potentials cease arriving at the axon terminal. Neurotransmitters remaining in the synaptic cleft are broken down by enzymes or taken up by the axon terminal or glial cells.
- Types of neurotransmitters include acetylcholine, amino acids, biogenic amines, neuropeptides, and gases such as NO (Table 39.1). Many of the biogenic amines and neuropeptides are also released into the general body circulation as hormones.

Animation: Neurons Synaptic Transmissions

39.4 Integration of Incoming Signals by Neurons

- Neurons carry out integration by summing excitatory postsynaptic potentials (EPSPs) and inhibitory postsynaptic potentials (IPSPs); the summation may push the membrane potential of the postsynaptic cell toward or away from the threshold for an action potential (Figure 39.16).
- The combined effects of summation in all the neurons in the nervous system control behavior in animals and underlie complex mental processes in mammals.

UNDERSTAND & APPLY

Test Your Knowledge

1. Nerve signals travel in the following manner:
   a. A dendrite of a sensory neuron receives the signal; its cell body transmits the signal to a motor neuron's axon, and the signal is sent to the target.
   b. An axon of a motor neuron receives the signal; its cell body transmits the signal to a sensory neuron's dendrite, and the signal is sent to the target.
   c. Efferent neurons conduct nerve impulses toward the cell body of sensory neurons, which send them on to interneurons and, ultimately, to afferent motor neurons.
   d. A dendrite of a sensory neuron receives the signal; the cell's axon transmits the signal to an interneuron, and the signal is transmitted by efferent neurons to effectors.
   e. The axons of oligodendrocytes transmit nerve impulses to the dendrites of astrocytes.
2. Glial cells:
   a. are unable to divide after an animal is born.
   b. called Schwann cells form the insulating myelin sheath around axons.
   c. called astrocytes form the nodes of Ranvier in the brain.
   d. called oligodendrocytes cover the surfaces of blood vessels in the PNS.
   e. are neuronal cells that provide nutrition and support to nonneuronal cells.
3. An example of a synapse could be the site where:
   a. neurotransmitters released by an axon travel across a gap and are picked up by receptors on a muscle cell.
   b. an electrical impulse arrives at the end of a dendrite causing ions to flow onto axons of presynaptic neurons.
   c. postsynaptic neurons transmit a signal across a cleft to a presynaptic neuron.
   d. oligodendrocytes contact the dendrites of an afferent neuron directly.
   e. an on–off switch stimulates an electrical impulse in a presynaptic cell to stimulate other presynaptic cells.
4. The resting potential in neurons requires:
   a. membrane transport channels to be constantly open for Na^+ and K^+ flow.
   b. the inside of neurons to be positive relative to the outside.
   c. the diffusion of K^+ out of the cell and a charge difference between the inside and outside of the axon set up by this movement of K^+.
   d. an active Na^+/K^+ pump, which pumps Na^+ and K^+ into the neuron.
   e. three Na^+ ions to be pumped through three Na^+ gates and two K^+ ions to be pumped through two K^+ gates.
5. The major role of the Na^+/K^+ pump is to:
   a. cause a rapid firing of the action potential so the inside of the membrane becomes momentarily positive.
   b. decrease the resting potential to zero.
   c. hyperpolarize the membrane above resting value.
   d. cause an action potential to enter a refractory period.
   e. maintain the resting potential at a constant negative value.

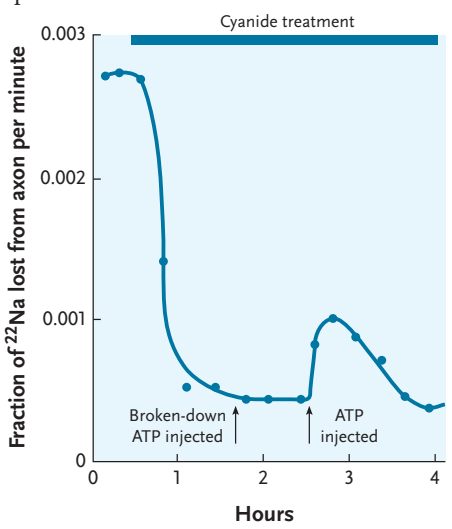
6. In the propagation of a nerve impulse:
   a. the refractory period begins as the K^+ channel opens, allowing K^+ ions to flow outward along their concentration gradient.
   b. Na^+ ions flow out of the axon with their concentration gradient.
   c. positive charges lower the membrane potential to its lowest action potential.
   d. gated K^+ channels open at the same time as the activation gate of Na^+ channels closes.
   e. the depolarizing stimulus lowers the membrane potential to open the Na^+ gates.
7. Which of the following does *not* contribute to propagation of action potentials?
   a. As the area outside the membrane becomes negative, it attracts ions from adjacent regions; as the inside of the membrane becomes positive, it attracts negative ions from nearby in the cytoplasm. These events depolarize nearby regions of the axon membrane.
   b. The refractory period allows the impulse to travel in only one direction.
   c. Each segment of the axon prevents the adjacent segments from firing.
   d. The magnitude of the action potential stays the same as it travels down the axon.
   e. Up to a limit, increasing the intensity of the stimulus increases the number of action potentials.
8. Which of the following statements best describes saltatory conduction?
   a. It inhibits direct neurotransmitter release.
   b. It transmits the action potential at the nodes of Ranvier and thus speeds up impulses on myelinated axons.
   c. It increases neurotransmitter release at the presynaptic membrane.
   d. It decreases neurotransmitter uptake at chemically gated postsynaptic channels.
   e. It removes neurotransmitters from the synaptic cleft.
9. Transmission of a nerve impulse to its target cell requires:
   a. endocytosis of neurotransmitters by excitatory presynaptic vesicles.
   b. thousands of molecules of neurotransmitter that had been stored in the postsynaptic cell to be released into the synaptic cleft.
   c. Ca^{2+} ions to diffuse through voltage-gated Ca^{2+} channels.
   d. a fall in Ca^{2+} in the cytoplasm to trigger a protein that causes the presynaptic vesicle to fuse with the plasma membrane.
   e. an action potential to open the Ca^{2+} gates so that Ca^{2+} ions, in higher concentration outside the axon, can flow back into the cytoplasm of the neuron.
10. Which of the following matches between neurotransmitter and site(s) of action is correct?
   a. Acetylcholine: Neuromuscular junctions in PNS
   b. Norepinephrine: Mostly acts on CNS and PNS as well as on effectors such as muscle
   c. Serotonin: Many CNS pathways, including those involved in vital brain functions such as memory and learning
   d. Endorphins: CNS interneurons in a number of pathways, including those regulating appetite, reproductive behavior, muscular movement, sleep, and emotional states such as anxiety
   e. Nitrous oxide: Released by special, unmyelinated sensory neurons in spinal cord

Discuss the Concepts

1. In some cases of ADHD (attention deficit hyperactivity disorder), the impulsive, erratic behavior typical of affected people can be calmed with drugs that stimulate certain brain neurons. Based on what you have learned about neurotransmitter activity in this chapter, can you suggest a neural basis for this effect?
2. Most sensory neurons form synapses either on interneurons in the spinal cord or on motor neurons. However, in many vertebrates, certain sensory neurons in the nasal epithelium synapse directly on brain neurons that activate behavioral responses to odors. Suggest at least one reason why natural selection might favor such an arrangement.
3. How did evolution of chemical synapses make higher brain functions possible?
4. Search for Internet resources using the term "Pediatric Neurotransmitter Disease" and, for one such disease, explain how the symptoms relate to neurotransmitter function.



Design an Experiment

Design an experiment to test whether neurons are connected via electrical or chemical synapses.

Interpret the Data

You learned in this chapter that Na^+/K^+ active transport pumps in the plasma membrane of the axons are responsible for creating the imbalance between Na^+ and K^+ inside and outside of the neuron that produces the resting potential.

In early research studying the role of ions, and the involvement of active transport of ions in signaling in neurons, investigators used the giant axon of a squid as a model. The diameter of a giant axon is far greater than that of a mammalian axon, which enabled researchers to isolate it easily and use it in *in vitro* experiments. In one early experiment, researchers investigated the active transport of Na^+ out of the axon in response to the presence of cyanide. Experimentally they hooked up a section of axon to a syringe, immersed the axon in artificial seawater, introduced radioactive ^{22}Na (as $^{22}NaCl$) into the axon, and then quantified the transport of ^{22}Na out through the axon's plasma membrane. The rate of ^{22}Na transport out of the axon was determined by measuring the radioactivity released into the fluid surrounding the axon over a period of time. The **Figure** shows the results of the experiment.

1. What is the effect of cyanide on Na^+ transport out of the squid axon? How do the data show the effect?
2. What is the effect of injecting broken-down ATP (ATP hydrolyzed to break it down into its component parts) on the transport of Na^+ out of the cyanide-treated axon?
3. What is the effect of injecting intact ATP on the transport of Na^+ out of the cyanide-treated axon? What does this result mean with respect to Na^+ active transport?

Source: P. C. Caldwell et al. 1960. The effects of injecting "energy-rich" phosphate compounds on the active transport of ions in the giant axons of *Loligo. Journal of Physiology* 152:561–590.

Apply Evolutionary Thinking

A biologist hypothesized that the mechanism for the propagation of action potentials down a neuron evolved only once. What evidence would you collect from animals living today to support or refute that hypothesis?

40.2 The Peripheral Nervous System
40.3 The Central Nervous System and Its Functions
40.4 Memory, Learning, and Consciousness

Nervous Systems

Why it matters . . . The conductor's baton falls and the orchestra plays the first notes of a Mozart symphony. Unaware of the complex interactions of their nervous systems, the musicians translate printed musical notation into melodious sounds played on their instruments. Although their fingers and arms move to produce precise harmonies, the musicians are only vaguely conscious of these movements, learned through years of practice. Their only conscious endeavor is to interpret the music in line with the conductor's directions.

Near the stage, a common housefly moves in random twists and turns. Although far less complex than that of a human, the fly's nervous system contains networks of neurons that work in the same way, in patterns adapted to its lifestyle.

The fly does not register the sounds reverberating through the hall as a significant sensory input. However, some of its receptors are exquisitely sensitive to the presence of potential food molecules, including those in the sweat on the conductor's face. The fly swoops and turns and alights on the tip of his nose. When sensory receptors in the fly's footpads detect organic matter on the surface of the nose, they trigger an automated feeding response: the fly's proboscis lowers and its gut begins contractions that suck up the nutrients.

The conductor's eyes notice the insect's approach, and sensory receptors in his skin pinpoint the spot where it lands. Without missing a beat, the conductor's hand flicks toward that exact spot. But his nervous system and effectors, although highly sophisticated, are no match for the escape reflexes of the fly. The fly's sensory receptors detect the motion of the fingers, sending impulses to the fly's leg and wing muscles that launch it into flight long before the fingers reach the nose.

The fly wanders into the orchestra, attracted to potential nutrients on various musicians, and lands on the left hand of the timpanist, who is listening with pleasure to the music while he awaits

his entrance late in the first movement. His right hand holds a mallet. With a skill born of long practice in hitting drums, gongs, and bells with speed and precision, the timpanist deftly swings his mallet and dispatches the fly, ending the latest contest between mammalian and arthropod nervous systems.

The nervous systems underlying these behaviors are one of the features that set animals apart from other organisms. As animals evolved, the need to find food, living space, and mates, and to escape predators and other dangers, provided a powerful selection pressure for increasingly complex and capable nervous systems. Neurons, described in the previous chapter, provide the structural and functional basis for all these systems. We can trace some of the developments along this extended evolutionary pathway by examining the nervous systems of living animals, from invertebrates to mammals, and especially humans.

40.1 Invertebrate and Vertebrate Nervous Systems Compared

The nervous systems of most invertebrates are relatively simple, typically containing fewer neurons, arranged in less complex networks, than vertebrate systems. Our comparative survey of nervous systems begins with the simplest invertebrates.

Cnidarians and Echinoderms Have Nerve Nets

Cnidarians and echinoderms are radially symmetrical animals with body parts arranged regularly around a central axis, like the spokes of a wheel. Their nervous systems, called **nerve nets,** are loose meshes of neurons organized within that radial symmetry.

The nerve nets of cnidarians such as sea anemones extend into each "spoke" of the body **(Figure 40.1A).** Their neurons lack clearly differentiated dendrites and axons. When part of the animal is stimulated, impulses are conducted through the nerve net in all directions from the point of stimulation. Although there is no cluster of neurons that plays the coordinating role of a brain, nerve cells may be more concentrated in some regions. For example, in scyphozoan jellyfish, which swim by rhythmic contractions of their bells, neurons are denser in a ring around the margin of the bell, in the same area as the contractile cells that produce the swimming movements.

In echinoderms, especially sea stars, the nervous system is a modified nerve net, with some neurons organized into **nerves,** bundles of axons enclosed in connective tissue and following the same pathway. A *nerve ring* surrounds the centrally located mouth, and a *radial nerve* branches to connect to nerve nets throughout each arm **(Figure 40.1B).** If the radial nerve serving an arm is cut, the arm can still move, but not in coordination with the other arms.

More Complex Invertebrates Have Cephalized Nervous Systems

More complex invertebrates have neurons with clearly defined axons and dendrites, and more specialized functions. Some neurons are concentrated into functional clusters called **ganglia** (singular, *ganglion*). A key evolutionary development in invertebrates is a trend toward *cephalization,* the formation of a distinct head region containing ganglia that constitute a **brain,** the control center of the nervous system that integrates major sensory input with motor output. **Nerve cords**—bundles of nerves—extend from the brain to the rest of the body. Another evolutionary trend is toward bilateral symmetry of the body and the nervous system, in which body parts are mirror images on left and right sides. These trends toward cephalization and bilateral symmetry are illustrated here in flatworms, arthropods, and mollusks.

In flatworms, a brain consisting of a pair of ganglia at the anterior end is connected to nerve nets in the rest of the body by two or more longitudinal nerve cords **(Figure 40.1C).** The brain integrates inputs from sensory receptors, including a pair of anterior eyespots that respond to light. The brain and longitudinal nerve cords constitute the flatworm's central **nervous system (CNS),** the simplest one known, while the nerves from the CNS to the rest of the body constitute the **peripheral nervous system (PNS).**

Arthropods such as insects have a head region that contains a brain consisting of dorsal and ventral pairs of ganglia, and major sensory structures, usually eyes and antennae **(Figure 40.1D).** A ventral nerve cord enlarges into a pair of ganglia in each body segment. In arthropods with fused body segments, as in the thorax of insects, the ganglia are also fused into larger masses forming secondary control centers.

Although different in basic plan from the arthropod system, the nervous systems of mollusks (such as clams, snails, and octopuses) also rely on neurons clustered into paired ganglia and connected by major nerves. Different mollusks have varying degrees of cephalization, with cephalopods having the most pronounced cephalization of any invertebrate group. In the head of an octopus, for example, a cluster of ganglia is fused into a complex, lobed brain with clearly defined sensory and motor regions. Paired nerves link different lobes with muscles and sensory receptors, including prominent optic lobes linked by nerves to large, complex eyes **(Figure 40.1E).** Octopuses are capable of rapid movement to hunt prey and to escape from predators, behaviors that rely on rapid, sophisticated processing of sensory information.

Vertebrates Have Highly Specialized Nervous Systems

In vertebrates, the CNS consists of the brain and spinal cord, and the PNS consists of all the nerves and ganglia that connect the brain and spinal cord to the rest of the body **(Figure 40.1F).** The head contains specialized sensory organs that are connected directly to the brain by nerves.

The structure of the vertebrate nervous system reflects its pattern of development. The nervous system of a vertebrate embryo begins as the hollow **neural tube** (discussed more in Chapter 50), the anterior end of which develops into the brain and the rest into the **spinal cord.** The cavity of the neural tube becomes the fluid-filled **ventricles** of the brain and the **central canal** through the spinal cord. Adjacent tissues give rise to nerves that connect the brain and spinal cord with all body regions.

Early in embryonic development, the anterior part of the neural tube enlarges into three distinct regions: the **forebrain, midbrain,** and **hindbrain (Figure 40.2).** The hindbrain subdivides and eventually gives rise to the *cerebellum,* which integrates sensory signals from the eyes, ears, and muscle spindles with motor signals from the *telencephalon,* and the *pons,* a major traffic center for information passing between the cerebellum and the higher integrating centers of the adult telencephalon. The hindbrain also gives rise to the *medulla oblongata* (commonly shortened to medulla), which controls many vital involuntary tasks such as respiration and blood circulation.

The midbrain gives rise to the adult midbrain, which, with the pons and the medulla, constitutes the brain stem (see Figure 40.2). The midbrain has centers for coordinating reflex responses (involuntary reactions) to visual and auditory (hearing) input and relays signals to the telencephalon.

The forebrain of the embryo eventually gives rise to the *cerebrum* (or adult telencephalon) and the thalamus and hypothalamus of the adult (see Figure 40.2). The cerebrum is the largest part of the brain. It controls higher functions such as thought, memory, language, and emotions, as well as voluntary movements. The *thalamus* is a center that receives sensory input and relays it to the regions of the cerebral cortex concerned with pertinent motor responses, and the *hypothalamus* is the primary center for homeostatic control over the internal environment. In fishes, the cerebrum is little more than a relay station for olfactory (sense of smell) information. In amphibians, reptiles, and birds, it becomes progressively larger and contains greater concentrations of integrative functions. In mammals, the cerebrum is the major integrative structure of the brain.

In the following sections, we examine vertebrate nervous systems, and the human nervous system in particular, beginning with the peripheral nervous system.

STUDY BREAK 40.1

40.2 The Peripheral Nervous System

Afferent neurons in the peripheral nervous system transmit signals to the CNS, and signals from the CNS are sent via efferent neurons in the PNS to the effectors that carry out responses **(Figure 40.3).** The afferent part of the system includes all the neurons that transmit sensory information from their receptors. The efferent part of the system consists of the axons of neurons that carry signals to the muscles and glands, acting as effectors. In mammals, 31 pairs of **spinal nerves** carry signals between the spinal cord and the body trunk and limbs, and 12 pairs of **cranial nerves** connect the brain directly to the head, neck, and body trunk. The efferent part of the PNS is further divided into somatic and autonomic systems (see Figure 40.3).

The Somatic System Controls the Contraction of Skeletal Muscles, Producing Body Movements

The **somatic nervous system** controls body movements that are primarily conscious and voluntary. Its neurons, called motor neurons, carry efferent signals from the CNS to the skeletal muscles. The dendrites and cell bodies of motor neurons are located in the spinal cord; their axons extend from the spinal cord to the skeletal muscle cells they control. As a result, the somatic portions of the cranial and spinal nerves consist only of axons.

Although the somatic system is primarily under conscious, voluntary control, some contractions of skeletal muscles are unconscious and involuntary. These include the reflexes, shivering, and the constant muscle contractions that maintain body posture and balance.

The Autonomic System Is Divided into Sympathetic and Parasympathetic Divisions

The **autonomic nervous system** controls largely involuntary processes including digestion, secretion by sweat glands, circulation of the blood, many functions of the reproductive and excretory systems, and contraction of smooth muscles in all parts of the body. It is organized into *sympathetic* and *parasympathetic* divisions, which are always active, and have opposing effects on the organs they affect, thereby enabling precise control **(Figure 40.4).** For example, in the circulatory system, sympathetic neurons stimulate the force and rate of the heartbeat, and parasympathetic neurons inhibit these activities. In the digestive system, sympathetic neurons inhibit the smooth muscle contractions that move materials through the small intestine, and parasympathetic neurons stimulate the same activities. These opposing effects control involuntary body functions precisely.

The pathways of the autonomic nervous system include two neurons **(Figure 40.5).** The first neuron has its dendrites and cell body in the CNS, and its axon extends to a ganglion in the PNS. There, it synapses with the dendrites and cell body of the second neuron in the pathway. The axon of the second neuron extends from the ganglion to the effector carrying out the response. The sympathetic ganglia are arrayed as an orderly chain along the spinal cord (see Figure 40.4), whereas those of the parasympathetic are irregularly placed and often next to, or within, the effector structures.

The **sympathetic division** predominates in situations involving stress, danger, excitement, or strenuous physical activity. Signals from the sympathetic division increase the force and rate of the heartbeat, raise the blood pressure by constricting selected blood vessels, dilate air passages in the lungs, induce sweating, and open the pupils wide. Activities that are less important in an emergency, such as digestion, are suppressed by the sympathetic system. The **parasympathetic division,** in contrast, predominates during quiet, low-stress situations, such as while relaxing. During relaxation the influence of the parasympathetic division reduces the effects of the sympathetic division, such as rapid heartbeat and elevated blood pressure, and activities such as digestion predominate.

STUDY BREAK 40.2

Which of the two autonomic nervous system divisions predominates in the following scenarios? (a) You are hiking on a trail and suddenly a bear appears in your path. (b) It is a hot, sunny day. You find a shady tree and sit down. Leaning against its trunk, you feel your eyes becoming heavy.

40.3 The Central Nervous System and Its Functions

The central nervous system (CNS) integrates incoming sensory information from the PNS into compensating responses, thus managing bodily activities.

The CNS Is Protected by the Meninges and by Cerebrospinal Fluid

The brain and spinal cord are surrounded and protected by three layers of connective tissue called **meninges** (*meninga* = membrane), and by **cerebrospinal fluid,** which circulates through the ventricles of the brain, through the central canal of the spinal cord, and between two of the meninges. The fluid cushions the brain and spinal cord from jarring movements and impacts, and it both nourishes the CNS and protects it from toxic substances.

The Blood–Brain Barrier Regulates Exchanges between Blood and Brain

The brain is shielded from many changes in the blood by a highly selective **blood–brain barrier.** That is, unlike the epithelial cells forming capillary walls elsewhere in the body, which allow small molecules and ions to pass freely from the blood to surrounding fluids, those forming capillaries in the brain are sealed together by tight junctions (see Section 5.5 and Figure 5.27). The tight junctions set up a blood–brain barrier that prevents most substances dissolved in the blood from entering the cerebrospinal fluid and thus protects the brain and spinal cord from viruses, bacteria, and toxic substances that may be circulating in the blood.

Molecules that are lipid soluble such as steroids, alcohol, and anesthetics can move directly across the epithelial cell membranes by diffusion. Aside from relatively free movement of salts and water, a few other substances—most significantly glucose and ketones, the only molecules that brain and spinal cord cells can oxidize for energy—are moved across the plasma membrane by highly selective transport proteins.

The Brain Integrates Sensory Information and Formulates Responses; the Spinal Cord Relays Signals between the PNS and the Brain and Controls Reflexes

The *brain* is the major center that receives, integrates, stores, and retrieves information. Its interneuron networks generate responses that provide the basis for our voluntary movements, consciousness, emotions, learning, reasoning, language, and memory, among many other complex activities.

You learned earlier about the structures of the adult brain (see Figure 40.2). Each of these structures contains both **gray matter,** consisting of nerve cell bodies and dendrites, and **white matter,** consisting of axons, many of them surrounded by myelin sheaths **(Figure 40.6).** (The myelination of the axons gives white matter its color.)

The pons and medulla, along with the midbrain, form a stalklike structure known as the **brain stem,** which connects the "higher" centers with the spinal cord. All but two of the twelve pairs of cranial nerves also originate from the brain stem. These higher centers, which make up most of the mass of the brain in humans, are generally referred to as the *telencephalon (cerebrum).* The cerebrum, the largest part of the brain in humans, is organized into the left and right *cerebral hemispheres,* which have many fissures and folds (see Figure 40.6). Each hemisphere consists of **cerebral cortex,** a thin outer shell of gray matter covering a thick core of white matter. The *basal nuclei,* consisting of several regions of gray matter, are located deep within the white matter.

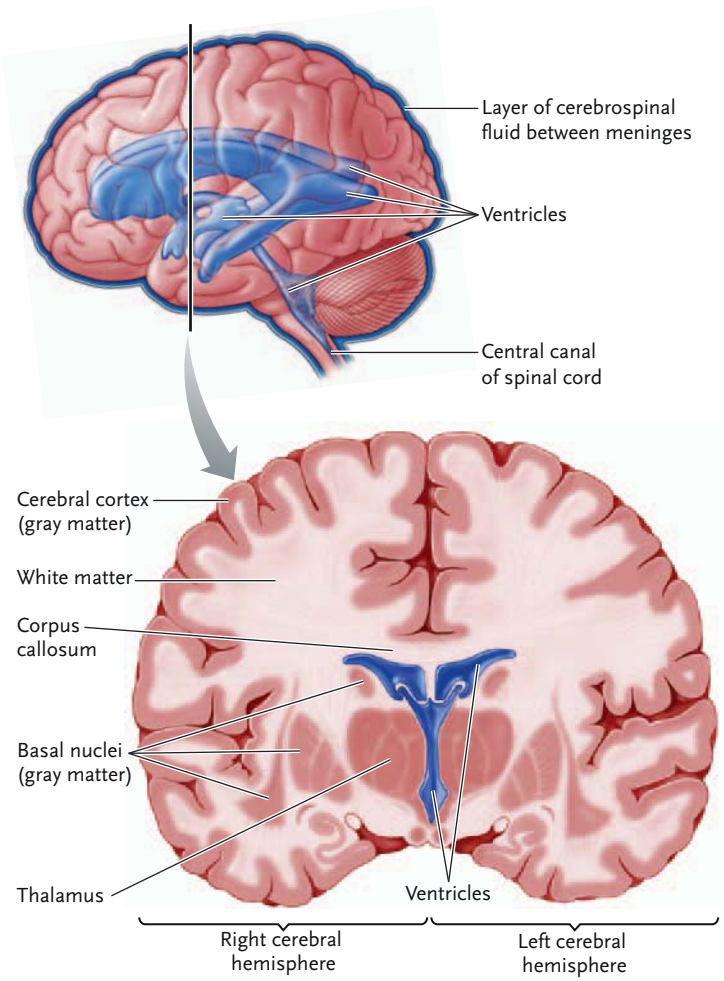

FIGURE 40.6 **The human brain, illustrating the distribution of gray matter and white matter, and the locations of the four ventricles (in blue) with their connection to the central canal of the spinal cord.**

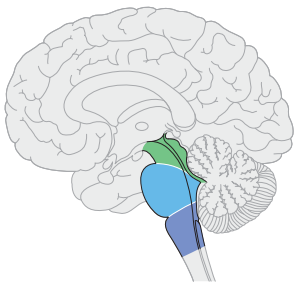
© Cengage Learning 2014



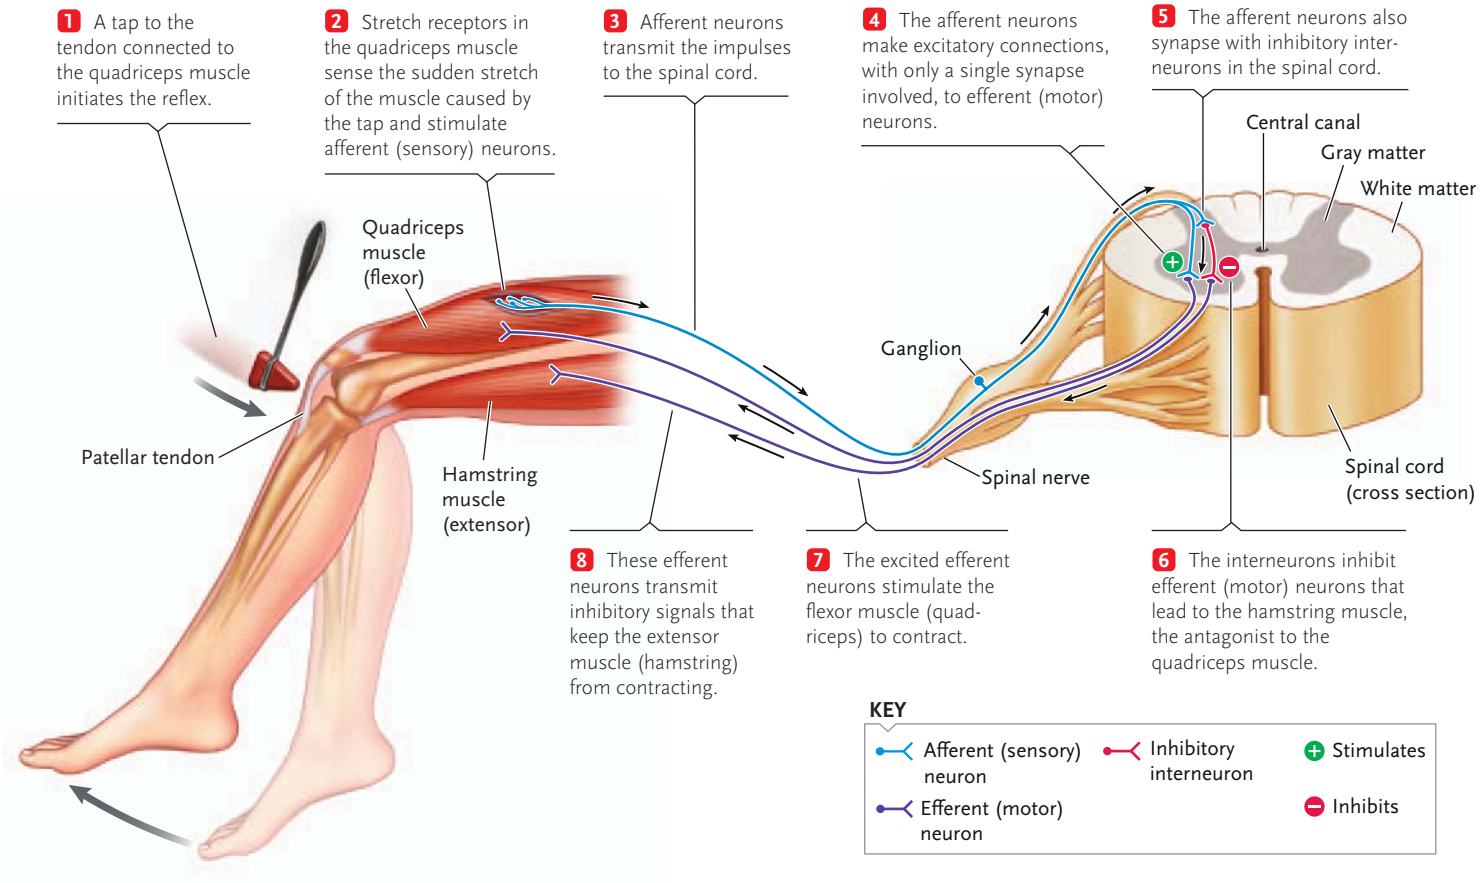
The *spinal cord,* which extends dorsally from the brain stem, carries impulses between the brain and the PNS and contains the interneuron circuits that control motor reflexes. In cross section, the spinal cord has a butterfly-shaped core of gray matter surrounded by white matter. Pairs of spinal nerves emerge from the spinal cord at spaces between the vertebrae.

The afferent axons entering the spinal cord make synapses with interneurons in the gray matter, which send axons upward through the white matter of the spinal cord to adjacent segments of the cord and, in some cases, through to the brain. Conversely, axons from interneurons of the brain pass downward through the white matter of the cord and make synapses with the dendrites and cell bodies of efferent neurons in the gray matter of the cord. The axons of these efferent neurons exit the spinal cord through the spinal nerves.

The gray matter of the spinal cord also contains pathways involved in **reflexes,** programmed movements that take place without conscious effort; an example is the knee-jerk response, in which a tap to the tendon just below the knee cap (patella) causes the leg to kick **(Figure 40.7).** The existence of only a single synapse between the efferent and afferent neurons in the reflex facilitates a rapid response—about 50 ms between tap and the start of the kick.

Similarly, a reflex pathway is involved for the rapid withdrawal of your hand if you touch a hot surface. You may recall from experience that when a reflex movement withdraws your hand from a hot surface or other damaging stimulus, you feel the pain shortly *after* the hand is withdrawn. This is the extra time required for impulses to travel from the neurons of the reflex via interneurons to the brain (see substance P in Table 39.1).

The Brain Stem Regulates Many Vital Housekeeping Functions of the Body



Gray-matter centers in the brain stem control many vital body functions without conscious involvement or control by the cerebrum. Among these functions are the heart and respiration rates, blood pressure, constriction and dilation of blood vessels, coughing, and reflex activities of the digestive system such as vomiting. Damage to the brain stem has serious and sometimes lethal consequences.

CLOSER LOOK

FIGURE 40.7 Organization of the spinal cord and the knee-jerk reflex.

Only a few neurons and a single interneuron are shown; many neurons and interneurons actually participate in the reflex.

SUMMARY In a knee-jerk reflex, a tap on the tendon just below the knee causes a sequence of events that causes the leg to kick. The tap stimulates afferent neurons that make excitatory connections to efferent neurons with a single synapse, and to inhibitory interneurons. Excited efferent neurons stimulate the flexor muscle of the leg to contract. The inhibitory interneurons connect to efferent neurons that lead to the extensor muscle of the leg; those neurons inhibit that muscle from contracting.

THINK LIKE A SCIENTIST Physicians sometimes test knee-jerk reflexes in patients. If the response to the test is significantly slower than normal, what might the physician conclude?

© Cengage Learning 2014

A complex network of interconnected neurons known as the reticular formation (*reticulum* = little net) runs through the length of the brain stem, connecting to the thalamus at the anterior end and to the spinal cord at the posterior end **(Figure 40.8).** Most incoming sensory input goes to the reticular formation, which integrates the information and then sends signals to other parts of the CNS. The reticular formation has two parts. The ascending reticular formation, also called the reticular activating system, contains neurons that convey stimulatory signals via the thalamus to arouse and activate the cerebral cortex. It is responsible for the sleep–wake cycle; depending on the level of stimulation of the cortex, various levels of alertness and consciousness are produced. Lesions in this part of the brain stem result in coma. The other part, the descending reticular formation, receives information from a variety of sources including the hypothalamus and connects with interneurons in the spinal cord that control skeletal muscle contraction, thereby controlling muscle movement and posture. The reticular formation filters incoming signals, helping to discriminate between important and unimportant ones. Such filtering is necessary because the brain is unable to process every one of the signals from millions of sensory receptors. For example, the action of the reticular formation enables you to sleep through many sounds but waken to specific ones, such as a cat meowing to be let out, or a baby crying.

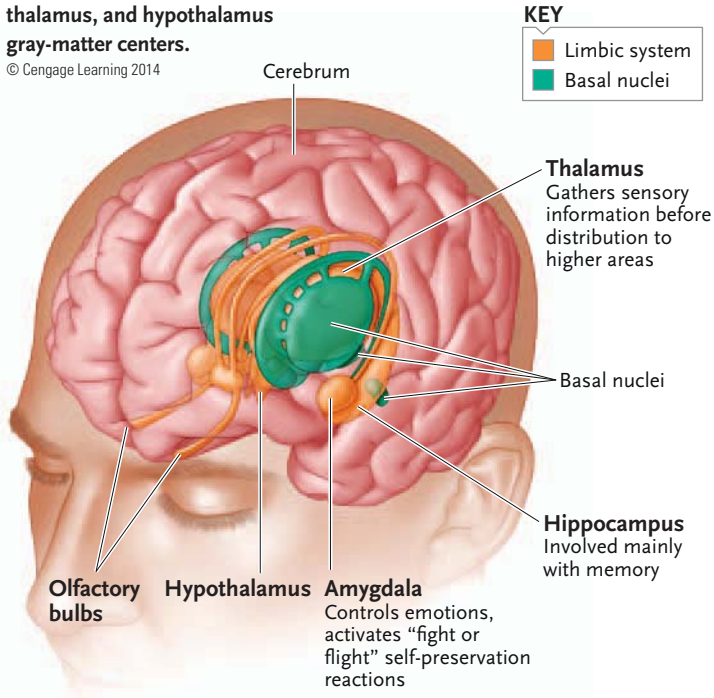
The Cerebellum Integrates Sensory Inputs to Coordinate Body Movements

Although the cerebellum is an outgrowth of the pons (see Figure 40.8), it is separate in structure and function from the brain stem. Through its extensive connections with other parts of the brain, the cerebellum receives sensory input from receptors in muscles and joints, from balance receptors in the inner ear, and from the receptors of touch, vision, and hearing. These signals convey information about how the body trunk and limbs are positioned, the degree to which different muscles are contracted or relaxed, and the direction in which the body or limbs are moving. The cerebellum integrates these sensory signals and compares them with signals from the cerebrum that control voluntary body movements. Outputs from the cerebellum to the cerebrum, brain stem, and spinal cord modify and fine-tune the movements to keep the body in balance and directed toward targeted positions in space. The human cerebellum also contributes to the learning and memory of complex motor skills such as playing the guitar.

Gray-Matter Centers Control a Variety of Functions

The thalamus, hypothalamus, and basal nuclei **(Figure 40.9)** contribute to the control and integration of voluntary movements, body temperature and glandular secretions, osmotic balance of the blood and extracellular fluids, wakefulness, and the emotions, among other functions. Some of the gray-matter centers route information to and from the cerebral cortex, brain stem, and cerebellum.



The **thalamus** (see Figure 40.9) forms a major switchboard that receives sensory information and relays it to the regions of the cerebral cortex concerned with motor responses to sensory information. Part of the thalamus near the brain stem cooperates with the reticular formation in alerting the cerebral cortex to full wakefulness, or in inducing drowsiness or sleep.

The **hypothalamus** is a region of the brain located in the floor of the cerebrum (see Figure 40.9) that contains clusters of neurons known as *nuclei.* Suspended just below it and connected to it by a stalk of tissue is the *pituitary gland,* consisting of two fused lobes, the *anterior pituitary* and the *posterior pituitary,* which release hormones. The hypothalamus regulates basic homeostatic functions of the body both directly and through the release of hormones.

Some nuclei in the hypothalamus set and maintain body temperature, most notably by regulating basal metabolic rate. This is an interesting example of an endocrine circuit, in which a hypothalamic hormone causes the release of a hormone from the anterior pituitary that in turn causes the release of a thyroid hormone. Other nuclei monitor the osmotic balance of the blood plasma. If osmotic pressure rises above normal levels, these neurons secrete a hormone from their terminals in adjacent areas of the hypothalamus and from the posterior pituitary to increase thirst and recover more water from urine. (More detail on the structure and functions of the hypothalamus and pituitary and endocrine circuits is given in Chapter 42.)

These and other nuclei of the hypothalamus are able to detect changes in blood temperature, ionic and nutrient composition, and the presence of hormones released in other areas of the body because they are *not* protected by the blood–brain barrier.

The wide-ranging influence of the hypothalamic nuclei can be seen in their coordination of autonomic system functions, such as the control of the heartbeat, contraction of smooth muscle cells in the digestive system, and glandular secretions. A particular hypothalamic structure, the *suprachiasmatic nucleus,* is the main generator of the biological clock that times our myriad daily behavioral and metabolic rhythms.

The **basal nuclei** are gray-matter centers that surround the thalamus on both sides of the brain (see Figure 40.9). They moderate voluntary movements directed by motor centers in the cerebrum. Damage to the basal nuclei can affect the planning and fine-tuning of movements, leading to stiff, rigid motions of the limbs and unwanted or misdirected motor activity, such as tremors of the hands and inability to start or stop intended movements at the intended place and time. Parkinson disease, in which affected individuals exhibit all of these symptoms, results from degeneration of centers in and near the basal nuclei.

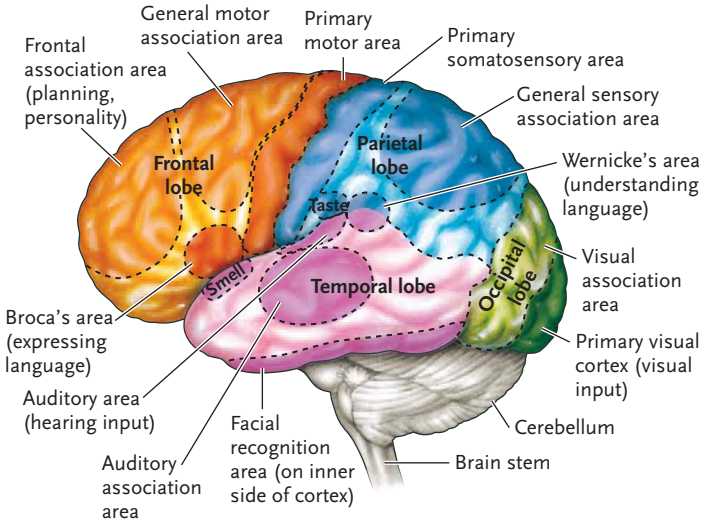
Parts of the thalamus, hypothalamus, and basal nuclei, along with other nearby gray-matter centers—the amygdala, hippocampus, and olfactory bulbs—form a functional network called the **limbic system** (*limbus* = edge, border), sometimes called our "emotional brain" (see Figure 40.9). The **amygdala** routes information about experiences that have an emotional component through the limbic system. The **hippocampus** is involved in sending information to the frontal lobes, and the **olfactory bulbs** relay inputs from odor receptors to both the cerebral cortex and the limbic system. The olfactory connection to the limbic system may explain why certain odors can evoke particular, sometimes startlingly powerful emotional responses.

The limbic system controls emotional behavior and influences the basic body functions regulated by the hypothalamus and brain stem. Stimulation of different parts of the limbic system produces anger, anxiety, fear, satisfaction, pleasure, or sexual arousal. Connections between the limbic system and other brain regions bring about emotional responses such as smiling, blushing, or laughing.

The Cerebral Cortex Carries Out All Higher Brain Functions in Humans

The cerebral cortices of each hemisphere contain the processing centers for the integration of neural input and the initiation of neural output. The white matter of the cerebral hemispheres, by contrast, contains the neural routes for signal transmission between parts of the cerebral cortex, or from the cerebral cortex to other parts of the CNS. No information processing occurs in the white matter.

Over the course of evolution, the surface area of the cerebral cortex increased by continually folding in on itself, thereby expanding the structure into sophisticated information encoding and processing centers. Primates have cerebral cortices with the largest number of convolutions. In humans, each cerebral hemisphere is divided by surface folds into *frontal, parietal, temporal,* and *occipital* lobes **(Figure 40.10).** Uniquely in mammals, the cerebral cortex of the cerebral hemispheres is organized into six layers of neurons; these layers are the newest part of the cerebral cortex in an evolutionary sense.



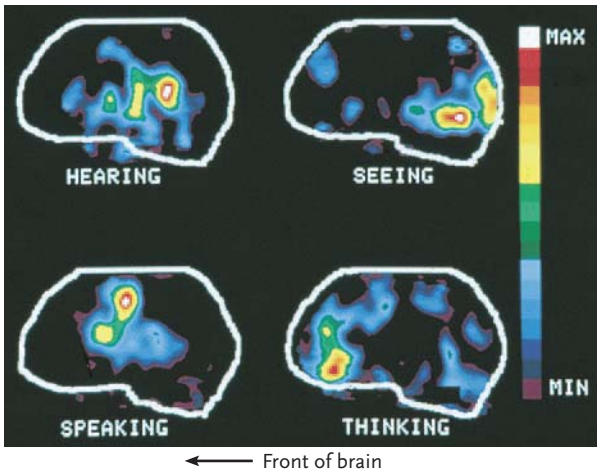


FIGURE 40.10 **The lobes of the cerebrum, showing major regions and association areas of the cerebral cortex.**

© Cengage Learning 2014

The two cerebral hemispheres can function separately, and each has its own communication lines internally and with the rest of the CNS and the body. The left cerebral hemisphere responds primarily to sensory signals from, and controls movements in, the right side of the body. The right hemisphere has the same relationships to the left side of the body. Thick axon bundles, forming a structure called the **corpus callosum** (see Figure 40.6), connect the two cerebral hemispheres and coordinate their functions.

STUDYING THE FUNCTIONS OF THE CEREBRAL CORTEX Physicians and researchers have learned much about the functions of various regions of the cerebral cortex by studying normal subjects and patients with brain damage from stroke, infection, tumors, or mechanical disturbance. Scanning techniques such as **positron emission tomography (PET)** and **functional magnetic resonance imaging (fMRI)** allow researchers to identify the functions of specific brain regions in noninvasive ways. For a PET scan **(Figure 40.11),** an individual is given a dose of a radioactive compound, typically a modified form of glucose if brain activity is to be studied. When an area of the brain becomes active, more glucose is needed there to be broken down to provide energy. Therefore, the amount of radioisotope that becomes localized to a particular area correlates with the amount of brain activity in that area. The scanner detects the decay of the radioisotope of the modified glucose, and a computer converts the results into multicolored two- or three-dimensional images. The colors reflect the amount of radioactivity detected and provide a quantitative view of the amount of brain activity.

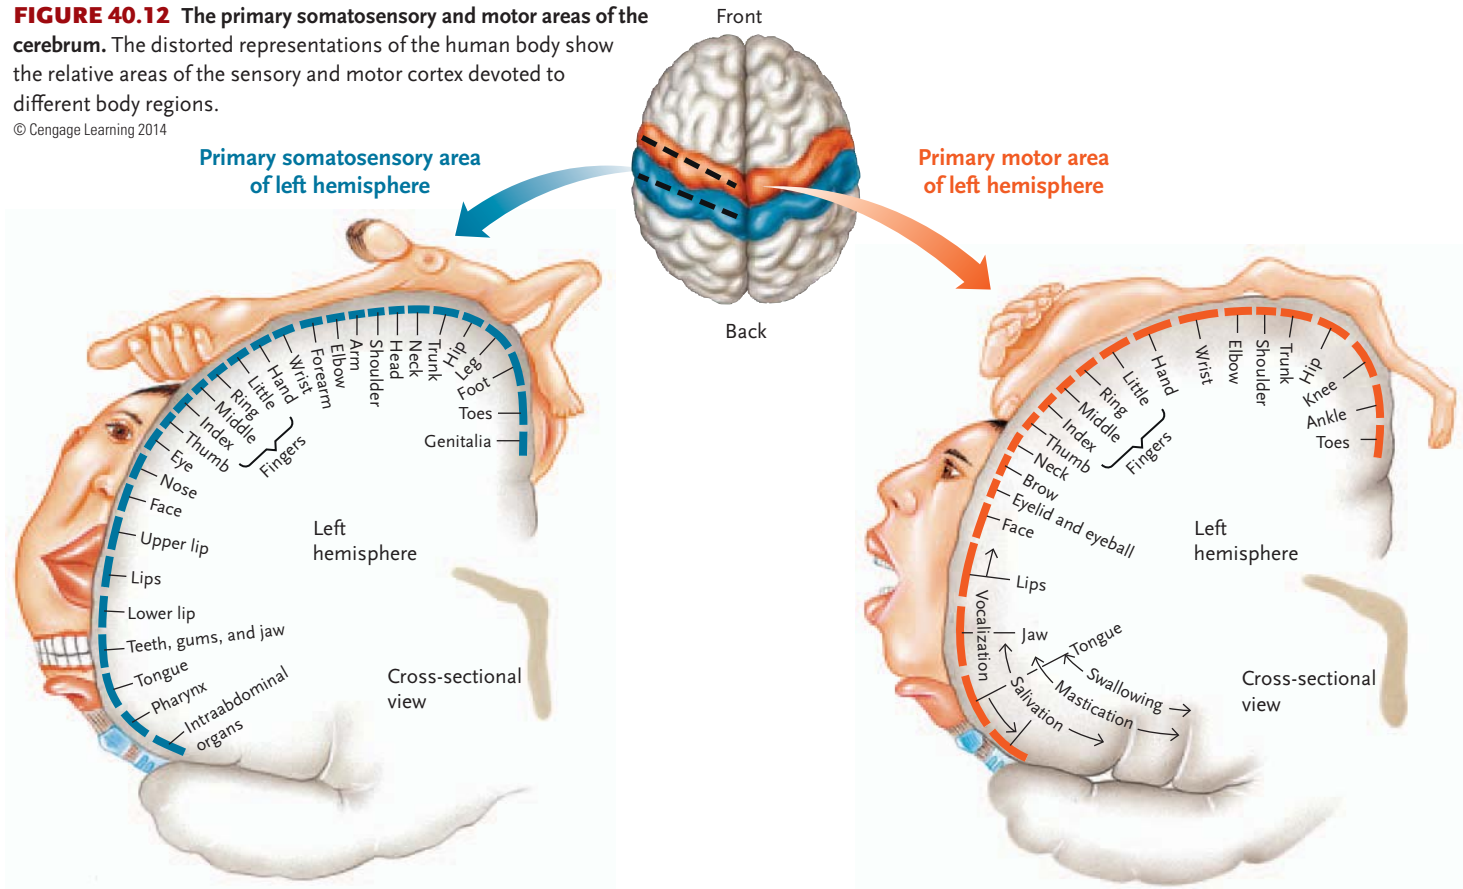
FIGURE 40.11 PET scans showing regions of the brain active when a person performs specific mental tasks. The colors show the relative activity of the sections, with white being the most active.



In fMRI, a doughnut-shaped magnet surrounding the subject's head creates a magnetic field about 10,000 times greater than that of Earth's. When an area of the brain becomes active, the blood flow to that area suddenly increases, bringing with it oxygen carried by hemoglobin in the red blood cells. This oxygen is released to supply oxygen to the tissues, producing deoxygenated hemoglobin. An fMRI scanner detects this deoxygenation of hemoglobin as oxygen used by the neurons because oxygenated and deoxygenated hemoglobin have different properties—the oxygenated form slightly repels a magnetic field, whereas the deoxygenated form becomes slightly magnetic when a magnetic field is applied. The chapter opener image combines an fMRI result with a PET scan to show the brain activity associated with reading aloud.

SENSORY REGIONS OF THE CEREBRAL CORTEX Areas that receive and integrate sensory information are distributed over the cerebral cortex. In each hemisphere, the **primary somatosensory area,** which registers information on touch, pain, temperature, and pressure, runs in a band across the parietal lobes of the brain (see Figure 40.10). Experimental stimulation of this band in one hemisphere causes prickling or tingling sensations in specific parts on the opposite side of the body, beginning with the toes at the top of each hemisphere and running through the legs, trunk, arms, and hands, to the head **(Figure 40.12).**

Other sensory regions of the cerebral cortex have been identified with hearing, vision, smell, and taste (see Figure 40.10). Regions of the temporal lobes on both sides of the brain receive auditory inputs from the ears, while inputs from the eyes are processed in the primary visual cortex in both occipital lobes. Olfactory input from the nose is processed in the olfactory bulbs, located on the ventral side of the temporal lobes. Regions in the parietal lobes receive inputs from taste receptors on the tongue and other locations in the mouth.

FIGURE 40.12 The primary somatosensory and motor areas of the cerebrum. The distorted representations of the human body show the relative areas of the sensory and motor cortex devoted to different body regions.

MOTOR REGIONS OF THE CEREBRAL CORTEX The **primary motor area** of the cerebral cortex runs in a band just in front of the primary somatosensory area (see Figure 40.10). Experimental stimulation of points along this band in one hemisphere causes movement of specific body parts on the opposite side of the body, corresponding generally to the parts registering in the primary somatosensory area at the same level (see Figure 40.11). Other areas that integrate and refine motor control are located nearby.

In both the primary somatosensory and primary motor areas, some body parts, such as the lips and fingers, are represented by large regions, and others, such as the arms and legs, are represented by relatively small regions. As shown in Figure 40.12, the relative sizes produce a distorted image of the human body that is quite different from the actual body proportions. The differences are reflected in the precision of touch and movement in structures such as the lips, tongue, and fingers. Such differences are also seen in many other animals, reflecting their adaptations to sensing the environment.

ASSOCIATION AREAS The sensory and motor areas of the cerebral cortex are surrounded by **association areas** (see Figure 40.10) that integrate information from the sensory areas, formulate responses, and pass them on to the primary motor area. Two of the most important association areas are *Wernicke's area* and *Broca's area* (see Figure 40.10), which function in spoken and written language. They are usually present on only one side of the brain—in the left hemisphere in 97% of the human population. Comprehension of spoken and written language depends on coordination of inputs from the visual, auditory, and general sensory association areas by Wernicke's area. Interneuron connections lead from Wernicke's area to Broca's area, where the motor programs for coordination of the lips, tongue, jaws, and other structures producing the sounds of speech are generated before being passed to the primary motor area. The brain-scan images in Figure 40.11 dramatically illustrate how these brain regions participate as a person performs different linguistic tasks.

People with damage to Wernicke's area have difficulty comprehending spoken and written words, even though their hearing and vision are unimpaired. Although they can speak, their words usually make no sense. People with damage to Broca's area have normal comprehension of written and spoken language, and know what they want to say, but are unable to speak except for a few slow and poorly pronounced words. Often, such people are also unable to write. Other areas of the brain are involved in language functions as well.

Some Higher Functions Are Distributed in Both Cerebral Hemispheres; Others Are Concentrated in One Hemisphere

Most of the other higher functions of the human brain—such as abstract thought and reasoning; spatial recognition; mathematical, musical, and artistic ability; and the associations forming the basis of personality—involve the coordinated participation of many regions of the cerebral cortex. Some of these regions are equally distributed in both cerebral hemispheres, and some are more concentrated in one hemisphere.

Among the functions more or less equally distributed between the two hemispheres is the ability to recognize faces. This function is concentrated along the bottom margins of the occipital and temporal lobes (see Figure 40.10). People with damage to these lobes are often unable to recognize even close relatives by sight but can recognize voices immediately.

Typically some brain functions are more localized in one of the two hemispheres, a phenomenon called **lateralization.** The unequal distribution of these functions was originally worked out in the 1960s by Roger Sperry and Michael S. Gazzaniga of the California Institute of Technology (Sperry received a Nobel Prize for his research in 1981) in subjects who had had their corpus callosum (see Figure 40.6) cut surgically **(Figure 40.13).**

Studies of people with split hemispheres as well as surveys of brain activity by PET and fMRI have confirmed that, for the vast majority of people, the left hemisphere specializes in spoken and written language, abstract reasoning, and precise mathematical calculations. The right hemisphere specializes in nonverbal conceptualizing, intuitive thinking, musical and artistic abilities, and spatial recognition functions such as fitting pieces into a puzzle. The right hemisphere also handles mathematical estimates and approximations that can be made by visual or spatial representations of numbers. Thus the left hemisphere in most people is verbal and mathematical, and the right hemisphere is intuitive, spatial, artistic, and musical.

STUDY BREAK 40.3

1. What is the blood–brain barrier, and what is its function?
2. What is the difference between gray matter and white matter?
3. What is the function of the brain stem?
4. Distinguish the structure and functions of the cerebellum from those of the cerebral cortex.

THINK OUTSIDE THE BOOK

The most common cause of brain damage is a cerebrovascular accident (CVA), commonly called a stroke. Use the Internet or research literature to outline what the biological cause of a stroke is, and why a stroke produces different symptoms in different stroke victims.

40.4 Memory, Learning, and Consciousness

We set memory, learning, and consciousness apart from the other functions because they appear to involve coordination of structures from the brain stem to the cerebral cortex. **Memory** is the storage and retrieval of a sensory or motor experience, or

Investigating the Functions of the Cerebral Hemispheres

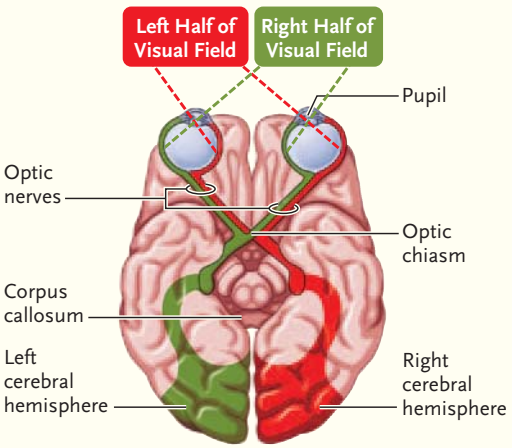
Question: Do the two cerebral hemispheres have different functions?

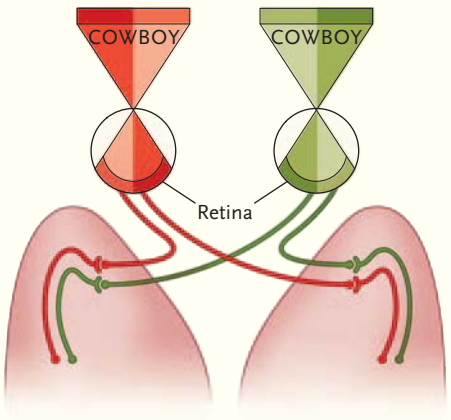
Experiment: Roger Sperry and Michael Gazzaniga studied split-brain individuals, in whom the corpus callosum connecting the two cerebral hemispheres had been surgically severed to relieve otherwise uncontrollable epileptic convulsions. In one experiment, they tested how subjects perceived words that were projected onto a screen in front of them.

The retinas of the eyes gather visual information and send signals via the optic nerves to the cerebral hemispheres **(Figure A).** Light from the *left* half of the visual field reaches light receptors on the *right* sides of the retinas, and parts of the two optic nerves carry signals to the *right* cerebral hemisphere. Light from the *right* half of the visual field reaches light receptors on the *left* sides of the retinas, and signals are sent to the *left* cerebral hemisphere.

The researchers projected words such as COWBOY in such a way that the subjects could see only the left half of the word (COW) with the left eye, and the right half of the word (BOY) with the right eye **(Figure B).** Sperry asked the subjects to say what word they saw, and he asked them to write the perceived word with the left hand—a hand that was deliberately blocked from the subject's view.

FIGURE A Pathway of visual information from eyes to cerebral hemisphere





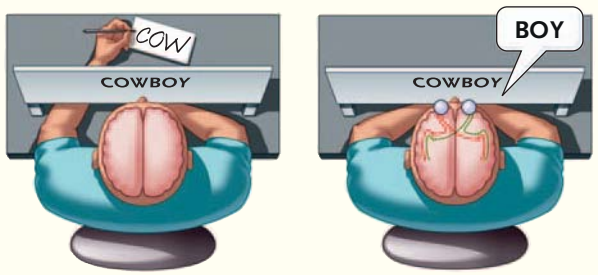


FIGURE B Experimental set up—COW seen by right sides of retinas and BOY by left sides

Results: The split-brain subjects said the word in the right half of the visual field (BOY), but wrote the word in the left half of the visual field (COW) **(Figure C).**

FIGURE C Results given by split-brain subjects

© Cengage Learning 2014

Conclusions: The studies showed that the left and right hemispheres are specialized in different tasks. The left hemisphere processes language and was able to recognize BOY but received no information about COW. The right hemisphere directs motor activity on the left side of the body and was able to direct the left hand to write COW. However, the subjects could not say what word they wrote. That is, cutting the corpus callosum interrupted communication between the two halves of the cerebrum. In effect, one cerebral hemisphere did not know what the other was doing, and information stored in the memory on one side was not available to the other. In normal individuals, information is shared across the corpus callosum; they would see COWBOY and be able to speak and write the entire word.

THINK LIKE A SCIENTIST Consider this study performed on split-brain patients. The researcher presents an image to only one side of the visual field. The patient is asked to describe the object. If, for instance, the researcher presented a flower vase to the right visual field, would the patient be able to describe it?

a thought. **Learning** involves a change in the response to a stimulus based on information or experiences stored in memory. **Consciousness** may be defined as awareness of ourselves, our identity, and our surroundings, and an understanding of the significance and likely consequences of events that we experience.

Memory Takes Two Forms, Short Term and Long Term

Psychology research and our everyday experience indicate that humans have at least two types of memory. **Short-term memory** stores information for seconds, minutes, or at most an hour or so. **Long-term memory** stores information from days to years or even for life. Short-term memory, but not long-term memory, is usually erased if a person experiences a disruption such as a sudden fright, a blow, a surprise, or an electrical shock. For example, a person knocked unconscious by an accident typically cannot recall the accident itself or the events just before it, but long-standing memories are not usually disturbed.

To explain these differences, investigators propose that short-term memories depend on transient changes in neurons that can be erased relatively easily, such as changes in the membrane potential of interneurons caused by EPSPs and IPSPs (excitatory and inhibitory postsynaptic potentials; see Section 39.3). By contrast, storage of long-term memory is considered to involve more or less permanent molecular, biochemical, or structural changes in interneurons, establishing signal pathways that cannot be switched off easily.

All memories probably register initially in short-term form. They are then either erased and lost, or committed to long-term form. The intensity or vividness of an experience, the attention focused on an event, emotional involvement, or the degree of repetition may all contribute to the conversion from short-term to long-term memory. People with injuries to the hippocampus cannot remember information for more than a few minutes; long-term memory is limited to information stored before the injury occurred.

How are neurons and neuron pathways permanently altered to create long-term memory? One change that has been much studied is **long-term potentiation:** a long-lasting increase in the strength of synaptic connections in activated neural pathways following brief periods of repeated stimulation. The synapses become increasingly sensitive over time, so that a constant level of presynaptic stimulation is converted into a larger postsynaptic output that can last hours, weeks, months, or years. (*Insights from the Molecular Revolution* describes experiments investigating the basis of long-term potentiation in neurons of the hippocampus.) Other changes consistently noted as part of long-term memory include more or less permanent alterations in the number and the area of synaptic connections between neurons, in the number and branches of dendrites, and in gene transcription and protein synthesis in interneurons.

Experiments have shown that protein synthesis is critical to long-term memory storage in animals as varied as mollusks, *Drosophila,* and rats. For example, goldfish were trained to avoid an electrical shock by swimming to one end of an aquarium when a light was turned on. The fish could remember the training for about a month under normal conditions; if exposed to a protein synthesis inhibitor while being trained, they forgot the training within a day.

Learning Involves Combining Past and Present Experiences to Modify Responses

All animals appear to be capable of learning to some degree. Learning involves three sequential mechanisms: (1) storing memories; (2) scanning memories when a stimulus is encountered; and (3) modifying the response to the stimulus in accordance with the information stored as memory.

One of the simplest forms of memory is **sensitization**—increased responsiveness to mild stimuli after experiencing a strong stimulus. The process was nicely illustrated by Eric Kandel of Columbia University and his associates in experiments with a shell-less marine snail known as the Pacific sea hare, *Aplysia californica,* which is frequently used in research involving reflex behavior, memory, and learning. Many of its neuron circuits have been completely worked out, allowing investigators to follow the reactions of each neuron active in pathways such as learning. The first time the researchers administered a single sharp tap to the siphon (which admits water to the gills), the slug retracted its gills by a reflex movement. However, at the next touch, whether hard or gentle, the siphon retracted much more quickly and vigorously. Sensitization in *Aplysia* has been shown to involve changes in synapses, which become more reactive when more serotonin is released by action potentials. Kandel received a Nobel Prize in 2000 for his research. (Learning and its relationship to animal behavior are considered further in Chapter 56.)

Consciousness Involves Different States of Awareness

The spectrum of human consciousness ranges from alert wakefulness to daydreaming, dozing, and sleep. Even during sleep there is some degree of awareness, because sleepers can respond to stimuli and waken, unlike someone who is unconscious. Moving between the states of consciousness has been found to involve changes in neural activity over the entire surface of the telencephalon.

When an individual is fully awake, an EEG (electroencephalogram; a chart of the brain electrical activity detectable by electrodes placed on the scalp) records a pattern of rapid, irregular *beta waves* **(Figure 40.14).** With thought processes at rest and eyes closed, the person's EEG pattern changes to slower and more regular *alpha waves.* As drowsiness and light sleep come on, the wave trains gradually become larger, slower, but again less regular; these slower pulsations are called *theta waves.* During the transition from drowsiness to deep sleep, the EEG pattern shifts to even slower *delta waves.* The heart and

Knockout Mice with a Bad Memory

Long-term potentiation (LTP) in neurons of the hippocampus is thought to be central to the conversion of short-term to long-term memory. The neurotransmitter glutamate is most often involved in the process. One of the receptors that binds glutamate in postsynaptic membranes of the hippocampus is the *NMDA (N-methyl-D-aspartate) receptor.* A prolonged series of stimuli causes glutamate to bind to the receptor, which opens an ion channel that forms part of the receptor's structure. Among other effects, Ca^{2+} ions flowing inward through the channel activate a protein kinase in the cytoplasm called *CaMKII.* (Recall that protein kinases are enzymes that, when activated, add phosphate groups to target proteins; addition of the phosphate groups increases or reduces activity of the proteins.)

One of the target proteins for the activated CaMKII is itself. After it adds phosphate groups to its own structure, CaMKII no longer needs to be activated by calcium—it remains turned on at elevated levels. Its more or less permanent activation makes the neuron more sensitive to incoming signals and increases the number of the signals it sends to other neurons. Researchers hypothesize that this change is a major contributor to LTP in the neuron. Among the supporting evidence is the observation that chemical blockage of the NMDA receptor impairs spatial learning and long-term memory in mice.

Research Question

Does activation of CaMKII contribute to LTP in neurons of the hippocampus?

Experiment

A research group at the Massachusetts Institute of Technology led by a Nobel Prize-winning scientist, Susumu Tonegawa, applied molecular techniques to answer this question. Tonegawa's group created a strain of "knockout" mice (see Section 18.2) that lack NMDA receptors *only* in the hippocampus. The researchers then compared normal and knockout mice in two ways.

1. To test for LTP in hippocampal neurons, the investigators dissected out brain slices and used microelectrodes to repeatedly stimulate the neurons.
2. To test for effects on spatial learning and long-term memory, the researchers placed the knockout mice in a pool in which they had to swim until they could find a submerged platform to rest on.

Results

The results are shown in the **Table.**

Conclusion

The data show that the lack of NMDA receptors in the hippocampus is sufficient to produce significant memory defects. The results support the hypothesis that the NMDA receptor is involved in the conversion from short-term to long-term memory, and that the hippocampus has a central role in this activity. The novel approach used by the Tonegawa group provided a new, molecular research method by which to analyze higher brain function.

THINK LIKE A SCIENTIST What do you think was the key aspect of the researchers' experimental design that allowed them to make the conclusions they did?

Sources: J. Z. Tsien et al. 1996. Subregion- and cell type-restricted gene knockout in mouse brain. *Cell* 87:1317–1326; J. Z. Tsien et al. 1996. The essential role of hippocampal CA1 NMDA receptor-dependent synaptic plasticity on spatial memory. *Cell* 87:1327–1338.

	Effect of repeated stimulation of hippocampal neurons	Spatial learning and long-term memory
Normal mouse with NMDA receptors 	Long-term potentiation	Normal—easily found platform in initial trials and readily able to remember its location in later trials
Knockout mouse—no NMDA receptors 	No long-term potentiation	Slower than normal mice in finding platform in initial trials and unable to remember its location in later trials

breathing rates become slower and the skeletal muscles increasingly relax, although the sleeper may still change position.

Periodically during deep sleep, the delta wave pattern is replaced by the rapid, irregular beta waves characteristic of the waking state. The person's heartbeat and breathing rate increase, the limbs twitch, and the eyes move rapidly behind the closed eyelids, giving this phase its name of **rapid-eye-movement (REM) sleep.** The REM sleep phase occurs about every 1.5 hours while a healthy adult is sleeping, and lasts for 10 to 15 minutes. Sleepers do most of their dreaming during REM sleep, and most research subjects awakened from REM sleep report they were experiencing vivid dreams.

As mentioned earlier, the reticular activating system controls the sleep-wake cycle. It sends signals to the spinal cord, cerebellum, and cerebral cortex, and receives signals from the same locations. The flow of signals along these circuits determines whether we are awake or asleep.

Many other animals also alternate periods of wakefulness and sleep or inactivity. Although sleep obviously has restorative effects on mental and physical functions, the physiological basis of these effects remains unknown.

In the previous chapter we learned about neurons, and in this chapter we have discussed the organization of neurons into nervous systems, as well as the structures of the brain and their functions. In the next chapter, we consider the sensory systems that provide input for the brain to process.

STUDY BREAK 40.4

An aging person often experiences a progressive decline in cognitive function. This typically begins with short-term memory loss and the inability to learn new information. What parts of the brain might be changing?

UNANSWERED QUESTIONS

Did memory and learning evolve once or multiple times within the animal kingdom?

Memory is highly adaptive because it enables animals to avoid stimuli that previously caused pain or danger, and to seek out environments that lead to rewarding or pleasurable experiences. Of course, some of this ability is hard wired—we do not need to learn that bitter tastes are unpleasant and sweet tastes are pleasant. But the environmental stimuli that predict where to expect sweet versus bitter, or hot versus cold stimuli can vary. So it makes sense that animals capable of movement can learn and remember the stimuli that tend to be together in the environment. But did this ability emerge independently in different phyla? If so, we might expect the underlying mechanisms to be quite different in the different phylogenetic groups, even if evolutionary adaptations have converged onto similar memory abilities (see Section 23.3 on convergent evolution). Or did memory evolve one time in a common ancestor before the various animal phyla diverged? In this case, we might expect to find shared underlying mechanisms no matter how distantly related the organisms. We do not know the answer to these questions. But given what we do know about memory mechanisms, a common origin seems likely even for animals as distantly related as invertebrates and vertebrates.

Genetic studies have provided many key insights into mechanisms of memory formation. One of the most remarkable findings from genetic investigation is that many of the same genes and biochemical signaling pathways are utilized for memory formation and storage no matter what species one examines. In several cases, genetic pathways relevant to human cognition also appear to underlie memory in animals as distant from humans as fruit flies. Cyclic AMP (cAMP) signaling is one of the best examples; this signaling pathway was first connected to memory in invertebrates of the genus *Aplysia* (sea hares) and *Drosophila* (fruit flies), then in rodents, and more recently in humans. In fact, the conversion from short-term to long-term memory in fruit flies, sea hares, bees, mice, rats, and probably humans involves activation of a gene called the cAMP responsive enhancer binding protein (CREB). The discovery of shared genetic mechanisms of memory supports the idea that memory mechanisms in vertebrate and invertebrate animals share an evolutionary origin. What about similarities in the neural circuits that support memory formation?

Similarities at the neural circuit level between humans and mice or rats are relatively easy to detect because the overall organization of rodent and human brains is similar. Thus, we can compare the requirements for neural circuits that are likely to be related through evolution. The similarities are harder to establish when we compare invertebrates and vertebrates because their brains are so different in size and structure. But even here, there are some hints that the way neural circuits store memories is at least analogous. A good example comes from studies of the neural circuits involved in conversion of short-term to long-term memory. An emerging theme is that different neural circuits may be required for short-term and long-term memory. Initially, this "dissection" of neural circuit function came from precise surgical lesion of brain regions in rodents and chickens. In certain cases, these lesions caused disruptions of either short-term or long-term memory, but not both. Similar effects are seen in people with localized brain damage.

More modern genetic approaches now permit disruptions that are specific not only to brain regions, but to individual neuronal cell types within a region. In our laboratory, we used this approach recently to determine which neurons are involved in short-term and long-term memory formation in fruit flies. We used a Pavlovian learning test in which the flies learn that a specific odor predicts that they will receive an electric shock. We then used precise genetic manipulations to test which neuron cell types require cAMP signaling for either short-term or long-term memory. We focused on a brain region called the mushroom bodies because previous work already had demonstrated that this is an olfactory learning center in insects. To our surprise, we found that two different neuronal cell types are required for short-term versus long-term memory.

We do not know why brains have evolved specialized circuits for short-term and long-term storage of the same memory. Perhaps it reflects an important feature for storing information within a neural network. The question is whether this feature emerged independently in different phyla or once in a common ancestor.

THINK LIKE A SCIENTIST You come across two related species of beetles and you observe their behaviors. One beetle species seems always to feed on a single food source from a single plant species; we call it a "specialist." The second beetle species forages widely across many different food sources; it is a "generalist." You decide to study their learning abilities in the lab, and you design a fairly artificial learning task. You try to teach these animals that a pure chemical odor predicts an electric shock. If you had to guess (and you do), which beetle species will exhibit better learning in your experiment? Why?

Josh Dubnau

Josh Dubnau is an associate professor at Cold Spring Harbor Laboratory where his research focuses on memory in fruit flies. One theme in Dr. Dubnau's work is an attempt to use both reductionist methods and more holistic observations at the organismal level. You can learn more about Dubnau's research by visiting http://dubnaulab.cshl.edu/.

40.1 Invertebrate and Vertebrate Nervous Systems Compared

- The simplest nervous systems are the nerve nets of cnidarians. Echinoderms have modified nerve nets, with some neurons grouped into nerves (Figure 40.1A and B).
- Flatworms, arthropods, and mollusks have a simple central nervous system (CNS), consisting of ganglia in the head region (a brain), and a peripheral nervous system (PNS), consisting of nerves from the CNS to the rest of the body (Figure 40.1C–E).
- In vertebrates, the CNS consists of a large brain located in the head and a hollow spinal cord, and the PNS consists of all the nerves and ganglia connecting the CNS to the rest of the body (Figure 40.1F).
- In the vertebrate embryo, the anterior end of the hollow neural tube develops into the brain, and the rest develops into the spinal cord. The embryonic brain enlarges into the forebrain, midbrain, and hindbrain, which develop into the adult structures (Figure 40.2).

Animation: Comparisons of animal nervous systems

40.2 The Peripheral Nervous System

- Afferent neurons in the PNS conduct signals to the CNS, and signals from the CNS travel via efferent neurons to the effectors—muscles and glands—that carry out responses (Figure 40.3).
- The somatic system of the PNS controls the skeletal muscles, producing voluntary body movements as well as involuntary muscle contractions that maintain balance, posture, and muscle tone.
- The autonomic system of the PNS, which controls involuntary functions, is organized into the sympathetic division and the parasympathetic division. The pathways of the autonomic system include two neurons (Figures 40.4 and 40.5).

Animation: Vertebrate nervous system divisions

Animation: Autonomic nerves

40.3 The Central Nervous System and Its Functions

- The brain and the spinal cord are surrounded and protected by the meninges. Cerebrospinal fluid provides nutrients and cushions the CNS. A blood–brain barrier allows only selected substances to enter the cerebrospinal fluid.
- Each adult brain structure contains gray matter and white matter. Functionally, the brain integrates sensory information and generates responses. The cerebrum is divided into right and left cerebral hemispheres, which are connected by a thick band of nerve fibers, the corpus callosum. Each hemisphere consists of the cerebral cortex, a thin layer of gray matter covering a thick core of white matter. Other collections of gray matter, the basal nuclei, are deep in the telencephalon (Figure 40.6).
- The spinal cord carries signals between the brain and the PNS. Its neuron circuits control reflex muscular movements and some autonomic reflexes (Figure 40.7).
- The medulla, pons, and midbrain form the brain stem, which connects the cerebrum, thalamus, and hypothalamus with the spinal cord.
- Gray-matter centers in the pons and medulla control involuntary functions. Centers in the midbrain coordinate responses to visual and auditory sensory inputs.
- The reticular formation receives sensory inputs from all parts of the body and sends outputs to the cerebral cortex that help maintain balance, posture, and muscle tone. It also regulates states of wakefulness and sleep (Figure 40.8).
- The cerebellum integrates sensory inputs on the positions of muscles and joints, along with visual and auditory information, to coordinate body movements.
- The telencephalon's subcortical gray-matter centers control many functions. The thalamus receives, filters, and relays sensory and motor information to and from regions of the cerebral cortex. The hypothalamus regulates basic homeostatic functions of the body and contributes to the endocrine control of body functions. The basal nuclei affect the planning and fine-tuning of body movements (Figure 40.9).
- The limbic system includes parts of the thalamus, hypothalamus, and basal nuclei, as well as the amygdala and hippocampus. It controls emotions and influences the basic body functions controlled by the hypothalamus and brain stem (Figure 40.9).
- The primary somatosensory areas of the cerebral cortex register incoming information on touch, pain, temperature, and pressure from all parts of the body. In general, the right cerebral hemisphere receives sensory information from the left side of the body and vice versa (Figures 40.10 and 40.12).
- The primary motor areas control voluntary movements of skeletal muscles (Figures 40.10 and 40.12).
- The association areas integrate sensory information and formulate responses that are passed on to the primary motor areas. Wernicke's area integrates visual, auditory, and other sensory information into the comprehension of language; Broca's area coordinates movements of the lips, tongue, jaws, and other structures to produce the sounds of speech (Figure 40.10).
- Long-term memory and consciousness are equally distributed between the two cerebral hemispheres. Spoken and written language, abstract reasoning, and precise mathematical calculations are left hemisphere functions; nonverbal conceptualizing, mathematical estimation, intuitive thinking, spatial recognition, and artistic and musical abilities are right hemisphere functions (Figure 40.13).

40.4 Memory, Learning, and Consciousness

- Memory is the storage and retrieval of a sensory or motor experience or a thought. Short-term memory involves temporary storage of information, whereas long-term memory is essentially permanent.
- Learning involves modification of a response through comparisons made with information or experiences that are stored in memory.
- Consciousness is the awareness of ourselves, our identity, and our surroundings. It varies through states from full alertness to sleep and is controlled by the reticular activating system (Figure 40.14).

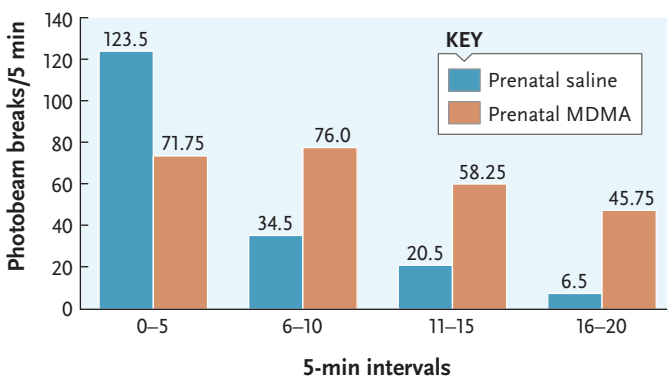
UNDERSTAND & APPLY

Test Your Knowledge

1. Ganglia first became enlarged and fused into a lobed brain in the evolution of:
   a. vertebrates.
   b. annelids.
   c. flatworms.
   d. cephalopods.
   e. mammals.
2. The hindbrain subdivides and eventually gives rise to the:
   a. spinal cord.
   b. cerebellum.
   c. mesencephalon.
   d. thalamus.
   e. cerebrum.
3. The autonomic nervous system is subdivided into:
   a. afferent and efferent systems.
   b. sympathetic and parasympathetic divisions.
   c. skeletal and smooth muscle innervations.
   d. voluntary and involuntary controls.
   e. peripheral and central systems.
4. People with severe insect-sting allergies carry an EpiPen, an autoinjector containing medication that they can use in an emergency. The medication causes smooth muscles in the lung passages to relax so they can breathe, but causes their hearts to pound rapidly. This is an example of stimulation of the:
   a. parasympathetic system.
   b. sympathetic system.
   c. somatic nervous system.
   d. limbic system.
   e. voluntary system.
5. Which of the following statements about the blood–brain barrier is *incorrect*?
   a. It is formed of capillary walls that are composed of tight junctions.
   b. It transports glucose to brain cells by means of transport proteins.
   c. It allows alcohol to pass through its lipid bilayer.
   d. Oxygen can move through the lipid bilayer.
   e. It reduces blood supply to brain cells compared with other body cells.
6. Which one of the following structures participates in a reflex?
   a. the gray matter of the brain
   b. the white matter of the brain
   c. the gray matter of the spinal cord
   d. an interneuron that stimulates an afferent neuron
   e. an interneuron that inhibits an afferent neuron
7. A segment of the brain stem that coordinates spinal reflexes with higher brain centers and regulates breathing and wakefulness is the:
   a. reticular formation.
   b. white matter of the pons.
   c. white matter of the medulla.
   d. hypothalamus.
   e. cerebellum.
8. Cushioning and nourishing the brain and spinal cord and filling the ventricles of the brain is (are):
   a. meninges.
   b. myelin.
   c. cerebrospinal fluid.
   d. ganglia.
   e. glucose.
9. Which structure and function are correctly paired below?
   a. thalamus: relays emotion signals through the limbic system
   b. basal nuclei: relay inputs from odor receptors to the cerebrum
   c. hypothalamus: releases hormones; sets up daily rhythms
   d. amygdala: relays sensory information to the cerebrum
   e. olfactory bulbs: moderate motor centers in the cerebrum
10. A patient had a tumor in Wernicke's area. It was initially diagnosed when the patient could not:
    a. understand the morning newspaper.
    b. hear a child crying.
    c. see the traffic light turn red.
    d. speak.
    e. feel if the car heater was on.

Discuss the Concepts



1. Meningitis is an inflammation of the meninges, the membranes that cover the brain and spinal cord. Diagnosis involves using a needle to obtain a sample of cerebrospinal fluid to analyze for signs of infection. Why analyze this fluid and not blood?
2. An accident victim arrives at the emergency room with severe damage to the reticular formation. Based on information in this chapter, describe some of the symptoms that the examining physician might discover.
3. In the 1930s and 1940s, prefrontal lobotomy, in which neural connections in the frontal lobes of both cerebral hemispheres were severed, was used to treat behavioral conditions such as extreme anxiety and rebelliousness. Although the procedure calmed patients, it had side effects such as apathy and a seriously disrupted personality. In view of the information presented in this chapter, why do you think the operation had these effects?

Design an Experiment

How would you demonstrate, using mice, that gene activity in the brain is altered by aging?

Interpret the Data

Animal studies are often used to assess the effects of prenatal exposure to drugs. For example, Jack Lipton used rats to study the behavioral effect of prenatal exposure to MDMA (3,4-methylenedioxymethamphetamine), the active ingredient in the illicit drug ecstasy. He injected female rats with either MDMA or saline solution when they were 14 to 20 days pregnant, and their offspring's brains were forming. When those offspring were 21 days old, Lipton tested their response to a new environment. He placed each young rat in a new cage and used a photobeam system to record how much each rat moved around before settling down. The **Figure** shows his results.

Reprinted from J. B. Koprich et al. 2003. Prenatal 3,4-methylenedioxmethamphetamine (ecstasy) alters exploratory behavior, reduces monoamine metabolism, and increases forebrain tyrosine hydroxylase fiber density of juvenile rats. *Neurotoxicology and Teratology* 25:509–517. With permission from Elsevier.

1. Which rats moved most (caused the most photobeam breaks) during the first 5 min in a new cage, those prenatally exposed to MDMA or the controls?
2. How many photobeam breaks did the MDMA-exposed rats make during their second 5 min in the new cage?
3. Which rats moved most during the last 5 min of the study?
4. Does this study support the hypothesis that exposure to MDMA affects a developing rat's brain?

Source: J. B. Koprich et al. 2003. Prenatal 3,4-methylenedioxmethamphetamine (ecstasy) alters exploratory behavior, reduces monoamine metabolism, and increases forebrain tyrosine hydroxylase fiber density of juvenile rats. *Neurotoxicology and Teratology* 25:509–517.

Apply Evolutionary Thinking

How do paleontologists contribute to our understanding of the evolution of the brain?

Two fruit bats fighting for food.

41

Sensory Systems

Why it matters . . . An insectivorous bat searches for food. As it flies, the bat emits a steady stream of ultrasonic clicking noises. Receptors in the bat's ears detect echoes of the clicks bouncing off objects in the environment and send signals to the brain, where they are integrated into a sound map that the animal uses to navigate through the complex environment. This ability, called **echolocation,** is so keenly developed that a bat can detect and avoid a thin wire in the dark.

Besides recognizing obstacles, the bat's auditory system is keenly tuned to the distinctive pattern of echoes from the fluttering wings of its favorite food, a moth. Although the slow-flying moth would seem doomed to become a meal for the foraging bat, natural selection has provided some species of moths with a highly sensitive auditory sense as well. On each side of its abdomen is an "ear," a thin membrane that resonates at the frequencies of the clicks emitted by the bat. The moth's ears register the clicks while the bat is still about 30 m away and initiate a response that turns its flight path directly away from the source of the clicks.

In spite of the moth's evasive turns, if the bat approaches within about 6 m of it, echoes from the moth begin to register in the bat's auditory system, and the bat increases the frequency of its clicks, enabling it to pinpoint the moth's position. But, as the bat closes in, the increased frequency of the clicks sets off another programmed response that alters the moth's flight into sudden loops and turns, ending with a closed-wing, vertical fall toward the ground. After dropping a few feet, the moth resumes its fluttering flight and may again be detected by the bat, and so it goes.

Echolocation is not confined to bats. Porpoises use echolocation to locate food fishes in murky waters, and whales use echolocation to keep track of the sea bottom and rocky obstacles. Two bird species, the oilbird and the cave swiftlet, use echolocation to avoid obstacles and find their nests in dark caves.

Natural selection has produced highly adaptive sensory receptors in all animals. These systems, the subject of this chapter, provide animals with a steady stream of information about their

internal and external environments. After integrating the information in the central nervous system (CNS), animals respond in ways that enable them to survive and reproduce.

We begin this chapter with a survey of animal sensory systems and the ways in which they work. Then we examine several individual receptor types and their characteristics.

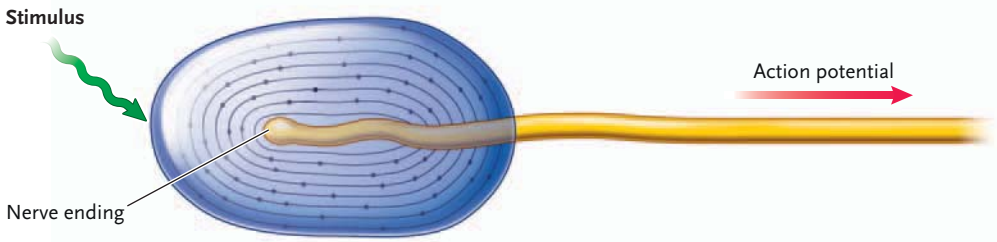
41.1 Overview of Sensory Receptors and Pathways

A **stimulus** is a change detected by the body. A variety of energy forms are stimuli, including heat, light, sound, and pressure. Stimuli are detected by **sensory receptors.** Sensory receptors associated with eyes, ears, skin, and other surface organs detect stimuli from the external environment. Sensory receptors associated with internal organs detect stimuli arising in the body interior. The receptors occur in three structural forms **(Figure 41.1).** Two of the forms involve peripheral endings of an afferent neuron, while the third form is a specialized cell that synapses with an afferent neuron.

Each sensory receptor has a defined **receptive field,** a region surrounding the receptor within which the receptor responds to a stimulus. Sensory receptors respond to stimuli in their receptive fields by undergoing a change in membrane potential. The change, called a **receptor potential,** varies in magnitude with the magnitude of the stimulus; thus, it is a graded potential (see Section 39.4). In most receptors, the change is caused by changes in the rate at which channels conduct positive ions such as Na^+, K^+, or Ca^{2+} across the plasma membrane. The conversion of a stimulus into a receptor potential is called **sensory transduction.** If the receptor potential is large enough, it will trigger an action potential in the afferent neuron that travels along the axon into the interneuron networks of the CNS. These interneurons integrate the sensory stimuli, and the brain formulates a compensating response (see Section 40.3).

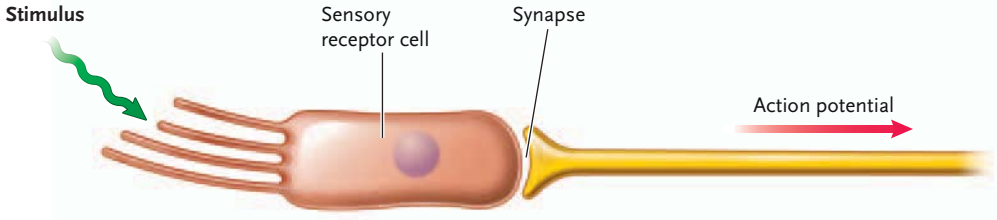
Five Basic Types of Receptors Are Common to Almost All Animals

Many sensory receptors are positioned individually in body tissues. Others are part of complex sensory organs, such as the eyes or ears, which are specialized for reception of physical or chemical stimuli. Commonly, sensory receptors are classified into five major types, based on the type of stimulus that each detects:



1. **Mechanoreceptors** detect mechanical energy when it deforms membranes. Changes in pressure, body position,

A. Sensory receptor consisting of free nerve endings—dendrites of an afferent neuron



In sensory receptors consisting of free dendrites of afferent neurons, a stimulus causes a change in membrane potential that generates action potentials in the axon of the neuron. Examples are pain receptors and some mechanoreceptors.

B. Sense organ—sensory receptor involving nerve endings of an afferent neuron enclosed in a specialized structure

In sensory receptors involving endings of an afferent neuron enclosed in a specialized structure, a stimulus affecting the structure triggers an action potential in the neuron. Some mechanoreceptors are of this type.

C. Sensory receptor formed by a cell that synapses with an afferent neuron

In sensory receptors consisting of separate cells, a stimulus causes a change in membrane potential that releases a neurotransmitter from the cell. The neurotransmitter triggers an action potential in the axon of an afferent neuron to which the sensory receptor cell is synapsed. Examples are photoreceptors, chemoreceptors, and some mechanoreceptors.

or acceleration are detected by mechanoreceptors, for instance. The auditory receptors in the ears are examples of mechanoreceptors.

2. **Photoreceptors** detect the energy of light. In vertebrates, photoreceptors are mostly located in the retina of the eye.
3. **Chemoreceptors** detect specific molecules, or chemical conditions such as acidity. The taste buds on the tongue are examples of chemoreceptors.
4. **Thermoreceptors** detect the flow of heat energy. Receptors of this type are located in the skin.
5. **Nociceptors** detect tissue damage or noxious chemicals; their activity registers as pain. Pain receptors are located in the skin, and also in some internal organs.

In addition to these major types, some animals have receptors that can detect electrical or magnetic fields.

Although humans are traditionally said to have five senses—vision, hearing, taste, smell, and touch—our sensory receptors actually detect more than four times as many kinds of environmental stimuli. Among these are external heat, internal temperature, gravity, acceleration, the positions of muscles and joints, body balance, internal pH, and the internal concentration of substances such as oxygen, carbon dioxide, salts, and glucose.

Afferent Neurons Link Receptors to the CNS

Sensory pathways begin at a sensory receptor and proceed by afferent neurons to a particular location in the CNS. For example, action potentials arising in the retina of the eye travel along the optic nerve to the visual cortex where they are interpreted by the brain as differences in the pattern, color, and intensity of light.

One way in which the intensity and extent of a stimulus is registered is by the frequency (number per unit time) of action potentials traveling along each axon of an afferent pathway. That is, the stronger the stimulus, the more frequently afferent neurons fire action potentials (see Section 39.2). A light touch to the hand, for example, causes action potentials to flow at low frequencies along the axons of afferent neurons to the primary somatosensory area of the cerebral cortex. As the pressure increases, the frequency of action potentials rises in proportion.

The second way in which the intensity and extent of a stimulus are registered is by the number of afferent neurons that the stimulus activates to generate action potentials in the pathway. The more sensory receptors that are activated, the larger the number of axons that carry information to the brain. A light touch activates a relatively small number of receptors in a small area near the surface of the finger, for example. As the pressure increases, the resulting indentation of the finger's surface increases in area and depth, activating more and different types of receptors.

Many Receptor Systems Reduce Their Response When Stimuli Remain Constant

In many systems, the effect of a stimulus is lessened if it continues at a constant level. This **sensory adaptation** reduces the frequency of action potentials generated in afferent neurons.

For example, when you go to bed, you are initially aware of the touch and pressure of the covers on your skin. Within a few minutes, the sensations lessen or are lost even though your position remains the same. The loss reflects adaptation of mechanoreceptors in your skin. By contrast, nociceptors do not adapt to painful stimuli; the frequency of action potentials remains elevated as long as the stimulus is detected.

Sensory adaptation also increases the sensitivity of receptor systems to *changes* in environmental stimuli, which may be more important to survival than keeping track of environmental factors that remain constant. Consider a cat sitting motionless, focused on its prey, a mouse. As long as the environmental stimuli are constant, the cat's position remains fixed. However, if the mouse moves, the cat will respond rapidly and pounce.

Many prey animals take advantage of adaptation in predators as a means for concealment or defense. These animals often become motionless when they sense a predator in their environment. Natural selection has favored those that "freeze" in this situation because they may remain undetected by the adapted senses of their predator.

Nonadapting receptors, such as those detecting pain, are also essential for survival. Pain signals a potential danger to some part of the body, and the signals are maintained until a response by the animal compensates for the stimulus causing the pain.

Perception of a Stimulus Results from Interpretation of Sensory Input

Action potentials from sensory receptors are the signals the brain uses to generate an interpretation—the **perception**—of the external and internal environments. Consider your perception of the world; it differs from reality for several reasons: (1) you lack receptors for particular types of energy, such as X-rays; (2) sensory input begins to be processed before it reaches the cerebral cortex, so some features of the stimuli may be enhanced and others may be diminished; and (3) input is processed further by the cerebral cortex, including comparison with other input and with memories of similar situations. Each individual has different perceptions of the world. Certainly, human perception of the world is significantly different from the perceptions of other organisms.

STUDY BREAK 41.1

1. **Define sensory transduction.**
2. **Sensory receptors send signals to the CNS in the same way. How are stimuli of different kinds perceived as being different?**

41.2 Mechanoreceptors and the Tactile and Spatial Senses

Mechanical stimuli such as touch and movement are detected by mechanoreceptors. The mechanical forces of a stimulus create tension in the plasma membrane of a receptor, causing ion

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

channels to open and producing a receptor potential. If the receptor potential is large enough, an action potential is triggered in the associated afferent neuron leading to the CNS. Sensory information from mechanoreceptors informs the brain of the body's contact with objects in the environment; provides information on the movement, position, and balance of body parts; and underlies the sense of hearing.

Receptors for Touch and Pressure Occur throughout the Body

In vertebrates, mechanoreceptors detecting touch and pressure are embedded in the skin and other surface tissues, in skeletal muscles, in the walls of blood vessels, and in internal organs. In humans, receptive fields for touch in the skin are smallest in the fingertips, lips, and tip of the tongue, giving these regions the greatest sensitivity to mechanical stimuli. In other areas, such as the skin of the back, arms, and legs, the receptive fields are much larger.

You can compare the receptive fields of touch receptors by pressing two toothpicks lightly against a fingertip and then against the skin of your arm or leg. On your fingertip, the points can be quite close together—separated by only a millimeter or so—and still be discerned as separate. On your arm or leg, they must be nearly 5 cm (almost 2 inches) apart to be distinguished.

Human skin contains several types of touch and pressure receptors **(Figure 41.2).** Some are free nerve endings, the dendrites of afferent neurons with no specialized structures surrounding them. Free nerve endings wrapped around hair follicles respond when the hair is bent, making you instantly aware, for example, of a breath of air, or a spider on your arm. Other mechanoreceptors, such as Pacinian corpuscles, have structures surrounding the nerve endings that contribute to reception of stimuli.

Proprioceptors Provide Information about Movements and Position of the Body

Mechanoreceptors called **proprioceptors** (*proprius* = one's own) detect stimuli that are used in the CNS to maintain body balance and equilibrium and to monitor the position of the head and limbs. The activity of these receptors allows you to touch the tip of your nose with your eyes closed, for example, or reach and brush away that spider on your arm.

TENSION RECEPTORS IN VERTEBRATES In the muscles and tendons of vertebrates, proprioceptors detect the position and movement of the limbs. The sensory receptors that detect the length of a muscle and its contraction are muscle spindles, bundles of small, specialized muscle cells wrapped with the dendrites of afferent neurons (yellow in the figure) and enclosed in connective tissue **(Figure 41.3).** When the muscle stretches, the spindle stretches also, stimulating the dendrites and triggering the production of action potentials. The strength of the response of stretch receptors to stimulation depends on how much and how fast the muscle is stretched. The proprioceptors of tendons, called **Golgi tendon organs,** are dendrites that branch within the fibrous connective tissue bundles that make up the tendon (see Figure 41.3). When a muscle contracts in response to action potentials that travel along the axons of efferent neurons (blue in the figure), the pull on the tendon tightens the connective tissue bundles, which in turn increases the tension on the bone to which the tendon is attached. The Golgi tendon organ responds to the tension by producing action potentials in the afferent neuron at a rate related to the amount of tension.

Proprioceptors allow the CNS to monitor the body's position and help keep the body in balance. They also allow muscles to apply constant force under a constant load, and to adjust almost instantly if the load changes. When you hold a cup while someone fills it with coffee, for example, the muscle spindles in your biceps muscle detect the additional stretch as the cup becomes heavier. Signals from the spindles allow you to compensate for the additional weight by increasing the contraction of the muscle, keeping the cup level with no conscious effort on your part. Proprioceptors are typically slow to adapt, so that

the body's position and balance are constantly monitored.

THE VESTIBULAR APPARATUS IN VERTEBRATES

The inner ear of most terrestrial vertebrates has two specialized sensory structures, the *vestibular apparatus* and the *cochlea.* The **vestibular apparatus (Figure 41.4)** detects rotational motions of the head and provides information about the up–down positioning of the head as well as changes in the rate of linear movement of the head. The vestibular apparatus consists of three *semicircular canals,* the *utricle,* and the *saccule,* which are all filled with a fluid called *endolymph.* The **semicircular canals,** which are positioned at angles corresponding to the three planes of space, detect rotational ("spinning") motions. Each canal has a swelling at its base called an *ampulla,* which is topped with sensory hair cells that synapse with afferent neurons. The surface of a hair cell at the other end from the synapse is covered with **stereocilia** (singular, *stereocilium*), which are actually microvilli (cell processes reinforced by bundles of microfilaments). The stereocilia extend into a gelatinous structure, the **cupula** (*cupula* = little cup), which protrudes into the endolymph of the canals.

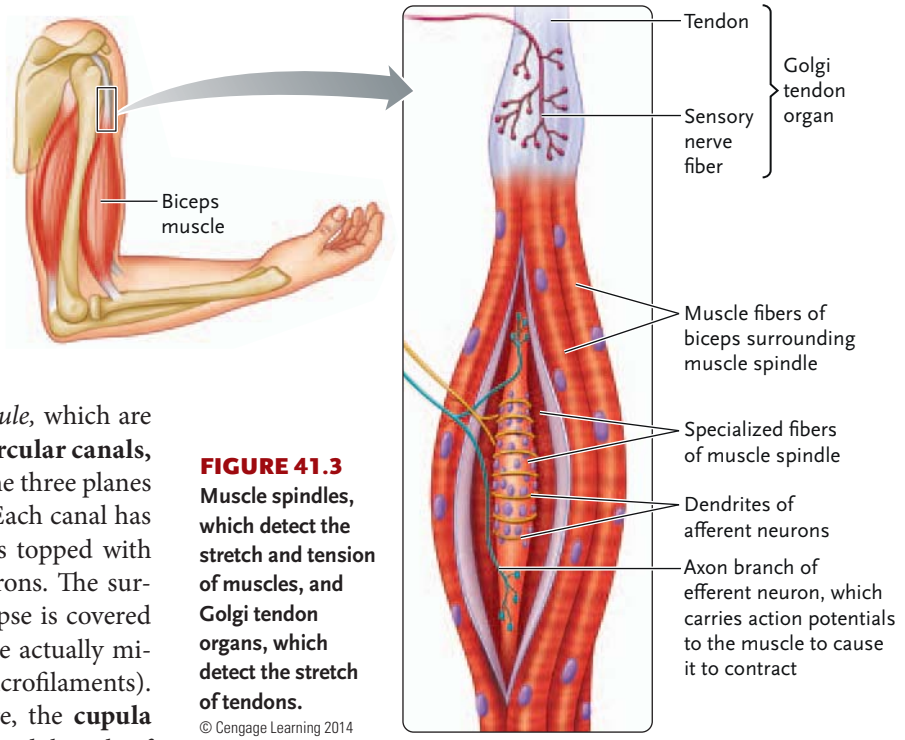

FIGURE 41.3 **Muscle spindles, which detect the stretch and tension of muscles, and Golgi tendon organs, which detect the stretch of tendons.**

When the head rotates horizontally, vertically, or diagonally, the endolymph in the semicircular canal corresponding to that direction lags behind, pulling the cupula with it. The displacement of the cupula bends the sensory hair cells. Channels at the tips of the stereocilia open and K^+ enters, causing the sensory hair cell to depolarize. The depolarization opens Ca^{2+} channels in the main part of the hair cell, and entry of Ca^{2+} causes the release of neurotransmitter from the hair cell into the synapse. The neurotransmitter triggers action potentials in the afferent neuron.

The **utricle** and **saccule** provide information about the position of the head with respect to gravity (up versus down), as well as changes in the rate of linear movement of the head. They are saclike structures in a bony chamber located between the semicircular canals and the cochlea. Oriented approximately 30° to each other, both utricle and saccule contain sensory hair cells with stereocilia. The hair cells are covered with a gelatinous *otolithic membrane* (which is similar to a cupula) in which **otoliths** (*oto* = ear; *lithos* = stone), small crystals of calcium carbonate, are embedded (see Figure 41.4).

When an animal is upright, the sensory hairs in the utricle are oriented vertically, and those in the saccule are oriented horizontally. When the head is tilted in any direction other than straight up and down, or when there is a change in linear motion of the body, the otolithic membrane of the utricle moves and bends the sensory hairs. Depending on the direction of movement, the hair cells release more or less neurotransmitter, which changes the rate of action potentials in the afferent neurons. The utricle and saccule adapt quickly to the head's motion, decreasing their response when there is no change in the rate and direction of movement. For instance, when you move your head to the left, that new position becomes the "norm." Then, if you move your head again, signals from the utricle and saccule tell your brain that your head is moving to a new position.

THE LATERAL LINE SYSTEM IN AMPHIBIANS AND FISHES

Fishes and some aquatic amphibians detect vibrations and currents in the water through a series of mechanoreceptors along the length of the body called the **lateral line system (Figure 41.5).** In fish, the mechanoreceptors, known as *neuromasts,* also provide information about the fish's orientation with respect to gravity and its swimming velocity. Each dome-shaped neuromast has sensory hair cells clustered in its base. Stereocilia on the hair cells extend into a cupula similar to that of the vertebrate vestibular apparatus, which moves with pressure changes in the surrounding water. Movement of the cupula bends the stereocilia, which leads to the triggering of action potentials in associated afferent neurons.

Vibrations detected by the lateral line enable fishes to avoid obstacles, orient in a current, and monitor the presence of other moving objects in the water. The system is also responsible for the ability of schools of fish to move in unison, turning and diving in what appears to be a perfectly synchronized aquatic ballet. In actuality, the movement of each fish creates a pressure wave in the water that is detected by the lateral line systems of other fishes in the school. Schooling fish can still swim in unison even if blinded, but if the nerves leading from the lateral line system to the brain are severed, the ability to school is lost.

STATOCYSTS

Many aquatic invertebrates, including jellyfish, some gastropods, and some arthropods, have organs of equilibrium called **statocysts** (*statos* = standing; *kystis* = bladder, pouch). Most statocysts are fluid-filled chambers with walls that contain sensory hair cells enclosing one or more movable stonelike bodies called **statoliths (Figure 41.6);** statoliths are similar to vertebrate otoliths. When the animal moves, the statoliths lag behind the movement, bending the sensory hairs and triggering action potentials in afferent neurons. In this way, the statocysts signal the brain about the body's position and orientation with respect to gravity.

STUDY BREAK 41.2

1. What is the function of proprioceptors?
2. What properties qualify proprioceptors as mechanoreceptors?

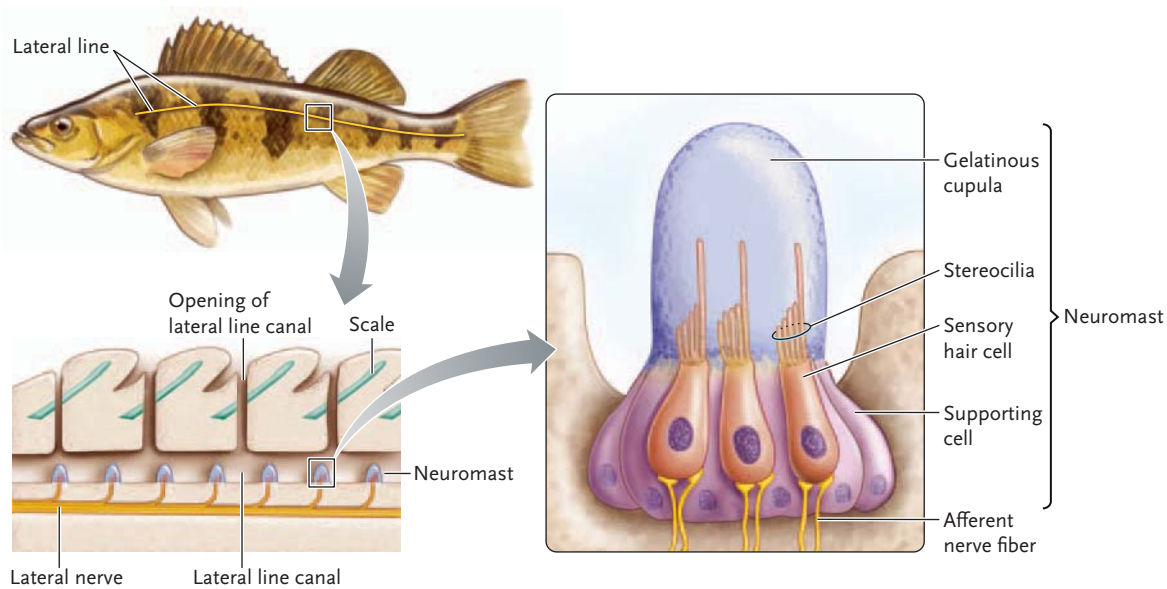

FIGURE 41.5 The lateral line system of fishes. The sensory receptor of the lateral line, the neuromast, has a gelatinous cupula that is pushed and pulled by vibrations and currents transmitted through the lateral line canal. As the cupula moves, the stereocilia of the sensory hair cells are bent, generating action potentials in afferent neurons that lead to the brain.

41.3 Mechanoreceptors and Hearing

Sounds are vibrations that travel as waves produced by the alternating compression and rarefaction of the air. The loudness, or *intensity,* of a sound depends on the amplitude ("height") of the wave. The *pitch* of a sound—a high note or a low note—depends on the frequency of the waves, measured in hertz (cycles per second). The more cycles per second, the higher the pitch. Some animals, such as the bat in the *Why It Matters* for this chapter, can hear sounds well above 100,000 hertz. Humans can hear sounds between about 20 and 20,000 hertz, thus we are deaf to the bat's sonar clicks.

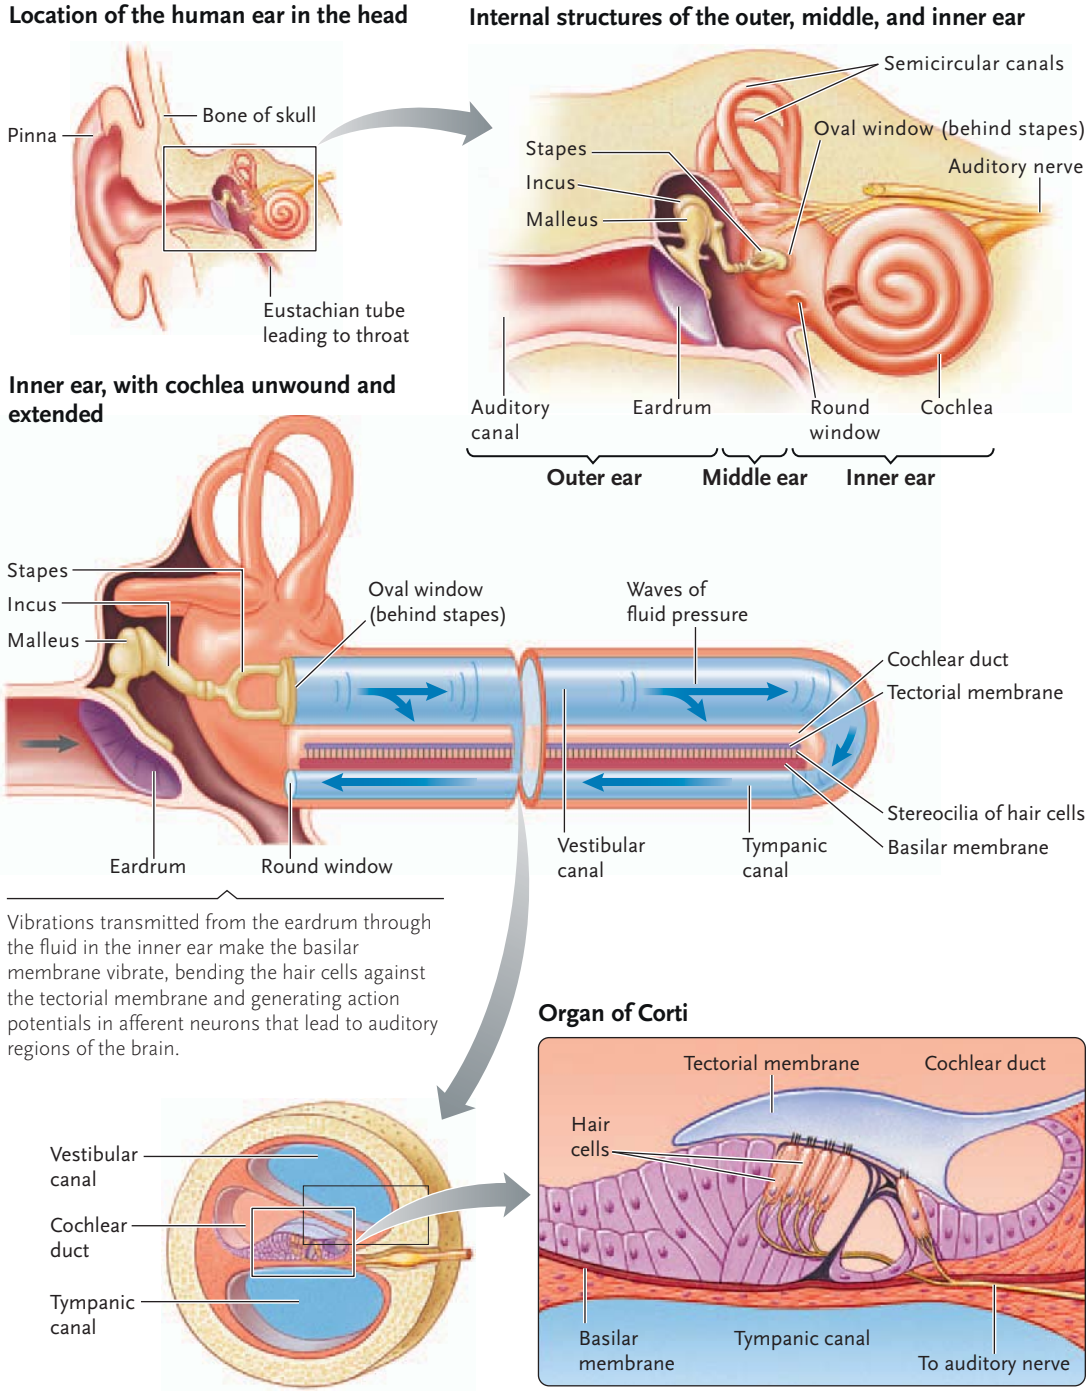
Invertebrates Have Varied Vibration-Detecting Systems

Most invertebrates detect sound and other vibrations through mechanoreceptors in their skin or other surface structures. An earthworm, for example, quickly retracts into its burrow at the smallest vibration of the surrounding earth, even though it has no specialized structures serving as ears. Squids and octopuses have a system of mechanoreceptors on their head and tentacles, similar to the lateral line of fishes. Many insects have sensory receptors in the form of hairs or bristles that vibrate in response to sound waves.

Some insects, such as moths, grasshoppers, and crickets, have complex auditory organs on either side of the abdomen or on the first pair of walking legs **(Figure 41.7).** These "ears" consist of a thinned region of the insect's exoskeleton that forms a tympanum (*tympanum* = drum) over a hollow chamber. Sounds reaching the tympanum cause it to vibrate; mechanoreceptors connected to the tympanum translate the vibrations into nerve impulses.

Human Ears Are Representative of the Auditory Structures of Mammals

The auditory structures of terrestrial vertebrates transmit the vibrations of sound waves to sensory hair cells that respond by triggering action potentials. Here, we describe the human ear, which is representative of mammalian auditory structures **(Figure 41.8).**



The **outer ear** has an external structure, the **pinna** (*pinna* = feather, wing), which concentrates and focuses sound waves. The sound waves enter the auditory canal, which leads from the exterior, and strike a thin sheet of tissue, the **tympanic membrane** (eardrum), that vibrates back and forth in response.

Behind the tympanic membrane is the **middle ear,** an air-filled cavity containing three small, interconnected bones: the **malleus** (hammer), the **incus** (anvil), and the **stapes** (stirrup). The stapes fits within a thin, elastic membrane, the **oval window,** and is held in place by a ligament. The vibrations of the tympanic membrane, transmitted by the malleus and incus, push the stapes back and forth within the oval window. The levering action of the bones, combined with the much larger size of the tympanic membrane compared to the oval window, amplifies the vibrations transmitted to the oval window by more than 20 times.

Inside the oval window is the **inner ear.** It contains several fluid-filled compartments, including the semicircular canals, utricle, saccule, and a spiraled tube, the **cochlea** (*cochlea* = snail shell). The cochlea twists through about two and a half turns; if stretched out flat, it would be about 3.5 cm long. Thin membranes divide the cochlea into three longitudinal chambers, the *vestibular canal* at the top, the *cochlear duct* in the middle, and the *tympanic canal* at the bottom (see Figure 41.8). The vestibular canal and the tympanic canal join at the outer tip of the cochlea, so that the fluid within them is continuous.

FIGURE 41.8
Structures of the human ear.
© Cengage Learning 2014

Within the cochlear duct is the **organ of Corti** (also called the **spiral organ**); it contains the sensory hair cells that detect sound vibrations transmitted to the inner ear (see Figure 41.8).

The vibrations of the oval window pass through the fluid in the vestibular canal, make the turn at the end, and travel back through the fluid in the tympanic canal. At the end of the tympanic canal, they are transmitted to the **round window,** a thin membrane that faces the middle ear.

The vibrations traveling through the inner ear cause the basilar membrane to vibrate in response. The **basilar membrane,** which forms part of the floor of the cochlear duct, anchors the sensory hair cells in the organ of Corti. The stereocilia of these cells are embedded in the **tectorial membrane,** which extends the length of the cochlear canal. When the basilar membrane vibrates, the stereocilia of the hair cells are bent back and forth in relation to the stationary tectorial membrane. The back and forth bending of the sensory hair cells alternately opens and closes ion channels in the stereocilia of the cells, causing alternating depolarization and hyperpolarization. Neurotransmitter release from the sensory hair cells triggers action potentials in the associated afferent neurons.

Pitch discrimination, the ability to distinguish between various frequencies of incoming sound stimuli, depends on the shape and properties of the basilar membrane. The basilar

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

membrane is narrow at the oval window end and wide at its outer end. Due to its shape, different sound frequencies cause different regions of the basilar membrane to vibrate maximally: the narrow end vibrates most with high-frequency pitches, and the wide end vibrates most with low-frequency pitches. Wherever the basilar membrane vibrates, the sensory hair cells in that area move back and forth and trigger action potentials. In essence, the sensory hair cells in a particular location in the basilar membrane are tuned to a particular sound frequency.

More than 15,000 hair cells are distributed in small groups along the basilar membrane, enabling a high degree of pitch discrimination. Each group of hairs is connected by synapses to afferent neurons, which in turn are bundled together in the *cochlear nerve,* a cranial nerve that carries information through intermediate regions and into the thalamus. From there, the signals are routed to specific regions in the temporal lobe, which integrates the information into the perception of sound at a corresponding pitch and loudness.

Another system protects the tympanic membrane from damage by changes in environmental atmospheric pressure. The system depends on the *Eustachian tube* (also called the *auditory tube*), a duct that leads from the air-filled middle ear to the throat (see Figure 41.8). As we swallow or yawn, the tube opens, allowing air to flow into or out of the middle ear to equalize the pressure on both sides of the tympanic membrane. When swelling or congestion due to infections prevents the tube from admitting air, we complain of having stopped-up ears—we can sense that a pressure difference between the outer and middle ear is bulging the tympanic membrane, interfering with the transmission of sounds and causing pain.

41.4 Photoreceptors and Vision

The great majority of animals have receptors that can detect and respond to light. As animals evolved and became more complex, the complexity of their visual sensory receptors increased, leading to the highly developed eyes of cephalopods and vertebrates.

Vision Involves Detection and Perception of Radiant Energy

Photoreceptors detect light at particular wavelengths, and centers in the brain integrate signals arriving from the receptors into a perception of light. All animals use forms of a single lipid-like pigment, *retinal* (synthesized from vitamin A), in photoreceptors to absorb light energy. The simplest eyes are capable only of distinguishing light from dark; the most complex eyes distinguish shapes and colors and focus an accurate image of objects being viewed onto a layer of photoreceptors.

Invertebrate Eyes Take Many Forms

Many types of eyes are seen among invertebrates. Some invertebrates, such as earthworms, do not have visual organs; instead, photoreceptors in their skin allow them to sense and respond to light. Earthworms respond negatively to light, as you can discover easily by shining a flashlight on an earthworm outside its burrow at night.

The eyes of other invertebrates range from collections of photoreceptors with no lens and no image-forming capability to eyes remarkably like those of vertebrates. The photoreceptors of invertebrates are depolarized when they absorb light, and generate action potentials or increase their release of neurotransmitter molecules when they are stimulated. Vertebrate photoreceptors function differently, as we will see.

The simplest eye is the **ocellus** (plural, *ocelli;* also called an *eyespot* or *eyecup*). An ocellus, which detects light but does not form an image, consists of fewer than 100 photoreceptor cells lining a cup or pit. In planarians, for example, photoreceptor cells in a cuplike depression below the epidermis are connected to the dendrites of afferent neurons that are bundled into nerves that travel from the ocelli to the cerebral ganglion **(Figure 41.9).** Each ocellus is covered on one side by a layer of pigment cells that blocks most of the light rays arriving from the opposite side of the animal. As a result, most of the light received by the pigment cells enters the ocellus from the side that it faces. Through integration of information transmitted

to the cerebral ganglion from the eyecups, planarians orient themselves so that the amount of light falling on the two ocelli is equal and diminishes as they swim. This reaction carries them directly away from the source of the light. Similar ocelli are found in a variety of animals, including insects, arthropods, and mollusks.

Two main types of image-forming eyes have evolved in invertebrates: *compound eyes* and *single-lens eyes.* The **compound eye** of insects, crustaceans, and a few annelids and mollusks contains hundreds to thousands of faceted visual units called **ommatidia** (*omma* = eye) fitted closely together **(Figure 41.10).** Each ommatidium samples a small part of the visual field. In insects, light entering an ommatidium is focused by a transparent **cornea** and a *crystalline cone* (just below the cornea) onto a bundle of photoreceptor cells. Microvilli of these cells interdigitate like the fingers of clasped hands, forming a central axis rich in **rhodopsin,** a **photopigment** (light-absorbing pigment) consisting of retinal bound covalently to an **opsin** protein. Absorption of light by rhodopsin causes action potentials to be generated in afferent neurons connected to the base of the ommatidium. From these signals, the brain receives a mosaic image of the world. Because even the slightest motion is detected simultaneously by many ommatidia, compound eyes are extraordinarily adept at detecting movement—a lesson soon learned by fly-swatting humans.

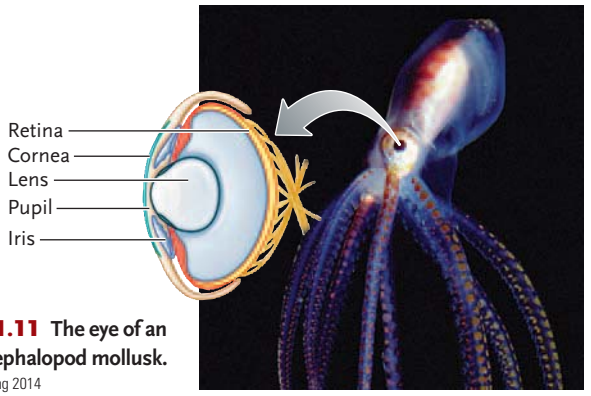

FIGURE 41.11 **The eye of an octopus, a cephalopod mollusk.**
© Cengage Learning 2014

The **single-lens eye** of cephalopods **(Figure 41.11)** resembles a vertebrate eye in that both types operate like a camera. In the cephalopod eye, light enters through the transparent cornea, a **lens** concentrates the light, and a layer of photoreceptors at the back of the eye, the **retina,** records the image. Behind the cornea is the **iris,** which surrounds the **pupil,** the opening through which light enters the eye. Muscles in the iris adjust the size of the pupil to vary the amount of light entering the eye. When the light is bright, circular muscles in the iris contract, shrinking the size of the pupil and reducing the amount of light that enters. In dim light, radial muscles contract and enlarge the pupil, increasing the amount of light that enters the eye. Muscles move the lens forward and back with respect to the retina to focus the image. This is an example of **accommodation,** a process by which the lens changes to enable the eye to focus on objects at different distances.

A neural network lies under the retina, meaning that light rays do not have to pass through the neurons to reach the photoreceptors. The vertebrate eye has the opposite arrangement. This and other differences in structure and function indicate that cephalopod and vertebrate eyes evolved independently.

The Structure of Vertebrate Eyes

The human eye **(Figure 41.12)** has similar structures—cornea, iris, pupil, lens, and retina—to those of the cephalopod eye just described. Light entering the eye through the cornea passes through the iris and then the lens. The lens focuses an image on the retina, and the axons of afferent neurons originating in the retina converge to form the optic nerve leading from the eye to the brain.

A clear fluid called the **aqueous humor** fills the space between the cornea and lens. This fluid carries nutrients to the lens and cornea, which do not contain any blood vessels. The main chamber of the eye, located between the lens and the retina, is filled with the jellylike **vitreous humor** (*vitrum* = glass). The outer wall of the eye contains a tough layer of connective tissue (the *sclera*). Inside it is a darkly pigmented layer (the *choroid*) that prevents light from entering except through the pupil. It also contains the blood vessels nourishing the retina.

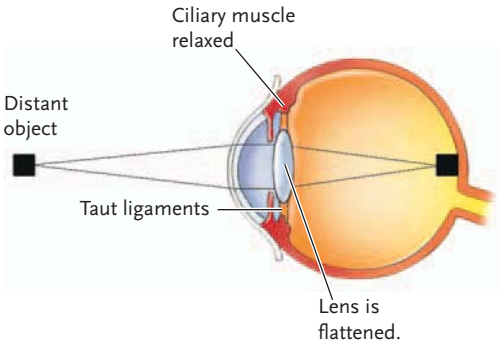
Two types of photoreceptors, rods and cones, occur in the retina along with layers of neurons that carry out an initial integration of visual information before it is sent to the brain. The **rods** are specialized for detection of light at low intensities; the **cones** are specialized for detection of different wavelengths (colors).

Accommodation does not occur by forward and back movement of the lens, as described for cephalopods. Rather, the lens of most terrestrial vertebrates is focused by changing its shape. The lens is held in place by fine ligaments that anchor it to a surrounding layer of connective tissue and muscle, the **ciliary body.** These ligaments keep the lens under tension when the ciliary muscle is relaxed. The tension flattens the lens, which is soft and flexible, and focuses light from distant objects on the retina **(Figure 41.13A).** When the ciliary muscles contract, they relieve the tension of the ligaments, allowing the lens to assume a more spherical shape and focusing light from nearby objects on the retina **(Figure 41.13B).**

The Retina of Mammals and Birds Contains Rods and Cones and a Complex Network of Neurons

The retina of a human eye contains about 120 million rods and 6 million cones organized into a densely packed, single layer. Neural networks of the retina are layered on top of the photoreceptor cells, so that light rays focused by the lens on the retina must pass through the neurons before reaching the photoreceptors. The light must also pass through a layer of fine blood vessels that covers the surface of the retina.

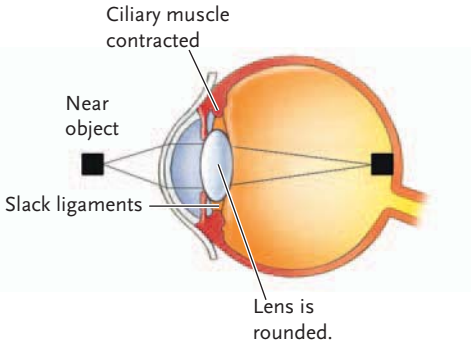
In mammals and birds with eyes specialized for daytime vision, cones are concentrated in and around a small region of the retina, the **fovea** (see Figure 41.12). The image focused by the lens is centered on the fovea, which is circular and less than a millimeter in diameter in humans. The rods are spread over the remainder of the retina. We can see distinctly only the image focused on the fovea; the surrounding image is what we term *peripheral vision.* Mammals and birds with eyes specialized for night vision have retinas containing mostly rods, and lacking a defined fovea. Some fishes and many reptiles have cones generally distributed throughout their retina and very few rods.



The rods of mammals are much more sensitive than the cones to low-intensity light; in fact, they can respond to a single photon of light. This is why, in dim light, we can detect objects better by looking slightly to the side of the object. This action directs the image away from the cones in the fovea to the highly light-sensitive rods in surrounding regions of the retina.

SENSORY TRANSDUCTION BY RODS AND CONES Photoreceptors have three parts: (1) an outer segment consisting of stacked, flattened, membranous discs; (2) an inner segment where the cell's metabolic activities occur; and (3) the synaptic terminal, where neurotransmitter molecules are stored and released **(Figure 41.14A).** The photopigments of rods and cones consist of the light-absorbing pigment, retinal, bonded covalently to an opsin.

FIGURE 41.13 **Accommodation in terrestrial vertebrates: the lens changes shape rather than moving forward and back to focus on (A) distant and (B) near objects.**



© Cengage Learning 2014

A. Focusing on distant object

When the eye focuses on a distant object, the ciliary muscles relax, allowing the ligaments that support the lens to tighten. The tightened ligaments flatten the lens, bringing the distant object into focus on the retina.

B. Focusing on near object

When the eye focuses on a near object, the ciliary muscles contract, loosening the ligaments and allowing the lens to become rounder. The rounded lens focuses a near object on the retina.

In response to light, the retinal changes from a bent to a straight structure.

© Cengage Learning 2014

The photopigments are embedded in the membranous discs of the photoreceptors' outer segments **(Figure 41.14B).**

Just as we saw in invertebrates, the retinal-opsin photopigment in rods is rhodopsin. In the dark, the retinal of rhodopsin is in an inactive form known as *cis*-retinal (see Figure 41.14B), and the rods steadily release the neurotransmitter glutamate. When rhodopsin absorbs a photon of light, retinal converts to its active form, *trans*-retinal (see Figure 41.14B), and the rods *decrease* the amount of glutamate they release. This will be discussed in the next section.

Rhodopsin is a membrane-embedded G-protein–coupled receptor (see Section 7.4). An extracellular signal received by a G-protein–coupled receptor activates the receptor, which triggers a signal transduction pathway within the cell, leading to a cellular response. Here, activated rhodopsin triggers a pathway that leads to the closure of Na^+ channels in the plasma membrane **(Figure 41.15).** Closure of the channels hyperpolarizes the photoreceptor's membrane, thereby decreasing neurotransmitter release. The response is graded: as light absorption increases, the amount of neurotransmitter released is reduced proportionately; if light absorption decreases, neurotransmitter release increases proportionately.

VISUAL PROCESSING IN THE RETINA In the retina of all vertebrates, the two types of photoreceptors are linked to a network of neurons that carries out initial processing of visual information. The retina of mammals contains four types of neurons **(Figure 41.16).** The rods and cones form synaptic connections with bipolar cells, where the processing of visual information begins. **Ganglion cells** receive synaptic signals from the **bipolar cells.** The axons of the ganglion cells extend over the retina and collect at the back of the eyeball to form the optic nerve, which carries action potentials into the brain. The point where the optic nerve exits the eye lacks photoreceptors, resulting in a *blind spot* several millimeters in diameter. Two other types of neurons form lateral connections in the retina: **horizontal cells** receive and integrate inputs from multiple photoreceptors located lateral to the region of light reception; and **amacrine cells** receive inputs from bipolar cells and excite ganglion cells.

Signals from the rods and cones move vertically from the photoreceptors to bipolar cells and then to ganglion cells. Because the human retina has over 120 million photoreceptors, but only about 1 million ganglion cells, each ganglion cell receives signals from a clearly defined set of photoreceptors that constitute the receptive field for that cell. Therefore, stimulat-

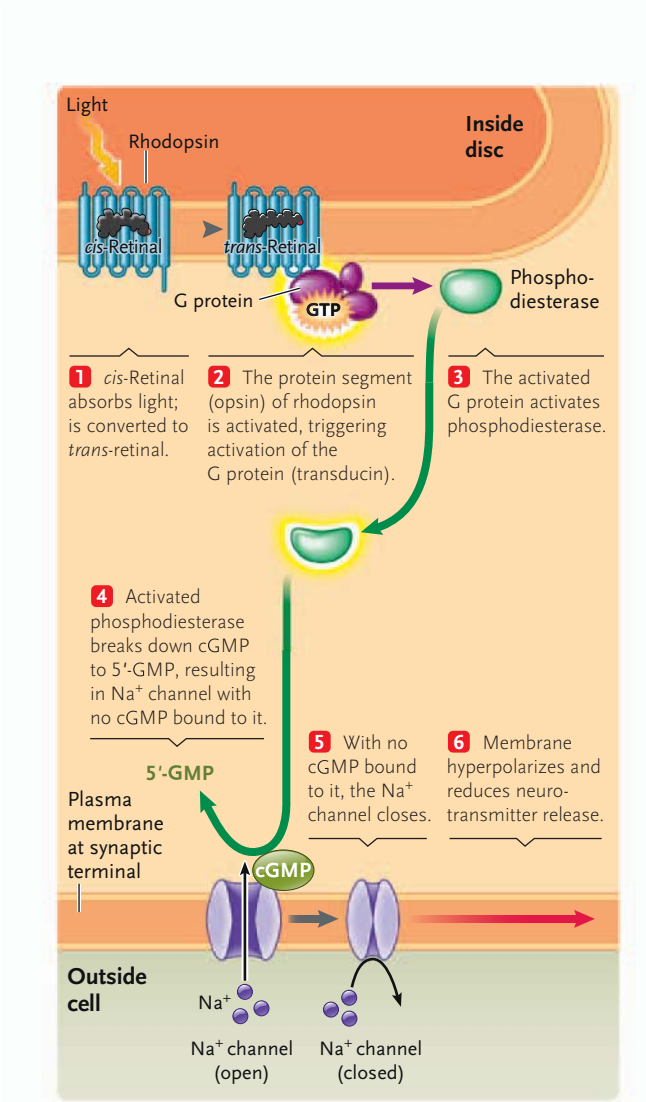

FIGURE 41.15 The signal transduction pathway that closes Na^+ channels in photoreceptor plasma membranes when rhodopsin absorbs light.

© Cengage Learning 2014

ing numerous photoreceptors in a ganglion cell's receptive field results in only a single message to the brain from that cell. Receptive fields are typically circular and are of different sizes. Smaller receptive fields result in sharper images because they send more precise information to the brain regarding the location in the retina where the light was received.

Signals may also move laterally from a rod or cone through a horizontal cell and continue to bipolar cells through the horizontal cell's inhibitory connections. To understand this, consider a spot of light falling on the retina. Photoreceptors detect the light and send a signal to bipolar cells and horizontal cells. The horizontal cells inhibit more distant bipolar cells that are outside the spot of light, causing the light spot to appear lighter and its surrounding dark area to appear darker. This type of visual processing is called **lateral inhibition** and serves to both sharpen the edges of objects and enhance contrast in an image.

Three Kinds of Opsin-Containing Photopigments in Cones Underlie Color Vision

Many invertebrates and some species in each class of vertebrates have color vision. Color vision depends on the cone photoreceptors. Most mammals have only two types of cones, but humans and other primates have three types, the *blue, green,* and *red cones.* The rhodopsin photopigment in each of the human or primate cone types has the same retinal but a different opsin. The three cone opsins are different from the opsin of the rod rhodopsin. The three cone rhodopsins absorb light over different, but overlapping, wavelength ranges, with peak absorptions at 445 nm (blue light) for blue cones, 535 nm (green light) for green cones, and 570 nm (red light) for red cones. The farther a wavelength is from the peak color absorbed, the less strongly the cone responds.

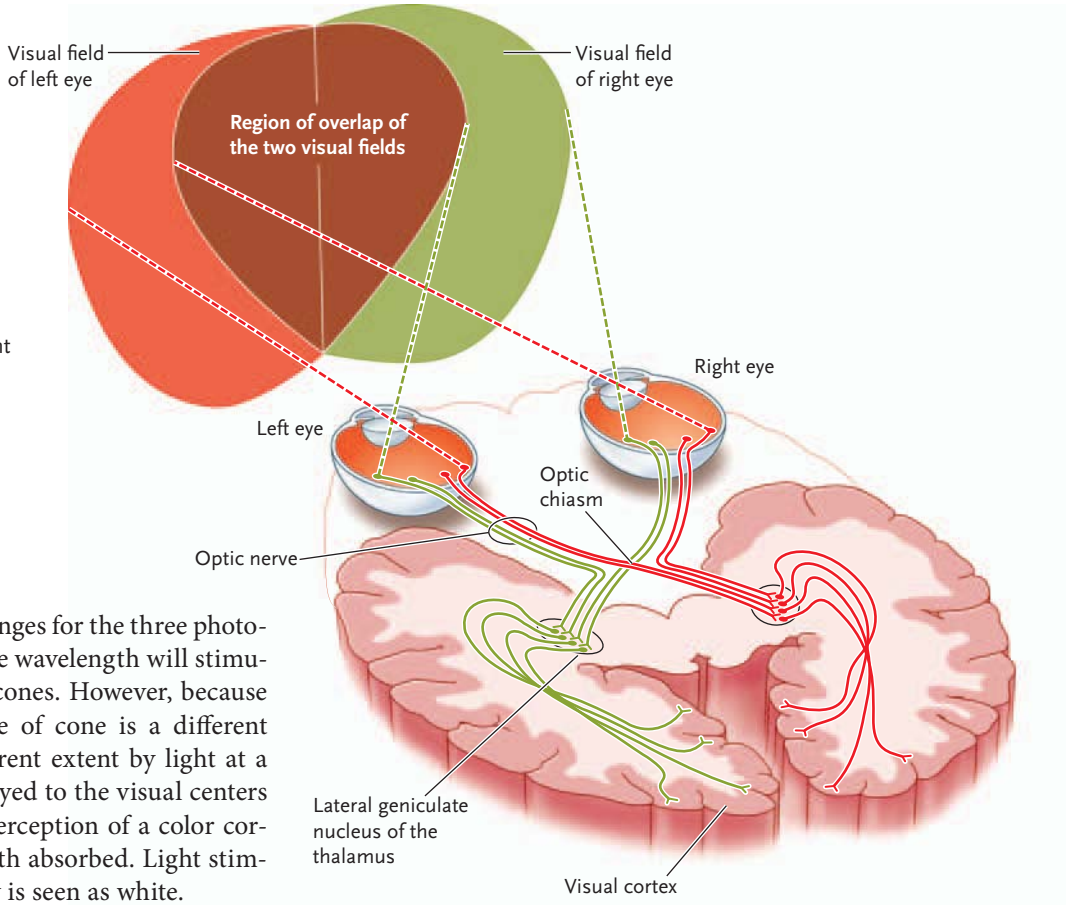

FIGURE 41.17 Neural pathways for vision. Because half of the axons carried by the optic nerves cross over in the optic chiasm, the left half of the field seen by both eyes is transmitted to the visual cortex in the right cerebral hemisphere. The right half of the field seen by both eyes is transmitted to the visual cortex in the left cerebral hemisphere. As a result, the right hemisphere of the brain sees objects to the left of the center of vision, and the left hemisphere sees objects to the right of the center of vision.

© Cengage Learning 2014

Having overlapping wavelength ranges for the three photoreceptors means that light at any visible wavelength will stimulate at least two of the three types of cones. However, because the maximal absorption of each type of cone is a different wavelength, it is stimulated to a different extent by light at a given wavelength. The differences, relayed to the visual centers of the brain, are integrated into the perception of a color corresponding to the particular wavelength absorbed. Light stimulating all three receptor types equally is seen as white.

The Visual Cortex Processes Visual Information

Just behind the eyes, the optic nerves converge before entering the base of the brain. A portion of each optic nerve crosses over to the opposite side, forming the **optic chiasm** (*chiasma* = crossing place). Most of the axons enter the **lateral geniculate nuclei** in the thalamus, where they make synapses with interneurons leading to the visual cortex **(Figure 41.17).**

Because of the optic chiasm, the left half of the image seen by both eyes is transmitted to the visual cortex in the right cerebral hemisphere, and the right half of the image is transmitted to the left cerebral hemisphere. The right hemisphere thus sees objects to the left of the center of vision, and the left hemisphere sees objects to the right of the center of vision. Communication between the right and left hemispheres integrates this information into a perception of the entire visual field seen by the two eyes.

If you look at a nearby object with one eye and then the other, you will notice that the point of view is slightly different. Integration of the visual field by the brain creates a single picture with a sense of distance and depth. The greater the difference between the images seen by the two eyes, the closer the object appears to the viewer.

The two optic nerves together contain more than a million axons, more than all other afferent neurons of the body put together. Almost one-third of the cerebral cortex in humans is devoted to visual information. These numbers give some idea of the complexity of the information integrated into the visual image formed by the brain.

STUDY BREAK 41.4

For vertebrate photoreception, define: (a) photopigment; (b) photoreceptor; and (c) receptive field.

41.5 Chemoreceptors

Chemoreceptors form the basis of taste (gustation) and smell (olfaction), and measure the levels of internal body molecules such as oxygen, carbon dioxide, and hydrogen ions.

Invertebrate Receptors for Taste and Smell

In many invertebrates, the same receptors serve for the senses of smell and taste. These receptors may be confined to certain locations or distributed over the body surface. For example, the cnidarian *Hydra* has chemoreceptor cells around its mouth that respond to glutathione, a chemical released from prey organisms ensnared in the cnidarian's tentacles. Stimulation of these chemoreceptors causes the tentacles to retract, resulting in ingestion of the prey. By contrast, earthworms have taste/smell receptors distributed over their entire body surface.

Some terrestrial invertebrates, particularly insects, have clearly differentiated taste and smell receptors. In insects, taste receptors occur inside hollow sensory bristles called *sensilla* (singular, *sensillum*), which may be located on the antennae, mouthparts, or feet **(Figure 41.18).** Pores in the sensilla admit

molecules from potential food to the chemoreceptors, which are specialized to detect sugars, salts, amino acids, or other chemicals. Many female insects have chemoreceptors on their ovipositors, which allow them to lay their eggs on food appropriate for the hatching larvae.

Insect olfactory receptors detect airborne molecules. Some insects use odor as a means of communication, such as the pheromones released into the air as sexual attractants by female moths. Olfactory receptors in the bristles of male silkworm moth antennae **(Figure 41.19)** have been shown experimentally to be able to detect pheromones released by a female of the same species in concentrations as low as one attractant molecule per 10^{17} air molecules; when as few as 40 of the 20,000 receptor cells on its antennae have been stimulated by pheromone molecules, the male moth responds to attract the female's attention. Ants, bees, and wasps identify members of the same hive or nest and communicate by means of odor molecules.

Taste and Smell Receptors Are Differentiated in Terrestrial Vertebrates

In terrestrial animals, taste involves the detection of potential food molecules in objects that are touched, while smell involves the detection of airborne molecules. Although both taste and smell receptors have hairlike extensions containing the proteins that bind environmental molecules, the hairs of taste receptors are derived from microvilli and contain microfilaments, while the hairs of smell receptors are derived from cilia and contain microtubules. Another significant difference between taste and smell in vertebrates is that information from taste receptors is typically processed in the parietal lobes, while information from smell receptors is processed in the olfactory bulbs and the temporal lobes.

Taste Receptors Are Located in Taste Buds

The taste receptors of most vertebrates form part of a structure called a taste bud, a small, pear-shaped capsule with a pore at the top that opens to the exterior **(Figure 41.20).** The sensory hairs of the taste receptors pass through the pore of a taste bud and project to the exterior. The opposite ends of the receptor cells form synapses with dendrites of an afferent neuron.

The taste receptors of terrestrial vertebrates are concentrated in the mouth. Humans have about 10,000 taste buds scattered over the tongue, roof of the mouth, and throat. Those on the tongue are embedded in outgrowths called *papillae* (*papula* = pimple), which give the surface of the tongue its rough texture.

Taste receptors on the human tongue are thought to respond to five basic tastes: sweet, sour, salty, bitter, and umami ("savory"). Some of the receptors for umami respond to the amino acid glutamate (familiar as monosodium glutamate, or MSG). Recent research indicates that the classes of receptors may all have many subtypes, each binding a specific molecule within that class.

Signals from the taste receptors are relayed to the thalamus. From there, some signals lead to gustatory centers in the cerebral cortex, which integrate them into the perception of taste. Other signals lead to the brain stem and limbic system,

which links tastes to involuntary visceral and emotional responses. Through these connections, a pleasant taste may lead to salivation, secretion of digestive juices, sensations of pleasure, and even sexual arousal, whereas an unpleasant taste may produce revulsion, nausea, and even vomiting.

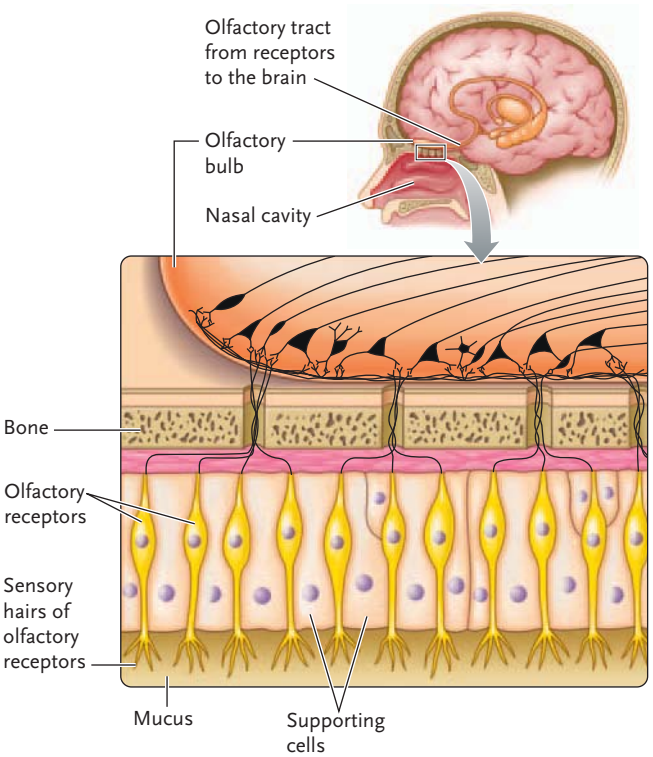

FIGURE 41.21 Olfactory receptors in the roof of the nasal passages in humans. Axons from these receptors pass through holes in the bone separating the nasal passages from the brain, where they make synapses with interneurons in the olfactory bulbs.

© Cengage Learning 2014

Olfactory Receptors Are Concentrated in the Nasal Cavities in Terrestrial Vertebrates

Receptors that detect odors are located in the nasal cavities. Bloodhounds have more than 200 million receptors in patches of olfactory epithelium in the upper nasal passages; humans have about 5 million olfactory receptors.

On one end, each olfactory receptor cell has 10 to 20 sensory hairs that project into a layer of mucus covering the olfactory area in the nose **(Figure 41.21).** To be detected, airborne molecules must dissolve in the watery mucus solution. On the other end, the olfactory receptors make synapses with interneurons in the olfactory bulbs. Olfactory receptors are the only receptor cells that make direct connections with brain interneurons, rather than via afferent neurons.

From the olfactory bulbs, nerves conduct signals to the olfactory centers of the cerebral cortex, where they are integrated into the perception of tantalizing or unpleasant odors. Most odor perceptions arise from a combination of different olfactory receptors. In the early 1990s, Richard Axel and Linda Buck discovered that about 1,000 different human genes give rise to an equivalent number of olfactory receptor types, each of which responds to a different class of chemicals. Axel and Buck received the Nobel Prize in 2004 in recognition of their research.

Olfaction contributes to the sense of taste because vaporized molecules from foods are conducted from the throat to the olfactory receptors in the nasal cavities. Olfactory input is the reason why anything that dulls your sense of smell—such as a head cold, or holding your nose—diminishes the apparent flavor of food.

Many mammals use odors as a means of communication. Individuals of the same family or colony are identified by their odor; odors are also used to attract mates and to mark territories and trails. Dogs, for example, use their urine to mark home territories with identifying odors.

STUDY BREAK 41.5

1. **How do we distinguish different kinds of smells?**
2. **For terrestrial vertebrates, describe the pathway by which a signal generated by taste receptors leads to a response.**

41.6 Thermoreceptors and Nociceptors

Thermoreceptors detect changes in the surrounding temperature. Nociceptors respond to stimuli that may potentially damage tissues. Both types of receptors consist of free nerve endings formed by the dendrites of afferent neurons, with no specialized receptor structures surrounding them.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

FIGURE 41.22 The pit organs of an albino Western diamondback rattlesnake *(Crotalus atrox)*, located in depressions on both sides of the head below the eyes. These thermoreceptors detect infrared radiation emitted by warm-bodied prey animals such as mice.

Thermoreceptors Can Detect Warm and Cold Temperatures and Temperature Changes

Most animals have thermoreceptors. Some invertebrates, such as mosquitoes and ticks, use thermoreceptors to locate their warm-blooded prey. Some snakes, including rattlesnakes and pythons, use thermoreceptors called *pit organs* to detect the body heat of warm-blooded prey animals **(Figure 41.22).**

In mammals, current evidence suggests the existence of five thermoreceptor ranges. These begin at less than 8°C and extend to above 52°C. At the extremes, the neural signals are perceived as painful.

Some neurons in the hypothalamus of mammals also function as thermoreceptors, an ability that has only recently been investigated. Not only do these neurons sense changes in brain temperature, but they also receive afferent thermal information. These neurons are highly sensitive to shifts from the normal body temperature, and trigger involuntary responses such as sweating, panting, or shivering, which restore normal body temperature.

Nociceptors Protect Animals from Potentially Damaging Stimuli

The signals from nociceptors—receptors in vertebrates and invertebrates that detect damaging stimuli—are interpreted by the brain as pain. Pain is a protective mechanism; in humans, it prompts us to do something immediately to remove or decrease the damaging stimulus. Often pain elicits a reflex response—such as withdrawing the hand from a hot surface—that proceeds before we are even consciously aware of the sensation.

Various types of stimuli cause pain, including mechanical damage such as a cut or a blow to the body, and temperature extremes. Some nociceptors are specific for a particular type of damaging stimulus, whereas others respond to all kinds.

The axons that transmit pain in vertebrates are part of the somatic component of the PNS (see Section 40.2). They synapse with interneurons in the gray matter of the spinal cord, and activate neural pathways in the CNS by releasing the neurotransmitters glutamate or substance P (see Table 39.1). Glutamate-releasing axons produce sharp, prickling sensations that can be localized to a specific body part—the pain of stepping on a sharp stone, for example. Substance P-releasing axons produce dull, burning, or aching sensations, the location of which may not be easily identified—the pain of tissue damage such as stubbing your toe.

As part of their protective function, pain receptors adapt very little, if at all. Some pain receptors, in fact, gradually intensify the rate at which they send out action potentials if the stimulus continues at a constant level.

The CNS also has a pain-suppressing, or gating, system. In response to stimuli such as exercise, sex, and stress, the brain releases *endorphins,* natural painkillers that bind to membrane receptors on substance P neurons, reducing the amount of neurotransmitter released.

Nociceptors contribute to the taste of some spicy foods, particularly those that contain hot peppers. In fact, researchers who study pain often use *capsaicin,* the organic compound that gives jalapeños and other peppers their hot taste, to identify nociceptors. To some, the burning sensation from capsaicin is addictive. Nociceptors in the mouth, nose, and throat immediately transmit pain messages to the brain when they detect capsaicin. The brain responds by releasing endorphins, which act as a painkiller and create temporary euphoria. *Insights from the Molecular Revolution* describes experiments investigating the molecular basis of the pain caused by capsaicin.

STUDY BREAK 41.6

What distinguishes thermoreceptors and nociceptors from the other types of sensory receptors discussed previously?

THINK OUTSIDE THE BOOK

You have now learned about various types of sensory receptors. On your own or collaboratively, investigate the role of breakdowns in sensory receptor pathways in causing human disease. Pick two diseases caused in this way and outline how the change in the sensory receptor pathway brings about disease symptoms.

41.7 Magnetoreceptors and Electroreceptors

Some animals manifest the capacity to gain information about their environment by sensing magnetic or electrical fields. In so doing, they directly sense stimuli that humans can detect only with scientific instruments.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Some Like It Hot: What is the nature of the capsaicin receptor?

Biting into a jalapeño pepper (a variety of *Capsicum annuum*) can produce a burning pain in your mouth strong enough to bring tears to your eyes. This painfully hot sensation is due primarily to *capsaicin* **(Figure 1),** a chemical that probably evolved in pepper plants as a defense against foraging animals. As you learned in this chapter, pain is an interpretation by the brain of action potentials generated by stimulation of nociceptors.

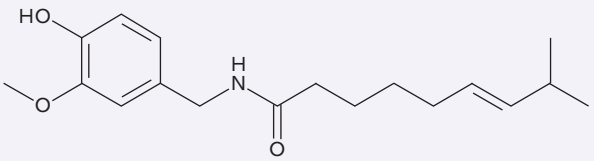

FIGURE 1 Capsaicin

Research Question

What is the molecular nature of the capsaicin nociceptor?

Experiment

David Julius and his coworkers at the University of California, San Francisco, performed experiments to isolate the capsaicin receptor. Based on other studies, they knew that capsaicin activates an ion channel that leads to Ca^{2+} movement into the cell. (Experimentally, an increase in Ca^{2+} within a cell can be detected by using a particular fluorescent dye and analysis under a microscope.) Using that information, they carried out the steps shown in **Figure 2.**

Results

The researchers identified a transformant that showed capsaicin-stimulated Ca^{2+} uptake. They reasoned that the transformant had received a cDNA clone that expressed a capsaicin receptor. The group then injected mRNA transcribed from the identified cDNA clone into both frog oocytes and cultured mammalian cells. Tests showed that both types of cells responded to capsaicin by admitting Ca^{2+}, confirming that the researchers had identified the capsaicin receptor cDNA.

Among the effects they noted when the receptor was introduced into oocytes was a response to heat. Increasing the temperature of the solution surrounding the oocytes from 22°C to about 48°C produced a strong calcium inflow.

Conclusion

The capsaicin nociceptor is activated both by capsaicin and heat in cells with the receptor. Therefore the feeling that your mouth is on fire when you eat a hot pepper probably results from the fact that, as far as your nociceptors and CNS are concerned, it *is* on fire.

THINK LIKE A SCIENTIST In their paper, the researchers stated that their results proved that "the molecular target of capsaicin action on sensory neurons is a proteinaceous ion channel." How do their results lead to this conclusion?

Magnetoreceptors Are Used for Navigation

Some animals that navigate long distances, including migrating butterflies, beluga whales, sea turtles, homing pigeons, and foraging honeybees, have **magnetoreceptors** that allow them to detect and use Earth's magnetic field as a source of directional information.

The pattern of Earth's magnetic field differs from region to region yet remains almost constant over time, largely unaf-

FIGURE 41.23 A loggerhead sea turtle.

fected by changing weather and day and night. As a result, animals with magnetic receptors are able to monitor their location reliably. Although relatively little is known about the receptors that detect magnetic fields, they may depend on the fact that moving a conductor, such as an electroreceptor cell, through a magnetic field generates an electric current. Some magnetoreceptors may depend on the effect of Earth's magnetic field on the mineral *magnetite*.

In one interesting laboratory experiment, Kenneth Lohmann of the University of North Carolina tested a hypothesis that magnetoreception plays a central role in the migration of loggerhead sea turtles **(Figure 41.23).** Lohmann used an experimental system in the laboratory in which the direction loggerhead sea turtle hatchlings swam was analyzed in different magnetic fields. The results showed that, in the normal magnetic field of the Earth, the hatchlings swam in a direction that mimicked the direction they follow normally when migrating at sea. When tested in a magnetic field 180° reversed from that of Earth's magnetic field, hatchlings swam in a direction 180° opposite of the direction they follow when migrating at sea. Lohmann concluded that the loggerhead sea turtle hatchlings have the ability to detect Earth's magnetic field and use it as a way to orient their migration. Lohmann believes that the magnetoreceptor system in the turtles involves magnetite.

Electroreceptors Are Used for Location of Prey or for Communication

Many sharks and bony fishes, some amphibians, and even some mammals (such as the star-nosed mole and duckbilled platypus) have specialized **electroreceptors** that detect electrical fields. The plasma membrane of an electroreceptor cell is depolarized by an electrical field, leading to the generation of action potentials. The electrical stimuli detected by the receptors are used to locate prey or navigate around obstacles in muddy water, or, by some fishes, to communicate. Some electroreception systems are passive—they detect electric fields in the environment, not the animal's own electric currents. Passive systems are used mainly to find prey. For example, the electroreceptors of sharks and rays can locate fish buried under the sand from the electrical currents generated by their prey's heartbeat or by the muscle contractions that move water over their gills.

Other electroreception systems are active—the animal emits and receives low voltage electrical signals, either to locate prey or to communicate with members of the same species. The electrical signals are generated by special electric organs. A few species, such as the electric eel and the electric catfish, produce discharges on the order of several hundred volts. These discharges are used to stun or kill prey. The voltage is high enough to stun, but not kill, a human.

STUDY BREAK 41.7

What are three ways electroreceptors are used in aquatic vertebrates?

UNANSWERED QUESTIONS

What happens when the senses get scrambled—when listening to music causes you to "see" colors, or when you "taste" certain words?

Synesthesia ("joined senses") occurs when two senses, normally separate, are perceived together. For the most part, people with synesthesia—synesthetes—are born with it, and it tends to run in families. A recent study by Michael Esterman and his colleagues at the University of California, Berkeley, showed that the posterior parietal cortex, a region of the brain thought to be involved in sensory integration, appears to be crucial to sensory commingling. Some researchers think that this commingling is how the senses function early in development, when the nervous system is still immature. They believe that the senses normally separate from one another around four months after birth. In synesthetes, however, this separation is incomplete and two of their senses remain mingled.

London's Science Museum collaborated with Jamie Ward of University College London in an experiment that paired visual images and music. They wanted to determine if volunteers visiting the museum would prefer combinations of music and images designed by synesthetes over combinations that were designed by nonsynesthetes. Interestingly, people found the synesthetic combinations more pleasing than the nonsynesthetic ones. Thus, it is possible that everyone may have a built-in understanding of what sounds and colors go together.

In an evolutionary context, which "sense" developed first?

The descriptions of the senses in this chapter focus primarily on vertebrate sensory systems, but the nervous systems of many invertebrates can be quite complex. Indeed, squids, sea hares, leeches, horseshoe

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

crabs, lobsters, and cockroaches have been quite instrumental in helping scientists understand the nervous system. Clearly, vertebrates are not the only multicellular organisms to develop senses.

However, is a nervous system necessary for organisms to have senses? Can single-celled organisms (which, of course, do not have nervous systems) respond to stimuli? The answer is yes. Consider *Paramecium tetraurelia,* a single-celled, ciliated protist that lives in water. It can detect substances in its environment and swim toward certain chemicals while avoiding others. It also responds to solid objects by turning when it runs into one. Thus, it has a "chemical sense" similar to taste or smell, and it responds to a type of "touch." We will probably never know which sense developed first, but some type of touch or chemical sense seems the most likely.

THINK LIKE A SCIENTIST

1. You serve your college roommate, who is very fond of scrambled eggs, scrambled eggs colored with green food coloring. You video your roommate eating the eggs, and show the video in your biology class. What sensory receptors are you hoping to stimulate most noticeably? If you were to suggest to your professor an imaging test for synesthetes, what imaging method might you choose (see Chapter 40)?
2. Does the fact that some prokaryotes contain a microbial rhodopsin suggest to you that the sense of vision has early evolutionary origins?

Rona Delay

Rona Delay is an associate professor in the Department of Biology at the University of Vermont. Her research centers on understanding how sensory receptors change or transduce information about the external world into a language the brain can understand. The focus of her research is the sense of smell. To learn more about Dr. Delay's work, go to www.uvm.edu/~biology/?Page=faculty/ronadelay.php&SM=facultysubmenu.html.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

41.1 Overview of Sensory Receptors and Pathways

- Sensory receptors are formed by the endings of afferent neurons, endings of afferent neurons enclosed in specialized structures, or specialized cells adjacent to the neurons. They detect stimuli such as mechanical pressure, sound waves, light, or specific chemicals. Action potentials generated by the receptors are carried by the axons of afferent neurons to pathways leading to specific parts of the brain, where signals are processed into sensory sensations (Figure 41.1).
- Receptors are specialized as mechanoreceptors, photoreceptors, chemoreceptors, thermoreceptors, and nociceptors. Some animals have receptors that detect electrical or magnetic fields.
- The routing of information from sensory receptors to particular regions of the brain identifies a specific stimulus as a sensation. The intensity of a stimulus is determined by the frequency of action potentials traveling along the neural pathways and the number of afferent neurons carrying action potentials.
- Many sensory systems show sensory adaptation, in which the frequency of action potentials decreases while a stimulus remains constant. Some sensory receptors, such as those related to pain, show no sensory adaptation.
- The brain uses signals from sensory receptors to generate an interpretation of the external and internal environments. That interpretation is our perception of the world. Each type of organism has a unique perception of the world.

41.2 Mechanoreceptors and the Tactile and Spatial Senses

- Mechanoreceptors detect touch, pressure, acceleration, or vibration. Touch and pressure receptors are free nerve endings or encapsulated nerve endings of sensory neurons (Figure 41.2).
- Mechanoreceptors called proprioceptors detect stimuli used by the CNS to monitor and maintain body and limb positions.
- Receptors in muscles, tendons, and joints of vertebrates detect changes in stretch and tension of body parts (Figure 41.3).
- Proprioceptors based on sensory hair cells generate action potentials when the hairs are moved (Figures 41.4–41.6).

Animation: Sensory receptors in the human skin

Animation: Dynamic equilibrium

Animation: Stretch reflex

41.3 Mechanoreceptors and Hearing

- Many invertebrates have mechanoreceptors in their skin or other surface structures that detect sound and other vibrations.
- Hearing relies on sensory hair cells in organs that respond to the vibrations of sound waves.
- In terrestrial vertebrates, the ear consists of three parts. The outer ear directs sound to the tympanic membrane (eardrum). Vibrations of the tympanic membrane are transmitted through one or more bones in the middle ear to the fluid-filled inner ear. In the inner ear, the vibrations are transmitted through membranes that bend the stereocilia of hair cells, leading to bursts of action potentials that are reflected in the frequency of the sound waves (Figure 41.8).

Animation: Ear structure and function

Animation: Hearing

41.4 Photoreceptors and Vision

- Invertebrates possess many forms of eyes, from the simplest, an ocellus, to single-lens eyes that are similar to vertebrate eyes (Figures 41.9–41.11).
- The photoreceptors of all animal eyes contain the pigment retinal, which absorbs the energy of light and uses it to generate changes in membrane potential.
- The transparent cornea admits light into the vertebrate eye. Behind the cornea, the iris controls the diameter of the pupil, regulating the amount of light that strikes the lens. The lens focuses an image on the retina lining the back of the eye, where photoreceptors and

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

neurons carry out the initial integration of information detected by the photoreceptors (Figure 41.12).

- In terrestrial vertebrates, the lens is focused by adjusting its shape (Figure 41.13). The retina contains two types of photoreceptors, rods and cones. Rods are specialized for detecting light of low intensity; cones are specialized for detecting light of different wavelengths, which are perceived as colors.
- The light-absorbing pigment in photoreceptor cells consists of retinal combined with an opsin protein. When it absorbs light, retinal changes form, initiating reactions that alter the amount of neurotransmitter released by the photoreceptor cells (Figures 41.14 and 41.15).
- Rods and cones are linked to neurons in the retina that perform the initial processing of visual information. The processed signal is sent via the optic nerve through the lateral geniculate nuclei to the visual cortex (Figures 41.16 and 41.17).

Animation: Eye structure

Animation: Organization of cells in the retina

Animation: Vision

41.5 Chemoreceptors

- Chemoreceptors respond to the presence of specific molecules in the environment. In vertebrates, they form parts of receptor organs for taste (gustation) and smell (olfaction).
- Taste receptors detect molecules from food or other objects that come into direct contact with the receptor and are used primarily to identify foods (Figures 41.18 and 41.20).
- Olfactory receptors detect molecules from distant sources; besides identifying food, they are used to detect predators and prey, identify family and group members, locate trails and territories, and communicate (Figures 41.19 and 41.21).

Animation: Olfaction

Animation: Taste

41.6 Thermoreceptors and Nociceptors

- Thermoreceptors, which consist of free nerve endings located at the body surface and in limited numbers in the body interior, detect changes in body temperature.
- Nociceptors, located on both the body surface and interior, detect stimuli that can damage body tissues. Information from these receptors is integrated in the brain into the sensation of pain.

41.7 Magnetoreceptors and Electroreceptors

- Some vertebrates have electroreceptors that detect electrical currents and fields, or magnetoreceptors that detect magnetic fields (Figure 41.23).

UNDERSTAND & APPLY

Test Your Knowledge

1. An ambulance siren in close proximity to a dog can cause the dog to howl in pain. Which receptors are responsible for this response?
   a. Thermoreceptors and chemoreceptors
   b. Photoreceptors and nociceptors
   c. Mechanoreceptors and nociceptors
   d. Chemoreceptors and mechanoreceptors
   e. Photoreceptors and chemoreceptors
2. The sensation of sheets lessens if you lie still in bed. The response is due to:
   a. sensory adaptation of mechanoreceptors.
   b. sensory adaptation of nociceptors.
   c. pH change receptors associated with sleep.
   d. the vestibular apparatus.
   e. vibration detecting systems.
3. The following situation is associated with movement and position in the human body:
   a. Statoliths in statocysts bend sensory hairs and trigger action potentials.
   b. If sensory hairs in the utricle are oriented horizontally and those in the saccule are oriented vertically, the person is lying down.
   c. When the head rotates, the endolymph in the semicircular canal pulls the cupula with it to activate sensory hair cells.
   d. Displacement of the utricle and saccule generates action potentials.
   e. If the body is spinning at a constant rate and direction, the cupula is displaced and action potentials are initiated.
4. Neuromast function is best described as:
   a. nonadapting pain receptors.
   b. stereocilia that bend and generate action potentials.
   c. statoliths that detect motion.
   d. motor axons that activate motion.
   e. cupulas that detect vibrations.
5. Structures in the vertebrate ear are activated by sound waves in the following order:
   a. oval window, tympanic membrane, semicircular canals, Golgi tendon organ, incus, malleus, stapes.
   b. organ of Corti, malleus, incus, stapes, auditory nerve, tympanic membrane.
   c. eustachian tube, round window, vestibular canal, tympanic canal, cochlear canal, oval window, pinna.
   d. basilar membrane, tectorial membrane, otoliths, utricle, saccule, malleus, cochlea.
   e. pinna, tympanic membrane, malleus, incus, stapes, oval window, cochlear duct.
6. The eyes of vertebrates and cephalopods are similar in structure and function. A difference between the vertebrate eye and the cephalopod eye is that the vertebrate eye has:
   a. an iris surrounding the pupil, whereas in cephalopods the pupil surrounds the iris.
   b. a lens that changes shape when focusing, whereas in cephalopods the lens moves back and forth to focus.
   c. a retina that moves in the socket when recording the image, whereas in cephalopods the retina changes shape when stimulated.
   d. a pupil that shrinks in size in bright light, whereas cephalopods have a pupil that enlarges in bright light.
   e. retinal synthesized from vitamin A, whereas cephalopods lack retinal.

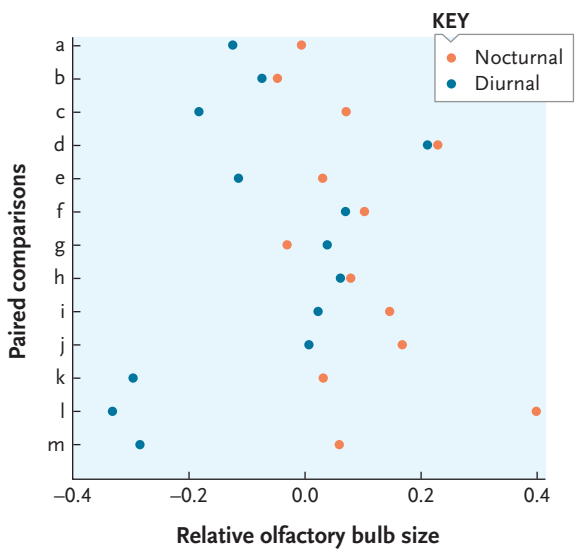
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

7. Which of the following events does not occur during light absorption in the vertebrate eye?
   a. The retinal component of rhodopsin changes from *cis* to *trans* form.
   b. Rhodopsin, a G-protein–coupled receptor, triggers a signal transduction pathway to close Na^+ channels in the plasma membrane.
   c. The light stimulus passes from rods and cones to bipolar cells and horizontal cells and then to ganglion cells, whose axons compose the optic nerve.
   d. As light absorption increases, the rhodopsin response causes an increase in the release of neurotransmitters.
   e. When integrating information across the retina, horizontal cells connect the rods and cones, and amacrine cells join with the bipolar cells and ganglion cells.
8. The variety of color seen by humans is directly dependent on the:
   a. activation of three different photopsins in cones.
   b. transmission of an image to separate brain hemispheres by the optic chiasm.
   c. transmission of impulses from rods across the lateral geniculate nuclei.
   d. lateral inhibition by amacrine cells.
   e. light stimulation of all photoreceptor types equally.
9. In terrestrial animals:
   a. the hairs of taste receptors are derived from cilia and contain microtubules.
   b. the hairs of smell receptors are derived from microvilli and contain microfilaments.
   c. signals from taste receptors are relayed to the temporal lobes.
   d. information from olfactory receptors is processed in the parietal lobes.
   e. connections from the olfactory bulbs lead to the limbic system.
10. In the human response to temperature or pain:
   a. all Ca^{2+} channels act as pain receptors.
   b. cold receptors are activated between 27°C and 37°C.
   c. pain receptors decrease the rate at which they send out action potentials if the pain is constant.
   d. nociceptors activated by capsaicin transmit pain messages to the brain.
   e. the CNS releases glutamate or substance P to dull the pain sensation.

Discuss the Concepts



1. Humans have about 200 million photoreceptors in two eyes, and about 32,000 sensory hair cells in two ears. About 3% of the somatosensory cortex is devoted to hearing, whereas roughly 30% of it is devoted to visual processing. Suggest an explanation for these differences from the perspective of natural selection and adaptation.
2. In owls and many other birds of prey, the fovea is located toward the top of the retina rather than at the center as in humans. This arrangement correlates with the birds' hunting behavior, in which they look down when they fly, scanning the ground for a meal. With this arrangement in mind, why do you think a standing owl would turn its head upside down?
3. A patient made an appointment with her doctor because she was experiencing recurrent episodes of dizziness. Her doctor asked questions to distinguish whether she had sensations of lightheadedness, as if she were going to faint, or vertigo, as if she or objects near her were spinning around. Why was this clarification important in the evaluation of her condition?

Design an Experiment

The fruit fly *Drosophila melanogaster* can distinguish a large repertoire of odors in the environment. Their response may be to move toward food or away from danger. Moreover, particular odors play an important role in their mating behavior. The olfactory organs of a fruit fly are the antennae and an elongated bulge on the head called the maxillary pulp. Because of the ease with which fruit fly genes can be manipulated, identifying and studying their olfactory receptors likely would contribute significantly to our understanding of neural pathways of odor recognition more generally. How could you identify candidate fruit fly genes that encode components of olfactory receptors?

Interpret the Data

The graph in the **Figure** plots relative olfactory bulb size for pairs of closely related birds (a through m), with each pair having a species that is more active at night (nocturnal) and one that is more active during the day (diurnal). The researchers hypothesized that nocturnal birds would have larger olfactory bulbs because they need to depend on senses other than sight.

From S. Healy and T. Guilford. 1990. Olfactory-bulb size and nocturnality in birds. *Evolution* 44:339–346. Copyright © 1990 Wiley Publishing. Reproduced with permission of Blackwell Publishing Ltd.

1. From these data, which, if any, of the bird pairs supports the hypothesis of the researchers?
2. Do any of the pairs provide evidence against the hypothesis?
3. Looking at these data as a whole, can you draw any overall conclusions?

Be sure to explain your answers.

Source: S. Healy and T. Guilford. 1990. Olfactory-bulb size and nocturnality in birds. *Evolution* 44:339–346.

Apply Evolutionary Thinking

In 2005, researchers took saliva and blood samples from six cats, including domestic cats, a tiger, and a cheetah, and found that all have a defective gene for one of the two chemoreceptor proteins needed to identify food as sweet. (The scientists conjecture that the lack of a sweet tooth may explain why cats are finicky eaters.) What are the evolutionary implications of the finding?

Two North American bull elks contesting for cows. The shorter days of autumn trigger hormone production, battling, and reproductive behavior.

42

STUDY OUTLINE

42.1 Hormones and Their Secretion
42.2 Mechanisms of Hormone Action
42.3 The Hypothalamus and Pituitary
42.4 Other Major Endocrine Glands of Vertebrates
42.5 Endocrine Systems in Invertebrates

The Endocrine System

Why it matters . . . Every September, as the days grow shorter, bull elks *(Cervus canadensis)* begin to strut their stuff. Although they have grazed peacefully together at high mountain elevations from the Yukon to Arizona, they now become testy with each other. They also rasp at tree branches and plow the ground with their antlers. Soon, they descend to lower elevations, where the cow elks have been feeding in large nursery groups with their calves and yearlings.

The bulls move in among the cows and chase away the male yearlings. As part of the mating ritual, the bulls bugle, square off, strut, and circle; then they clash their antlers together, attempting to drive each other from the cows. The winning males claim harems of about 10 females each.

After the mating season ends, tranquility returns. The cows again graze in herds; the males form now-friendly bachelor groups that also feed quietly in the meadows. Eating is their major occupation, storing nutrients in preparation for the winter. The young will be born eight to nine months later, when summer returns.

The next year, the shortening days of late summer and fall again trigger the transition to mating behavior. Detected by the eyes and registered in the brain, reduced day length initiates changes in the secretion of long-distance signaling molecules called **hormones** (*horme* = to excite). Hormones released from one group of cells are transported through the circulatory system to other cells, their target cells, whose activities they change. Among the changes will be a rise in the concentration of hormones responsible for mating behavior.

We too are driven by our hormones. They control our day-to-day sexual behavior—sometimes as outlandish as that of a bugling bull elk—as well as a host of other functions, from the concentration of salt in our blood, to body growth, to the secretion of digestive juices. Along with the central nervous system, hormones coordinate the activities of multicellular life.

The best-known hormones are secreted by cells of the **endocrine system** (*endo* = within; *krinein* = to separate), although hormones actually are produced by many organ systems in the body. The endocrine system, like the nervous system, regulates and coordinates distant organs. The two systems are structurally, chemically, and functionally related, but they control different types of activities. The nervous system, through its high-speed electrical signals, enables an organism to interact rapidly with the external environment, while the endocrine system mainly controls activities that involve slower, longer-acting responses. Typical responses to hormones may persist for hours, weeks, months, or even years.

The mechanisms and functions of the endocrine system are the subjects of this chapter. As in other chapters of this unit, we pay particular attention to the endocrine system of humans and other mammals.

42.1 Hormones and Their Secretion

Cells signal other cells using neurotransmitters, hormones, and local regulators. Recall from Chapters 39, 40, and 41 that a neurotransmitter is a chemical released by an axon terminal at a synapse that affects the activity of a postsynaptic cell. Our focus in this chapter is hormones and local regulators.

The Endocrine System Includes Four Major Types of Cell Signaling

Four types of cell signaling occur in the endocrine system: classical endocrine signaling, neuroendocrine signaling, paracrine regulation, and autocrine regulation. In *classical endocrine signaling,* hormones are secreted into the extracellular fluid (ECF) by the cells of ductless secretory organs called **endocrine glands (Figure 42.1A).** (In contrast, *exocrine glands,* such as the sweat and salivary glands, release their secretions into ducts that lead outside the body or into the cavities of the digestive tract, as described in Section 38.2.) The hormones are circulated throughout the body in the blood and, as a result, most body cells are exposed to a wide variety of hormones. (The cells of the central nervous system are sequestered from the general circulatory system by the blood–brain barrier, described in Section 40.3.) Only *target cells* of a hormone, those with *receptor proteins* recognizing and binding that hormone, respond to it. Through these responses, hormones control such vital functions as digestion, osmotic balance, metabolism, cell division, reproduction, and development. The action of hormones may either speed up or inhibit these cellular processes. For example, growth hormone stimulates cell division, whereas glucocorticoids inhibit glucose uptake by most cells in the body.

Hormones are cleared from the body by enzymatic breakdown, mainly in the liver and kidneys, but also in target cells

themselves. Breakdown products are excreted in urine and feces. Depending on the hormone, the breakdown takes minutes to days.

In *neuroendocrine signaling,* specialized neurons called **neurosecretory neurons** release a hormone called a *neurohormone* into the circulatory system when appropriately stimulated **(Figure 42.1B).** The neurohormone is distributed by the circulatory system and elicits a response in target cells that have receptors for the hormone. Note that both neurohormones and neurotransmitters are secreted by neurons. An important distinction between neurohormones and neurotransmitters is that neurohormones are carried to target cells by the blood, whereas neurotransmitters act across a synaptic cleft (see Figure 39.6B). However, both neurohormones and neurotransmitters function in the same way—they cause cellular responses by interacting with specific receptors on target cells.

In *paracrine regulation,* a cell releases a signaling molecule that diffuses through the ECF and acts on nearby cells—regulation is *local* rather than at a distance, as is the case with hormones and neurohormones **(Figure 42.1C).** In some cases the local regulator acts on the same cells that produced it; this is called *autocrine regulation* **(Figure 42.1D).** For example, many of the growth factors that regulate cell division and differentiation act in both a paracrine and autocrine fashion.

Hormones and Local Regulators Can Be Grouped into Four Classes Based on Their Chemical Structure

More than 60 hormones and local regulators have been identified in humans. Many human hormones are either identical or very similar in structure and function to those in other animals, but other vertebrates as well as invertebrates have hormones not found in humans. Most hormones and local regulators fall into four molecular classes: amine, peptide, steroid, and fatty acid–derived molecules.

Amine hormones are involved in classical endocrine and neuroendocrine signaling. Most amine hormones are based on tyrosine. With one major exception, they are hydrophilic molecules, which diffuse readily into the blood and ECF. On reaching a target cell, they bind to receptors at the cell surface. The amine hormones include dopamine, epinephrine, and norepinephrine, already familiar as neurotransmitters released by some neurons (see Section 39.3). The exception is thyroxine, a hydrophobic amine hormone secreted by the thyroid gland. This hormone, which is based on a pair of tyrosines, passes freely through the plasma membrane and binds to a receptor inside the target cell, as do steroid hormones (see following discussion and Section 7.5).

The *peptide hormones* consist of amino acid chains, ranging in length from as few as 3 amino acids to more than 200. Some have carbohydrate groups attached to the amino acid chain. They are involved in classical endocrine signaling (for example, insulin) and neuroendocrine signaling (for example, gonadotropin-releasing hormone). Peptide hormones are released into the ECF, and from there they enter the blood. One large group of peptide hormones, the **growth factors,** regulates the division and differentiation of many cell types in the body. Many growth factors act in both paracrine and autocrine manners, as well as in classical endocrine signaling. Because they can switch cell division on or off, growth factors are an important focus of cancer research.

Steroid hormones are involved in classical endocrine signaling. All are hydrophobic molecules derived from cholesterol. They combine with hydrophilic carrier proteins to form water-soluble complexes that can diffuse through the ECF and enter the bloodstream. On contacting a cell, the hormone is released from its carrier protein, passes through the plasma membrane of the target cell, and binds to internal receptors in the nucleus or cytoplasm. Steroid hormones include aldosterone, cortisol, and the sex hormones. Steroid hormones may vary little in structure, but produce very different effects. For example, testosterone and estradiol, two major sex hormones responsible for the development of mammalian male and female characteristics, respectively, differ in little more than the presence or absence of a methyl group (see Figure 3.15).

Fatty acid-derived molecules are involved in paracrine and autocrine regulation. **Prostaglandins,** for example, are important as local regulators. Virtually every cell can secrete prostaglandins, and they are present at essentially all times. In semen, they enhance the transport of sperm through the female reproductive tract by increasing the contractions of smooth muscle cells, particularly in the uterus. During childbirth, prostaglandins secreted by the placenta work with a peptide hormone called oxytocin to stimulate labor contractions (see Sections 38.4 and 50.4). Other prostaglandins induce contraction or relaxation of smooth muscle cells in many parts of the body, including blood vessels and air passages in the lungs. When released as a product of membrane breakdown in injured cells, prostaglandins may also intensify pain and inflammation.

Many Hormones Are Regulated by Feedback Pathways

The secretion of many hormones is regulated by feedback pathways. Most of these pathways are controlled by negative feedback—that is, a product of the pathway inhibits an earlier step in the pathway (see Section 38.4). For example, in some mammals, secretion by the thyroid gland is regulated by a negative feedback loop **(Figure 42.2).** Secretory neurons in the hypothalamus secrete thyroid-releasing hormone (TRH) into the ECF and capillaries connecting the hypothalamus to the pituitary gland. In response, the pituitary releases thyroid-stimulating hormone (TSH) into the blood to stimulate the thyroid gland to release thyroid hormones. As the thyroid hormone concentration in the blood increases, it begins to inhibit TSH secretion by the pituitary; this action is the negative feedback step. The result is that secretion of the thyroid hormones is reduced.

Body Processes Are Regulated by Coordinated Hormone Secretion

Although we will talk mostly about individual hormones in the remainder of the chapter, body processes are affected by more than one hormone. For example, the blood concentrations of glucose, fatty acids, and ions such as Ca^{2+}, K^+, and Na^+ are regulated by the coordinated activities of several hormones secreted by different glands. Similarly, body processes such as oxidative metabolism, digestion, growth, sexual development, and reactions to stress are all controlled by multiple hormones.

In many of these systems, negative feedback loops adjust the levels of secretion of hormones that act in antagonistic ("opposing") ways, creating a balance that maintains homeostasis. For example, consider the regulation of fuel molecules such as glucose, fatty acids, and amino acids in the blood. We usually eat three meals a day and fast to some extent between meals. During these periods of eating and fasting, four hormone systems act in coordinated fashion to keep the fuel levels in balance: (1) insulin and glucagon, secreted by the pancreas; (2) growth hormone, secreted by the anterior pituitary; (3) epinephrine and norepinephrine, released by the sympathetic nervous system and the adrenal medulla; and (4) glucocorticoid hormones, released by the adrenal cortex.

The entire system of hormones regulating fuel metabolism resembles the fail-safe mechanisms designed by human engineers, in which redundancy, overlapping controls, feedback loops, and multiple safety valves ensure that vital functions are maintained at constant levels in the face of changing and even extreme circumstances.

STUDY BREAK 42.1

1. **Distinguish between a hormone and an exocrine secretion.**
2. **How is endocrine signaling different from autocrine signaling?**

42.2 Mechanisms of Hormone Action

Hormones control cell functions by binding to receptor molecules on or in their target cells. Small quantities of hormones can typically produce profound effects in cells and body functions as a result of **amplification** (see Figure 7.5). In amplification, binding of a hormone to a receptor triggers activation of many proteins, each of which then activates an even larger number of proteins for the next step in the cellular reaction pathway, and so on, increasing in magnitude for each step in the pathway. It has been estimated that, by amplification, a single molecule of epinephrine acting on a liver cell will liberate 10^6 molecules of glucose from stored glycogen.

Hydrophilic Hormones Bind to Surface Receptors, Activating Protein Kinases Inside Cells

Hormones that bind to receptor molecules in the plasma membrane—primarily hydrophilic amine and peptide hormones—produce their responses through signal transduction pathways (see Section 7.2). In brief, when a surface receptor binds a hormone, the receptor is activated and transmits the signal through the plasma membrane. Within the cell, the signal is transduced, changed into a form that causes the cellular response **(Figure 42.3A).** Typically, the reactions of signal transduction pathways involve protein kinases, enzymes that add phosphate groups to proteins. Adding a phosphate group to a protein may activate it or inhibit it, depending on the protein and the reaction. The particular response produced by a hormone depends on the kinds of protein kinases activated, the type of cell that can respond, and the types of target proteins they phosphorylate.

Two major types of surface receptors bind hydrophilic hormones: receptor tyrosine kinases and G-protein–coupled receptors. Receptor tyrosine kinases have a built-in protein kinase on the cytoplasmic side of the receptor (Figure 42.3A illustrates this type of receptor). Binding of a signal molecule to this type of receptor turns on the receptor's protein kinase, which activates the receptor. The activated receptor then initiates a signaling cascade within the cell, typically involving protein kinases, which phosphorylate target proteins, resulting in a cellular response. The cytoplasmic reactions that receptor tyrosine kinases control when they are activated are described in detail in Section 7.3. Insulin, a peptide hormone that lowers glucose concentration in the blood, elicits a cellular response using a signal transduction pathway initiated by activating a receptor tyrosine kinase. Insulin acts mainly by binding to receptors on liver cells, adipose tissue (fat), and skeletal muscle cells to stimulate glucose transport into cells, conversion of glucose to glycogen, and other metabolic activities.

G-protein–coupled receptors lack a built-in protein kinase. This type of receptor responds to the binding of a hormone by activating a G protein associated with the cytoplasmic end of the receptor. The activated G protein then activates an effector molecule, which then generates a second messenger molecule. Sec-

ond messengers activate protein kinases in the cell, which elicit the cellular response by phosphorylating target proteins. The cytoplasmic reactions that G-protein–coupled receptors control when activated are described in detail in Section 7.4. Glucagon, a peptide hormone that raises glucose concentration in the blood, elicits a cellular response using a signal transduction pathway initiated by activating a G-protein–coupled receptor. When glucagon binds to surface receptors on liver cells, it triggers the breakdown of glycogen stored in those cells into glucose. The glucose then is released into the circulatory system.

Hydrophobic Hormones Bind to Receptors Inside Cells, Activating or Inhibiting Genetic Regulatory Proteins

After passing through the plasma membrane, the hydrophobic steroid and thyroid hormones bind to internal receptors in the nucleus or cytoplasm (**Figure 42.3B,** and described in detail in Section 7.5). Binding of the hormone activates the receptor, which then binds to a regulatory sequence of specific genes. Depending on the gene, binding the regulatory sequence either activates or inhibits its transcription, leading to changes in protein synthesis that accomplish the cellular response. The characteristics of the response depend on the specific genes controlled by the activated receptors, and on the presence of other proteins that modify the activity of the receptor.

One of the actions of the steroid hormone aldosterone illustrates the mechanisms triggered by internal receptors **(Figure 42.4).** If blood pressure falls below optimal levels, aldosterone is secreted by the adrenal glands. The hormone affects only kidney cells that contain the aldosterone receptor in their cytoplasm. When activated by aldosterone, the receptor binds to the regulatory sequence of a gene, leading to the synthesis of proteins that increase reabsorption of Na^+ by the kidney cells. The resulting increase in Na^+ concentration in body fluids increases water retention and, with it, blood volume and pres-

sure. These changes then feedback negatively on the processes that initiated aldosterone secretion.

Target Cells May Respond to More Than One Hormone, and Different Target Cells May Respond Differently to the Same Hormone

A single target cell may have receptors for several hormones and respond differently to each hormone. For example, vertebrate liver cells have receptors for the pancreatic hormones insulin and glucagon. Insulin increases glucose uptake and conversion to glycogen, which decreases blood glucose levels, while glucagon stimulates the breakdown of glycogen into glucose, which increases blood glucose levels.

Conversely, particular hormones interact with different types of receptors in or on a range of target cells. Different responses are then triggered in each target cell type because the receptors trigger different transduction pathways. For example, the amine hormone epinephrine secreted by the adrenal medulla prepares the body for handling stress (including dangerous situations) and physical activity. (Epinephrine is discussed in more detail in Section 42.4.) In mammals, epinephrine can bind to several different G-protein–coupled receptors (see Section 7.4) known as **adrenergic receptors** because of the adrenal origin of the hormones that bind to them. These receptors are categorized into two types: α-adrenergic receptors and β-adrenergic receptors. (The experimental demonstration that binding of epinephrine to a specific adrenergic receptor triggers a cellular response is described in **Figure 42.5.**) When epinephrine binds to an adrenergic receptor on a smooth muscle cell, such as that of a blood vessel, it triggers a response pathway that causes the cells to constrict, reducing circulation to peripheral organs. When epinephrine binds to β_1-adrenergic receptors on heart muscle cells, the contraction rate of the cells increases, which in turn enhances blood supply. When epinephrine binds to β_2-adrenergic receptors on liver cells, it stimulates the breakdown of glycogen to glucose, which is released from the cell. The overall effect of these, and a number of other, responses to epinephrine secretion is to supply energy to the major muscles responsible for locomotion—the body is now prepared for handling stress or for physical activity.

Different receptors binding hydrophobic hormones also may generate diverse responses. *Insights from the Molecular Revolution* (pp. 954–955) describes an investigation that tested the cellular responses produced by different receptors binding the same steroid hormone.

In summary, the mechanisms by which hormones work have four major features:

1. Only the cells that contain surface or internal receptors for a particular hormone respond to that hormone.

FIGURE 42.5 Experimental Research

Demonstration That Binding of Epinephrine to β-Adrenergic Receptors Triggers a Signal Transduction Pathway within Cells

Question: Is binding of epinephrine to β-adrenergic receptors necessary for triggering a signal transduction pathway within cells?

Experiment: Epinephrine triggers a signal transduction pathway. First, activation of adenylyl cyclase causes the level of the second messenger cAMP to increase, and then cAMP activates protein kinases in a signaling cascade that generates a cellular response (see Section 7.4). Richard Cerione and his colleagues at Duke University Medical Center studied whether the signal transduction pathway is stimulated by binding of epinephrine to β-adrenergic receptors.

1. Epinephrine was added to animal cells lacking β-adrenergic receptors.

Result: No change occurred to the low level of cAMP in those cells. This result demonstrated that epinephrine alone was not able to trigger an increase in cAMP.

2. Liposomes—artificial spherical phospholipid membranes—containing purified β-adrenergic receptors were fused with the animal cells, and then epinephrine was added.

Result: When the liposomes fused with the animal cells, β-adrenergic receptors became part of the fused cell's plasma membrane. Then, adding epinephrine triggered synthesis of cAMP, resulting in high levels of cAMP in the cells. This result demonstrated that β-adrenergic receptors must be present in the membrane for epinephrine to trigger an increase in cAMP in the cell. The simplest interpretation was that epinephrine bound to the β-adrenergic receptors, activating adenylyl cyclase within the cell.

Conclusion: The cellular response depended on binding of the hydrophilic hormone to a specific plasma membrane–embedded receptor.

THINK LIKE A SCIENTIST How could this system be used to study what structural features of the receptor molecules are important for controlling the associated signal transduction pathway?

© Cengage Learning 2014

2. Once bound by their receptors, hormones may produce a response that involves stimulation or inhibition of cellular processes through the specific types of internal molecules triggered by the hormone action.
3. Because of the amplification that occurs in both the surface and internal receptor mechanisms, hormones are effective in very small concentrations.
4. The response to a hormone differs among target organs.

In the next two sections, we discuss the major endocrine cells and glands of vertebrates. The locations of these cells and glands in the human body and their functions are summarized in **Figure 42.6** and **Table 42.1.** Peptide hormones secreted by other body regions, including the stomach and small intestine, the thymus gland, the kidneys, and the heart, will be described in the chapters in which these tissues and organs are discussed.

STUDY BREAK 42.2

1. **Compare and contrast the mechanisms by which glucagon and aldosterone cause their specific responses.**
2. **Explain how one type of target cell could respond to different hormones, and how the same hormone could produce different effects in different cells.**

42.3 The Hypothalamus and Pituitary

The hormones of vertebrates work in coordination with the nervous system. The action of several hormones is closely coordinated by the hypothalamus and the connected pituitary.

The hypothalamus is a region of the brain located in the floor of the cerebrum (see Section 40.3). The **pituitary gland,** consisting mostly of two fused lobes, is suspended just below it by a slender stalk of tissue that contains both neurons and blood vessels **(Figure 42.7).** The **posterior pituitary** contains axons and nerve endings of neurosecretory neurons that originate in the hypothalamus. The **anterior pituitary** contains nonneuronal endocrine cells that form a distinct gland. The two lobes are separate in structure and embryonic origins.

Under Regulatory Control by the Hypothalamus, the Anterior Pituitary Secretes Eight Hormones

The secretion of hormones from the anterior pituitary is controlled by peptide neurohormones called **releasing hormones (RHs)** and **inhibiting hormones (IHs),** released by the hypothalamus. These neurohormones are carried in the blood from the hypothalamus to the anterior pituitary in a *portal vein,* a special vein that connects the capillaries of the two glands. The portal vein provides a critical link between the brain and the endocrine system, ensuring that most of the blood reaching the anterior pituitary first passes through the hypothalamus.

RHs and IHs regulate the anterior pituitary's secretion of another group of hormones; those hormones in turn control many other endocrine glands of the body, and some body processes directly.

Secretion of hypothalamic RHs is controlled by neurons containing receptors that monitor the blood to detect changes in body chemistry and temperature. For example, TRH is secreted in response to a drop in body temperature. Input to the hypothalamus also comes through numerous connections from control centers elsewhere in the brain, including the brain stem and limbic system. Negative feedback pathways regulate secretion of the releasing hormones, such as the pathway regulating TRH secretion.

Under the control of the hypothalamic RHs, the anterior pituitary secretes six major hormones into the bloodstream: prolactin, growth hormone, thyroid-stimulating hormone, adrenocorticotropic hormone, follicle-stimulating hormone, and luteinizing hormone. Two additional hormones with more complex regulation, melanocyte-stimulating hormone (MSH) and endorphins, are also produced in pituitary tissue. **Prolactin (PRL)** influences reproductive activities and parental care in

TABLE 42.1 The Major Human Endocrine Glands and Hormones

Secretory Tissue or Gland	Hormones	Molecular Class	Target Tissue	Principal Actions
Hypothalamus	Releasing and inhibiting hormones	Peptide	Anterior pituitary	Regulate secretion of anterior pituitary hormones
Anterior pituitary	Thyroid-stimulating hormone (TSH)	Peptide	Thyroid gland	Stimulates secretion of thyroid hormones and growth of thyroid gland
	Adrenocorticotropic hormone (ACTH)	Peptide	Adrenal cortex	Stimulates secretion of glucocorticoids by adrenal cortex
	Follicle-stimulating hormone (FSH)	Peptide	Ovaries in females, testes in males	Stimulates egg growth and development and secretion of sex hormones in females; stimulates sperm production in males
	Luteinizing hormone (LH)	Peptide	Ovaries in females, testes in males	Regulates ovulation in females and secretion of sex hormones in males
	Prolactin (PRL)	Peptide	Mammary glands	Stimulates breast development and milk secretion
	Growth hormone (GH)	Peptide	Bone, soft tissue	Stimulates growth of bones and soft tissues; helps control metabolism of glucose and other fuel molecules
	Melanocyte-stimulating hormone (MSH)	Peptide	Melanocytes in skin of some vertebrates	Promotes darkening of the skin
	Endorphins	Peptide	Pain pathways of PNS	Inhibit perception of pain
Posterior pituitary	Antidiuretic hormone (ADH)	Peptide	Kidneys	Raises blood volume and pressure by increasing water reabsorption in kidneys
	Oxytocin	Peptide	Uterus, mammary glands	Promotes uterine contractions; stimulates milk ejection from breasts
Thyroid gland	Calcitonin	Peptide	Bone	Lowers calcium concentration in blood
	Thyroxine and triiodothyronine	Amine	Most cells	Increase metabolic rate; essential for normal body growth
Parathyroid glands	Parathyroid hormone (PTH)	Peptide	Bone, kidneys, intestine	Raises calcium concentration in blood; stimulates vitamin D activation
Adrenal medulla	Epinephrine and norepinephrine	Amine	Sympathetic receptor sites throughout body	Reinforce sympathetic nervous system; contribute to responses to stress
Adrenal cortex	Aldosterone (mineralocorticoid)	Steroid	Kidney tubules	Helps control body's salt–water balance by increasing Na^+ reabsorption and K^+ excretion in kidneys
	Cortisol (glucocorticoid)	Steroid	Most body cells, particularly muscle, liver, and adipose cells	Increases blood glucose by promoting breakdown of proteins and fats
Testes	Androgens, such as testosterone*	Steroid	Various tissues	Control male reproductive system development and maintenance; most androgens are made by the testes
	Oxytocin	Peptide	Uterus	Promotes uterine contractions when seminal fluid is ejaculated into vagina during sexual intercourse

*Small amounts secreted by ovaries and adrenal cortex.

**Small amounts secreted by testes.

TABLE 42.1 The Major Human Endocrine Glands and Hormones—*Continued*

Secretory Tissue or Gland	Hormones	Molecular Class	Target Tissue	Principal Actions
Ovaries	Estrogens, such as estradiol**	Steroid	Breast, uterus, other tissues	Stimulate maturation of sex organs at puberty, and development of secondary sexual characteristics
	Prolactins, such as progesterone**	Steroid	Uterus	Prepare and maintain uterus for implantation of fertilized egg and the growth and development of embryo
Pancreas (islets of Langerhans)	Glucagon (alpha cells)	Peptide	Liver cells	Raises glucose concentration in blood; promotes release of glucose from glycogen stores and production from noncarbohydrates
	Insulin (beta cells)	Peptide	Most cells	Lowers glucose concentration in blood; promotes storage of glucose, fatty acids, and amino acids
Pineal gland	Melatonin	Amine	Brain, anterior pituitary, reproductive organs, immune system, possibly others	Helps synchronize body's biological clock with day length; may inhibit gonadotropins and initiation of puberty
Many cell types	Growth factors	Peptide	Most cells	Regulate cell division and differentiation
	Prostaglandins	Fatty acid	Various tissues	Have many diverse roles

**Small amounts secreted by testes.

vertebrates. In mammals, PRL stimulates development of the secretory cells of mammary glands during late pregnancy, and stimulates milk synthesis after a female mammal gives birth. Stimulation of the mammary glands and the nipples, as occurs during suckling, leads to PRL release.

Growth hormone (GH) stimulates cell division, protein synthesis, and bone growth in children and adolescents, thereby causing body growth. GH also stimulates protein synthesis and cell division in adults. For these actions, GH binds to target tissues, mostly liver cells, causing them to release **insulin-like growth factor (IGF),** a peptide that directly stimulates growth processes. GH also controls a number of major metabolic processes in mammals of all ages, including the conversion of glycogen to glucose and fats to fatty acids as a means of regulating their levels in the blood. In addition, GH stimulates body cells to take up fatty acids and amino acids and limits the rate at which muscle cells take up glucose. These actions help maintain the availability of glucose and fatty acids to tissues and organs between feedings; this is particularly important for the brain. In humans, deficiencies in GH secretion during childhood produce *pituitary dwarfs,* who remain small in stature through childhood and into adulthood. Overproduction of GH during childhood or adolescence, often due to a tumor of the anterior pituitary, produces *pituitary giants,* who may grow above 2.4 m (8 ft) in height.

The other four major hormones secreted by the anterior pituitary control endocrine glands elsewhere in the body. **Thyroid-stimulating hormone (TSH)** stimulates the thyroid gland to grow in size and secrete thyroid hormones. **Adrenocorticotropic hormone (ACTH)** triggers hormone secretion by cells in the adrenal cortex. **Follicle-stimulating hormone (FSH)** controls egg development and the secretion of sex hormones in female mammals, and sperm production in males. **Luteinizing hormone (LH)** regulates part of the menstrual cycle in human females and the secretion of sex hormones in males. FSH and LH are grouped together as **gonadotropins** because they regulate the activity of the gonads (ovaries and testes). The roles of the gonadotropins and sex hormones in the reproductive cycle are described in Chapter 49.

Melanocyte-stimulating hormone (MSH) and **endorphins** are two other hormones produced by the anterior pituitary. MSH is named because of its effect in some vertebrates on melanocytes, skin cells that contain the black pigment melanin. For example, an increase in secretion of MSH produces a marked darkening of the skin of fishes, amphibians, and reptiles. The darkening is produced by a redistribution of melanin from the centers of the melanocytes throughout the cells. In adult humans, the pituitary secretes little or no MSH.

Endorphins, peptide hormones produced by the hypothalamus and pituitary, are also released by the anterior pituitary (see Table 42.1). In the peripheral nervous system (PNS), endorphins act as neurotransmitters in pathways that control pain, thereby inhibiting the perception of pain.

The Posterior Pituitary Secretes Two Hormones into the Circulatory System

The neurosecretory neurons in the posterior pituitary secrete two peptide hormones, antidiuretic hormone and oxytocin, directly into the circulatory system (see Figure 42.7).

Two Receptors for Estrogens

Estrogens have many different effects on female sexual development, behavior, and the menstrual cycle. One negative effect is to stimulate the growth of tumors in breast and uterine cancer. This cancer-enhancing effect can be reduced by administering *antiestrogens,* estrogen-like chemicals that bind competitively to estrogen receptors and block the sites that would normally be bound by the hormone. The antiestrogen *tamoxifen,* for example, inhibits the growth of breast tumors by blocking the activity of estrogen in breast tissue, but patients receiving it are at increased risk of developing uterine cancer.

Research Question

How can tamoxifen have opposite effects in two different tissues?

Experiment

A group of investigators led by Thomas Scanlan and Peter Kushner at the University of California, San Francisco, joined by others at the Karolinska Institute and the Karo Bio Company in Sweden, had discovered that humans have two highly similar estrogen receptors, ERα and ERβ. Could differences between them account for the opposing effects of tamoxifen in breast and uterine tissues?

To find out, the researchers constructed two pairs of recombinant DNA plasmids **(Figure 1).** One pair consisted of either the ERα receptor gene or the ERβ receptor gene, adjacent to a promoter for continuous transcription of the receptor gene in human tissue culture cells that were not derived from breast cancer **(Figure 1A).** The other pair consisted of the firefly luciferase gene, which catalyzes a light-producing reaction, adjacent to one of two gene regulatory sequences, ERE or AP1, which act in estrogen-regulated systems **(Figure 1B).** In this experiment, the luciferase gene acts as a reporter gene, meaning that it provides a sensitive measure of the events occurring with the estrogen receptors and the gene regulatory sequences—luciferase has nothing to do with estrogen or estrogen activity.

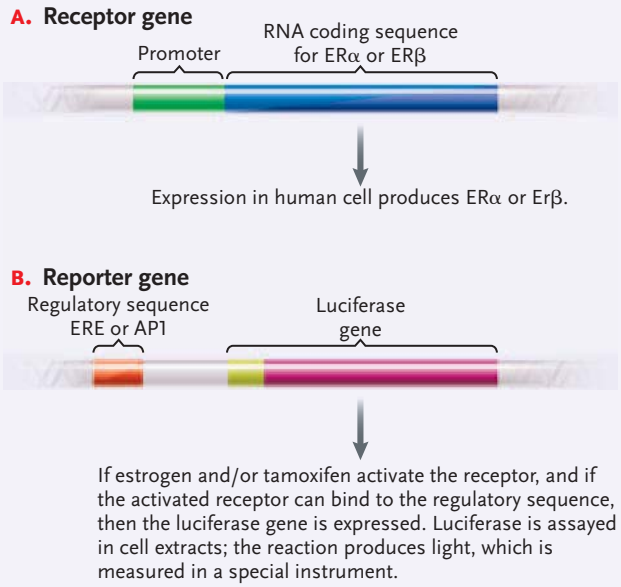

FIGURE 1 **Schematic of the receptor genes and reporter genes on the recombinant DNA plasmids.**

The researchers introduced one receptor gene plasmid and one reporter gene plasmid in four possible combinations into human cell lines that do not normally make estrogen receptors. Estrogen receptors are produced in all four of the resulting cell lines because the gene for the receptor is transcribed from the introduced plasmid. Two of the cell lines make the ERα receptor and two make the ERβ receptor.

With this experimental design, the researchers could test whether the ERα or ERβ receptor is activated by binding estrogen and/or tamoxifen, and also whether the activated receptor would bind to the luciferase plasmid. If these two conditions were met, luciferase would be synthesized, and its activity could be measured.

© Cengage Learning 2014

Antidiuretic hormone (ADH) stimulates kidney cells to absorb more water from urine, thereby increasing the volume of the blood. The hormone is released when sensory receptor cells of the hypothalamus detect an increase in the blood's osmotic pressure during periods of body dehydration or after a salty meal. Ethyl alcohol reduces ADH secretion, explaining in part why alcoholic drinks increase the volume of urine excreted. Nicotine and emotional stress, in contrast, stimulate ADH secretion and water retention. The posterior pituitary also releases a flood of ADH when an injury results in heavy blood loss or some other event triggers a severe drop in blood pressure. ADH helps maintain blood pressure by reducing water loss and also by causing small blood vessels in some tissues to constrict.

Hormones with structure and action similar to ADH are also secreted in fishes, amphibians, reptiles, and birds. In amphibians, these ADH-like hormones increase the amount of water entering the body through the skin and from the urinary bladder.

We have noted that **oxytocin** stimulates the ejection of milk from the mammary glands of a nursing mother. Stimulation of the nipples in suckling sends neuronal signals to the hypothalamus, and leads to release of oxytocin from the posterior pituitary. The released oxytocin stimulates more oxytocin secretion by a positive feedback mechanism. Oxytocin causes the smooth muscle cells surrounding the individual alveoli of the mammary glands to contract, forcibly expelling the milk through the nipples. The entire cycle, from the onset of suckling to milk ejection, takes less than a minute in mammals. Oxytocin also plays a key role in childbirth, as discussed in Sections 38.4 and 50.4.

In males, oxytocin is secreted into the seminal fluid by the testes. Like prostaglandins, when the seminal fluid is ejaculated into the vagina during sexual intercourse, oxytocin stimulates contractions of the uterus that aid movement of sperm through the female reproductive tract.

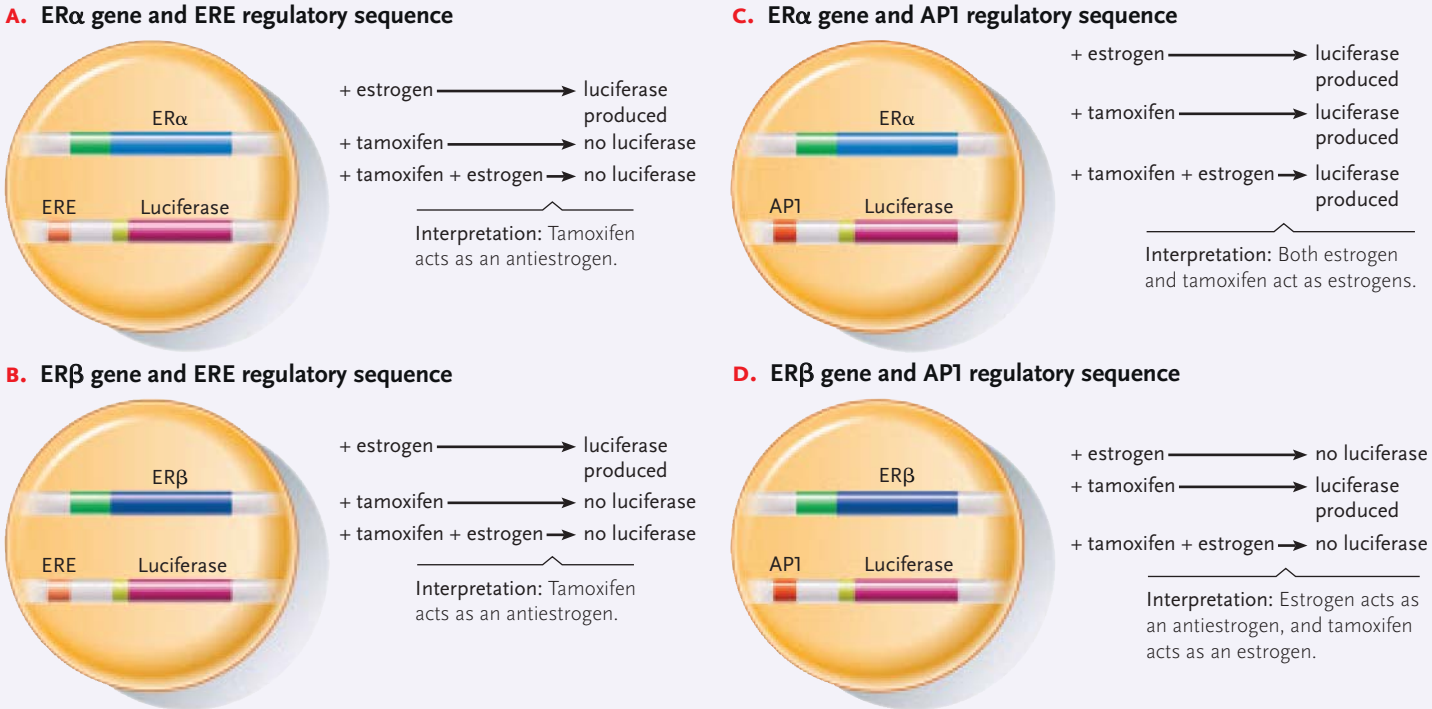
Results

The results are shown in **Figure 2.**



Conclusion

The experiments indicate that the previously baffling and opposing effects of tamoxifen on breast and uterine tissues occur because different estrogen receptors—ERα or ERβ—are present, and act on genes controlled by either the ERE or AP1 regulatory sequences. The results emphasize the fact that hormones can have distinct effects in different cell types depending on the types of receptors present.

THINK LIKE A SCIENTIST The researchers also performed the experiment of Figure 2D with cultured human breast cancer cells. The same general results were obtained, except that tamoxifen resulted in a significantly higher level of luciferase. Propose an explanation for this result.

STUDY BREAK 42.3

1. **Summarize the functional relationship between the hypothalamus and the anterior pituitary gland.**
2. **What, in addition to the hormones they secrete, distinguishes the anterior and posterior pituitary glands?**

42.4 Other Major Endocrine Glands of Vertebrates

Besides the hypothalamus and pituitary, the body has seven major endocrine glands or tissues, many of them regulated by the hypothalamus–pituitary connection. These glands are the thyroid gland, parathyroid glands, adrenal medulla, adrenal cortex, gonads, pancreas, and pineal gland (shown in Figure 42.6 and summarized in Table 42.1).

The Thyroid Hormones Stimulate Metabolism, Development, and Maturation

The **thyroid gland,** which is located in the front of the throat in humans, has a shape similar to that of a bowtie. It secretes the same hormones in all vertebrates. The primary circulating thyroid hormone, **thyroxine,** is known as $\mathbf{T_4}$ because it contains four iodine atoms. The thyroid also secretes smaller amounts of a closely related hormone, **triiodothyronine** or $\mathbf{T_3}$, which contains three iodine atoms. A supply of iodine in the diet is necessary for production of these hormones. Normally, their concentrations are kept at finely balanced levels in the blood by negative feedback loops such as that described in Figure 42.2.

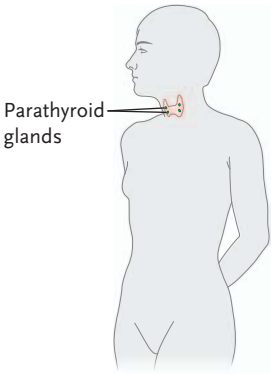
© Cengage Learning 2014

Both T_4 and T_3 enter cells; however, once inside the cell, most of the T_4 is converted to T_3, the form that combines with internal receptors. Binding of T_3 to receptors alters gene expression, which brings about the hormone's effects.

The thyroid hormones are vital to growth, development, maturation, and metabolism in all vertebrates. They interact with GH for their effects on growth and development. Thyroid hormones also increase the sensitivity of many body cells to the effects of epinephrine and norepinephrine, hormones released by the adrenal medulla as part of the "fight-or-flight response" (discussed further later in this chapter).



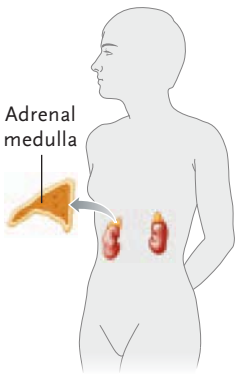
In amphibians such as frogs, thyroid hormones trigger **metamorphosis,** or change in body form from tadpole to adult **(Figure 42.8).** Thyroid hormones also contribute to seasonal changes in the plumage of birds and coat color in mammals.

In human adults, low thyroid output, *hypothyroidism,* causes affected individuals to be sluggish mentally and physically; they have a slow heart rate and weak pulse, and often feel confused and depressed. Hypothyroidism in infants and children leads to cretinism, that is, stunted growth and diminished intelligence. Overproduction of thyroid hormones in human adults, *hyperthyroidism,* produces nervousness and emotional instability, irritability, insomnia, weight loss, and a rapid, often irregular heartbeat. The most common form of hyperthyroidism is *Graves' disease,* characterized by inflamed, protruding eyes in addition to the other symptoms mentioned.

Insufficient iodine in the diet can cause *goiter,* enlargement of the thyroid. Without iodine, the thyroid cannot make T_3 and T_4 in response to stimulation by TSH. Because the thyroid hormone concentration remains low in the blood, TSH continues to be secreted, and the thyroid grows in size. Dietary iodine deficiency has been eliminated in developed regions of the world by the addition of iodine to table salt.

In mammals, the thyroid also has specialized cells that secrete the peptide hormone **calcitonin.** The hormone lowers the level of Ca^{2+} in the blood by inhibiting the ongoing dissolution of calcium from bone. Calcitonin secretion is stimulated when Ca^{2+} levels in blood rise above the normal range and inhibited when Ca^{2+} levels fall below the normal range.

The Parathyroid Glands Regulate Ca^{2+} Level in the Blood



The **parathyroid glands** occur only in tetrapod vertebrates—amphibians, reptiles, birds, and mammals. Each is a spherical structure about the size of a pea. Mammals have four parathyroids located on the posterior surface of the thyroid gland, two on each side. The single hormone they produce, called **parathyroid hormone (PTH),** is secreted in response to a fall in blood Ca^{2+} levels. PTH stimulates bone cells to dissolve the mineral matter of bone tissues, releasing both calcium and phosphate ions into the blood. The released Ca^{2+} is then available for enzyme activation, conduction of nerve signals across synapses, muscle contraction, blood clotting, and other uses. How blood Ca^{2+} levels control PTH and calcitonin secretion is shown in **Figure 42.9.**

PTH also stimulates enzymes in the kidneys that convert **vitamin D,** a steroidlike molecule, into its fully active form in the body. The activated vitamin D increases the absorption of Ca^{2+} and phosphates from ingested food by promoting the synthesis of a calcium-binding protein in the intestine; it also increases the release of Ca^{2+} from bone in response to PTH.

PTH underproduction causes Ca^{2+} concentration to fall steadily in the blood, disturbing nerve and muscle function—the muscles twitch and contract uncontrollably, and convulsions and cramps occur. Without treatment, the condition is usually fatal, because the severe muscular contractions interfere with breathing. Overproduction of PTH results in the loss of so much calcium from the bones that they become thin and fragile. At the same time, the elevated Ca^{2+} concentration in the blood causes calcium deposits to form in soft tissues, especially in the lungs, arteries, and kidneys (where the deposits form kidney stones).

The Adrenal Medulla Releases Two "Fight-or-Flight" Hormones

The adrenal glands (*ad* = to; *renes* = kidneys) of mammals consist of two distinct regions. The central region, the **adrenal medulla,** contains secretory cells of neural crest origin (see Chapter 50); the tissue surrounding it, the **adrenal cortex,** contains endocrine cells with a different developmental origin. The two regions secrete hormones with entirely different functions. Non-

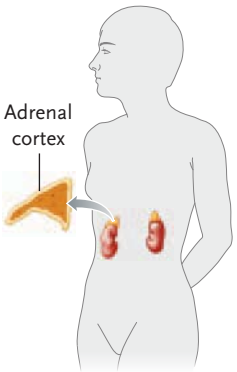
mammalian vertebrates have glands equivalent to the adrenal medulla and adrenal cortex of mammals, but they are separate. Most of the hormones produced by these glands have essentially the same functions in all vertebrates. The only major exception is aldosterone, which is secreted by the adrenal cortex or its equivalent only in tetrapod vertebrates.



In most species, the adrenal medulla secretes two amine hormones, **epinephrine** and **norepinephrine,** which are **catecholamines,** chemical compounds derived from the amino acid tyrosine that circulate in the bloodstream. They bind to receptors in the plasma membranes of their target cells. (Epinephrine and norepinephrine are also secreted by some cells of the CNS and neurons of the sympathetic nervous system. In these cases, epinephrine and norepinephrine function as neurotransmitters in a broad array of brain and body functions; see Section 39.3.)

Epinephrine and norepinephrine are secreted from sympathetic neurons and the adrenal medulla when the body encounters stresses such as emotional excitement, danger (fight-or-flight situations), anger, fear, infections, injury, even midterm and final exams. Epinephrine in particular prepares the body for handling stress or physical activity. The heart rate increases. Glycogen and fats break down, releasing glucose and fatty acids into the blood as fuel molecules. In the heart, skeletal muscles, and lungs, the blood vessels dilate to increase blood flow. Elsewhere in the body, the blood vessels constrict, raising blood pressure, reducing blood flow to the intestines and kidneys, and inhibiting smooth muscle contractions, thereby reducing water loss and slowing digestive processes. Airways in the lungs also dilate, helping to increase the flow of air.

The effects of norepinephrine on heart rate, blood pressure, and blood flow to the heart muscle are similar to those of epinephrine. However, in contrast to epinephrine, norepinephrine causes blood vessels in skeletal muscles to constrict. This antagonistic effect is largely canceled out because epinephrine is secreted in much greater quantities.

No known human diseases are caused by underproduction of the hormones of the adrenal medulla, as long as the sympathetic nervous system is intact. Overproduction of epinephrine and norepinephrine, which can occur if there is a tumor in the adrenal medulla, leads to symptoms duplicating a stress response.

The Adrenal Cortex Secretes Two Groups of Steroid Hormones That Are Essential for Survival

The adrenal cortex of mammals secretes two major types of steroid hormones: glucocorticoids help maintain the blood concentration of glucose and other fuel molecules, and mineralocorticoids regulate the levels of Na^+ and K^+ ions in the blood and ECF.

THE GLUCOCORTICOIDS

The glucocorticoids help maintain glucose levels in the blood by three major mechanisms: (1) stimulating the synthesis of glucose from noncarbohydrate sources such as fats and proteins; (2) reducing glucose uptake by body cells except those in the central nervous system; and (3) promoting the breakdown of fats and proteins, which releases fatty acids and amino acids into the blood as alternative fuels when glucose supplies are low. The absence of down-regulation of glucose uptake to the CNS keeps the brain well supplied with glucose between meals and during periods of extended fasting. **Cortisol** is the major glucocorticoid secreted by the adrenal cortex.

Secretion of glucocorticoids is ultimately under control of the hypothalamus **(Figure 42.10).** Low glucose concentrations

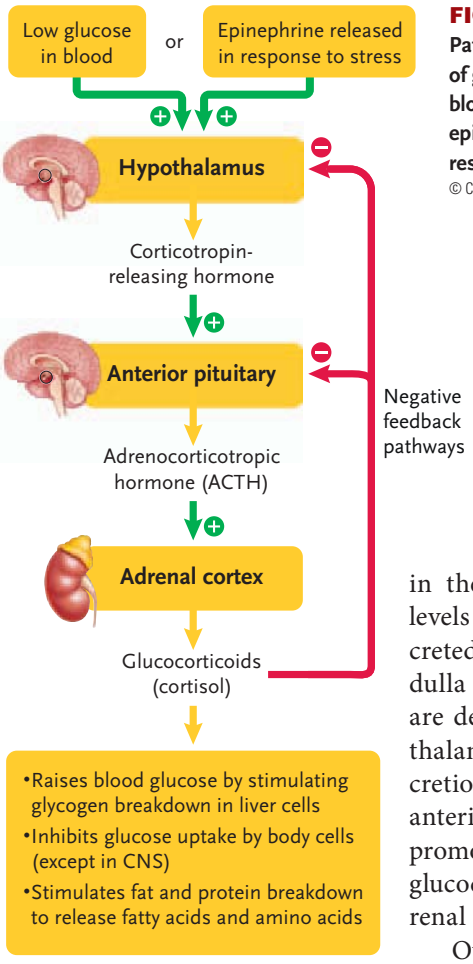

FIGURE 42.10
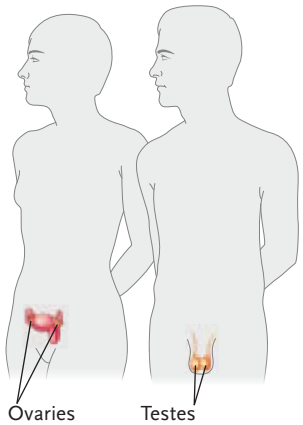
Pathways linking secretion of glucocorticoids to low blood sugar and epinephrine secretion in response to stress.
© Cengage Learning 2014

in the blood or elevated levels of epinephrine secreted by the adrenal medulla in response to stress are detected in the hypothalamus, leading to secretion of ACTH by the anterior pituitary. ACTH promotes the secretion of glucocorticoids by the adrenal cortex.

Overproduction of glucocorticoids makes blood glucose rise and increases fat deposition in adipose tissue and protein breakdown in muscles and bones. The loss of proteins from muscles causes weakness and fatigue; loss of proteins from bone, particularly collagens, makes the bones fragile and susceptible to breakage. Underproduction of glucocorticoids causes blood glucose concentration to fall below normal levels and diminishes tolerance to stress.



Glucocorticoids have antiinflammatory properties and, consequently, they are used clinically to treat conditions such as arthritis or dermatitis. They also suppress the immune system and are used in the treatment of autoimmune diseases such as rheumatoid arthritis.

THE MINERALOCORTICOIDS In tetrapods, the mineralocorticoids, primarily **aldosterone,** increase the amount of Na^+ reabsorbed from the fluids processed by the kidneys and absorbed from foods in the intestine. They also reduce the amount of Na^+ secreted by salivary and sweat glands and increase the rate of K^+ excretion by the kidneys. The net effect is to keep Na^+ and K^+ balanced at the levels required for normal cellular functions, including those of the nervous system. Secretion of aldosterone is tightly linked to blood volume and indirectly linked to blood pressure (see Section 42.2 and Chapter 48).

Moderate overproduction of aldosterone causes excessive water retention in the body, so that tissues swell and blood pressure rises. Conversely, moderate underproduction can lead to excessive water loss and dehydration. Severe underproduction is rapidly fatal unless mineralocorticoids are supplied by injection or other means.

The adrenal cortex also secretes small amounts of androgens, steroid sex hormones responsible for maintenance of male characteristics, which are synthesized primarily by the gonads. These hormones have significant effects only if they are overproduced, as can occur with some tumors in the adrenal cortex. The result is altered development of the primary or secondary sex characteristics.

The Gonadal Sex Hormones Regulate the Development of Reproductive Systems, Sexual Characteristics, and Mating Behavior

The **gonads,** the testes and ovaries, are the primary source of sex hormones in vertebrates. The steroid hormones they produce, the **androgens, estrogens,** and **progestins,** have similar functions in regulating the development of male and female reproductive systems, sexual characteristics, and mating behavior. Both males and females produce all three types of hormones, but in different proportions. Androgen production is predominant in males, whereas estrogen and progestin production is predominant in females. An outline of the actions of these hormones is presented here, and a more complete picture is given in Chapter 49.

The **testes** of male vertebrates secrete androgens, steroid hormones that stimulate and control the development and maintenance of male reproductive systems and masculine characteristics. The principal androgen is **testosterone,** the male sex hormone. In young adult males, a jump in testosterone levels stimulates puberty and the development of secondary sexual characteristics, including the growth of facial and body hair, muscle development, changes in vocal cord morphology, and development of normal sex drive. The synthesis and secretion of testosterone by cells in the testes is controlled by the release of luteinizing hormone (LH) from the anterior pituitary, which in turn is controlled by **gonadotropin-releasing hormone (GnRH)** secreted by the hypothalamus.

A large number of synthetic derivatives of androgens, known as **anabolic-androgenic steroids (AAS)** (also referred to as **anabolic steroids**), mimic the effects of androgens. They have been in the news over the years because of their use by bodybuilders and other athletes in sports in which muscular strength is important. *Focus on Basic Research* discusses the potential adverse effects of anabolic-androgenic steroids.

The **ovaries,** under the stimulatory influence of follicle-stimulating hormone (FSH), produce estrogens, steroid hor-

Neuroendocrine and Behavioral Effects of Anabolic-Androgenic Steroids in Humans

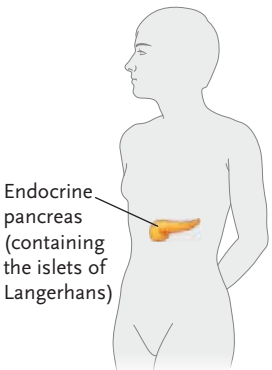
Anabolic-androgenic steroids (AAS) are synthetic derivatives of the natural steroid hormone testosterone. They were designed to have potent anabolic (tissue building) activity and low androgenic (masculinizing) activity in therapeutic doses.

AAS are used for treating conditions such as delayed puberty and subnormal growth in children, as well as for therapy in chronic conditions such as cancer, AIDS, severe burns, liver and kidney failure, and anemias. Because of their anabolic effects, which include an increase in muscle mass, strength, and endurance, as well as acceleration of recovery from injuries, AAS are used by some athletes such as bodybuilders, weight lifters, baseball players, and football players. This use is actually abuse, because the doses typically administered for these purposes are far higher than therapeutic doses. AAS abuse is significant: in the early 1990s, about 1 million Americans had used or were using AAS to increase strength, muscle mass, or athletic ability.

Are AAS harmful at high doses? When researchers gave rodents doses of AAS comparable to those associated with human AAS abuse, they observed significant increases in aggression, anxiety, and sexual behaviors. These changes occur as a result of alterations in the neurotransmitters and other signaling molecules associated with those behaviors. All of these changes have been hypothesized to occur in human AAS abusers.

To study the effect of high doses of AAS on the human endocrine system, R. C. Daly and colleagues at the National Institute of Mental Health in Bethesda, Maryland, administered the AAS methyltestosterone (MT) to normal (medication-free) human volunteers over a period of time in an in-patient clinic. The subjects were examined for the effects of MT on pituitary–gonadal, pituitary–thyroid, and pituitary–adrenal hormones, and the researchers attempted to correlate endocrine changes with psychological symptoms caused by the MT.

The researchers found, for instance, that high doses of MT caused a significant decrease in the levels of gonadotropins and gonadal steroid hormones in the blood. At the same time, thyroxine and TSH levels increased. No significant increases were seen in pituitary–adrenal hormones.



The decrease in testosterone levels correlated significantly with cognitive problems, such as increased distractibility and forgetfulness. The increase in thyroxine correlated significantly with a rise in aggressive behavior, notably anger, irritability, and violent feelings. There were no changes in activities associated with pituitary–adrenal hormones—energy, disturbed sleep, and sexual arousal—as was expected by the lack of change in those hormones.

In sum, behavioral changes associated with high doses of an AAS suggest that AAS-induced hormonal changes may well contribute to the adverse behavioral and mood changes that occur during AAS abuse.

© Cengage Learning 2014

mones that stimulate and control the development and maintenance of female reproductive systems. The principal estrogen is **estradiol,** which stimulates maturation of sex organs at puberty and the development of secondary sexual characteristics. Ovaries also produce progestins, principally **progesterone,** the steroid hormone that prepares and maintains the uterus for implantation of a fertilized egg and the subsequent growth and development of an embryo. The synthesis and secretion of progesterone by cells in the ovaries is controlled by the release of LH from the anterior pituitary, which in turn is controlled by the same GnRH as in males.

The Pancreatic Islet of Langerhans Hormones Regulate Glucose Metabolism

Most of the pancreas, a relatively large gland located just behind the stomach, forms an exocrine gland that secretes digestive enzymes into the small intestine (see Chapter 47). However, about 2% of the cells in the pancreas are endocrine cells that form the islets of Langerhans. Found in all vertebrates, the islets secrete the peptide hormones insulin and glucagon into the bloodstream.

Insulin and glucagon regulate the metabolism of fuel substances in the body. **Insulin,** secreted by *beta cells* in the islets, acts mainly on cells of skeletal muscles, liver cells, and adipose tissue (fat). (Brain cells do not require insulin for glucose uptake.) Insulin lowers circulating blood glucose, fatty acid, and amino acid levels and promotes their storage. That is, the actions of insulin include stimulation of glucose transport into cells, glycogen synthesis from glucose, uptake of fatty acids by adipose tissue cells, fat synthesis from fatty acids, and protein synthesis from amino acids. Insulin also inhibits glycogen degradation to glucose, fat degradation to fatty acids, and protein degradation to amino acids.

Glucagon, secreted by *alpha cells* in the islets, has effects opposite to those of insulin: it stimulates glycogen, fat, and protein degradation. Glucagon also promotes the use of amino acids and other noncarbohydrates as the input for glucose synthesis; this aspect of glucagon function operates during fasting. Negative feedback mechanisms that are keyed to the concentration of glucose in the blood control secretion of both insulin and glucagon to maintain glucose homeostasis **(Figure 42.11).**

Diabetes mellitus, a disease that afflicts more than 14 million people in the United States and at least 200 million people worldwide, results from problems with insulin production or action. The three classic diabetes symptoms are frequent urination, increased thirst (and consequently increased fluid intake), and increased glucose in the blood (hyperglycemia). Frequent urina-

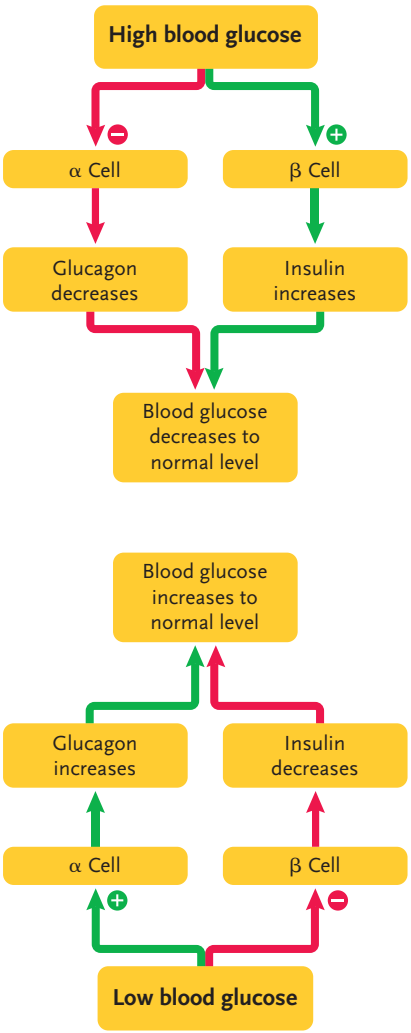

FIGURE 42.11 The action of insulin and glucagon in maintaining the concentration of blood glucose at an optimal level.
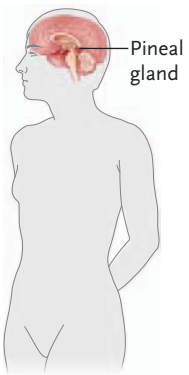
© Cengage Learning 2014



tion occurs because body cells are not stimulated to take up glucose, leading to abnormally high glucose concentration in the blood. Excretion of the excess glucose in the urine requires water to carry it, which causes increased fluid loss from the blood. Food intake is necessary to offset the negative energy balance resulting from the decreased glucose uptake by cells or else weight loss will occur. Two of these classic symptoms gave the disease its name: *diabetes* is derived from a Greek word meaning "siphon," referring to the frequent urination; and *mellitus,* a Latin word meaning "sweetened with honey," refers to the sweet taste of a diabetic's urine. (Before modern blood or urine tests were developed, physicians tasted a patient's urine to detect the disease.)

The disease occurs in two major forms called *type 1* and *type 2*. Type 1 diabetes, which occurs in about 10% of diabetics, results from insufficient insulin secretion by the pancreas. This type of diabetes is usually caused by an autoimmune reaction that destroys pancreatic beta cells. To survive, type 1 diabetics must receive regular insulin injections (typically, a genetically engineered human insulin called Humulin); careful dieting and exercise also have beneficial effects, because active skeletal muscles do not require insulin to take up and utilize glucose.

In type 2 diabetes, insulin is usually secreted at or above normal levels, but the target cells of affected people have significantly reduced responsiveness to the hormone compared with the cells of normal people. About 90% of patients in the developed world with type 2 diabetes are obese. A genetic predisposition can also be a factor. Most affected people can lead a normal life by controlling their diet and weight, exercising, and taking drugs that enhance insulin action or secretion.

Diabetes has long-term effects on the body. Its cells, unable to utilize glucose as an energy source, start breaking down proteins and fats to generate energy. The protein breakdown weakens blood vessels throughout the body, particularly in the arms and legs and in critical regions such as the kidneys and retina of the eye. The circulation becomes so poor that tissues degenerate in the arms, legs, and feet. At advanced stages of the disease, bleeding in the retina causes blindness. The breakdown of circulation in the kidneys can lead to kidney failure. In addition, in type 1 diabetes, acidic products of fat breakdown (ketones) are produced in abnormally high quantities and accumulate in the blood. The resulting lowering of blood pH can disrupt heart and brain function, leading to coma and death if the disease is untreated.

The Pineal Gland Regulates Some Biological Rhythms

The **pineal gland** is found at different locations in the brains of vertebrates—for example, in mammals, it is at roughly the center of the brain, while in birds and reptiles, it is on the surface of the brain just under the skull. The pineal gland regulates some biological rhythms.

The earliest vertebrates had a third, light-sensitive eye at the top of the head, and some species, such as lizards and tuataras (New Zealand reptiles), still have an eyelike structure in this location. In most vertebrates, the third eye became modified into a pineal gland, which in many groups retains some degree of photosensitivity. In mammals, it is too deeply buried in the brain to be affected directly by light; nonetheless, specialized photoreceptors in the eyes make connections to the pineal gland.

In mammals, the pineal gland secretes a peptide hormone, **melatonin,** that helps to maintain daily biorhythms. Secretion of melatonin is regulated by an inhibitory pathway. Light hitting the eyes generates signals that inhibit melatonin secretion; consequently, the hormone is secreted most actively during periods of darkness. Melatonin targets a part of the hypothalamus called the *suprachiasmatic nucleus,* which is the primary biological clock coordinating body activity to a daily cycle. The nightly release of melatonin may help synchronize the biological clock with daily cycles of light and darkness. The physical and mental discomfort associated with jet lag may reflect the time required for melatonin secretion to reset a traveler's daily biological clock to match the period of daylight in a new time zone.

Melatonin also plays a role in other vertebrates. In some fishes, amphibians, and reptiles, melatonin and other hor-

1. What effect does parathyroid hormone have on the body?
2. What hormones are secreted by the adrenal medulla, and what are their functions?
3. What are the two types of hormones secreted by the adrenal cortex, and what are their functions?
4. To what molecular class of hormones do estradiol and progesterone belong, and where do they act in the body?

THINK OUTSIDE THE BOOK

Individuals who are allergic to bee stings are at risk for anaphylactic shock. Physicians recommend that such individuals carry an EpiPen, a container of epinephrine for immediate injection in case of a sting. Individually or collaboratively, use the Internet or research literature to determine what anaphylactic shock is and how it develops, and how an epinephrine injection is an effective treatment.

42.5 Endocrine Systems in Invertebrates

In even the simplest animals, such as the cnidarian *Hydra,* hormones produced by neurosecretory neurons control reproduction, growth, and development of some body features. In annelids, arthropods, and mollusks, endocrine cells and glands produce hormones that regulate reproduction, water balance, heart rate, and sugar levels.

Some hormones occur in related forms in invertebrates and vertebrates. For example, fruit flies, mollusks, and humans have insulin-like hormones and receptors, even though molecular studies suggest that their last common ancestor existed more than 800 million years ago. Both invertebrates and vertebrates secrete peptide and steroid hormones, but most of the hormones' structures differ between the two groups, and therefore most have no effect when injected into members of the other group. However, the reaction pathways stimulated by the hormones are the same in both groups, suggesting that these regulatory mechanisms appeared very early in animal evolution.

Hormones have been studied in detail in only a few invertebrate groups, with the most extensive studies focusing on regulation of metamorphosis in insects. Butterflies, moths, and flies undergo the most dramatic changes as they mature into adults. They hatch from the egg as a caterpillar-like *larva.* During the larval stage, growth is accompanied by one or more *molts,* in which an old exoskeleton is shed and a new one forms. The insect then enters a typically nonmotile stage, the *pupa,* in which the body forms a thick, resistant coating, and finally it transforms into an adult.

Three major hormones regulate molting and metamorphosis in insects: **prothoracicotropic hormone (PTTH),** a peptide hormone secreted by neurosecretory neurons in the brain; **ecdysone** (*ekdysis* = getting out), a steroid hormone secreted by the *prothoracic glands;* and **juvenile hormone (JH),** a terpenoid (a type of unsaturated hydrocarbon) secreted by the *corpora allata,* a pair of glands just behind the brain **(Figure 42.12).** The outcome of the molt depends on the level of JH. If it is high, the molt produces a larger larva; if it is low, the molt leads to pupation and the emergence of the adult.

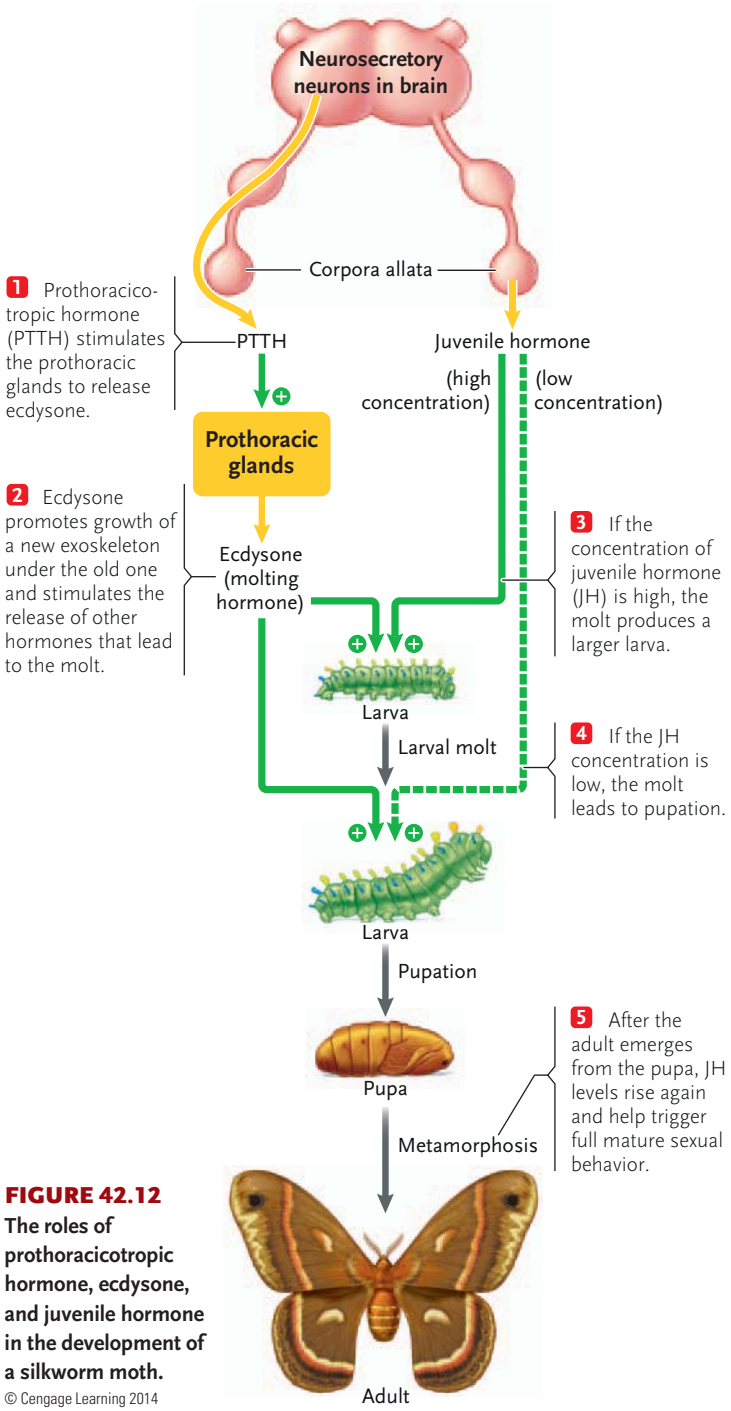

FIGURE 42.12
The roles of prothoracicotropic hormone, ecdysone, and juvenile hormone in the development of a silkworm moth.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Hormones that control molting have also been detected in crustaceans, including lobsters, crabs, and crayfish. Before growth reaches the stage at which the exoskeleton is shed, **molt-inhibiting hormone (MIH),** a peptide neurohormone secreted by a gland in the eye stalks, inhibits ecdysone secretion **(Figure 42.13).** As body size increases to the point requiring a molt, MIH secretion is inhibited, ecdysone secretion increases, and the molt is initiated.

In the next chapter, we discuss the structure and functions of muscles, and their interactions with the skeletal system to cause movement. Muscle function depends primarily on the action of the nervous system, but the endocrine system plays a role in the control of smooth muscle contraction.

UNANSWERED QUESTIONS

What is the role of estrogens in breast cancer?

Breast cancer is the most common cancer in Western women, with over 230,000 new cases diagnosed in the United States in 2011. The etiology of breast cancer remains largely unknown. A number of risk factors have been identified, including family history and reproductive factors; however, ~80% of newly diagnosed women have no known risk factors. For example, women with an inherited mutation in the *BRCA1* gene have a 70% to 80% likelihood of developing breast cancer during their lifetime, yet only one-third of women with a strong family history of breast cancer carry a *BRCA1* mutation or have some other known mutation that would predispose them to cancer. The failure in identifying strong risk factors has led to an absence of specific targets for breast cancer prevention.

Currently, the only gene that has been successfully targeted for breast cancer prevention is the estrogen receptor (ER) gene. Estrogen induces cell proliferation in the breast and exerts its effects through binding to the ER, leading to activation or inhibition of several downstream signaling targets. ER activity can be inhibited by tamoxifen and other antiestrogens, or by bilateral ovariectomy (removal of both ovaries), which lowers circulating estrogen levels. The link between high lifetime exposure to estrogens and increased breast cancer risk has been established clearly through observational studies in women.

Paradoxically, estrogens also can prevent breast cancer or inhibit the growth of antiestrogen resistant tumors, likely through their ability to induce differentiation and apoptosis. In fact, the synthetic estrogen diethylstilbestrol (DES) was prescribed for the treatment of breast cancer until it was replaced with antiestrogens in the early 1980s. Further, an exposure to estradiol, as single agent hormone replacement therapy, prevents breast cancer and its metastasis. The seemingly dual effects of estrogen may reflect the critical role that timing of exposure appears to play in affecting breast cancer risk.

How does the timing of estrogenic exposures affect breast cancer risk?

Millions of pregnant women in the 1940s to 1970s took DES in the U.S. and Europe, initially to prevent miscarriage but also to aid various pregnancy-related conditions, such as morning sickness. It was subsequently proven ineffective and even dangerous. Most notable, young daughters exposed to DES *in utero* exhibited an unusually high incidence of clear cell vaginal adenocarcinoma (a malignant tumor), and the practice of treating pregnant women with DES stopped. The DES daughters have now reached the age when breast cancer is commonly detected (older than 40 years old), and the findings indicate that these daughters exhibit two times higher risk of developing breast cancer as well. Risk also is increased in mothers themselves.

Research from my laboratory at Georgetown University, using preclinical models of breast cancer, shows that maternal exposure to estrogenic dietary compounds during pregnancy, such as high fat diet, increases mammary cancer risk among female offspring. This increase is not limited to daughters but also is seen in granddaughters and great granddaughters, and mothers, without any further intervening exposures. Our studies suggest that these multigenerational effects are inherited via permanent changes in the epigenome (the set of epigenetic modifications in the genome), rather than through genetic changes, such as mutations. Genes which are epigenetically silenced in the mammary tissue from generation to generation following maternal dietary exposures during pregnancy include those that regulate proliferation of progenitor cells (they are daughters of stem cells) and their differentiation. The increased methylation of these genes, in turn, is proposed to be a hallmark of increased breast cancer susceptibility. Importantly, epigenetic changes are in principle reversible by compounds which demethylate silenced genes, and many such compounds are currently available and used to treat some

cancers. Our preclinical studies suggest that these same compounds may also prevent *in utero* estrogen-exposed animals from developing mammary cancer.

The period when estrogens appear to be protective is around puberty, when the breast begins to grow. Pregnancy is characterized by 50- to 100-fold increase in circulating estrogen levels, and women who had their first child before age 20 have half the risk of developing breast cancer than women who were over 30 when their first child was born. Other estrogenic exposures at young adulthood also reduce lifetime breast cancer risk. Women who consumed high levels of soy foods during childhood, which contain the estrogenic isoflavone genistein, have a reduced risk of developing breast cancer. Similar findings have been obtained in preclinical animal models. Work done in my laboratory is investigating whether the protective effect of childhood genistein/soy intake is mediated by epigenetic changes that involve genes which may protect mammary epithelial cells from malignant transformation.

THINK LIKE A SCIENTIST What are the benefits and weaknesses of using *in vitro* (tissue-culture based) and *in vivo* (animal model) approaches versus performing human studies to understand the role of estrogen in breast cancer etiology.

Leena Hilakivi-Clarke

Leena Hilakivi-Clarke is a professor of Oncology at Georgetown University in Washington D.C. Her research involves understanding why timing of estrogenic exposures, including those originating from diet, determines whether they increase, reduce, or have no effect on breast cancer risk and risk of recurrence of this disease. Learn more about her research from http://clarkelabs.georgetown.edu/index.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

42.1 Hormones and Their Secretion

- Hormones are substances secreted by cells that control the activities of cells elsewhere in the body. The cells that respond to a hormone are its target cells. The best-known hormones are secreted by the endocrine system.
- The endocrine system includes four major types of cell signaling: classical endocrine signaling, in which endocrine glands secrete hormones; neuroendocrine signaling, in which neurosecretory neurons release neurohormones into the circulatory system; paracrine regulation, in which cells release local regulators that diffuse through the ECF to regulate nearby cells; and autocrine regulation, in which cells release local regulators that regulate the same cells that produced them (Figure 42.1).
- Most hormones and local regulators fall into one of four molecular classes: amines, peptides, steroids, and fatty acids.
- Many hormones are controlled by negative feedback mechanisms (Figure 42.2).

42.2 Mechanisms of Hormone Action

- Hormones typically are effective in very low concentrations in the body fluids because of amplification.
- Hydrophilic hormones bind to receptor proteins embedded in the plasma membrane, activating them. The activated receptors transmit a signal through the plasma membrane, triggering signal transduction pathways that cause a cellular response. Hydrophobic hormones bind to receptors in the cytoplasm or nucleus, activating them. The activated receptors control the expression of specific genes, the products of which cause the cellular response (Figure 42.3).
- As a result of the types of receptors they have, target cells may respond to more than one hormone, or they may respond differently to the same hormone.
- The major endocrine cells and glands of vertebrates are the hypothalamus, pituitary gland, thyroid gland, parathyroid glands, adrenal medulla, adrenal cortex, testes, ovaries, islets of Langerhans of the endocrine pancreas, and pineal gland. Hormones are also secreted by endocrine cells in the stomach and intestine, thymus gland, kidneys, and heart. Most body cells are capable of releasing prostaglandins (Figure 42.6).

Animation: Major human endocrine glands

Animation: The Organs of the Endocrine System

Animation: Endocrine System

42.3 The Hypothalamus and Pituitary

- The hypothalamus and pituitary together regulate many other endocrine cells and glands in the body (Figure 42.7).
- The hypothalamus produces hormones (releasing hormones and inhibiting hormones) that control the secretion of eight hormones by the anterior pituitary: prolactin (PRL), growth hormone (GH), thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), melanocyte-stimulating hormone (MSH), and endorphins.
- The posterior pituitary secretes antidiuretic hormone (ADH), which regulates body water balance, and oxytocin, which stimulates the contraction of smooth muscle in the uterus as a part of childbirth and triggers milk release from the mammary glands during suckling of the young.

Animation: Anterior pituitary function

42.4 Other Major Endocrine Glands of Vertebrates

- The thyroid gland secretes the thyroid hormones and, in mammals, calcitonin. The thyroid hormones stimulate the oxidation of carbohydrates and lipids, and coordinate with growth hormone to stimulate body growth and development. Calcitonin lowers the Ca^{2+} level in the blood by inhibiting the release of Ca^{2+} from bone. In amphibians, such as the frog, thyroid hormones trigger metamorphosis (Figure 42.8).
- The parathyroid glands secrete parathyroid hormone, which stimulates bone cells to release Ca^{2+} into the blood. PTH also stimulates the activation of vitamin D, which promotes Ca^{2+} absorption into the blood from the small intestine (Figure 42.9).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The adrenal medulla secretes epinephrine and norepinephrine, which reinforce the sympathetic nervous system in responding to stress. The adrenal cortex secretes glucocorticoids, which help maintain glucose at normal levels in the blood, and mineralocorticoids, which regulate Na^+ balance and ECF volume. The adrenal cortex also secretes small amounts of androgens (Figure 42.10).
- The gonadal sex hormones—androgens, estrogen, and progestins—play a major role in regulating the development of reproductive systems, sexual characteristics, and mating behavior.
- The islet of Langerhans cells of the endocrine pancreas secrete insulin and glucagon, which together regulate the concentration of fuel substances in the blood. Insulin lowers the concentration of glucose in the blood and inhibits the conversion of noncarbohydrate molecules into glucose. Glucagon raises blood glucose by stimulating glycogen, fat, and protein degradation (Figure 42.11).
- The pineal gland secretes melatonin, which interacts with the hypothalamus to set the body's daily rhythms.

Animation: Parathyroid hormone action

Animation: Hormones and glucose metabolism

42.5 Endocrine Systems in Invertebrates

- Hormones control development and function of the gonads, manage salt and water balance in the body fluids, and control molting in insects and crustaceans.
- Three major hormones—prothoracicotropic hormone (PTTH), ecdysone, and juvenile hormone (JH)—control molting and metamorphosis in insects. Hormones that control molting are also present in crustaceans (Figures 42.12 and 42.13).

UNDERSTAND & APPLY

Test Your Knowledge

1. Amine hormones are usually:
   a. hydrophilic when secreted by the thyroid gland.
   b. based on tyrosine.
   c. paracrine but not autocrine.
   d. not transported by the blood.
   e. repelled by the plasma membrane.
2. Prostaglandins would be best described as inducers of:
   a. male and female characteristics.
   b. cell division.
   c. nerve transmission.
   d. smooth muscle contractions.
   e. cell differentiation.
3. When the concentration of thyroid hormone in the blood increases, it:
   a. inhibits TSH secretion by the pituitary.
   b. stimulates TRH secretion by the hypothalamus.
   c. stimulates the pituitary to secrete TRH.
   d. stimulates the pituitary to secrete TSH.
   e. activates a positive feedback loop.
4. Which of the following statements about endocrine targeting and reception is correct?
   a. The idea that one hormone affects one type of tissue is illustrated when epinephrine binds to smooth muscle cells in blood vessels as well as to beta cells in heart muscle.
   b. The idea that one hormone affects one type of tissue is illustrated when epinephrine cannot activate both the receptors on liver cells and the beta receptors of heart muscle.
   c. The idea that a target cell can respond to more than one hormone is illustrated by a vertebrate liver cell responding to insulin and glucagon.
   d. The idea that a minute concentration of hormone can cause widespread effects demonstrates the specificity of cells for certain hormones.
   e. The idea that the response to a hormone is the same among different target cells is shown when different liver cells are activated by insulin.
5. The posterior pituitary secretes:
   a. hormones that control the hypothalamus.
   b. IGF, which simulates cell division and protein synthesis.
   c. ADH, which increases water absorption in the kidneys.
   d. oxytocin, which controls egg and sperm development.
   e. prolactin, which stimulates milk synthesis.
6. Blood levels of calcium are regulated directly by:
   a. insulin synthesized by the alpha cells of the pancreas.
   b. PTH made by the pituitary.
   c. vitamin D activated in the liver.
   d. prolactin synthesized by the anterior pituitary.
   e. calcitonin secreted by specialized thyroid cells.
7. If the human body is stressed, glucocorticoids:
   a. promote the breakdown of proteins in the muscles and bones.
   b. increase the amount of sodium reabsorbed from urine in the kidneys.
   c. decrease potassium secretion from the kidneys.
   d. decrease glucose uptake by cells in the nervous system.
   e. inhibit the synthesis of glucose from noncarbohydrate sources.
8. When blood glucose rises:
   a. alpha cells increase glucagon secretion.
   b. beta cells increase insulin secretion.
   c. urination decreases in a person with type 1 diabetes who has not recently received an insulin injection.
   d. glucagon stimulates the breakdown of amino acids into glycogen.
   e. target cells decrease their insulin receptors.
9. In mammals:
   a. the suprachiasmatic nucleus of the pineal gland controls both male and female reproductive systems.
   b. estradiol is produced by the hypothalamus to control ovulation.
   c. melatonin controls anabolic steroid production.
   d. GnRH stimulates LH to control testosterone production.
   e. progesterone increases the secretion of LH from the posterior pituitary.
10. Insect development is regulated by:
    a. ecdysone, a peptide secreted by the brain.
    b. juvenile hormone, a terpenoid secreted by the corpora allata near the brain.
    c. molt-inhibiting hormone, a steroid secreted by the prothoracic glands.
    d. prothoracicotropic hormone, a steroid secreted by the hypothalamus.
    e. melatonin, a peptide secreted by the brain in the larval stage.

Discuss the Concepts

1. A physician sees a patient whose symptoms include sluggishness, depression, and intolerance to cold. What disorder do these symptoms suggest?
2. A 20-year-old woman with a malignant brain tumor has her pineal gland removed. What kinds of side effects might this loss have?
3. In integrated pest management, a farmer uses a variety of tools to combat unwanted insects. These include applications of either hormones or hormone-inhibiting compounds to prevent insects from reproducing successfully. How might each of these hormone-based approaches disrupt reproduction?

Design an Experiment

The Environmental Protection Agency (EPA) defines *endocrine disruptors* as chemical substances that can "interfere with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body that are responsible for the maintenance of homeostasis (normal cell metabolism), reproduction, development, and/or behavior." The chemicals, sometimes called environmental estrogens, come from both natural and human-made sources. A simple hypothesis is that endocrine disruptors act by mimicking hormones in the body. Many endocrine disruptors affect sex hormone function and, therefore, reproduction.

Examples of endocrine disruptors are the synthetic chemicals DDT (a pesticide), dioxins, and natural chemicals such as phytoestrogens (estrogen-like molecules in plants), which are found in high levels in soybeans, carrots, oats, onions, beer, and coffee.

Design an experiment to investigate whether a new synthetic chemical (pick your own interesting scenario) is an endocrine disruptor. (*Hint:* You probably want to work with a model organism.)

Interpret the Data

Researchers measured prolactin and growth hormone in the blood plasma of six subjects at regular intervals over a 24-hour period. The investigators were interested in determining if the levels of these two hormones cycle over a 24-hour period. The **Figure** presents the results of their experiments, with the *y* axis values showing the amount of each hormone expressed as a percentage of the 24-hour mean value, and each point showing the average of the six subjects' levels.

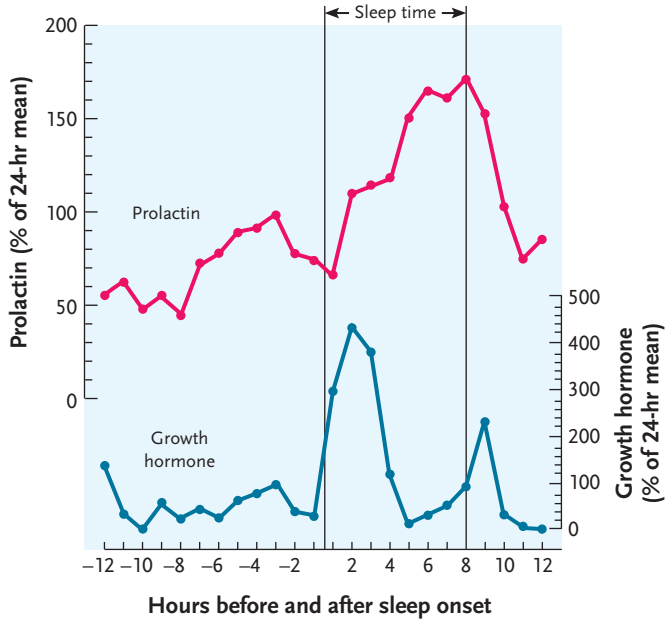

FIGURE **Mean concentrations of prolactin and growth hormone in plasma, averaged for six subjects and expressed as a percentage of the average concentrations measured for the 24-hour period.**

From J. F. Sassin et al. 1972. Human prolactin: 24-hour pattern with increased release during sleep. *Science* 177:1205–1207. Reprinted with permission from AAAS.

1. How did the level of growth hormone change over the 24-hour period and, in particular, how did it relate to the sleep period?
2. How did the level of prolactin change over the 24-hour period and, in particular, how did it relate to the sleep period?
3. Is there any consistent relationship between the patterns of prolactin and growth hormone in the plasma in the 24-hour period?
4. Do the results support the hypothesis that the changes in prolactin level over a 24-hour period are associated with the sleep–wake cycle?

Source: J. F. Sassin et al. 1972. Human prolactin: 24-hour pattern with increased release during sleep. *Science* 177:1205–1207.

Movement of vertebrates such as these dolphins occurs as a result of contractions and relaxations of skeletal muscles. When stimulated by the nervous system, actin filaments in the muscles slide over myosin filaments to cause muscle contractions.

STUDY OUTLINE

43.1 Vertebrate Skeletal Muscle: Structure and Function

43.2 Skeletal Systems

43.3 Vertebrate Movement: The Interactions between Muscles and Bones

Muscles, Bones, and Body Movements

Why it matters . . . A Mexican leaf frog *(Pachymedusa dacnicolor)* detects an approaching cricket. In a total of 260 msec—about one quarter of a second—the frog lunges forward at just the right moment, thrusts out its sticky tongue, and captures the prey. How does the frog move so swiftly, and so surely?

As its prey draws near, neuronal signals travel from the frog's brain to the muscles that extend the frog's hind legs, causing those muscles to contract and propel the frog forward on its forelimbs toward the cricket. Within 50 msec after the jump begins, other signals contract the muscles of the lower jaw, opening the mouth. Then, a muscle on the upper surface of the tongue contracts, which raises the tongue and flips it out of the mouth **(Figure 43.1).** Within 80 msec after the lunge begins, the tip of the frog's tongue contacts the cricket. The tongue, with the cricket, folds back into the frog's mouth, aided by contraction of a muscle on the bottom of the tongue.

In Section 38.2 you learned about the three types of muscle tissue: skeletal, cardiac, and smooth. *Skeletal muscle* is so named because most muscles of this type are attached by tendons to the skeleton of vertebrates. *Cardiac muscle* is the contractile muscle of the heart, and *smooth muscle* is found in the walls of tubes and cavities in the body, including blood vessels and intestines. In this chapter we describe the structure and function of skeletal muscles, the skeletal systems of invertebrates and vertebrates, and how muscles bring about movement.

Kiisa Nishikawa/Northern Arizona University

FIGURE 43.1 A Mexican leaf frog *(Pachymedusa dacnicolor)* capturing a grasshopper. The frog's movements were captured using a high-speed video camera linked to a millisecond timer, with a grid in the background that allowed precise measurement of the distances body parts traveled during the capture.

43.1 Vertebrate Skeletal Muscle: Structure and Function

Vertebrate **skeletal muscles** connect to bones of the skeleton. The cells forming skeletal muscles are typically long and cylindrical and contain many nuclei (shown in Figure 38.5A). Skeletal muscle is controlled by the somatic nervous system.

Most skeletal muscles in humans and other vertebrates are attached at both ends to bones of the skeleton and across a joint. (Some, such as those that move the lips, are attached to other muscles or connective tissues under skin.) Depending on its points of attachment, contraction of a single skeletal muscle may extend or flex body parts, or may rotate one body part with respect to another. The human body has more than 600 skeletal muscles, ranging in size from the small muscles that move the eyeballs to the large muscles that move the legs.

Skeletal muscles are attached to bones by cords of connective tissue called *tendons* (see Section 38.2). Tendons vary in length from a few millimeters to some, such as those that connect the muscles of the forearm to the bones of the fingers, that are 20 to 30 cm long.

The Striated Appearance of Skeletal Muscle Fibers Results from a Highly Organized Internal Structure

A skeletal muscle consists of bundles of elongated, cylindrical cells called **muscle fibers** that are 10 to 100 mm in diameter and run the entire length of the muscle **(Figure 43.2).** Muscle fibers are multinucleate—they contain many nuclei—reflecting their development by fusion of smaller cells. Some very small muscles, such as some of the muscles of the face, contain only a few hundred muscle fibers; others, such as the larger leg muscles, contain hundreds of thousands. In both cases, the muscle fibers are held in parallel bundles by sheaths of connective tissue that surround them in the muscle and merge with the tendons that connect muscles to bones or other structures. Muscle fibers are supplied with nutrients and oxygen by an extensive network of blood vessels that penetrates the muscle tissue.

Muscle fibers are packed with **myofibrils,** cylindrical contractile elements about 1 μm in diameter that run lengthwise inside the cells. Each myofibril consists of a regular arrangement of **thick filaments** (13–18 nm in diameter) and **thin filaments** (5–8 nm in diameter) (see Figure 43.2). The thick and thin filaments alternate with one another in a packed set.

The thick filaments are parallel bundles of myosin molecules. Each myosin molecule consists of two protein subunits that together form a *head* connected to a long double helix forming a *tail.* The head is bent toward the adjacent thin filament to form a *crossbridge.* In vertebrates, each thick filament contains some 200 to 300 myosin molecules and forms as many crossbridges. The thin filaments consist mostly of two linear chains of actin molecules twisted into a double helix, which creates a groove running the length of the molecule. Bound to

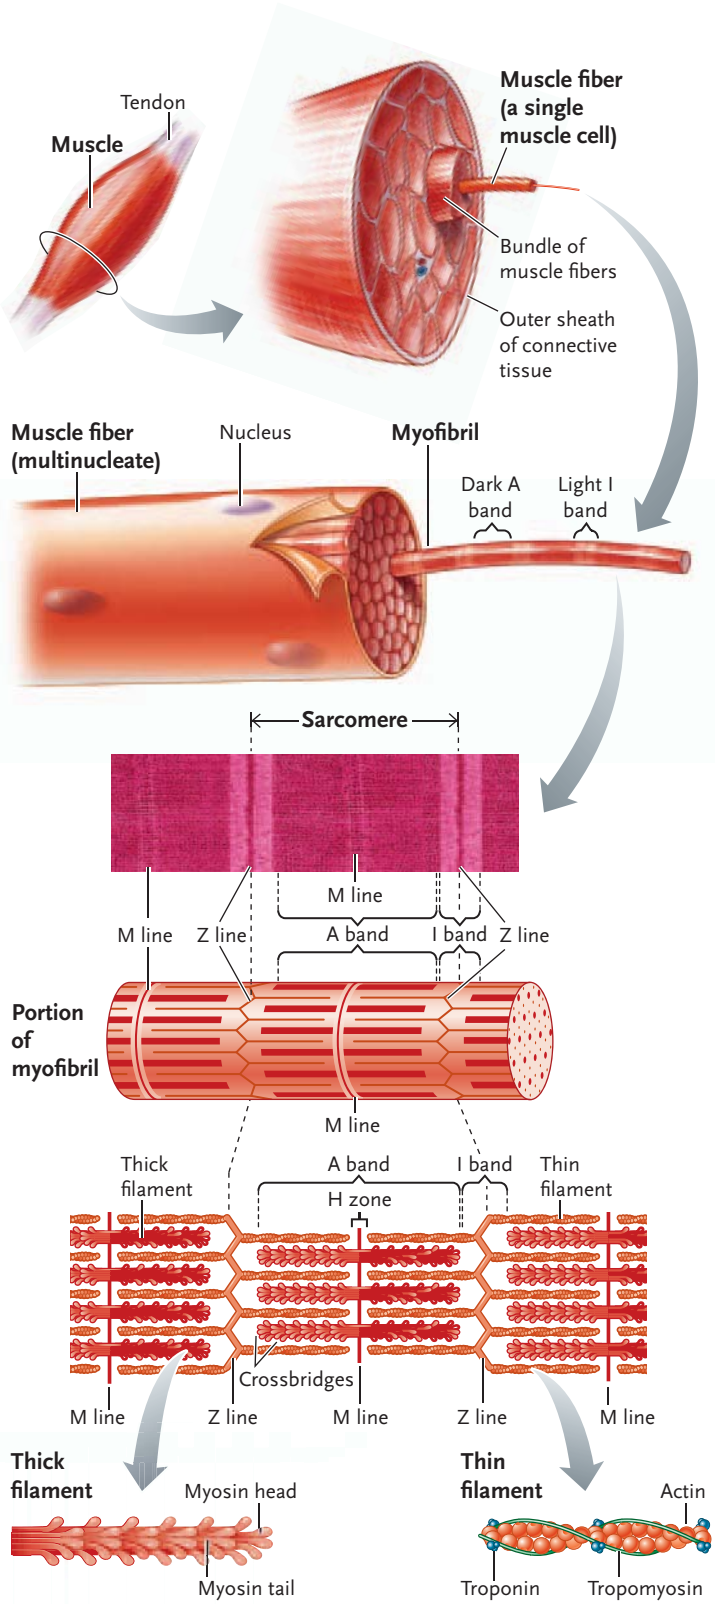

FIGURE 43.2 Skeletal muscle structure. Muscles are composed of bundles of multinucleate cells called muscle fibers; within each muscle fiber are longitudinal bundles of myofibrils. The unit of contraction within a myofibril, the sarcomere, consists of overlapping myosin thick filaments and actin thin filaments. The myosin molecules in the thick filaments each consist of two subunits organized into a head and a double-helical tail. The actin subunits in the thin filaments form twisted, double helices, with tropomyosin molecules arranged head-to-tail in the groove of the helix and troponin bound to the tropomyosin at intervals along the thin filaments.

the actin are *tropomyosin* and *troponin* proteins. Tropomyosin molecules are elongated fibrous proteins that are organized end to end next to the groove of the actin double helix. Troponin is a three-subunit globular protein that binds to tropomyosin at intervals along the thin filaments.

The arrangement of thick and thin filaments forms a pattern of alternating dark and light bands, giving skeletal muscle a striated appearance under the microscope (see Figure 43.2). The dark bands, called *A bands,* consist of stacked thick filaments along with the parts of thin filaments that overlap both ends. The lighter-appearing middle region of an A band, which contains only thick filaments, is the *H zone.* In the center of the H zone is a disc of proteins called the *M line,* which holds the stack of thick filaments together. The light bands, called *I bands,* consist of the parts of the thin filaments not in the A band. In the center of each I band is a thin *Z line,* a disc to which the thin filaments are anchored. The region between two adjacent Z lines is a **sarcomere** (*sarco-* = flesh, *meros* = segment); sarcomeres are the basic units of contraction in a myofibril.

At each junction of an A band and an I band, the plasma membrane folds into the muscle fiber to form a **T (transverse) tubule (Figure 43.3).** Encircling the sarcomeres is the **sarcoplasmic reticulum,** a complex system of vesicles modified from the smooth endoplasmic reticulum. Segments of the sarcoplasmic reticulum are wrapped around each A band and I band and are separated from the T tubules in those regions by small gaps.

An axon of an efferent neuron leads to each muscle fiber. The axon terminal makes a single synapse with a muscle fiber called a **neuromuscular junction** (see Figure 43.3). The neuromuscular junction, T tubules, and sarcoplasmic reticulum are key components in the pathway for stimulating skeletal muscle contraction.

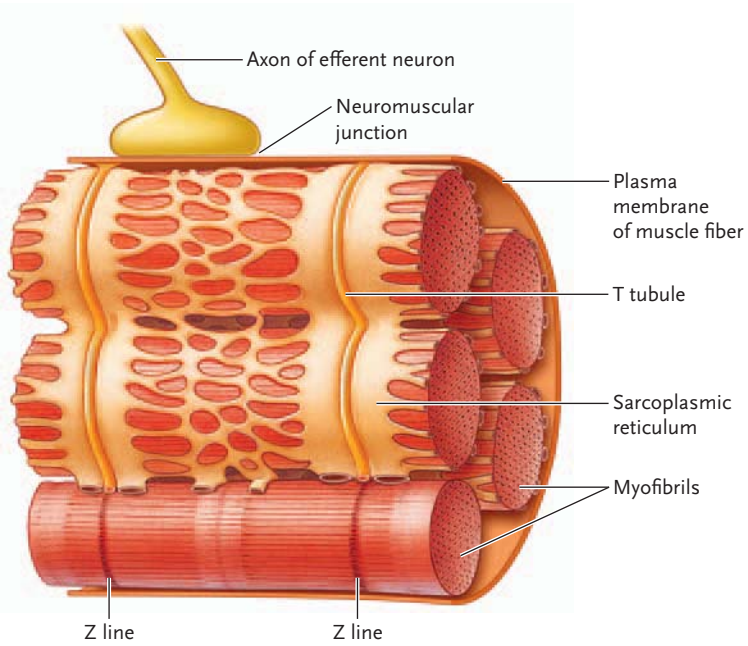

FIGURE 43.3 Components in the pathway for the stimulation of skeletal muscle contraction by neural signals. T (transverse) tubules are infoldings of the plasma membrane into the muscle fiber originating at each A band–I band junction in a sarcomere. The sarcoplasmic reticulum encircles the sarcomeres (it is cut away from the bottom myofibril in the figure), and segments of it end in close proximity to the T tubules.

During Muscle Contraction, Thin Filaments on Each Side of a Sarcomere Slide over Thick Filaments

The precise control of body motions depends on an equally precise control of muscle contraction by a signaling pathway that starts with action potentials traveling down an efferent neuron. These neural signals carry information from nerves to muscle fibers and trigger contraction.

MECHANISM OF MUSCLE FIBER CONTRACTION Contraction of a muscle fiber involves a process in which the thin filaments on each side of a sarcomere slide over the thick filaments toward the center of the A band, which brings the Z lines closer together, shortening the sarcomeres and contracting the muscle **(Figure 43.4).** This **sliding filament model** of muscle contraction depends on dynamic interactions between actin and myosin proteins in the two filament types. **Figure 43.5** presents a molecular model showing how an action potential arriving at the neuromuscular junction leads to the cyclic actin–myosin interactions that are the basis for muscle fiber contraction. That is, like neurons, skeletal muscle fibers are *excitable,* meaning that the electrical potential of their plasma membrane can change in response to a stimulus. The action potential leads to an increase in the concentration of Ca^{2+} in the cytosol of the muscle fiber (steps 1–3). The increase in Ca^{2+} triggers the crossbridge cycle, in which repeated power strokes pull the actin thin filament over the myosin thick filament (steps 4–6). When action potentials stop arriving at the neuromuscular junction, the muscle fiber stops contracting and relaxes (step 7).

Crossbridge cycles based on actin and myosin power movements in all living organisms, from cytoplasmic streaming in plant cells and amoebae to muscle contractions in animals.

Although the force produced by a single myosin crossbridge is comparatively small, it is multiplied by the hundreds of crossbridges acting in a single thick filament, and by the billions of thin filaments sliding in a contracting sarcomere. The force, multiplied further by the many sarcomeres and myofibrils in a muscle fiber, is transmitted to the plasma membrane of a muscle fiber by the attachment of myofibrils to elements of the cytoskeleton. From the plasma membrane, it is transmitted to bones and other body parts by the connective tissue sheaths surrounding the muscle fibers and by the tendons.

Several gene mutations affecting muscle and nerve tissues interrupt the transmission of force and cause severe disabilities. Duchenne muscular dystrophy (DMD), for example, is caused by a mutation that weakens the cytoskeleton of the muscle fiber, causing the cells to rupture when contractile forces are generated.

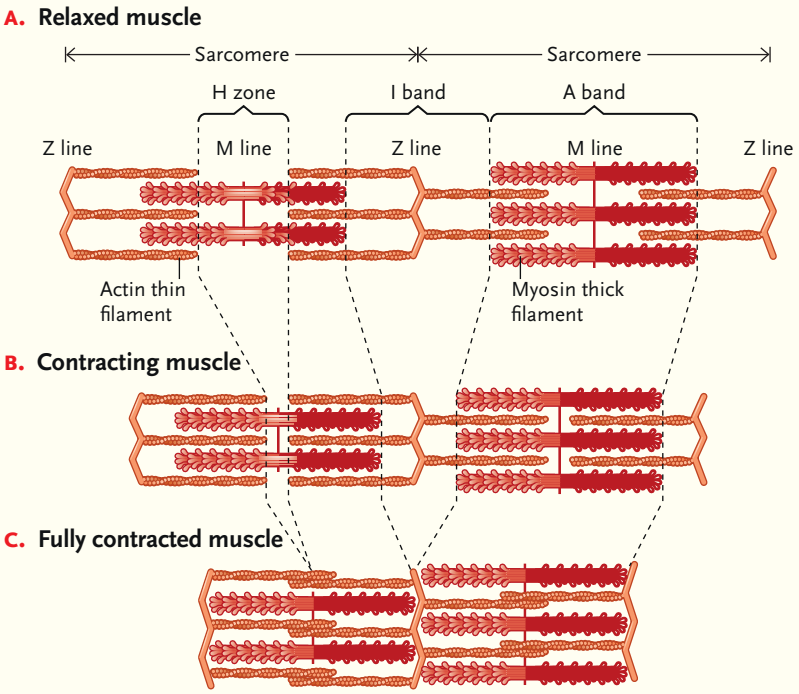

FIGURE 43.4 **Experimental Research**

The Sliding Filament Model of Muscle Contraction

Question: What is the mechanism of muscle contraction?

Experiment: In 1954, Andrew Huxley and Ralph Niedergerke of the University of Cambridge, UK, and Hugh Huxley and Jean Hanson of the Massachusetts Institute of Technology used high-resolution light microscopy techniques to study how the actin and myosin arrangements changed during muscle contraction.

Results: Their micrographs provided important evidence for the sliding of filaments as the muscle went from being relaxed to fully contracted **(Figure).** The key observations were that: (1) the I band and the H zone each decrease in length in proportion to the shortening of the sarcomere; and (2) the A band remains constant in length.

Conclusion: This classic piece of research supported the sliding filament model in which muscle shortening (sarcomere shortening) results from increased overlap of thin and thick filaments not from any change in length of those filaments. It set the path for research into the molecular basis of muscle contraction.

THINK LIKE A SCIENTIST Earlier research by other scientists had reported that myosin has ATPase activity. Interpret that result in terms of the sliding filament model.

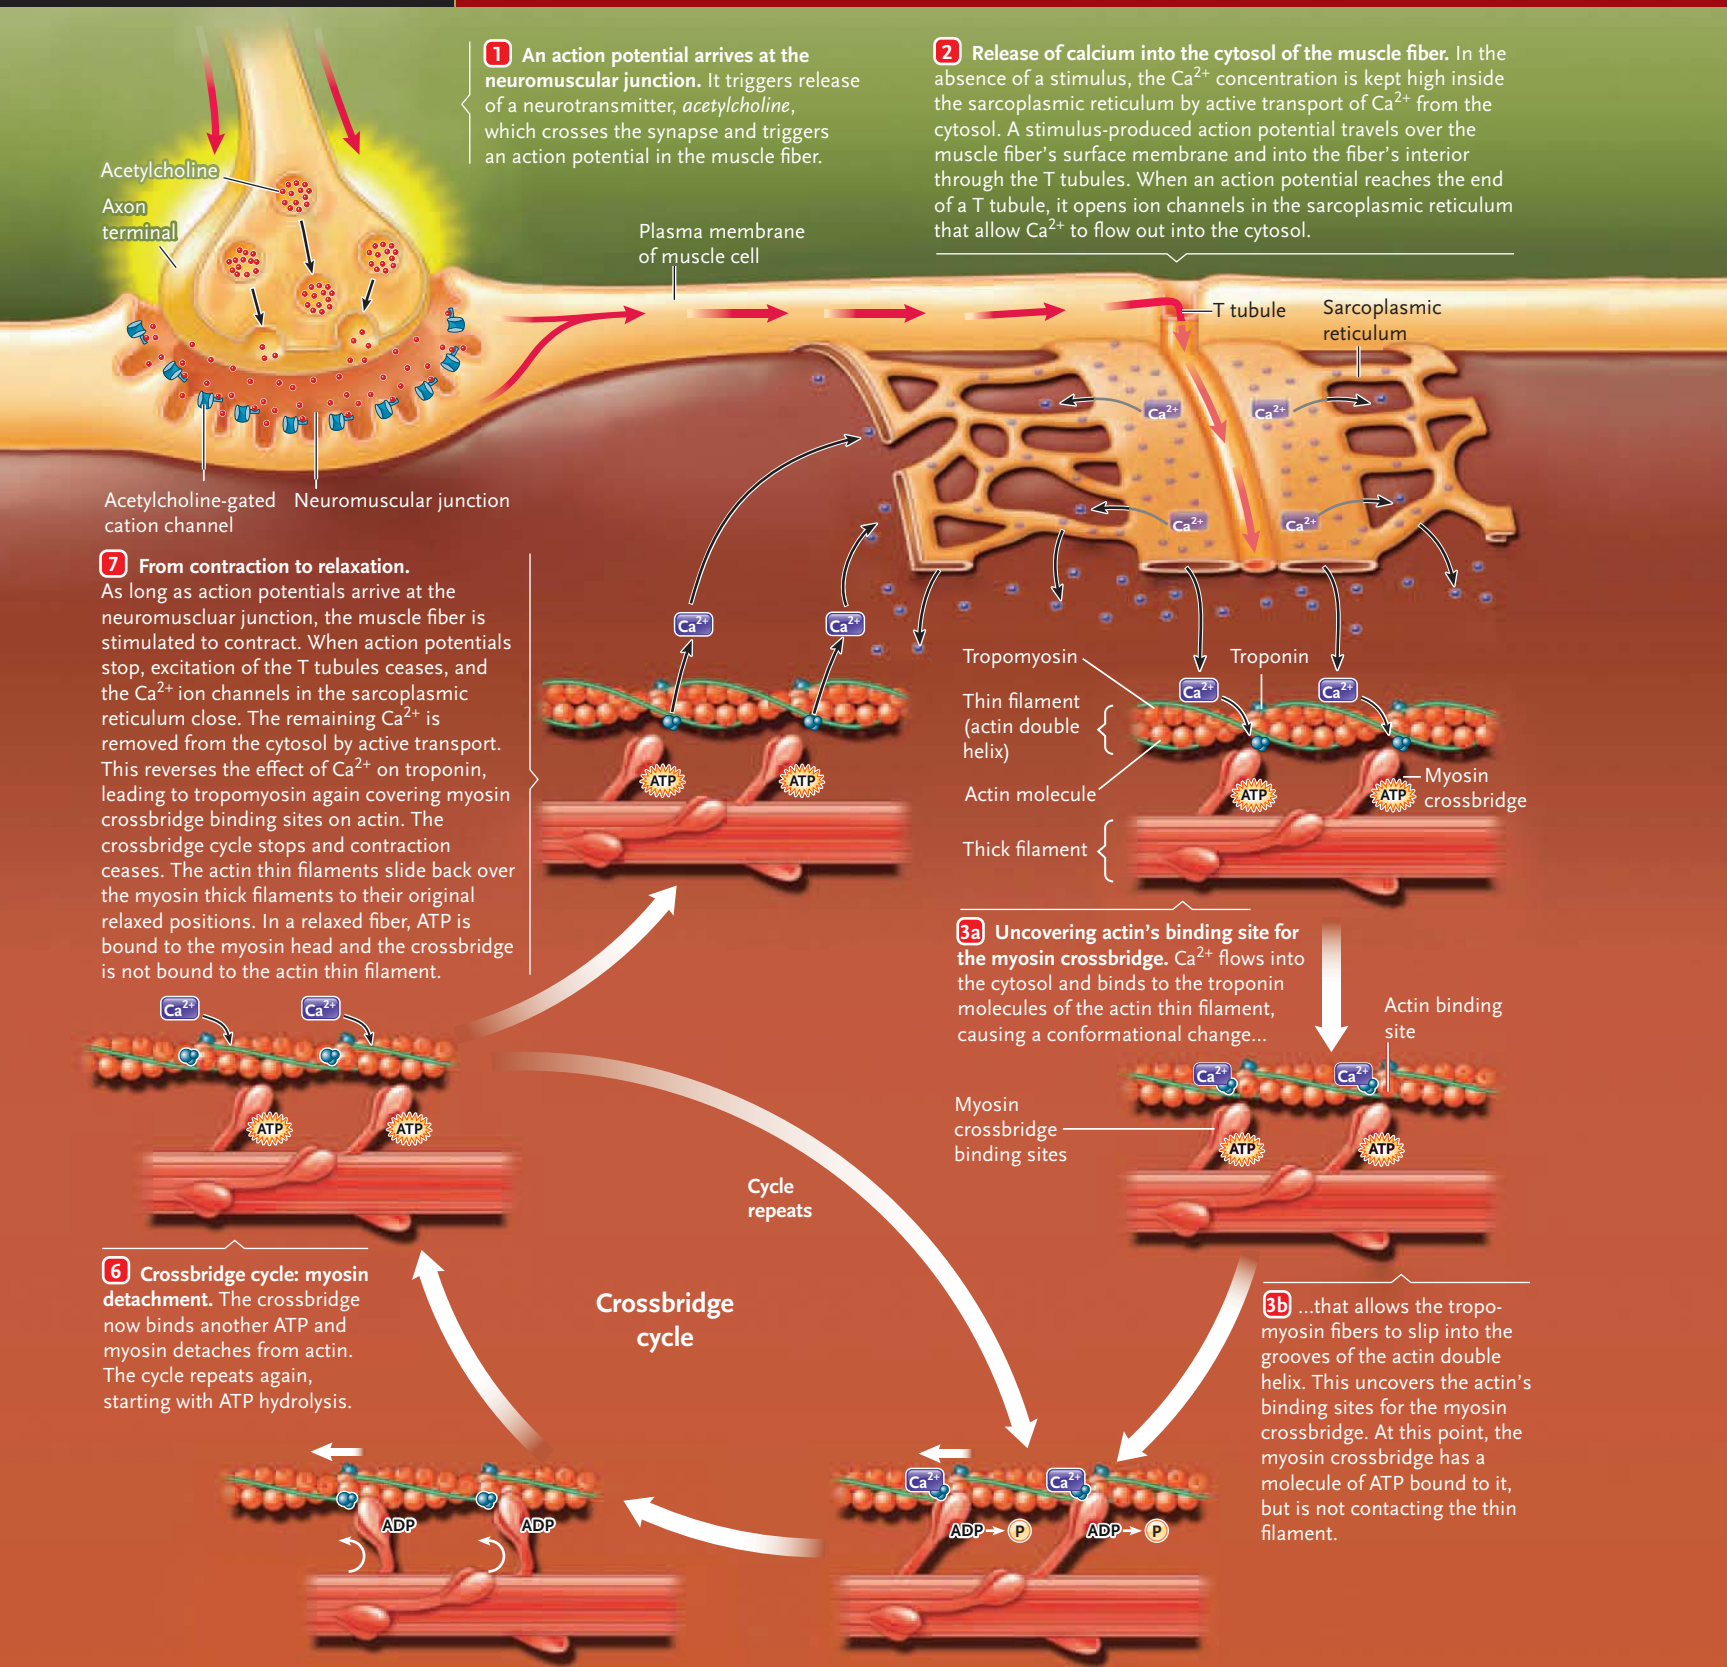
© Cengage Learning 2014

DEADLY INTERRUPTIONS OF THE CROSSBRIDGE CYCLE The mechanism controlling vertebrate muscle contraction can be blocked by several toxins and poisons. For example, the bacterium *Clostridium botulinum,* which grows in improperly preserved food, produces botulinum toxin, which blocks acetylcholine release in neuromuscular junctions. Affected body muscles are unable to contract, including the diaphragm, the muscle that is essential for inflating the lungs. When the diaphragm becomes paralyzed, the victim dies from respiratory failure. The toxin is so poisonous that 0.0000001 g is enough to kill a human; 600 g could wipe out the entire human population. A very low concentration of the same toxin, under the brand name Botox, is injected under the skin as a cosmetic treatment to remove or reduce wrinkles—if muscles cannot contract, then wrinkles cannot form.

In a natural process, within a few hours after an animal dies, Ca^{2+} diffuses into the cytoplasm of muscle cells and initiates the crossbridge cycle, producing *rigor mortis,* a strong tension of essentially all the skeletal muscles that stiffens the entire body. The crossbridges become locked to the thin filaments because ATP production stops (remember that ATP is required to release the crossbridges from actin). The stiffness reverses as actin and myosin are degraded.

The Response of a Muscle Fiber to Action Potentials Ranges from Twitches to Tetanus

A single action potential arriving at a neuromuscular junction usually causes a single, weak contraction of a muscle fiber called a **muscle twitch (Figure 43.6A).** After a muscle twitch begins, the tension of the muscle fiber increases in magnitude for about 30 to 40 msec, and then peaks as the action potential runs its course through the T tubules and the Ca^{2+} channels begin to close. Tension then decreases as the Ca^{2+} ions are pumped back into the sarcoplasmic reticulum, falling to zero in about 50 msec after the peak.



If a muscle fiber is restimulated after it has relaxed completely, a new twitch identical to the first is generated (see Figure 43.6A). However, if a muscle fiber is restimulated before it has relaxed completely, the second twitch is added to the first, resulting in *twitch summation,* a summed, stronger contraction **(Figure 43.6B).** If action potentials arrive so rapidly (about 25 msec apart) that the fiber cannot relax at all between stimuli, the Ca^{2+} channels remain open continuously and twitch summation produces a peak level of continuous contraction called **tetanus (Figure 43.6C).** (Do not confuse this with the disease of the same name, in which a bacterial toxin causes uncontrolled and continuous muscle contraction.) Contractile activity decreases if either the stimuli cease or the muscle fatigues.

Tetanus (or tetanic contraction) is an essential part of muscle fiber function. If you lift a moderately heavy weight, for ex-

CLOSER LOOK

FIGURE 43.5 Molecular model for muscle contraction.

1 An action potential arrives at the neuromuscular junction. It triggers release of a neurotransmitter, *acetylcholine*, which crosses the synapse and triggers an action potential in the muscle fiber.

2 Release of calcium into the cytosol of the muscle fiber. In the absence of a stimulus, the Ca^{2+} concentration is kept high inside the sarcoplasmic reticulum by active transport of Ca^{2+} from the cytosol. A stimulus-produced action potential travels over the muscle fiber's surface membrane and into the fiber's interior through the T tubules. When an action potential reaches the end of a T tubule, it opens ion channels in the sarcoplasmic reticulum that allow Ca^{2+} to flow out into the cytosol.

3a Uncovering actin's binding site for the myosin crossbridge. Ca^{2+} flows into the cytosol and binds to the troponin molecules of the actin thin filament, causing a conformational change...

3b ...that allows the tropomyosin fibers to slip into the grooves of the actin double helix. This uncovers the actin's binding sites for the myosin crossbridge. At this point, the myosin crossbridge has a molecule of ATP bound to it, but is not contacting the thin filament.

4 Crossbridge cycle: binding. Using the energy of ATP hydrolysis, the myosin crossbridge bends away from the tail and binds to an exposed myosin cross-bridge binding site on an actin molecule. This bending compresses a molecular spring in the myosin head.

5 Crossbridge cycle: snapping back. The binding of the crossbridge to actin triggers release of the molecular spring in the crossbridge, which snaps back toward the tail producing the power stroke (motor) that pulls the thin filament over the thick filament. ADP is released.

6 Crossbridge cycle: myosin detachment. The crossbridge now binds another ATP and myosin detaches from actin. The cycle repeats again, starting with ATP hydrolysis.

7 From contraction to relaxation. As long as action potentials arrive at the neuromuscluar junction, the muscle fiber is stimulated to contract. When action potentials stop, excitation of the T tubules ceases, and the Ca^{2+} ion channels in the sarcoplasmic reticulum close. The remaining Ca^{2+} is removed from the cytosol by active transport. This reverses the effect of Ca^{2+} on troponin, leading to tropomyosin again covering myosin crossbridge binding sites on actin. The crossbridge cycle stops and contraction ceases. The actin thin filaments slide back over the myosin thick filaments to their original relaxed positions. In a relaxed fiber, ATP is bound to the myosin head and the crossbridge is not bound to the actin thin filament.

SUMMARY An action potential arriving at the neuromuscular junction results in a release of acetylcholine, which triggers an action potential in the muscle fiber. This action potential leads to an increase in the concentration of Ca^{2+} in the fiber's cytosol, which triggers the crossbridge cycle. Repeated power strokes of the crossbridge cycle pull the actin thin filaments over the myosin thick filament.

THINK LIKE A SCIENTIST Muscles can be studied outside of the body to determine how muscle contraction is controlled. If you added an inhibitor of myosin ATPase to a muscle preparation, what would you expect the result to be on muscle contraction?

ample, many of the muscle fibers in your arms enter tetanus and remain in that state until the weight is released. Even body movements that require relatively little effort, such as standing still but in balance, involve tetanic contractions of some muscle fibers.

Muscle Fibers Differ in Their Rate of Contraction and Resistance to Fatigue

Muscle fibers differ in their rate of contraction and resistance to fatigue, and thus can be classified as slow fibers, fast aerobic fibers, and fast anaerobic fibers. Their properties are summarized in **Table 43.1.** The proportions of the three types of muscle fibers tailor the contractile characteristics of each muscle to suit its function within the body.

TABLE 43.1 Characteristics of Slow and Fast Muscle Fibers in Skeletal Muscle

	Fiber Type		
Property	Slow	Fast Aerobic	Fast Anaerobic
Contraction speed	Slow	Fast	Fast
Contraction intensity	Low	Intermediate	High
Fatigue resistance	High	Intermediate	Low
Myosin–ATPase activity	Low	High	High
Oxidative phosphorylation capacity	High	High	Low
Enzymes for anaerobic glycolysis	Low	Intermediate	High
Mitochondria	Many	Many	Few
Myoglobin content	High	High	Low
Fiber color	Red	Red	White
Glycogen content	Low	Intermediate	High

© Cengage Learning 2014

Slow muscle fibers contract relatively slowly, and the intensity of contraction is low because their myosin crossbridges hydrolyze ATP relatively slowly. They can remain contracted for relatively long periods without fatiguing. Slow muscle fibers typically contain many mitochondria and make most of their

ATP by oxidative phosphorylation (cellular respiration; see Chapter 8). They have a low capacity to make ATP by anaerobic glycolysis. They also contain high concentrations of the oxygen-storing protein **myoglobin,** which greatly enhances their oxygen supplies. Myoglobin is closely related to hemoglobin, the oxygen-carrying protein of red blood cells. Myoglobin gives slow muscle fibers, such as those in the legs of ground birds such as chickens and ostriches, a deep red color. In sharks and bony fishes, strips of slow muscles concentrated in a band on either side of the body are used for slow, continuous swimming and maintaining body position.

Fast muscle fibers contract relatively quickly and powerfully because their myosin crossbridges hydrolyze ATP faster than those of slow muscle fibers. Fast muscle fibers fall into two groups: *fast aerobic fibers* and *fast anaerobic fibers.*

Fast aerobic fibers have abundant mitochondria, a rich blood supply, and a high concentration of myoglobin, which makes them red in color. They have a high capacity for making ATP by oxidative phosphorylation, and an intermediate capacity for making ATP by anaerobic glycolysis. They fatigue more quickly than slow fibers, but not as quickly as fast anaerobic fibers. Fast aerobic muscle fibers are abundant in the flight muscles of migrating birds such as ducks and geese.

Fast anaerobic fibers typically contain high concentrations of glycogen, relatively few mitochondria, and a more limited blood supply than fast aerobic fibers. They generate ATP mostly by anaerobic glycolysis and have a low capacity to produce ATP by oxidative phosphorylation. Fast anaerobic fibers produce especially rapid and powerful contractions but are more susceptible to fatigue. Because of their limited myoglobin supply and few mitochondria, they are pale in color. Some ground birds have flight muscles consisting almost entirely of fast anaerobic muscle fibers. These muscles can produce a short burst of intensive contractions allowing the bird to escape a predator, but they cannot produce sustained flight. Most muscles of lampreys, sharks, fishes, amphibians, and reptiles also contain fast anaerobic muscle fibers, allowing the animals to move quickly to capture prey and avoid danger.

The muscles of humans and other mammals are mixed, and contain different proportions of slow and fast muscle fibers, depending on their functions. Muscles specialized for prolonged, slow contractions, such as the postural muscles of the back, have a high proportion of slow fibers and are a deep red color. The muscles of the forearm that move the fingers have a higher proportion of fast fibers and are a paler red than the back muscles. These muscles can contract rapidly and powerfully, but they fatigue much more rapidly than the back muscles.

The number and proportions of slow and fast muscle fibers in individuals are inherited characteristics. However, particular types of exercises can convert some fast muscle fibers between aerobic and anaerobic types. Endurance training, such as long-distance running, converts fast muscle fibers from the anaerobic to the aerobic type, and regimens such as weight lifting induce the reverse conversion. If the training regimens stop, most of the fast muscle fibers revert to their original types. *Insights from the Molecular Revolution* discusses a study of gene expression changes associated with training.

Skeletal Muscle Control Is Divided among Motor Units

The control of muscle contraction extends beyond the ability to turn the crossbridge cycle on and off. You can adjust a handshake from a gentle squeeze to a strong grasp, or exactly balance a feather or dumbbell in the hand. Entire muscles are controlled in this way because muscle fibers are activated in blocks called **motor units.**

The muscle fibers in each motor unit are controlled by branches of the axon of a single efferent neuron **(Figure 43.7).** As a result, all those fibers contract each time the neuron fires an action potential. All the muscle fibers in a motor unit are of the same type—either slow, fast aerobic, or fast anaerobic. When a motor unit contracts, its force is distributed throughout the entire muscle because the fibers are dispersed throughout the muscle rather than being concentrated in one segment.

For a delicate movement, only a few efferent neurons carry action potentials to a muscle, and only a few motor units contract. For more powerful movements, more efferent neurons carry action potentials, and more motor units contract.

Muscles that can be controlled precisely and delicately, such as those moving the fingers in humans, have many motor units in a small area, with only a few muscle fibers—about 10 or so—in each unit. Muscles that produce grosser body movements, such as those moving the legs, have fewer motor units in the same volume of muscle but thousands of muscle fibers in each unit. In the calf muscle that raises the heel, for example, most motor units contain nearly 2,000 muscle fibers. Other skeletal muscles fall between these extremes, with an average of about 200 muscle fibers per motor unit.

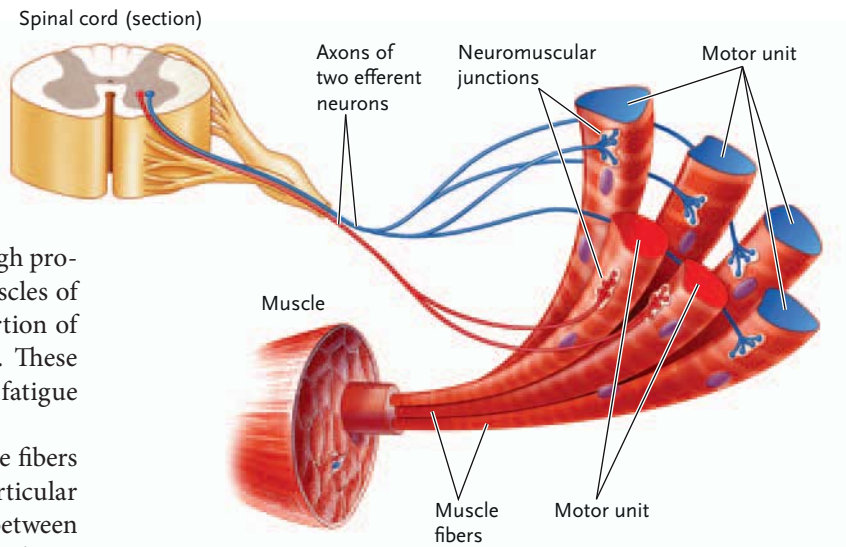

FIGURE 43.7 Motor units in vertebrate skeletal muscles. Each motor unit consists of groups of muscle fibers activated by branches of a single efferent (motor) neuron.

Training Effects on Gene Expression in Racehorses

In response to exercise training, a number of phenotypic and biochemical changes occur. The changes have been studied extensively in humans and other mammals. Endurance training (a highly aerobic form of exercise) results in, for example, an increased aerobic capacity, an increase in the number of mitochondria, and a shift from carbohydrate to fat metabolism. Resistance training (a high-intensity form of exercise) results in, for example, an increase in protein synthesis, muscle development, and a switch from slow to fast muscle fibers. In contrast, less is known about changes in gene expression that must underlie the changes that occur as a result of endurance and resistance exercise.

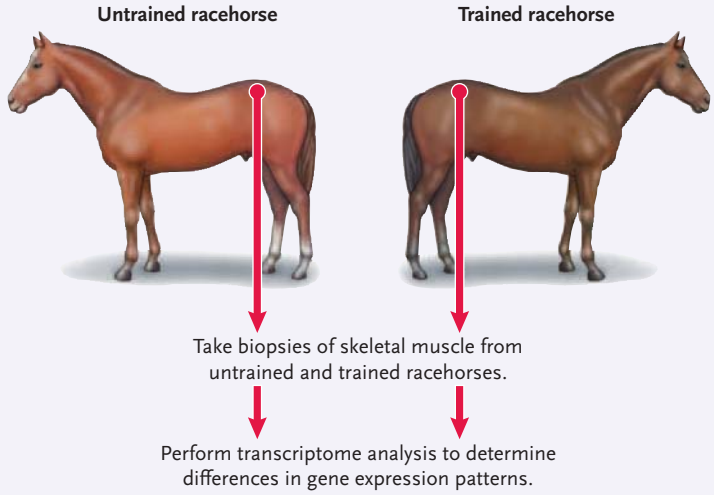
Research Question

Does a training regimen combining endurance plus high-intensity exercise cause changes in the expression of genes related to both aerobic capacity and muscle growth?

Experiment

Emmeline Hill and colleagues at the Animal Genomics Laboratory, University College Dublin, Ireland, tested the hypothesis using Thoroughbred racehorses. Their experimental design is shown in the **Figure.** Muscle biopsies were taken from the skeletal (gluteus medius) muscles of untrained racehorses and of racehorses trained over a ten-month period using an endurance plus high-intensity exercise program. The researchers used transcriptome analysis to compare the genes expressed in the trained racehorses and the untrained (control) racehorses. As discussed in Chapter 19, the transcriptome is the complete set of gene transcripts in a cell. If a researcher has the complete genome of an organism, the transcriptome can be studied both qualitatively and quantitatively using a high-throughput method.

Results



The researchers found that the genes represented in the skeletal muscle transcriptome were those involved in muscle contraction, aerobic respiration, and mitochondrial function. Seventy-four known genes showed a different expression pattern in the trained racehorses: 16 of those genes showed increased expression, and the other 58 genes showed decreased expression. The increased-expression group included genes for the mitochondrion, oxidative phosphorylation, and fatty acid metabolism. The decreased-expression group included genes for components of the cytoplasm of muscle fibers, and the cytoskeleton. The greatest decrease in the latter group was shown for a gene encoding a negative regulator of muscle growth.

Conclusion

Endurance plus high-intensity training in racehorses results in significant changes in the expression of genes involved in exercise-related metabolism, oxidative phosphorylation, and muscle structure.

THINK LIKE A SCIENTIST Thoroughbred racehorses have been bred since the 1700s for speed and stamina. Thus, they are highly specialized animals. How would you determine whether the training-related gene expression changes found in the study are specific to racehorses or if they are common to endurance plus high-intensity training in mammals?

Invertebrates Move Using a Variety of Striated Muscles

Invertebrates also have muscle cells in which actin-based thin filaments and myosin-based thick filaments produce movements by the sliding filament model. Muscles that are striated, which occur in virtually all invertebrates except sponges, have thick and thin filaments arranged in sarcomeres entirely similar to those of vertebrates, except for variations in sarcomere length and the ratio of thin to thick filaments.

In invertebrates, an entire muscle is typically controlled by one or a few motor neurons. Nevertheless, invertebrate muscles are capable of finely graded contractions because individual neurons make large numbers of synapses with the muscle cells. As action potentials arrive more frequently at the synapses, more Ca^{2+} is released into the cells, and the muscles contract more strongly.

STUDY BREAK 43.1

1. What is the mechanism by which muscle contraction occurs in response to a stimulus from the nervous system?
2. Outline the molecular events that take place in the sliding filament model of muscle contraction.
3. With respect to contraction intensity, fatigue resistance, oxidative phosphorylation capacity, number of mitochondria, and myoglobin content, what are the differences between slow, fast aerobic, and fast anaerobic muscle fibers?

THINK OUTSIDE THE BOOK

You learned in Chapter 38 that smooth muscle is found in the walls of tubes and cavities of the body, including blood vessels and the urinary bladder. Smooth muscle cells have actin and myosin molecules arranged in a loose network rather than in bundles. Individually or collaboratively, research the mechanism of smooth muscle contraction and outline how it differs from the skeletal muscle contraction mechanism.

43.2 Skeletal Systems

Animal skeletal systems provide physical support for the body and protection for the soft tissues. They also act as a framework against which muscles work to move parts of the body or the entire organism. The three main types of skeletons found in both invertebrates and vertebrates are *hydrostatic skeletons, exoskeletons,* and *endoskeletons.*

A Hydrostatic Skeleton Consists of Muscles and Fluid

A **hydrostatic skeleton** (*hydro-* = water, *statikos* = causing to stand) is a structure consisting of muscles and fluid that provides support for the animal or part of the animal; no rigid support, like a bone, is involved. A hydrostatic skeleton consists of a body compartment or compartments filled with water or body fluids, which are incompressible liquids. When the muscular walls of the compartment contract, they pressurize the contained fluid. If muscles in one part of the compartment are contracted while muscles in another part are relaxed, the pressurized fluid will move to the relaxed part of the compartment, distending it. In short, the contractions and relaxations of the muscles surrounding the compartments change the shape of the animal. Hydrostatic skeletons are the primary support systems of cnidarians, flatworms, roundworms, and annelids. In all these animals, compartments containing fluids under pressure make the body semirigid and provide a mechanical support on which muscles act.

For example, in flatworms, roundworms, and annelids, striated muscles in the body wall act on the hydrostatic skeleton to produce creeping, burrowing, or swimming movements. Among these animals, annelids have the most highly developed musculoskeletal systems, with an outer layer of circular muscles surrounding the body, and an inner layer of longitudinal muscles running its length **(Figure 43.8).** Contractions of the circular muscles reduce the diameter of the body and increase the length of the worm; contractions of the longitudinal muscles shorten the body and increase its diameter. Annelids move along a surface or burrow by means of alternating waves of contraction of the two muscle layers that pass along the body, working against the fluid-filled body compartments of the hydrostatic skeleton.

Many arthropods have hydrostatic skeletal elements. In the larvae of flying insects, for example, internal fluids held under pressure by the muscular body wall provide some body support.

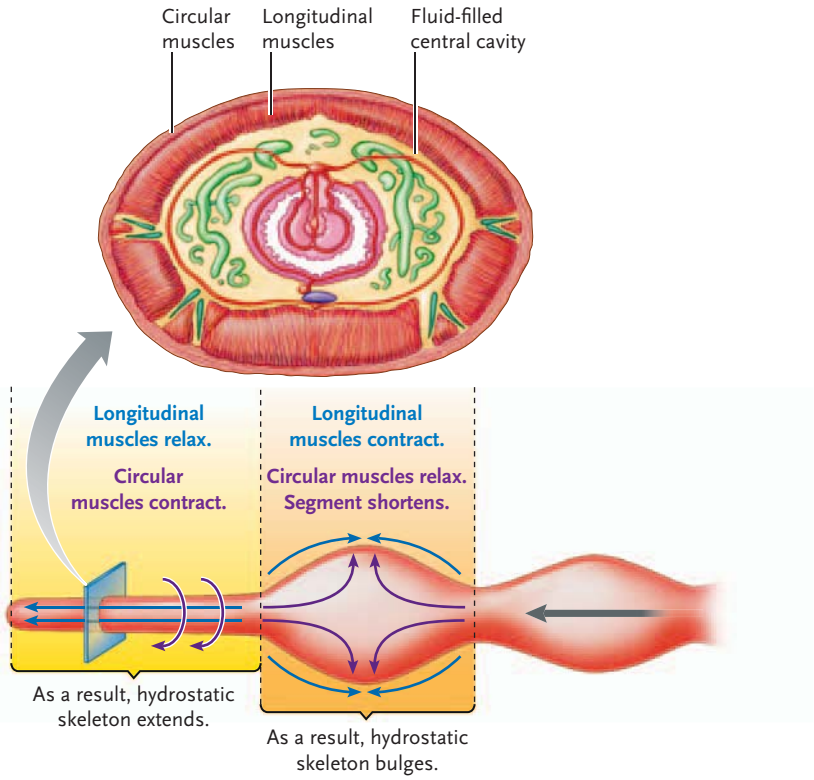

FIGURE 43.8 Movement of an earthworm, showing how muscles in the body wall act on its hydrostatic skeleton. Contraction of the circular muscles reduces body diameter and increased body length, while contraction of the longitudinal muscles decreases body length and increases body diameter.

© Cengage Learning 2014

Some structures of echinoderms are supported by hydrostatic skeletons. The tube feet of sea stars and sea urchins, for example, have muscular walls enclosing the fluid of the water vascular system (see Figure 32.2).

In vertebrates, the erectile tissue of the penis is a fluid-filled hydrostatic skeletal structure.

An Exoskeleton Is a Rigid, External Body Covering

An **exoskeleton** (*exo* = outside) is a rigid, external body covering, such as a shell, that provides support. In an exoskeleton, the force of muscle contraction is applied against that covering. An exoskeleton also protects delicate internal tissues such as the brain and respiratory organs.

Many mollusks, such as clams and oysters, have an exoskeleton consisting of a hard calcium carbonate shell secreted by glands in the mantle. Arthropods, such as insects, spiders, and crustaceans, have an external skeleton in the form of a chitinous cuticle, secreted by underlying tissue that covers the outside surfaces of the animals. Like a suit of armor, the arthropod exoskeleton has movable joints, flexed and extended by muscles that extend across the inside surfaces of the joints **(Figure 43.9).** The exoskeleton protects against dehydration, serves as armor against predators, and provides the levers against which muscles work. In many flying insects, elastic

© Cengage Learning 2014

flexing of the exoskeleton contributes to the movements of the wings.

In vertebrates, the shell of a turtle or tortoise is an exoskeletal structure, as are the bony plates, abdominal ribs, collar bones, and most of the skull of the alligator.

An Endoskeleton Consists of Supportive Internal Body Structures Such as Bones

An **endoskeleton** (*endon* = within) consists of internal body structures, such as bones, that provide support. In an endoskeleton, the force of contraction is applied against those structures. Like exoskeletons, endoskeletons also protect delicate internal tissues such as the brain and internal organs.

Echinoderms have an endoskeleton consisting of *ossicles* (*ossiculum* = little bone), formed from calcium carbonate crystals. The shells of sand dollars and sea urchins are the endoskeletons of these animals.

The endoskeleton is the primary skeletal system of vertebrates. An adult human, for example, has an endoskeleton consisting of 206 bones **(Figure 43.10).**

Bones of the Vertebrate Endoskeleton Are Organs with Several Functions

The vertebrate endoskeleton supports and maintains the overall shape of the body and protects key internal organs. In addition, the skeleton is a storehouse for calcium and phosphate ions, releasing them as required to maintain optimal levels of these ions in body fluids. Bones are also sites where new blood cells form.

Bones are complex organs built up from multiple tissues of several kinds, blood vessels, nerves, and, in some, stores of adipose tissue. Bone tissue is distributed between dense, compact bone regions, which have essentially no spaces other than the microscopic canals of the osteons (see Figure 38.4D), and spongy bone regions, which are opened by larger spaces (see Figure 43.10). Compact bone tissue generally forms the outer surfaces of bones, and spongy bone tissue the interior. The interior of some flat bones, such as the hip bones and the ribs, are filled with *red marrow,* a tissue that is the primary source of new red blood cells in mammals and birds. The shaft of long bones such as the femur has a large central canal filled with adipose tissue called *yellow marrow,* a source of some white blood cells.

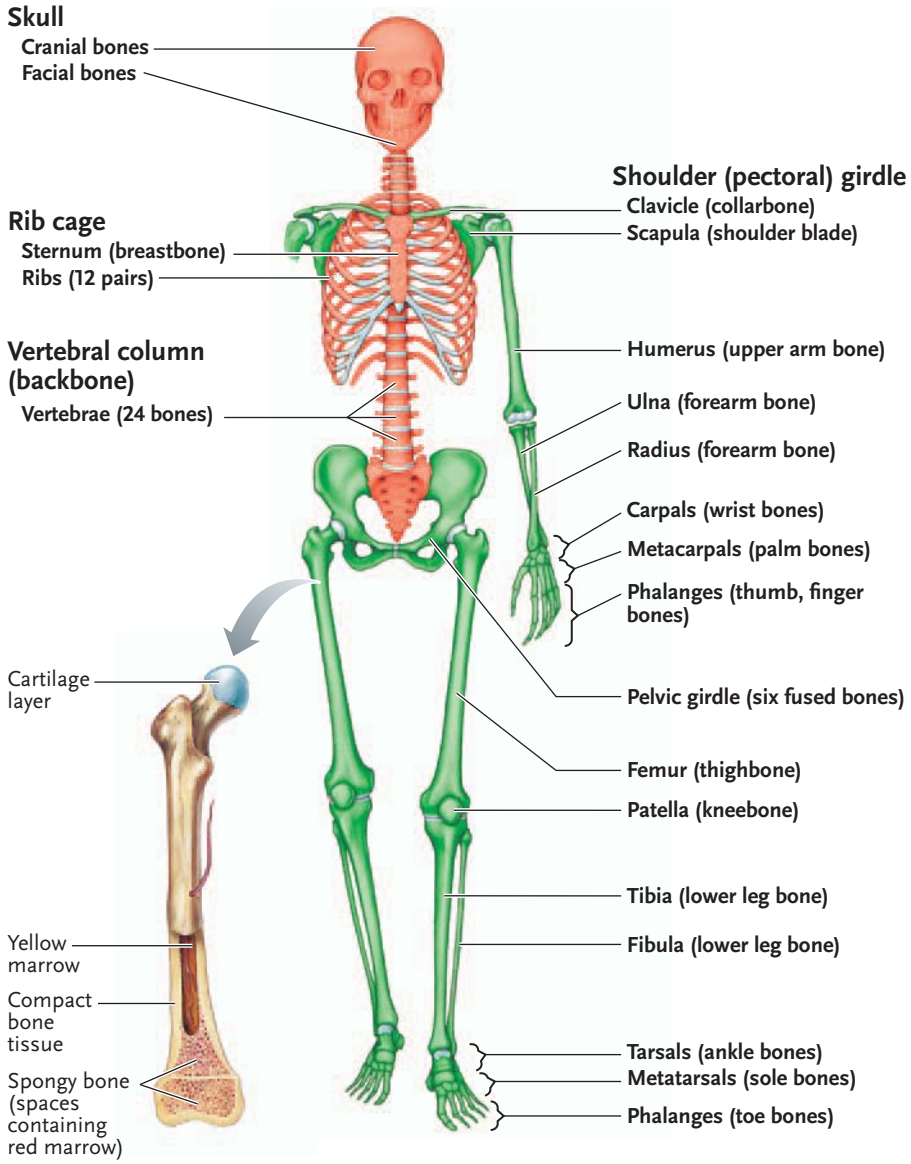

FIGURE 43.10 Major bones of the human body. The skull, vertebral column, sternum, and rib cage form the central part of the structure, called the axial skeleton (shaded red). The shoulder, hip, leg, and arm bones form the appendicular skeleton (shaded green). The inset shows the structure of a limb bone, with the location of red and yellow marrow. The internal spaces lighten the bone's structure. The cartilage layer forms a smooth, slippery cushion between bones in a joint.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Throughout the life of a vertebrate, calcium and phosphate ions are constantly deposited and withdrawn from bones. Hormonal controls maintain the concentration of Ca^{2+} ions at optimal levels in the blood and extracellular fluids (see Figure 42.9), ensuring that calcium is available for proper functioning of the nervous system, muscular system, and other physiological processes.

2. **What are the functions of the bones of the vertebrate endoskeleton?**

43.3 Vertebrate Movement: The Interactions between Muscles and Bones

The skeletal systems of all animals act as a framework against which muscles work to move parts of the body or the entire organism. In this section, the muscle–bone interactions that are responsible for the movement of vertebrates are described.

Joints of the Vertebrate Endoskeleton Allow Bones to Move and Rotate

The bones of the vertebrate skeleton are connected by joints. *Synovial joints,* the most-movable joints, consist of the ends of two bones enclosed by a fluid-filled capsule of connective tissue **(Figure 43.11A).** Examples are the shoulders, elbows, wrists, fingers, knees, ankles, and toes. Within the joint, the ends of the bones are covered by a smooth layer of cartilage and lubricated by synovial fluid, which permits the bones to slide easily as the joint moves. Synovial joints are held together by straps of connective tissue called *ligaments* that extend across the joints outside the capsule **(Figure 43.11B).**

In **cartilaginous joints,** which are less movable, the ends of bones are covered with layers of cartilage, but have no fluid-filled capsule surrounding them. Fibrous connective tissue covers and connects the bones of these joints. They occur between the vertebrae and some rib bones.

The bones connected by movable joints work like levers. A lever is a rigid structure that can move around a pivot point known as a *fulcrum.* Levers differ with respect to where the fulcrum is along the lever and where the force is applied. The most common type of lever system in the body—exemplified by the elbow joint—has the fulcrum at one end, the load at the opposite end, and the force applied at a point between the ends **(Figure 43.12).** For this lever, the force applied must be much greater than the load, but it increases the distance the load moves as compared with the distance over which the force is applied. This allows small muscle movements to produce large body movements, and also allows movements such as running or throwing to be carried out at high speed.

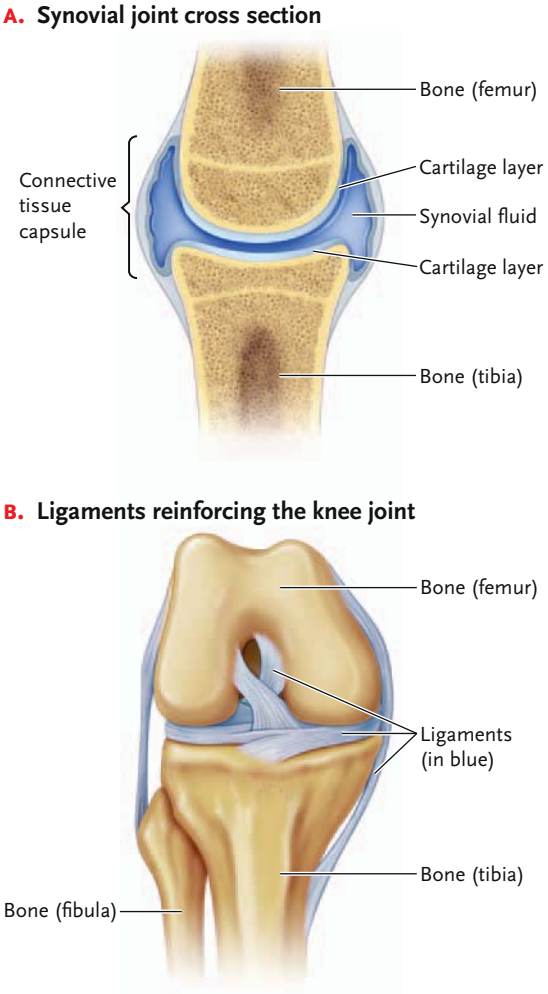

FIGURE 43.11 **The synovial joint, the human knee.**
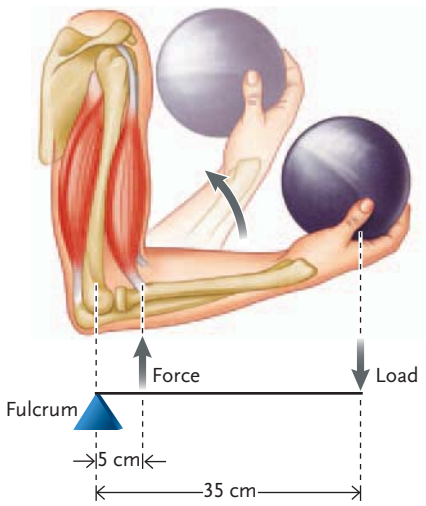
© Cengage Learning 2014

At a joint, a muscle that causes movement in the joint when it contracts is called an **agonist.** Most of the bones of vertebrate skeletons are moved by muscles arranged in **antagonistic pairs:**



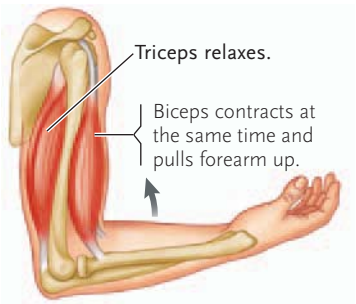


FIGURE 43.12 **The body lever: the lever formed by the bones of the forearm.** The fulcrum (the hinge of joint) is at one end of the lever, the load is placed on the opposite end, and then force is exerted at a point on the lever between the fulcrum and the load.

A. When the biceps muscle contracts and raises the forearm, its antagonistic partner, the triceps muscle relaxes.

B. When the triceps muscle contracts and extends the forearm, the biceps muscle relaxes.

extensor muscles extend the joint, meaning increasing the angle between the two bones, while **flexor muscles** do the opposite. (Antagonistic muscles are also used in invertebrates for movement of body parts—for example, the limbs of insects and other arthropods; see Figure 43.9.) In humans, one such pair is formed by the biceps brachii muscle at the front of the upper arm and the triceps brachii muscle at the back of the upper arm **(Figure 43.13).**

Vertebrates Have Muscle–Bone Interactions Optimized for Specific Movements

Vertebrates differ widely in the patterns by which muscles connect to bones, and in the length and mechanical advantage of the levers produced by these connections. These differences produce limbs and other body parts that are adapted for either power or speed, or the most advantageous compromise between these characteristics. Among burrowing mammals such as the mole, for example, the limb bones are short, thick, and heavy, and the points at which muscles attach produce levers that are slow to move but that need to apply smaller forces to move a load when compared with a human biceps. In contrast, a mammal such as the deer has relatively light and thin bones with muscle attachments producing levers that can generate rapid movement, moving the body easily over the ground.

2. What are antagonistic muscle pairs?

UNANSWERED QUESTIONS

How can muscle growth processes be controlled to improve the clinical treatment of muscular dystrophy and related disorders?

The mechanisms by which different muscle types develop and their impact on organismal metabolism are not well known. However, we do know that one of the proteins produced in muscle cells, myostatin, is a growth factor that inhibits skeletal muscle growth and development. Myostatin is therefore a potential therapeutic target for treating Duchenne muscular dystrophy, a degenerative and sometimes fatal disease associated with the progressive loss of skeletal muscle mass. Animals with nonfunctioning and mutant forms of the myostatin gene (for example, the Belgian Blue and Piedmontese cattle breeds) or myostatin knockout mice, in which the gene has been removed experimentally (see Section 18.2 and *Focus on Model Research Organisms* in Chapter 45), have significantly enhanced musculature that is commonly referred to as *double muscling*. Such mutations and enhanced skeletal muscle mass have also been described in a racing dog breed, the whippet, and recently in a young boy.

Our laboratory develops novel technologies to inhibit myostatin activity—in essence, inhibiting the inhibitor—and thereby stimulate skeletal muscle growth in both clinical and agricultural settings. We have recently determined that myostatin can also negatively regulate cardiac muscle growth. Thus, disrupting myostatin production or availability may help heart attack patients. Replacing damaged skeletal and cardiac muscle using adult or embryonic stem cells engineered to match either tissue type is another highly promising technique for treating these disorders. This technique could also be improved by using "antimyostatin" technologies that enhance growth of the transplanted cells.

How much do the metabolic processes of skeletal muscle specifically contribute to energy storage and whole body form?

Complications associated with obesity, particularly diabetes mellitus type 2 (see Section 42.4), have reached near-epidemic proportions worldwide. Type 2 diabetes is caused not by a lack of the pancreatic hormone insulin (as in type 1 diabetes) but by insulin resistance, in which tissue responses to insulin are inadequate. In both types of diabetes, however, the body is unable to process and store metabolites properly, especially glucose. Type 2 diabetes can be a debilitating and fatal disease if poorly managed and often aggravates other diseases as well. Scientists now recognize that growth and metabolic processes are integrated and controlled by the same hormones, growth factors, and cytokines. Indeed, skeletal muscle is the largest consumer of metabolites and has the greatest potential to impact their circulating levels. Recent studies suggest that even small increases in muscle mass can significantly reduce fat mass and improve insulin responsiveness. Enhancing skeletal muscle growth in obese patients with type 2 diabetes could therefore improve treatments for both. The same antimyostatin technologies used to treat muscle growth disorders could therefore be used to treat severe obesity and type 2 diabetes

43.1 Vertebrate Skeletal Muscle: Structure and Function

- Skeletal muscles move the joints of the body. They are formed from long, cylindrical cells called muscle fibers, which are packed with myofibrils, contractile elements consisting of myosin thick filaments and actin thin filaments. The two types of filaments are arranged in an overlapping pattern of contractile units called sarcomeres (Figure 43.2).
- Infoldings of the plasma membrane of the muscle fiber form T tubules. The sarcomeres are encircled by the sarcoplasmic reticulum, a system of vesicles with segments separated from T tubules by small gaps (Figure 43.3).
- In the sliding filament mechanism of muscle contraction, the simultaneous sliding of thin filaments on each side of sarcomeres over the thick filaments shortens the sarcomeres and the muscle fibers, producing the force that contracts the muscle (Figure 43.4).
- The sliding motion of thin and thick filaments is produced in response to an action potential arriving at the neuromuscular junction. The action potential causes the release of acetylcholine, which triggers an action potential in the muscle fiber that spreads over its plasma membrane and stimulates the sarcoplasmic reticulum to release Ca^{2+} into the cytosol. The Ca^{2+} combines with troponin, inducing a conformational change that moves tropomyosin away from the myosin-binding sites on thin filaments. Exposure of the sites allows myosin crossbridges to bind and initiate the crossbridge cycle in which the myosin heads of thick filaments attach to a thin filament, pull, and release in cyclic reactions powered by ATP hydrolysis (Figure 43.5).
- When action potentials stop, Ca^{2+} is pumped back into the sarcoplasmic reticulum, leading to Ca^{2+} release from troponin, which allows tropomyosin to cover the myosin-binding sites in the thin filaments, thereby stopping the crossbridge cycle (Figure 43.5).
- A single action potential arriving at a neuromuscular junction causes a muscle twitch. Restimulation of a muscle fiber before it has relaxed completely causes a second twitch, which is added to the first, causing a summed, stronger contraction. Rapid arrival of action potentials causes the twitches to sum to a peak level of contraction called tetanus. Normally, muscles contract in a tetanic mode (Figure 43.6).
- Muscle fibers occur in three types. Slow muscle fibers contract relatively slowly, but do not fatigue rapidly. Fast aerobic fibers contract relatively quickly and powerfully, and fatigue more quickly than slow fibers. Fast anaerobic fibers can contract more rapidly and powerfully than fast aerobic fibers, but fatigue more rapidly. The fibers differ in their number of mitochondria and capacity to produce ATP (Table 43.1).
- Skeletal muscles are divided into motor units, consisting of a group of muscle fibers activated by branches of a single motor neuron. The total force produced by a skeletal muscle is determined by the number of motor units that are activated in the muscle (Figure 43.7).
- Invertebrate muscles contain thin and thick filaments arranged in sarcomeres, and contract by the same sliding filament mechanism that operates in vertebrates.

43.2 Skeletal Systems

- A hydrostatic skeleton is a structure consisting of a muscle-surrounded compartment or compartments filled with fluid under pressure. Contraction and relaxation of the muscles change the shape of the animal (Figure 43.8).
- In an exoskeleton, a rigid external covering provides support for the body. The force of muscle contraction is applied against the covering. An exoskeleton can also protect delicate internal tissues (Figure 43.9).
- In an endoskeleton, the body is supported by rigid structures within the body, such as bones. The force of muscle contraction is applied against those structures. Endoskeletons also protect delicate internal tissues. In vertebrates, the endoskeleton is the primary skeletal system (Figure 43.10).
- Bone tissue is distributed between compact bone, with no spaces except the microscopic canals of the osteons, and spongy bone tissue, which has spaces filled by red or yellow marrow (Figure 43.10).
- Calcium and phosphate ions are constantly exchanged between the blood and bone tissues. The turnover keeps the Ca^{2+} concentration balanced at optimal levels in body fluids.

43.3 Vertebrate Movement: The Interactions between Muscles and Bones

- The bones of a skeleton are connected by joints. A synovial joint, the most movable type, consists of a fluid-filled capsule surrounding the ends of the bones forming the joint. A cartilaginous joint, which is less movable, has smooth layers of cartilage between the bones with no surrounding capsule (Figure 43.11).
- The bones moved by skeletal muscles act as levers, with a joint at one end forming the fulcrum of the lever, the load at the opposite end, and the force applied by attachment of a muscle at a point between the ends (Figure 43.12).
- At a joint, an agonist muscle, perhaps assisted by other muscles, causes movement. Most skeletal muscles are arranged in antagonistic pairs, in which the members of a pair pull a bone in opposite directions. When one member of the pair contracts, the other member relaxes and is stretched (Figure 43.13).
- Vertebrates have a variety of patterns in which muscles connect to bones, giving different properties to the levers produced. Those properties are specialized for the activities of the animal.

UNDERSTAND & APPLY

Test Your Knowledge

1. Vertebrate skeletal muscle:
   a. is attached to bone by means of ligaments.
   b. may bend but not extend body parts.
   c. may rotate one body part with respect to another.
   d. is found in the walls of blood vessels and intestines.
   e. consists of cells that contain no nuclei.
2. In muscle fiber in a completely relaxed state:
   a. sarcomeres are regions between two H zones.
   b. discs of M line proteins called the A band separate the thick filaments.
   c. I bands are composed of the same thick filaments seen in the A bands.
   d. Z lines are adjacent to H zones, which attach thick filaments.
   e. dark A bands contain overlapping thick and thin filaments with a central thin H zone composed only of thick filaments.
3. The sliding filament contractile mechanism:
   a. causes thin filaments on each side of a sarcomere to slide over thick filaments toward the center of the A band, bringing the Z lines closer together.
   b. is inhibited by the influx of Ca^{2+} into the muscle fiber cytosol.
   c. lengthens the sarcomere to separate the I regions.
   d. depends on the isolation of actin and myosin until a contraction is completed.
   e. uses myosin crossbridges to stimulate delivery of Ca^{2+} to the muscle fiber.
4. During contraction of skeletal muscle:
   a. ATP stimulates Ca^{2+} to move out of the cytosol, which allows tropomyosin to bind myosin causing contraction of the thin filament.
   b. myosin crossbridges use ATP to relax the molecular spring in the myosin head, which pulls the thick filaments away from the thin actin filaments.
   c. actin binds ATP, allowing troponin in the thick filaments to form the myosin crossbridge.
   d. action potentials cause the release of Ca^{2+} allowing tropomyosin fibers to uncover the actin binding sites needed for the myosin crossbridge.
   e. botulinum toxin could increase the release of acetylcholine at the contracting muscle site.
5. When marathoners are running a race, most likely their:
   a. muscles have low concentrations of myoglobin.
   b. slow muscle fibers will do most of the work for the run.
   c. slow muscle fibers will remain in constant tetanus over the length of the run.
   d. fast muscle fibers will be employed in the middle of the run.
   e. slow muscle fibers are using ATP obtained primarily by anaerobic respiration.
6. Which description is characteristic of a motor unit?
   a. A single motor unit's muscle fibers vary among the slow/fast aerobic and slow/fast anaerobic forms.
   b. When receiving an action potential, a motor unit is controlled by a single efferent axon that causes all its fibers to contract.
   c. When a motor unit contracts, certain sections of the muscle as a whole remain relaxed.
   d. If a motor unit controls walking, it is found in large numbers in the same volume of muscle.
   e. If a motor unit controls finger movement, it contains a large number of muscle fibers that are stimulated over a large area.
7. Which of the following is *not* an example of a hydrostatic skeletal structure?
   a. the tube feet of sea urchins
   b. the body wall of annelids
   c. the mantle of squids
   d. the body wall of cnidarians
   e. the penis of mammals
8. Endoskeletons:
   a. protect internal organs and provide structures against which the force of muscle contraction can work.
   b. differ from exoskeletons in that endoskeletons do not support the external body.
   c. cannot be found in echinoderms.
   d. are composed of cartilaginous structures that form the skull.
   e. compose the arms and legs.
9. Connecting the bones of the vertebrate skeleton are:
   a. nonmovable synovial joints.
   b. ligaments holding together connective tissue of fibrous joints.
   c. cartilaginous joints held together by fluid-filled capsules.
   d. synovial joints lubricated by synovial fluid.
   e. fibrous joints that move around a fulcrum allowing small muscle movements to produce large body movements.
10. The movement of vertebrate muscles is:
    a. controlled primarily by cartilaginous joints with agonist muscles.
    b. antagonistic when it causes movement in the joint.
    c. caused by extensor muscles that flex the joint.
    d. caused by flexor muscles that extend the joint.
    e. exemplified by the biceps and triceps contracting or relaxing simultaneously.

Discuss the Concepts

1. A coach must train young athletes for the 100-meter sprint. They need muscles specialized for speed and strength, rather than for endurance. What kinds of muscle characteristics would the training regimen aim to develop? How would it be altered to train marathoners?
2. What kind of exercise program might the coach in question 1 recommend to an older person developing osteoporosis? Why?
3. Based on material in this chapter and in Chapter 42 on endocrine controls, outline some possible causes and physiological effects of calcium deficiency in an active adult.

Design an Experiment

Design an experiment using rats to determine whether endurance training alters the proportion of slow, fast aerobic, and fast anaerobic muscle fibers.

Interpret the Data

Osteogenesis imperfecta (OI) is a genetic disorder caused by a mutation in a gene for collagen. As bones develop, collagen forms a scaffold for deposition of mineralized bone tissue. In children with OI, the scaffold forms improperly, causing them to be born with multiple fractures in their fragile bones and to require many corrective surgeries. The **Tables** show the results of an experimental test of a new drug. Treated children with OI, all less than 2 years old, were compared to similarly affected children of the same age who were not treated with the drug.

TABLE 1 Effect of Drug on Bone Properties in Children with OI

Treated Child	Vertebral Area, in cm^2 (Before Treatment)	Vertebral Area, in cm^2 (After Treatment)	Fractures Per Year
1	14.7	16.7	1
2	15.5	16.9	1
3	16.7	16.5	6
4	17.3	11.8	0
5	13.6	14.6	6
6	19.3	15.6	1
7	15.3	15.9	0
8	19.9	13.0	4
9	10.5	13.4	4
Mean	11.4	14.9	2.6

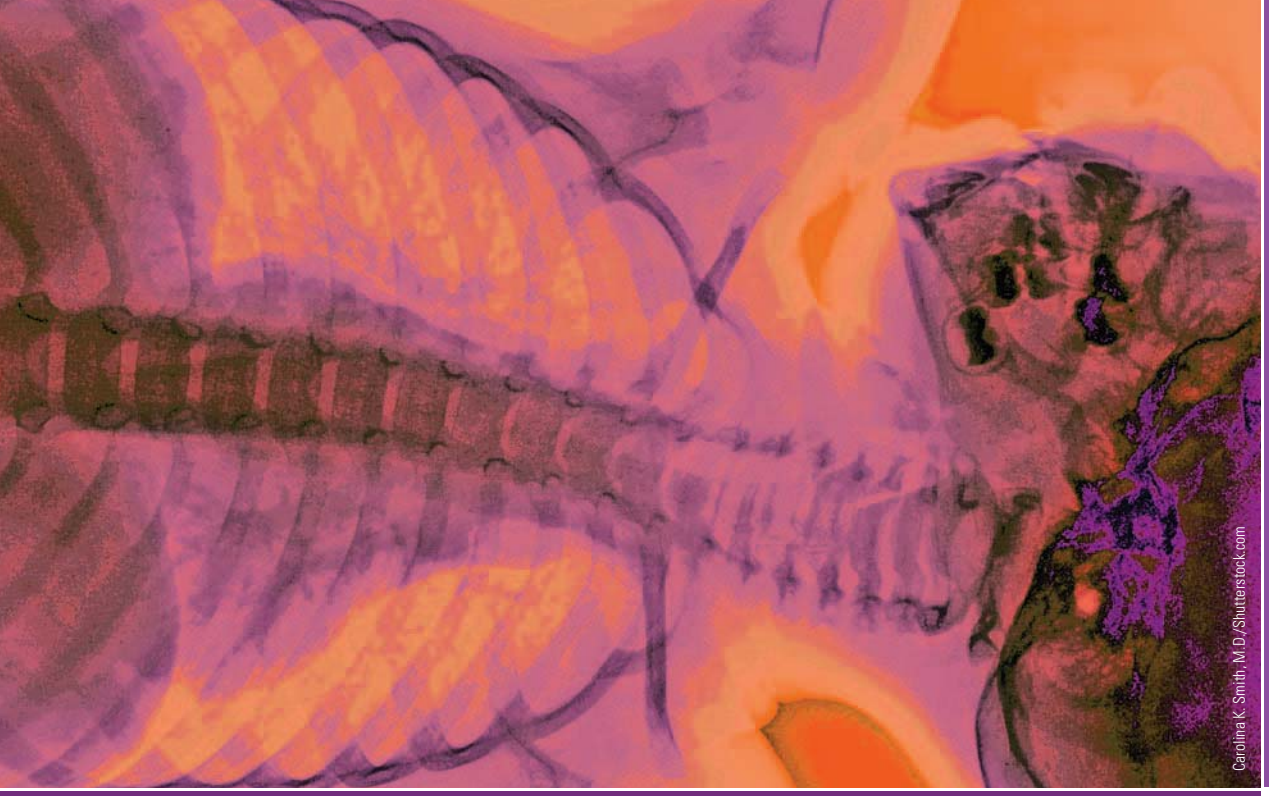
TABLE 2 Bone Properties in Children with OI Who Received No Drug Treatment

Control Child	Vertebral Area, in cm^2 (Initial)	Vertebral Area, in cm^2 (Final)	Fractures Per Year
1	18.2	13.7	4
2	16.5	12.9	7
3	16.4	11.3	8
4	13.5	17.7	5
5	16.2	16.1	8
6	18.9	17.0	6
Mean	16.6	13.1	6.3



© Cengage Learning 2014

1. An increase in the vertebral area during the 12-month period of the study indicates bone growth. How many of the treated children showed an increase?
2. How many of the untreated children showed an increase?
3. How did the rate of fractures in the two groups compare?
4. Do the results shown support the hypothesis that giving young children who have OI this drug, which slows bone breakdown, can increase bone growth and reduce fractures?

Apply Evolutionary Thinking

What characteristics of vertebrate muscle suggest that the genes for muscle structure were inherited from invertebrate ancestors?

STUDY OUTLINE

44.1 Animal Circulatory Systems: An Introduction
44.2 Blood and Its Components
44.3 The Heart
44.4 Blood Vessels of the Circulatory System
44.5 Maintaining Blood Flow and Pressure
44.6 The Lymphatic System

The Circulatory System

Why it matters . . . Dr. Augustus Waller, a physician at St. Mary's Hospital, performed experiments in the emerging field of *electrophysiology.* Among other discoveries, Waller made an apparatus that detected the electrical currents produced each time the heart beats. Waller made his finding by experimenting on himself. He already knew that the heart creates an electrical current as it beats; other scientists had found this out by attaching electrodes directly to the heart of experimental animals. Looking for a painless alternative to that procedure, Waller reasoned that because the human body can conduct electricity, his arms and legs might conduct the currents generated by the heart if they were connected to a galvanometer, a device that can detect electrical currents. Accordingly, Waller set up two metal pans containing saltwater and connected wires from the pans to a galvanometer. He put his bare left foot in one of the pans, and his right hand in the other one. The technique worked; the indicator of the galvanometer jumped each time his heart beat. He demonstrated his procedure at a meeting of the Royal Society in London in 1909 using his bulldog, Jimmie.

Waller also invented a method for recording the changes in current, which became the first electrocardiogram (ECG). He constructed a galvanometer by placing a column of mercury in a fine glass tube, with a conducting salt solution layered above the mercury. Changes in the current passing through the tube caused corresponding changes in the surface tension of the mercury, which produced movements that could be detected by reflecting a beam of light from the mercury surface. By placing a moving photographic plate behind the mercury tube, Waller could record the movements of the reflected light on the plate (**Figure 44.1** shows one of his records).

The beating of the heart is part of the actions of the **circulatory system,** an organ system consisting of a fluid, a heart, and vessels for moving important molecules, and often cells, from

one tissue to another. Examples of transported molecules are oxygen (O_2), nutrients, hormones, carbon dioxide (CO_2), and other wastes.

We study the circulatory system in this chapter, with emphasis on the circulation in humans and other mammals. We also discuss the **lymphatic system,** an accessory system of vessels and organs that helps balance the fluid content of the blood and surrounding tissues and participates in the body's defenses against invading disease organisms.

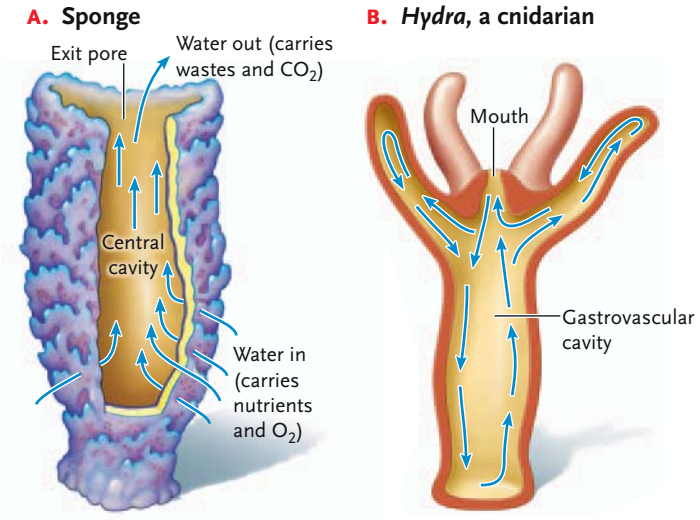

FIGURE 44.2 Invertebrates with no circulatory system.

44.1 Animal Circulatory Systems: An Introduction

As you learned in the discussion of homeostasis in Section 38.4, the cells of all organisms must take in nutrients and O_2 from the external environment, and eliminate wastes such as CO_2 to that same environment. For very small or very thin animals, movement of such molecules occurs primarily by diffusion (see Section 6.2). Diffusion is slow over distances of even a few millimeters, however, making this mechanism unsuitable for larger and more complex animals. Circulatory systems overcome the problem by bringing fluids for gas and nutrient exchange close to the cells, where diffusion and other transport mechanisms can be effective. You will learn more about gas exchange in Chapter 46's discussion of the respiratory system.

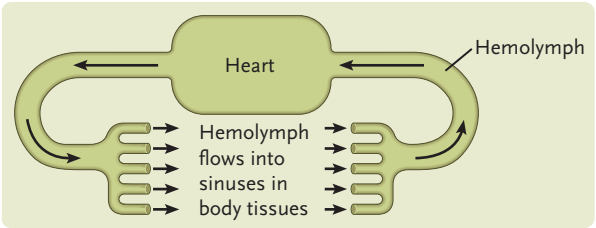
Simple Animals Have No Distinct Circulatory System

The least complex animals, including sponges, cnidarians, and flatworms, have no distinct circulatory system. These animals are aquatic or, like parasitic flatworms, live surrounded by the body fluids of a host animal. Their bodies are structured as thin sheets of cells that lie close to the fluids of the surrounding external environment. Substances diffuse between the cells and the external environment through the animal's external surface, or through the surfaces of internal channels and cavities that are open to the environment.

In sponges, water carrying nutrients and O_2 is pumped by surface cells with beating flagella through hundreds of pores in the body wall surrounding a central cavity; it passes through the cavity and leaves through a large exit pore, now carrying CO_2 and wastes **(Figure 44.2A).** Hydras, jellyfish, sea anemones, and other cnidarians have a central **gastrovascular cavity** with a mouth that opens to the outside and extensions that radiate into the tentacles and all other body regions **(Figure 44.2B).** Water enters and leaves through the mouth, serving both digestion and circulation.

Circulatory Systems of Complex Animals Share Basic Elements

In larger and more complex animals, most cells lie in cell layers too deep within the body to exchange substances directly with the external environment by diffusion. Instead, the animals have a set of tissues and organs—a circulatory system—that conducts O_2, CO_2, nutrients, and wastes between body cells and specialized regions of the animal where substances are exchanged with the external environment. In terrestrial vertebrates, for example, oxygen from the environment is absorbed in the lungs and is carried by the blood to all parts of the body; CO_2 released from body cells is carried by the blood to the lungs, where it is released to the environment. Wastes are conducted from body cells to the kidneys, which remove the wastes from the circulation and excrete them into the environment.



The animal circulatory systems carrying out these roles have three basic components:

1. **Fluid:** A specialized fluid medium carries O_2, CO_2, nutrients, and wastes, as well as cells, and plays a major role in homeostasis (see Section 38.4).
2. **Heart:** A muscular heart pumps the fluid through the circulatory system.
3. **Vessels:** Tubular vessels serve as conduits to distribute the fluid pumped by the heart.

Animal circulatory systems are either *open* or *closed* **(Figure 44.3).** In an **open circulatory system,** vessels leaving the heart release a bloodlike fluid called **hemolymph** directly into body spaces called **sinuses** that surround organs. Thus, there is no distinction between hemolymph and *interstitial fluid,* the fluid immediately surrounding body cells (see Section 38.4).

A. Open circulatory system: no distinction between hemolymph and interstitial fluid

B. Closed circulatory system: blood separated from interstitial fluid

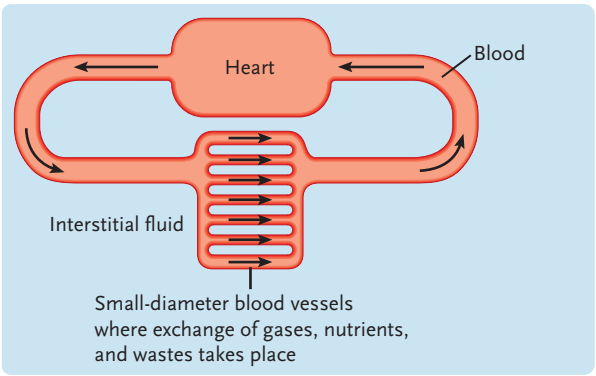

FIGURE 44.3 Open and closed circulatory systems.

© Cengage Learning 2014

After flowing through the sinuses, the hemolymph re-enters the heart through valves in the heart wall. In a **closed circulatory system,** the fluid—blood—is confined to blood vessels and is distinct from the interstitial fluid. Substances are exchanged between the blood and the interstitial fluid and then between the interstitial fluid and cells.

Most Invertebrates Have Open Circulatory Systems

Arthropods and most mollusks have open circulatory systems with one or more muscular hearts **(Figure 44.4).** In an open system, most of the fluid pressure generated by the heart dissipates when the hemolymph is released into the sinuses. As a result, hemolymph flows relatively slowly. Open systems operate efficiently in these animals because they lead relatively sedentary lives; as a consequence, their tissues do not require O_2 and nutrients at the rate and quantities required by more active species. Among highly mobile and active species with open systems, such as insects and crustaceans, other adaptations compensate for the relatively slow distribution of hemolymph. In insects, for example, O_2 and CO_2 are exchanged efficiently with the environment by specialized air passages that branch throughout the body rather than by the hemolymph (these air passages, called *tracheae,* are discussed in Chapter 46).

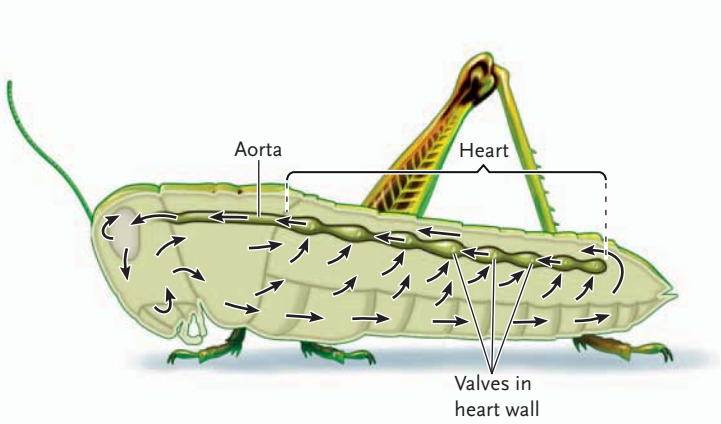

FIGURE 44.4 Open circulatory system of a grasshopper.

© Cengage Learning 2014

Some Invertebrates and All Vertebrates Have Closed Circulatory Systems

Annelids, cephalopod mollusks such as squids and octopuses, and all vertebrates have closed circulatory systems. In these systems, vessels called **arteries** conduct blood away from the heart at relatively high pressure. From the arteries, the blood enters highly branched networks of microscopic, thin-walled vessels called **capillaries** that are well adapted for diffusion of substances. Nutrients and wastes are exchanged between the blood and body tissues as the blood moves through the capillaries. The blood then flows at relatively low pressure from the capillaries to larger vessels, the **veins,** which carry it back to the heart.

In many animals, but particularly the vertebrates, closed systems allow precise control of the distribution and rate of blood flow to different body regions by means of muscles that contract or relax to adjust the diameter of the blood vessels.

Vertebrate Circulatory Systems Have Evolved from Single to Double Blood Circuits

Several evolutionary trends accompanied the invasion of terrestrial habitats by the different vertebrate groups. Among the most significant is a trend from an effectively single circuit of blood pumped by the heart in sharks and bony fishes to the two separate circuits of birds and mammals. As part of this development, the heart evolved from one series of chambers to a double pump acting in two parallel series. In other words, depending on the vertebrate, the heart may consist of one or two **atria** (singular, *atrium*), the chambers that receive blood returning to the heart, and one or two **ventricles,** the chambers that pump blood from the heart.

THE SINGLE BLOOD CIRCUIT OF FISHES In fishes, the heart consists of two chambers arranged in a single line **(Figure 44.5A).** The ventricle of the heart pumps blood into arteries leading to capillary networks in the gills, where the blood releases CO_2 and picks up O_2. The oxygenated blood is delivered to capillary networks in other body tissues where it delivers O_2 and picks up CO_2. The deoxygenated blood enters veins that carry it back to the atrium of the heart, and the single circuit is repeated.

The circulatory system of fishes is highly suited to the environments in which these animals live. Their bodies, sup-

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ported by water and adapted for swimming, do not use as much energy in locomotion as do animals of an equivalent size moving on the land or in the air. Hence, fishes require less O_2 for their activities than terrestrial vertebrates do, and their relatively simple circulatory systems reflect this reduced O_2 requirement.

DOUBLE BLOOD CIRCUITS Vertebrate hearts changed significantly with the evolution of the first air-breathing fishes, such as the lungfish (see Section 32.5). In these fishes, the lung evolved as a respiratory organ in addition to gills. The lung necessitated a separate circuit because it is an additional organ for oxygenating the blood.

In amphibians, the separation into two circuits was accomplished by division of the atrium into two parallel chambers, the left and right atria, to produce a three-chambered heart, and by adaptations that keep oxygenated and deoxygenated blood partially separate as they are pumped by the single ventricle **(Figure 44.5B).** In water, amphibians obtain O_2 primarily through the skin; the lungs are used only when the animal is in air. Oxygenated blood from lungs and skin enters veins that lead to the left atrium, whereas deoxygenated blood from the rest of the body enters the right atrium. Simultaneous contraction of the atria moves the two types of blood into the single ventricle, where some mixing occurs before the ventricle pumps the two types of blood into largely separate circuits. Most of the oxygenated blood enters the **systemic circuit** that supplies the blood for most of the tissues and cells of the body. The bulk of the deoxygenated blood enters the **pulmocutaneous circuit** that leads to the lungs and skin. Because the blood flows through separate systemic and pulmocutaneous circuits, the blood leaving the heart flows through only one capillary network in each circuit before returning to the heart. This separation greatly increases the blood pressure and flow in the systemic circuit as compared with that of fishes.

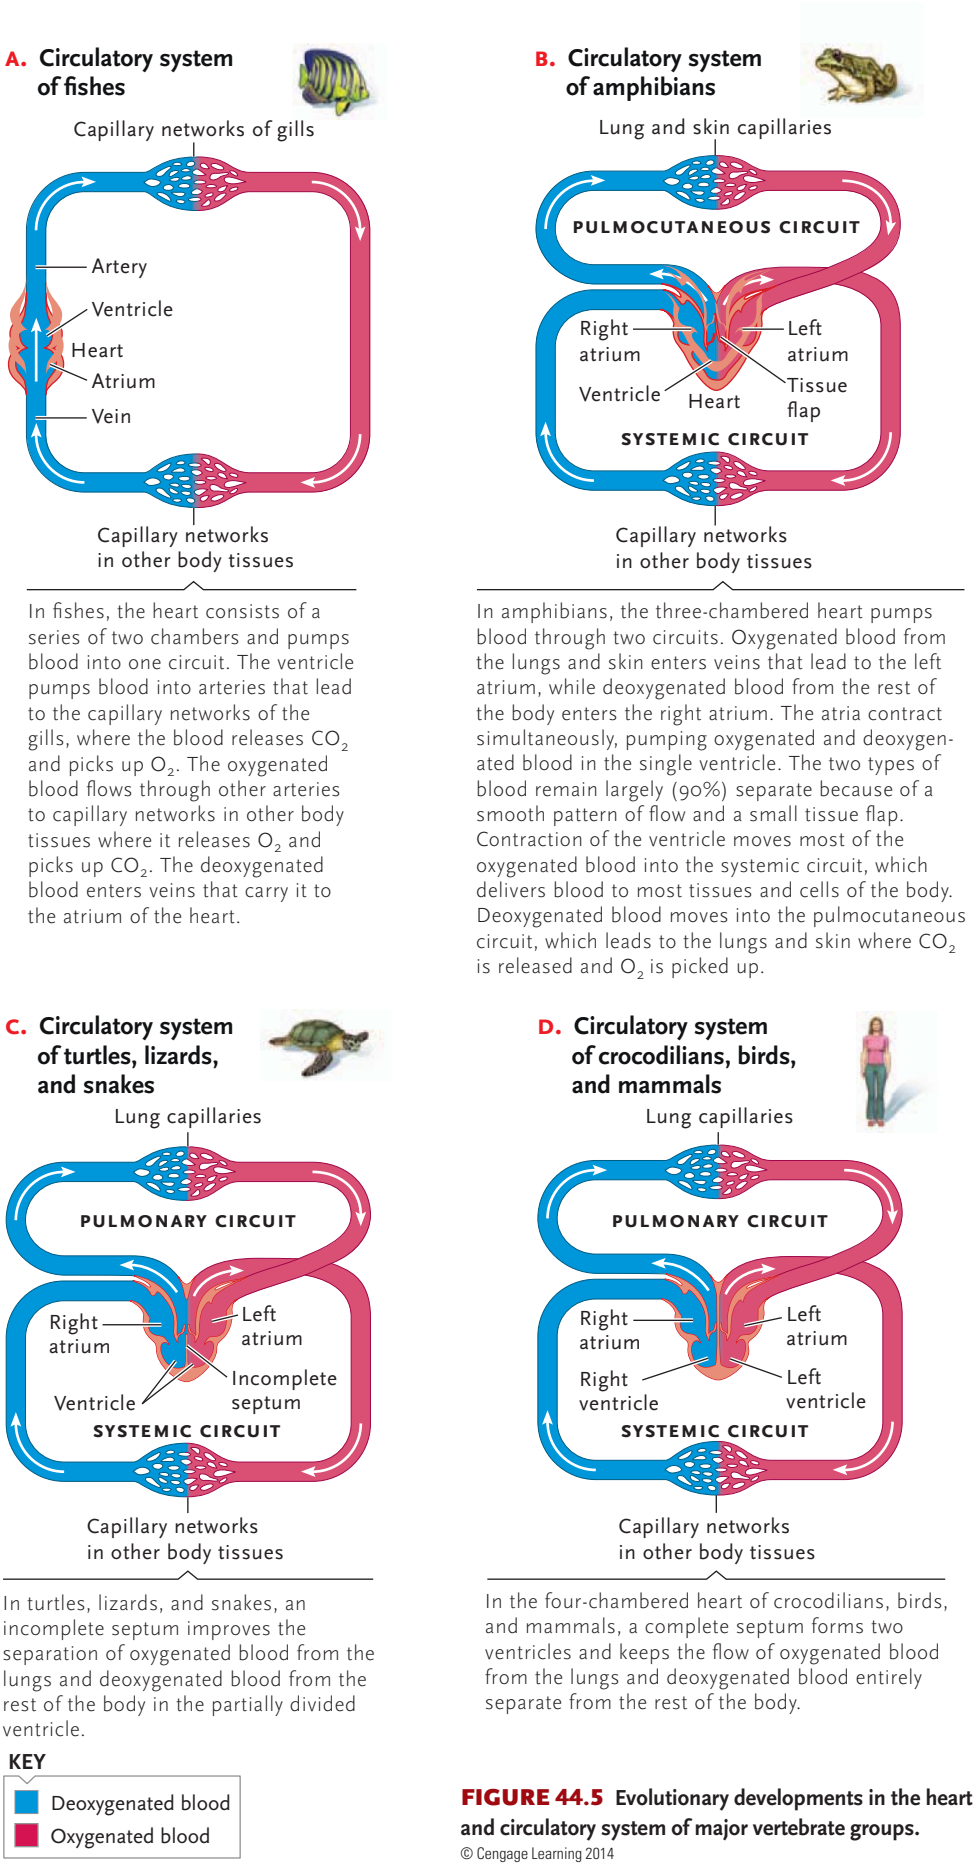

FIGURE 44.5 **Evolutionary developments in the heart and circulatory system of major vertebrate groups.**

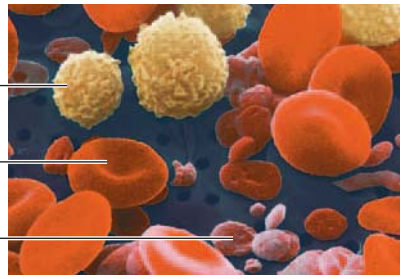
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Turtles, lizards, and snakes also have two atria and a single ventricle. The ventricle is divided into right and left halves by a flap of connective tissue called the *septum* to keep the flow of oxygenated and deoxygenated blood almost completely separate in a systemic and a **pulmonary circuit (Figure 44.5C).** The septum is incomplete in turtles, lizards, and snakes, allowing some mixing of oxygenated and deoxygenated blood. In crocodilians (crocodiles and alligators), the septum is complete **(Figure 44.5D).**

Birds (which share ancestry with crocodilians) and mammals have a double heart consisting of two atria and two ventricles (as in Figure 44.5D). In effect, each half of the heart operates as a separate pump, restricting the blood circulation to completely separate pulmonary and systemic circuits. Blood is pumped by a ventricle in each circuit, so that both operate at relatively high pressure.

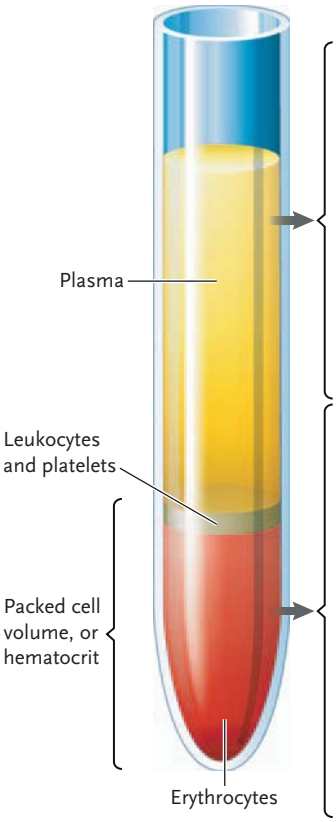
STUDY BREAK 44.1

1. What are the three basic features of animal circulatory systems?
2. Distinguish between an open circulatory system and a closed circulatory system. Why do you think humans could not function with an open circulatory system?
3. Distinguish among atria, ventricles, arteries, and veins.
4. Distinguish among the systemic, pulmocutaneous, and pulmonary circuits.



44.2 Blood and Its Components

In vertebrates, blood is a complex tissue containing a variety of cells suspended in a liquid matrix called the **plasma.** In addition to transporting molecules, blood stabilizes the pH and salt composition of body fluids and serves as a conduit for cells of the immune system. It also helps regulate body temperature by transferring heat between warmer and cooler body regions, and between the body and the external environment (the role of the blood in temperature regulation is discussed in Chapter 48).



For an average-sized adult human, the total blood volume is 4 to 5 L—more than a gallon—and makes up about 8% of body weight. The plasma, a clear, straw-colored fluid, makes up about 55% of the volume of blood in human males and 58% in human females on average. Suspended in the plasma are three main types of blood cells—*erythrocytes, leukocytes,* and *platelets*—which constitute the hematocrit, the remainder of the blood volume. The typical components of human blood are shown in **Figure 44.6.**

FIGURE 44.6 Typical components of human blood. The colorized scanning electron micrograph shows the three major cellular components. The sketch of the test tube shows what happens when you centrifuge a blood sample. The blood separates into three layers: a thick layer of straw-colored plasma on top, a thin layer containing leukocytes and platelets, and a thick layer of erythrocytes. The table shows the relative amounts and functions of the various components of blood.

NCI/Photo Researchers, Inc.

Plasma Portion: 55% (males)–58% (females) of total volume

Component	Percentage of Plasma Volume	Functions
1. Water	91–92	Solvent
2. Plasma proteins (albumin, globulins, fibrinogen, etc.)	7–8	Defense, clotting, lipid transport, roles in extracellular fluid volume, etc.
3. Ions, sugars, lipids, amino acids, hormones, vitamins, dissolved gases	1–2	Roles in extracellular fluid volume, pH, etc.

Cellular Portion (Hematocrit): 45% (males)–42% (females) of total volume

Component	Cells per Microliter	Functions
1. Erythrocytes (red blood cells)	4,800,000–5,400,000	Oxygen, carbon dioxide transport
2. Leukocytes (white blood cells)		
Neutrophils	3,000–6,750	Phagocytosis during inflammation
Lymphocytes	1,000–2,700	Immune response
Monocytes/macrophages	150–720	Phagocytosis in all defense responses
Eosinophils	100–360	Defense against parasitic worms
Basophils	25–90	Secrete substances for inflammatory response and for fat removal from blood
3. Platelets	250,000–300,000	Roles in clotting

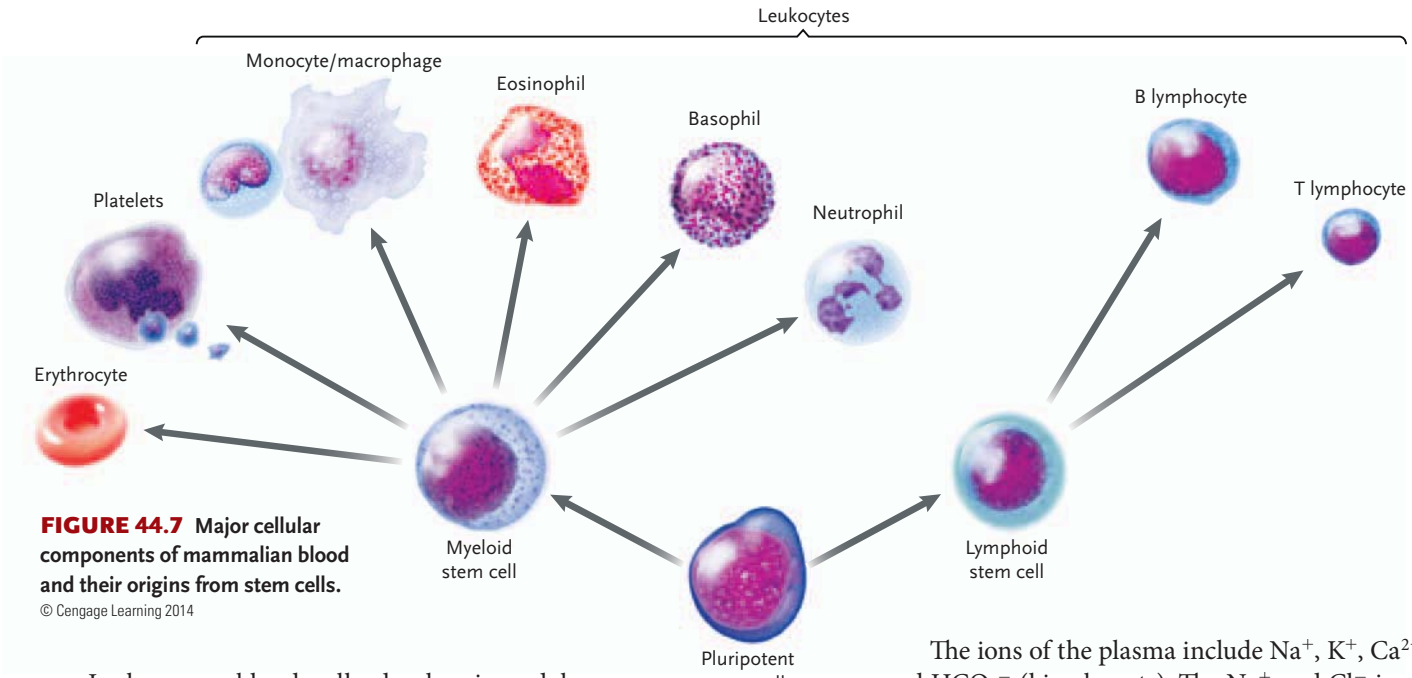

FIGURE 44.7 **Major cellular components of mammalian blood and their origins from stem cells.**

© Cengage Learning 2014

In humans, blood cells develop in red bone marrow primarily in the vertebrae, sternum (breastbone), ribs, and pelvis. Blood cells originate from cells called *pluripotent* (*plura* = multiple; *potens* = power) *stem cells* that retain the embryonic capacity to divide **(Figure 44.7).** Pluripotent stem cells differentiate into two other types of cells, myeloid stem cells and lymphoid stem cells. Myeloid stem cells give rise to erythrocytes, platelets, and four types of leukocytes: the neutrophils, basophils, eosinophils, and monocytes/macrophages. Lymphoid stem cells give rise to two other types of leukocytes that function in the immune system: the B lymphocytes and T lymphocytes (see Chapter 45).

Plasma Is an Aqueous Solution of Proteins, Ions, Nutrient Molecules, and Gases

Plasma is so complex that its complete composition is unknown. Among its known components are water (91%–92% of its volume), glucose and other sugars, amino acids, plasma proteins, dissolved gases (mostly O_2, CO_2, and nitrogen), ions, lipids, vitamins, hormones and other signal molecules, and metabolic wastes, including urea and uric acid.

The plasma proteins fall into three classes, the *albumins,* the *globulins,* and *fibrinogen*. The **albumins,** the most abundant proteins of the plasma, are important for osmotic balance and pH buffering. They also transport a wide variety of substances through the circulatory system, including hormones, therapeutic drugs, and metabolic wastes. The **globulins** transport lipids (including cholesterol) and fat-soluble vitamins; a specialized subgroup of globulins, the *immunoglobulins,* constitute antibodies and other molecules contributing to the immune response. Some globulins are also enzymes. **Fibrinogen** plays a central role in the blood-clotting mechanism. All plasma proteins except immunoglobulins are synthesized in the liver; the immunoglobulins are synthesized by B and T lymphocytes (see Chapter 45).

The ions of the plasma include Na^+, K^+, Ca^{2+}, Cl^-, and HCO_3^- (bicarbonate). The Na^+ and Cl^- ions—the components of common table salt—are the most abundant. Some ions, particularly the bicarbonate ion, help maintain arterial blood at its characteristic pH, which in humans is about pH 7.4 (the bicarbonate ion and its role in pH balance are discussed further in Chapter 46).

Erythrocytes Are the Oxygen Carriers of the Blood

Erythrocytes—the red blood cells—carry O_2 from the lungs to body tissues. Each microliter of human blood contains about 5 million small, flattened, and disclike erythrocytes. Indentations on each flattened surface make them *biconcave*—thinner in the middle than at the edges (see Figure 44.6). They are about 7 μm in diameter and 2 μm thick. Erythrocytes are highly flexible cells, able to squeeze through narrow capillaries.

As they mature, mammalian erythrocytes lose their nuclei, cytoplasmic organelles, and ribosomes, thereby limiting their metabolic capabilities and life span. The remaining cytoplasm contains enzymes that carry out glycolysis and large quantities of *hemoglobin,* the O_2-carrying protein of the blood. Most of the ATP produced by glycolysis (see Chapter 8) is used to power active transport mechanisms that move ions in and out of erythrocytes.

Hemoglobin, the protein that gives erythrocytes and the blood its red color, consists of four polypeptides, each linked to a nonprotein *heme* group that contains an iron atom in its center (see Figure 3.19). The iron atom binds O_2 molecules as blood circulates through the lungs and releases the O_2 as blood flows through other body tissues. Chapter 46 describes the mechanisms of gas exchange and transport, including the process by which hemoglobin transports O_2.

Hemoglobin can also combine with carbon monoxide (CO), a by-product of combustion. The combination, which is

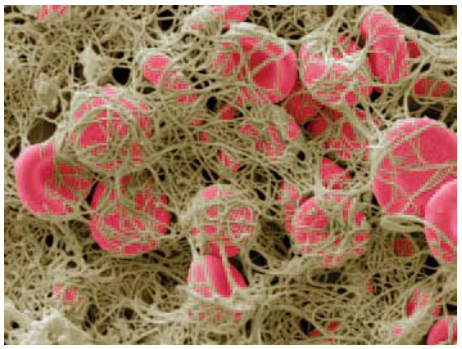
essentially irreversible, blocks hemoglobin's ability to combine with O_2, and can quickly lead to death. CO is also present in cigarette smoke.

Some 2 to 3 million erythrocytes are produced in the average human each *second*. The life span of an erythrocyte in the circulatory system is about 120 days. At the end of their useful life, erythrocytes are engulfed and destroyed by *macrophages* (*macros* = big; *phagein* = to eat) (see Figure 44.7), a type of leukocyte, in the spleen, liver, and bone marrow.

A negative feedback mechanism keyed to the blood's O_2 content stabilizes the number of erythrocytes. If the O_2 content drops below the normal level, the kidneys release **erythropoietin** (EPO), a hormone that stimulates stem cells in bone marrow to increase erythrocyte production. EPO is also secreted after blood loss and when mammals move to higher altitudes. As new red blood cells enter the bloodstream, the O_2-carrying capacity of the blood rises. If the O_2 content of the blood rises above normal levels, EPO production falls in the kidneys and red blood cell production drops. The gene encoding human EPO has been cloned, allowing researchers to produce this protein in large quantities. It can then be injected into the body to stimulate erythrocyte production; for example, in patients with anemia (lower-than-normal hemoglobin levels) caused by kidney failure or chemotherapy. It can also supplement or even replace blood transfusions. Some endurance athletes such as triathletes, bicycle racers, marathon runners, and cross-country skiers have used EPO to increase their erythrocyte levels to enhance performance. Such "blood doping" is deemed illegal by the governing organizations of most endurance sports and, as a result, many athletes have been sanctioned or banned in recent years.



Human blood groups are determined by antigens, the carbohydrate portions of particular glycoproteins on the surfaces of erythrocytes. Section 12.2 described the antigens of the human ABO blood group and how they are important in transfusions.

Disorders of erythrocytes are responsible for a number of human disabilities and diseases. The *anemias,* which result from too few, or malfunctioning, erythrocytes, prevent O_2 from reaching body tissues in sufficient amounts. Shortness of breath, fatigue, and chills are common symptoms of anemia. Anemia can be produced, for example, by blood loss from a wound, by certain infections, or by dietary insufficiencies.

Leukocytes Provide the Body's Front Line of Defense against Disease

Leukocytes eliminate dead and dying cells from the body, remove cellular debris, and defend against invading organisms. They are called white cells because they are colorless, in contrast to the strongly pigmented red blood cells. Also unlike red blood cells, leukocytes retain their nuclei, cytoplasmic organelles, and ribosomes as they mature, and hence are fully functional cells.

Some types of leukocytes are capable of continued division in the blood and body tissues. The specific types of leukocytes and their functions in the immune system are discussed in Chapter 45.

FIGURE 44.8 **Red blood cells caught in a meshlike network of fibrin threads during formation of a blood clot.**

Platelets Induce Blood Clots That Seal Breaks in the Circulatory System

Blood **platelets** are oval or rounded vesicles about 2 to 4 μm in diameter that contain enzymes and other factors that take part in blood clotting. When blood vessels are damaged, collagen fibers in the extracellular matrix are exposed to the leaking blood. Platelets in the blood then stick to the collagen fibers and release signaling molecules that induce additional platelets to stick to them. The process continues, forming a plug that helps seal the damaged site. As the plug forms, the platelets release other factors that convert the soluble plasma protein fibrinogen into long, insoluble threads of **fibrin.** Cross-links between the fibrin threads form a meshlike network that traps blood cells and platelets and further seals the damaged area **(Figure 44.8).** The entire mass is a blood clot.

Mutations or diseases that interfere with the enzymes and factors taking part in the clotting mechanism can have serious effects and lead to uncontrolled bleeding. In the most common form of hemophilia, for example, a mutation in a single protein (called *clotting factor VIII*) interferes with the clotting reaction (see Section 13.2). Bleeding is uncontrolled in afflicted individuals; even small cuts and bruises can cause life-threatening blood loss.

1. Outline the life cycle of an erythrocyte.
2. How does the body compensate for a lower-than-normal level of oxygen in the blood?
3. What are the roles of leukocytes and platelets?

44.3 The Heart

In mammals, the heart is structured from cardiac muscle cells (see Figure 38.5) forming a four-chambered pump, with two atria at the top of the heart pumping blood into two ventricles at the bottom of the heart **(Figure 44.9).** The powerful contractions of the ventricles push the blood at relatively high pressure into arteries leaving the heart. This arterial pressure is responsible for the blood circulation. Valves in the heart keep the blood from moving backward. Between each atrium and ventricle is an

atrioventricular valve (AV valve), and between the ventricles and the arteries leaving the heart (the aorta and pulmonary arteries) are **semiluminar valves (SL valves).**

The heart of mammals pumps the blood through two completely separate circuits of blood vessels: the systemic circuit and the pulmonary circuit **(Figure 44.10):**

1. The right atrium (toward the right side of the body) receives blood returning to the heart in vessels coming from the entire body, except for the lungs: the *superior vena cava* conveys blood from the head and forelimbs, and the *inferior vena cava* conveys blood from the abdominal organs and the hind limbs. This blood is depleted of O_2 and has a high CO_2 content.
2. The right atrium pumps blood into the right ventricle, which contracts to push the blood into the **pulmonary arteries** leading to the lungs. In the capillaries of the lungs, the blood releases CO_2 and picks up O_2. The oxygenated blood completes this pulmonary circuit by returning in **pulmonary veins** to the heart.
3. Blood returning from the pulmonary circuit enters the left atrium, which pumps the blood into the left ventricle.
4. The left ventricle, the most thick-walled and powerful of the heart's chambers, contracts to send the oxygenated blood coursing into a large artery, the **aorta,** which branches into arteries leading to all body regions except the lungs. In the capillary networks of these body regions, the blood releases O_2 and picks up CO_2. The O_2-depleted blood collects in veins, which complete the systemic circuit. The blood from the veins enters the right atrium (step 1, above).

The amount of blood pumped by the two halves of the heart is normally balanced so that neither side pumps more than the other. More details of gas exchange in the pulmonary circuit are presented in Chapter 46.

The heart also has its own circulation, called the *coronary circulation.* The aorta gives off two **coronary arteries** that course over the heart. The coronary arteries branch extensively, leading to dense capillary beds that serve the cardiac muscle cells. The blood from the capillary networks collects into veins that empty into the right atrium.

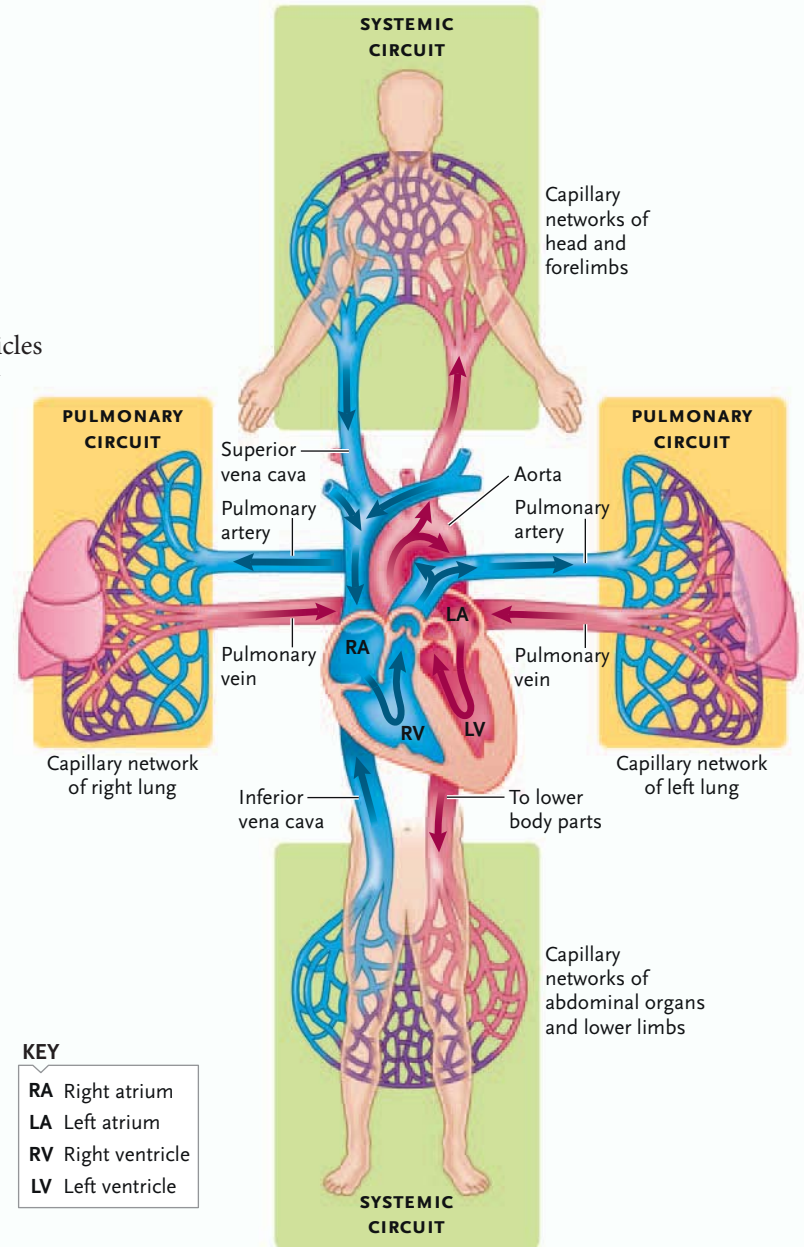

FIGURE 44.10 **The pulmonary and systemic circuits of mammals.** The right half of the heart pumps blood into the pulmonary circuit, and the left half of the heart pumps blood into the systemic circuit.

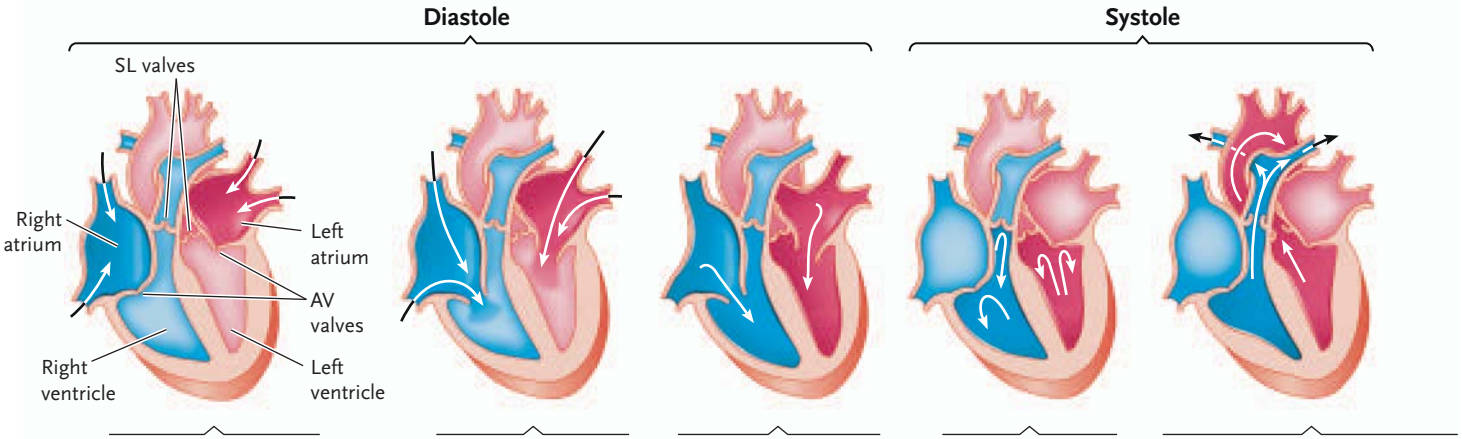

FIGURE 44.11 The cardiac cycle. The figure shows one cardiac cycle beginning at the start of diastole.
© Cengage Learning 2014

The Heartbeat Is Produced by a Cycle of Contraction and Relaxation of the Atria and Ventricles

Average heart rates vary among vertebrates, depending on body size and the overall level of metabolic activity. A human heart beats 72 times per minute, on average. The resting heart rate of a trained endurance athlete may be only 60% of this rate. The heart of a flying bat may beat 1,200 times a minute, whereas that of an elephant beats only 30 times a minute. The period of ventricular contraction and emptying of the heart is called the **systole** and the period of relaxation and filling of the heart between contractions is called the **diastole.** The systole–diastole sequence of the heart is called the **cardiac cycle (Figure 44.11).** At an average heart rate, the cardiac cycle takes a little over 0.8 sec.

The heart valves make a "lub-dub" sound when the heart beats, which you can hear by listening to the heart through a stethoscope. The "lub" sound occurs when the AV valves are pushed shut by the contraction of the ventricles; the "dub" sound is made when the SL valves are forced shut as the ventricles relax. *Heart murmurs* are abnormal sounds produced by turbulence created in the blood when one or more of the valves fails to open or close completely and blood flows backward.

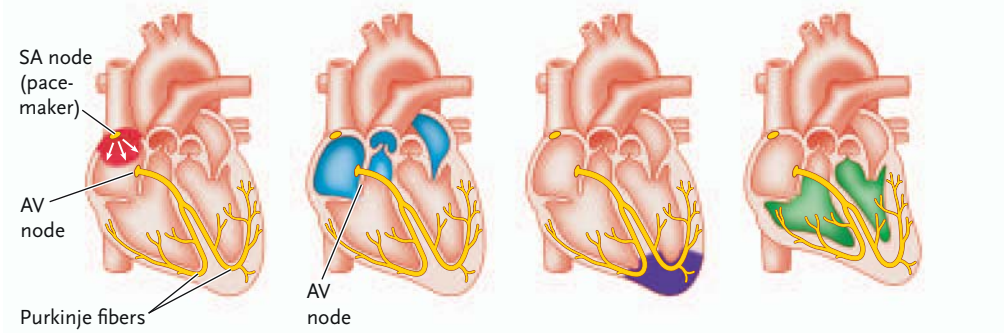
In an adult human at rest, each ventricle pumps roughly 5 L of blood per minute—an amount roughly equivalent to the entire volume of blood in the body. At maximum rate and strength, the human heart pumps about five times the resting amount.

The Cardiac Cycle Is Initiated within the Heart

Contraction of cardiac muscle cells is triggered by action potentials that spread along the muscle cell membranes. Some crustaceans, such as crabs and lobsters, have **neurogenic hearts,** that is, hearts that beat under the control of signals from the nervous system. Other animals, including all insects and all vertebrates, have **myogenic hearts,** that is, hearts that maintain their contraction rhythm autonomously. Indeed, it is the ability to sustain contractile rhythmicity in the mammalian heart that makes heart transplants possible.

Figure 44.12 illustrates the electrical control of the cardiac cycle. Two nodes, the sinoatrial node and atrioventricular node, generate the electrical signals. The **sinoatrial node (SA node)** controls the rate and timing of cardiac contraction in mammalian myogenic hearts by coordinating the contractions of individual cardiac muscle cells. The SA node consists of **pacemaker cells,** which are specialized cardiac muscle cells in the upper wall of the right atrium near the entry point for blood from the systemic circuit. Ion channels in these cells open and close in a cyclic, self-sustaining pattern that alternately depolarizes and repolarizes their plasma membranes. The regularly timed depolarizations initiate waves of contraction that travel over the heart.

The **atrioventricular node (AV node)** is located in the heart wall between the right atrium and right ventricle, just above the insulating layer between the atria and the ventricles. Cells of the AV node are excited by the atrial wave of contraction, generating a signal that travels to the bottom of the heart via **Purkinje fibers.** The signal then induces a wave of contraction that begins at the bottom of the heart and proceeds upward. The transmission of a signal from the AV node to the ventricles takes about 0.1 sec; this delay gives the atria time to finish their contraction before the ventricles contract.



As Augustus Waller found (see *Why It Matters*), the electrical signals passing through the heart can be detected by attaching electrodes to different points on the surface of the body. The signals change in a regular pattern corresponding to the

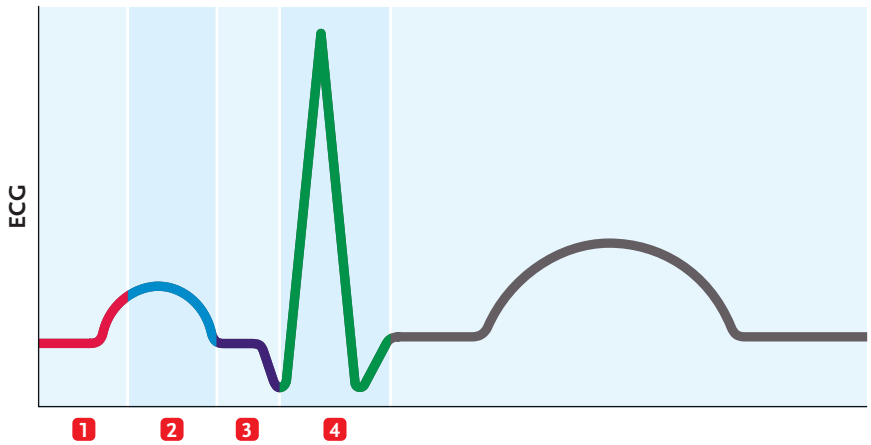
CLOSER LOOK

FIGURE 44.12 The electrical control of the cardiac cycle.

The top part of the figure shows how a signal originating at the SA node leads to ventricular contraction. The bottom part of the figure shows the electrical activity for each of the stages as seen in an ECG. The colors in the hearts show the location of the signal at each step and correspond to the colors in the ECG.



1 Depolarization signal. Pacemaker cells of SA node generate rhythmic depolarization signals initiating waves of contractions that travel over the heart. The waves cause cells of the atria to contract in unison and fill the ventricles with blood.

2 Contraction signal. A layer of connective tissue that separates and insulates the atria from the ventricles prevents a contraction signal from the SA node from spreading directly to the ventricles.

3 Signal from AV node. AV node cells excited by the atrial wave of contraction produce a signal that travels to the bottom of the heart via Purkinje fibers, which travel through the insulating layer to the bottom of the heart, where they branch into the walls of the ventricles.

4 Wave of contraction. The signal carried by the Purkinje fibers induces a wave of contraction that begins at the bottom of the heart and proceeds upward, squeezing the blood from the ventricles into the aorta and pulmonary arteries.

SUMMARY Waves of rhythmic depolarization signals generated by the SA node cause waves of contraction that travel over the heart, starting with the atria. AV node cells excited by atrial contraction generate a signal that travels to the bottom of the heart and then induces a wave of contraction that moves upward, causing the ventricles to contract.

THINK LIKE A SCIENTIST What effect do you think a dysfunction of the SA node would have on the cardiac cycle?

electrical signals that trigger the cardiac cycle, producing what is known as an **electrocardiogram** (**ECG;** also **EKG,** from German *elektrokardiogramm*). Many malfunctions of the heart alter the ECG pattern in characteristic ways, providing clues to the location and type of heart disease.

Arterial Blood Pressure Cycles between a High Systolic and a Low Diastolic Pressure

The pressure that a fluid in a confined space exerts is called *hydrostatic pressure.* That is, fluid in a container exerts some pressure on the wall of the container. Blood vessels are essen-

tially tubular containers that are part of a closed system filled with fluid. Hence, the blood in vessels exerts hydrostatic pressure against the walls of the vessels. **Blood pressure** is the measurement of that hydrostatic pressure on the walls of the arteries as the heart pumps blood through the body. Blood pressure is determined by the force and amount of blood pumped by the heart and the size and flexibility of the arteries. In any person, blood pressure changes continually in response to activity, temperature, body position, emotional state, diet, and medications being taken.

For most healthy adults at rest, the systolic pressure measured at the upper arm using a blood pressure cuff is between 90 and 120 mm Hg, and the diastolic pressure is between 60 and 80 mm Hg. The numbers, written in the form 120/80 mm Hg and stated verbally as "120 over 80," refer to the height of a column of mercury in millimeters that would be required to balance the pressure exactly. The systolic and diastolic blood pressures in the pulmonary arteries are typically much lower, about 24/8 mm Hg.

The blood pressure in the systemic and pulmonary circuits is highest in the arteries leaving the heart, and drops as the blood passes from the arteries into the capillaries. By the time the blood returns to the heart, its pressure has dropped to 2 to 5 mm Hg, with no differentiation between systolic and diastolic pressures. The reduction in pressure occurs because the blood encounters resistance as it moves through the vessels, produced primarily by the friction created when blood cells and plasma proteins move over each other and over vessel walls.

Some people have **hypertension,** commonly called high blood pressure, a medical condition in which blood pressure is chronically elevated above normal values to at least 140/90. In some cases, no specific medical cause can be found to explain the hypertension. In other cases, the hypertension results from another medical condition, such as kidney disease or disorders affecting the adrenal cortex. Hypertension can also be caused by certain medications, such as ibuprofen and steroids. Age is also a contributor to hypertension because over time the walls of blood vessels become stiffer as more collagen fibers are added, decreasing the elasticity of the arteries. During systole, these arteries cannot expand as much as they once could, and this results in a higher arterial blood pressure.

Hypertension is rarely severe enough to cause symptoms. However, in the long term, the increased pressure in the arteries can cause damage to organs. Hence, hypertension is treated because of the correlation with an increased risk for a number of medical conditions, including myocardial infarction (heart attack), cardiovascular accident (stroke), chronic renal failure, and retinal damage. Treatments to reduce hypertension typically involve lifestyle changes, such as weight loss and regular exercise; in the case of moderate to severe hypertension, drugs are also prescribed.

What happens to blood pressure during exercise? During static exercise involving a sustained contraction of a muscle group or groups, such as weight lifting, both systolic and diastolic pressures increase. In elite weight lifters, for instance, blood pressure during lifts can reach 300/150 mm Hg. However, during dynamic exercise involving intermittent and rhythmical muscle contractions, such as running, bicycling, and swimming, only the systolic pressure increases.

4. Describe the electrical events that occur during the cardiac cycle in a mammalian heart.

THINK OUTSIDE THE BOOK

Arrhythmia is any variation from the normal heartbeat rhythm. On your own or collaboratively, research two examples of arrhythmia and outline the physiological reasons for them.

44.4 Blood Vessels of the Circulatory System

Both the systemic and pulmonary circuits consist of a continuum of different blood vessel types that begin and end at the heart **(Figure 44.13).** From the heart, large arteries carry blood and branch into progressively smaller arteries that deliver the blood to the various parts of the body. When a small artery reaches the organ it supplies, it branches into yet smaller vessels, the **arterioles.** Within the organ, arterioles branch into capillaries, the smallest vessels of the circulatory system. The capillaries form a network in the organ that is used to exchange substances between the blood and the surrounding cells. Capillaries rejoin to form small **venules,** which merge into the small veins that leave the organ. The small veins progressively join to form larger veins that eventually become the large veins that enter the heart.

Arteries Transport Blood Rapidly to the Tissues and Serve as a Pressure Reservoir

Arteries have relatively large diameters and, therefore, provide little resistance to blood flow. Structurally, they are adapted to the relatively high pressure of the blood passing through them. The walls of arteries consist of three major tissue layers: (1) an outer layer of connective tissue containing collagen fibers mixed with fibers of the protein elastin, which gives the vessel recoil ability; (2) a relatively thick middle layer of vascular smooth muscle cells also mixed with elastin fibers; and (3) a one-cell-thick inner layer of flattened cells that forms an *endothelium,* a specialized type of epithelial tissue that lines the entire circulatory system (see Figure 44.13).

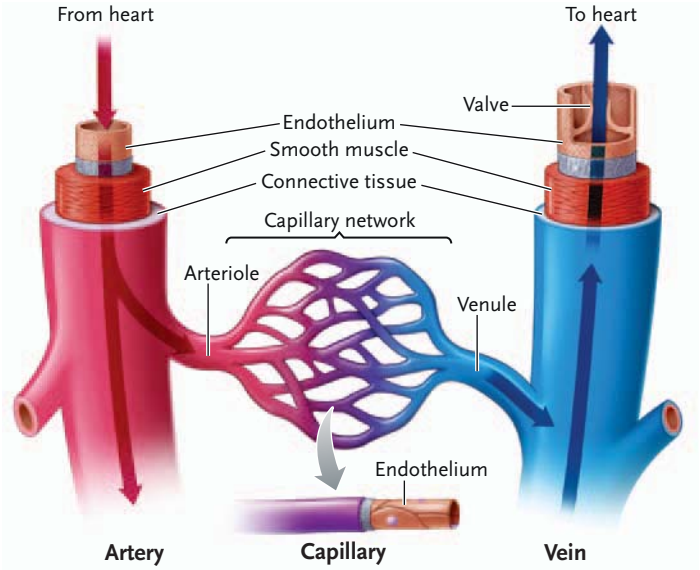

FIGURE 44.13 **The structure of arteries, capillaries, and veins and their relationship in blood circuits.**

© Cengage Learning 2014

In addition to being the conduits for blood traveling to the tissues, arteries also act as a pressure reservoir to generate the force for blood movement when the heart is relaxing. When contraction of the ventricles pumps blood into the arteries, the amount of blood flowing into the arteries is greater than the amount flowing out into the smaller vessels downstream because of the higher resistance to blood flow in those smaller vessels. The arteries can accommodate the excess volume of blood because their elastic walls allow the arteries to expand in diameter. When the heart then relaxes and blood is no longer being pumped into the arteries, the arterial walls recoil passively to their original state. The recoil pushes the excess blood from the arteries into the smaller downstream vessels. As a result, blood flow to tissues is continuous during systole and diastole.

Capillaries Are the Sites of Exchange between the Blood and Interstitial Fluid

Capillaries, which thread through nearly every tissue in the body, are arranged in networks that bring them within 10 μm of most body cells. They form an estimated 2,600 km^2 of total surface area for the exchange of gases, nutrients, and wastes with the interstitial fluid. Capillary walls consist of a single layer of endothelial cells.

CONTROL OF BLOOD FLOW THROUGH CAPILLARIES Blood flow through the capillary networks is controlled by contraction of smooth muscle in the arterioles **(Figure 44.14).** The capillaries themselves do not have smooth muscle but, in many cases, a small ring of smooth muscle called a *precapillary sphincter* is present at the junction between an arteriole and a capillary. Variation in the contraction of arteriole and sphincter smooth muscles adjusts the rate of flow through the capillary networks between the two flow limits. For example, during exercise, flow of blood through the capillary networks is increased severalfold over the resting state by relaxation of the precapillary sphincters.

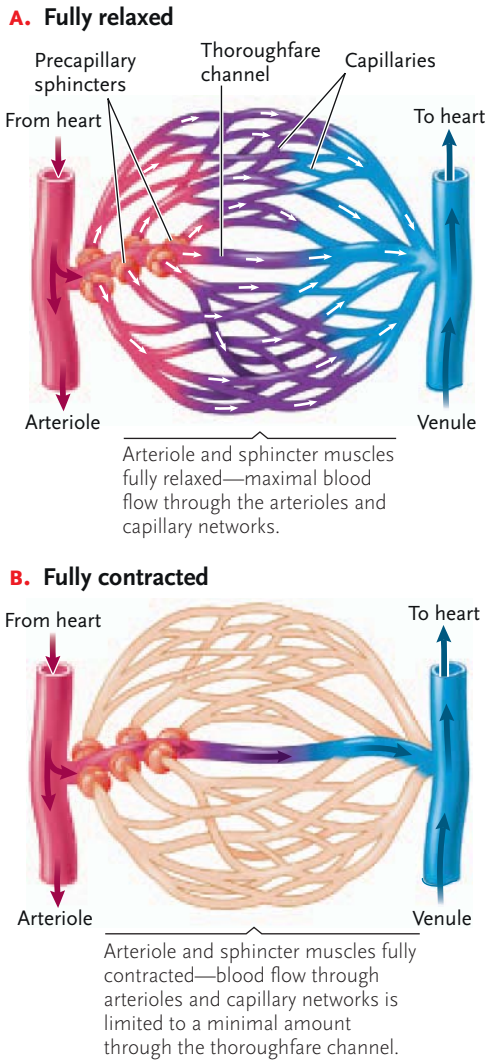

FIGURE 44.14 **Control of blood flow through arterioles and capillary networks when arteriole and sphincter muscles are: (A) fully relaxed; and (B) fully contracted.**

© Cengage Learning 2014

CONTROL OF BLOOD VOLUME TO CAPILLARIES BY ARTERIOLES The volume of blood flowing through an organ is adjusted by regulating the internal diameter of the arterioles of the organ. Although their total surface area is astoundingly large, the diameter of individual capillaries is so small that red blood cells must squeeze through most of them in single file. As a result, each capillary presents a high resistance to blood flow, so blood slows considerably as it moves through the capillaries **(Figure 44.15).** The slow movement of blood through the capillaries maximizes the time for exchange of substances between blood and tissues. As they leave the tissues, the capillaries rejoin to form veins. Veins have a reduced total cross-sectional area compared with capillaries, so the rate of flow increases as blood returns to the heart.

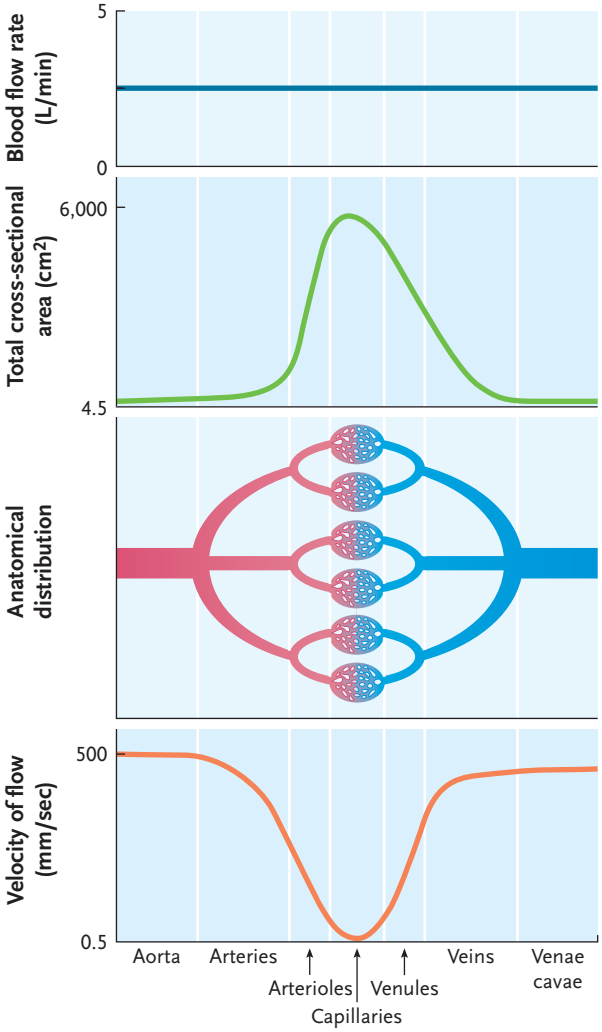

FIGURE 44.15 Blood flow rate and velocity of flow in relation to total cross-sectional area of the blood vessels. The blood flow rate is identical throughout the circulatory system and is equal to the cardiac output. The velocity of flow in the different types of blood vessels is inversely related to the total cross-sectional area of all the vessels of a particular type: for example, the velocity is highest in the aorta, which has the smallest cross-sectional area, and lowest in the capillaries, which collectively have the largest total cross-sectional area.

© Cengage Learning 2014

EXCHANGE OF SUBSTANCES ACROSS CAPILLARY WALLS In most body tissues, narrow spaces between the capillary endothelial cells allow water, ions, and small molecules such as glucose to pass freely between the blood and interstitial fluid. Erythrocytes, platelets, and most plasma proteins are too large to pass between the cells and are retained inside the capillaries, except for molecules that are transported through the epithelial cells by specific carriers. Leukocytes, however, are able to squeeze actively between the cells and pass from the blood to the interstitial fluid.

There are exceptions to these general properties in some tissues; in the brain, for example, the capillary endothelial cells are tightly sealed together, preventing essentially all molecules and even ions from passing between them. The tight seals set up the **blood–brain barrier,** which limits the exchange between capillaries and brain tissues to molecules and ions that are specifically transported through the capillary endothelial cells (see Section 40.3 for additional discussion of the blood–brain barrier).

FORCES DRIVING THE EXCHANGE Two major mechanisms drive the exchange of molecules and ions between the capillaries and the interstitial fluid: (1) diffusion along concentration gradients; and (2) bulk flow.

Diffusion along concentration gradients occurs both through the spaces between the capillary endothelial cells and through their plasma membranes. Ions or molecules such as O_2 and glucose, which are more concentrated inside the capillaries, diffuse outward along their gradients; other ions or molecules that are more concentrated outside, such as CO_2, diffuse inward. Some molecules, such as O_2 and CO_2, diffuse directly through the lipid bilayer of the endothelial cell plasma membranes; others, such as glucose, pass by facilitated diffusion through transport proteins. The total diffusion is greatest at the ends of capillaries nearest the arterioles, where the concentration differences between blood plasma and interstitial fluid are highest, and least at the ends nearest the venules, where the inside/outside concentrations of diffusible substances are almost equal.

Bulk flow, which carries water, ions, and molecules out of the capillaries, is driven by the pressure of the blood, which is higher than the pressure of the interstitial fluid. Like diffusion, bulk flow is greatest in the ends of the capillaries nearest the arterioles, where the pressure difference is highest, and drops off steadily as the blood moves through the capillaries and the pressure difference becomes smaller.

Venules and Veins Serve as Blood Reservoirs in Addition to Conduits to the Heart

The walls of venules and veins are thinner than those of arteries and contain little elastin. Many veins have flaps of connective tissue that extend inward from their walls. These flaps form one-way valves that keep blood flowing toward the heart (see Figure 44.13).

Rather than stretching and contracting elastically, like arteries, the relatively thin walls of venules and veins can expand and contract over a relatively wide range, allowing them to act as blood reservoirs as well as conduits. At times, the venules and veins may contain from 60% to 80% of the total blood volume of the body. The stored volume is adjusted by skeletal muscle contraction and by the valves, in response to metabolic conditions and signals carried by hormones and neurotransmitters **(Figure 44.16).**

When you sit without moving for long periods of time, as you might during an airline flight, the lack of skeletal muscular activity greatly reduces the return of venous blood to the heart. As a result, the blood pools in the veins of the body below the heart, making the hands, legs, and feet swell. The motionless blood can also form clots, particularly in the veins of the legs, a condition called **deep vein thrombosis.** Deep vein thrombosis

often does not cause symptoms, but can cause serious medical problems if a clot breaks loose and moves elsewhere in the body, such as to the lungs. Raising the arms and getting up at intervals to exercise or contracting and relaxing the leg muscles as you sit can relieve this condition.

Disorders of the Circulatory System Are Major Sources of Human Disease

The layer of endothelial cells lining the arteries and veins is normally smooth and does not impede blood flow. However, several conditions, including bacterial and viral infections, chronic hypertension, smoking, and a diet high in fats, can damage the endothelial cells, exposing the underlying smooth muscle tissue, which begins a cycle of injury and repair leading to lesions. (*Focus on Applied Research* in Chapter 3 discussed the relationship between fats and cholesterol and coronary artery disease, and the *Unanswered Question* in Chapter 3 discussed how the enzymes that synthesize fatty acids and cholesterol are regulated in cells.) Thickened deposits of material called *atherosclerotic plaques* may form at the damaged sites **(Figure 44.17).** The plaques, which consist of cholesterol-rich fatty substances, smooth muscle cells, and collagen deposits, reduce the diameter of the blood vessel and impede blood flow. Worse, the damaged endothelial lining may stimulate platelets to adhere and trigger the formation of blood clots. The clots further reduce the vessel diameter and flow and may break loose, along with segments of plaque material, to block finer vessels in other regions of the body.

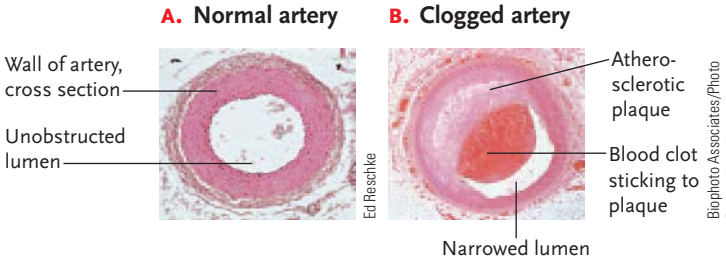

FIGURE 44.17 Atherosclerosis. (A) A normal coronary artery. **(B)** A coronary artery that is partially clogged by an atherosclerotic.

Atherosclerosis has its most serious effects in the smaller arteries of the body, particularly in the fine coronary arteries that serve the heart muscle. Here, the plaques and clots reduce or block the flow of blood to the heart muscle cells. Serious blockage can cause a heart attack—the death of cardiac muscle cells deprived of blood flow. The blockage of arteries in the brain by plaque material or blood clots released from atherosclerotic arteries is also a common cause of stroke—a loss of critical brain functions because of the death of nerve cells in the brain. Heart attacks and strokes are the most common causes of death in North America and Europe.

The risk of heart attacks and stroke can be reduced by avoiding the conditions that damage the blood vessel endothelium. A diet low in fats and cholesterol, avoidance of cigarette smoke, and a program of exercise can reduce epithelial damage and plaque deposition. Medication and exercise, or exercise alone, can also reduce the effects of hypertension. There are good indications that these preventive programs can also reduce the size of existing atherosclerotic plaques.

STUDY BREAK 44.4

1. **How is blood flow through capillary networks controlled?**
2. **Explain how, in contrast to most body tissues, the brain does not allow exchange of molecules and ions with blood.**
3. **Describe the two major mechanisms that drive the exchange of molecules and ions between the capillaries and the interstitial fluid.**

44.5 Maintaining Blood Flow and Pressure

Arterial blood pressure is the principal force moving blood to the tissues. The three main mechanisms for regulating blood pressure are controlling *cardiac output* (the pressure and amount of blood pumped by the left and right ventricles), the degree of constriction of the blood vessels (primarily the arterioles), and the total blood volume. The sympathetic division of the autonomic nervous system and the endocrine system interact to coordinate these mechanisms.

Cardiac Output Is Controlled by Regulating the Rate and Strength of the Heartbeat

Regulation of the rate and strength of the heartbeat starts at stretch receptors called *baroreceptors* (a type of mechanoreceptor; see Section 41.2), located in the walls of blood vessels. By

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Identifying the Role of a Hormone Receptor in Blood Pressure Regulation Using Knockout Mice

When the body experiences stress, the sympathetic division of the autonomic nervous system stimulates the adrenal medulla to release the hormones epinephrine and norepinephrine. These hormones increase the strength and rate of the heartbeat and change arteriole diameter, causing a temporary increase in blood pressure. The hormones exert their effects by binding to specific membrane-embedded receptors on target cells, activating them and triggering a cellular response via a signal transduction pathway. These G-protein–coupled receptors (see Section 7.4) are known as *adrenergic receptors* because of the adrenal origin of the hormones that bind to them.

Different types of adrenergic receptors are responsible for different responses to epinephrine and norepinephrine. For blood pressure regulation, the α_1-adrenergic receptor is a key receptor. Binding of norepinephrine, and to a lesser extent, epinephrine, to α_1 receptors on arteriolar smooth muscle causes vasoconstriction of arterioles, thereby contributing to an increase in blood pressure.

Researchers have identified three subtypes of α_1-adrenergic receptors: α_{1A}, α_{1B}, and α_{1D}.

Some experimental results using drugs suggested that the α_{1D}-adrenergic receptor plays an important role in the control of blood pressure. Because the drugs used could not affect just one subtype of receptor selectively, confirmation of that conclusion was needed from more directed studies.

Research Question

What is the role of the α_{1D}-adrenergic receptor in the regulation of blood pressure by vasoconstriction?

Experiments

Gozoh Tsujimoto and colleagues at the Tokyo University of Pharmacy and Life Sciences, and the National Children's Medical Research Center, Tokyo, Japan, answered the question by making and studying mice with a knockout (deletion) of each of the two copies of the α_{1D} gene encoding the α_{1D} receptor (the technique for making a gene knockout is described in Section 18.2). They compared the cardiovascular functions of the $\alpha_{1D}^-/\alpha_{1D}^-$ knockout mice with normal mice.

Results

The cardiovascular functions of the $\alpha_{1D}^-/\alpha_{1D}^-$ knockout mice were:

1. Modestly hypotensive (slightly lower-than-normal blood pressure) but a normal heart rate.
2. Normal levels of circulating norepinephrine and epinephrine.
3. Increasing doses of norepinephrine progressively increased blood pressure, but the response was markedly reduced versus normal mice.
4. The response to the vasoconstrictor norepinephrine was considerably reduced. This was shown in experiments in which the researchers measured the effects of norepinephrine on contraction of segments of the aorta (see also Figure 44.18). Far less contraction was seen than in normal mice. This result showed that the α_{1D} receptor is directly involved in vascular smooth muscle contraction.

Conclusion

The researchers concluded that the α_{1D}-adrenergic receptor participates directly in sympathetic nervous system–driven regulation of blood pressure by vasoconstriction.

THINK LIKE A SCIENTIST What was the key element of the experimental design that enabled the researchers to draw the conclusions they did about the role of the α_{1D}-adrenergic receptor in cardiovascular function?

Source: A. Tanoue et al. 2002. The α_{1D}-adrenergic receptor directly regulates arterial blood pressure via vasoconstriction. *Journal of Clinical Investigation* 109:765–775.

© Cengage Learning 2014

detecting the amount of stretch of the vessel walls, baroreceptors provide information about blood pressure. The baroreceptors in the cardiac muscle, the aorta, and the carotid arteries (which supply blood to the brain) are the most crucial. Signals sent by the baroreceptors go to the medulla within the brain stem. In response, the brain stem sends signals via the autonomic nervous system that adjust the rate and force of the heartbeat: the heart beats more slowly and contracts less forcefully when arterial pressure is above normal levels, and it beats faster and contracts more forcefully when arterial pressure is below normal levels.

The O_2 content of the blood, detected by chemoreceptors in the aorta and carotid arteries, also influences cardiac output. If the O_2 concentration falls below normal levels, the brain stem integrates this information with the signals sent from baroreceptors and issues signals that increase the rate and force of the heartbeat. Too much O_2 in the blood has the opposite effect, reducing the cardiac output.

Hormones Regulate Both Cardiac Output and Arteriole Diameter

Hormones secreted by several glands contribute to the regulation of blood pressure and flow. As part of the stress response, the adrenal medulla reinforces the action of the sympathetic nervous system by secreting epinephrine and norepinephrine into the bloodstream (see Section 42.4). Epinephrine in particular raises the blood pressure by increasing the strength and rate of the heartbeat and stimulating vasoconstriction of arterioles in some parts of the body, including the skin, gut, and kidneys. At the same time, by inducing the vasodilation of arterioles that deliver blood to the heart, skeletal muscles, and lungs, epinephrine increases the blood flow to these structures. *Insights from the Molecular Revolution* shows how gene manipulation experiments illuminated the role of a receptor for these hormones in regulating blood pressure.

Demonstration of a Vasodilatory Signal Molecule

Question: What causes arterial vasodilation?

Experiment: In live mammals, the neurotransmitter acetylcholine (see Chapter 39) is a potent vasodilator. Furchgott conducted *in vitro* experiments with strips of rabbit aorta to determine how acetylcholine-caused vasodilation occurred. He attached the aorta strips to an apparatus that recorded the tension of the strips. Contraction increases tension whereas relaxation (which is equivalent to vasodilation in the intact blood vessel) decreases tension. To the strips he first added norepinephrine to cause them to contract, and then added acetylcholine. He compared two key experimental setups: (1) aorta strips from which the endothelial cells had been removed by rubbing; and (2) gently handled aorta strips with intact endothelium.

Results: Furchgott's results are shown in the **Figure.** Relaxation occurred on acetylcholine treatment only in the strips with intact endothelium. Furchgott hypothesized that the endothelial cells produced the vasodilatory signal molecule, which he named *endothelium-derived relaxing factor (EDRF)*. He obtained more evidence that the endothelium released EDRF by performing an experiment, in which he reconstituted arteriole tissue by combining isolated smooth muscle and layers of endothelium. This tissue also relaxed in Furchgott's experimental system, supporting his hypothesis.

Conclusion: Vasodilation of arterioles occurs as a result of release of a signal molecule from the endothelial cells of the arterioles. Subsequently, Furchgott's EDRF signal molecule was determined to be nitric oxide (NO) (see Section 39.3).

THINK LIKE A SCIENTIST How might you demonstrate experimentally that NO is EDRF?

The adrenal cortex and the posterior pituitary release hormones that regulate blood pressure. Those hormones and their effects are described in Chapter 48.

Local Controls Regulate Arteriole Diameter

Several automated mechanisms operate locally to increase the flow of blood to body regions engaged in increased metabolic activity, such as the muscles of your legs during an extended uphill bike ride. Low O_2 and high CO_2 concentrations, produced by the increased oxidation of glucose and other fuels, induce vasodilation of the arterioles serving muscles. Vasodilation, which increases the flow of blood and the O_2 supply, occurs when a signal molecule is released from arteriole endothelial cells in body regions engaged in increased metabolic activity. In 1980 Robert Furchgott of the State University of New York, Health Science Center at Brooklyn, New York, reported the first evidence for a vasodilatory signal molecule produced by arterial endothelial cells **(Figure 44.18).** Subsequently, Louis Ignarro of the UCLA School of Medicine and Ferid Murad of the University of Texas Medical School at Houston determined that Furchgott's signal molecule was the gas nitric oxide (NO). The three researchers received the Nobel Prize in 1998 for their "discoveries concerning nitric oxide as a signaling molecule in the cardiovascular system." NO is quickly broken down enzymatically after its release, ensuring that its effects are local.

2. What are the three main mechanisms for regulating blood pressure?
3. How does epinephrine affect blood pressure?

44.6 The Lymphatic System

Under normal conditions, a little more fluid from the blood plasma in the capillaries enters the tissues than is reabsorbed from the interstitial fluid into the plasma. The **lymphatic system** is an extensive network of vessels that collects the excess interstitial fluid and returns it to the venous blood **(Figure 44.19).** The interstitial fluid picked up by the lymphatic system is called **lymph.** This system also collects fats that have been absorbed from the small intestine and delivers them to the blood circulation (see Chapter 47). The lymphatic system is a key component of the immune system.

Vessels of the Lymphatic System Extend throughout Most of the Body

Vessels of the lymphatic system collect the lymph and transport it to *lymph ducts* that empty into veins of the circulatory system. The *lymph capillaries,* the smallest vessels of the lymphatic sys-

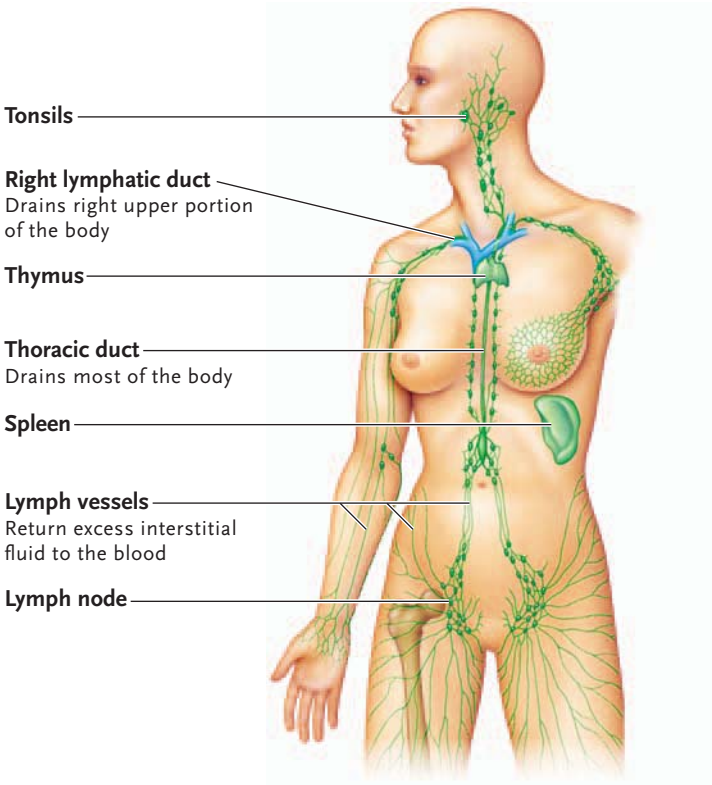

FIGURE 44.19 The human lymphatic system. Patches of lymphoid tissue in the small intestine and in the appendix also are part of the lymphatic system.
© Cengage Learning 2014

tem, are distributed throughout the body, intermixed intimately with the capillaries of the circulatory system. Although they are several times larger in diameter than the blood capillaries, the walls of lymph capillaries also consist of a single layer of endothelial cells surrounded by a thin network of collagen fibers. Interstitial fluid enters the lymph capillaries—becoming lymph—at sites in their walls where the endothelial cells overlap, forming a flap that is forced open by the higher pressure of the interstitial fluid. The openings are wide enough to admit all components of the interstitial fluid, including infecting bacteria, damaged cells, cellular debris, and lymphocytes.

The lymph capillaries merge into *lymph vessels* containing one-way valves that prevent the lymph from flowing backward. The lymph vessels lead to the thoracic duct and the right lymphatic duct (see Figure 44.19), which empties the lymph into a vein beneath the clavicles (collarbones), adding it to the plasma in the vein.

Movements of the skeletal muscles adjacent to the lymph vessels and breathing movements help move the lymph through the vessels, just as they help move the blood through veins. Over a day's time, the lymphatic system returns about 3 to 4 L of fluid to the bloodstream.

Lymphoid Tissues and Organs Act as Filters and Participate in the Immune Response

The tissues and organs of the lymphatic system include the *lymph nodes,* the *spleen,* the *thymus,* and the *tonsils.* They play primary roles in filtering viruses, bacteria, damaged cells, and cellular debris from the lymph and bloodstream, and in defending the body against infection and cancer. Patches of lymphoid tissue are also scattered in other regions of the body, such as the small intestine and the appendix.

The **lymph nodes** are small, bean-shaped organs spaced along the lymph vessels and clustered along the sides of the neck, in the armpits and groin, and in the center of the abdomen and chest cavity (see Figure 44.19). Spaces in the nodes contain macrophages, a type of leukocyte that engulfs and destroys cellular debris and infecting bacteria and viruses in the lymph. The lymph nodes also contain other leukocytes, which produce antibodies that aid in the destruction of invading pathogens (discussed more in Chapter 45). Cancer cells that lodge in the nodes may be destroyed or may remain to grow and divide, forming new tumors within the nodes. Therefore, during surgery to reduce the risk of cancer spread, lymph nodes near a tumor typically are inspected and may be removed.

The lymph nodes may become enlarged and painful if large numbers of bacteria or viruses carried by the lymph become trapped inside them. A physician usually checks for swollen nodes, particularly in the neck, armpits, and groin, as indicators of an infection in the region of the body served by the nodes.

STUDY BREAK 44.6

What is lymph, and how does it enter the lymph capillaries?

UNANSWERED QUESTIONS

How did vertebrate blood clotting evolve?

Vertebrate blood clotting is a complex process involving about two dozen different proteins found in the blood plasma. The system has the properties of a biochemical amplifier in that the exposure of a tiny amount of tissue initiates a series of proteolytic events, one protease activating another successively, with the climax being a large amount of localized thrombin that transforms fibrinogen into a fibrin clot.

Many years ago when I was a graduate student working in a laboratory devoted to blood proteins, I asked myself the question, How could blood clotting ever have evolved? The process seemed much too complicated to have been concocted in one fell swoop, so, I reasoned, it must have begun in a simpler fashion and gradually become more complicated. Certainly, other people had been asking similar questions about complex organs—the evolution of the eye, for example, had been considered by many scientists, including Charles Darwin—but facts about the evolution of individual proteins were just beginning to emerge.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

In particular, Vernon Ingram, a scientist working at MIT, had just determined the amino acid sequences of the alpha and beta chains of hemoglobin and found that these two proteins were about 45% identical. They must be the products of a gene duplication, he reported. Given his observation, it seemed to me that the proteases involved in blood clotting ought also to be the products of gene duplication. At the time, none of their amino acid sequences was known, but several had unique properties that distinguished them from other proteases, so it stood to reason that they were related. Yet, some nonproteolytic proteins were also involved, and they must have been added to the process independently.

So where to start? I decided to compare the blood clotting process in a wide range of animals. As it happens, most animals, invertebrate and vertebrate alike, have a kind of blood (see Section 46.2), and in most cases it can be coagulated by various stressful events. But the vertebrate process looked unique to me and must have evolved independently of the system that occurs in lobsters (Crustacea), for example. Among the vertebrates, the most primitive (early diverging) creature I could get my hands on was the lamprey (see Section 32.4, where its place in the vertebrate lineage is discussed).

Because I was hoping to find a simple, predecessor scheme, I was a little disappointed to find that lampreys have a rather sophisticated coagulation process that involved many of the proteins observed in mammals. Certainly, a small amount of tissue factor provoked a thrombin generation that converted fibrinogen to fibrin, just as in humans, at least in a general way. At the time there was no way to determine whether lampreys use the equivalent of *all* the clotting factors on the way to generating thrombin. Some of the most important proteins in the human system occur in minute amounts, and there was no possibility of ever isolating them from the lamprey, short of collecting several barrels of lamprey blood.

Many years later, after the sequences for many of the clotting factors had been reported for humans, my colleague Da-Fei Feng and I were able to align the sequences with a computer and make a phylogenetic tree. It fit the notion of a series of gene duplications very well. Moreover, it implied that most of the duplications had occurred a long time ago, at the very dawn of the vertebrates.

In 2003, the complete genomic sequence of a modern bony fish, the pufferfish, was determined, and one could scan through it and see what genes it has. It has all but a few of the more peripheral clotting proteins found in humans, the central theme being the same. However, the amount of sequence difference between human and pufferfish proteins compared with the degree of difference observed between the duplicated genes suggested some of the gene duplications had occurred not long before the appearance of bony fish. Why not look at the lamprey genome, which diverged 50 million to 100 million years before the appearance of bony fish, to see if the preduplication genes were there? The reason is that the lamprey genome has not been totally sequenced.

Recently, various genome centers around the world have begun maintaining "trace databases." These are uncurated collections of raw DNA sequences determined by random shotgun methods and robotized sequencers. The data are not assembled in any way, and each entry is at best a fragment of a gene. Several hundred organisms, from bacteria to monkeys, are being logged automatically. Among them is the lamprey. So now one can get a glimpse of what genes the lamprey has. We have been scrutinizing this database, even while recognizing its limitations. The reason is that I am getting on in years and can't wait for some mammoth operation with the resources to assemble all the lamprey DNA fragments into a complete genome.

My initial searching of the lamprey trace database showed that the lamprey may lack at least two of the mainline clotting factors (Factors VIII and IX), each of which in other vertebrates is the result of a gene duplication. Now, very recently, a draft assembly of the lamprey genome sequence has been posted, and it bears out these conclusions completely. Furthermore, a Japanese team has been trying to clone clotting factors from another species of lamprey, and the ones they have found match perfectly with the ones found in the database. The missing ones are still missing.

Although the step-by-step evolution of vertebrate blood clotting factors is still technically an "unanswered question," I'm hoping these efforts will spur others to go for a more convincing, fully assembled lamprey genome that will cement the case.

THINK LIKE A SCIENTIST

1. Will studying lamprey clotting factors have much potential in leading to a genetic cure for hemophilia in humans?
2. Deep venous thrombosis (DVT) is a condition in which a blood clot forms in a vein deep inside the body (mainly in the lower extremities), often after major surgery or extended bed rest. (Surgery patients are given heparin, an anticoagulant, to forestall clot formation.) Explain very generally how a DVT occurs (that is, how a blood clot forms), and speculate on the use of lampreys to research DVT.

Russell Doolittle

Russell Doolittle is professor emeritus at the University of California at San Diego. Finding out how blood clotting evolved is one of his major research interests. To learn more about Dr. Doolittle, go to http://www-biology.ucsd.edu/faculty/doolittle.html.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

44.1 Animal Circulatory Systems: An Introduction

- Only the simplest invertebrates—the sponges, cnidarians, and flatworms—have no circulatory systems (Figure 44.2).
- Animals with circulatory systems have a muscular heart that pumps a specialized fluid, such as blood, from one body region to another through tubular vessels. The blood carries O_2 and nutrients to body tissues and carries away CO_2 and wastes.
- Most invertebrates have an open circulatory system, in which the heart pumps hemolymph into vessels that empty into body spaces called sinuses before returning to the heart. Some invertebrates and all vertebrates have a closed system, in which the blood is confined in blood vessels throughout the body and does not mix directly with the interstitial fluid (Figure 44.3).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- In invertebrates, open circulatory systems occur in arthropods and most mollusks, whereas closed circulatory systems occur in annelids and in mollusks such as squids and octopuses. In vertebrates, the circulatory system has evolved from a heart with a single series of chambers, pumping blood through a single circuit, to a double heart that pumps blood through separate pulmonary and systemic circuits (Figures 44.4 and 44.5).

Animation: Examples of ECGs

Animation: Circulatory systems

44.2 Blood and Its Components

- Mammalian blood is a fluid connective tissue consisting of erythrocytes, leukocytes, and platelets, suspended in a fluid matrix, the plasma (Figure 44.6).
- Plasma contains water, ions, dissolved gases, glucose, amino acids, lipids, vitamins, hormones, and plasma proteins. The plasma proteins include albumins, globulins, and fibrinogen.
- Erythrocytes contain hemoglobin, which transports O_2 between the lungs and all body regions (Figure 44.7).
- Leukocytes defend the body against infecting pathogens.
- Platelets are functional cell fragments that trigger clotting reactions at sites of damage to the circulatory system.

Animation: The Blood

Animation: Hemostasis

44.3 The Heart

- The mammalian heart is a four-chambered pump. Two atria at the top of the heart pump the blood into two ventricles at the bottom of the heart, which pump blood into two separate pulmonary and systemic circuits of blood vessels (Figures 44.9 and 44.10).
- In both circuits, the blood leaves the heart in large arteries, which branch into smaller arteries, the arterioles. The arterioles deliver the blood to capillary networks, where substances are exchanged between the blood and the interstitial fluid. Blood is collected from the capillaries in small veins, the venules, which join into larger veins that return the blood to the heart (Figure 44.10).
- Contraction of the ventricles pushes blood into the arteries at a peak (systolic) pressure. Between contractions, the blood pressure in the arteries falls to a minimum (diastolic) pressure. The systole–diastole sequence is the cardiac cycle (Figure 44.11).
- Contraction of the atria and ventricles is initiated by signals from the SA node (pacemaker) of the heart (Figure 44.12).

Animation: The human heart

Animation: Electrical and Mechanical events of the Heart

Animation: Human blood circulation

44.4 Blood Vessels of the Circulatory System

- Blood is carried from the heart to body tissues in arteries; small branches of arteries, the arterioles, deliver blood to the capillaries, where substances are exchanged with the interstitial fluid. The blood is collected from the capillaries in venules and then returned to the heart in veins (Figure 44.13).
- The walls of arteries consist of an inner endothelial layer, a middle layer of smooth muscle, and an outer layer of elastic fibers. The smallest arteries, the arterioles, constrict and dilate to regulate blood flow and pressure into the capillaries.
- Capillary walls consist of a single layer of endothelial cells. Blood flow through capillaries is controlled by variation in contraction of the smooth muscles of arterioles and precapillary sphincters (Figure 44.14).
- In the capillary networks, the rate of blood flow is considerably slower than that in arteries and veins. This maximizes the time for exchange of substances between blood and tissues. Diffusion along concentration gradients and bulk flow drive the exchange of substances (Figure 44.15).
- Venules and veins have thinner walls than arteries, allowing the vessels to expand and contract over a wide range. As a result, they act as blood reservoirs as well as conduits.
- The return of blood to the heart is aided by pressure exerted on the veins when surrounding skeletal muscles contract and by respiratory movements. One-way valves in the veins prevent the blood from flowing backward (Figure 44.16).

Animation: Vessels

44.5 Maintaining Blood Flow and Pressure

- Blood pressure and flow are regulated by controlling cardiac output, the degree of blood vessel constriction (primarily arterioles), and the total blood volume. The autonomic nervous system and the endocrine system coordinate these mechanisms.
- Regulation of cardiac output starts with baroreceptors, which detect blood pressure changes and send signals to the medulla. In response, the brain stem sends signals via the autonomic nervous system that alter the rate and force of the heartbeat.
- Hormones secreted by several glands contribute to the regulation of blood pressure and flow.
- Local controls respond primarily to O_2 and CO_2 concentrations in tissues. Low O_2 and high CO_2 concentration causes dilation of arteriole walls, increasing the arteriole diameter and blood flow. High O_2 and low CO_2 concentrations have the opposite effects. NO released by arterial endothelial cells acts locally to increase arteriole diameter and blood flow (Figure 44.18).

44.6 The Lymphatic System

- The lymphatic system, a key component of the immune system, is an extensive network of vessels that collect excess interstitial fluid—which becomes lymph—and returns it to the venous blood (Figure 44.19).
- The tissues and organs of the lymphatic system include the lymph nodes, the spleen, the thymus, and the tonsils. They remove viruses, bacteria, damaged cells, and cellular debris from the lymph and bloodstream, and defend the body against infection and cancer.

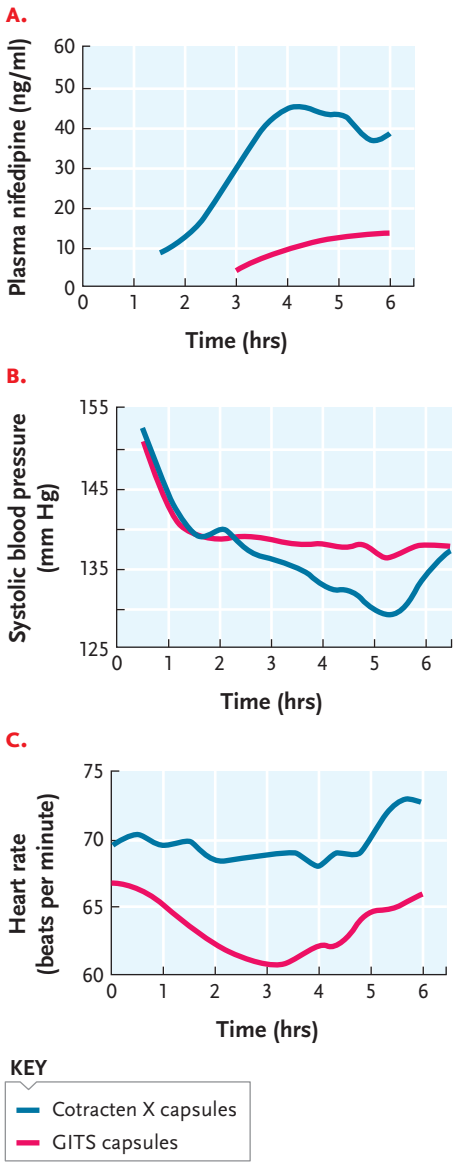
Test Your Knowledge

1. Compared with vertebrates, most invertebrates:
   a. lead more mobile lives.
   b. require a higher level of oxygen.
   c. have more complex layers of cells.
   d. have blood and interstitial fluid mixing directly in body spaces.
   e. require faster delivery and greater quantities of nutrients.
2. Which circulatory system description best matches the group(s) of animals?
   a. Cephalopod mollusks such as squids and octopuses have open circulatory systems with ventricles that pump blood away from the heart.
   b. Fishes have a single-chambered heart with an atrium that pumps blood through gills for oxygen exchange.
   c. Amphibians have the most oxygenated blood in the pulmocutaneous circuit and the most deoxygenated blood in the systemic circuit.
   d. Amphibians and reptiles use a two-chambered heart to separate oxygenated and deoxygenated blood.
   e. Birds and mammals pump blood to separate pulmonary and systemic systems from two separate ventricles in a four-chambered heart.
3. A healthy student from the coastal city of Boston enrolls at a college in Boulder, Colorado, a mile above sea level. An analysis of her blood in her first months at college would show:
   a. decreased macrophage activity.
   b. increased secretion of erythropoietin by the kidneys.
   c. increased signaling ability of platelets.
   d. anemia caused by malfunctioning erythrocytes.
   e. increased mitosis of leukocytes.
4. A characteristic of blood circulation through or to the heart is that:
   a. the superior vena cava conveys blood to the head.
   b. the inferior vena cava conveys blood to the right atrium.
   c. the pulmonary arteries convey blood from the lungs to the left atrium.
   d. the pulmonary veins convey blood into the left ventricle.
   e. the aorta branches into two coronary arteries that convey blood from heart muscle.
5. The heartbeat includes:
   a. the systole when the heart relaxes and fills.
   b. the diastole when the heart contracts and empties.
   c. pressure that causes the AV valves to open, filling the ventricles.
   d. rising pressure in the ventricles to open the AV valves and close the SL valves.
   e. the "lub" sound when the SL valves open and the "dub" sound when the AV valves close.
6. Keeping the mammalian cardiac cycle balanced is/are:
   a. an AV node between the right atria atrium and right ventricle, which induces a wave of contraction.
   b. pacemaker cells, which compose the AV node and signal the SA node.
   c. an insulating layer that isolates the SA node from the right atrium.
   d. ion channels in pacemaker cells, which close to depolarize their plasma membranes.
   e. neurogenic stimuli from the nervous system.
7. Hydrostatic pressure is best described as:
   a. the uncoordinated contractions that occur during heart attacks.
   b. a premature ventricular contraction that signifies a skipped beat.
   c. a high point of pressure called diastolic blood pressure.
   d. an arterial vasodilation caused by carbon dioxide.
   e. the pressure of blood on the walls of arteries.
8. Characteristics of veins and venules are:
   a. thick walls.
   b. large muscle mass in the walls.
   c. a large quantity of elastin in the walls.
   d. low blood volume compared with arteries.
   e. one-way valves to prevent backflow of blood.
9. When capillaries exchange substances:
   a. red blood cells move through the capillary lumen in double file.
   b. blood flow resistance is lower than it is in arteries and veins.
   c. water, ions, glucose, and erythrocytes pass freely between blood and tissues.
   d. diffusion along a concentration gradient and bulk flow are operating.
   e. diffusion is greatest closest to the arterioles.
10. How do lymphatic vessels and capillaries differ from other vessels and capillaries in the circulatory system?
    a. Lymph capillaries are larger in diameter than blood capillaries.
    b. Lymph capillary walls contain several layers of endothelial cells, which allows for efficient filtering of lymph.
    c. Lymph vessels are only distributed in specific regions of the body.
    d. Movement of lymph does requires skeletal muscle movement.
    e. The lymphatic system moves up to 8 L of fluid through the bloodstream daily.

Discuss the Concepts

1. *Aplastic anemia* develops when certain drugs or radiation destroy red bone marrow, including the stem cells that give rise to erythrocytes, leukocytes, and platelets. Predict some symptoms a person with aplastic anemia would be likely to develop. Include at least one symptom related to each type of blood cell.
2. In addition to the engine exhaust of boats and cars, carbon monoxide is also a component of cigarette smoke. What might be the impact of this phenomenon on a smoker's health?
3. In some people, the pressure of the blood pooling in the legs leads to a condition called *varicose veins,* in which the veins stand out like swollen, purple knots. Explain why this might happen, and why veins closer to the leg surface are more susceptible to the condition than those in deeper leg tissues.



Design an Experiment

Mice in which the apolipoprotein E gene has been knocked out (deleted) by genetic engineering methods have high levels of plasma cholesterol and readily develop atherosclerosis, particularly on diets high in cholesterol. The immunosuppressant drug rapamycin is being touted also to be a drug that can affect atherosclerosis. Design an experiment to determine whether and at what dose rapamycin is effective in reducing atherosclerosis caused by dietary cholesterol.

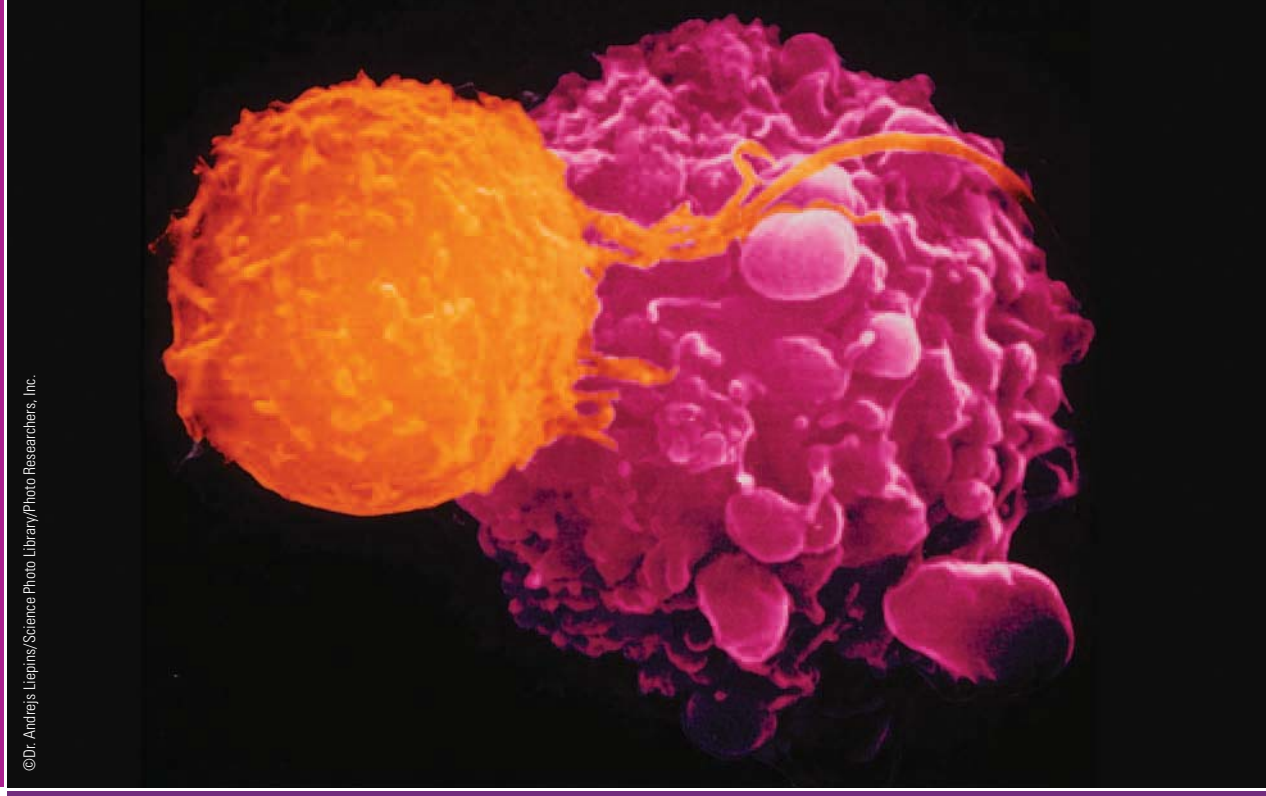
Interpret the Data

Nifedipine is an antihypertension medication that is also used to reduce the workload on the heart. The study below compares the effects of two different types of capsules used to administer the drug to patients (GITS—red line, and Cotracten X—blue line). Each graph shows changes with time following initial administration of the capsules. **Figure A** compares the levels of nifedipine in the blood with each capsule type. The ability of the different capsules to reduce workload on the heart by altering blood pressure or heart rate is shown in **Figures B and C,** respectively.

M. J. Brown and C. B. Toal. 2008. Formulation of long-acting nifedipine tablets influences the heart rate and sympathetic nervous system response in hypertensive patients. *British Journal of Clinical Pharmacology* 65:646–652. Reprinted by permission of John Wiley and Sons.

1. Are elevated plasma levels of nifedipine (above 10 ng/mL) required for the drug to perform its actions?
2. Do both types of capsule appear to cause a reduction in the workload of the heart?
3. Which type of capsule would you expect to have fewer side effects?



Source: M. J. Brown and C. B. Toal. 2008. Formulation of long-acting nifedipine tablets influences the heart rate and sympathetic nervous system response in hypertensive patients. *British Journal of Clinical Pharmacology* 65:646–652.

Apply Evolutionary Thinking

What is the evolutionary advantage of closure of the septum between the two ventricles to create a double circulatory system?

45.5 Defenses in Other Animals

Defenses against Disease

Why it matters . . . **Acquired immune deficiency syndrome (AIDS)** is a constellation of disorders that follows infection by the **human immunodeficiency virus (HIV)** (see Figure 17.11). AIDS was first identified in the early 1980s, now infects about 33 million people worldwide, and continues to spread. One important aim of researchers is to develop an anti-AIDS *vaccine*—a substance that, when swallowed or injected, provides protection against infection by HIV.

The development of vaccines began with efforts to control smallpox, a dangerous infectious viral disease that once infected millions of people worldwide. In 1796, an English country doctor, Edward Jenner, used a scientific approach to protect people against smallpox infection. He knew that milkmaids never got smallpox if they had contracted cowpox, a similar but mild disease of cows that can be transmitted to humans. Jenner tested whether a deliberate infection with cowpox would protect humans from smallpox. He scratched material from a cowpox sore into a boy's arm, and 6 weeks later, after the cowpox infection had subsided, he scratched fluid from human smallpox sores into the boy's skin. (Jenner's use of the boy as an experimental subject would now be considered unethical.) The boy remained free from smallpox. Jenner carried out additional, carefully documented case studies with other patients with the same results. His technique became the basis for worldwide **vaccination** (*vacca* = cow) against smallpox. With improved vaccines, smallpox has now been eradicated from the human population.

Vaccination takes advantage of the **immune system** (*immunis* = exempt), the inherited mechanisms that protect the body from pathogens. The immune system is our main defense against infectious disease. This chapter focuses on the immune system and other defenses against infection, such as the skin. Our description emphasizes human and other mammalian systems, in which most of the scientific discoveries revealing the structure and function of the immune system have been made. At the end of the chapter, we compare briefly the mammalian systems with the protective systems of nonmammalian vertebrates and invertebrates. Recognize that natural protection systems are not

confined to animals. That is, all organisms have some ability to defend themselves against infectious agents such as viruses. For example, restriction enzymes (see Section 18.1), the molecular biologist's tool for cloning and other DNA manipulations, are a bacterium's natural defense against infecting bacteriophages. Plants also have defense mechanisms (see Chapter 37).

45.1 Three Lines of Defense against Pathogens

Every organism is exposed constantly to *pathogens,* disease-causing viruses or organisms such as infectious bacteria, protists, fungi, and parasitic worms. Humans and other mammals have three lines of defense against these threats:

1. **Physical barriers;** they are not part of the immune system.
2. The **innate immune system,** the inherited mechanisms that protect the body from many kinds of pathogens in a nonspecific way. The innate immune system is found in all animals and is one of two components of the immune system of vertebrates.
3. The **adaptive immune system,** the inherited mechanisms leading to the synthesis of molecules that target pathogens in a specific way. The adaptive immune system is only found in vertebrates and is the other component of the vertebrate immune system.

Reaction to an infection takes minutes in the case of the innate immune system versus days for the adaptive immune system. Importantly, the three lines of defense are not either–or systems. Rather, they are cumulative actions of the body to defend against pathogens, meaning that physical barriers and the innate immune system still function against a specific pathogen even when the adaptive immune system is operational.

Epithelial Surfaces Are Anatomical Barriers That Help Prevent Infection

The body surface—the skin covering the body exterior and the epithelial surfaces covering internal body cavities and ducts, such as the lungs and intestinal tract—is the first line of defense. The tight junctions between epithelial cells of the body surface (see Section 5.5) keep most pathogens (as well as toxic substances) from entering the body.

Many epithelial surfaces are coated with a mucus layer secreted by the epithelial cells that protects against pathogens as well as toxins and other chemicals. In the respiratory tract, ciliated cells constantly sweep the mucus, with its trapped bacteria and other foreign matter, into the throat, where it is coughed out or swallowed.

Many of the body cavities lined by mucous membranes have environments that are hostile to pathogens. For example, the strongly acidic environment of the stomach kills most bacteria and destroys many viruses that are carried there. Most of the pathogens that survive the stomach acid are destroyed by the digestive enzymes and bile secreted into the small intestine. The vagina, too, is acidic, which prevents many pathogens from surviving there. The mucus coating in some locations contains the enzyme lysozyme, which was secreted by the epithelial cells. Lysozyme breaks down the walls of some bacteria, causing them to lyse.

The Immune System Protects the Body from Pathogens That Have Crossed External Barriers

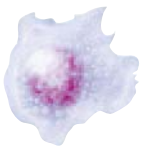
The body's second line of defense is a series of generalized internal chemical, physical, and cellular reactions that attack pathogens that have breached the first line. These defenses include inflammation, which creates internal conditions that inhibit or kill many pathogens, and specialized cells that engulf or kill pathogens or infected body cells.

This second line of defense involves mechanisms of the *innate immune system,* and **innate immunity** is the term for this initial response by the body to eliminate cellular pathogens, such as bacteria and viruses, and prevent infection. You are born with an innate immune system. Innate immunity provides an immediate, *nonspecific* response; that is, it targets any invading pathogen and has no memory of prior exposure to the pathogen. ("Memory" here means immunological memory, in which the body has a cellular record that it has been exposed previously.) It provides some protection against invading pathogens while a more powerful, specific response system is mobilized.

The third and most effective line of defense involves mechanisms of the *adaptive immune system,* and **adaptive** (also called **acquired**) **immunity** is the term for this response. Adaptive immunity is *specific:* it recognizes individual pathogens and mounts an attack that neutralizes or eliminates them directly. It is so named because it is stimulated and shaped by the presence of a specific pathogen or foreign molecule. Adaptive immunity takes several days to become protective. It is triggered by specific molecules on pathogens that are recognized as being foreign to the body. The body retains a cellular memory of its first exposure to a foreign molecule, which enables it to respond more quickly if the pathogen is encountered again in the future.

As stated earlier, the innate immune system and the adaptive immune system together constitute the immune system. The defensive reactions of the system are termed the **immune response.** Functionally, the two components of the immune system interconnect and communicate at the chemical and cellular levels. The immune system is the product of a long evolutionary history of compensating adaptations by both pathogens and their targets. Over millions of years of vertebrate history, the mechanisms by which pathogens attack and invade have become more efficient, but the defenses of animals against the invaders have kept pace.

White Blood Cells Are Key Participants in Both Immune Systems



White blood cells—leukocytes—and their derivatives, along with several types of plasma proteins, are responsible for the activities of the two immune systems. **Table 45.1** lists the major

types of leukocytes and their functions. Most types of leukocytes are present in the blood only transiently as they travel to the tissues for their roles in the immune systems. Note that several of the types of white blood cells are **phagocytes.** Recall from Section 5.3 that phagocytes are cells that engulf bacteria or other cellular debris; the engulfment process is called **phagocytosis.**

Most leukocytes originate from stem cells in the bone marrow, from where they are released into the blood. The exception is lymphocytes (see Section 44.2 and Figure 44.7), which form in the bone marrow and then migrate to the thymus (a type of lymphoid tissue), where they mature. From the thymus, mature T lymphocytes are released into the blood and into the lymphatic system. Recall from Section 44.6 that lymphoid tissues are part of the lymphatic system. As a brief recap, the lymphatic system is an extensive network of vessels that collects excess interstitial fluid and returns it to the venous blood (see Figure 44.19). The interstitial fluid picked up is called lymph when it is within the lymphatic system. The lymphatic system, which includes the lymph nodes, the spleen, the thymus, and the tonsils, has a function in immunity. Potential pathogens that gain access to the lymph are filtered through the lymph nodes where white blood cells act to inactivate them. The spleen, the largest lymphoid tissue, performs a similar function to inactivate pathogens in blood coming through it.

TABLE 45.1 Major Types of Leukocytes and Their Functions

Type of Leukocyte	Function
Monocyte	
	Differentiates into a macrophage when released from blood into damaged tissue
Macrophage	
	Phagocyte that engulfs infected cells, pathogens, and cellular debris in damaged tissues; helps activate lymphocytes carrying out immune response
Neutrophil	
	Phagocyte that engulfs pathogens and tissue debris in damaged tissues
Eosinophil	
	Secretes substances that kill eukaryotic parasites such as worms
Lymphocyte	
	Main subtypes involved in innate and adaptive immunity are natural killer (NK) cells, B cells, plasma cells, helper T cells, and cytotoxic T cells. NK cells function as part of innate immunity to kill virus-infected cells and some cancerous cells of the host. The other cell types function as part of adaptive immunity: they produce antibodies, destroy infected and cancerous body cells, and stimulate macrophages and other leukocyte types to engulf infected cells, pathogens, and cellular debris.
Basophil	
	Located in blood, responds to IgE antibodies in an allergic response by secreting histamine, which stimulates inflammation

STUDY BREAK 45.1

1. **What features of epithelial surfaces protect against pathogens?**
2. **What are the key differences between innate immunity and adaptive immunity?**

45.2 Innate Immunity: Nonspecific Defenses

In most cases, the body needs 7 to 10 days to develop a fully effective immune response against a pathogen that is invading the body for the first time. Innate immunity holds off invading pathogens in the meantime, killing or containing them until adaptive immunity comes fully into play. We have already discussed the body's anatomical barriers. Now let us look at the internal mechanisms of innate immunity in vertebrates: secreted molecules and cellular components. As you will see, cellular pathogens (such as bacteria) and viral pathogens elicit different responses.

Innate Immunity Provides an Immediate, General Defense against Invading Cellular Pathogens

Cellular pathogens—typically microorganisms—usually enter the body when injuries break the skin or epithelial surfaces. The innate immune system is available immediately to try to combat those pathogens. In particular, neutrophils and macrophages, which are both phagocytic cells, play an important role in innate immunity.

RECOGNITION OF A PATHOGENIC MICROORGANISM How does the host body recognize the pathogen as foreign? The answer is that the host has mechanisms to distinguish self from nonself. The innate immune system recognizes *pathogen-associated molecular patterns* that are associated with patho-

genic organisms but are absent in the host. The patterns are recognized by *pattern recognition receptors* on the surface membranes or within the cytosol of phagocytic cells. *Toll-like receptors* are examples of such receptors. A repertoire of over a dozen toll-like receptors have been identified in mammals. Each type recognizes a different, specific set of molecular patterns on pathogens. Recognition of a pathogen by a toll-like receptor triggers a cellular response by the phagocytic cell. (Receptors and cellular responses triggered by them are discussed more generally in Chapter 7.) Several types of responses can occur depending on the receptor. For example, one response is to cause the phagocytic cell to engulf and destroy the pathogenic microorganism. Another is to secrete chemicals with antimicrobial properties, or chemicals that contribute to *inflammation* or that activate the *complement system*.

ANTIMICROBIAL PEPTIDES All of our epithelial surfaces, namely skin, the lining of the gastrointestinal tract, the lining of the nasal passages and lungs, and the lining of the genitourinary tracts, are protected by antimicrobial peptides called *defensins*. Some defensins are secreted by the epithelial cells, whereas others are secreted by neutrophils. And some defensins are secreted continuously, whereas others are secreted only in response to detection of pathogen-associated molecular patterns (such as by toll-like receptors). The defensins attack the plasma membranes of the pathogens, eventually disrupting them, thereby killing the cells.

INFLAMMATION A tissue's rapid response to injury, including infection by most pathogens, involves **inflammation** (*inflammare* = to set on fire), the heat, pain, redness, and swelling that initially, or exclusively occur at the site of an infection. Inflammation at the site of an infection is called **local inflammation.** This inflammatory response is highly similar regardless of the triggering event, be it pathogen, mechanical damage, or chemical injury. Overall, the response operates to isolate the injured area and stop the spread of damage.

Several interconnecting mechanisms initiate local inflammation **(Figure 45.1).** Consider bacteria entering a tissue as a re-

FIGURE 45.1 The steps producing inflammation.

1 A break in the skin introduces bacteria, which reproduce at the wound site. Activated resident macrophages engulf the pathogens and secrete cytokines and chemokines.

2 Mast cells in the area are activated by the tissue damage and release histamine.

3 Histamine and cytokines dilate local blood vessels and increase their permeability. The cytokines also make the blood vessel wall sticky, causing neutrophils and monocytes to attach.

4 Chemokines attract neutrophils and monocytes, which squeeze out between cells of the blood vessel wall and migrate to the infection site.

5 The newly arrived monocytes differentiate into macrophages. Neutrophils and macrophages engulf the pathogens and destroy them.

sult of a wound. Toll-like receptors on **macrophages** ("big eaters"; see Table 45.1)—a type of phagocyte—in the area of the wound recognize and bind to surface molecules on the pathogen, activating the macrophage to phagocytize (engulf) the pathogen (see Figure 45.1, step 1). Activated macrophages also secrete **cytokines,** molecules that bind to receptors on other host cells and, through signal transduction pathways, trigger a response. Usually, too few macrophages are present in the area of a bacterial infection to remove all of the bacteria.

The tissue damage also activates **mast cells,** which then release **histamine,** an inflammatory signaling molecule (step 2). The histamine, along with cytokines from activated macrophages, dilates local blood vessels around the infection site and increases their permeability, which increases blood flow and leakage of fluid from the vessels into body tissues (step 3). The response initiated by cytokines directly causes the heat, redness, and swelling of inflammation.

Cytokines also make the endothelial cells of the blood vessel wall stickier, causing circulating **neutrophils** and **monocytes** (see Table 45.1) to attach to it in massive numbers (step 3). From there, the neutrophils and monocytes are attracted to the infection site by **chemokines,** proteins also secreted by activated macrophages (step 4). Once they are located in the damaged tissue, the monocytes differentiate into macrophages. Both the neutrophils (which, like macrophages, have toll-like receptors that enable them to recognize pathogens) and the new macrophages engulf the pathogens (step 5).

Once a neutrophil or macrophage has engulfed a pathogen, it uses a variety of mechanisms to destroy it. These mechanisms include attacks by enzymes and defensins located in lysosomes and the production of toxic chemicals. The harshness of these attacks usually kills the neutrophils as well, while macrophages usually survive to continue their pathogen-scavenging activities. Dead and dying neutrophils, in fact, are a major component of the pus formed at infection sites. The pain of inflammation is caused by the migration of macrophages and neutrophils to the infection site and their activities there.

Some pathogens, such as parasitic worms, are too large to be engulfed by macrophages or neutrophils. In that case, macrophages, neutrophils, and **eosinophils** (see Table 45.1) cluster around the pathogen and secrete lysosomal enzymes and defensins in amounts that are often sufficient to kill the pathogen.

If tissue damage is extensive, or the infection spreads to the blood, a **systemic inflammation**—inflammation throughout the body—likely will occur. In systemic inflammation, chemical signaling molecules released by infected tissues may stimulate the release of neutrophils from the bone marrow, thereby increasing the number of white blood cells circulating in the blood. Systemic inflammation may also involve the onset of **fever.** That is, several chemicals released by macrophages in response to the infection act as **pyrogens** (*pyro* = fire; *gen* = production). Pyrogens stimulate release from the hypothalamus of *prostaglandins,* chemical messengers that act locally (see Section 42.1). The prostaglandins act to turn up the hypothalamic thermostat regulating body temperature, which produces the fever. How fever fights infection is uncertain. Some models propose that it enhances phagocytosis or interferes with bacterial propagation.

THE COMPLEMENT SYSTEM The **complement system** is a group of more than 30 interacting plasma proteins that circulate in the blood and interstitial fluid. Complement proteins are activated when they recognize molecules on the surfaces of pathogens. Then, some of the proteins assemble into **membrane attack complexes,** which insert into the plasma membrane of many types of bacterial cells and create pores that allow ions and small molecules to pass through. As a result, the bacteria can no longer maintain osmotic balance, and they swell and lyse.

Combating Viral Pathogens Requires a Different Innate Immune Response

You have learned that recognition of specific nonself pathogen-associated molecular patterns on the surfaces of cellular pathogens in the extracellular fluid such as bacteria is key to initiating innate immune responses. However, most viruses are within infected cells and not in the extracellular fluid. Therefore, the host must use other strategies to provide some immediate protection against viral infections until the adaptive immune system, which can discriminate between viral and host proteins, is effective. Two strategies involve interferon and natural killer cells.

INTERFERON When a virus infects a cell, the cell synthesizes and releases cytokines called **interferons** in response to being exposed to the viral genome. Interferons act both on the infected cell that produces them, an autocrine effect, and on neighboring uninfected cells, a paracrine effect (see Section 42.1). They work by binding to cell-surface receptors, triggering a signal transduction pathway that changes the gene expression pattern of the cells. The key changes include activation of a ribonuclease enzyme that degrades most cellular RNA and inactivation of a protein required for protein synthesis, thereby inhibiting most protein synthesis in the cell. These effects on RNA and protein synthesis inhibit replication of the viral genome, while putting the cell in a weakened state from which it may or may not recover.

NATURAL KILLER CELLS Cells that have been infected with a virus must be destroyed, and that is the role of **natural killer (NK) cells.** NK cells are a type of **lymphocyte,** a leukocyte that carries out most of its activities in tissues and organs of the lymphatic system (see Figure 44.19). NK cells circulate in the blood and kill target host cells—not only cells that are infected with a virus, but also some cells that have become cancerous.

NK cells can be activated by cell-surface receptors or by interferons secreted by virus-infected cells. NK cells are not phagocytes; instead, they secrete granules containing *perforin,* a protein that creates pores in the target cell's membrane. Unregulated diffusion of ions and molecules through the pores causes osmotic imbalance, swelling, and rupture of the infected cell. NK cells also kill target cells indirectly by secreting *proteases*

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(protein-degrading enzymes) that pass through the pores. The proteases trigger **apoptosis** (a type of programmed cell death) by activating other enzymes that cause DNA degradation which, in turn, induces pathways leading to the cell's death.

How does an NK cell distinguish a target cell from a normal cell? The surfaces of most vertebrate cells have particular *major histocompatibility complex (MHC) proteins* on them. You will learn about the role of these proteins in adaptive immunity in the next section; for now, just consider them to be tags on the cell surface. NK cells monitor the level of MHC proteins and respond differently depending on their level. An appropriately high level, as on normal cells, inhibits the killing activity of NK cells. Viruses often inhibit the synthesis of MHC proteins in the cells they infect, lowering the levels of those proteins and identifying them to NK cells. Cancer cells also have low or, in some cases, no MHC proteins on their surfaces, which makes them a target for destruction by NK cells as well.

STUDY BREAK 45.2

1. What are the usual characteristics of the inflammatory response?
2. What processes specifically cause each characteristic of the inflammatory response?
3. What is the complement system?
4. Why does combating viral pathogens require a different response by the innate immune system than combating bacterial pathogens? What are the two main strategies a host uses to protect against viral infections?

45.3 Adaptive Immunity: Specific Defenses

Adaptive immunity is a vertebrate-specific defense mechanism that recognizes specific molecules as being foreign and clears those molecules from the body. The foreign molecules recognized may be free, as in the case of toxins, or they may be on the surface of viruses or cells such as pathogenic bacteria, cancer cells, pollen, or cells of transplanted tissues and organs.

Adaptive immunity develops only after the body is exposed to the foreign molecules and, hence, takes several days to become effective. This would be a significant problem in the case of invading pathogens were it not for the innate immune system, which combats the invaders in a nonspecific way within minutes after they enter the body. The two key distinctions between innate and adaptive immunity are:

1. Innate immunity is nonspecific whereas adaptive immunity is specific.
2. Innate immunity retains no memory of exposure to the pathogen whereas adaptive immunity retains a memory of the foreign molecule that triggered the response, thereby enabling a rapid, more powerful response if that pathogen is encountered again at a later time.

In Adaptive Immunity, B lymphocytes and T lymphocytes Detect Foreign Molecules and Clear Them from the Body

A foreign molecule that triggers an adaptive immune response is called an **antigen** (meaning "*anti*body *gen*erator"). Antigens are macromolecules; most are large proteins (including glycoproteins and lipoproteins) or polysaccharides (including lipopolysaccharides). Some nucleic acids can also act as antigens, as can various large, artificially synthesized molecules.

Some antigens enter the body from the environment, for example antigens on pathogens introduced beneath the skin, antigens in vaccinations, and inhaled or ingested macromolecules, such as toxins. Other antigens are produced within the body, for example proteins encoded by viruses that have infected cells and altered proteins produced by mutated genes, such as those in cancer cells.

Two types of lymphocytes, B cells and T cells, recognize antigens in the body. **B cells** differentiate from stem cells in the bone marrow (see Section 44.2). It is easy to remember this as "B for bone." However, the "B" actually refers to the *bursa of Fabricus,* a lymphatic organ found only in birds in which B cells were first discovered. Differentiated B cells are released into the blood and carried to capillary beds serving the tissues and organs of the lymphatic system. Like B cells, **T cells** originate from stem cells in the bone marrow. In immature form, they are released into the blood and carried to the **thymus,** an organ of the lymphatic system where they mature. The "T" in "T cell" refers to the thymus. As you will see, two types of T cells—*helper T cells* and *cytotoxic T cells*—are involved in adaptive immunity.

The role of lymphocytes in adaptive immunity was demonstrated by experiments in which all of the leukocytes in mice were killed by irradiation with X-rays. These mice were then unable to develop adaptive immunity. Injecting lymphocytes from normal mice into the irradiated mice restored the response; other body cells extracted from normal mice could not restore the response. (For more on the use of mice as an experimental organism in biology, see *Focus on Model Research Organisms*.)

There are two types of adaptive immune responses: *antibody-mediated immunity* and *cell-mediated immunity.* In **antibody-mediated immunity** (also called **humoral immunity**), B-cell derivatives called **plasma cells** secrete **antibodies,** highly specific protein molecules that circulate in the blood and lymph recognizing and binding to antigens and clearing them from the body. In **cell-mediated immunity,** a particular type of T cell becomes activated and, with other cells of the immune system, attacks infected cells directly and kills them.

The body's reaction to an infection is not an either–or choice between antibody-mediated immunity and cell-mediated immunity. Rather, both responses typically occur and, depending on the infection, the relative strength of the two responses varies. Complicated chemical signaling controls how the two responses develop.

The Mighty Mouse

Vasiliy Koval/Shutterstock.com

The mouse *(Mus musculus)* and its cells have been used to great advantage as models for research on mammalian developmental genetics, immunology, and cancer. The availability of the mouse as a research tool enables scientists to carry out experiments with a mammal that would not be practical or ethical with humans.

The small size of the mouse makes it relatively inexpensive and easy to maintain in the laboratory, and its short generation time, compared with most other mammals, allows genetic crosses to be carried out within a reasonable time span. For example, within 18 to 22 days after fertilization, a female gives birth to a litter of about 5 to 10 offspring.

Mice have a long and highly productive history as experimental animals. The first example of a lethal allele was found in mice, and pioneering experiments on the transplantation of tissues between individuals were conducted with mice. During the 1920s, Fred Griffith laid the groundwork for the research showing that DNA is the hereditary molecule in his work with pneumonia-causing bacteria in mice (see Section 14.1). More recently, genetic experiments with mice have revealed more than 500 mutations that cause hereditary diseases, immunological defects, and cancer in mammals, including humans.

The mouse has also been the mammal of choice for experiments that introduce and modify genes through genetic engineering. Genetic engineering has produced, for example, "knockout" mice, in which a gene of interest is completely nonfunctional (see Section 18.2). The effects of the lack of function of a gene in the knockout mice often allow investigators to determine the role of the normal form of the gene by comparing normal mice with knockout mice. Some knockout mice have been developed to be defective in genes homologous to human genes that cause serious diseases, such as cystic fibrosis. This allows researchers to study the disease in mice with the goal of developing cures or therapies.

The mouse has also been the main experimental choice for studies of immune responses. The results obtained have provided valuable insights into how the human immune systems work. However, mice and humans are separated by 65 million years of evolution and, as a result, the two organisms have significant differences in immune system mechanisms. These differences lead researchers to be cautious in relating mouse studies directly to humans when using mice in clinical studies involving the immune systems. For instance, the mouse model of multiple sclerosis has some differences from the human disease.

In 2002 the sequence of the mouse genome was reported. The sequence is enabling researchers to refine and expand their use of the mouse as a model organism for studies of mammalian biology and mammalian diseases.

The steps of the adaptive immune response are similar for antibody-mediated immunity and cell-mediated immunity:

1. *Antigen encounter and recognition:* lymphocytes encounter and recognize an antigen.
2. *Lymphocyte activation:* the lymphocytes are activated by binding to the antigen and proliferate by cell division to produce many clones of identical cells.
3. *Antigen clearance:* the many clones of activated lymphocytes clear the antigen from the body.
4. *Development of immunological memory:* some activated lymphocytes differentiate into **memory cells** that circulate in the blood and lymph, ready to initiate a rapid immune response upon a later exposure to the same antigen.

The following discussions of antibody-mediated immunity and cell-mediated immunity expand on these steps.

Antibody-Mediated Immunity Involves the Recognition of Antigens by T Cells, and the Activation of B Cells and Their Differentiation into Antibody-Secreting Cells

The antibody-mediated immunity type of adaptive immune response begins as soon as an antigen is encountered and recognized in the body. In antibody-mediated immunity, antigens are recognized by T cells that are activated as a result of the interaction and differentiate and proliferate, producing cells that activate B cells. Activated B cells differentiate into antibody-secreting cells. The antibodies are specific to the antigens that elicited the antibody-mediated immunity and they clear those antigens from the body.

ANTIGEN ENCOUNTER AND RECOGNITION BY LYMPHOCYTES

Antigens are encountered by B cells and T cells in the lymphatic system. Each B cell and each T cell is specific for a particular antigen, meaning that the cell can bind to only one particular molecular structure. The binding is specific because the plasma membrane of each B cell and T cell is studded with thousands of identical receptors for the antigen, the **B-cell receptors** on B cells and the **T-cell receptors** on T cells **(Figure 45.2).**

B-cell receptors and T-cell receptors are encoded by different genes and thus have different structures. The B-cell receptor on a B cell **(Figure 45.2A)** corresponds to the antibody secreted by that cell when it is activated and differentiates into a plasma cell (see later). Like its corresponding antibody, a B-cell receptor is a protein consisting of four polypeptide chains. At one end, the protein has two identical *antigen-binding sites,* the regions that bind to a specific antigen. At the opposite end from the antigen-binding sites are *transmembrane domains,* which embed in the plasma membrane. T-cell receptors **(Figure 45.2B)** consist of a protein made up of two different polypeptides.

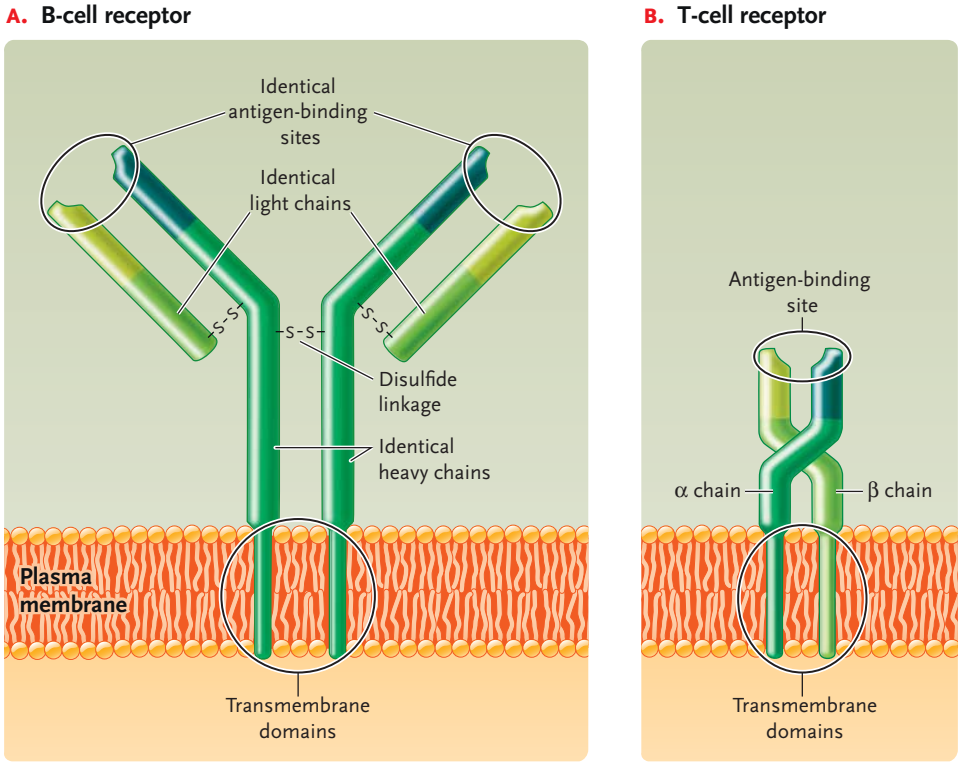

FIGURE 45.2 Antigen-binding receptors on B cells and T cells. The B-cell receptor corresponds to the antibody secreted by the cell when it is activated and differentiates into a plasma cell.
© Cengage Learning 2014

T-cell receptors also have an antigen-binding site at one end and transmembrane domains at the other end.

Considering the entire populations of B cells and T cells in the body, there are multiple cells that can recognize each antigen but, most importantly, the populations (in normal persons) contain cells capable of recognizing any antigen. For example, each of us has about 10 trillion B cells that collectively have about 100 million different kinds of B-cell receptors. Importantly, these cells are present *before* the body has encountered the antigens.

The binding between antigen and receptor is an interaction between two molecules that fit together like an enzyme and its substrate. A given B-cell receptor or T-cell receptor does not bind to the whole antigen molecule, but to small regions of it called **epitopes** or *antigenic determinants*. Therefore, several different B cells and T cells, each with different receptors, may bind to the population of a particular antigen encountered in the lymphatic system.

ANTIBODIES Antibodies are the core molecules of antibody-mediated immunity. Antibodies are large, complex Y-shaped molecules that belong to a class of proteins known as **immunoglobulins** (Ig). Each antibody molecule consists of four polypeptide chains: two identical **light chains** and two identical **heavy chains** about twice or more the size of the light chain **(Figure 45.3).**

Each polypeptide chain of an antibody molecule has a **constant (C) region** and a **variable (V) region.** The constant region of each antibody type has the same amino acid sequence for that part of the heavy chain, and likewise for that part of the light chain. The variable region of both the heavy and light chains, by contrast, has a different amino acid sequence for each antibody molecule in a population. The variable regions are the top halves of the polypeptides in the arms of the Y-shaped molecule; the three-dimensional folding of the variable regions of each arm creates the antigen-binding site. The antigen-binding site is the same for the two arms of an antibody molecule because its two heavy chains are identical, as are its two light chains, as mentioned earlier. However, the antigen-binding sites are different from antibody molecule to antibody molecule because of the amino acid differences in the variable regions of the two chain types.

Different constant regions of the heavy chains in the tail part of the Y-shaped structure determine the **antibody class.** Humans have five different classes of antibodies—*IgM, IgG, IgA, IgE,* and *IgD*. The B-cell receptors on B cells are **IgM** molecules, and IgM is the first type of antibody secreted in an antibody-mediated immune response. **IgG** is the most abundant antibody circulating in the blood and lymphatic system. IgG is produced in large amounts when the body is exposed a second time to the same antigen. It also activates the complement system when it binds an antigen. **IgA** is found mainly in secretions at particular locations in the body where the antibodies it secretes bind to surface groups on pathogens and block their attachment to body

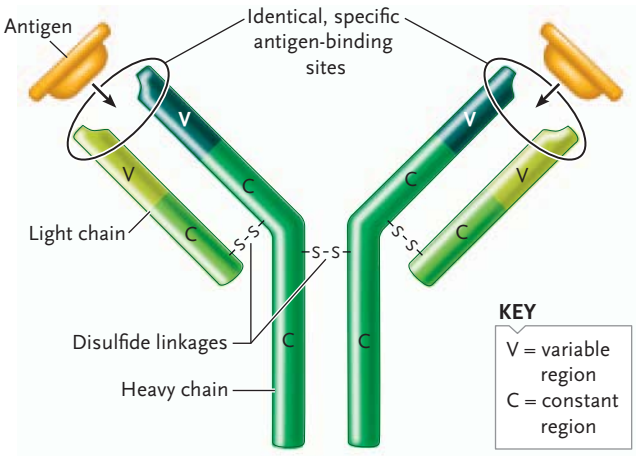

FIGURE 45.3 The arrangement of light and heavy polypeptide chains in an antibody molecule. Disulfide (—S—S—) linkages hold the chains together, and the whole molecule folds into a Y-shape. The bonds between the two arms of the Y form a hinge that allows the arms to flex independently of one another. As shown, two sites, one at the tip of each arm of the Y, bind the same antigen.

surfaces. **IgE** is secreted by plasma cells of the skin and tissues lining the gastrointestinal tract and respiratory tract. IgE binds to basophils and mast cells, triggering release of histamine, which causes an inflammatory response (see later in this chapter). **IgD** also serves as a B-cell receptor.

THE GENERATION OF ANTIBODY DIVERSITY The human genome has approximately 20,000 genes, far fewer than necessary to encode 100 million different antibodies if two genes encoded one antibody, one gene for the heavy chain and one for the light chain. Instead, antibody diversity is generated during B-cell differentiation by a process involving three rearrangements of DNA segments that encode parts of the light and heavy chains. **Figure 45.4** shows the process that produces light-chain genes for an IgM antibody, the B-cell receptor; the production of IgM heavy-chain genes, and the light-chain and heavy-chain genes for the other classes of antibodies, is similar. The genes for the two different subunits of the T-cell receptor undergo similar rearrangements to produce the great diversity in antigen-binding capability of those receptors.

Light-chain genes have one C segment, but heavy-chain genes have five types of C segments, each of which encodes one of the constant regions of IgM, IgD, IgG, IgE, and IgA. In the assembly of functional heavy-chain genes, the inclusion of one of the five C segment types therefore specifies the class of antibody that will be made by the cell.

LYMPHOCYTE ACTIVATION Let us now follow the development of an antibody-mediated immune response for a bacterial pathogen in the circulation or in a tissue. Circulating viruses are dealt with in the same way. We follow the steps of recognition of an antigen by lymphocytes, activation of lymphocytes by antigen binding, and production of antibodies **(Figure 45.5).** T cells are key players in the initial steps of this process. Two phases are involved: in the first, particular T cells are activated; in the second, those T cells help B cells become activated and secrete antibodies. The numbered steps in the following description correspond to the events shown in Figure 45.5:

1. **Engulfment of bacterium.** A type of phagocyte called a **dendritic cell** engulfs a bacterium. Dendritic cells, which have the same origin as leukocytes, are so named because they have many surface projections resembling dendrites of neurons. They recognize a bacterium as foreign through

the same recognition mechanism used by macrophages in the innate immune system.

2. **Degradation of bacterium and release of antigens.** Engulfment of a bacterium activates the dendritic cell; the activated cell migrates to a nearby lymph node. Then the vesicle within the dendritic cell that contains the engulfed bacterium fuses with a lysosome, which leads to degradation of the bacterium's proteins into short peptides. Those peptides function as antigens.
3. **Presentation of antigens on dendritic cell surface.** Within the dendritic cell, the antigens bind intracellularly to **class II major histocompatibility complex (MHC)** proteins. These proteins are named for a large cluster of 128 genes encoding them, called the **major histocompatibility complex.** Each individual of each vertebrate species has a unique combination of MHC proteins on almost all body cells, meaning that no two individuals of a species except identical siblings are likely to have exactly the same MHC proteins on their cells. The two classes of MHC proteins, class I and class II, have different functions in adaptive immunity, as you will see.

   An antigen bound to a class II MHC protein migrates to the cell surface where the antigen is displayed. The cell is now an **antigen-presenting cell (APC),** which can present the antigen to T cells.
4. **Interaction of antigen-presenting cell with lymphocyte.** The key function of an antigen-presenting cell is to present the antigen to a lymphocyte. For antibody-mediated immunity, that lymphocyte is a **$CD4^+$ T cell**, so called because it has CD4 receptors on its surface in addition to T-cell receptors. A specific $CD4^+$ T cell having a T-cell receptor with an antigen-binding site that recognizes an epitope of a bacterial antigen binds to the antigen on the antigen-presenting cell, the CD4 receptor interacts directly with the class II MHC protein and the two cells become linked together.
5. **Activation of T cell.** When the antigen-presenting cell binds to the $CD4^+$ T cell, the antigen-presenting cell secretes an *interleukin* (meaning "between leukocytes"), a type of cytokine that activates the associated T cell.
6. **Production of helper T cells.** The activated T cell secretes other interleukins, which act in an autocrine manner (see Section 42.1) to stimulate **clonal expansion,** the proliferation of the activated $CD4^+$ T cell by cell division to produce a clone of cells. These clonal cells differentiate into **helper T cells,** so named because they assist with the activation of other lymphocytes, in this case B cells. A helper T cell is an example of an **effector T cell,** meaning that it is involved in effecting—bringing about—the specific immune response to the antigen.
7. **Presentation of antigens on B cell surface.** Antibodies are produced in and secreted by activated B cells. The activation of a B cell requires the B cell to present the antigen on its surface, and then to link with a helper T cell that has differentiated as a result of encountering and recognizing the *same* antigen. Antigen presentation on a B cell surface begins when B-cell receptors on the B cell bind to antigens on the surface of the bacterium it encounters. The bacterium plus B-cell receptor is then taken into the cell where the antigen is processed in the same way as in dendritic cells (see steps 2 and 3). The result is the presentation of antigen pieces on the B-cell surface in a complex with class II MHC proteins.
8. **Interaction of B cell with helper T cell.** When a B cell encounters a helper T cell (from step 6) displaying the same antigen, usually in a lymph node or in the spleen, the two cells become tightly linked together.
9. **Activation of B cell.** The linkage between cells stimulates the helper T cell to secrete interleukins that activate the B cell and then stimulate the B cell to proliferate, producing a clone of those B cells with identical B-cell receptors.
10. **Production of plasma cells and memory B cells.** Many of the cloned cells differentiate into relatively short-lived **plasma cells,** which now secrete the same antibody that was displayed on the parental B cell's surface to circulate in lymph and blood to attach the pathogen. The other cloned cells differentiate into **memory B cells,** which are long-lived cells that set the stage for a much more rapid response should the same antigen be encountered later.

Remember that there is an enormous diversity of randomly generated lymphocytes in the body, each with a particular receptor that may potentially recognize a particular antigen. **Clonal selection** is the term used for the process by which a particular lymphocyte is specifically selected for cloning when it recognizes a particular foreign antigen (**Figure 45.6;** this figure is an expansion of step 10 of Figure 45.5). The process of clonal selection was proposed in the 1950s by several scientists, most notably F. Macfarlane Burnet, Niels Jerne, and David Talmage. Burnet received the Nobel Prize in 1960 for his research in immunology.

CLEARING THE BODY OF FOREIGN ANTIGENS Two important mechanisms to clear foreign antigens from the body are neutralization and agglutination **(Figure 45.7).** In **neutralization,** toxins produced by invading bacteria, such as tetanus toxin, can be *neutralized* by antibodies **(Figure 45.7A).** The antibodies bind to the toxin molecules, preventing them from carrying out their damaging action. In **agglutination** (clumping), the pathogen is immobilized by the antibodies **(Figure 45.7B).** For instance, for intact bacteria at an infection site or in the circulatory system, antibodies will bind to antigens on their surfaces. Because the two arms of an antibody molecule bind to different copies of the antigen molecule, an antibody molecule may bind to two bacteria with the same antigen. A population of antibodies against the bacterium, then, link many bacteria together into a lattice causing *agglutination* of the bacteria. Agglutination immobilizes the bacteria, preventing them from infecting cells. Antibodies can also agglutinate viruses, thereby preventing them from infecting cells.

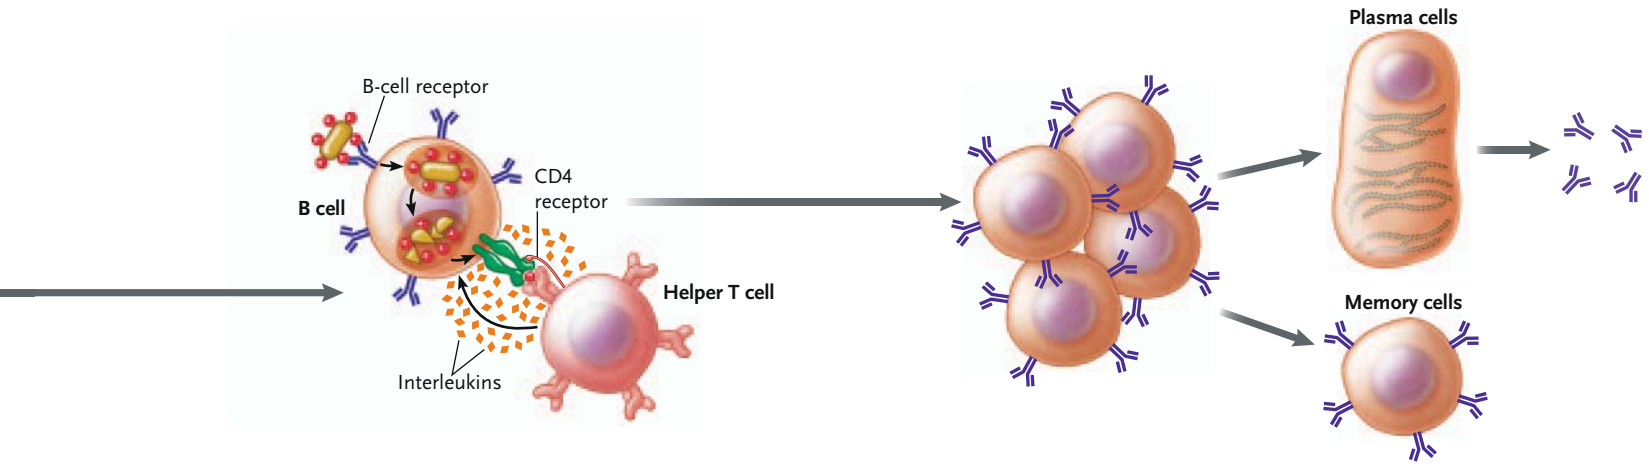
More important, antibodies aid the innate immune response triggered by the pathogens. That is, antibodies bound to antigens stimulate the complement system. Membrane attack complexes are formed and insert themselves into the plasma membranes of the bacteria, leading to their lysis and death. In the case of viral infections, membrane attack complexes can insert themselves into the membranes surrounding enveloped viruses, which disrupts the membrane and prevents the viruses from infecting cells.



Antibodies also enhance phagocytosis of bacteria and viruses. Phagocytic cells have receptors on their surfaces that recognize the heavy-chain end of antibodies (the end of the molecule opposite the antigen-binding sites). Antibodies bound to bacteria or viruses therefore bind to phagocytic cells, which then engulf the pathogens and destroy them.

For simplicity, the adaptive immune response has been described here in terms of a single antigen. Recognize that pathogens have many different types of antigens on their surfaces, which means that many different B cells are stimulated to proliferate and many different antibodies are produced. Pathogens therefore are attacked by many different types of antibodies, each targeted to one epitope on the pathogen's surface.

IMMUNOLOGICAL MEMORY Once an immune reaction has run its course and the invading pathogen or toxic molecule has been eliminated from the body, division of the plasma cells and

B-cell activation by helper T cells and differentiation of B cells into antibody-producing cells

7 Presentation of antigens on B cell surface. The B-cell receptor binds to antigen on the bacterium. Bacterium is engulfed and its macromolecules degraded. The antigens produced are displayed on cell surface bound to class II MHC proteins.

8 Interaction of B cell with helper T cell. The T-cell receptor of a helper T cell recognizes the antigen on the B cell and links the two cells together.

9 Activation of B cell. Interleukins secreted by the helper T cell activate the B cell and then stimulate B-cell proliferation to produce a clone of cells.

10 Production of plasma cells and memory B cells. Some cloned B cells differentiate into plasma cells, which secrete antibodies, while a few differentiate into memory B cells.

SUMMARY The first phase of the antibody-mediated immune response, T-cell activation, involves engulfment of a pathogen by a dendritic cell, presentation of antigens from the pathogen on the surface of that cell, interaction of the now antigen-presenting cell with and activation of a $CD4^+$ T cell, and proliferation of the T cell to produce helper T cells. The second phase, B-cell activation, involves the presentation of antigens of the pathogen on the B cell surface, interaction of the antigen-presenting B cell with a helper T cell that was produced after encountering the same antigen, activation and proliferation of the B cell, and differentiation of the B cells into antibody-producing plasma cells and memory B cells.

THINK LIKE A SCIENTIST What is the key cellular event involved in the antibody-mediated immune response responsible for the production of antibodies specific for an antigen?

helper T cell clones stops. Most or all of the clones die and are eliminated from the bloodstream and other body fluids. However, long-lived memory B cells and **memory helper T cells** (which differentiate from helper T cells), derived from encountering the same antigen, remain in an inactive state in the lymphatic system. Their persistence provides an **immunological memory** of the foreign antigen.

Immunological memory is illustrated in **Figure 45.8.** When exposed to a foreign antigen (A in the figure) for the first time, a **primary immune response** results, following the steps already described. The first antibodies appear in the blood in 3 to 14 days and, by week 4, the primary response has essentially gone away. IgM is the main antibody type produced in a primary immune response. The primary immune response curve is followed whenever a new foreign antigen enters the body.

When a foreign antigen (here, antigen A) enters the body for a second or subsequent time, a **secondary immune response** results, while any new antigen (here, antigen B) introduced at the same time produces a primary response (see Figure 45.8). The secondary response is more rapid than a primary response because it involves the memory B cells and memory T cells that have been stored in the meantime, rather than having to initiate the clonal selection of a new B cell and T cell. Moreover, less antigen is needed to elicit a secondary response than a primary response, and many more antibodies are produced. The predominant antibody produced in a sec-

ondary immune response is IgG; the switch occurs at the gene level in the memory B cells.

Immunological memory forms the basis of vaccinations, in which antigens in the form of living or dead pathogens or antigenic molecules themselves are introduced into the body. After the primary immune response, memory B cells and memory T cells remaining in the body can mount an immediate and intense immune reaction against similar antigens in the dangerous pathogen. In Edward Jenner's experiment (discussed in *Why It Matters*) introducing the cowpox virus, a related, less virulent form of the smallpox virus, into healthy individuals initiated a primary immune response. After the response ran its course, a bank of memory B and T cells remained in the body, able to recognize quickly the similar antigens of the smallpox virus and initiate a secondary immune response. Similarly, a polio vaccine developed by Jonas Salk uses inactivated polio viruses. Although the viruses are inactive, their surface groups can still act as antigens. The antigens trigger an immune response, leaving memory B and T cells able to mount an intense immune response against active polio viruses.

ACTIVE AND PASSIVE IMMUNITY **Active immunity** is the production of antibodies in the body in response to exposure to a foreign antigen—the process that has been described up until now. **Passive immunity** is the acquisition of antibodies as a result of direct transfer from another person or by the injection. This form of immunity provides immediate protection against antigens that the antibodies recognize without the person receiving the antibodies having developed an immune response. Examples of passive immunity include the transfer of IgG antibodies from mother to fetus through the placenta and the transfer of IgA antibodies in the first breast milk fed from the mother to the baby. Compared with active immunity, passive immunity is a short-lived phenomenon in that the antibodies typically break down within a month. However, in that time, the protection plays an important role. For example, a breast-fed baby is protected until it is able to mount an immune response itself, an ability that is not present until about a month after birth. Importantly, in passive immunity, the body does not develop a memory of the pathogen, which means that there is no protection against future infection with the same pathogen.

DRUG EFFECTS ON ANTIBODY-MEDIATED IMMUNITY Several drugs used to reduce the rejection of transplanted organs target helper T cells. Cyclosporin A, used routinely after organ transplants, blocks the activation of helper T cells and, in turn, the activation of B cells. Unfortunately, cyclosporin and other immunosuppressive drugs also leave the treated individual more susceptible to infection by pathogens.

Antibodies Have Many Uses in Research

The ability of the antibody-mediated immune system to generate antibodies against essentially any antigen provides an invaluable research tool to scientists, who can use antibodies to identify biological molecules and determine their locations and functions in cells. To obtain the antibodies, a molecule of interest is injected into a test animal such as a mouse, rabbit, goat, or sheep. In response, the animal develops antibodies capable of binding to the molecule. The antibodies are then extracted and purified from a blood sample.

To identify the cellular location of a molecule, antibodies made against the molecule are combined with a visible marker such as a dye molecule or heavy metal atom. When added to a tissue sample, the marked antibodies can be seen in the light or electron microscope localized to cellular structures such as membranes, ribosomes, or chromosomes, showing that the molecule forms part of the structure.

Antibodies can also be used to "grab" a molecule of interest from a preparation containing a mixture of all kinds of cellular molecules. For such studies, the antibodies are often attached to plastic beads that are packed into a glass column. When the mixture passes through the column, the molecule is trapped by attachment to the antibody and remains in the column. It is then released from the column in purified form by adding a reagent that breaks the antigen–antibody bonds.

Injecting a molecule of interest into a test animal typically produces a wide spectrum of antibodies that react with different parts of the antigen. Some of the antibodies also cross-react with other, similar antigens, producing false results that can complicate the research. These problems have been solved by producing **monoclonal antibodies,** each of which reacts only against the same segment (epitope) of a single antigen.

Georges Köhler and Cesar Milstein pioneered the production of monoclonal antibodies in 1975. In their technique, a test animal (usually a mouse) is injected with a molecule of interest **(Figure 45.9).** After the animal has developed an immune response, fully activated B cells are extracted from the spleen and placed in a cell culture medium. Because B cells normally stop dividing and die within a week when cultured, they are induced to fuse with cancerous lymphocytes called *myeloma cells,* forming single, composite cells called **hybridomas.** Hybridomas combine the desired characteristics of the two cell types—they produce antibodies like fully activated B cells, and they divide continuously and rapidly like myeloma cells.

Single hybridoma cells are then separated from the culture and used to start clones. Because all the cells of a clone are descended from a single hybridoma cell, they all make the same highly specific antibody, able to bind the same part of a single antigen. In addition to their use in scientific research, monoclonal antibodies are also widely used in medical applications such as pregnancy tests, screening for prostate cancer, and testing for AIDS and other sexually transmitted diseases.

In Cell-Mediated Immunity, Cytotoxic T Cells Expose "Hidden" Pathogens to Antibodies by Destroying Infected Body Cells

In **cell-mediated immunity,** cytotoxic T cells directly destroy host cells infected by pathogens, particularly those infected by a virus **(Figure 45.10).** For this type of immunity, T cells are the only type of lymphocyte involved. The numbered steps in the following description correspond to the events depicted in the figure:

1. **Presentation of antigens on cell surface.** The killing process begins when some of the pathogens break down inside infected host cells, releasing antigens that are fragmented by enzymes in the cytoplasm. The cell becomes an antigen-presenting cell with antigen fragments bound to class I MHC proteins displayed on the cell surface.
2. **Activation of T cell.** The antigen-presenting cell encounters a **$CD8^+$ T cell,** a cell that has CD8 receptors on its surface in addition to T-cell receptors. A specific $CD8^+$ T cell having a T-cell receptor with an antigen-binding site that recognizes an epitope of the antigen binds to the antigen on the antigen-presenting cell, the CD8 receptor interacts directly with the class I MHC protein and the two cells become linked together. This

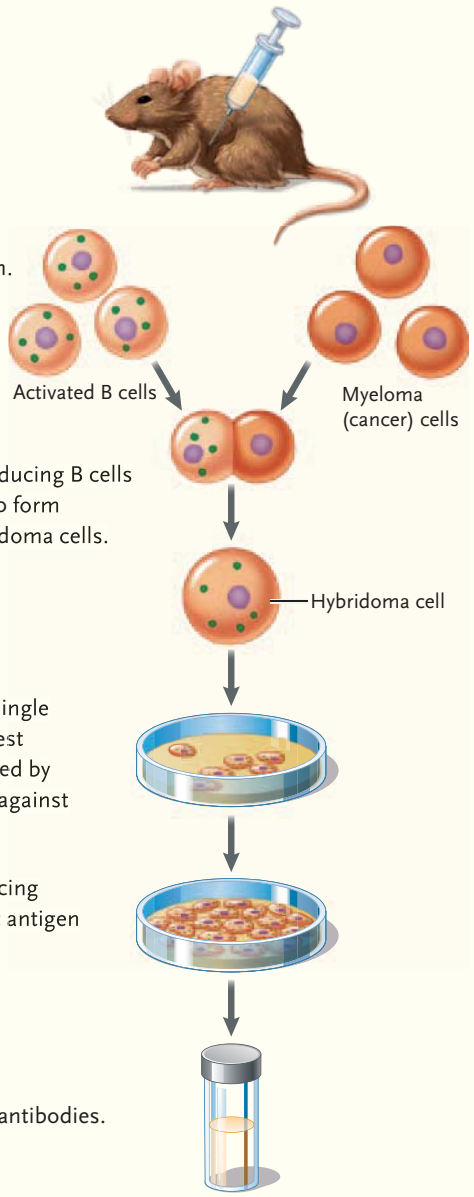

FIGURE 45.9 **Research Method**

Production of Monoclonal Antibodies

Purpose: Injecting an antigen into an animal produces a collection of different antibodies that react against different parts of the antigen. Monoclonal antibodies are produced to provide antibodies that all react against the same epitope of a single antigen.

Protocol:

1. Inject antigen into mouse.
2. Extract activated B cells from spleen.
3. Fuse antibody-producing B cells with cancer cells to form fast-growing hybridoma cells.
4. Grow clone from single hybridoma cells; test antibodies produced by clone for reaction against antigen.
5. Grow clone producing antibodies against antigen to large size.
6. Extract and purify antibodies.

Outcome: Monoclonal antibodies are highly specific in their ability to bind to the same part of a single antigen. They are widely used in scientific research and have many medical applications.

Source: G. Köhler and C. Milstein. 1975. Continuous cultures of fused cells secreting antibody of predefined specificity. *Nature* 256:495–497.

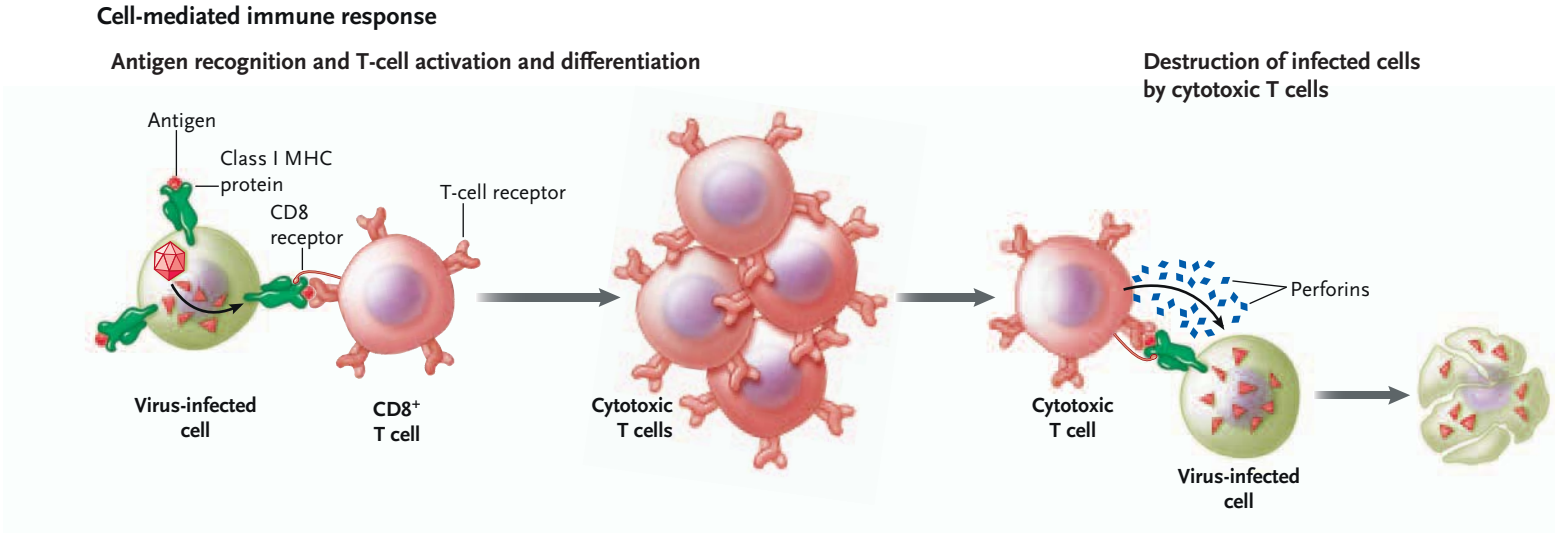
© Cengage Learning 2014

linkage event plus the presence of cytokines secreted by helper T cells generated in the antibody-mediated immune system in response to the same infection activates the T cell. (Recall that an infection triggers both antibody-mediated and cell-mediated immune responses, and review Figure 45.5 for the production of helper T cells.)

3. **Production of cytotoxic T cells.** The activated $CD8^+$ T cell proliferates to form a clone. Some of the cells in the clone differentiate into **cytotoxic T cells,** whereas a few differentiate into **memory cytotoxic T cells.** Cytotoxic T cells are another type of effector T cell.
4. **Attack of infected cell by cytotoxic T cell.** T-cell receptors on the cytotoxic T cells again recognize the antigen fragment bound to class I MHC proteins on the infected cells (the antigen-presenting cells). The cytotoxic T cell releases perforins.
5. **Destruction of infected cell.** The infected cell undergoes apoptosis brought about by the perforins as well as proteases secreted by the cytotoxic T cell acting in a way similar to that seen for natural killer (NK) cells (see earlier in the chapter). Rupture of dead, infected cells releases the pathogens to the interstitial fluid, where they are open to attack by antibodies and phagocytes.

Cytotoxic T cells can also kill cancer cells if their class I MHC molecules display fragments of altered cellular proteins that do not normally occur in the body. Another mechanism used by cytotoxic T cells to kill cells, and a process used by some cancer cells to defeat the mechanism, is described in *Insights from the Molecular Revolution.*

STUDY BREAK 45.3



1. How, in general, do antibody-mediated and cell-mediated immune responses help clear the body of antigens?
2. Describe the general structure of an antibody molecule.
3. What are the principles of the mechanism used for generating antibody diversity?
4. What is clonal selection?
5. How does immunological memory work?

THINK OUTSIDE THE BOOK

In this section you learned about the DNA rearrangements that occur to produce functional light-chain and heavy-chain genes. Susumu Tonegawa received a Nobel Prize in 1987 for his discovery of this mechanism of antibody diversity. He published the research in: N. Hozumi and S. Tonegawa. 1976. Evidence for somatic rearrangement of immunoglobulin genes coding for variable and constant regions. *Proceedings of the National Academy of Sciences USA* 73:3628–3632. Read the paper and make a flow chart outlining the experiments the investigators used in their research.

CLOSER LOOK **FIGURE 45.10 The cell-mediated immune response.**

1 Presentation of antigens on cell surface. Viral proteins are degraded into fragments that act as antigens. The antigens are displayed on the cell surface bound to class I MHC proteins.

2 Activation of T cell. A T-cell receptor on a $CD8^+$ T cell recognizes an antigen bound to a class I MHC protein on an infected cell, the CD8 receptor binds directly to the class I MHC protein, and the two cells link together. The interaction along with cytokines from helper T cells activates the T cell.

3 Production of cytotoxic T cells. The activated $CD8^+$ T cell proliferates and forms a clone. The cloned cells differentiate into cytotoxic T cells and memory cytotoxic T cells.

4 Attack of infected cell by cytotoxic T cell. A T-cell receptor on a cytotoxic T cell recognizes the antigen bound to a class I MHC protein on the infected cell. The T cell releases perforins.

5 Destruction of infected cell. The perforins insert into the membrane of the infected cell, forming pores. Leakage of ions and other molecules (along with other events) causes the cell to lyse.

SUMMARY In cell-mediated immunity, cytotoxic T cells directly destroy host cells infected by pathogens. The steps involved are as follows: presentation of pathogen antigens on the surface of an infected cell; activation of an interacting $CD8^+$ T cell; proliferation of the T cell and differentiation into cytotoxic T cells and memory T cells; recognition of surface antigens on the infected cell by a T-cell receptor on a cytotoxic T cell; and release of perforins from the T cell, which leads to destruction of the infected cell.

THINK LIKE A SCIENTIST What is the purpose of memory cytotoxic T cells in the cell-mediated immune response?

45.4 Malfunctions and Failures of the Immune System

The immune system is highly effective, but it is not foolproof. Some malfunctions of the immune system cause the body to react against its own proteins or cells, producing **autoimmune disease.** In addition, some viruses and other pathogens have evolved means to avoid destruction by the immune system. A number of these pathogens, including the HIV virus, even use parts of the immune response to promote infection. Another malfunction causes the *allergic reactions* that most of us experience from time to time.

An Individual's Own Molecules Are Normally Protected against Attack by the Immune System

B cells and T cells are involved in the development of **immunological tolerance,** which protects the body's own molecules from attack by the immune system. In this system, molecules present in an individual from birth are not recognized as foreign by circulating B and T cells, and do not elicit an immune response. The process of excluding self-reactive B and T cells goes on throughout the life of an individual.

Evidence that immunological tolerance is established early in life comes from experiments with mice. For example, if a foreign protein is injected into a mouse at birth, during the period in which tolerance is established, the mouse will not develop antibodies against the protein if it is injected later in life.

Autoimmune Disease Occurs When Immunological Tolerance Fails

The mechanisms setting up immunological tolerance sometimes fail, leading to an **autoimmune reaction**—the production of antibodies against molecules of the body. In most cases, the effects of such anti-self antibodies are not serious enough to produce recognizable disease. However, in about 5% to 10%

Some Cancer Cells Kill Cytotoxic T Cells to Defeat the Immune System

Among the arsenal of weapons employed by cytotoxic T cells to eliminate infected and cancerous body cells is the *Fas–FasL* system. Fas is a receptor that occurs on the surfaces of many body cells; FasL is a signal molecule that is displayed on the surfaces of some cell types, including cytotoxic T cells. If a cell with the Fas receptor binds the FasL signal displayed on a cytotoxic T cell, a cascade of internal reactions initiates apoptosis and kills the cell with the Fas receptor.

Research Question
Can cancer cells use the FasL signal to defeat the immune system?

Experiments
A group of Swiss researchers at the Universities of Lausanne and Geneva observed that many patients with malignant melanoma, a dangerous skin cancer, had a breakdown product associated with FasL in their bloodstream. This led them to hypothesize that some cancer cells survive elimination by the immune system by making and displaying the FasL signal, and thus killing any cytotoxic T cells that attack the tumor. Four experiments supported their hypothesis.

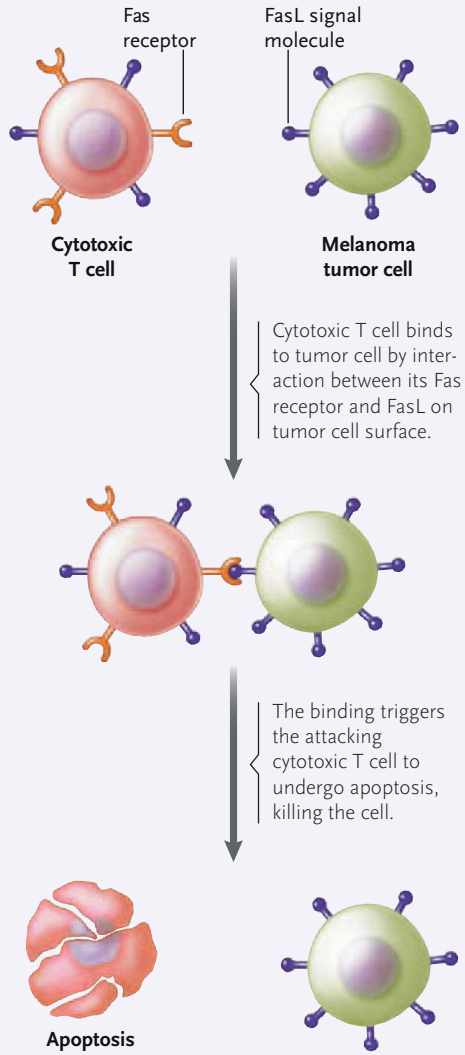
Experiment 1
The investigators extracted proteins from melanoma cells and tested whether FasL was present by using antibodies made against FasL.

Result
The test was positive, showing that the tumor cells had expressed the FasL protein.

Experiment 2
The investigators used a molecular probe to see if the mRNA encoding FasL was present in the tumor cells.

Result
FasL mRNA was identified in the cells, indicating that the gene for FasL was active in those cells.

Experiment 3
The researchers used fluorescently tagged antibodies against the FasL protein to see if, under the light microscope, they could detect FasL on cells in sections of melanoma tissue from patients.



Result
The investigators saw intense staining of the cells, showing that FasL was present.

Experiment 4
The researchers tested for the presence of the Fas receptor on the surface of the tumor cells.

Result
No Fas receptors were detected, indicating that Fas receptor synthesis was turned off in the melanoma cells.

Conclusion
The results show that the FasL of melanoma cells kills cytotoxic T cells that invade the tumor **(Figure).** At the same time, the absence of Fas receptors ensures that the tumor cells do not kill each other. The presence of FasL and absence of the Fas receptor may explain why melanomas are rarely destroyed by an immune reaction, and also why many other types of cancer also escape immune destruction.

Melanoma cells originate from pigment cells in the skin called *melanocytes.* Normal melanocytes do not contain FasL, indicating that synthesis of the protein is turned on as a part of the changes transforming normal melanocytes into cancer cells.

THINK LIKE A SCIENTIST If you were a researcher trying to develop therapeutic agents to combat melanoma, what might you target?

of the human population, anti-self antibodies cause serious problems.

For example, *type 1 diabetes* (see Section 42.4) is caused by an autoimmune reaction against the pancreatic beta cells producing insulin. The anti-self antibodies gradually eliminate the beta cells until the individual is incapable of producing insulin. **Systemic lupus erythematosus (lupus)** is caused by production of a wide variety of anti-self antibodies against blood cells, blood platelets, and internal cell structures and molecules such as mitochondria and proteins associated with DNA in the cell nucleus. People with lupus often become anemic and have problems with blood circulation and kidney function because antibodies, combined with body molecules, accumulate and clog capillaries and the microscopic filtering tubules of the kidneys. Lupus patients may also develop anti-self antibodies against the heart and kidneys. **Rheumatoid arthritis** is caused by a self-attack on connective tissues, particularly in the joints, causing pain and inflammation. **Multiple sclerosis**

results from an autoimmune attack against a protein of the myelin sheaths insulating the surfaces of neurons. Multiple sclerosis can seriously disrupt nervous function, producing such symptoms as muscle weakness and paralysis, impaired coordination, and pain.

The causes of most autoimmune diseases are unknown. In some cases, an autoimmune reaction can be traced to injuries that expose body cells or proteins that are normally inaccessible to the immune system, such as the lens protein of the eye, to B and T cells. For a number of autoimmune diseases, genetic causes (for example, particular mutations, or combinations of alleles in the body) and/or environmental causes (for example, chemicals or drugs) are considered likely.

Some Pathogens Have Evolved Mechanisms That Avoid Their Destruction by the Immune System

Several pathogens regularly change their surface groups to avoid destruction by the immune system. By the time the immune system has developed antibodies against one version of the surface proteins, the pathogens have switched to different surface proteins that the antibodies do not match. These new proteins take another week or so to stimulate the production of specific antibodies; by this time, the surface groups have changed again. The changes continue indefinitely, always keeping the pathogens one step ahead of the immune system. Pathogens that use these mechanisms to sidestep the immune system include the protozoan causing African sleeping sickness, the bacterium causing gonorrhea, and the viruses causing influenza, the common cold, and AIDS.

Some viruses, such as HIV, the virus that causes AIDS, use parts of the immune system to get a free ride to the cell interior. The structure and life cycle of HIV were described in Section 17.2. For example, HIV has a surface molecule that is recognized and bound by the CD4 receptor on the surface of helper T cells. Binding to CD4 locks the virus to the cell surface and stimulates the membrane covering the virus to fuse with the plasma membrane of the helper T cell. (The protein coat of the virus is wrapped in a membrane derived from the plasma membrane of the host cell in which it was produced.) The fusion introduces the virus into the cell, initiating the infection. Within the cell, the viral-encoded reverse transcriptase makes a DNA copy of the viral RNA genome. The DNA copy integrates into the host cell's chromosome where it is replicated as the cell multiplies. In this integrated state, the virus is protected from attack by the immune system. When the helper T cell is stimulated by an antigen, the integrated HIV genome is expressed to produce new viral RNA genomes and mRNAs that direct host cell ribosomes to make viral proteins, and new HIV virus particles are generated. Once released from the cell (which kills the cell), the viral particles may infect more body cells or another person. HIV also infects and kills macrophages. With time, more and more helper T cells and macrophages are destroyed, eventually crippling the body's immune response. The infected person becomes susceptible to opportunistic infections by viruses, bacteria, and fungi, and to development of otherwise rare forms of cancer. These secondary infections signal the appearance of full-blown AIDS. Steady debilitation and death typically follow within a period of years in untreated persons. Fortunately, the development of AIDS can be greatly slowed by drugs that interfere with reverse transcription of the viral genomic RNA into the DNA copy that integrates into the host's genome.

Some pathogens enter a **latent state** during an infection, meaning that the pathogen cannot be isolated from the infected organism and identified. Pathogens in a latent state are not recognized by the immune system. For example, herpes simplex virus can enter peripheral nerves and remain in a latent state for years. Its sudden emergence from latency causes cold sores. Similarly, the bacterium *Mycobacterium tuberculosis,* the causative agent of tuberculosis, may enter a latent state during which no symptoms of tuberculosis are exhibited and the person is not infectious. Emergence from this latent state causes the development of tuberculosis.

Allergies Are Produced by Overactivity of the Immune System

The substances responsible for allergic reactions form a distinct class of antigens called **allergens,** which induce B cells to secrete an overabundance of IgE antibodies **(Figure 45.11).** The IgE antibodies, in turn, bind to receptors on mast cells in connective tissue and on **basophils,** a type of leukocyte in blood (see Table 45.1), inducing them to secrete histamine, which produces a severe inflammation. Most of the inflammation occurs in tissues directly exposed to the allergen, such as the surfaces of the eyes, the lining of the nasal passages, and the air passages of the lungs. Signal molecules released by the activated mast cells also stimulate mucosal cells to secrete floods of mucus and cause smooth muscle in airways to constrict (histamine also causes airway constriction). The resulting allergic reaction can vary in severity from a mild irritation to serious and even life-threatening debilitation. **Asthma** is a severe response to allergens involving constriction of airways in the lungs. **Antihistamines** (substances that block histamine receptors) are usually effective in countering the effects of the histamine released by mast cells.

An individual is *sensitized* by a first exposure to an allergen, which may produce only mild allergic symptoms or no reaction at all **(Figure 45.11A).** However, the sensitization produces memory B and T cells; at the next and subsequent exposures, the system is poised to produce a greatly intensified allergic response **(Figure 45.11B).**

In some persons, inflammation stimulated by an allergen is so severe that the reaction brings on a life-threatening condition called **anaphylactic shock.** Among other symptoms, extreme constriction of air passages in the lungs interferes with breathing, and massive leakage of fluid from capillaries causes the blood pressure to drop precipitously. Death may result in minutes if the condition is not treated promptly. In persons who have become sensitized to the venom of wasps and bees,

for example, a single sting may bring on anaphylactic shock within minutes. Allergies developed against drugs such as penicillin and certain foods can have the same drastic effects. Anaphylactic shock can be controlled by immediate injection of epinephrine (adrenaline), which reverses the condition by constricting blood vessels and dilating air passages in the lungs.

STUDY BREAK 45.4

1. What is immunological tolerance?
2. Explain how a failure in the immune system can result in an allergy.

THINK OUTSIDE THE BOOK

A number of so-called new-generation drugs have been developed to treat patients with rheumatoid arthritis. One of them is abatacept (Orencia). Use the Internet or research literature to develop an outline of how abatacept works with respect to the adaptive immune system described in this section.

45.5 Defenses in Other Animals

This chapter has emphasized the mammalian immune system, the focus of most immunology research. As you have learned, the mammalian immune system consists of both the innate immune system and the adaptive immune system. In fact, all vertebrates have both types of immune systems, whereas other animals have only an innate immune system.

Like all other physiological systems, mammalian defenses against pathogens are the result of evolution, and evidence of their functions can be seen in other vertebrate groups and also in invertebrates. For example, molecular studies in sharks and rays have revealed DNA sequences that are clearly related to the sequences coding for antibodies in mammals. If injected with an antigen, sharks produce antibodies, formed from light- and heavy-chain polypeptides, capable of recognizing and binding the antigen. Although embryonic gene segments for the two polypeptides are arranged differently in sharks than they are in mammals, antibody diversity is produced by the same kinds of genetic rearrangements in both. Sharks also mount highly efficient nonspecific defenses, including production of a steroid that appears to kill bacteria and neutralize viruses.

Invertebrates lack an adaptive immune system, but do have an innate immune system. That is, their reactions to invading pathogens most closely resemble the nonspecific defenses of humans and other vertebrates. However, all invertebrates have phagocytic cells, which patrol tissues and engulf pathogens and other invaders. Some of the signal molecules that stimulate phagocytic activity, such as interleukins, appear to be similar in invertebrates and vertebrates, indicated evolutionary relatedness.

Invertebrates lack antibodies, but proteins of the immunoglobulin (Ig) family are widely distributed. In at least some invertebrates, these Ig proteins have a protective function. In moths, for example, an Ig-family protein called *hemolin* binds to the surfaces of pathogens and marks them for removal by phagocytes.

Many invertebrates produce antimicrobial proteins such as lysozyme that are able to kill bacteria and other invading cells. Insects, for example, secrete lysozyme in response to bacterial infections.

UNANSWERED QUESTIONS

How does HIV evade the adaptive immunity system?

In cell-mediated immunity, a pathogen-infected antigen-presenting cell presents an antigen fragment bound to a class I major histocompatibility complex (MHC) protein to a $CD8^+$ T cell, stimulating the T cell to differentiate into cytotoxic T cells. The mature cytotoxic T cells specifically recognize viral antigen bound to MHC on infected cells and destroy them. Cytotoxic T cells act particularly against host cells infected by viral pathogens. HIV infects host cells but, rather than being eliminated by the host, this virus establishes a chronic infection that leads to the development of AIDS. That is, HIV evades the adaptive immunity system.

My research group at the University of Michigan Medical School has investigated the mechanism of this evasion. We have learned that the virus down-regulates the display of class I MHC proteins on the surface of HIV-infected cells, which limits the presentation of viral antigens by those cells. The down-regulation occurs by the action of the HIV Nef (*ne*gative *f*actor) protein. Nef binds to class I MHC molecules and inhibits them from moving through the Golgi complex to the cell surface. Without class I MHC molecules on the cell surface to present antigens, the immune response is compromised. The action of Nef, therefore, enhances the ability of HIV to cause a persistent infection that ultimately leads to AIDS.

A major research question addressed by my laboratory is: how does Nef disrupt the movement of class I MHC molecules from the ER through the Golgi complex to the cell surface? Recent experiments have shown that the disruption results from an interaction of Nef with two cellular proteins, adaptor protein 1 and β-COP. The normal function of these cellular proteins is to help target other cellular proteins to their correct locations within the cell. By sequentially linking the two cellular proteins to MHC, Nef promotes the trafficking of the class I MHC proteins to lysosomes (where they are degraded), rather than to the cell surface. Nef links adaptor protein 1 to a tyrosine residue in the MHC-I protein.

There are different types of MHC-I proteins expressed by cells and these proteins are highly polymorphic. The diversity of MHC-I proteins allows cells to present a wide range of antigens. All cells express six alleles of MHC-I: two alleles of MHC-I HLA-A, two alleles of MHC-I HLA-B, and two alleles of MHC-I HLA-C. MHC-I HLA-A and HLA-B proteins have the tyrosine amino acid that Nef needs to attach adaptor protein 1 and disrupt antigen presentation. However, HLA-C molecules lack this tyrosine and HLA-C is not down-regulated by Nef. HLA-C may be protective in HIV disease. There is growing evidence that individuals who naturally express higher levels of HLA-C have a more favorable prognosis in HIV disease. This may result from the fact that HLA-C is resistant to the effects of Nef.

My research team is now working to develop pharmaceutical reagents aimed at blocking Nef action as a means of reducing HIV's attack on the immune system.

THINK LIKE A SCIENTIST HLA-C is the most recently evolved of the human MHC-I proteins. Can you think of why new MHC-I molecules might evolve in a species?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

45.1 Three Lines of Defense against Pathogens

- Humans and other vertebrates have three lines of defense against pathogens: (1) a nonspecific system involving physical barriers set up by epithelial surface (not part of the immune system); (2) innate immunity, a nonspecific inborn system that defends the body against pathogens and toxins penetrating the first line; and (3) adaptive immunity, a specific inborn system that recognizes and eliminates particular pathogens and retains a memory of that exposure so as to respond rapidly if the pathogen is encountered again. The response is carried out by lymphocytes, a specialized group of leukocytes (Table 45.1).

  Animation: White blood cells

45.2 Innate Immunity: Nonspecific Defenses

- In the innate immune system, molecules on the surfaces of pathogens are recognized as foreign by receptors on host cells. The pathogen is then combated by the inflammation and complement systems.
- Epithelial surfaces secrete defensins, a type of antimicrobial peptide, in response to attack by a microbial pathogen. Defensins disrupt the plasma membranes of pathogens, killing them.
- Inflammation is characterized by heat, pain, redness, and swelling at the infection site. Several interconnecting mechanisms initiate inflammation, including pathogen engulfment, histamine secretion, cytokine release, and local blood vessel dilation and permeability increase (Figure 45.1).
- Large arrays of complement proteins are activated when they recognize molecules on the surfaces of pathogens. Some complement proteins form membrane attack complexes, which insert into the plasma membrane of many types of bacteria and cause their lysis. Fragments of other complement proteins coat pathogens, stimulating phagocytes to engulf them.
- Two nonspecific defenses are used to combat viral pathogens: interferons and natural killer cells.

  Animation: Inflammatory response

  Animation: Complement proteins

  Animation: Innate defenses

45.3 Adaptive Immunity: Specific Defenses

- Adaptive immunity is a vertebrate-specific defense mechanism that is carried out by B and T cells, and targets particular pathogens or toxin molecules.
- Antibodies consist of two light and two heavy polypeptide chains, each with variable and constant regions. The variable regions of the chains combine to form the specific antigen-binding site (Figure 45.3).

- Antibodies occur in five different classes: IgM, IgD, IgG, IgA, and IgE. Each class is determined by its constant region.
- Antibody diversity is produced by genetic rearrangements in developing B cells that combine gene segments into intact genes encoding the light and heavy chains. The rearrangements producing heavy-chain genes and T-cell receptor genes are similar. The light- and heavy-chain genes are transcribed into pre-mRNAs, which are processed into finished mRNAs, which are translated on ribosomes into the antibody polypeptides (Figure 45.4).
- The antibody-mediated immune response has two general phases: T-cell activation and B-cell activation and antibody production. T-cell activation begins when a dendritic cell engulfs a pathogen and displays antigens derived from the pathogen on its surface, making the cell an antigen-presenting cell. The antigen-presenting cell secretes interleukins, which activate the T cell. The T cell then secretes other interleukins, which stimulate the T cell to proliferate, producing a clone of cells. The clonal cells differentiate into helper T cells (Figure 45.5).
- B-cell receptors on B cells recognize antigens on a pathogen and engulf it. The B cells then display the antigens. The T-cell receptor on a helper T cell activated by the same antigen binds to the antigen on the B cell. Interleukins from the T cell stimulate the B cell to produce a clone of cells with identical B-cell receptors. The clonal cells differentiate into plasma cells, which secrete antibodies specific for the antigen, and memory B cells, which provide immunological memory of the antigen encounter (Figures 45.5).
- Clonal expansion is the process of selecting a lymphocyte specifically for cloning when it encounters an antigen from among a randomly generated, large population of lymphocytes with receptors that specifically recognize the antigen (Figure 45.6).
- Antibodies clear the body of antigens by neutralizing or agglutinating them, or by aiding the innate immune response (Figure 45.7).
- In immunological memory, the first encounter of an antigen elicits a primary immune response and later exposure to the same antigen elicits a rapid secondary response with a greater production of antibodies (Figure 45.8).
- Active immunity is the production of antibodies in the body in response to an antigen. Passive immunity is the acquisition of antibodies by direct transfer from another person.
- Antibodies are widely used in research to identify, locate, and determine the functions of molecules in biological systems.
- Monoclonal antibodies are made by isolating fully active B cells from a test animal, fusing them with cancer cells to produce hybridomas, and using single hybridomas to start clones of cells, all of which make highly specific antibodies against the same epitope of an antigen (Figure 45.9).
- In cell-mediated immunity, cytotoxic T cells recognize and bind to antigens displayed on the surfaces of infected body cells, or to cancer cells. They then kill the infected body cell (Figure 45.10).

Animation: Gene rearrangements

Animation: Antibody-mediated response

Animation: Cell-mediated response

45.4 Malfunctions and Failures of the Immune System

- In immunological tolerance, molecules present in an individual at birth normally do not elicit an immune response.
- In some people, the immune system malfunctions and reacts against the body's own proteins or cells, producing autoimmune disease.
- Some pathogens have evolved mechanisms that avoid their destruction by the immune system.
- The first exposure to an allergen sensitizes an individual by leading to the production of memory B and T cells, which cause a greatly intensified response at the next and subsequent exposures.
- Most allergies result when antigens act as allergens by stimulating B cells to produce IgE antibodies, which leads to the release of histamine. Histamine produces the symptoms characteristic of allergies (Figure 45.11).

45.5 Defenses in Other Animals

- Vertebrates have both the innate immune system and the adaptive immune system.
- Invertebrates lack an adaptive immune system using innate immune systems for nonspecific defenses, including surface barriers, phagocytes, and antimicrobial molecules.

UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following most accurately describes mammal defenses against disease-causing viruses or organisms?
   a. The three lines of defense work independently of each other in defending against a particular pathogen.
   b. Physical barriers are part of the immune system.
   c. The adaptive immune system reacts faster to pathogens than the innate immune system.
   d. Once the adaptive immune system is activated in response to a specific pathogen, the innate immune system stops functioning against that specific pathogen.
   e. White blood cells are key participants in adaptive immunity but not innate immunity.
2. Which of the following is *not* a component of the inflammatory response?
   a. macrophages
   b. neutrophils
   c. B cells
   d. mast cells
   e. eosinophils
3. When a person's immune system resists infection by a pathogen after being vaccinated against it, this is the result of:
   a. innate immunity.
   b. immunological memory.
   c. a response with defensins.
   d. an autoimmune reaction.
   e. systemic inflammation.
4. One characteristic of a B cell is that it:
   a. has the same structure in both invertebrates and vertebrates.
   b. recognizes antigens held on class I major histocompatibility complex proteins.
   c. binds viral infected cells and directly kills them.
   d. makes many different B-cell receptors on its surface.
   e. has a B-cell receptor on its surface, which is the IgM molecule.
5. Antibodies:
   a. are each composed of four heavy and four light chains.
   b. display a variable end, which determines the antibody's location in the body.
   c. belonging to the IgE group are the major antibody class in the blood.
   d. found in large numbers in the mucous membranes belong to class IgG.
   e. function primarily to identify and bind antigens free in body fluids.

6. Place the following steps of recognition of an antigen by lymphocytes in the order in which they would occur:
    1. Bacteria degraded
    2. Dendritic cell engulfs bacteria
    3. T cells activated
    4. Antigens bind to class II MHC proteins
    5. Plasma cells and memory cells produced

    a. 1, 2, 3, 4, 5.
    b. 3, 2, 1, 4, 5.
    c. 4, 3, 1, 2, 5.
    d. 2, 1, 4, 3, 5.
    e. 5, 4, 3, 2, 1.

7. An antigen-presenting cell:
    a. can be a $CD8^+$ T cell.
    b. derives from a phagocytic cell and exposes an antigen to a lymphocyte.
    c. secretes antibodies.
    d. cannot be a B cell.
    e. cannot stimulate helper T cells.

8. Antibodies function to:
    a. deactivate the complement system.
    b. neutralize natural killer cells.
    c. clump bacteria and viruses for easy phagocytosis by macrophages.
    d. eliminate the chance for a secondary response.
    e. kill viruses inside of cells.

9. After Sally punctured her hand with a dirty nail, she received both a vaccine and someone else's antibodies against tetanus toxin. The immunity conferred here is:
    a. both active and passive.
    b. active only.
    c. passive only.
    d. first active; later passive.
    e. innate.

10. Drugs are administered to patients to enhance the immune response when treating:
    a. organ transplant recipients.
    b. anaphylactic shock.
    c. rheumatoid arthritis.
    d. HIV infection.
    e. type I diabetes.

Discuss the Concepts

1. HIV wreaks havoc with the immune system by attacking helper T cells and macrophages. Would the impact be altered if the virus attacked only macrophages? Explain.
2. Given what you know about how foreign invaders trigger immune responses, explain why mutated forms of viruses, which have altered surface proteins, pose a monitoring problem for memory cells.
3. Cats, dogs, and humans may develop myasthenia gravis, an autoimmune disease in which antibodies develop against acetylcholine receptors in the synapses between neurons and skeletal muscle fibers. Based on what you know of the biochemistry of muscle contraction (see Section 43.1), explain why people with this disease typically experience severe fatigue with even small levels of exertion, drooping of facial muscles, and trouble keeping their eyelids open.

Design an Experiment

Space, the final frontier! Indeed, but being in space has some problems. Astronauts in space show a decline in their ability to mount an immune response and, consequently, develop a decreased resistance to infection. Two potentially important differences in physiology in space versus on Earth are more fluid flowing to the head and a lack of weight-bearing on the lower limbs. Could they be involved somehow in the deleterious effect on the immune system? Design an experiment to be done on Earth to answer this question.

Interpret the Data

In 2003, Michelle Khan and her coworkers published their findings on a 10-year study in which they followed cervical cancer incidence and HPV status in 20,514 women. All women who participated in the study were free of cervical cancer when the test began. Pap tests were taken at regular intervals, and the researchers used a DNA probe hybridization test to detect the presence of specific types of HPV in the women's cervical cells.

The results are shown as a graph of the incidence rate of cervical cancer by HPV type **(Figure).** Women who are HPV positive are often infected by more than one type, so the data were sorted into groups based on the women's HPV status ranked by type: either positive for HPV16; or negative for HPV16 and positive for HPV 18; or negative for HPV16/18 and positive for any other cancer-causing HPV; or negative for all cancer-causing HPV.

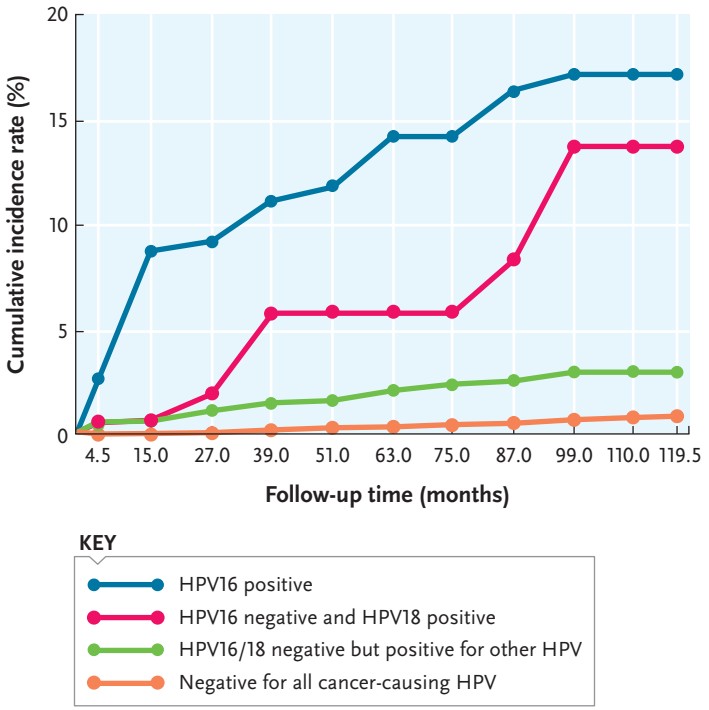

FIGURE Cumulative incidence rate of cervical cancer correlated with HPV status in 20,514 women aged 16 years and older.

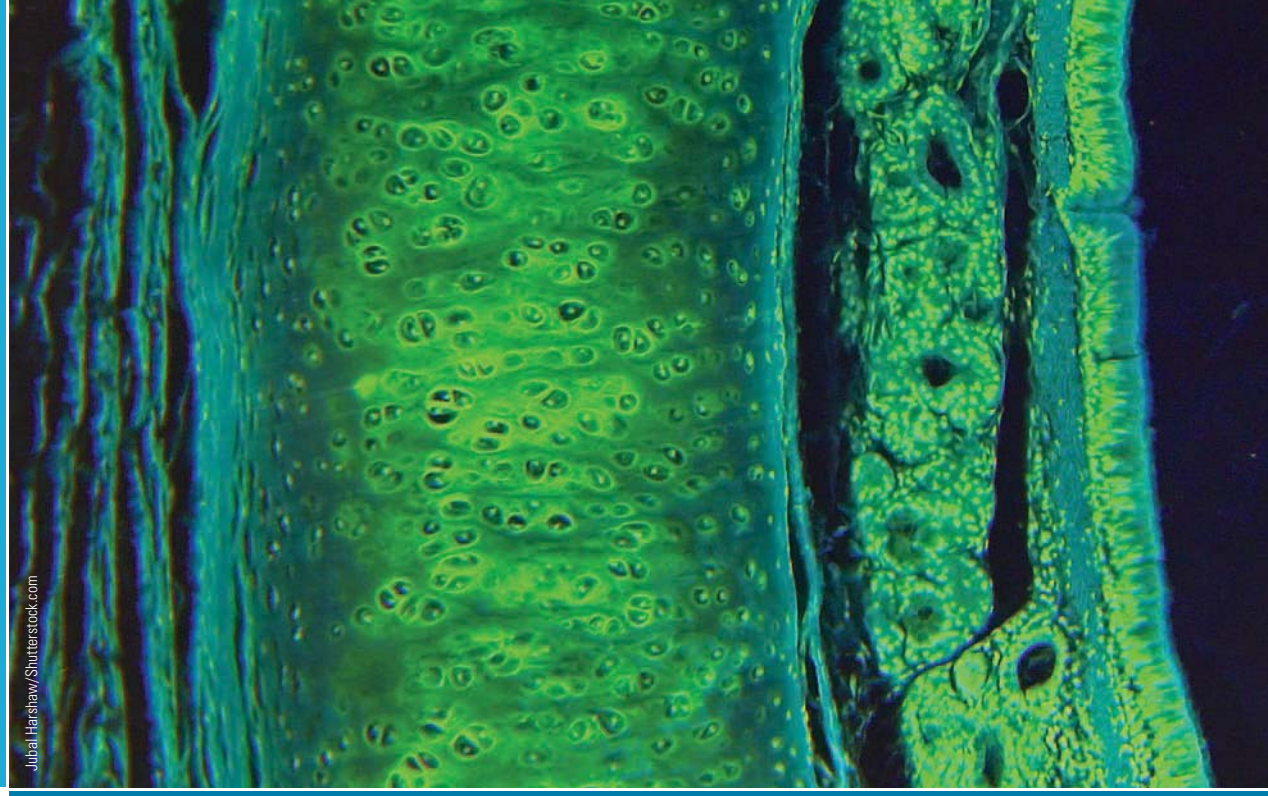
M. J. Khan et al. 2005. The elevated 10-year risk of cervical neoplasia in women with human papillomavirus (HPV) type 16 or 18 and the possible utility of type-specific HPV testing in clinical practice. *Journal of the National Cancer Institute* 97:1072–1079. By permission of Oxford University Press.

1. At 110 months into the study, what percentage of women who were not infected with any type of cancer-causing HPV had cervical cancer? What percentage of women who were infected with HPV16 also had cervical cancer?
2. In which group would women infected with both HPV16 and HPV18 fall?
3. Is it possible to estimate from this graph the overall risk of cervical cancer associated with infection of cancer-causing HPV of any type?
4. Do these data support the conclusion that being infected with HPV16 or HPV18 raises the risk of cervical cancer?



Source: M. J. Khan et al. 2005. The elevated 10-year risk of cervical neoplasia in women with human papillomavirus (HPV) type 16 or 18 and the possible utility of type-specific HPV testing in clinical practice. *Journal of the National Cancer Institute* 97:1072–1079.

Apply Evolutionary Thinking

Defensins are found in a wide range of organisms, including plants as well as animals. What are the evolutionary implications of this observation?

STUDY OUTLINE

46.1 The Function of Gas Exchange
46.2 Adaptations for Respiration
46.3 The Mammalian Respiratory System
46.4 Mechanisms of Gas Exchange and Transport
46.5 Respiration at High Altitudes and in Ocean Depths

Gas Exchange: The Respiratory System

Why it matters . . . On October 25, 1999, at 9:19 A.M. EDT, a Learjet N47BA took off from Orlando International Airport. Two minutes later, at 9:21 EDT, the pilots reported passing through 9,500 feet. As the jet continued its climb, the pressure of the outside air dropped steadily and with it the availability of the oxygen (O_2) that all animal life requires, including the two pilots and three passengers on the jet. Normally, the cabin pressure in aircraft is maintained at a level equivalent to an altitude of 8,000 feet, more than sufficient to keep O_2 available to all on board. But, unknown to the pilots, the pressurization system was not functioning normally.

At 9:27 EDT, the controller at the Jacksonville Control Center instructed the jet to climb to 39,000 feet. The first officer's acknowledgment was the last radio transmission anyone was to hear from N47BA.

When humans experience increasingly higher altitudes, each breath brings less O_2 into the body. Of all the cells affected by reduced O_2, the ones most sensitive are those of the eyes and brain. Without an O_2 supply at 25,000 feet, most people progress from fully alert to unconscious in about 3 minutes; at 40,000 feet, the progression takes only 15 seconds.

The jet continued its climb, eventually reaching an altitude of 46,000 feet. When the pilots stopped responding to communications, military jets were sent to investigate. The military pilots could see no movement in the Learjet cabin and there was no response to their transmissions. The forward windshields of the Learjet were frosted over, indicating that warm air from the engines was not ventilating the cabin correctly. Evidently, the aircraft was maintaining its course through the autopilot, without conscious human direction.

Many hours later, at 12:11 P.M. CDT, one of the two engines failed: the aircraft, now unbalanced, rolled over and dived to a shattering impact in a field near Aberdeen, South Dakota. The subsequent investigation pointed to faulty operation of a valve controlling cabin pressurization as

a likely cause of the accident. This tragic loss of life emphasizes the vital importance of O_2 to the survival of humans and other animals. In this chapter we discuss the respiratory system, the system that allows an animal to exchange CO_2 produced in the body for O_2 from the surroundings. The respiratory systems of animals reflect the environmental conditions under which they live, and this general principle has resulted in a truly remarkable array of adaptations.

46.1 The Function of Gas Exchange

Physiological respiration is the process by which animals exchange gases with their surroundings—how they take in O_2 from the outside environment and deliver it to body cells, and remove CO_2 from body cells and deliver it to the environment **(Figure 46.1).** The absorbed O_2 is used as the final electron acceptor for the oxidative reactions that produce ATP in mitochondria (see Section 8.4). The CO_2 released to the environment is a product of those oxidative reactions. Because they use O_2 and release CO_2, these ATP-producing reactions are called *cellular respiration.*

How gas exchange occurs in an animal depends on its respiratory medium—air or water—and the nature of its respiratory surface. The **respiratory medium** is the environmental source of O_2 and the "sink" for released CO_2. For aquatic animals the respiratory medium is water; for terrestrial animals, it is air. Amphibians and some fishes use both water and air as respiratory media. The exchange of gases with the respiratory medium by animals is called **breathing,** whether the medium is air or water.

The **respiratory surface,** formed by a layer of epithelial cells, provides the interface between the body and the respiratory medium. Oxygen is absorbed across the respiratory surface, and CO_2 is released. In all animals, the exchange of gases across the respiratory surface occurs by simple diffusion, movement of molecules from a region of higher concentration to a region of lower concentration (see Section 6.2).

Generally, the concentration of O_2 is higher in the respiratory medium than on the internal side of the respiratory surface, and thus the net diffusion of O_2 is inward. Carbon dioxide moves in the opposite direction because the CO_2 concentration is higher on the internal side of the respiratory surface than in the respiratory medium.

Respiratory surfaces typically have two structural properties that favor a high rate of diffusion:

1. *Respiratory surfaces are thin.* The rate of diffusion is inversely proportional to the square of the distance over which the diffusion occurs; diffusion rates are therefore higher through thin surfaces such as the single layer of epithelial cells forming many respiratory surfaces.
2. *Respiratory surfaces have large surface areas.* The rate of diffusion is directly proportional to the surface area across which diffusion occurs, meaning that large surface areas allow for higher rates of gas exchange than small surface areas.

In addition, the rate of diffusion becomes higher with larger concentration gradients and with increasing temperature.

In some relatively small animals, such as sponges, ctenophores, roundworms, flatworms, and some annelids, the entire body surface serves as the respiratory surface. All these animals are invertebrates that live in aquatic or moist environments.

In larger animals, specialized structures, *gills* and *lungs,* form the primary respiratory surface for exchanging gases with water and air, respectively. In insects, a **tracheal system,** an extensive system of branching tubes, channels air from the outside to the internal organs and most individual cells of the animal.

Because gases must dissolve in water to enter and leave epithelial cells, the respiratory surface must be wetted to function in gas exchange, either directly by the respiratory medium or by a thin film of water. For this reason, in water-breathing animals, **gills** are *evaginations* of the body: they extend outward into the respiratory medium. In terrestrial animals, **lungs** are typically pockets or *invaginations* of the body surface, buried deeply in the body interior where they are less susceptible to drying out. Terrestrial animals also have adaptations that moisten dry air before it reaches the respiratory surface. For example, in humans and other mammals, moisture is added to air as it passes through the mouth, nasal passages, throat, and air passages leading to the lungs.

The organ system responsible for gas exchange is termed the **respiratory system.** The respiratory system consists of all the parts of the body involved in exchanging air between the external environment and the blood. In mammals, this includes the airways leading to and into the lungs, the lungs themselves,

and the structures of the chest used to move air through the airways into and out of the lungs.

Adaptations That Increase Ventilation and Perfusion of the Respiratory Surface Maximize the Rate of Gas Exchange

Two primary adaptations help animals maintain the difference in concentration between gases outside and inside the respiratory surface, thereby keeping the rate of gas exchange at maximal levels:

1. **Ventilation,** the flow of the respiratory medium (air or water, depending on the animal) over the external side of the respiratory surface.
2. **Perfusion,** the flow of blood or other body fluids on the internal side of the respiratory surface.

VENTILATION As they respire, animals remove O_2 from the respiratory medium and replace it with CO_2. Without ventilation, the concentration of O_2 would fall in the respiratory medium close to the respiratory surface, and the concentration of CO_2 would rise, gradually reducing the concentration gradients and dropping the rate of gas exchange below the minimum level required to sustain life. Examples of ventilation include the one-way flow of water over the gills in fish and many other aquatic animals and the in-and-out flow of air in the lungs of most vertebrates and in the tracheal system of insects.

PERFUSION The constant replacement of blood or another fluid on the internal side of the respiratory surface helps to keep the inside/outside concentration differences of O_2 and CO_2 at a maximum. In animals without a circulatory system, such as roundworms and flatworms, body movements help circulate body fluids beneath the skin. Most animals without a circulatory system are small or have thin, greatly flattened bodies, because all body cells must be located close to the respiratory surface to exchange O_2 and CO_2 adequately. In animals with a circulatory system, the circulatory system brings blood to the internal side of the respiratory surface, transporting CO_2 from all cells of the body—no matter how far they are from the respiratory surface—to exchange for O_2, which is then taken to all cells of the body.

Adaptations That Increase the Area of the Respiratory Surface Maximize the Quantity of Gases Exchanged

Most animals have adaptations that increase the quantity of gases exchanged by increasing the area of the respiratory surface. In animals whose skin serves as the respiratory surface, an elongated or flattened body form increases the area of the respiratory surface **(Figure 46.2A).**

In animals with gills, the respiratory surface is increased by highly branched structures that include many fingerlike or platelike projections **(Figure 46.2B).** Similarly, in animals with lungs or tracheae, the respiratory surface is increased by a multitude of branched tubes, folds, or pockets **(Figure 46.2C).**

Water and Air Have Advantages and Disadvantages as Respiratory Media

Because their respiratory surfaces are exposed directly to the environment, water breathers easily keep the respiratory surface wetted. However, aquatic animals face two main challenges in obtaining O_2 from water compared with terrestrial animals. First, water contains approximately one-thirtieth as much O_2 as air does (at 15°C). Therefore, to obtain the same amount of O_2, an aquatic animal must process 30 times as much of its respiratory medium as a terrestrial animal does. Second, water is about 1,000 times as dense as air and about 50 times as viscous. Therefore, it takes significantly more energy to move water than air over a respiratory surface. For this reason, ventilation in most aquatic animals takes place in a one-way direction. In bony fishes, for instance, water enters the mouth, flows over the gills, and exits through the gill covers, all in one direction.

In addition, temperature and solutes affect the O_2 content of water. That is, as either the temperature or the amount of solutes increases, the amount of gas that can dissolve in water decreases. Therefore, for obtaining O_2, aquatic animals that live in warm water are at a disadvantage compared with those that live in cold water. And, because levels of solutes (such as sodium chloride) are higher in seawater than in freshwater, aquatic animals living in seawater are at a disadvantage.

The relatively high O_2 content, low density, and low viscosity of air greatly reduce the energy required to ventilate the re-

spiratory surface. These advantages allow animals with lungs to breathe in and out, reversing the direction of flow of the respiratory medium, without a large energy penalty. As you will see later, reversing the direction of flow decreases the efficiency of gas exchange.

Another advantage of breathing air is that gas molecules diffuse nearly 10,000 times faster through air than through water. This increases the rate at which molecules of the gases at the respiratory surface exchange with those located farther away in the air and reduces the requirement for ventilation as compared with water.

A major disadvantage of air is that it evaporates water constantly from the respiratory surface unless the air is saturated with water vapor. Therefore, except in an environment with 100% humidity, animals lose water (and heat) by evaporation during breathing and must replace the water to keep the respiratory surface from drying and causing the death of the surface cells.

We next turn to the adaptations that allow water-breathing and air-breathing animals to obtain O_2 and release CO_2 in aquatic and terrestrial environments. These adaptations allow animals to exploit the advantages and circumvent the disadvantages of water and air as respiratory media.

STUDY BREAK 46.1

1. Distinguish between the roles of the respiratory medium and the respiratory surface in respiratory systems.
2. What is an advantage of water over air as a respiratory medium? What are two key advantages of air over water as a respiratory medium?

46.2 Adaptations for Respiration

Although most animals that live in water exchange gases through the skin or gills, some, such as whales, seals, and dolphins, exchange gases through lungs (which originally evolved in aquatic creatures). And although most animals that live on land exchange gases through lungs, some, such as sow bugs and land crabs, exchange gases through gills, and others, such as insects, exchange gases using a tracheal system.

Aquatic Gill Breathers Exchange Gases More Efficiently Than Skin Breathers

Gills provide water-breathing animals, and a few air-breathers, with more efficient gas exchange than skin breathers have. In combination with the organized circulatory system common to these animals, gills also allow animals to live in more diverse habitats, and to achieve greater body mass, than animals that breathe primarily or exclusively through the skin.

EXTERNAL AND INTERNAL GILLS Gills are respiratory surfaces that are branched and folded evaginations of the body surface. **External gills** lack protective coverings; they extend out from the body and are in direct contact with the water. With no protective coverings, external gills are exposed to mechanical damage and must be immersed in water to keep them from collapsing or drying. For these reasons, animals with external gills, including some annelids and mollusks **(Figure 46.3A),** aquatic in-

sects, the larval forms of some bony fishes, and some amphibians, are limited to relatively protected aquatic environments.

Internal gills, by contrast, are located within chambers of the body that have a cover providing physical protection for the gills and protecting them from drying. Water must be brought to internal gills. Covered internal gills allow animals to live in highly diverse aquatic habitats and even in moist terrestrial habitats. Most crustaceans, mollusks, sharks, and bony fishes have internal gills. Some invertebrates, such as clams and oysters, use beating cilia to circulate water over their internal gills **(Figure 46.3B).** Others, such as the cuttlefish, use contractions of the muscular mantle to pump water over their gills **(Figure 46.3C).** In adult bony fishes, the gills extend into a chamber covered by gill flaps or *opercula* (singular, *operculum;* "little lid") on either side of the head. The operculum also serves as part of a one-way pumping system that ventilates the gills **(Figure 46.3D).**

Many Animals with Internal Gills Use Countercurrent Flow to Maximize Gas Exchange

Sharks, fishes, and some crabs take advantage of one-way flow of water over the gills to maximize the amounts of O_2 and CO_2 exchanged with water. In this mechanism, called **countercurrent exchange,** the water flowing over the gills moves in a direction opposite to the flow of blood under the respiratory surface.

Figure 46.4 illustrates countercurrent exchange in the uptake of O_2. At the point where fully oxygenated water first passes over a gill filament in countercurrent flow, the blood flowing beneath it in the opposite direction is also almost fully oxygenated. However, O_2 concentration is still higher in the water than in the blood, and the gas diffuses from the water into the blood, raising the concentration of O_2 in the blood almost to the level of the fully oxygenated water. At the opposite end of the filament, much of the O_2 has been removed from the water, but the blood flowing under the filament, which has just arrived from body tissues and is fully deoxygenated, contains even less O_2. As a result, O_2 also diffuses from the water to the blood at this end of the filament. All along the gill filament, the same relationship exists, so that at any point, the water is more highly oxygenated than the blood, and O_2 diffuses from the water into the blood across the respiratory surface.

The overall effect of countercurrent exchange is the removal of 80% to 90% of the O_2 content of water as it flows over the gills. In comparison, by breathing in and out and constantly reversing the direction of air flow, mammals manage to remove only about 25% of the O_2 content of air. Efficient removal of O_2 from water is important because of the much lower O_2 content of water compared with air.

Insects Use a Tracheal System for Gas Exchange

Insects breathe air by a respiratory system consisting of air-conducting tubes called **tracheae** (singular, *trachea*). The tracheae are invaginations of the outer epidermis of the animal,

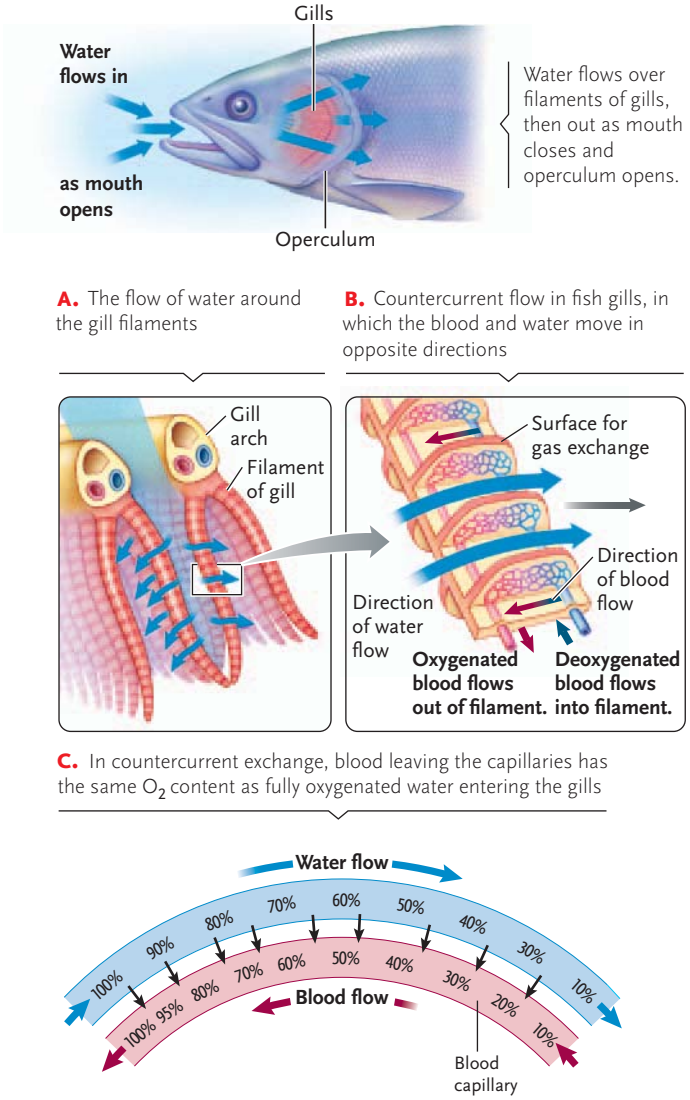

FIGURE 46.4 Ventilation and countercurrent exchange in bony fishes. **(A)** Water flows around the gill filaments. **(B)** Water and blood flow in opposite directions through the gill filaments. **(C)** Countercurrent exchange: oxygen from the water diffuses into the blood, raising its oxygen content. reinforced by rings of chitin, the material of the insect exoskeleton. They lead from the body surface and branch so extensively inside the animal that almost every cell is served by a microscopic branch **(Figure 46.5).** Some branches even penetrate inside larger cells, such as those of insect flight muscles. The finest branches of the tracheae, called *tracheoles,* form the respiratory surface of the insect system. Tracheoles are dead-end tubes with very small fluid-filled tips that are in contact with cells of the body. Air is transported by the tracheal system to those tips, and gas exchange occurs directly across the plasma membranes of the body cells in contact with the tips. At places within the body, the tracheae expand into internal air sacs that act as reservoirs to increase the volume of air in the system.

Air enters and leaves the tracheal system at openings in the insect's chitinous exoskeleton called **spiracles** (*spiraculum* =

airhole). In adult insects, the spiracles are located in a row on either side of the thorax and abdomen. The spiracles open and close in coordination with body movements to compress and expand the air sacs and pump air in and out of the tracheae. During insect flight, alternating compression and expansion of the thorax by the flight muscles also pumps air through the tracheal system.

Lungs Allow Animals to Live in Completely Terrestrial Environments

Lungs are one of the primary adaptations that allowed animals to invade terrestrial environments fully. Some fishes and amphibians have lungs, as do all reptiles, birds, and mammals. All lungs are invaginated structures located internally in the body.

In some fishes, such as lungfishes, lungs and air breathing evolved as adaptations to survive in oxygen-poor water or temporarily in air when the water level dropped and exposed them. The lungs of these fishes consist of thin-walled sacs, which branch off from the mouth, pharynx, or parts of the digestive system; air is obtained by **positive pressure breathing,** a gulping or swallowing motion that forces air into the lungs.

The lungs of mature amphibians such as frogs and salamanders are also thin-walled sacs with relatively little folding or pocketing. Amphibians also fill their lungs by positive pressure breathing, in this case using a rhythmic motion of the floor of the mouth as the pump, in coordination with opening and closing of the nostrils **(Figure 46.6).**

The lungs of reptiles, birds, and mammals have many pockets and folds that increase the area of the respiratory surface, which contains dense, highly branched capillary networks. Mammalian lungs consist of millions of tiny air pockets, the **alveoli,** each surrounded by dense capillary networks. Reptiles and mammals fill their lungs by **negative pressure breathing**—by muscular contractions that expand the lungs, lowering the pressure of the air in the lungs and causing air to be pulled inward. (Mammalian negative pressure breathing is described in more detail in the next section.)

In birds, a countercurrent exchange system provides the most complex and efficient vertebrate lungs **(Figure 46.7).** In addition to paired lungs, birds have nine pairs of air sacs that branch off the respiratory tract. The air sacs, which collectively contain several times as much air as the lungs, set up a pathway that allows air to flow in one direction through the lungs, rather than in and out as in other vertebrates. Within the lungs, air flows through an array of fine, parallel tubes that are surrounded by a capillary network. The blood flows in the direction opposite to the air flow, setting up a countercurrent exchange. The countercurrent exchange allows bird lungs to extract about one-third of the O_2 from the air as compared with about one-fourth in the lungs of mammals.

STUDY BREAK 46.2

1. What advantages do gills confer on a water-breathing animal over skin breathing?
2. What is countercurrent exchange, and how is it beneficial for gas exchange?
3. How does the tracheal system of insects facilitate gas exchange with the cells of the body?
4. Distinguish between positive pressure breathing and negative pressure breathing in animals with lungs.

46.3 The Mammalian Respiratory System

All mammals have a pair of lungs and a muscular diaphragm in the chest cavity that plays an important role in negative pressure breathing. (Birds and reptiles lack muscular diaphragms, illustrating their separate evolutionary lineage.) Rapid ventilation of the respiratory surface and perfusion by blood flow through dense capillary networks maximizes gas exchange.

The Airways Leading from the Exterior to the Lungs Filter, Moisten, and Warm the Entering Air

The human respiratory system is typical for a terrestrial mammal **(Figure 46.8).** Air enters and leaves the respiratory system through the nostrils and mouth. Hairs in the nostrils and mucus covering the surface of the airways filter out and trap dust and other large particles. Inhaled air is moistened and warmed as it moves through the mouth and nasal passages.

Next, air moves into the throat, or **pharynx,** which forms a common pathway for air entering the **larynx** (or "voice box") and food entering the esophagus, the tube that leads to the stomach. The airway through the larynx is open except during swallowing.

From the larynx, air moves into the trachea (or "windpipe"), which branches into two airways, the **bronchi** (singular, *bronchus*). The bronchi lead to the two elastic, cone-shaped lungs, one on each side of the chest cavity. Inside the lungs, the bronchi narrow and branch repeatedly, becoming progressively narrower and more numerous. The terminal airways, the **bronchioles,** lead into cup-shaped pockets, the alveoli (singular, *alveolus;* shown in Figure 46.8 insets).

Each of the 150 million alveoli in each lung is surrounded by a dense network of capillaries. By the time inhaled air reaches the alveoli, it has been moistened to the saturation point and brought to body temperature. The many alveoli provide an enormous area for gas exchange. If the alveoli of an adult human were flattened out in a single layer, they would cover an area approaching 100 square meters—about the size of a tennis court.

The larynx, trachea, and larger bronchi are nonmuscular tubes encircled by rings of cartilage that prevent the tubes from compressing. The largest of the rings, which reinforces the larynx, stands out at the front of the throat as the Adam's apple; smaller supporting rings can be felt at the front of the throat just below the larynx. The walls of the smaller bronchi and the bronchioles contain smooth muscle cells that contract or relax to control the diameter of these passages, and with it, the amount of air flowing to and from the alveoli.

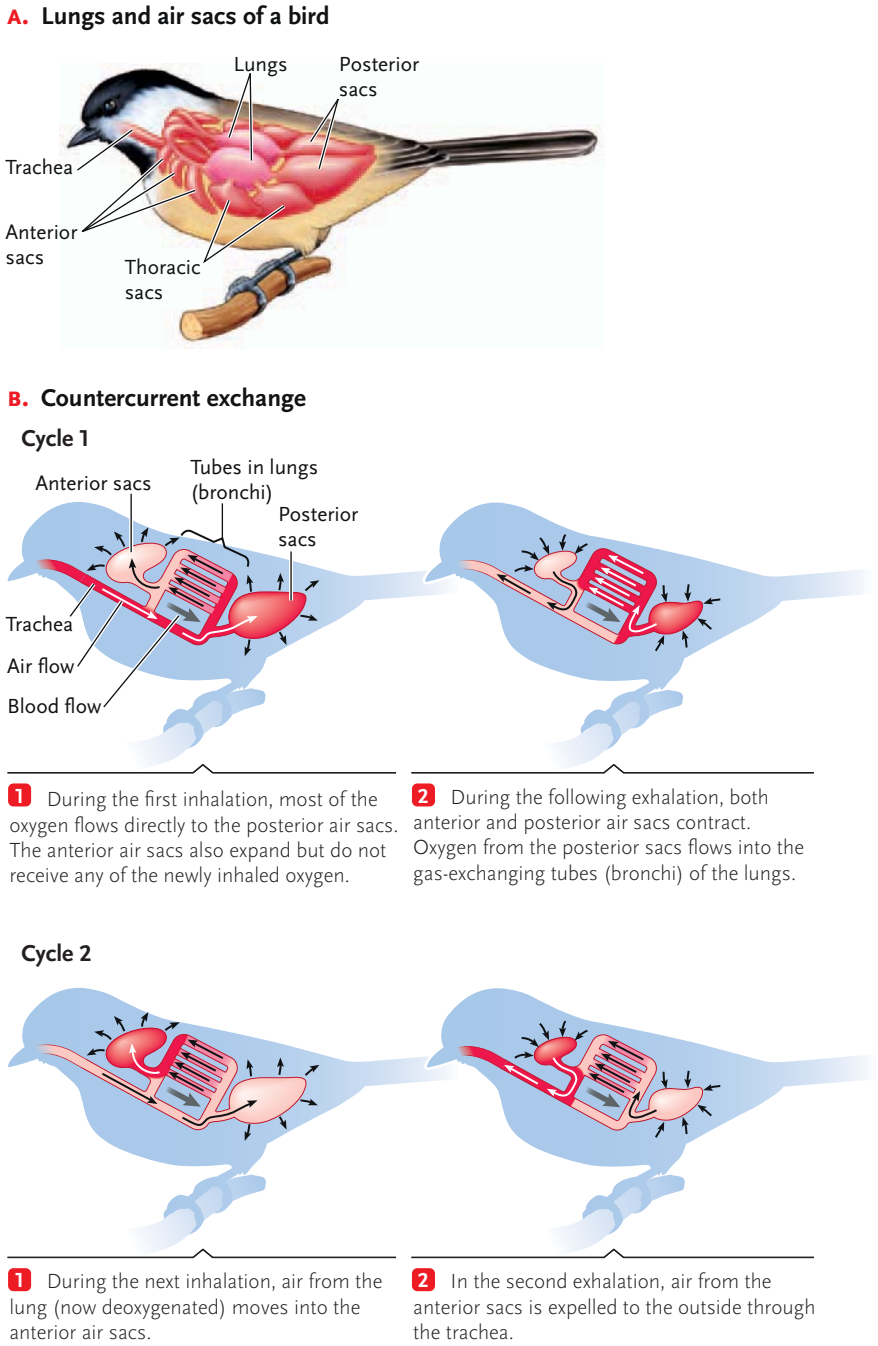

FIGURE 46.7 Countercurrent exchange in bird lungs. (A) Unlike mammalian lungs, bird lungs do not expand and contract. Changes in pressure in the expandable air sacs move air in and out. **(B)** Air flows in one direction through the tubes of the lungs; blood flows in the opposite direction in the surrounding capillary network. Two cycles of inhalation and exhalation are needed to move a specific volume of air through the bird respiratory system.

The epithelium lining each bronchus contains cilia and mucus-secreting cells. Bacteria and airborne particles such as dust and pollen are trapped in the mucus and then moved upward and into the throat by the beating of the cilia lining the airways. Infection-fighting macrophages also patrol the respiratory epithelium.

Tobacco smoke, by paralyzing the cilia lining the respiratory tract, interferes with the processes that clear bacteria and

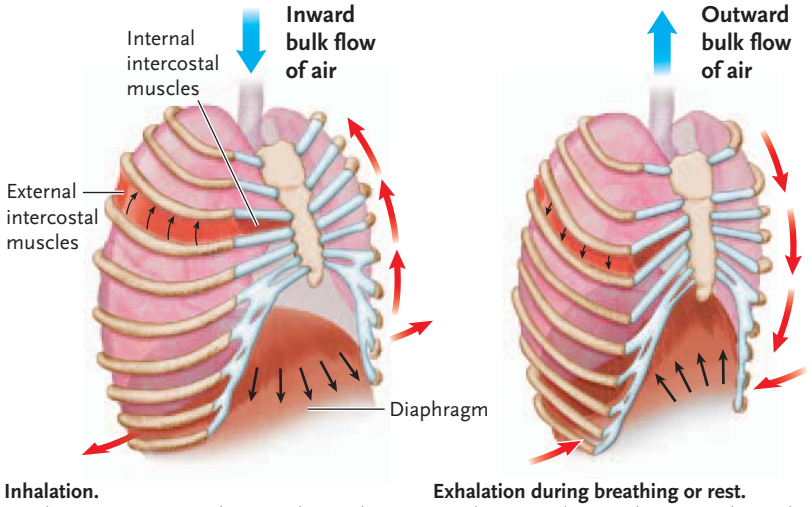
airborne particles from the lungs. As a result, the bacteria and foreign matter may persist in the lungs.

Contractions of the Diaphragm and Muscles between the Ribs Ventilate the Lungs



The lungs are located in the rib cage above the *diaphragm,* a dome-shaped sheet of skeletal muscle separating the chest cavity from the abdominal cavity. The lungs are covered by a double layer of epithelial tissue called the **pleura.** The inner pleural layer is attached to the surface of the lungs, and the outer layer is attached to the surface of the chest cavity. A narrow space between the inner and outer layers is filled with slippery fluid, which allows the lungs to move within the chest cavity without rubbing or abrasion as they expand and contract.

Contraction of muscles between the ribs and the diaphragm brings air into the lungs by a negative pressure mechanism. As an inhalation begins, the diaphragm contracts and flattens, and one set of muscles between the ribs, the *external intercostal* muscles, contracts, pulling the ribs upward and outward **(Figure 46.9).** These movements expand the chest cavity and lungs, lowering the air pressure in the lungs below that of the atmosphere. As a result, air is drawn into the lungs, expanding and filling them.

The expansion of the lungs is much like filling two rubber balloons. Like balloons, the lungs are elastic, and resist stretching as they are filled. Also like balloons, the stretching stores energy, which can be released to expel air from the lungs. When a person at rest exhales, the diaphragm and muscles between the ribs relax, and the elastic recoil of the lungs expels the air.

When physical activity increases the body's demand for O_2, other muscles help expel the air by forcefully reducing the volume of the chest cavity. Contractions of abdominal wall muscles increase abdominal pressure, exerting an upward-directed force on the diaphragm and thus pushing it upward. Contractions of *internal intercostal* muscles pull the chest wall inward and downward, causing it to flatten. As a result, the dimensions of the chest cavity decrease.

Inhalation.
Diaphragm contracts and moves down. The external intercostal muscles contract and lift rib cage upward and outward. The lung volume expands.

Exhalation during breathing or rest.
Diaphragm and external intercostal muscles return to the resting positions. Rib cage moves down. Lungs recoil passively.

FIGURE 46.9 The respiratory movements of humans during breathing at rest. The movements of the rib cage and diaphragm fill and empty the lungs. Inhalation is powered by contractions of the external intercostal muscles and diaphragm, and exhalation is passive. During exercise or other activities characterized by deeper and more rapid breathing, contractions of the internal intercostal muscles and the abdominal muscles add force to exhalation.

© Cengage Learning 2014

The Volume of Inhaled and Exhaled Air Varies over Wide Limits

The volume of air entering and leaving the lungs during inhalation and exhalation is called the **tidal volume.** In a person at rest, the tidal volume amounts to about 500 mL. As physical activity increases, the tidal volume increases to match the body's needs for O_2; at maximal levels, the tidal volume reaches about 3,400 mL in females and 4,800 mL in males. The maximum tidal volume is called the **vital capacity** of an individual.

Even after the most forceful exhalation, about 1,000 mL of air remains in the lungs in females, and about 1,200 mL in males; this is the **residual volume** of the lungs. In fact, the lungs cannot be deflated completely because small airways collapse during forced exhalation, blocking further outflow of air. Because air cannot be removed from the lungs completely, some gas exchange can always occur between blood flowing through the lungs and the air in the alveoli.

The Centers That Control Breathing Are Located in the Brain Stem

Breathing is controlled by centers in the medulla and pons, which form part of the brain stem **(Figure 46.10).** Groups of interneurons in the centers regulate the rate and depth of breathing, ranging from shallow, slow breathing when the body is at rest to the deep and rapid breathing of intense physical exercise, excitement, or fear. Over these extremes, the air entering and leaving lungs of a human male varies from as little as 5 to 6 L per minute to (for a brief time only) as much as 150 L per minute.

INTERNEURONS THAT REGULATE BREATHING Signals from interneurons in the medulla carried by efferent (motor) neurons of the autonomic system produce the breathing movements. Signals from a dorsal group of interneurons stimulate inhalation by causing the diaphragm and the external intercostal muscles to contract, which expands the chest cavity and produces an inhalation. In a person at rest, the signals are switched off as the lungs become moderately full: the rib muscles and the diaphragm relax, and a passive exhalation occurs. These signals act as the primary generator of breathing rhythm.

A ventral group of interneurons in the medulla can send signals for both inhalation and exhalation. These neurons become active only during physical exercise, fear, or other situations that require more oxygen when active rather than passive exhalation is needed. In that case, some of the ventral neurons send signals that stimulate the abdominal and internal intercostal muscles to contract, thereby causing active exhalation. Other neurons in the ventral group become stimulated by signals from the dorsal group, and then help increase inhalation activity when faster and deeper breathing is required.

Two interneuron groups in the pons modulate the signals originating from the medulla, fine-tuning and smoothing the muscle contractions so that inhalations and exhalations are gradual and controlled rather than sudden and abrupt. Signals sent from higher brain centers in the cerebrum can override the control of respiratory rate and depth by the brain stem. For example, as you speak or sing, or hold your breath, you can consciously alter or stop breathing to match the demands of these activities. Breathing rate and depth are also modified by emotional states, controlled by centers in the limbic system of the brain (see Section 40.3). Thus breathing is altered as you laugh, gasp, groan, cry, and sigh.

RECEPTORS THAT SEND INFORMATION TO THE BRAIN CENTERS The brain centers controlling the rate and depth of breathing integrate sensory information sent by chemoreceptors that monitor O_2 and CO_2 levels in the blood and body fluids. The integration of sensory information serves to match breathing rate to the metabolic demands of the body. The chemoreceptors are located centrally on the surface of the medulla, and peripherally in **carotid bodies** in the carotid arteries leading to the brain and in **aortic bodies** in the large arteries leaving the heart (see Figure 46.10).

Surface receptors of the medulla detect changes in pH in the cerebrospinal fluid; the pH is determined mostly by the CO_2 concentration in the blood. (Remember that pH decreases as CO_2 levels increase.) The receptors in the carotid and aortic bodies detect changes in CO_2 and O_2 concentrations in the blood.

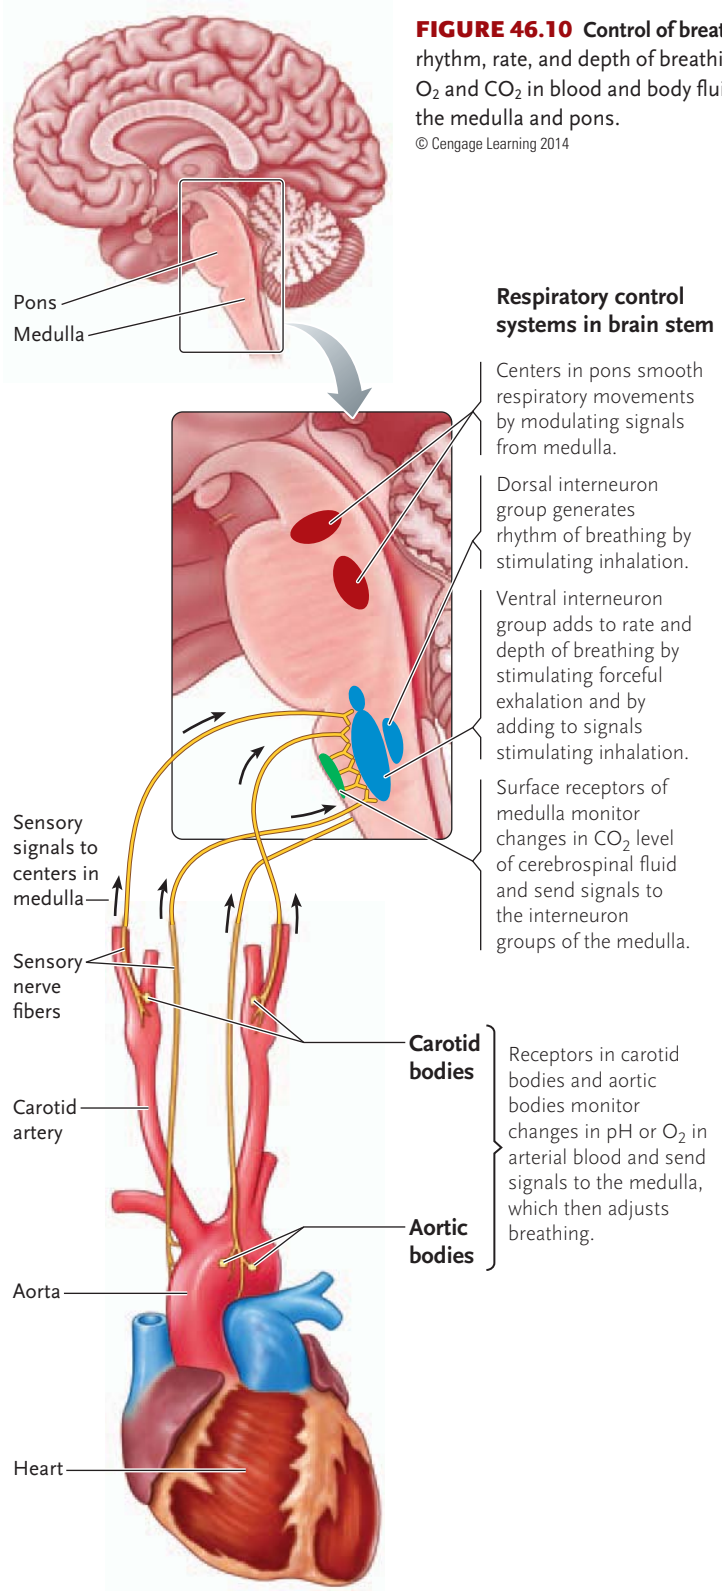

FIGURE 46.10 Control of breathing. Centers in the pons (red) and centers in the medulla (blue) control the rhythm, rate, and depth of breathing. Receptors in the carotid arteries and aorta detect changes in the levels of O_2 and CO_2 in blood and body fluids. Signals from these receptors are integrated in the respiratory centers of the medulla and pons.

© Cengage Learning 2014

The CO_2 receptors in the medulla have the greatest effects on breathing. If increased body activities cause the CO_2 concentration to rise in the blood, the medulla receptors trigger interneuron groups in the medulla that increase the rate and depth of breathing. If CO_2 concentration falls, the receptors send signals to the medulla that lead to a slowing of the rate and depth of breathing.

The peripheral receptors in the carotid and aortic bodies detect changes in pH or O_2 concentration in arterial blood. When these receptors detect a decrease in blood pH they send signals to the medulla that cause the medulla to increase the rate and depth of breathing. Although the receptors in the carotid and aortic bodies also detect the O_2 level in arterial blood, the receptors do not respond until blood O_2 level falls below 60% of normal. This reaction makes the O_2 receptors act as a backup system that comes into play only when blood O_2 concentration falls to critically low levels.

Thus, the level of CO_2 in the blood and body fluids is much more closely monitored, and has a much greater effect on breathing, than the O_2 level. This reflects the fact that small fluctuations in blood pH have much greater effects on the ability of hemoglobin to carry oxygen, and on enzyme activity in the blood and interstitial fluid, than fluctuations in the O_2 level.

LOCAL CONTROLS Other, automated controls within the lungs match the rates of ventilation and perfusion by responding to O_2 concentrations in the blood. If air flow lags behind capillary blood flow, so that the O_2 level falls in the blood, the reduced O_2 concentration causes smooth muscles in the walls of arterioles in the lungs to contract. This reduces the flow of blood, thereby giving it more time to pick up O_2. Conversely, if blood flow lags behind, the rising blood O_2 concentration causes the smooth muscle cells in arteriole walls to relax, dilating the arterioles and increasing the rate of blood flow through lung capillaries. These local controls, in combination with the neural controls that regulate rate and depth of breathing, ensure that the respiratory system meets the body's varying need to obtain O_2 and release CO_2.

46.4 Mechanisms of Gas Exchange and Transport

In both the lungs and body tissues, gas exchange occurs when the gas diffuses from an area of higher concentration to an area of lower concentration. In this section, we consider the mechanics of gas exchange between air and the blood in mammals, and the means by which gases are transported between the lungs and other body tissues. A major part of this story involves hemoglobin, the vertebrate respiratory pigment.

The Proportion of a Gas in a Mixture Determines Its Partial Pressure

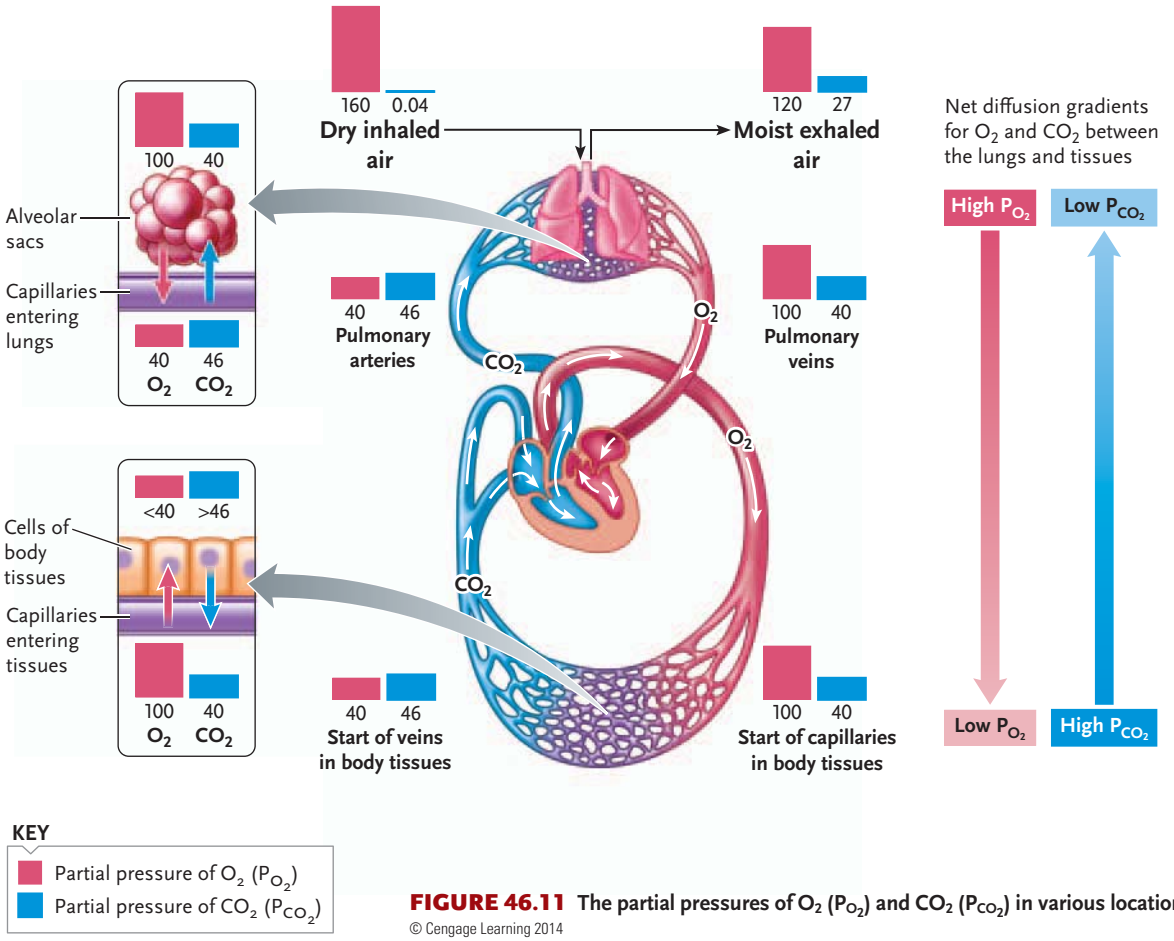
For gases, it is typical to consider concentration differences as differences in pressure. When gases are present in a mixture, the pressure of each individual gas, called its **partial pressure,** is determined by its proportion in the mixture. Air, water, and blood all contain mixtures of gases, including oxygen, carbon dioxide, nitrogen, and other gases, so each gas exerts only a part of the total gas pressure. For example, the proportion of O_2 in dry air is about 21%, or 21/100. In dry air at sea level, the total atmospheric pressure under standard conditions is 760 mm Hg. The partial pressure of O_2, written as P_{O_2}, is equivalent to 760 × 21/100, or about 160 mm Hg. The proportion of CO_2 in dry air is about 0.04%, so its partial pressure, P_{CO_2}, is equivalent to 760 × 0.04/100, or about 0.3 mm Hg. For O_2 to diffuse inward across a respiratory surface, its partial pressure outside the surface must be greater than inside; for CO_2 to diffuse outward, its partial pressure inside must be greater inside than outside.

In the lungs, even though the P_{O_2} is reduced by mixing with the air in the residual volume, it is still much higher than the P_{O_2} in deoxygenated blood entering the network of capillaries in the lungs **(Figure 46.11).** As a result, O_2 readily diffuses passively down its partial pressure gradient from the alveolar air into the plasma solution in the pulmonary capillaries. Conversely, the P_{CO_2} in the lungs is much lower than the P_{CO_2} in the tissues. As a result, CO_2 readily diffuses passively down its partial pressure gradient from the pulmonary capillaries into the alveolar air.

Hemoglobin Greatly Increases the O_2-Carrying Capacity of the Blood

After entering the plasma, O_2 diffuses into erythrocytes, where it combines with hemoglobin. The combination with hemoglobin removes O_2 from the plasma, lowering the P_{O_2} of the plasma and allowing additional O_2 molecules to diffuse from alveolar air to the blood.

Recall from Section 44.2 that a mammalian hemoglobin molecule has four heme groups, each containing an iron atom that can combine reversibly with an O_2 molecule. A hemoglobin molecule can therefore bind a total of four molecules of O_2.



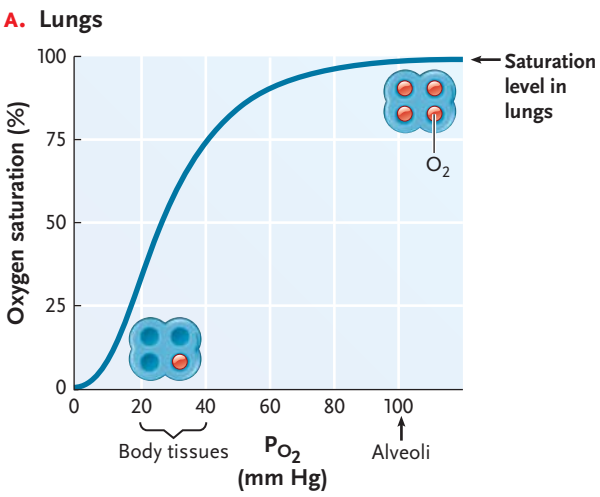


FIGURE 46.11 The partial pressures of O_2 (P_{O_2}) and CO_2 (P_{CO_2}) in various locations in the body.

The combination of O_2 with hemoglobin allows blood to carry about 60 times more O_2 (about 200 mL per liter) than it could if the O_2 simply dissolved in the plasma (about 3 mL per liter). About 98.5% of the O_2 in blood is carried by hemoglobin and about 1.5% is carried in solution in the blood plasma.

The reversible combination of hemoglobin with O_2 is related to the partial pressure of O_2 in a pattern shown by the *hemoglobin–O_2* dissociation curve in **Figure 46.12A.** (The curve is generated by measuring the amount of hemoglobin saturated at a given P_{O_2}.) The curve is S-shaped with a plateau region, rather than linear. The top, plateau part of the curve above 60 mm Hg is in the blood P_{O_2} range found in the pulmonary capillaries where O_2 is binding to hemoglobin. For this part of the curve, the blood remains highly saturated with O_2 over a relatively large range of P_{O_2}. Even at P_{O_2} levels much higher than shown on the graph (P_{O_2} theoretically can go up to 760 mm Hg), only a small extra amount of O_2 will bind to hemoglobin. The steep part of the curve between 0 and 60 mm Hg is in the blood P_{O_2} range found in the capillaries in the rest of the body. For this part of the curve, small changes in P_{O_2} result in a large change in the amount of O_2 bound to hemoglobin.

In the alveoli, in which the P_{O_2} is about 100 mm Hg and the pH is 7.4, most hemoglobin molecules are 100% saturated, meaning that almost all have bound four O_2 molecules.

In the capillaries of body tissues, where the P_{O_2} varies between about 20 and 40 mm Hg depending on the level of metabolic activity and the pH is about 7.2, hemoglobin can hold less O_2. As a result, most hemoglobin molecules release two or three of their O_2 molecules to become between 25% and 50% saturated. The drop in pH to 7.2 (red line) in active body tissues reduces the amount of O_2 hemoglobin can hold as compared with pH 7.4. The reduction in binding affinity at lower pH increases the amount of O_2 released in active tissues.

FIGURE 46.12 Hemoglobin–O_2 dissociation curves, which show the degree to which hemoglobin is saturated with O_2 at increasing P_{O_2}, in lungs (A) and body tissues (B).

© Cengage Learning 2014

The P_{O_2} of alveolar air is about 100 mg Hg (see Figure 46.11). As a result, most of the hemoglobin molecules are fully saturated in the blood leaving the alveolar networks, meaning that most of the hemoglobin molecules are bound to four O_2 molecules (see Figure 46.12A). The P_{O_2} of blood plasma has risen to approximately the same level as in the alveolar air, about 100 mm Hg. The blood has also changed color, reflecting the bright red color of oxygenated hemoglobin as compared with the darker red color of deoxygenated hemoglobin.

The oxygenated blood exiting from the alveoli collects in venules, which merge into the pulmonary veins leaving the lungs. These veins carry the blood to the heart, which pumps the blood through the systemic circulation to all parts of the body.

As the oxygenated blood enters the capillary networks of body tissues **(Figure 46.12B),** it encounters regions in which the P_{O_2} in the interstitial fluid and body cells is lower than that in the blood, ranging from about 40 mm Hg downward to 20 mm Hg or less (see Figure 46.11). As a result, O_2 diffuses from the blood plasma into the interstitial fluid, and from the fluid into body cells. As O_2 diffuses from the blood plasma into body tissues, it is replaced by O_2 released from hemoglobin.

Several factors contribute to the release of O_2 from hemoglobin, including increased acidity (lower pH) in active tissues. The acidity increases because oxidative reactions release CO_2, which combines with water to form carbonic acid (H_2CO_3). The lowered pH alters hemoglobin's conformation, reducing its affinity for O_2, a phenomenon called the **Bohr effect.** As a result of the reduced affinity, O_2 is released and used in cellular respiration.

The net diffusion of O_2 from blood to body cells continues until, by the time the blood leaves the capillary networks in the body tissues, much of the O_2 has been removed from hemoglobin. The blood, now with a P_{O_2} of 40 mm Hg or less (see Figures 46.11 and 46.12B), returns in veins to the heart, which pumps it through the pulmonary arteries to the lungs for another cycle of oxygenation.

Carbon Dioxide Diffuses down Concentration Gradients from Body Tissues into the Blood and Alveolar Air

The CO_2 produced by cellular oxidations diffuses from active cells into the interstitial fluid, where it reaches a partial pressure of about 46 mm Hg. Because this P_{CO_2} is higher than the 40 mm

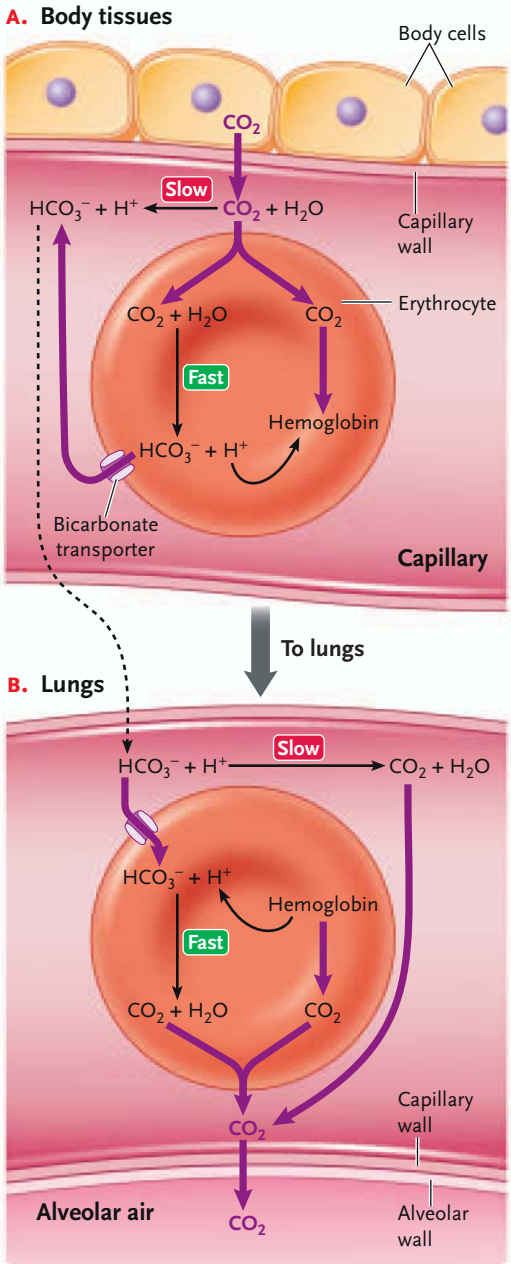

FIGURE 46.13 The reactions occurring during the transfer of CO_2 from (A) body tissues (B) to alveolar air.

© Cengage Learning 2014

In body tissues, some of the CO_2 released into the blood combines with water in the blood plasma to form HCO_3^- and H^+. However, most of the CO_2 diffuses into erythrocytes, where some combines directly with hemoglobin and some combines with water to form HCO_3^- and H^+. The H^+ formed by this reaction combines with hemoglobin; the HCO_3^- is transported out of erythrocytes to add to the HCO_3^- in the blood plasma.

In the lungs, the reactions are reversed. Some of the HCO_3^- in the blood plasma combines with H^+ to form CO_2 and water. However, most of the HCO_3^- is transported into erythrocytes, where it combines with H^+ released from hemoglobin to form CO_2 and water. CO_2 is released from hemoglobin. The CO_2 diffuses from the erythrocytes and, with the CO_2 in the blood plasma, diffuses from the blood into the alveolar air.

Hg P_{CO_2} in the blood entering the capillary networks of body tissues (see Figure 46.11), CO_2 diffuses from the interstitial fluid into the blood plasma **(Figure 46.13A).**

Some of the CO_2 remains in solution as a gas in the plasma. However, most of the CO_2, about 70%, combines with water to produce carbonic acid (H_2CO_3), which dissociates into bicarbonate (HCO_3^-) and H^+ ions. The reaction takes place both in the blood plasma and inside erythrocytes, where an enzyme, *carbonic anhydrase,* greatly speeds the reaction.

Most of the H^+ ions produced by the dissociation of carbonic acid combine with hemoglobin or with proteins in the plasma. The combination, by removing excess H^+ from the blood solution, *buffers* the blood pH, helping to maintain it at its near-neutral set point of 7.4. (Buffers are discussed in Section 2.5. The discussion includes the carbonic acid–bicarbonate buffer system used to buffer blood pH in humans and many other animals.) pH homeostasis is important because many enzymes are sensitive to minor changes in pH. The combined pathways absorbing CO_2 in the blood—solution in the plasma, conversion to bicarbonate, and combination with hemoglobin—help maintain the concentration gradient for gaseous CO_2 and keep its diffusion from the interstitial fluid into the blood at optimal levels.

The blood leaving the capillary networks of body tissues is collected in venules and veins and returned to the heart, which pumps it through the pulmonary arteries into the lungs. As the blood enters the capillary networks surrounding the alveoli, the entire process of CO_2 uptake is reversed **(Figure 46.13B).** The P_{CO_2} in the blood, now about 46 mm Hg, is higher than the P_{CO_2} in the alveolar air, about 40 mm Hg (see Figure 46.11). As a result, CO_2 diffuses from the blood into the air. The diminishing CO_2 concentrations in the plasma, along with the lower pH encountered in the lungs, promote the release of CO_2 from hemoglobin. As CO_2 diffuses away, bicarbonate ions in the blood combine with H^+ ions, forming carbonic acid molecules that break down into water and additional CO_2. This CO_2 adds to the quantities diffusing from the blood into the alveolar air. By the time the blood leaves the capillary networks in the lungs, its P_{CO_2} has been reduced to the same level as that of the alveolar air, about 40 mm Hg (see Figure 46.11).

Carbon monoxide (CO), a colorless, odorless gas produced when fuels are incompletely burned, as in automobile exhaust or in a faulty furnace, gas appliance, or space heater, also binds to hemoglobin if it is inhaled into the lungs. It binds so strongly that it displaces O_2 from hemoglobin and reduces the amount of O_2 carried to body tissues drastically. If CO is inhaled in high quantity for even a few minutes, the reduction in oxygen delivered to the brain can lead to unconsciousness and brain damage. Sustained exposure leads to death by hypoxia (lack of oxygen). Because the brain regulates breathing based on CO_2 levels in blood rather than on O_2 levels, victims breathing CO can die from hypoxia without noticing anything amiss up to the point of unconsciousness.

The combination of CO with hemoglobin, carboxyhemoglobin, is bright red. This has led to a myth often seen in textbooks that victims of CO poisoning turn a "classic cherry red" in color. This occurs in less than 2% of cases. *Insights from the Molecular Revolution* describes recent research testing the molecular basis for the binding of CO to hemoglobin and to *myoglobin,* a muscle protein with structure and properties similar to hemoglobin (myoglobin is discussed in Section 43.1).

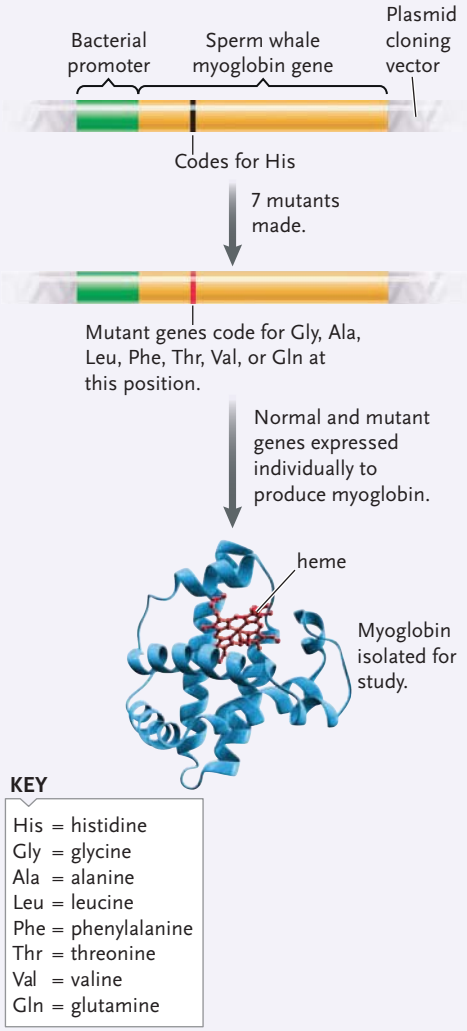
Giving Hemoglobin and Myoglobin Air

Carbon monoxide, like O_2, combines directly with the heme group in the proteins myoglobin and hemoglobin. A free heme group has an affinity for CO some 10,000 times greater than for O_2. When the heme group is incorporated into the proteins, its affinity is only 250 times greater than O_2 for hemoglobin and 30 times greater for myoglobin.



Research Question

How does combination with the proteins reduce the affinity of the heme group for CO so effectively?

Experiment

One hypothesis is that the reduction in affinity depends on a stabilizing hydrogen bond between O_2 and an amino acid, histidine, located in a protein pocket formed by a fold in the amino acid chain near the iron atom of the heme group. The thought here is that the hydrogen bond allows O_2 to displace a water molecule that occupies the pocket when neither O_2 nor CO is bound. Because carbon monoxide cannot form this hydrogen bond, it displaces the water molecule less readily than does O_2.

Research with myoglobin, conducted by John S. Olson and George Phillips and their colleagues at Rice University, supports the hydrogen-bond hypothesis. The team used a myoglobin gene isolated from a sperm whale and cloned in a plasmid expression vector (see Section 18.1). They mutated the DNA of the myoglobin gene so that one of seven other amino acids was substituted for the histidine in the pocket of the encoded protein **(Figure).** Plasmids containing normal and mutant genes were transformed individually into *E. coli.* The bacteria expressed the genes, enabling the researchers to isolate seven different pure forms of myoglobin to test for O_2-binding affinity (see Figure).

The seven amino acids substituted for the histidine—glycine, alanine, leucine, phenylalanine, threonine, valine, and glutamine—are all nonpolar, or uncharged (histidine is positively charged), and thus unlikely to form a hydrogen bond with O_2. Further, none of the amino acids except glycine and glutamine should be able to hold a water molecule stably in the binding pocket. To support the hydrogen-bond hypothesis, the affinity of O_2 for the altered myoglobin should be greatly reduced in the mutant forms of the molecule.

Results

Binding tests showed that the substitutions indeed reduced the affinity for O_2 by a factor that varied between 10 and 100 times. The greatest reduction was produced by the most nonpolar of the amino acids, leucine and phenylalanine. The smallest reduction was observed for glycine and glutamine.

Conclusion

The results support the hydrogen-bond hypothesis.

THINK LIKE A SCIENTIST The experiments involved expression of normal and modified myoglobin genes in *E. coli* using an expression vector. As stated, the genes were controlled by highly active bacterial promoter. What other features of the expression vector must have been needed in order for myoglobin to be made in *E. coli*?

46.5 Respiration at High Altitudes and in Ocean Depths

This chapter's introduction described some challenges to respiration that arise when humans travel to high altitude. In this concluding section we look at the effects of high altitude on respiration, along with the effects of increased pressure when humans and other mammals dive underwater.

High Altitudes Reduce the P_{O_2} of Air Entering the Lungs

As altitude increases, atmospheric pressure decreases, and with it, the P_{O_2} of alveolar air and the concentration gradient of O_2 across the respiratory surface. At 5,500 m (18,000 feet), the dry air pressure is about 380 mm Hg and the P_{O_2} is only 380 × 21/100 = about 80 mm Hg, half that at sea level.

Humans who travel from sea level to elevations of 1,800 m (about 6,000 feet) or more may experience one or more unpleasant symptoms, including headache, blurred vision, dizziness, nausea, and fatigue. However, a person who stays at higher altitude will adjust to live and function normally through **acclimatization,** a process by which, over a period of days, the body compensates to permit adequate oxygen delivery to the tissues. That is, in response to a drop in blood O_2 detected at the kidneys, the kidneys increase the secretion of the hormone *erythropoietin* (EPO), which stimulates erythrocyte production. If the person subsequently returns

Demonstration of a Molecular Basis for High-Altitude Adaptation in Deer Mice

Question: Do mutations in hemoglobin genes underlie high-altitude adaptation in deer mice?

Experiment: Hemoglobin of adult mammals consists of two α-globin and two β-globin polypeptides. Hemoglobin binds oxygen and transports it in the blood. In the low-oxygen environment of high altitudes, mammals can suffer hypoxia, a condition that results when insufficient oxygen is carried to the body tissues in arterial blood. Some mammals, such as deer mice *(Peromyscus maniculatus)*, live and thrive in a wide variety of environments, including at high altitude.

Deer mice have two gene loci each for the α-globin and β-globin polypeptides. Jay Storz and his colleagues at the University of Nebraska–Lincoln, and collaborators at the University of Kansas, the University of Porto in Portugal, and the University of Aarhus in Denmark, tested the hypothesis that, compared with their lowland relatives, deer mice living at high altitude have mutations in their α-globin and β-globin genes that lead to hemoglobin molecules adapted to carrying oxygen in low-oxygen environments.

The experimenters isolated DNA from deer mice living at high altitude and at low altitude and compared the sequences of the two α-globin and two β-globin genes.

Results: The investigators identified a number of mutations in the four genes of the high-altitude mice. The researchers determined that the mutations increase the oxygen-binding affinity of hemoglobin compared with the low-altitude hemoglobin. This increased binding affinity in turn would increase the O_2 concentration in arterial blood, thereby enabling the mice to tolerate chronic hypoxia.

Conclusion: The research identified specific mutations that correlate with the evolutionary adaptation of deer mice to high altitude.

Interestingly, the hemoglobin of high-altitude deer mice is functionally similar to fetal hemoglobins in humans and other placental mammals. Fetal hemoglobin consists of two α-globin and two γ-globin polypeptides (the γ-globin polypeptide is related to the β-globin polypeptide). The sequence difference from adult hemoglobin enables fetal hemoglobin to carry O_2 efficiently in the low-O_2 intrauterine environment.

THINK LIKE A SCIENTIST The alpine regions in which the high-altitude mice now live were covered with glaciers in the last Ice Age and were not free of ice until about 10,000 years ago. What does that information say about the adaptation of deer mice to high altitude?

Source: J. Storz et al. 2009. Evolutionary and functional insights into the mechanism underlying high-altitude adaptation of deer mouse hemoglobin. *Proceedings of the National Academy of Sciences USA* 106:14450–14455.

© Cengage Learning 2014

to live at lower altitudes, the then-higher blood O_2 signals a reduction in erythrocyte production. However, the erythrocyte count remains high for several weeks after high-altitude exposure. For this reason, athletes often train at high altitudes to increase their erythrocyte count, with the idea that it will improve their stamina and endurance at lower altitudes.

People who live at high altitudes from childhood develop more permanent changes, including an increase in the number of alveoli and more extensive capillary networks in the lungs. These anatomical characteristics are retained if they move to lower altitudes.

Some mammals evolutionarily adapted to high altitudes show genetically determined changes that are present throughout life. For example, deer mice that live at above 4,372 m (about 14,343 feet) have hemoglobin molecules with greater affinity for O_2 than the hemoglobin molecules of their lower-altitude relatives **(Figure 46.14).** As a result, hemoglobin becomes saturated with O_2 at the lower partial pressures typical of high altitudes. Increased binding affinity of hemoglobin for O_2 is also seen in birds adapted to life at high altitudes, such as the bar-headed goose *(Anser indicus)*. These birds have been observed flying over the peaks of the Great Himalayas, which have altitudes greater than 6,000 m.

Diving Mammals Are Adapted to Survive the High Partial Pressures of Gases at Extreme Depths

As a mammal such as a seal or whale dives from the surface, each additional 10 m of depth increases the partial pressure of dissolved gases by about 1 atmosphere. Below about 25 m or so, the pressure becomes so great that the lungs collapse and cease to function. Adaptations of diving mammals such as seals and whales allow these animals to survive the extreme pressure and lack of lung function, in some species for over an hour at ocean depths of more than a mile.

Among these adaptations are more blood per unit of body weight and more red blood cells, which are stored in the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

spleen and released during a dive. In addition, the muscles of these animals contain much greater quantities of the O_2-binding protein myoglobin than the muscles of land-dwelling mammals do. In all, the adaptations pack about twice as much O_2 per kilogram of body weight into a seal, for example, than into a human.

Other adaptations decrease O_2 consumption during a deep and prolonged dive. The heart rate slows by 80% to 90% and the circulation of blood to internal organs and muscles is cut by as much as 95%, leaving only the brain with its normal blood supply. Even though most of the blood supply to muscles is cut off, the muscles continue to work by shifting to anaerobic oxidation. The lactic acid produced by anaerobic respiration in the muscles is not released into the blood until the animal returns to the surface.

These combined adaptations give seals and whales an amazing ability to dive to great depths and remain underwater for extended periods. Although average dives are on the order of 10 to 20 minutes, some sperm whales, tracked by sonar, have reached depths of 2,250 m (more than 7,000 feet) and remained underwater for as long as 82 minutes.

STUDY BREAK 46.5

What are the key adaptations that diving mammals use to survive at significant ocean depths?

UNANSWERED QUESTIONS

Does prenatal nicotine exposure alter development of respiratory neurons in the brain stem?

In this chapter you learned that the muscles of breathing are controlled in the brain stem, by groups of interneurons in the medulla oblongata and pons. The control of respiratory muscles (and thus breathing) by these neurons is called "central ventilatory control." Neonatal mammals that are exposed to nicotine *in utero* show various breathing abnormalities, such as reduced ventilatory output, increased frequency and duration of apneas (suspension of breathing), and delayed arousal in response to hypoxia (reduced blood oxygen levels) during sleep. One or several of these abnormalities may underlie sudden infant death syndrome (SIDS), also called "crib death" because victims are typically found dead in their crib. Clinical studies have shown that exposure to tobacco smoke is the number one risk factor for SIDS. Accordingly, laboratories, such as our own, are using animal models to examine how nicotine exposure alters development of central ventilatory control.

Several research methods can be used, depending on the question being addressed. In all of our experiments, neonatal rodents are exposed to nicotine *in utero* by implanting a small osmotic pump under the skin of a female rat that is 4 to 5 days pregnant. The pump releases nicotine at a prescribed rate, and the developing neonates are exposed to nicotine as the drug passes from mother to neonate via the placenta. When the neonates are born (on the twenty-first day of pregnancy), we study their breathing responses while they are awake or asleep using a device called a plethysmograph. This device senses the tiny pressure changes that accompany breathing in these small animals, and by adjusting chamber size, animals can be studied from birth to adulthood.

We can also dissect the brain stem, spinal cord, and rib cage from a neonatal animal, and place the preparation in a chamber for *in vitro* studies. Remarkably, this preparation is able to maintain rhythmic firing of respiratory neurons for up to 6 hours, allowing us to apply drugs and neurotransmitters to brain stem respiratory neurons while recording the electrical activity of neurons and respiratory muscle nerves.

Finally, we can prepare a brain stem slice, containing the most important central respiratory neurons and the hypoglossal nerve (this nerve innervates the tongue muscles, and it contains axons with rhythmic, respiratory-related activity), for detailed electrophysiological studies using the patch clamp technique (see Section 39.2). This preparation allows us to examine how prenatal nicotine exposure influences the membrane potential and firing properties of respiratory neurons.

To date, our studies have shown abnormal breathing in awake neonates, as well as an increase in inhibitory neurotransmission in respiratory neurons. Recently, we have shown that the intrinsic biophysical properties of respiratory neurons are altered in the nicotine-exposed pups; this means that when the cells are subjected to natural synaptic input from neighboring neurons (for example, from chemoreceptor neurons), their response is altered because the change in intrinsic properties is due to changes in the cell membrane. Current and future studies are directed at understanding the detailed cellular mechanisms that lead to these changes in intrinsic membrane properties. Understanding these mechanisms will hopefully lead to the development of drugs that can counteract nicotine's impact on the brain, as well as to an increased awareness and acceptance of the link between prenatal nicotine exposure and breathing abnormalities, resulting in more aggressive smoking prevention strategies.

THINK LIKE A SCIENTIST

1. If nicotine affects surface receptors of the medulla oblongata, is an infant's breathing rate being altered by carbon dioxide level or oxygen level?
2. Given your understanding of the peripheral nervous system and control of heart rate (from Section 40.2), is research investigating the effects of nicotine on SIDS and breathing focused on the somatic system or the autonomic system, and if the autonomic system, which division?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

46.1 The Function of Gas Exchange

- Physiological respiration is the process by which animals exchange O_2 and CO_2 with the environment (Figure 46.1).
- The two primary operating features of gas exchange are the respiratory medium, either air or water, and the respiratory surface, a wetted epithelium over which gas exchange takes place.
- In some invertebrates, the skin serves as the respiratory surface. In other invertebrates and all vertebrates, gills or lungs provide the primary respiratory surface (Figure 46.2).
- Simple diffusion of molecules from regions of higher concentration to regions of lower concentration drives the exchange of gases across the respiratory surface. The area of the respiratory surface determines the total quantity of gases exchanged by diffusion.
- The concentration gradients of O_2 and CO_2 across the respiratory surface are kept at optimal levels by ventilation and perfusion.

46.2 Adaptations for Respiration

- Animals breathing water keep the respiratory surface wetted by direct exposure to the environment. The high density and viscosity of water, and its relatively low O_2 content as compared with air, require water-breathing animals to expend significant energy to keep their respiratory surface ventilated.
- Air is high in O_2 content, allowing air-breathing animals to maintain higher metabolic levels than water breathers. The low density and viscosity of air as compared with water allow air breathers to ventilate the respiratory surface with relatively little energy. To accommodate water loss by evaporation, lungs typically are invaginations of the body surface, allowing air to become saturated with water before it reaches the respiratory surface.
- Gills are evaginations of the body surface. Water moves over the gills by the beating of cilia or is pumped over the gills by contractions of body muscles (Figures 46.2B and 46.3A–D).
- Water moves in a one-way direction over the gills of sharks, bony fishes, and some crabs, allowing these animals to use countercurrent exchange to maximize the exchange of gases over the respiratory surface (Figure 46.4).
- Insects breathe by means of tracheae, air-conducting tubes that lead from the body surface and send branches to essentially every cell in the body. Gas exchange takes place in the fluid-filled tips at the ends of the branches (Figure 46.5).
- Lungs consist of an invaginated system of branches, folds, and pockets. They may be filled by positive pressure breathing, in which air is forced into the lungs by muscle contractions, or by negative pressure breathing, in which muscle contractions expand the lungs, lowering the air pressure inside them and allowing air to be pulled into the lungs (Figures 46.6 and 46.9).

Animation: Bony fish respiration

Animation: Frog respiration

Animation: Vertebrate lungs

Animation: Bird respiration

46.3 The Mammalian Respiratory System

- Air enters the respiratory system through the nose and mouth and passes through the pharynx, larynx, and trachea. The trachea divides into two bronchi, which lead to the lungs. Within the lungs, the bronchi branch into bronchioles, which lead into the alveoli, which are surrounded by dense networks of blood capillaries (Figure 46.8).
- Mammals inhale by a negative pressure mechanism. Air is exhaled passively by relaxation of the diaphragm and the external intercostal muscles between the ribs, and elastic recoil of the lungs. During deep and rapid breathing, the expulsion of air is forceful, driven by contraction of the internal intercostal muscles (Figure 46.9).
- The tidal volume of the lungs is the air moved in and out of the lungs during an inhalation and exhalation. The vital capacity is the total volume of air a person can inhale and exhale by breathing as deeply as possible. The air remaining in the lungs after as much air as possible is exhaled is the residual volume of the lungs.
- Breathing is controlled by a combination of local chemical controls and regulation by centers in the brain stem. These controls match the rate of air and blood flow in the lungs, and link the rate and depth of breathing to the body's requirements for O_2 uptake and CO_2 release (Figure 46.10).
- The basic rhythm of breathing is produced by interneurons in the medulla. When more rapid breathing is required, another group of interneurons in the medulla sends signals reinforcing inhalation and producing forceful exhalation. Two interneuron groups in the pons smooth and fine-tune breathing by stimulating or inhibiting the inhalation center in the medulla.
- Sensory receptors in the medulla, the carotid bodies, and the aortic bodies detect changes in the levels of O_2 and CO_2 in the blood and body fluids. The control centers in the medulla and pons adjust the rate and depth of breathing to compensate for changes in the blood gases.

Animation: Respiratory mechanics

Animation: Asthma

46.4 Mechanisms of Gas Exchange and Transport

- The partial pressure of O_2 is higher in the alveolar air than in the blood in the capillary networks surrounding the alveoli causing O_2 to diffuse from the alveolar air into the blood. Most of the O_2 entering the blood combines with hemoglobin inside erythrocytes (Figure 46.11).
- A hemoglobin molecule can combine with four O_2 molecules. The large quantities of O_2 that combine with hemoglobin maintain a large gradient in partial pressure between O_2 in the alveolar air and in the blood (Figure 46.12).
- In body tissues outside the lungs, the O_2 concentration in the interstitial fluid and body cells is lower than in the blood plasma. As a result, O_2 diffuses from the blood into the interstitial fluid, and from the fluid into body cells.
- The partial pressure of CO_2 is higher in the tissues than in the blood. About 10% of this CO_2 dissolves in the blood plasma;

70% is converted into H^+ and HCO_3^- (bicarbonate) ions. The remaining 20% combines with hemoglobin (Figures 46.11 and 46.13A).

- In the lungs, the partial pressure of CO_2 is higher in the blood than in the alveolar air. As a result, the reactions packing CO_2 into the blood are reversed, and the CO_2 is released from the blood into the alveolar air (Figure 46.13C).

46.5 Respiration at High Altitudes and in Ocean Depths

- In mammals that move to high altitudes, the number of red blood cells and the amount of hemoglobin per cell increase. These changes are reversed if the animals return to lower altitudes.
- Humans living at higher altitudes from birth develop more alveoli and capillary networks in the lungs.
- Some mammals and birds adapted to high altitudes have forms of hemoglobin with greater affinity for O_2, allowing saturation at the lower P_{O_2} typical of high altitudes (Figure 46.14).
- Marine mammals adapted to deep diving have a greater blood volume per unit of body weight, and their blood contains more red blood cells, with a higher hemoglobin content, than other mammals. Their muscles also contain more myoglobin than those of land mammals, allowing more O_2 to be stored in muscle tissues. During a dive, the heartbeat slows, and circulation is reduced to all parts of the body except the brain.

UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following describes a respiratory medium?
   a. the liver of an amphibian, in which the rate of diffusion is high
   b. neurons in the human brain, where CO_2 moves from the neurons to the blood
   c. the O_2 in the blood of humans
   d. epithelial cells of fish that are in contact with the air
   e. air and water
2. Which of the following describes a respiratory surface?
   a. a surface consisting of multiple layers of epithelial cells
   b. the exoskeleton of an insect
   c. the nasal passages of a mammal
   d. thin surface consisting of a single layer of epithelial cells
   e. the outer membrane of a mitochondrion
3. A geothermal HVAC (heating, ventilating, and air conditioning) system air-conditions your house by passing warm air pulled from the house past a continuous flow of cool water pulled from the ground. How this heat exchanger works is analogous to:
   a. countercurrent exchange of gases in fish gills or bird lungs.
   b. diffusion of O_2 from blood to cells in shark tissues.
   c. diffusion of CO_2 from cells to blood in crabs.
   d. use of O_2 in cells in insects.
   e. excretion of CO_2 from mammalian cells.
4. Tracheal systems are characterized by:
   a. closed circulatory tubes that move gases.
   b. spiracles that move gases between cells and body fluids.
   c. body movements that compress and expand air sacs to pump air.
   d. positive pressure breathing, which swallows air into the body.
   e. negative pressure breathing, which lowers air pressure at the respiratory surfaces.
5. The partial pressure of O_2 in the atmosphere is 160 mm Hg, but when O_2 moves into the blood its partial pressure is one third lower than the atmospheric partial pressure. Which structure is it moving through at this partial pressure?
   a. alveoli
   b. bronchi
   c. bronchioles
   d. tracheae
   e. pharynges
6. As a speed skater finishes the last lap of a race:
   a. his diaphragm and rib muscles contract when he exhales.
   b. positive pressure brings air into his lungs.
   c. his lungs undergo an elastic recoil when he inhales.
   d. his tidal volume is at vital capacity.
   e. his residual volume momentarily reaches zero.
7. A teenager is frightened when she is about to step onto the stage but then remembers to breathe deeply and slowly as she faces the audience. What is occurring here?
   a. Interneurons in the medulla cause the rib muscles to relax, followed later by stimulation and contraction of the intercostal muscles.
   b. Signals from the pons override the initial brain stem stimuli.
   c. The limbic system stabilized her emotional state, so there is no change in the mechanical movement of air.
   d. The brain signals the aortic bodies in the carotid arteries to adjust the breathing rate.
   e. Initial low CO_2 blood levels causing high pH are followed by increased CO_2 levels that lower pH.
8. Oxygen enters the blood in the lungs because relative to alveolar air:
   a. the CO_2 concentration in the blood is high.
   b. the CO_2 concentration in the blood is low.
   c. the O_2 concentration in the blood is high.
   d. the O_2 concentration in the blood is low.
   e. the process is independent of gas concentrations in the blood.
9. A hemoglobin O_2 dissociation curve:
   a. demonstrates that hemoglobin is about 50% saturated in the alveoli.
   b. shifts to the left when pH rises.
   c. demonstrates that hemoglobin holds less O_2 when the pH is higher.
   d. illustrates that oxygen saturation is not dependent on CO_2 levels.
   e. demonstrates why hemoglobin can bind O_2 at high pH in the lungs and release it at lower pH in the tissues.

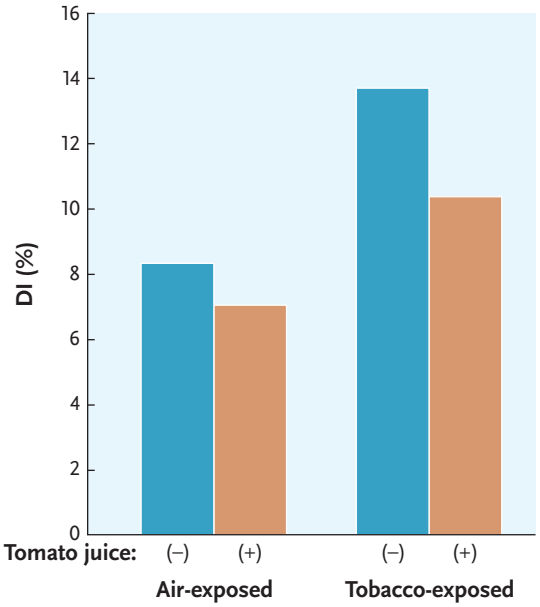
10. The majority of CO_2 in the blood:
    a. is in the form of carbonic acid and bicarbonate ions.
    b. dissociates to add H^1 to the blood to raise its pH to 7.4.
    c. has a lower P_{CO_2} than the P_{CO_2} in the alveolar air.
    d. increases in the lung capillaries, which have a higher pH than the tissue capillaries.
    e. can be displaced on the hemoglobin molecule by CO if CO is inhaled.

Discuss the Concepts



1. Smoking has traditionally been considered to reduce the ability of athletes to run without becoming exhausted. Why might this be true?
2. People are occasionally found unconscious from breathing too much CO_2 (as from a charcoal heater placed indoors) or too much CO (as from auto exhaust in a closed garage). Would it be more advantageous to give pure O_2 to a person breathing too much CO_2 than simply moving the person to fresh air? Why? Which—pure O_2 or fresh air—would be best for a person unconscious from breathing CO? Why?
3. Hyperventilation, or overbreathing, is breathing faster or deeper than necessary to meet the body's needs. Hyperventilation reduces the CO_2 content of blood, but does not significantly increase the amount of O_2 available to tissues. Why might this be so?

Design an Experiment

Propose a hypothesis for the effect of zero gravity on respiration, and design an experiment to test the hypothesis.

Interpret the Data

Lycopene, which is abundant in tomatoes, is thought to have a potential benefit in protecting against many types of cancers. In the study, the results of which are shown in the **Figure,** mice were exposed to tobacco smoke or normal air. The amount of lung tissue damage caused by each exposure was measured in mice that were given tomato juice (1) or water (2). To estimate the destruction of the alveolar wall, a destructive index (DI) was calculated from histological slides of the lung. All lungs will show some level of damage, but a DI above 10% is considered significant destruction.

S. Kasagi et al. 2006. Tomato juice prevents senescence-accelerated mouse P1 strain from developing emphysema induced by chronic exposure to tobacco smoke. *American Journal of Physiology–Lung Cellular and Molecular Physiology* 290:L396–L404. Reprinted by permission of The American Physiological Society.

1. What is the effect of tobacco smoke on the lung tissue in these mice?
2. Do these data suggest that lycopene has a protective effect against tobacco's effects?

Animal Nutrition

STUDY OUTLINE

47.1 Feeding and Nutrition
47.2 Digestive Processes
47.3 Digestion in Humans and Other Mammals
47.4 Regulation of the Digestive Process
47.5 Digestive Specializations in Vertebrates

Why it matters . . . In the inky darkness, a deep-sea anglerfish (a member of the order Lophiiformes) lies in wait, its gaping mouth lined with sharp teeth. Just above the mouth dangles a glowing lure suspended from a fishing-rodlike spine that projects from the fish's dorsal fin **(Figure 47.1).** The lure resembles a tiny fish; it even wiggles back and forth in imitation of swimming movements. Its glow is produced by bioluminescent bacteria that live symbiotically in the lure's tissues.

A hapless fish is attracted to the lure. As it comes within range, the mouth of the anglerfish expands suddenly, creating a powerful suction that whips the prey in. The backward-angling fangs keep the prey from escaping. The strike takes only 6 ms (milliseconds), among the fastest of any known fishes.

Contractions of throat muscles send the prey to the stomach of the anglerfish, which can expand to accommodate a meal as large as the anglerfish itself. In the fish's digestive tract, acids and enzymes dissolve the body of the prey, gradually breaking it into molecules small enough to be absorbed into the bloodstream. In this function, the digestive system of the anglerfish is the same as that of any other vertebrate, including humans—it provides nutrients that allow the animal to live. And the adaptations of the anglerfish for feeding, although bizarre to human sensibilities, are no more remarkable than those of many other animals.

Animal **nutrition**—which includes the processes by which food is ingested, digested, and absorbed into body cells and fluids—is the subject of this chapter. Our discussion begins with the basic categories of animal foods and **ingestion,** the feeding methods used to take food into the digestive cavity. Then we examine the process of **digestion,** which is the splitting of complex molecules in foods such as carbohydrates, proteins, and fats, into chemical subunits small enough to be absorbed into an animal's body fluids and cells. The chapter also presents the main struc-

tural and functional features of *digestive systems,* with special emphasis on humans and other mammals. The adaptations animals use to obtain and digest food are among their most strongly defining anatomical and functional characteristics.

47.1 Feeding and Nutrition

All organisms require sources of matter and energy for metabolism, homeostasis (maintaining their internal environment in a stable state; see Section 38.4), growth, and reproduction. For animals, meeting these nutritional requirements involves *feeding,* the uptake of food from the surroundings. Animals use various feeding methods ranging from the ingestion of molecules in liquid solutions to eating entire organisms in one gulp. Once the food is ingested, digestive processes convert its molecules into absorbable subunits. In this section, we survey animal nutritional requirements and feeding methods as an introduction to animal digestive processes.

Animals Require Both Organic and Inorganic Molecules for Nutrition

Plants and other photosynthesizers need only sunlight as an energy source and a supply of simple inorganic precursors such as water, carbon dioxide, and minerals to make all the organic molecules they require. In contrast, animals require a constant diet of organic molecules as a source of both energy and nutrients that they cannot make for themselves.

Animals are classified according to their sources of organic molecules. **Herbivores,** such as antelopes, horses, bison, giraffes, kangaroos, manatees, and grasshoppers, obtain organic molecules primarily by eating plants. **Carnivores,** such as cats, Tasmanian devils, penguins, sharks, and spiders, primarily eat other animals. We say "primarily" because many herbivores eat animal matter at times, and a number of carnivores occasionally eat plant material. An antelope will eat insects as it grazes, and a grizzly bear, although primarily carnivorous, also eats berries. **Omnivores,** such as crows, cockroaches, and humans, eat both plants and animals and, digestive enzymes allowing, may consume any source of organic matter.

Organic molecules are the basis for two of the most fundamental processes of life: they act as fuels for oxidative reactions that supply energy, and they are the building blocks for making complex biological molecules.

Energy supplies and requirements are usually described in terms of calories. A *calorie* (with a lowercase c) is the amount of energy required to raise the temperature of 1 g of pure water by 1°C, from 14.5°C to 15.5°C. In animal nutrition, calories are usually considered in units of 1,000 as kilocalories (kcal; the units listed on food packages in the United States [1 kcal = 4.2 kilojoules]) or Calories (with an uppercase C). One Calorie thus equals 1,000 calories. Animals consume three main types of energy-rich foodstuffs: carbohydrates, proteins, and fats. Carbohydrates contain about 4.2 kcal per gram, fats about 9.5 kcal per gram, and proteins about 4.1 kcal per gram.

Animals whose intake of organic fuels is inadequate, or whose assimilation of such fuels is abnormal, suffer from **undernutrition.** The opposite condition, **overnutrition,** is caused by excessive intake of specific nutrients. Both undernutrition and overnutrition are types of **malnutrition.**

An animal suffering from undernutrition is starving for one or more nutrients, taking in fewer calories than needed for daily activities. Animals with chronic undernutrition lose weight because they have to use energy-providing molecules of their own bodies as fuels. Mammals use stored fats and glycogen (animal starch) first. Once those stores have been used up, proteins are metabolized as fuels. The use of proteins as fuels leads to muscle wastage and, in the long term, to organ and brain damage, which eventually leads to death.

Organic molecules also serve as building blocks for carbohydrates, lipids, proteins, and nucleic acids. Animals can synthesize many of the organic molecules that they do not obtain directly in the diet by converting one type of building block into another. Typically they cannot make certain amino acids and fatty acids from other organic molecules. These required organic building blocks are called **essential amino acids** and **essential fatty acids** because they must be obtained in the diet. If they are not obtained in the diet over a period of time, the animal may have serious health consequences. For instance, protein synthesis cannot continue unless all 20 amino acids are present. In the absence of essential amino acids in the diet, the animal would have to break down its own proteins to provide them for new protein synthesis.

Animals must also take in **vitamins,** organic molecules required in small quantities that the animal cannot synthesize for itself. Many vitamins are *coenzymes,* nonprotein organic subunits associated with enzymes that assist in enzymatic catalysis (see Section 4.4).

Individual species differ in the vitamins and essential amino acids and fatty acids they require. Various species also have differing dietary requirements for inorganic elements such as calcium, iron, and magnesium. These species-specific required inorganic elements are known collectively as **essential minerals.**

The essential amino acids, fatty acids, vitamins, and minerals are known collectively as an animal's **essential nutrients.** The list of essential nutrients differs from animal to animal. For domesticated animals, this means that specific feed formulations must be given to each type of animal. For instance, the essential nutrients for cats and dogs are different, which is why there are specific cat foods and dog foods.

Animals Obtain Nutrients in Fluid, Particle, or Bulk Form

All animals have adaptations that allow them to obtain the food they need in particular environments. Although these adaptations are highly varied, animals can be classified into one of four groups according to overall feeding methods and the physical state of the organic molecules they consume. These four groups

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

are *fluid feeders, suspension feeders, deposit feeders,* and *bulk feeders* **(Figure 47.2).**

Fluid feeders obtain nourishment by ingesting liquids that contain organic molecules in solution. Invertebrate fluid feeders include aphids, mosquitoes, leeches, and spiders. Vertebrate fluid feeders include birds such as hummingbirds **(Figure 47.2A),** which feed on flower nectar; parasitic fishes such as lampreys, which feed on body fluids of their hosts; and some bats, which feed on nectar or blood. Many fluid feeders have mouthparts specialized to reach the source of their nourishment. For example, mosquitoes, bedbugs, and aphids have needlelike mouthparts that pierce body surfaces. Nectar-feeding birds and bats have long tongues that can extend deep within flowers. Some fluid feeders use enzymes or other chemicals to liquefy their food or to keep it liquid during feeding. For example, spiders inject digestive enzymes that liquefy tissues inside their victim and then suck up the liquid. The saliva of mosquitoes, leeches, and vampire bats includes an anticoagulant that keeps blood in liquid form during a feeding by inhibiting the clotting reaction.

Suspension feeders ingest small organisms that are suspended in water, such as bacteria, archaea, single-celled protists, algae, and small crustaceans, or fragments of these organisms. Among the suspension feeders are aquatic invertebrates such as clams, mussels, barnacles, many fishes, and some birds and whales. These animals strain food particles suspended in water through a body structure covered with sticky mucus or through a filtering network of bristles, hairs, or other body parts. The trapped particles are then funneled into the animal's mouth. Bits of organic matter are trapped by the gills of bivalves such as clams and oysters, and plankton is filtered from water by the sievelike fringes of horny fiber hanging in the mouths of baleen whales **(Figure 47.2B).**

Deposit feeders pick up or scrape particles of organic matter from solid material they live in or on. Earthworms are deposit feeders that eat their way through soil, taking the soil into their mouth and digesting and absorbing any organic material it contains. Some burrowing mollusks and tube-dwelling polychaete worms use body appendages to gather organic deposits from the sand or mud around them. Mucus on the appendages traps the organic material, and cilia move it to the mouth. The fiddler crab (*Uca* species) has claws of markedly different sizes **(Figure 47.2C).** The small claw picks up sediment and moves it to

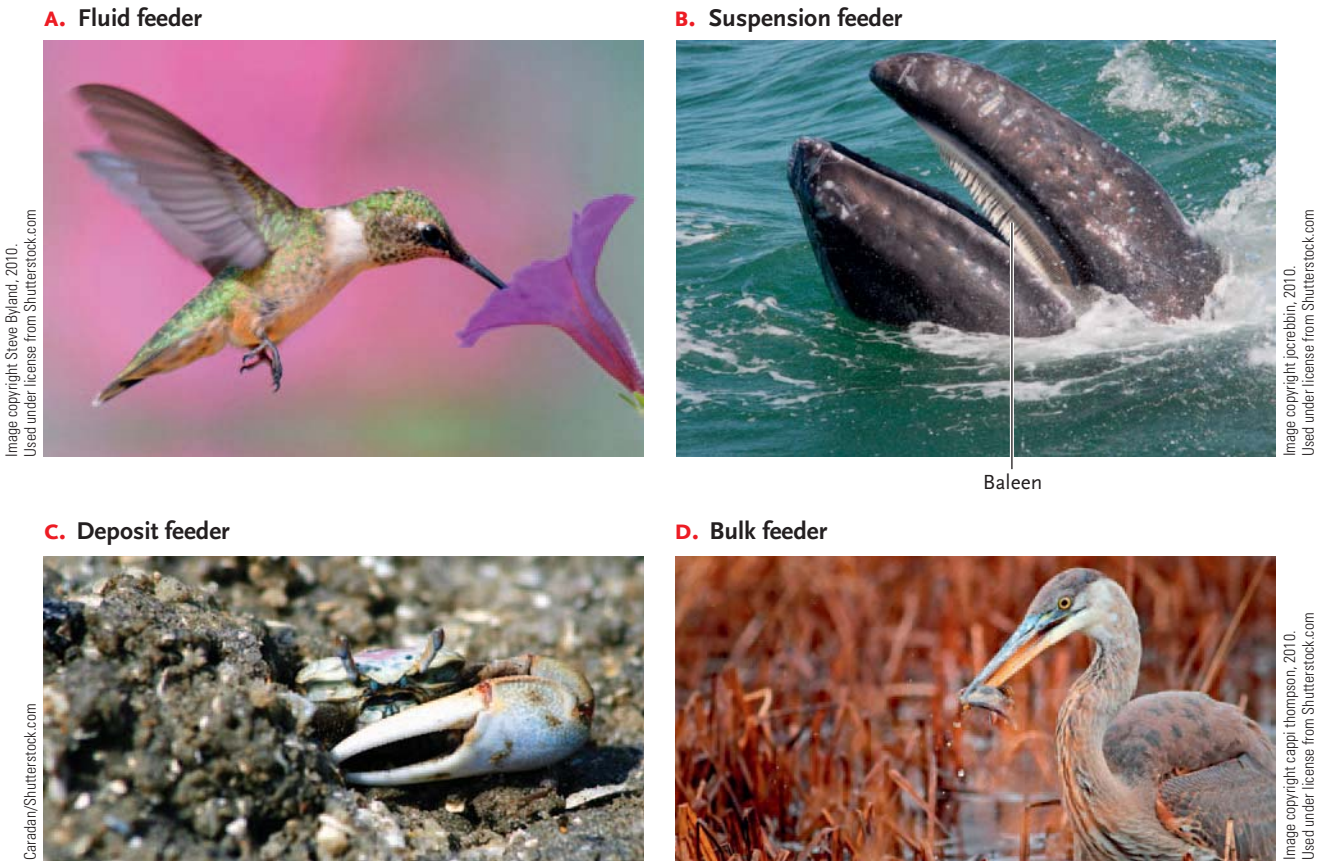

FIGURE 47.2 Adaptations for feeding. (A) A fluid feeder obtains nourishment by ingesting liquids containing nutrients. For example, a juvenile ruby-throated hummingbird *(Archilochus colubris)* obtains nectar from deep within a flower using its long bill and tongue. **(B)** A suspension feeder obtains nutrients by ingestion of small organisms in water. For example, a gray whale *(Eschrichtius robustus)* gulps water and mud from the sea bottom into its mouth, strains them out through its fringed baleen, and eats the crustaceans and other invertebrates that remain. **(C)** A deposit feeder obtains nutrients by picking up or scraping particles of organic matter from solid material. For example, a fiddler crab (*Uca* species) sifts edible material from the sediment it takes into its mouth. **(D)** A bulk feeder obtains nutrients by ingesting sizeable food items whole or in large pieces. This great blue heron *(Ardea herodias)* is feeding on a brook trout *(Salvelinus fontinalis)*.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the mouth where the contents are sifted. The edible parts of the sediment are ingested, and the rest is put back on the sediment as a small ball. The feeding-related movement of the small claw over the larger claw looks like the crab is playing the large claw like a fiddle and hence gives the crab its name.

Bulk feeders are animals that consume sizeable food items whole or in large chunks. Most mammals eat this way, as do reptiles, most birds and fishes, and adult amphibians. Depending on the animal, adaptations for bulk feeding include teeth for tearing or chewing, and claws and beaks for holding large food items **(Figure 47.2D),** and jaws that are hinged or otherwise modified to permit a food mass to enter the mouth.

We now take up the processes by which animals, having fed, undertake the mechanical and chemical breakdown of food into absorbable molecular subunits.

STUDY BREAK 47.1

1. What are carnivores, herbivores, and omnivores?
2. What are essential nutrients, and are they the same for all animals?
3. What is the difference between deposit feeders and suspension feeders?

47.2 Digestive Processes

Digestive processes break food molecules into molecular subunits that can be absorbed into body fluids and cells. The breakdown occurs by **enzymatic hydrolysis,** in which chemical bonds are broken by the addition of H^+ and OH^-, which are the components of a molecule of water (see Figure 3.5). Specific enzymes speed these reactions: *amylases* catalyze the hydrolysis of starches, *lipases* break down fats and other lipids, *proteases* hydrolyze proteins, and *nucleases* digest nucleic acids. Depending on the animal, the enzymatic hydrolysis of food molecules may take place inside or outside the body cells.

Intracellular Digestion Takes Place within Cells; Extracellular Digestion Occurs in an Internal Pouch or Tube

In **intracellular digestion,** cells take in food particles by endocytosis (described in Section 6.5). Inside the cell, the endocytic vesicle containing the food particles fuses with a lysosome, a vesicle containing hydrolytic enzymes (see Figure 5.16). The molecular subunits produced by the hydrolysis pass from the vesicle to the cytosol. Any undigested material remaining in the vesicle is released to the outside of the cell by exocytosis (also discussed in Section 6.5). Only a few animals, primarily sponges and some cnidarians, break down food exclusively by intracellular digestion. In sponges, water containing particles of organic matter and microorganisms enters the animal's saclike body through pores in the body wall (see Figure 31.8B). In the body cavity, individual *choanocytes* (collar cells) lining the body wall trap the food particles, take them in by endocytosis, and transport them to amoeboid cells, which digest them intracellularly (see Figure 31.8C).

Extracellular digestion takes place outside body cells, in a pouch or tube that is enclosed within the body. Epithelial cells lining the pouch or tube secrete enzymes that digest the food. Processing food in specialized compartments in this way prevents the animal from digesting its own body tissues.

Most invertebrates and all vertebrates digest food primarily by extracellular digestion. From an adaptive standpoint, extracellular digestion greatly expands the range of available food sources by allowing animals to digest much larger food items than single cells can take in. Extracellular digestion also allows animals to eat large batches of food, which can be stored and digested while the animal continues other activities.

Saclike Extracellular Digestive Systems Have a Single Opening through Which Food Enters and Undigested Matter Exits

Some animals, including flatworms and cnidarians such as hydras, corals, and sea anemones, have a saclike digestive system with a single opening, a mouth, that serves both as the entrance for food and the exit for undigested material. These animals lack a separate vascular system, so water taken into the digestive chamber also serves to circulate nutrients and other materials through the various tissue layers. Because the digestive chamber contributes both to digestion and to circulation, it is called a **gastrovascular cavity.** In the flatworm *Dugesia,* for example, food is brought to the mouth by a protrusible **pharynx** (a throat that can be stuck out) and then enters the gastrovascular cavity **(Figure 47.3);** glands in the cavity wall secrete enzymes that begin the digestive process. Cells lining the cavity take up the partially digested material by endocytosis and complete digestion intracellularly. Undigested matter is released to the outside through the pharynx and mouth.

Digestive Tracts Typically Process Nutrients in Five Successive Steps

For most invertebrates and all vertebrates, the extracellular digestive system consists of a *digestive tract* plus accessory digestive organs, the organs that secrete chemicals required for diges-

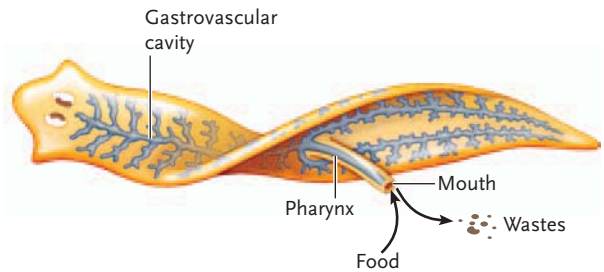

FIGURE 47.3 The digestive system of the flatworm *Dugesia*. The gastrovascular cavity (in blue) is a blind sac, with one opening to the exterior through which food is ingested and wastes are expelled.

tion. A **digestive tract** (also called *gastrointestinal [GI] tract, digestive tube, gut,* or *alimentary canal*) is tubelike with two openings that form a separate mouth and anus. In the digestive tract, the digestive contents move in one direction from the mouth to the anus through specialized regions of the tube. Structurally, the inside of the digestive tube—called the **lumen**—is external to all body tissues. In other words, although entirely enclosed, the lumen is, in a functional sense, *outside* of the body.

In most animals with a digestive tract, digestion occurs in five successive steps, with each step taking place in a specialized region of the tube. The tube thus acts as a biological disassembly line, with food entering at one end and passing through as many as five areas in which food processing occurs.

1. **Mechanical processing:** chewing, grinding, and tearing break food chunks into smaller pieces, increasing their mobility and the surface area exposed to digestive enzymes.
2. **Secretion of enzymes and other digestive aids:** enzymes and other substances that aid the process of digestion, such as acids, emulsifiers, and lubricating mucus, are released into the tube.
3. **Enzymatic hydrolysis:** food molecules are broken down through enzyme-catalyzed reactions into absorbable molecular subunits.
4. **Absorption:** the molecular subunits are absorbed from the digestive contents into body fluids and cells.
5. **Elimination:** undigested materials are expelled through the anus.

The material being digested is pushed along by muscular contractions of the wall of the digestive tube. During its progress through the tube, the digestive contents may be stored temporarily at one or more locations. The storage allows animals to take in larger quantities of food than they can process immediately, so that feedings can be spaced in time rather than continuous.

DIGESTION IN AN ANNELID The earthworm (genus *Lumbricus,* **Figure 47.4A**) is a deposit feeder. Food entering the mouth passes to the muscular pharynx. Contraction of the pharynx moves the food through the **esophagus** into the **crop,** where the contents are mixed with lubricating mucus. The **gizzard** carries out mechanical processing of the food, pulverizing it using muscular contractions and the sand particles it contains. The pulverized mixture enters a long **intestine,** where the organic matter is hydrolyzed by secreted enzymes. The molecular subunits are absorbed by cells lining the intestine as the mixture moves along by muscular contractions of the intestinal wall. Undigested residue is expelled through the anus.

DIGESTION IN AN INSECT Herbivorous insects such as the grasshopper **(Figure 47.4B)** tear leaves and other plant parts into small particles with hard external mouth parts. Food particles enter the mouth and pass through the pharynx, where salivary secretions moisten the mixture before it enters the esophagus and passes into the crop and then into the gizzard, which grinds it into smaller pieces. These food particles enter the **stomach,** in which food is stored and digestion begins. Insect stomachs have saclike outgrowths, the *gastric ceca* (*caecus* = blind), where enzymes hydrolyze the digestive contents; the products of digestion are absorbed through the walls of the ceca. The undigested contents then move into the intestine for further digestion and absorption. At the end of the intestine, water is absorbed from the undigested matter and the remnants are expelled through the anus. The digestive systems of other arthropods are similar to the insect system.

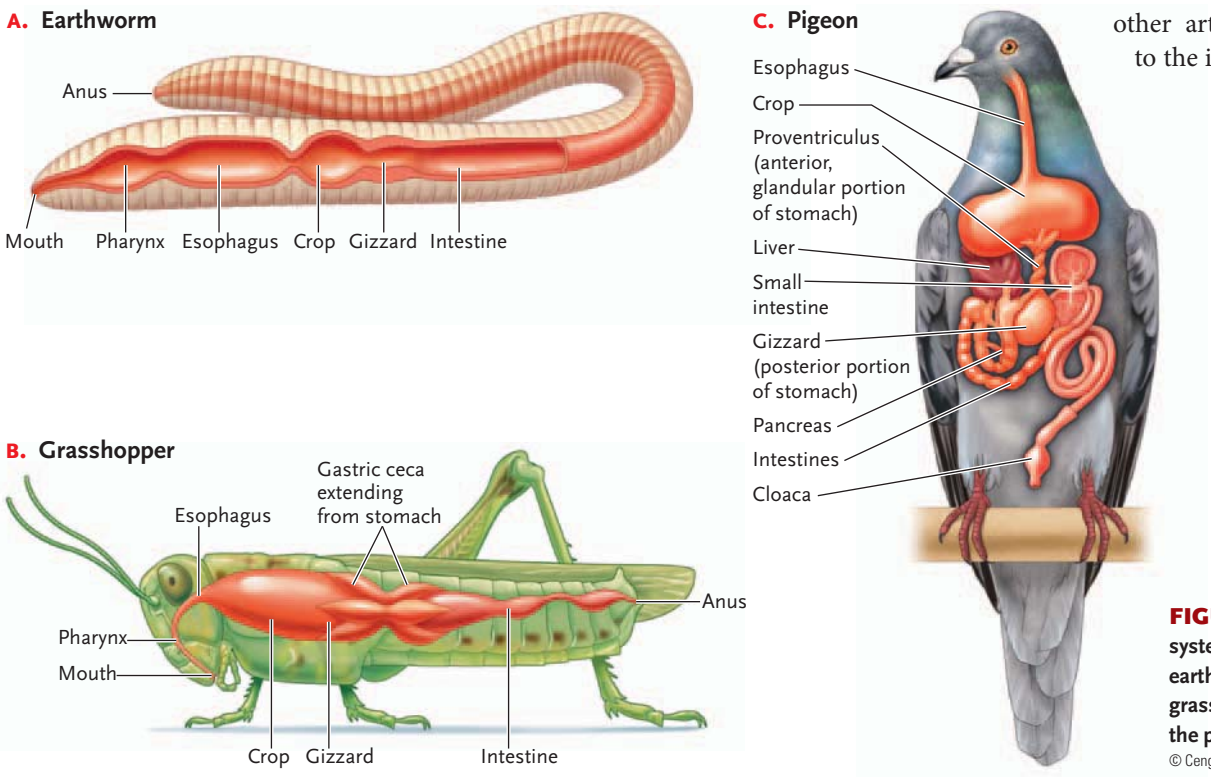

FIGURE 47.4 **The digestive systems of an annelid, the earthworm (A), an insect, the grasshopper (B), and a bird, the pigeon *(Columba)* (C).**

DIGESTION IN A BIRD A pigeon **(Figure 47.4C)** picks up food (such as seeds) with its bill. In the mouth the food is moistened by mucus-filled saliva and swallowed whole (birds have no teeth). The food passes through the pharynx into the esophagus. The anterior end of the esophagus is tubelike; at the posterior end is the pouchlike crop, in which the bird can store large quantities of food. From the crop, the food passes into the anterior glandular portion of the stomach, called the *proventriculus,* which secretes digestive enzymes and acids. The posterior end is the gizzard, in which the food is ground into fine particles, aided by ingested bits of sand and gravel. The food particles are released into the intestine, where the liver secretes bile and the pancreas secretes digestive enzymes. The molecular subunits produced by enzymatic digestion are absorbed as the mixture passes along the intestine, and the undigested residues are expelled through the anus.

Many of the structures of the pigeon's digestive system, including the mouth, pharynx, esophagus, stomach, intestine, liver, and pancreas, occur in almost all vertebrates.

STUDY BREAK 47.2

1. **Distinguish between intracellular digestion and extracellular digestion.**
2. **What are the five steps of food processing in a digestive tube?**

THINK OUTSIDE THE BOOK

Use the Internet or a research paper search tool such as PubMed (http://www.ncbi.nlm.nih.gov/PubMed/) to list the research question being addressed in three projects involving bird digestive systems.

47.3 Digestion in Humans and Other Mammals

Mammals digest foods using the same five steps as other animals with a digestive tract: mechanical processing, secretion of enzymes and other digestive aids, enzymatic hydrolysis, absorption of molecular subunits, and elimination. The mammalian digestive tract is a series of specialized digestive regions that perform these steps, including the mouth, pharynx, esophagus, stomach, small and large intestines, rectum, and anus **(Figure 47.5).** These regions are under the control of the nervous and endocrine systems. The accessory organs for the mammalian digestive system consist of the *salivary glands,* the *exocrine pancreas,* the *liver,* and the *gallbladder* (all are discussed in this section). The digestive system is not identical in all mammals. Specific adaptations have produced variants of the digestive system such as occurs in humans. An example is the digestive system of ruminants (discussed in Section 47.5).

Humans Require Specific Essential Amino Acids, Fatty Acids, Vitamins, and Minerals in Their Diet

The human digestive system meets our basic needs for fuel molecules and for a wide range of nutrients, including the molecular building blocks of carbohydrates, lipids, proteins, and nucleic acids. If the diet is adequate, the digestive system also absorbs the essential nutrients—the amino acids, fatty acids, vitamins, and minerals that cannot be synthesized within our bodies.

ESSENTIAL AMINO ACIDS AND FATTY ACIDS There are eight essential amino acids for adult humans: lysine, tryptophan, phenylalanine, threonine, valine, methionine, leucine, and isoleucine. Infants and young children also require histidine. The proteins in fish, meat, egg whites, milk, and cheese supply all the essential amino acids, provided those foods are eaten in adequate quantities. In contrast, the proteins of many plants are deficient in one or more of the essential amino acids. Corn, for example, contains inadequate amounts of lysine, and beans contain little methionine. Vegetarians and especially vegans, who eat a diet with no animal-derived nutrients, must choose their foods carefully to obtain all of the essential amino acids **(Figure 47.6).** Such diets typically include combinations of foods, each of which provides some amino acids, and that together contain all of the essential amino acids. An example is including in the diet rice or corn or other grains (low in lysine but high in methionine) with lentils or soybeans (for example, tofu) or other legumes (low in methionine but high in lysine).

If the diet lacks one or more essential amino acids, many enzymes and other proteins cannot be synthesized in sufficient quantities. The resulting protein deficiency is most damaging to the young, who synthesize proteins rapidly for development and growth. Even mild protein starvation during pregnancy or for some months after birth can affect a child's mental and physical development adversely.

Only two fatty acids, linoleic acid and linolenic acid, are essential in the human diet. Both are required for synthesis of phospholipids forming parts of biological membranes and certain hormones. Because almost all foods contain these fatty acids, most people have no problem obtaining them. However, people on a low-fat diet that is deficient in linoleic acid and linolenic acid are at serious risk for developing coronary heart disease. That is, there is an inverse correlation between the concentration of these essential fatty acids in the diet and the incidence of coronary heart disease. This is illustrated in the case of Hindu vegetarians from India. Their diet consists mainly of low-fat grains and legumes—clearly a low-fat diet—yet their rate of coronary heart disease is higher than that in the United States and Europe, where dietary fat content is higher.

VITAMINS Humans require 13 known vitamins in their diet. Many metabolic reactions depend on vitamins, and the absence of one vitamin can affect the functions of the others. These es-

sential nutrients fall into two classes: **water-soluble** (hydrophilic) **vitamins** and **fat-soluble** (hydrophobic) **vitamins** (summarized in **Table 47.1**). The body stores excess fat-soluble vitamins in adipose tissues, but any amount of water-soluble vitamins above daily nutritional requirements is excreted in the urine. Thus, meeting the daily minimum requirements of water-soluble vitamins is critical for good health. The body can tap its stores of fat-soluble vitamins to meet daily requirements; however, these stores are depleted quickly, so prolonged deficiencies of the fat-soluble vitamins also affect health negatively.

Most of you get all the vitamins you need through a normal and varied diet that includes meats, fish, eggs, cheese, and vegetables. Vitamin supplements are usually necessary only for strict

TABLE 47.1 Vitamins: Sources, Functions, and Effects of Deficiencies in Humans

Vitamin	Common Sources	Main Functions	Selected Effects of Chronic Deficiency
Fat-Soluble Vitamins			
A (retinol)	Yellow, orange and green vegetables and fruits; dairy products; liver	Component of visual pigments; bone metabolism; epithelial tissue maintenance	Night blindness; skin disorders; decreased immunity
D	Fish liver oil; egg yolk; fortified milk; produced in skin exposed to sunshine	Calcium and phosphorus absorption from gut	Bone deformities (rickets) in children; bone softening in adults
E (tocopherol)	Nuts; seeds; vegetable oils	Antioxidant; maintenance of cell membranes	Neuromuscular problems
K	Intestinal bacteria; green vegetables	Promotes synthesis of blood-clotting protein by liver	Abnormal blood clotting, bleeding
Water-Soluble Vitamins			
B_1 (thiamine)	Yeast; cereal grains; beans; nuts; meat	Connective tissue formation; needed for folate utilization; coenzyme forming part of enzyme in oxidative reactions	Beriberi (nervous system disorder that includes impaired sensory perception, limb weakness and pain, weight loss, cardiovascular malfunction)
B_2 (riboflavin)	Whole grains, poultry, fish, egg white, milk, lean meat	Coenzyme	Skin lesions
B_6 (pyridoxine)	Spinach, whole grains, tomatoes, potatoes, meat	Coenzyme in amino acid and fatty acid metabolism	Skin, muscle, and nerve damage
B_{12} (cobalamin)	Eggs; meats; dairy products	Coenzyme in nucleic acid metabolism; red blood cell formation	Anemia; brain and nervous system damage
Biotin	Legumes; egg yolk; some synthesized by colon bacteria	Coenzyme in fat and glycogen formation and amino acid metabolism	Scaly skin (dermatitis); sore tongue; brittle hair; depression; weakness
C (ascorbic acid)	Fruits and vegetables, especially citrus, berries, cantaloupe, cabbage, broccoli, green pepper	Vital for collagen synthesis; antioxidant	Scurvy (weakness, anemia, gum disease, and skin problems); delayed wound healing; impaired immunity
Folic acid	Leafy vegetables; legumes; whole grains; yeast; liver; egg yolks	Coenzyme in nucleic acid and amino acid metabolism	Anemia; diarrhea; impaired growth; birth defects
Niacin	Fruits and vegetables; nuts; grains; meats	Coenzyme of oxidative phosphorylation	Sensitivity to light; damage to skin, gut, and nervous system
Pantothenic acid	In many foods (meat, yeast, egg yolk especially)	Coenzyme in carbohydrate and fat oxidation; fatty acid and steroid synthesis	Fatigue; tingling in hands; headaches; nausea

vegetarians, newborns, the elderly, and individuals who are taking medication that affects the body's uptake of nutrients.

Vitamin D (calciferol) differs from other essential vitamins because humans can synthesize it themselves, through the action of ultraviolet light on lipids in the skin. However, many people are not exposed to enough sunlight to make sufficient quantities of the vitamin, and so must rely on dietary sources. And, although humans cannot make vitamin K, much of the requirement for this vitamin is supplied through the metabolic activity of bacteria living in the large intestine. Vitamin K deficiency, therefore, is exceedingly rare in healthy persons. Vitamin K plays a role in blood clotting, so individuals with vitamin K deficiency will bruise easily and show increased blood clotting times. Vitamin K deficiency can be caused in persons on long-term antibiotic therapy because the antibiotics kill intestinal bacteria.

Other mammals have essentially the same vitamin requirements as humans, with some differences. For example, most mammals, with the exception of primates, guinea pigs, and fruit bats, can synthesize vitamin C. No known animal

TABLE 47.2 Minerals: Sources, Functions, and Effects of Deficiencies in Humans[a]

Mineral	Common Sources	Main Functions	Selected Effects of Deficiency
Macrominerals			
Calcium (Ca)	Leafy green vegetables; legumes; whole grains; nuts; dairy products; eggs	Bone and tooth formation; blood clotting; neural and muscle action	Stunted growth; loss of bone mass
Chlorine (Cl)	Table salt; vegetables; meat; dairy products; eggs	HCl formation in stomach; contributes to body's acid–base balance; necessary for neural function and water balance	Muscle cramps; impaired growth; poor appetite
Magnesium (Mg)	Green leafy vegetables; legumes; nuts; dairy products; meat	Required for many enzymes; in bones and teeth; ATP processing	Weak, sore muscles; nervous system problems
Phosphorus (P)	Whole grains; legumes; nuts; dairy products; eggs; meats	In bones and teeth; component of nucleic acids, ATP and phospholipids; energy processing	Muscular weakness; loss of minerals from bone
Potassium (K)	Many vegetables and fruits; whole grains; dairy products	Muscle and neural function; water balance; acid–base balance; main positive ion in cell	Muscular weakness; cardiac abnormalities or failure
Sodium (Na)	Table salt; dairy products; eggs; meat	Acid–base balance; water balance; muscle and neural function; main positive ion in extracellular fluid	Muscle cramps
Sulfur (S)	Proteins from food sources, including legumes, nuts, dairy products, eggs, and meat	Component of body proteins	Same as protein deficiencies
Trace Minerals[b]			
Iodine (I)	Seafood; iodized salt	Thyroid hormone formation	Goiter (enlarged thyroid), with metabolic disorders
Iron (Fe)	Green leafy vegetables; legumes; whole grains; nuts; eggs; meats (particularly liver)	Component of hemoglobin, myoglobin, and electron carriers	Iron-deficiency anemia; weakness
Zinc (Zn)	Some vegetables; whole grains; legumes; nuts; fish; meats; many other foods	Component of many enzymes and some transcription factors; protein synthesis; DNA synthesis; cell division; immunity; wound healing	Impaired growth; loss of appetite; impaired immune function

[a]All of the minerals in this table have harmful effects when excess amounts are consumed.

[b]Other trace minerals not listed in the table are chromium (Cr), cobalt (Co), fluorine (F), manganese (Mn), molybdenum (Mo), and selenium (Se).

can synthesize B vitamins, but ruminants such as cattle and deer are supplied with those vitamins by microorganisms that live in the digestive tract (see Section 47.5).

MINERALS Some minerals are essential in the human diet **(Table 47.2).** *Macrominerals,* such as potassium, are required in amounts ranging from 50 mg to more than a gram per day. *Trace minerals,* such as iodine, are required only in small amounts, some less than 1 mg per day. All of the minerals, although listed as elements, are ingested as compounds or as ions in solution.

A normal and varied diet supplies adequate amounts of the essential minerals. Supplements may be required for those on a strict vegetarian diet, the very young, and the aged. Deficiencies of essential minerals have adverse effects, as Table 47.2 indicates. Excess intake of minerals can also have adverse effects. For instance, ingesting excess iron has been linked to liver, heart, and blood vessel damage, and too much sodium can lead to elevated blood pressure and excess water retention in tissues.

We now turn to the structures that extract nutrients from ingested foods. We begin with a survey of digestive structures common to all vertebrates.

Four Major Layers of the Digestive Tract Each Have Specialized Functions in Digestion

The wall of the digestive tract in mammals and other vertebrates contains four major layers, each with specialized functions. **Figure 47.7** shows these layers for the stomach.

1. The **mucosa,** which contains epithelial and glandular cells, lines the inside of the digestive tract. The epithelial cells, which absorb digested nutrients, seal off the digestive contents from body fluids. The glandular cells secrete enzymes, substances such as lubricating mucus that aid digestion, and substances that adjust the pH of the digestive contents.
2. The **submucosa** is a thick layer of connective tissue that contains neuron networks and blood and lymph vessels. It gives the digestive tract its elasticity and its ability to distend. The neuron networks provide local control of digestive activity and carry signals between the digestive tract and the central nervous system. The blood and lymph vessels have branches that go into the mucosa and into the surrounding muscle layer. The lymph vessels carry absorbed lipids to other parts of the body.
3. In most regions of the digestive tract, the **muscularis** is formed by two smooth muscle layers, a *circular layer* and a *longitudinal layer.* In a manner analogous to how similar layers of muscles alter the shape of an earthworm (see Figure 43.9), contraction of the circular muscles along with relaxation of the longitudinal muscles constricts the diameter of the gut and lengthens it, whereas contraction of the longitudinal muscles along with relaxation of the circular muscles causes the gut to assume a larger diameter and shortens it. The stomach also has an *oblique layer* running diagonally around its wall. The circular and longitudinal muscle layers of the muscularis coordinate their activities to push the digestive contents through the digestive tract **(Figure 47.8).** In this mechanism, called **peristalsis,** the circular muscle layer contracts in a wave that passes along the digestive tract, constricting it and pushing the digestive contents onward. Just in front of the advancing constriction, the longitudinal layer contracts, shortening and expanding the tube and making space for the contents to advance.
4. The outermost layer of the digestive tract, the **serosa,** consists of connective tissue that secretes an aqueous, slippery fluid. The fluid lubricates the areas between the digestive organs and other organs, reducing friction between them as they move together as a result of muscle movement. Along much of the length of the digestive tract, the serosa is continuous with the *mesentery,* a tissue that suspends the digestive tract from the inner wall of the abdominal cavity.

Powerful rings of smooth muscle called **sphincters** form valves between major regions of the digestive tract. By contracting and relaxing, sphincters control the passage of the digestive contents from one region to the next, and ultimately through the anus.

The specialized regions of the digestive tract that perform the sequential processes of digestion in humans allow us to extract nutrients efficiently from the highly varied foods we ingest. **Figure 47.9** summarizes the enzymatic digestion of carbohydrates, proteins, and fat in the regions human digestive tract. The rest of this section describes those digestion processes.

Food Begins Its Travel through the Digestive Tract in the Mouth, Pharynx, and Esophagus

The human digestive tract in its normal contracted state in a living adult is about 4.5 m long. Fully relaxed, as in a cadaver, it is about twice as long. Food begins its travel through this tract in the mouth, where the teeth cut, tear, and crush food items into small pieces. While this mechanical processing is in progress, three pairs of **salivary glands** secrete saliva through ducts that open on the inside of the cheeks and under the tongue.

Saliva, which is more than 99% water, moistens the food. Saliva contains **salivary amylase,** which hydrolyzes starches to the disaccharide maltose (see Figure 47.9). It also contains mucus, which lubricates the food mass, facilitating the formation of a **bolus** in preparation for swallowing. Bicarbonate ions (HCO_3^-) in saliva neutralize acids in the food and keep the pH of the mouth between 6.5 and 7.5, which is the optimal range for salivary amylase to function. Saliva also contains *lysozyme,* an enzyme that kills bacteria by breaking open their cell walls. Some 1 to 2 L of saliva are secreted into the mouth each day.

After chewing, the bolus is pushed by the tongue to the back of the mouth, where touch receptors detect the pressure and trigger the **swallowing reflex (Figure 47.10).** The reflex is an involuntary action produced by contractions of muscles in the walls of the pharynx that direct food into the esophagus. Peristaltic contractions of the esophagus, aided by mucus secreted by the esophagus, propel the bolus toward the stomach. The passage of a bolus down the esophagus stimulates the **gastroesophageal sphincter** at the junction between the esophagus and the stomach (see Figure 47.7) to open and admit the bolus to the stomach. After the bolus enters the stomach, the sphincter closes tightly. If the closure is imperfect, the acidic stomach contents can enter the esophagus and produce the irritation and pain we recognize as *acid reflux* or heartburn.

You can consciously initiate the swallowing reflex. However, once the swallowing reflex has begun, you cannot stop it voluntarily, as you might have noticed when you get that feeling of a piece of food or a pill being stuck in the throat or chest. This is because the muscles of the pharynx and upper esophagus are skeletal muscles, which you can control, while the muscles below are smooth muscles, which you cannot control.

Involuntary movements of the tongue and soft palate at the back of the mouth prevent food from backing into the mouth or nasal cavities. Entry into the trachea (the airway to the lungs) is blocked by closure of the *glottis* (the space between the vocal cords) and an upward movement of the *larynx* (the voice box) at the top of the trachea, which closes against a flaplike valve, the **epiglottis.** You can feel the larynx and the front of the epiglottis bob upward if you place your hand on your throat while you swallow. If these blocking mechanisms fail, touch receptors in the nasal passages and larynx trigger coughing and sneezing reflexes that clear these passages.

The Stomach Stores Food and Continues Digestion

The stomach is a muscular, elastic sac that stores food and adds secretions that further the process of digestion. The mucosal layer of the stomach is an epithelium covered with tiny **gastric pits** that are entrances to millions of **gastric glands.** These glands extend deep into the stomach wall and contain cells that secrete some of the products needed to digest food.

The entry of food into the stomach activates stretch receptors in its wall. Signals from the stretch receptors stimulate the secretion of **gastric juice (Figure 47.11),** which contains: **pepsinogen,** the precursor for the digestive enzyme **pepsin;** hydrochloric acid (HCl); and lubricating mucus. The stomach secretes about 2 L of gastric juice each day.

Pepsinogen is secreted by **chief cells** in the gastric glands and is converted to pepsin by the highly acid conditions of the stomach (see Figure 47.11). Once produced, pepsin itself catalyzes the reaction that converts more pepsinogen to pepsin. Pepsin begins the digestion of proteins by cleaving certain amino acid linkages to produce peptides (short amino acid chains of amino acids; see Figure 47.9). The activation of pepsinogen illustrates a common theme in the digestive system: powerful hydrolytic enzymes that would be dangerous to the cells secreting them are synthesized in the form of inactive precursors and are not converted into active form until they are exposed to the digestive contents.

Parietal cells (see Figure 47.11) secrete H^+ and Cl^-, which combine to form HCl in the lumen of the stomach. The HCl lowers the pH of the digestive contents to pH 2 or lower, the level at which pepsin reaches optimal activity. To put this pH in perspective, lemon juice is pH 2.4, and sulfuric acid or battery acid is approximately pH 1 (recall that pH is a log scale; see Section 2.5). The acidity of the stomach also helps break up food particles and causes proteins in the digestive contents to unfold, which exposes their peptide linkages to hydrolysis by pepsin. The acid also kills most of the bacteria that reach the stomach and stops the action of salivary amylase.

A thick coating of alkaline mucus, secreted by **mucous cells** (see Figure 47.11), protects the mucosal layer of the stomach from attack by pepsin and HCl. (Note that *mucus* is the noun, and *mucous* is the adjective.) Underneath the mucous barrier, tight junctions between cells prevent gastric juice from seeping into the stomach wall. Even so, some breakdown of the mucosal layer does occur. However, the damage is normally repaired quickly by the rapid division of mucosal cells.

Most bacteria cannot survive the highly acid environment of the stomach, but one, *Helicobacter pylori,* thrives there. In some people, the bacterium breaks down the mucous barrier, exposing the stomach wall to attack by HCl and pepsin. The resulting lesion, known as a **peptic** or **stomach ulcer,** causes stomach bleeding and pain. Ulcers are treated by taking an antibiotic that kills *H. pylori.* An untreated ulcer may perforate the stomach wall, with potentially fatal consequences. Barry J. Marshall of the University of Western Australia and J. Robin

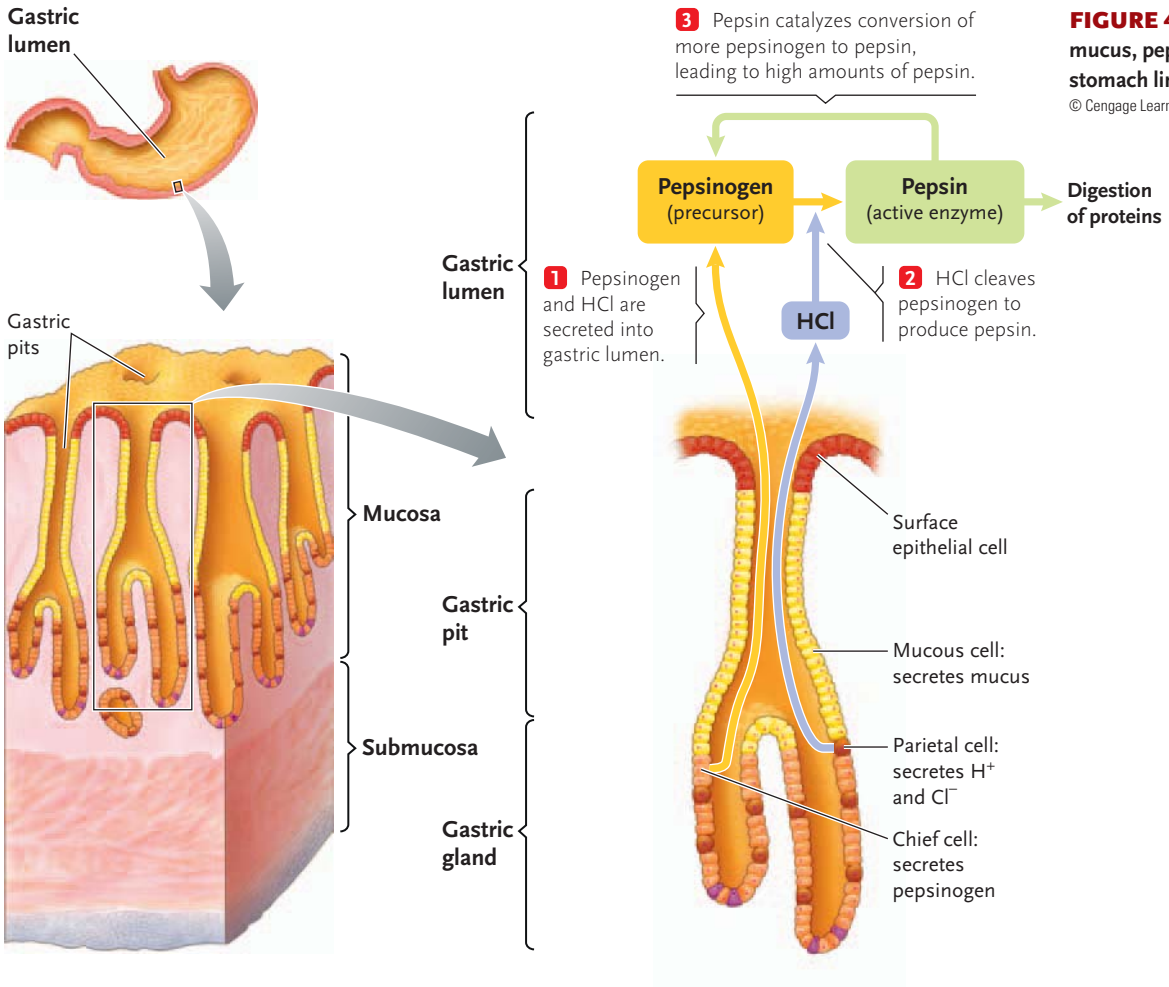

FIGURE 47.11 **Cells that secrete mucus, pepsin, and HCl in the stomach lining.**

© Cengage Learning 2014

Warren of Royal Perth Hospital received a 2005 Nobel Prize for their discovery that a bacterium is responsible for most human ulcers (described in Figure 26.13).

As part of the digestive process, contractions of the stomach walls continually mix and churn the contents, which can amount to as much as 2 L when the stomach is full. Peristaltic contractions of the stomach wall move the digestive contents toward the **pyloric sphincter** (*pylorus* = gatekeeper) at the junction between the stomach and small intestine. The arrival of a strong stomach contraction relaxes and opens the valve briefly, releasing a pulse of the stomach contents, now called **chyme,** into the small intestine (see Figure 47.8).

Depending on the volume and composition of the stomach contents, it can take from 1 to 6 hours for the stomach to empty after a meal. Feedback controls that regulate the rate of gastric emptying tend to match it to the rate of digestion, so that food is not moved along faster than it can be chemically processed. In particular, when chyme with high fat content and high acidity enters the first part of the small intestine, it stimulates the mucosal layer to secrete hormones that slow stomach emptying. Fat is digested more slowly than other nutrients, and it is digested only in the lumen of the small intestine. Therefore, further emptying of the stomach is prevented until the processing of fat has been completed in the small intestine. This is why a fatty meal, such as a greasy pizza, feels so heavy in the stomach. Highly acidic chyme must be neutralized by bicarbonate in the small intestine. Unneutralized stomach acid would inactivate digestive enzymes secreted in the small intestine and, therefore, such acid would inhibit further emptying of the stomach until it is neutralized.

Most Digestion and Absorption of Nutrients Occurs in the Small Intestine

Most digestion and absorption of nutrients occurs in the small intestine. No absorption of nutrients occurs in the mouth, pharynx, or esophagus; with the exception of a few substances, such as alcohol, aspirin, caffeine, and water, little absorption occurs in the stomach.

The "small" in the small intestine refers to its diameter, about 3 cm. It is about 6 m long and complexly coiled within the abdominal cavity. The lining of the small intestine folds into ridges that are densely covered by microscopic, fingerlike extensions, the **intestinal villi** (singular, *villus*). In addition, the epithelial cells covering the villi have a **brush border** consisting of fingerlike projections of the plasma membrane called **microvilli (Figure 47.12).** The intestinal villi and microvilli are estimated to increase the absorptive surface area of the small intestine to as much as 300 m^2, which is about the size of a doubles tennis court.

SECRETIONS OF THE PANCREAS, LIVER, AND MUCOSA OF THE SMALL INTESTINE When the stomach contents are emptied into the small intestine, they are mixed with secretions of the pancreas, liver, and the mucosa of the small intestine. About 7 to 9 L of these secretions enter the small intestine daily. About 95% of this amount is reabsorbed as water and nutrients as the digestive contents travel along the small intestine. Movement of the contents from the duodenum to the end of the small intestine takes about 3 to 5 hours.

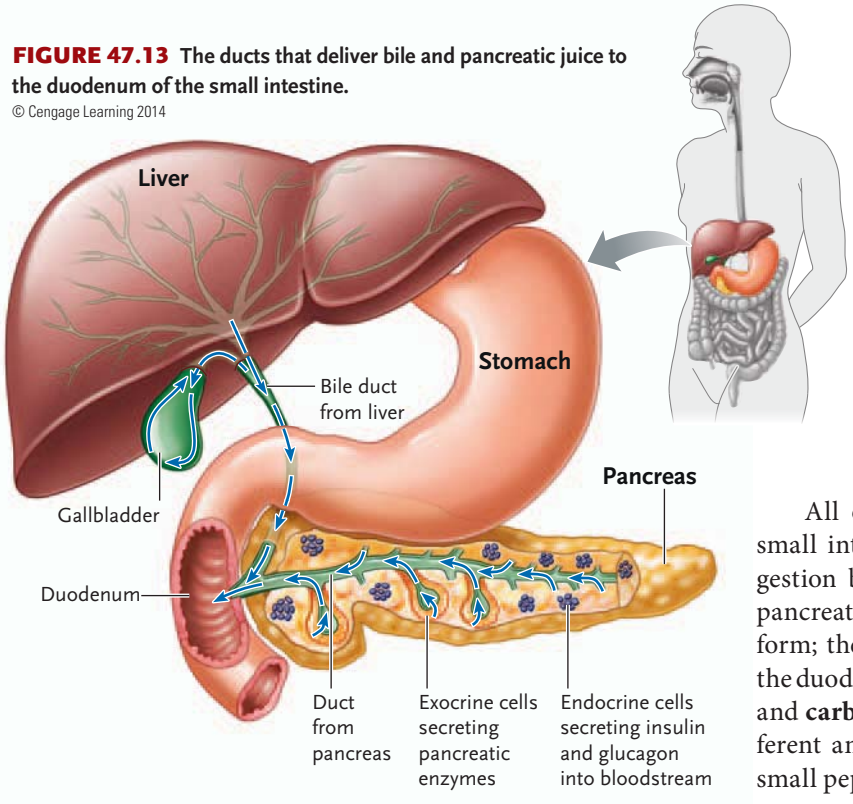

FIGURE 47.13 The ducts that deliver bile and pancreatic juice to the duodenum of the small intestine.

© Cengage Learning 2014

In humans, the **pancreas** is an elongated, flattened gland located between the stomach and duodenum (see Figures 47.5 and 47.13). Recall from Section 42.4 that most of the pancreas consists of an exocrine gland, with the remaining 2% consisting of endocrine cells that secrete the hormones insulin and glucagon. Exocrine cells in the pancreas secrete bicarbonate ions ($H_2CO_3^-$) and digestive enzymes—**pancreatic enzymes**—via a duct into the lumen of the first segment of the small intestine, a short region about 20 cm long called the **duodenum (Figure 47.13).** The bicarbonate ions neutralize the acid in the chyme, allowing optimal activity of the pancreatic enzymes, which include an amylase, proteases, nucleases, and lipase (see Figure 47.9).

All of the pancreatic enzymes act in the lumen of the small intestine. The amylase contributes to carbohydrate digestion by converting polysaccharides to disaccharides. The pancreatic proteases are secreted in an inactive precursor form; they are converted to active forms within the lumen of the duodenum. The active proteases are **trypsin, chymotrypsin,** and **carboxypeptidase.** Each of these enzymes hydrolyzes different amino acid linkages in peptide chains. Acting on the small peptides that were produced in the stomach, their action

produces small peptides and amino acids (see Figure 47.9). The pancreatic nucleases digest DNA and RNA to nucleotides.

The **liver** secretes bicarbonate ions and **bile,** a mixture of substances including **bile salts,** cholesterol, and **bilirubin.** These substances enter the duodenum via the same duct used by the secreted pancreatic enzymes. Bile salts are derivatives of cholesterol and amino acids that aid fat digestion. The problem is that fat is water-insoluble, yet it must be transferred from the aqueous chyme to the aqueous body fluids. In the small intestine, ingested fat aggregates into large, oily globules of triglyceride droplets. Bile salts attach to the surfaces of the globules and, by their detergent action, *emulsify* the fats—break them into tiny lipid droplets—during the churning motions of the small intestine. Mixing of oil and vinegar to make a salad dressing is a household example of emulsification. The emulsion increases the surface area available for hydrolysis of the triglycerides by pancreatic **lipase** to produce monoglycerides and fatty acids (see Figure 47.9).

Bilirubin, a waste product derived from worn-out red blood cells, is the yellow pigment that gives bile its color. Bacterial enzymes in the intestines modify bilirubin, resulting in the characteristic brown color of feces.

The liver secretes bile continuously. Between meals, when no digestion is occurring, bile is stored in the **gallbladder** (see Figure 47.13), where it is concentrated by the removal of water. After a meal, entry of chyme into the small intestine stimulates the gallbladder to release stored bile into the small intestine.

Brush-border epithelial cells on the villi of the small intestine mucosa secrete an aqueous salt and mucus mixture into the lumen. The mucus serves to protect and lubricate the digestive mixture. The aqueous salt solution provides water for the enzymatic digestion of food which mostly involves hydrolysis reactions. No digestive enzymes are secreted by the brush-border cells.

Disaccharides and small peptides in the digestive products in the lumen of the small intestine are absorbed by brush-border cells. As the molecules are transported across the plasma membranes of those cells, embedded enzymes in the membranes hydrolyze them to monosaccharides and individual amino acids, which are then transported into the extracellular fluid and blood.

FIGURE 47.14 **Absorption and digestion of disaccharides and small peptides by the brush-border cells of the small intestinal mucosa.**

© Cengage Learning 2014

DIGESTION BY ENZYMES OF THE BRUSH-BORDER CELLS Complete digestion of fats, but not of carbohydrates and proteins, takes place in the lumen of the small intestine. Completion of carbohydrate and protein digestion is performed by digestive enzymes that are integral proteins embedded in the plasma membranes of the brush-border cells of the small intestine mucosa **(Figure 47.14).** That is, disaccharides and small peptides are transported across the plasma membranes of the brush-border cells where embedded **disaccharidases** hydrolyze disaccharides to monosaccharides, and embedded **aminopeptidases** hydrolyze small peptides to individual amino acids.

One of the brush-border cell disaccharidases is *lactase,* the enzyme that breaks down the milk sugar lactose into its component glucose and galactose monosaccharides. Many adults lose the capacity to synthesize lactase. The lactose remaining in the intestine is broken down by bacteria, producing excess methane and CO_2. The accumulating gases distend the large intestine, producing pain, discomfort, and other symptoms known as **lactose intolerance.** Taking tablets containing lactase before eating milk products may limit or prevent those symptoms.

Nucleases and other enzymes digest the nucleic acids: **nucleotidases** break them down into nucleosides, and **nucleosidases** convert the nucleosides to nitrogenous bases, five-carbon sugars, and phosphates.

ABSORPTION BY THE BRUSH-BORDER CELLS OF THE SMALL INTESTINAL MUCOSA All products of carbohydrate and protein digestion are water-soluble. In the small intestine, lumen contents are absorbed by the brush-border cells by active transport or facilitated diffusion, depending on the substance. You have just learned about the absorption of disaccharides and small peptides and their breakdown into monosaccharides and amino acids (see Figure 47.14). Amino acids in the lumen contents are absorbed also, but no further digestion is necessary. The final products of digestion are then transported from the mucosal cells into the extracellular fluids, from where they enter the bloodstream in the capillary networks of the submucosa.

Nucleotides in the lumen contents are absorbed and then digested by cytosolic enzymes to the nitrogenous bases, ribose and deoxyribose sugars, and phosphates. These products move

to the bloodstream as for carbohydrate and protein digestion products.

The monoglyceride and fatty acid products of fat digestion are fat-soluble but water-insoluble. They enter the cell as shown in **Figure 47.15.** Once in the cell, they are used to resynthesize triglycerides, which aggregate and are coated with a layer of lipoprotein to form **chylomicrons.** Cholesterol absorbed in the small intestine is also packed into the chylomicrons. Chylomicrons leave the epithelial cell by exocytosis and are enter the lymphatic system.

Processing in the Liver

The capillaries absorbing nutrient molecules in the small intestine collect into veins that join to form a larger blood vessel, the **hepatic portal vein,** which leads to capillary networks in the liver. There, some of the nutrients leave the bloodstream and enter liver cells for chemical processing. Among the reactions taking place in the liver is the combination of excess glucose units into glycogen, which is stored in liver cells. This reaction reduces the glucose concentration in the blood exiting the liver to about 0.1%. If the glucose concentration in the blood entering the liver falls below 0.1% during a period of fasting between meals, the reaction reverses. The reversal adds glucose to return the blood concentration to the 0.1% level before it exits the liver. The hormonal activities controlling blood glucose levels in the blood are described in Section 42.4.

The liver also synthesizes the lipoproteins that transport cholesterol and fats in the bloodstream, detoxifies ethyl alcohol and other toxic molecules, and inactivates steroid hormones and many types of drugs.

Monoglycerides and fatty acids associate with bile salts to form water-soluble microdroplets called micelles. Micelles carry their contents to the microvillar membranes of the brush-border epithelial cells where the monoglycerides and fatty acids enter the cells by passive diffusion through the plasma membranes. Within the cells, triglycerides are resynthesized from the monoglycerides and fatty acids. The triglycerides aggregate and are coated with lipoproteins from the endoplasmic reticulum to form chylomicrons, which leave the cell by exocytosis and enter the lymphatic system.

FIGURE 47.15 **Absorption of monoglycerides and fatty acids, the products of fat digestion in the luman of the small intestine, by the brush-border cells of the small intestinal mucosa.**

© Cengage Learning 2014

As a result of the liver's activities, the blood leaving the liver has a markedly different concentration of nutrients than the blood carried into the liver by the hepatic portal vein. From the liver, blood is carried to the heart and then pumped by the heart to deliver nutrients to all parts of the body.

The Large Intestine Primarily Absorbs Water and Mineral Ions from Digestive Residues

The small intestine reabsorbs all but about 1 L of the 7 to 9 L of fluid released from the stomach. The remaining contents of the small intestine then move on to the large intestine. By this point, almost all nutrients have been hydrolyzed and absorbed.

A sphincter at the junction between the small and large intestines controls the passage of material between the two and prevents backward movement of the contents. The large intestine has an average diameter of 7.6 cm, more than twice that of the small intestine, but it is relatively short, about 1.5 m long in humans, as compared with the 6-m length of the small intestine. The inner surface of the large intestine is relatively smooth and contains no villi.

The large intestine has several distinct regions **(Figure 47.16).** At the junction with the small intestine, a part of the large intestine forms a blind pouch called the **cecum.** A finger-like sac, the **appendix,** extends from the cecum. The appendix is on average 100 mm long and 7 mm in diameter; it is a vestigial structure with no known function in digestion. Since it contains patches of lymphoid tissue, it is presumed to have some role as part of the immune system. The cecum merges with the **colon,** the main part of the large intestine, which

forms an inverted U. At its distal end, the colon connects with the final segment of the large intestine, the **rectum.**

The large intestine secretes mucus and bicarbonate ions and absorbs water and other ions, primarily sodium and chloride. The absorption of water condenses and compacts the digestive contents into solid masses, the **feces.** Normally, by the time the fecal matter reaches the rectum, it contains less than 200 mL of the fluid that enters the digestive tract each day. Diarrhea, by contrast, is an abnormal condition in which the fecal matter is highly fluid. The most common cause of diarrhea is a higher-than-normal rate of movement of materials through the small intestine, which does not leave adequate time for absorption of water to occur. The higher rate of movement can occur as a result of irritation of the small intestine wall caused by bacterial and viral infections, or because of emotional stress.

About 30% to 50% of the dry matter of feces in humans and other vertebrates consists of more than 500 species of bacteria that live as essentially permanent residents in the large intestine. Most common is the bacterium *Escherichia coli,* which also lives in the intestine of many other mammals. Intestinal bacteria metabolize sugars and other nutrients remaining in the digestive residue, and produce useful fatty acids and vitamins (such as vitamin K and the B vitamins folic acid and biotin), some of which are absorbed in the large intestine. Their activity also produces large quantities of gas—*flatus*—primarily CO_2, methane, and hydrogen sulfide. Most of the gas is absorbed through the intestinal mucosa, and the rest is expelled through the anus in the process of **flatulence.** The amount and composition of the gas produced depend on the type of food being ingested and the particular population of bacteria present in the large intestine. Some foods, such as beans, contain carbohydrates that humans cannot digest but that can be metabolized by the gas-producing intestinal bacteria. After eating such foods, humans may produce more gas than usual, and flatulence is more likely to occur.

When feces enter the rectum, they stretch the rectal wall. The stretching triggers a **defecation reflex** that opens the **anal sphincter** and expels the feces through the anus. Because the anal sphincter contains rings of voluntary skeletal muscle as well as involuntary smooth muscle (see Figure 47.16), you can resist the defecation reflex by tightening the striated muscle ring voluntarily.

Having completed the journey of ingested food through the digestive tract, we now turn our attention to the mechanisms that regulate the activities of the digestive system. These mechanisms coordinate one region of the digestive tract with another, and help match the production of nutrients with the body's needs.

STUDY BREAK 47.3

1. What are the two classes of vitamins? Which of the two types is more critical in the diet and why?
2. What are the four layers of the mammalian gut? Which layer is responsible for peristalsis?
3. How is pepsin produced? What is its function?
4. Distinguish between the functions of the small and large intestines in the process of digestion.

THINK OUTSIDE THE BOOK

Use the Internet or research literature to outline the mechanisms involved in vomiting, and to determine how vomiting is distinguished from regurgitation.

47.4 Regulation of the Digestive Process

The digestive process is regulated and coordinated at many steps by controls that are largely automated. The autonomic nervous system, local neuron networks in the digestive tract wall, and endocrine glands interact in these controls, in response to sensory information gathered by receptors in the digestive tract. The integration of the controls speeds up or slows down digestion to produce maximum efficiency in the breakdown of food molecules and the absorption of the nutrients.

Much of the control of the digestive system originates in the neuron networks of the submucosa. Other controls, par-

ticularly those regulating appetite and oxidative metabolism, originate in the brain, in control centers forming part of the hypothalamus.

The Digestive Tract Itself Has a Number of Control Systems

The movement of food through the digestive tract is controlled by receptors in and hormones secreted by various parts of the digestive system **(Figure 47.17).** Control starts with the mouth. Saliva is secreted constantly into the mouth. The presence of food activates receptors that increase the rate of salivary secretion by as much as 10-fold.

Swallowed food expands the stomach and sets off signals from stretch receptors in the stomach walls that increase the rate and strength of stomach contractions. At the same time, chemoreceptors in the stomach respond to the presence of food molecules, particularly proteins, with secretion of a hormone, **gastrin.** After traveling through the circulatory system, gastrin returns to the stomach, where it stimulates the secretion of HCl and pepsinogen (see Figure 47.11). These molecules are then used in the digestion of the protein that, as part of the swallowed meal, was responsible for their secretion. Gastrin also stimulates stomach and intestinal contractions, activities that keep the digestive contents moving through the digestive system when a new meal arrives.

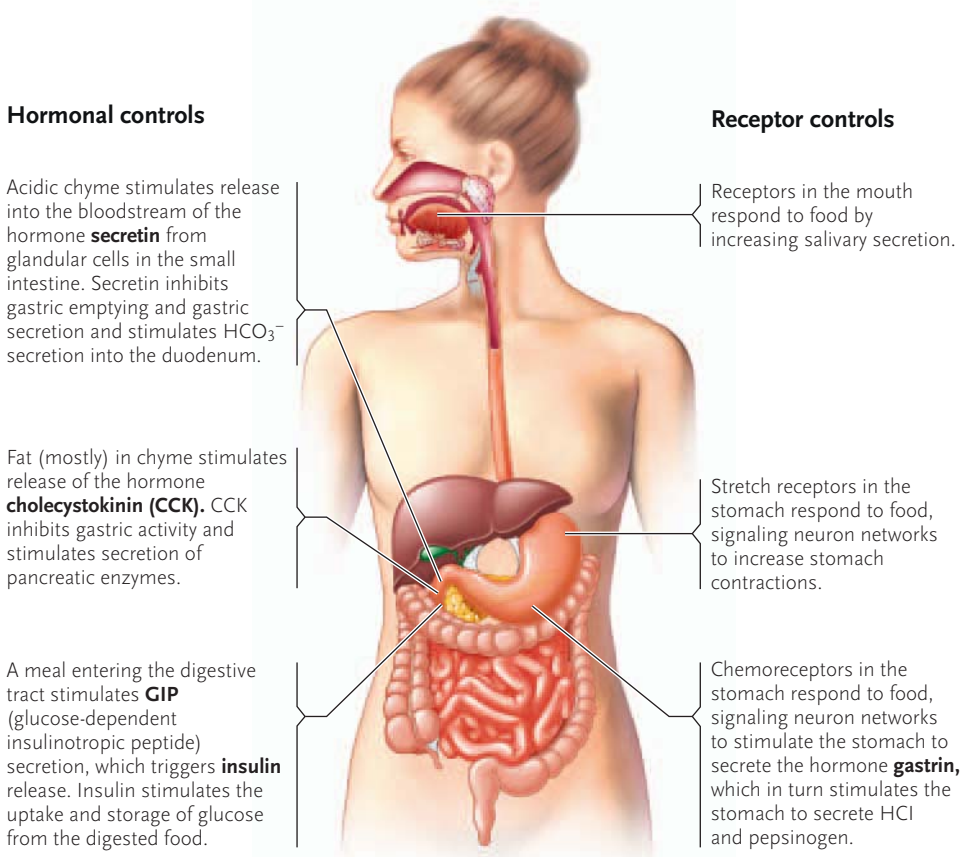

FIGURE 47.17 **Control of digestion by receptors and hormones in the digestive system.**

© Cengage Learning 2014

Three hormones secreted when food is present in the duodenum also participate in regulating the digestive processes:

1. **Secretin.** When chyme is emptied into the duodenum, its acidic nature stimulates the release of the hormone **secretin** from glandular cells in the small intestine; the hormone enters the bloodstream. Secretin inhibits further gastric emptying to prevent more acid from entering the duodenum until the newly arrived chyme is neutralized. It also inhibits gastric secretion to reduce acid production in the stomach, and it stimulates HCO_3^- secretion into the lumen of the duodenum to neutralize the acid. If the acid is not neutralized, the duodenal wall will become damaged.
2. **Cholecystokinin (CCK).** Fat, and to a lesser extent protein, in the chyme that enters the duodenum stimulates the release of the hormone **cholecystokinin (CCK).** CCK inhibits gastric activity, thereby allowing time for nutrients in the duodenum to be digested and absorbed. It also stimulates the secretion of pancreatic enzymes, used to digest the macromolecules in the chyme.
3. **Glucose-dependent insulinotropic peptide (GIP).** The hormone **glucose-dependent insulinotropic peptide (GIP)** acts primarily to stimulate insulin release by the pancreas. When a meal is ingested, the body must change its metabolic state to use and store the new nutrients absorbed. Those activities are mostly under the control of insulin. Therefore, when a meal enters the digestive tract, GIP secretion is stimulated to trigger the release of insulin. Insulin is particularly important in stimulating the uptake and storage of glucose and so, not surprisingly, glucose in the blood draining the duodenum is directly detected as well by pancreatic β-cells, the cells from which insulin is secreted (see Section 42.4).

The Hypothalamus Exerts Overall Controls

The hypothalamus contains two interneuron centers that work in opposition to control appetite and oxidative metabolism. One center stimulates appetite and reduces oxidative metabolism, and the other center stimulates the release of a peptide hormone called **α-melanocyte-stimulating hormone (α-MSH)**, which inhibits appetite.

A major link in the control pathways is the peptide hormone *leptin* (*leptos* = thin), discovered in mice by Jeffrey Friedman and his coworkers at the Rockefeller University. Fat-storing cells secrete leptin when the deposition of fat increases in the body. Leptin travels in the bloodstream and binds to receptors in both centers in the hypothalamus. Binding stimulates the center that reduces appetite and inhibits the center

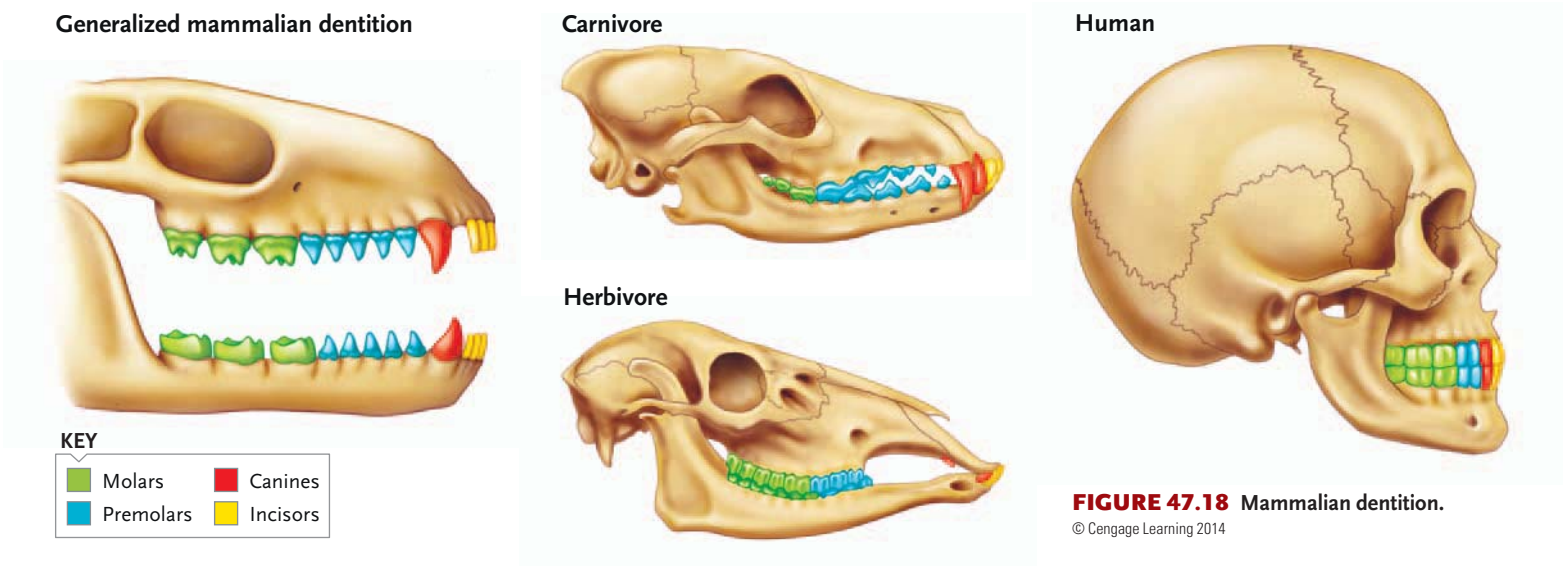

FIGURE 47.18 Mammalian dentition.

© Cengage Learning 2014

that stimulates appetite. At the same time, leptin binds to receptors on body cells, triggering reactions that oxidize fatty acids rather than converting them into fats. When fat storage is reduced, leptin secretion drops off, and signals from other pathways activate the appetite-stimulating center in the hypothalamus and turn off the appetite-inhibiting center.

These controls closely match the activity of the digestive system to the amount and types of foods that are ingested, and they coordinate appetite and oxidative metabolism with the body's needs for stored fats. *Insights from the Molecular Revolution* describes research identifying signal molecules and receptors that regulate appetite and feeding behavior in mammals.

2. How does the hypothalamus regulate the digestive process?

47.5 Digestive Specializations in Vertebrates

Natural selection has modified the basic vertebrate digestive system into a multitude of structural and functional variations. The most common modifications are in the form of the mouth, teeth, and jaws; the structure and function of the esophagus, stomach, and cecum; and the length of the digestive tract. Vertebrates also vary in the types of enzymes secreted by the digestive system. For example, humans secrete an amylase into the saliva, but cats and pigs secrete a salivary lipase.

Teeth Are Adapted to Feeding Methods

To anthropologists and paleontologists, dentition (the number, kind, and arrangement of teeth) opens a window to an animal's diet and feeding method—and hence reveals a great deal about its habitat and lifestyle. For example, snakes have sharp, pointed teeth that curve backward into the mouth, which helps to ensure that prey (dead or living) does not slip out of the animal's mouth as muscles contract to swallow. The dentition is combined with specializations in jaw structure; many snakes have jaws with elastic connections that allow them to open wide enough to swallow prey whole.

Tooth specialization is especially evident among mammals **(Figure 47.18).** Typically, mammals have four types of upper and lower teeth. **Incisors,** located at the front of the mouth, are flattened, chisel-shaped teeth used to nip or cut food. Horses use their prominent incisors to clip off blades of grasses. Pointed **canines** at the sides of the incisors are specialized for biting and piercing. Carnivores such as wolves and tigers use their long, sharp canines to pierce and kill prey, but the canines are minimally developed or absent in many herbivores. The blocky teeth at the sides of the mouth, the **premolars** and **molars,** have surface bumps, or *cusps,* that are used in crushing, grinding, and shearing food. Large premolars and molars with a ridged surface are characteristic of animals, such as deer, that consume fibrous plant material. The premolars and molars of some carnivores, such as cats, have sharp shearing surfaces that can slice meat efficiently. All four types of teeth are typically well developed in omnivores, such as humans.

The Length of the Intestine and Specializations of the Digestive Tract Reflect Feeding Patterns

There is a strong correlation between diet and the length of the digestive system **(Figure 47.19).** Vertebrates that feed primarily on nutrient-rich foods such as meat, blood, nectar, or insects, including carnivores (such as the dog), generally have a relatively short intestine. In contrast, herbivores (such as the rabbit) have a long intestinal tract and specializations of the esophagus, stomach, and cecum, or other structures that can store large volumes of plant material. Both the longer intestinal tract and greater storage capacity allow an herbivore to extract more nutrients

Food for Thought on the Feeding Response

A number of small proteins called *neuropeptides* regulate various physiological responses in humans and other mammals, including appetite and feeding, pain reception, and blood pressure regulation. They exert their effects by binding to receptors on the surfaces of neurons and other cells. For example, neuropeptide Y (NPY) strongly stimulates appetite and food uptake when it binds to neurons in the hypothalamus and other locations in the brain.

Research Question

What receptor in the hypothalamus binds NPY?

Experiments

A group of researchers at the Synaptic Pharmaceutical Corporation in New Jersey and Ciba-Geigy in Switzerland was one of several teams that tried to identify the receptor binding NPY in the hypothalamus. Their first step was to clone the gene for NPY **(Figure).** The cloned gene was identified by its expression: the encoded receptor inserted into the plasma membrane of a transformed mammalian cell and was detected by the binding of NPY.

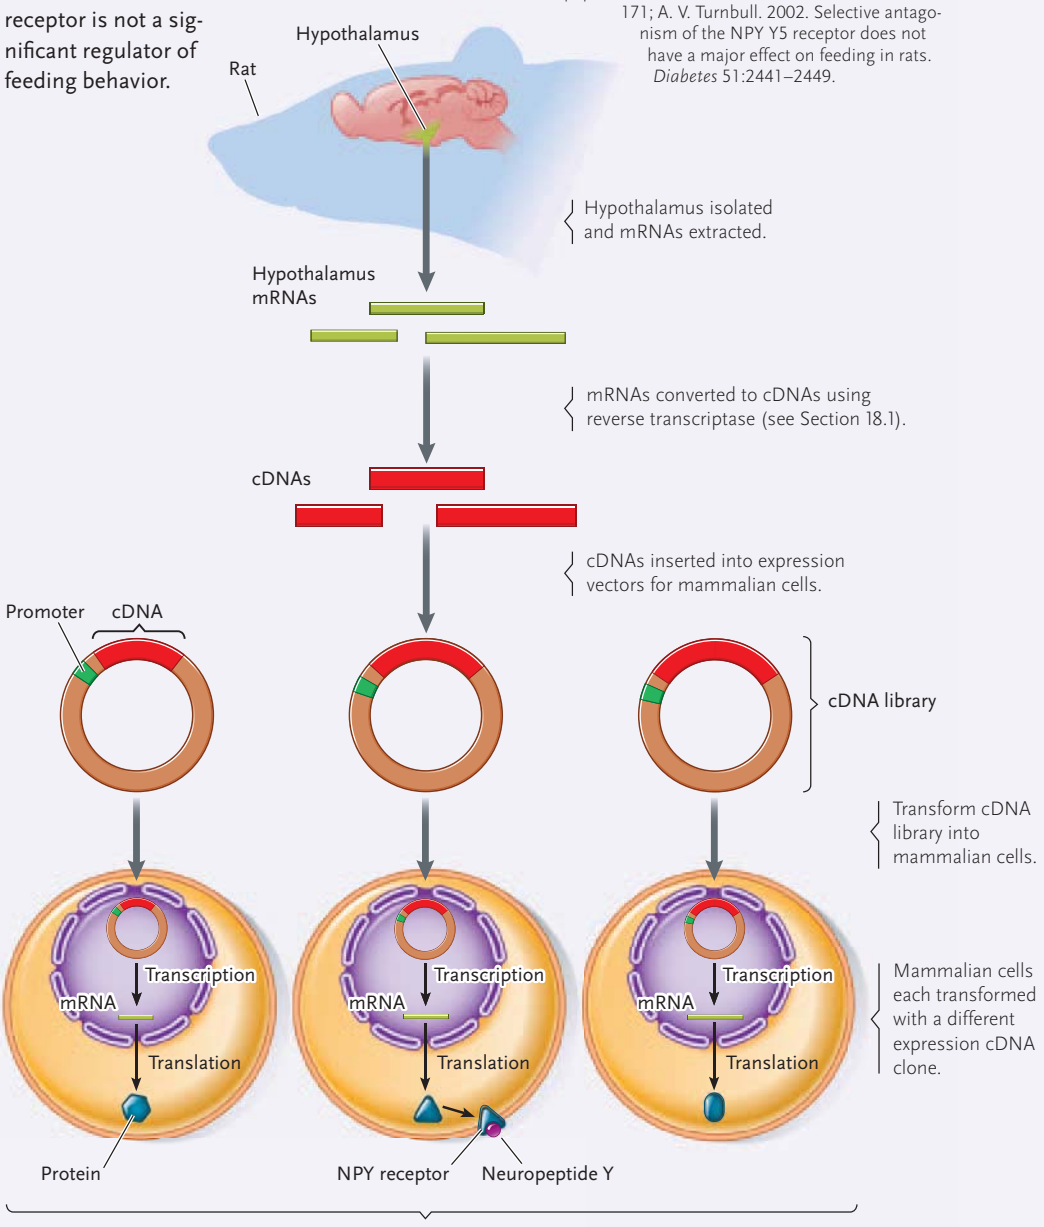
The sequence of the cloned gene showed that it encoded a previously unknown neuropeptide receptor, which they called Y5. A homologous gene for this receptor was then identified in the human genome.

Next, the cloned cDNA was used in a northern blotting experiment (see Section 18.2) to identify which tissues express the Y5 gene. The researchers probed several different rat tissues for the presence of Y5 mRNA.

Result

Their result showed that the Y5 gene is expressed only in the brain, with the strongest expression in the hypothalamus and the amygdala, a center associated with emotional responses.

Conclusion



The researchers had isolated a novel neuropeptide Y receptor gene, Y5. After testing the ability of various peptides to bind the Y5 receptor, and the effects of the binding on feeding behavior, they proposed that the binding of NPY initiates signals that stimulate hunger and the feeding response. Binding to receptors in the amygdala may add an emotional dimension to the craving for food. The researchers conjectured that studies of Y5 could help further our understanding of eating disorders and perhaps aid in the development of drugs to combat those disorders.

The Y5 receptor became a focus of considerable drug discovery efforts. However, one study has burst the bubble—drugs designed to inhibit the receptor are not effective in combating obesity. In this study, Andrew Turnbull and his colleagues at AstraZeneca in the United Kingdom showed that one such drug had no significant effect either on the increase in food intake induced by NPY itself either in normal or genetically obese rats, or on food intake or body weight in normal rats or in rats that were obese due to their diet. In short, the Y5 receptor is not a significant regulator of feeding behavior.

The difference between these results and those of the previous study may reflect the experimental design—the compounds used in the earlier study may have had other activities that were responsible for their effects on feeding behavior. Neuropeptide Y continues to be of interest for research.

THINK LIKE A SCIENTIST Suppose that, in contrast to what was found, the drug tested in Turnbull's research did decrease feeding rate in rats treated with the drug. Could you conclude from that result that the drug would be effective in humans? How could you test whether it is?

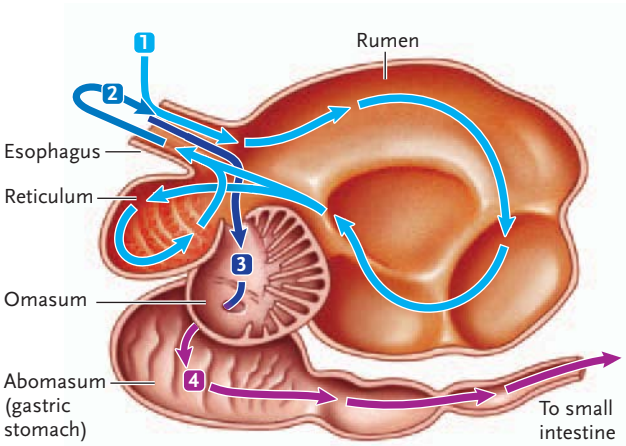
from plant matter, which is relatively difficult to digest. Both types of intestine appear during the life cycle of frogs: a frog tadpole, which eats algae primarily, has a relatively long, coiled intestine, but after metamorphosis, the adult frog, which eats insects primarily, has a short intestine.

Symbiotic Microorganisms Aid Digestion in a Number of Organisms

Many herbivores use the hydrolytic capabilities of microorganisms such as bacteria, protists, and fungi to aid digestion of plant material, housing them in specialized structures of the esophagus, stomach, or cecum. Unlike vertebrates, the microorganisms can synthesize *cellulase,* the enzyme that hydrolyzes the cellulose of plant cell walls into glucose subunits. This arrangement is a classic example of *mutualism* (a type of symbiosis in which both interacting organisms benefit); the herbivores benefit from the digestive capabilities of the microorganisms, and the microorganisms benefit from an ideal habitat and an abundant supply of nutrients.



The most remarkable adaptations for mutualistic digestion of plant matter among vertebrates occur in the **ruminants,** which include cattle, deer, goats, sheep, pronghorns, and antelopes. These animals have a complex, four-chambered stomach **(Figure 47.20).** The first three chambers are derived from the esophagus. After the ruminant's teeth tear, cut, and grind plant matter, boluses are swallowed. Most of them go to the **rumen** (the largest chamber), and the rest go to the **reticulum** (step 1). In these two chambers, symbiotic microorganisms hydrolyze cellulose in the plant matter into fuels for fermentation reactions (the oxygen level in the chambers is too low to support

FIGURE 47.20 A ruminant, the pronghorn *(Antilocapra americanus),* and its four-chambered system that digests plant matter with the aid of mutualistic microorganisms.

Association of Intestinal Bacteria Populations with Obesity in Humans

Question: Are particular populations of intestinal bacteria associated with obesity in humans?

Experiment: The human intestine contains 10^{13} to 10^{14} microorganisms, a number that is greater by an order of magnitude than the number of human somatic and germ cells. The mutualistic organisms in this intestinal flora synthesize essential amino acids and vitamins, and digest otherwise indigestible components of food, such as particular plant macromolecules.

Intestinal microorganisms consist largely of bacteria, with two groups predominating, the Firmicutes (a phylum of Gram-positive bacteria) and the Bacteroidetes (a phylum of Gram-negative bacteria). Research by Jeffrey Gordon and his group at Washington University School of Medicine, St. Louis, has shown that genetically obese mice (genotype *ob*/*ob*) have about 50% fewer Bacteroidetes, and correspondingly more Firmicutes, than do normal, lean, siblings (genotype ob^+/ob^+), leading to the conclusion that particular distributions of bacteria in the intestine correlate with obesity.

Gordon's group studied the relationship between intestinal populations of the two types of bacteria and body fat in humans. They worked with 12 people classified as being obese according to the standard criterion of having a body mass index (BMI) of ≥30. BMI is calculated from the formula, BMI = weight (kg)/[height (m)]^2. BMI does not measure body fat directly, although it correlates well with the amount of body fat found in nonathletes. **Figure A** shows the experimental design of Gordon's research.

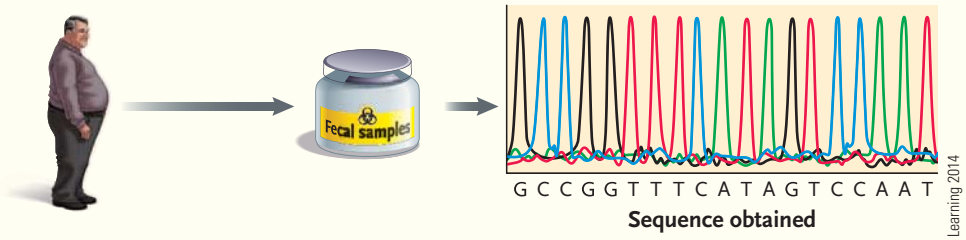

FIGURE A

Sequencing specific regions of the 16S rRNA gene (which encodes an rRNA found only in the ribosome of prokaryotes) enabled the researchers to identify the bacteria in the fecal sample. The regions sequenced vary significantly among species, permitting the identification of species present in a mixed sample without having to culture the organisms. Analyzing these sequences is one of the methods used in molecular phylogenetics (see Section 24.7).

Results: Most of the bacteria present in the obese individuals and in two lean individuals (controls) were Firmicutes or Bacteroidetes. As shown in **Figure B:** (1) Before embarking on the diet, obese individuals had more Fimicutes and fewer Bacteroidetes than lean individuals; and (2) over the course of the diet, as weight loss occurred, the relative abundance of Firmicutes decreased, and the relative abundance of Bacteroidetes increased.

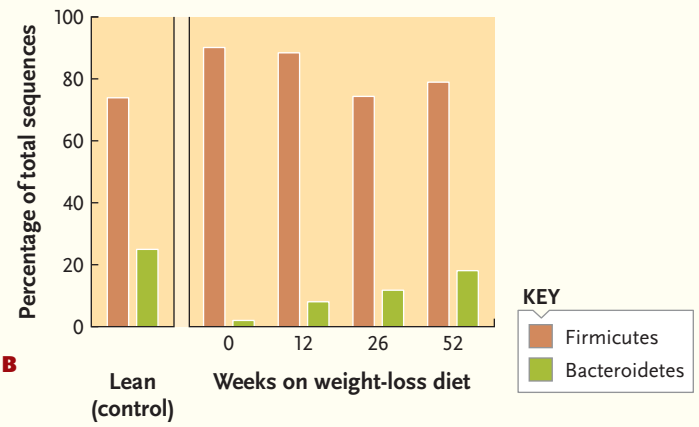

FIGURE B

Conclusion: Obese and lean individuals showed significant differences in their intestinal content of Firmicutes and Bacteroidetes. Moreover, the data from the effects of the weight-loss diet indicate a dynamic relationship between the intestinal populations of the two groups of bacteria and body fat content. Taken with the results of the mouse study, manipulation of intestinal microbial communities could be a potential way to control or treat obesity.

THINK LIKE A SCIENTIST How could you use germ-free genetically normal adult mice (mice without bacteria in their intestines) to test further the relationship between the bacterial population in genetically obese mice and obesity?

mitochondrial reactions). The fermentations generate various products, including alcohols, amino acids, and fatty acids, which are used as nutrients by the ruminants. Methane, another product, collects in the fermentation chambers. Ruminants belch the gas in huge quantities; a cow potentially can release more than 400 L of methane per day. In fact, cattle are estimated to contribute 20% of the methane polluting our atmosphere.

As part of the digestive process, a ruminant "chews its cud"—it regurgitates material from the rumen and reticulum, rechews it, and swallows it again (step 2). This process crushes the plants into smaller fragments, exposing more surface area to the microbial enzymes, and gives the enzymes more time to act. As a result, the food material is broken down further.

Reswallowed cud, consisting of matter that has been digested and liquefied by the microorganisms, bypasses the rumen and reticulum and instead goes to the **omasum,** where water is absorbed from the mass (step 3).

Matter then moves to the *abomasum* (the ruminant's gastric stomach) (step 4). There, the addition of acids and pepsin to the food mass kills the microorganisms and starts the process of typical vertebrate digestion. As the food mass moves to the small intestine, the dead microorganisms, which are a rich source of proteins, vitamins, and other nutrients, are digested and absorbed along with other hydrolyzable molecules in the digestive contents.

Although the ruminant digestive system is uniquely specialized, many other vertebrate species also have esophageal or gastric chambers containing plant-digesting symbiotic microorganisms. These include the camel, sloth, and langur monkey, and marsupials such as kangaroos and wallabies. One bird, the South American hoatzin *(Opisthocomus hoazin),* is known to have a crop in which microorganisms break down plant matter.

Many vertebrates house symbiotic, plant-digesting microorganisms in the cecum. Horses, elephants, rhinos, rabbits, koalas, many rodents, and some reptiles and birds, including the iguana and chicken, are all examples. However, because the cecum and the remainder of the large intestine have little capacity to absorb nutrients, microbial digestion in the cecum is not as productive as microbial digestion in the stomach.

Mutualistic microorganisms that synthesize essential amino acids and vitamins, and digest particular components of food that otherwise are indigestible, are found in all mammals. Recent research has demonstrated the importance of these microorganisms to nutrition. For example, **Figure 47.21** describes research experiments that correlate the particular array of bacteria in the human intestine with obesity.

We have seen that animals use various strategies to extract the available nutrients from foods. These nutritional strategies involve multiple steps combining both mechanical and chemical processing, which convert complex foodstuffs into the absorbable subunits that animals need to sustain life. Obtaining food is costly in terms of energy and risk, and animals have evolved many ways to make the most of it.

STUDY BREAK 47.5

1. How are the different types of teeth used in feeding?
2. What roles do symbiotic microorganisms play in digestion?

UNANSWERED QUESTIONS

How is energy partitioned in animals?

In this chapter you learned that ingested food molecules are broken down into smaller units that can be readily absorbed into body fluids and cells. The ingested energy is assimilated into the organism and partitioned into four main categories: maintenance metabolism, growth, reproduction, and storage. The top priority for energy allocation is maintenance metabolism—the energy required to seek and digest food and to support essential life processes. Researchers are studying the regulation of energy partitioning among the other categories when available energy exceeds that required for maintenance. The findings indicate that priorities for energy allocation vary between species as well as during an individual's life history. In the case of growth, for example, some species grow for a short period *(determinant growth),* while other species grow throughout their lives *(indeterminant growth).* Animal growth is controlled by genetic, environmental, and nutritional factors, but how such cues are integrated with each other and with other processes, such as reproduction and storage, remain to be determined. For example, the cues used to shut down growth and reproduction during fasting are not fully known. (In humans, malnourished juveniles become growth-retarded and adult females stop menstruating.) The extent to which severe energy restriction may result in metabolic adaptation (reduced metabolic rate) also needs to be examined.

How are foraging and feeding regulated?

In this chapter you also learned about the control of appetite and oxidative metabolism. While some of the players are known—among them hunger centers in the brain, appetite-stimulating hormones such as neuropeptide Y, and appetite-suppressing or satiety hormones such as leptin—a number of questions remain. For example, how are various sensory inputs, such as smell, integrated to initiate feeding? Similarly, how are other inputs, such as gut contents or increasing nutrient concentration in the blood, integrated to terminate feeding? Also, how is an animal's feeding strategy matched to nutrient quantity and quality in the environment and to the animal's metabolic pattern; for example, sluggish or active (tortoise or hare)? Inevitably, a complex of integrating chemicals—produced by the brain, gut, fat cells, and other tissues—will prove to be involved. Knowledge of this complex system will provide insight not only into obesity but into eating disorders such as anorexia as well.

How are lipids taken up and utilized?

Adipose and other cells take up lipids (mostly triglycerides) that have been hydrolyzed from chylomicrons and very-low-density lipoprotein (VLDL) by the enzyme lipoprotein lipase (LPL). Low-density lipoproteins (LDLs) are VLDL remnants and are the major means of delivering cholesterol to tissues. Normally, LDLs are taken up by receptor-mediated

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

endocytosis. Cholesterol can be scavenged by high-density lipoproteins (HDLs) through the action of the enzyme lecithin cholesterol acyltransferase (LCAT), taken up by the liver, and removed from the body. Researchers have found that defects in LPL, LCAT, and LDL disrupt normal lipid metabolism and lead to severe health risks. For example, genetic defects in the LDL receptor are associated with familial hypercholesterolemia, in which excess cholesterol is left in the blood and causes heart disease and other abnormalities. Continued research on lipid and lipoprotein metabolism will be important for understanding obesity, type 2 diabetes, and cardiovascular disease.

THINK LIKE A SCIENTIST

1. In the most general terms, how is allocation to maintenance metabolism different for tortoises and hares (hint: think temperature regulation)?
2. Given what you learned about lipids in the chapter on biological molecules, what is the importance of triglycerides in the diet of animals?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

47.1 Feeding and Nutrition

- Animals obtain organic molecules by eating other organisms. Herbivores primarily eat plants, carnivores primarily eat other animals, and omnivores eat animals, plants, and other sources of organic nutrients. The organic molecules are used as fuels for oxidative reactions providing energy and as building blocks for making complex biological molecules.
- Animals require essential substances in their diets—amino acids, fatty acids, vitamins, and minerals—that they cannot make for themselves.
- Animals may be classified with respect to feeding methods and the physical state of the organic molecules they eat. Fluid feeders ingest liquids containing organic molecules in solution. Suspension feeders eat small particles of organic matter or small organisms in suspension in fluids. Deposit feeders ingest small organic particles or organisms that are part of solid matter that the feeders live in or on. Bulk feeders consume large pieces of organisms, or entire large organisms (Figure 47.2).

47.2 Digestive Processes

- Digestion is the process of mechanical and chemical breakdown of food into molecular subunits small enough to be absorbed into body fluids and cells.
- Digestion may be intracellular or extracellular. Extracellular digestion allows food to be eaten in large batches, stored, and broken down while the animal carries out other activities.
- In animals with extracellular digestion, the digestive processes take place in an internal body cavity that is either a pouch or sac with one opening that serves as both mouth and anus, or a tube with two openings forming a mouth on one end and an anus on the other end (Figures 47.3 and 47.4).
- In animals with a digestive tract (also called digestive tube or gut), digestion occurs in five stages: (1) mechanical processing, including chewing and grinding of food; (2) secretion of enzymes and other digestive aids into the digestive tract; (3) enzymatic hydrolysis of food molecules into molecular subunits; (4) absorption of the molecular subunits across cell membranes; and (5) elimination of undigested matter.
- Food particles and molecules are pushed through the digestive tract by muscular contractions of its wall. Storage of food at various locations in the tube allows animals to digest food while engaged in other activities.

Animation: Examples of digestive systems

47.3 Digestion in Humans and Other Mammals

- Adult humans require 8 essential amino acids, 13 vitamins (Table 47.1), and a large number of essential minerals (Table 47.2).
- The mouth, pharynx, esophagus, stomach, intestine, and anus are common to the digestive system of mammals, including humans, and most vertebrates (Figure 47.5).
- The wall of the vertebrate digestive tract is formed from four layers of tissues: the mucosa, the submucosa, the muscularis, and the serosa (Figure 47.7).
- Coordinated contractions of the circular and smooth muscles produce peristaltic waves that move the digestive contents from the mouth to the anus (Figure 47.8).
- The enzymatic digestion of carbohydrates, proteins, and fat take place in particular regions of the human digestive tract (Figure 47.9)
- Digestion begins in the mouth, where the teeth break the food into smaller bits. Salivary amylase, an enzyme that digests starch, is secreted into the food in the mouth. After chewing, the food is swallowed and travels through the pharynx and esophagus to reach the stomach (Figure 47.10).
- In the stomach, hydrochloric acid, the protein-digesting enzyme pepsin, and mucus are added to the food mass. The stomach churns the acid contents into chyme, which is released in pulses into the small intestine (Figure 47.11).
- Absorption of nutrients begins in the small intestine. Specializations of the small intestine to optimize absorption are the intestinal villi and microvilli (Figure 47.12).
- In the small intestine, digestive juices from the pancreas and liver add enzymes and digestive aids to the food mass (Figure 47.13). The pancreatic juice contains digestive enzymes and bicarbonate ions that neutralize the acidity of the digestive contents. The liver secretion, bile, contains bile salts, which emulsify fats, cholesterol, bilirubin, and additional bicarbonate ions.

- Fat is digested to completion in the small intestine. Completion of carbohydrate and protein digestion is done by digestive enzymes that are embedded in the plasma membranes of the brush-border cells of the small intestine mucosa as the incompletely digested molecules are absorbed by those cells. The final products of digestion exit the cells and enter the bloodstream (Figure 47.14).
- The digestion products of fat digestion, the monoglycerides and fatty acids, are coated with bile salts to form microdroplets (micelles) that deliver the products to the brush-border epithelial cells. The monoglycerides and fatty acids enter the cells where they are used to resynthesize triglycerides. These are coated with a layer of lipoproteins to form chylomicrons, which leave the epithelial cell and enter the lymphatic system (Figure 47.15).
- Absorbed nutrients are delivered to the liver, where excess glucose is converted into glycogen and fats, and some of the amino acids are converted into plasma proteins or sugars. The liver also synthesizes cholesterol from lipids, carbohydrates, and other substances.
- The large intestine absorbs water and mineral ions from the digestive contents. At the end of the large intestine the undigested remnants, the feces, are expelled from the anus (Figure 47.16).

47.4 Regulation of the Digestive Process

- Digestion is regulated by signals from the autonomic nervous system, by the activity of neuron networks in the digestive tube wall, and by hormones secreted by the digestive system. The regulatory mechanisms operate in response to signals from sensory receptors that monitor the volume and composition of the digestive contents (Figure 47.17).

Animation: Chronology of leptin research

47.5 Digestive Specializations in Vertebrates

- Common variations in vertebrate digestive systems include modifications of the teeth, length of the digestive tract, and structure and function of the stomach.
- Mammals have four basic types of teeth—incisors for cutting, canines for piercing, and premolars and molars for cutting, grinding, and smashing food (Figure 47.18).
- Carnivores and vertebrates that eat other nutrient-rich foods have a relatively short digestive tract. Herbivores, which eat nutrient-poor foods, typically have a relatively long digestive tract that includes extensive storage regions (Figure 47.19).
- Many herbivores have digestive chambers in which symbiotic microorganisms digest plant matter into molecules that can be absorbed by the host (Figure 47.20).

UNDERSTAND & APPLY

Test Your Knowledge

1. Required molecules that animals cannot synthesize are called:
   a. nutrients.
   b. essential nutrients.
   c. enzymes.
   d. proteins.
   e. carbohydrates.
2. Which of the following accurately describes a feeding style?
   a. Deposit feeders obtain nutrients from organic molecules in solution.
   b. Deposit feeders scrape organic matter from solid material on which they live.
   c. Fluid feeders digest organisms suspended in water.
   d. Fluid feeders strain food with networks of mucus or bristles and hairs.
   e. Suspension feeders consume sizable food whole or in chunks.
3. The order of successive steps in digestion is:
   a. absorption follows enzymatic hydrolysis.
   b. secretion of enzymes follows absorption of digestive material.
   c. mechanical processing follows enzyme secretion.
   d. mechanical processing follows enzymatic hydrolysis.
   e. enzymatic hydrolysis precedes secretion of digestive aids.
4. The esophagus, crop, gizzard, and intestine are found in:
   a. birds and mammals.
   b. insects and mammals.
   c. flatworms and birds.
   d. earthworms and birds.
   e. sponges and cnidarians.
5. Which of the following is *not* an essential nutrient in humans?
   a. vitamin B
   b. calcium
   c. glycogen
   d. linoleic acid
   e. vitamin K
6. A specialized region of the digestive tract is/are the:
   a. submucosa formed by circular and longitudinal layers.
   b. serosa lining the digestive tract for absorption.
   c. mucosa composed of thick, elastic connective tissue for movement.
   d. muscularis, an outer layer that secretes a slippery material to prevent friction with other organs.
   e. sphincters, which form valves between major digestive organs.
7. If the fat in whole milk is ingested:
   a. the stomach, with its high pH, will stimulate cells of the duodenum to hasten stomach emptying.
   b. parietal cells in the stomach will absorb it.
   c. in the small intestine, bile salts emulsify the fats and then lipase hydrolyzes them.
   d. lactase deficiency in the small intestine would prevent its digestion.
   e. microvilli will absorb the fat in the form of chylomicrons directly into the blood of the hepatic portal vein.
8. The role of the liver in digestion is to:
   a. synthesize aminopeptidase and dipeptidase to digest polypeptides.
   b. synthesize lipase to form free fatty acids.
   c. secrete trypsin to break the bonds in polypeptides.
   d. secrete bile and bicarbonate ions to help emulsify fats.
   e. store bile between meals.

9. Which of the following best describes regulation of digestion?
   a. GIP inhibits insulin release from the pancreas.
   b. Gastrin stimulates pancreatic secretion of HCl and pepsinogen.
   c. Secretin stimulates gastric emptying into the duodenum.
   d. CCK stimulates gastric activity to activate the duodenum.
   e. Leptin binds different hypothalamic receptors to stimulate or inhibit appetite.
10. An example of a digestive specialization is seen in:
   a. the long intestines characteristic of herbivores.
   b. the incisors being the dominant teeth in wolves.
   c. the canine teeth being the dominant teeth in deer.
   d. salivary lipase being made by humans.
   e. cellulose being made by humans.

Discuss the Concepts

1. As a person ages, the number of cells in the body steadily decreases and their energy needs decline. If you were planning a diet for an older person, what kind(s) of nutrients would you emphasize, and why? Which ones would you recommend the person consume less of? Include vitamins and minerals in your answer.
2. Formulate a healthy diet for a young, actively growing 7-year-old child, and explain why you have included each part of the diet. Refer to Question 1, above, for some issues to consider.
3. A baby develops symptoms of protein deficiency, and the attending physician suggests the cause is a genetic defect leading to a nonfunctional enzyme associated with digestion. Name at least three enzymes that might be likely suspects, and for each one explain how the defect would result in a protein deficiency.

Design an Experiment

Design experiments to test whether cigarette smoke affects the functioning of the various parts of the digestive system.

Interpret the Data

The human *AMY-1* gene encodes salivary amylase, an enzyme that breaks down starch. The number of copies of this gene varies, and people who have more copies generally make more of the enzyme. In addition, the average number of *AMY-1* copies differs among cultural groups.

George Perry and his colleagues hypothesized that duplications of the *AMY-1* gene would confer a selective advantage in cultures in which starch is a large part of the diet. To test this hypothesis, the scientists compared the number of copies of the *AMY-1* gene among members of seven cultural groups that differed in their traditional diets. The **Figure** shows their results.

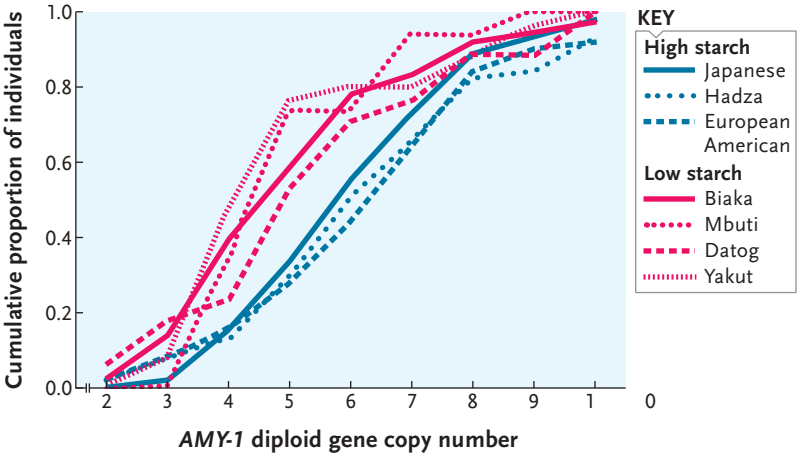

FIGURE **Number of copies of the *AMY-1* gene among members of cultures with traditional high-starch or low-starch diets.** The Hadza, Biaka, Mbuti, and Datog are tribes in Africa. The Yakut live in Siberia.

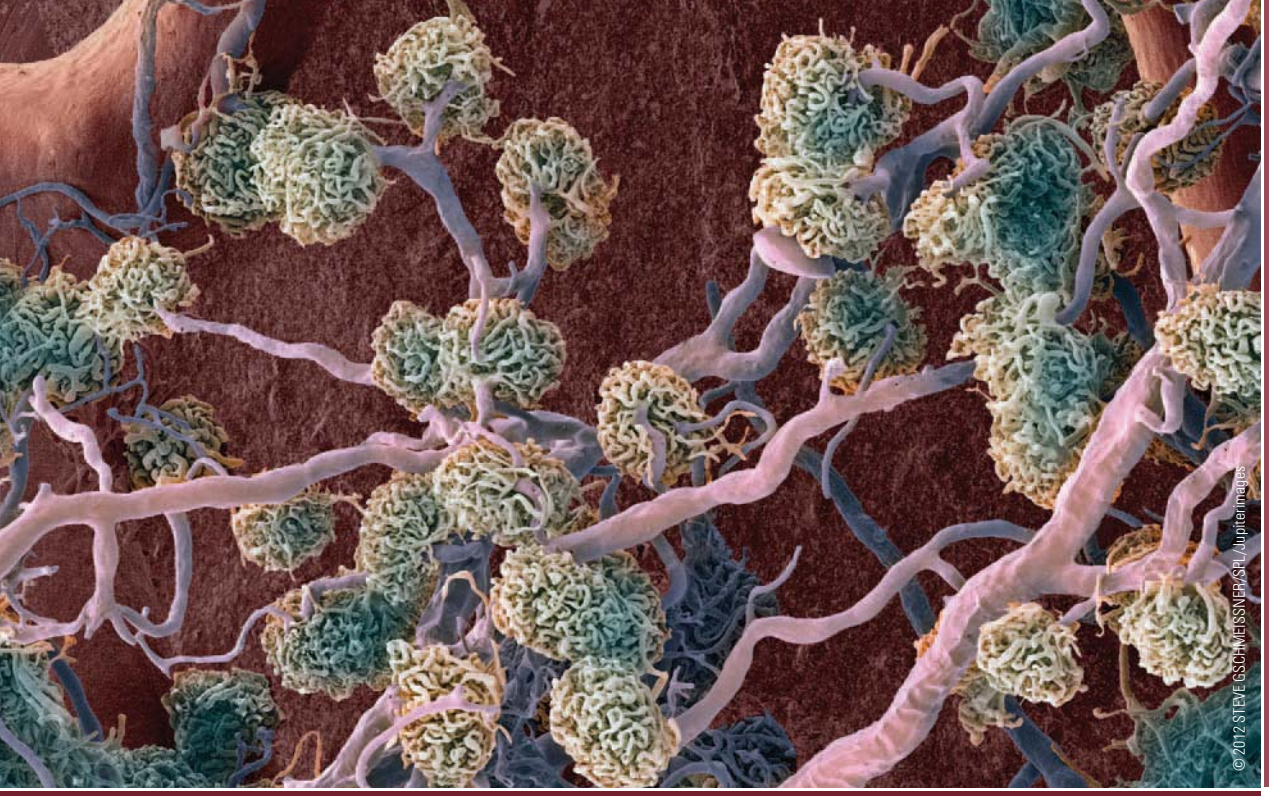
Reprinted by permission from Macmillan Publishers Ltd: G. Perry et al. 2007. Diet and the evolution of human amylase gene copy number variation. *Nature Genetics* 39:1256–1260.



1. Starchy tubers are a mainstay of Hadza hunter-gatherers in Africa, whereas fishing sustains Siberia's Yakut. Almost 60% of Yakut had fewer than 5 copies of the *AMY-1* gene. What percentage of the Hadza had fewer than 5 copies?
2. None of the Mbuti (rainforest hunter–gatherers) had more than 10 copies of *AMY-1*. Did any European Americans have more than 10 copies of *AMY-1*?
3. Do these data support the hypothesis that a starchy diet favors duplications of the *AMY-1* gene?

Source: G. Perry et al. 2007. Diet and the evolution of human amylase gene copy number variation. *Nature Genetics* 39:1256–1260.

Apply Evolutionary Thinking

What is the advantage of a tubelike digestive system over a saclike digestive system?

Regulating the Internal Environment

Why it matters . . . The nine crew of the World War II bomber *Lady Be Good* flew a night mission to Naples, Italy, from a base on the North African coast on August 4, 1943. Trouble during the flight forced the crew to turn back before reaching their destination. Navigational errors and a cloud layer led them to miss their home base and continue south over the Sahara Desert. Some 440 miles from the coastline, with the fuel running out, the crew members parachuted from the aircraft. In a few more minutes, the bomber crash-landed, leaving its crew miles behind.

The eight men who survived began a northward trek with only half a canteen of water among them, in desert heat that reached 130°F during the day. In a testimony to the physiological mechanisms that conserve water and cool the body, they continued onward for eight days. But then, one by one, they died as prolonged dehydration and the heat overwhelmed their homeostatic control systems for *water balance* (the equilibrium in inward and outward flow of water) and temperature regulation, and hyperthermia exceeded their capacity to survive. Rescue teams searched the desert for weeks after their disappearance, but no trace was found of the crew or their airplane.

The fate of the *Lady Be Good* remained unknown until 1958, when the aircraft was spotted from the air, sitting largely intact in the desert sands. A two-year search led to the remains of the crew, some of them more than a hundred miles north of the downed bomber. Diaries found among the scattered effects told the poignant story of the flight and the futile struggle against the fiery desert environment.

This story illustrates the trials of animal life under changing environmental conditions. Water and required nutrients may become more or less abundant. Temperatures may rise or fall. Through their homeostatic control systems, animals have an astounding capacity to compensate

for fluctuating external conditions and to maintain the internal environment of their bodies within the relatively narrow limits that cells can tolerate (homeostasis is discussed in Chapter 38).

These limits, and the compensating mechanisms that maintain them, are the subjects of this chapter. First we examine **osmoregulation,** the control of water and ion balance, and the closely related topic of **excretion,** which helps maintain the body's water and ion balance while ridding the body of metabolic wastes. Then we consider **thermoregulation,** the control of body temperature.

48.1 Introduction to Osmoregulation and Excretion

Living cells contain water, are surrounded by water, and constantly exchange water with their environment. For the simplest animals, the water of the external environment surrounds cells directly. For more complex animals, an aqueous extracellular fluid (ECF) surrounds the cells, and is separated from the external environment by a body covering. In animals with a circulatory system, the ECF includes both the interstitial fluid immediately surrounding cells and the plasma, the fluid portion of the blood, or other circulated fluid.

In this section, we review the mechanisms cells use to exchange water and solutes with the surrounding fluid through osmosis and diffusion.

Osmosis Is a Form of Passive Diffusion

In osmosis (see Section 6.3 and Figures 6.9 and 6.10), water molecules move across a selectively permeable membrane from a region where they are more highly concentrated to a region where they are less highly concentrated. The difference in water concentration is produced by differing numbers of solute molecules or ions on the two sides of the membrane. The side of the membrane with a *lower* solute concentration has a *higher* concentration of water molecules, so water will move osmotically to the other side, where water concentration is *lower.*

A key factor in osmosis for helping maintain differences in solute concentration on either side of biological membranes is the selective permeability of those membranes. Proteins are among the most important solutes in establishing the conditions that produce osmosis.

The total solute concentration of a solution, called its **osmolarity,** is measured in *osmoles*—the number of solute molecules and ions (in moles)—per liter of solution. Because the total solute concentration in the body fluids of most animals is less than 1 osmole, osmolarity is usually expressed in thousandths of an osmole, or *milliosmoles* (mOsm). As shown in

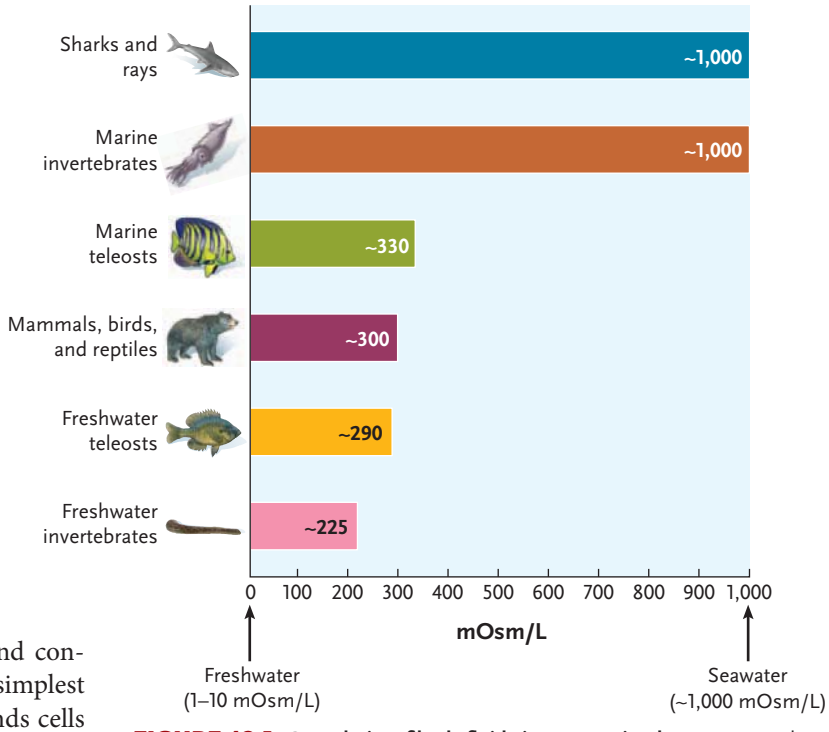

FIGURE 48.1 Osmolarity of body fluids in some animal groups. Reptiles include turtles, lizards, and snakes.

© Cengage Learning 2014

Figure 48.1, the osmolarity of body fluids in humans and other mammals is about 300 mOsm/L; marine fishes and marine invertebrates have higher values and freshwater fishes and freshwater invertebrates have lower values.

Considering solutions on either side of a selectively permeable membrane, a solution of higher osmolarity is said to be *hyperosmotic* to a solution of lower osmolarity, and a solution of lower osmolarity is said to be *hypoosmotic* to a solution of higher osmolarity. If the solutions on either side of a membrane have the same osmolarity, they are said to be *isoosmotic.* Water moves across the membrane between solutions that differ in osmolarity (see Figure 6.9), whereas when two solutions are isoosmotic, no net water movement occurs.

Animals Use Different Approaches to Keep Osmosis from Swelling or Shrinking Their Cells

For metabolic stability, animals must keep their cellular fluids and ECFs isoosmotic. In some animals, called **osmoconformers,** the osmolarity of the cellular and extracellular solutions matches the osmolarity of the environment. Most marine invertebrates are osmoconformers. Other animals, called **osmoregulators,** use control mechanisms to keep the osmolarity of cellular and extracellular fluids the same, but at levels that may differ from the osmolarity of the surroundings. Most freshwater and terrestrial invertebrates, and almost all vertebrates, are osmoregulators.

For terrestrial animals, one of the greatest challenges to osmoregulation is the limited supply of water in the environment, as the crew of the *Lady Be Good* experienced.

Excretion Is Closely Tied to Osmoregulation

Control over osmolarity is maintained partly by removing certain molecules and ions from cells and body fluids and releasing them into the environment; thus, excretion is closely related to osmoregulation. Animals excrete H^+ ions to keep the pH of body fluids near the neutral levels required by cells for survival. They also excrete toxic products of metabolism, such as nitrogenous (nitrogen-containing) compounds resulting from the breakdown of proteins and nucleic acids, and breakdown products of poisons and toxins. Excretion of ions and metabolic products is accompanied by water excretion because water serves as a solvent for those molecules. Animals that take in large amounts of water may also excrete water to maintain osmolarity.

Microscopic Tubules Form the Basis of Excretion in Most Animals

Except in the simplest animals, minute tubular structures carry out osmoregulation and excretion **(Figure 48.2).** The tubules are immersed in body fluids at one end (the *proximal end* of the tubules), and open directly or indirectly to the body exterior at the other end (the *distal end* of the tubules). The tubules are formed from a **transport epithelium**—a layer of cells with specialized transport proteins in their plasma membranes. The transport proteins move specific molecules and ions into and out of the tubule by either active or passive transport, depending on the particular substance and its concentration gradient.

Typically, the tubules function in a four-step process:

1. **Filtration.** Filtration is the nonselective movement of water and a number of solutes—ions and small molecules, but not large molecules such as proteins—into the proximal end of the tubules through spaces between cells. In animals with an open circulatory system, the water and solutes come from body fluids, with movement into the tubules driven by the higher pressure of the body fluids compared with the fluid inside the tubule. (The pressure here is the hydrostatic pressure of the plasma in the capillaries; that is, blood pressure.) In animals with a closed circulatory system, such as humans, the water and solutes from the capillary blood plasma exchange with the intratubular fluid, with the movement into the tubules similarly driven by hydrostatic pressure. (Open and closed circulatory systems are described in Section 44.1.)
2. **Tubular reabsorption.** Tubular reabsorption is a selective process in which some molecules (for example, glucose and amino acids) and ions are transported by the transport epithelium from the lumen of the tubule back into the ECF and eventually into the blood (in animals with closed circulatory systems) as the filtered solution moves through the excretory tubule.
3. **Tubular secretion.** Tubular secretion is a selective process in which specific small molecules and ions are transported from the ECF and blood into the tubules. Both tubular secretion and filtration play an important role in eliminating substances from the body fluid or blood. The difference between the two processes is that filtration is nonselective whereas tubular secretion is selective for substances transported.
4. **Release.** The fluid containing waste materials—urine—is released into the environment from the distal end of the tubule. In some animals, the fluid is stored in a bladder; in others, it is concentrated into a solid or semisolid form.

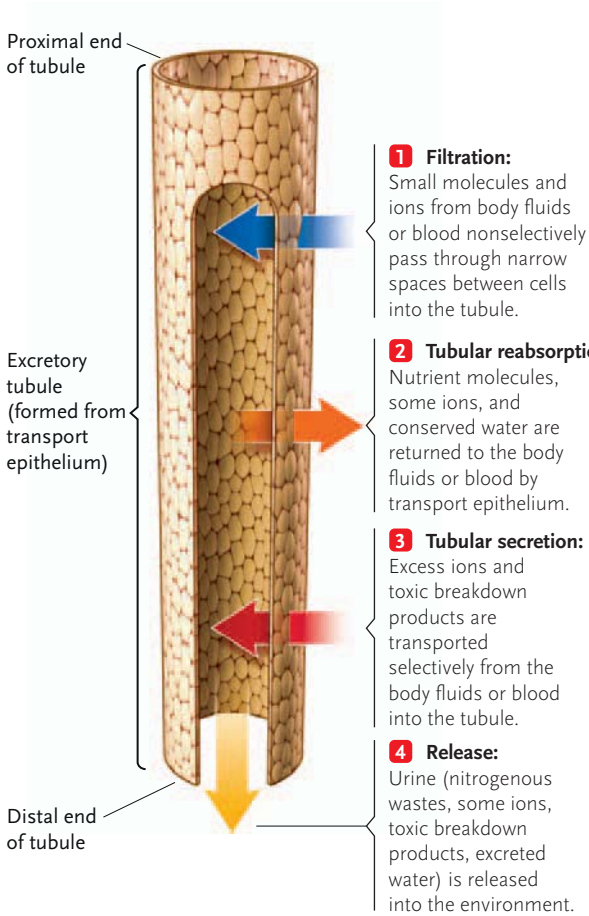

FIGURE 48.2 Common structures and operations of the tubules carrying out osmoregulation and excretion in animals. The tubules are typically formed from a single layer of cells with transport functions.

© Cengage Learning 2014

In all vertebrates and many invertebrates, the excretory tubules are concentrated in specialized organs, the *kidneys,* which are discussed in later sections.

Animals Excrete Nitrogen Compounds as Metabolic Wastes

The metabolism of ingested food is a source of both energy and molecules for the biosynthetic activities of an animal. Importantly, metabolism of ingested food produces water—called *metabolic water*—that is used in chemical reactions and is involved in physiological processes such as the excretion of wastes.

The nitrogenous products of the breakdown of proteins, amino acids, and nucleic acids are excreted by most animals as

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ammonia, urea, or *uric acid,* or a combination of these substances **(Figure 48.3).** The particular molecule or combination of molecules produced depends on a balance among toxicity, water conservation, and energy requirements.

AMMONIA Ammonia (NH_3) forms by a series of biochemical steps beginning with the removal of amino groups ($—NH_3^+$) from amino acids as a part of protein breakdown. Ammonia is readily soluble in water, but it is also highly toxic. Therefore, ammonia must either be excreted or converted to a nontoxic derivative. However, because of its toxicity, ammonia can be excreted from the body only in dilute solutions, making this path possible only in animals with a plentiful supply of water. Those animals include aquatic invertebrates, teleosts, and larval amphibians.

UREA All mammals, most amphibians, turtles, some marine fishes, and some terrestrial invertebrates combine ammonia with HCO_3^- and convert the product in a series of steps to *urea,* a soluble and relatively nontoxic substance. Although producing urea requires more energy than forming ammonia, excreting urea instead of ammonia requires only about 10% as much water.

URIC ACID Water is conserved further in some animals, including terrestrial invertebrates, lizards and snakes, and birds, by the formation of uric acid instead of ammonia or urea. Uric acid is nontoxic, and so insoluble that it precipitates in water as a crystal. (The white substance in bird droppings is uric acid.) The embryos of reptiles and birds also conserve water by forming uric acid, which is stored as a waste product.

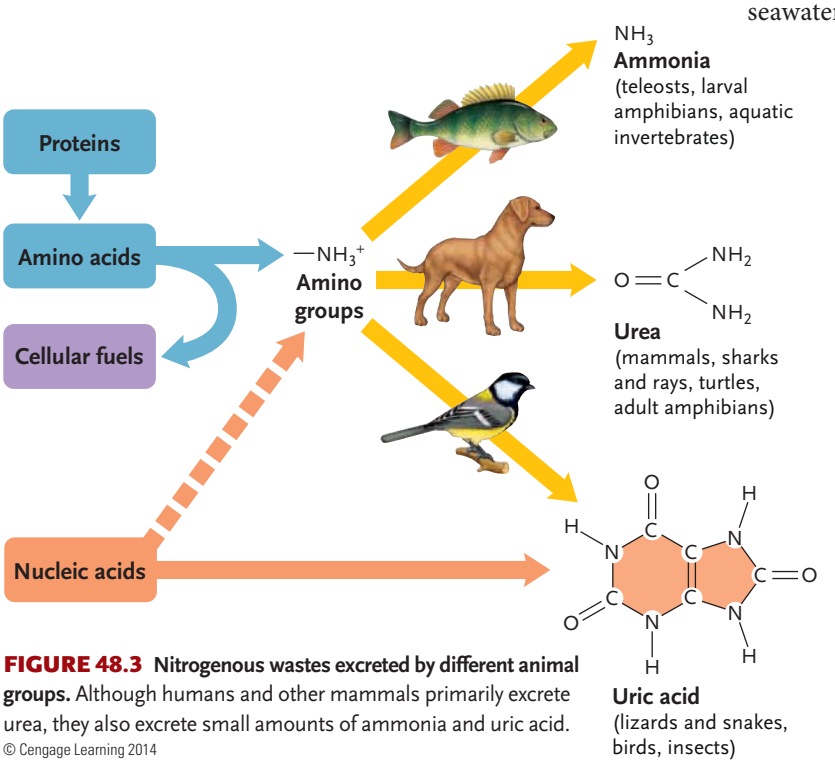

FIGURE 48.3 Nitrogenous wastes excreted by different animal groups. Although humans and other mammals primarily excrete urea, they also excrete small amounts of ammonia and uric acid.

© Cengage Learning 2014

Although making uric acid requires even more energy than making urea, molecule for molecule it contains four times as much nitrogen as ammonia. And, because uric acid precipitates from water, it can be excreted as a concentrated paste. These factors conserve about 99% of the water that would be required to excrete an equivalent amount of nitrogen as ammonia.

In the sections that follow, we look at the specifics of osmoregulation and excretion in different animal groups, beginning with the invertebrates.

STUDY BREAK 48.1

Define the terms *osmosis, osmolarity, hypoosmotic, osmoregulator,* and *transport epithelium.*

48.2 Osmoregulation and Excretion in Invertebrates

Except for the simplest groups, most invertebrates, whether osmoconformers or osmoregulators, carry out excretion by specialized excretory tubules.

Most Marine Invertebrates Are Osmoconformers; All Freshwater and Terrestrial Invertebrates Are Osmoregulators

Most marine invertebrates are osmoconformers. They release water, certain ions, and nitrogenous wastes—usually in the form of ammonia—directly from body cells to the surrounding seawater. The cells of these animals do not swell or shrink because the osmolarity of their intracellular and extracellular fluids and the surrounding seawater is the same, about 1,000 mOsm/L. Therefore, they do not have to expend energy to maintain their osmolarity. However, osmoconformers do expend energy to keep some ions, such as Na^+, at lower concentrations inside cells than in the surroundings.

By contrast, all freshwater invertebrates are osmoregulators because their cells could not survive if their internal ion concentrations were reduced to freshwater levels. These animals must expend energy to keep their internal fluids hyperosmotic to their surroundings. Although osmoregulation is energetically expensive, these invertebrates can live in more varied habitats than can osmoconformers.

Freshwater osmoregulators such as flatworms and mussels have cellular and extracellular fluids with an osmolarity higher than that of the external environment. This condition causes water to move constantly from the surroundings into their bodies. This excess water must be excreted, at a considerable cost in energy, to maintain the hyperosmotic state of their body fluids.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

These animals must also obtain the salts required to keep their body fluids hyperosmotic to fresh water. The salts are obtained from foods, and by actively transporting salt ions from the water into their bodies (even fresh water contains some dissolved salts). This active ion transport occurs through the skin or gills.

Terrestrial annelids (earthworms), arthropods (insects, spiders and mites, millipedes, and centipedes), and mollusks (land snails and slugs) must obtain salts from their surroundings, usually in their foods. Although they do not have to excrete water entering by osmosis, they must constantly replace water lost from their bodies.

In Invertebrate Osmoregulators, Specialized Excretory Tubules Participate in Osmoregulation and Carry Out Excretion

Invertebrate osmoregulators typically use specialized tubules for carrying out excretion. Three common types of these specialized tubules are *protonephridia,* found in flatworms and larval mollusks; *metanephridia,* found in annelids and most adult mollusks; and *Malpighian tubules,* found in insects and other arthropods. Each processes body fluids in a different way.

PROTONEPHRIDIA The flatworm *Dugesia* provides an example of the simplest form of invertebrate excretory tubule, the **protonephridium** (*protos* = first; *nephros* = kidney). In *Dugesia,* two branching networks of protonephridia run the length of the body **(Figure 48.4).** The proximal branches of the tubule network end with a *flame cell* containing a bundle of cilia that extend into the tubule and beat to move fluid through the tubule. When the hemolymph, the invertebrate equivalent to blood, passes through the protonephridia, some molecules and ions are reabsorbed and others, including nitrogenous wastes, are secreted into the tubules. The urine resulting from this filtration system is released through pores at the distal ends of the tubules where they reach the body surface.

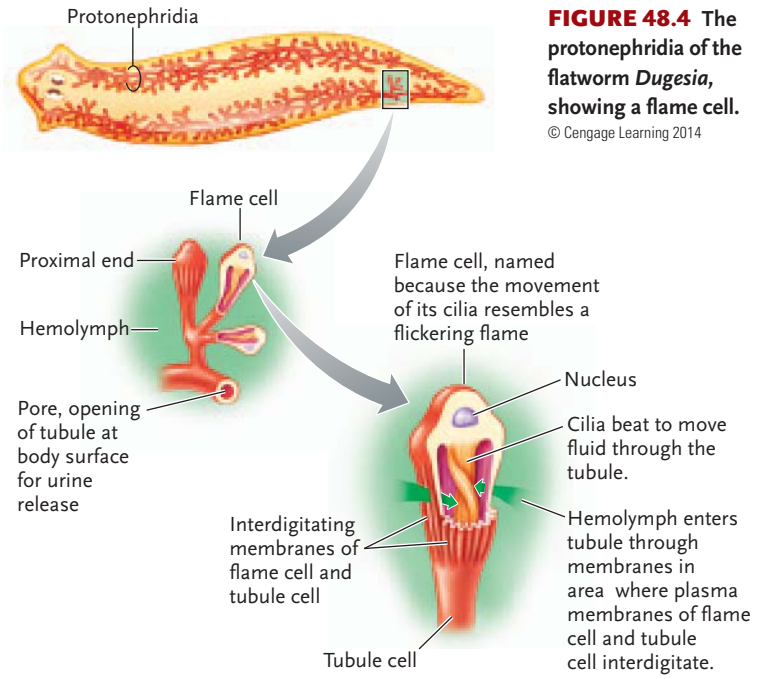

FIGURE 48.4 The protonephridia of the flatworm *Dugesia,* showing a flame cell.
© Cengage Learning 2014

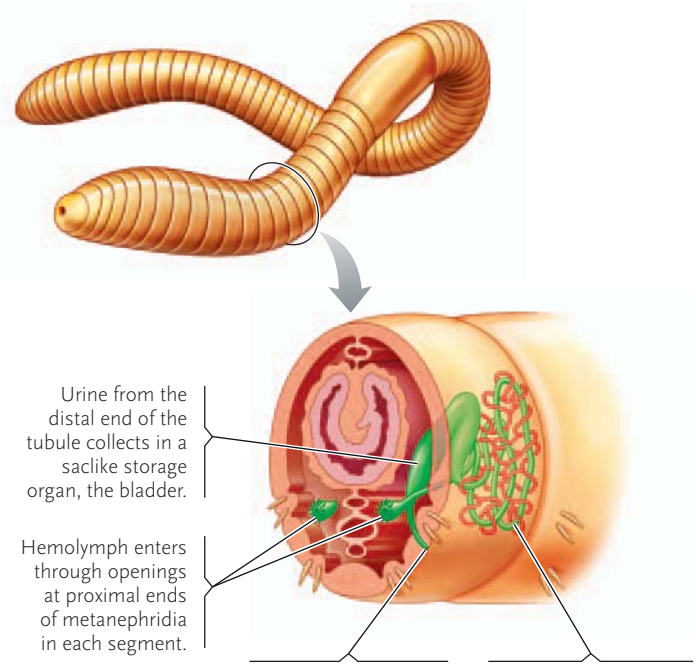

FIGURE 48.5 The metanephridium of an earthworm.
© Cengage Learning 2014

METANEPHRIDIA The excretory tubule of most annelids and adult mollusks, the **metanephridium** (*meta* = between), has a funnel-like proximal end surrounded with cilia that admits hemolymph. Like protonephridia, metanephridia are filtration systems. As hemolymph moves through the tubule, some molecules and ions are reabsorbed and other ions and nitrogenous wastes are secreted into the tubule and excreted from the distal end at the body surface.

Figure 48.5 shows the arrangement and operation of metanephridia in an earthworm. The proximal ends of a pair of metanephridia are located in each body segment, one on either side of the animal. Each tubule of the pair extends into the following segment, where it bends and folds into a convoluted arrangement surrounded by a network of blood vessels.

MALPIGHIAN TUBULES The excretory tubule of insects, the Malpighian tubule, has a closed proximal end that is immersed in the hemolymph **(Figure 48.6).** The distal ends of the tubules empty into the gut. Unlike other excretory systems, Malpighian tubules do not use pressure for the filtration step. Instead, they secrete K^+ into the lumen of the proximal segment, which makes the tubule fluid more positively charged and draws in Cl^- ions from the hemolymph surrounding the tubule. The accumulation of KCl makes the tubule fluid more concentrated, causing water from the hemolymph to move in by osmosis. Now organic wastes, in particular

© Cengage Learning 2014

uric acid, are secreted into the tubule. The tubule empties into the gut. When the fluid reaches the hindgut and rectum, K^+ and Cl^- are reabsorbed, followed by water. As the water is removed, uric acid precipitates as crystals, which mix with the undigested matter in the rectum and are released with the feces. In this way, nitrogenous waste excretion is accomplished with minimal water loss.

STUDY BREAK 48.2

How are protonephridia, metanephridia, and Malpighian tubules different? In which animal groups are each of these excretory tubules found?

48.3 Osmoregulation and Excretion in Mammals

In all vertebrates, specialized excretory tubules contribute to osmoregulation and carry out excretion. The excretory tubules, called **nephrons,** are located in a specialized organ, the kidney.

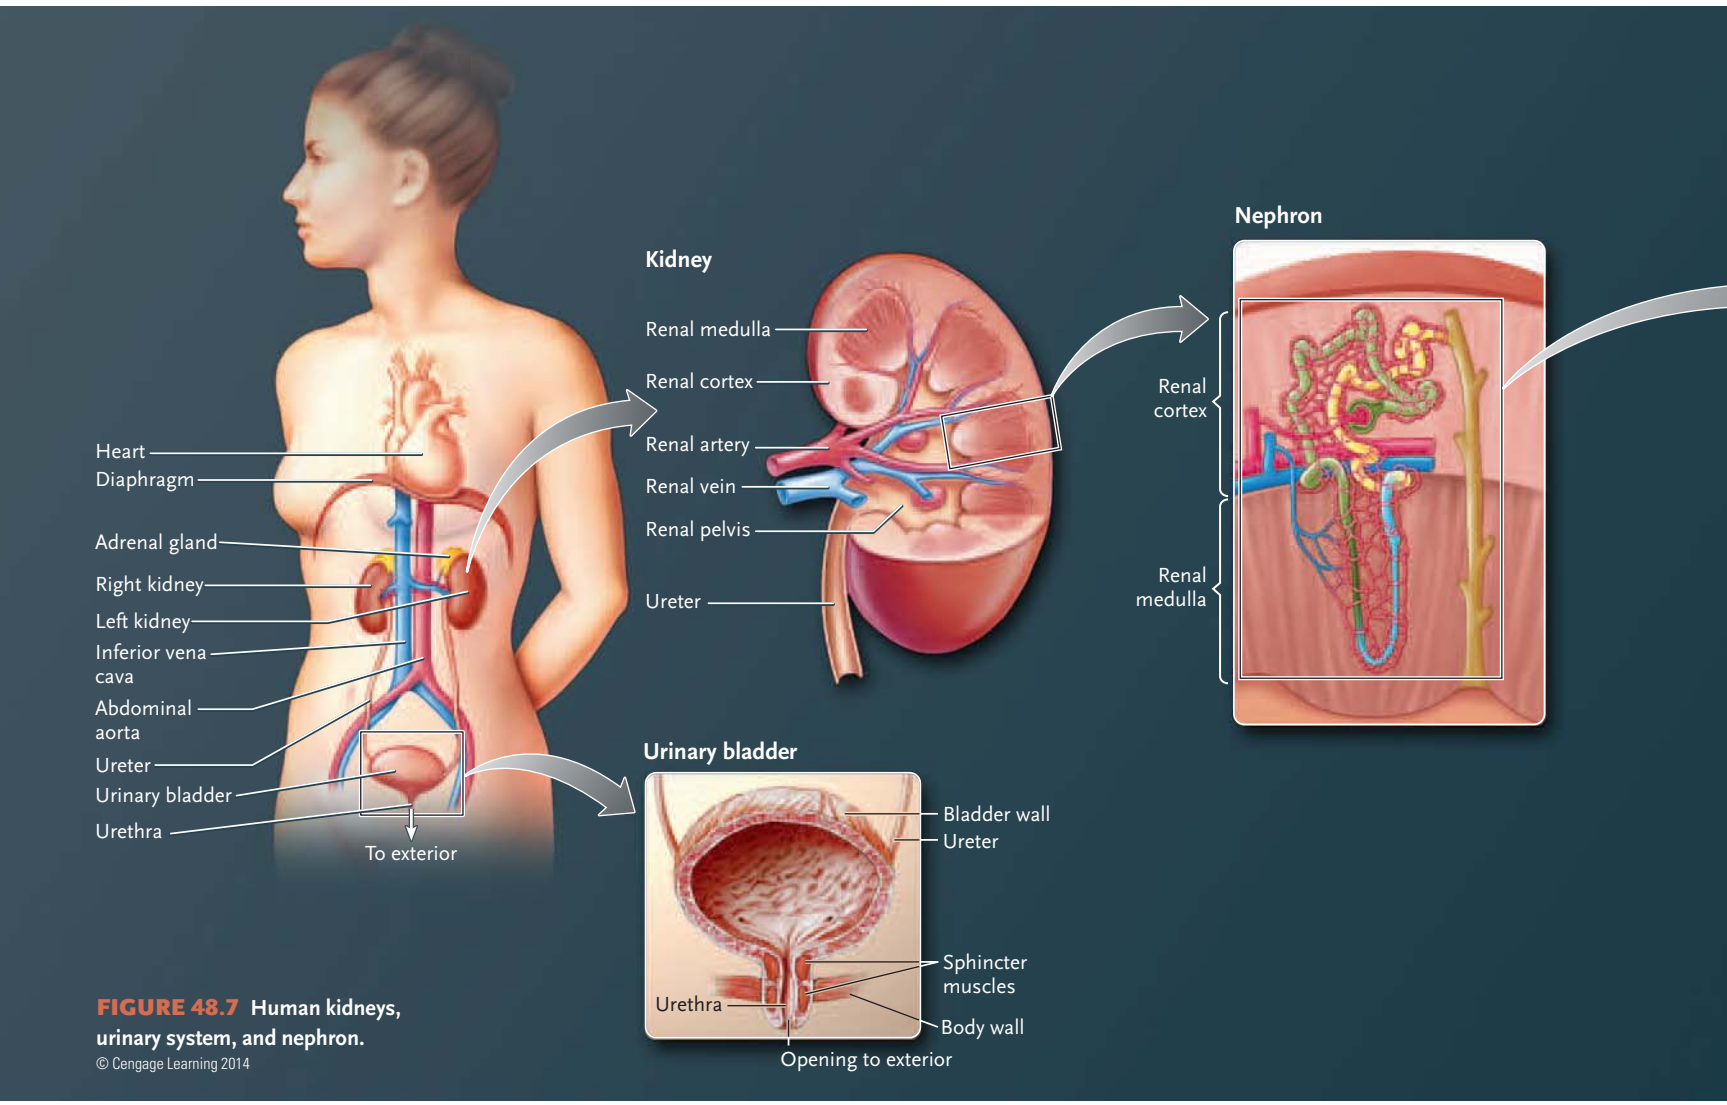

FIGURE 48.7 **Human kidneys, urinary system, and nephron.**

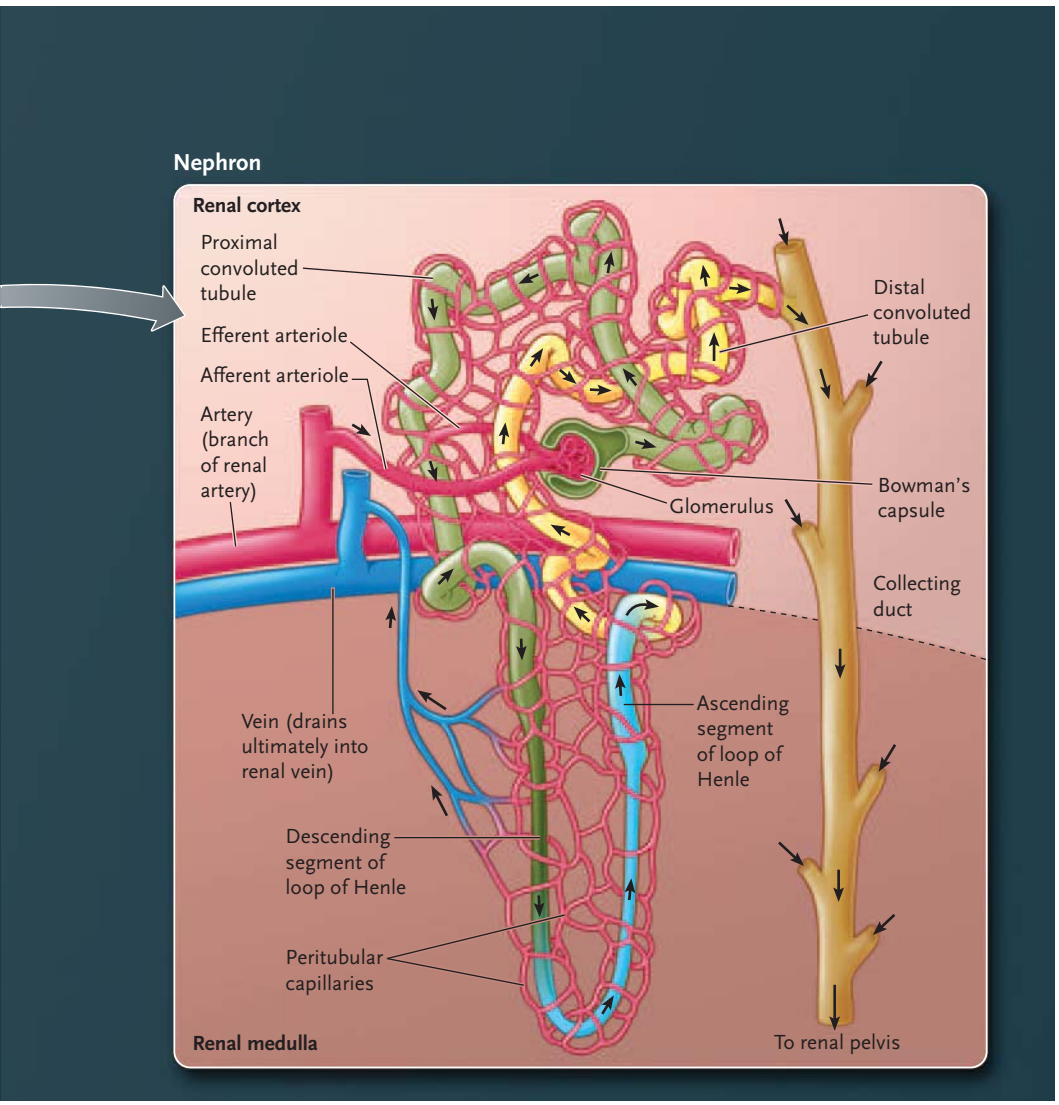
We begin our survey of vertebrate osmoregulation and excretion with a description of the structure and function of the mammalian kidney.

The Kidneys and Ureters, the Bladder, and the Urethra Form the Urinary System

Mammals have a pair of kidneys, located on either side of the vertebral column at the back of the abdominal cavity **(Figure 48.7).** Internally, the mammalian kidney is divided into an outer **renal cortex** surrounding a central region, the **renal medulla.**



The **renal artery** carries blood into the kidney, where metabolic wastes and excess ions are moved into urine. The filtered blood is routed away from the kidney by the **renal vein.** The urine leaving individual nephrons is processed further in **collecting ducts** and then drains into a central cavity in the kidney called the **renal pelvis.**

From the renal pelvis, the urine flows through a duct called the **ureter** to the **urinary bladder,** a storage sac located outside the kidneys. Urine leaves the bladder through the **urethra,** a tube that (in most mammals) opens to the outside. In human females, the opening of the urethra is just in front of the vagina; in males, the urethra opens at the tip of the penis. The two kidneys and ureters, the urinary bladder, and the urethra constitute the mammalian urinary system.

Two sphincter muscles control the flow of urine from the bladder to the urethra. In human infants, urination is an autonomic reflex triggered by stretch receptors in the bladder wall. When the bladder becomes full, the sphincters relax, smooth muscles in the bladder wall contract, and the urine is forced to the exterior. At about the age of two years, children learn to override the autonomic reflex by consciously contracting their sphincters until urination is convenient.

Mammalian Nephrons Are Differentiated into Regions with Specialized Functions

Each human kidney has more than a million nephrons. Nephrons are differentiated into regions that perform successive steps in excretion. At its proximal end, a human nephron forms the **Bowman's capsule,** an infolded region that cups around a ball of arterial capillaries called the **glomerulus** (see Figure 48.7). The capsule and glomerulus are located in the renal cortex. As blood flows through the glomerulus, plasma filters through the glomerular capillaries into Bowman's capsule; this process, called **glomerular filtration,** is the first step of urine formation.

Following Bowman's capsule, the nephron forms a **proximal convoluted tubule** that descends into the renal medulla in a U-shaped bend called the **loop of Henle** and then ascends again to form a **distal convoluted tubule.** The distal tubule drains the urine into a collecting duct that leads to the renal pelvis. As many as eight nephrons may drain into a single collecting duct. The combined activities of the proximal convoluted tubule, the loop of Henle, the distal convoluted tubule, and the collecting duct convert the filtrate entering the nephron into urine.

Unlike most capillaries in the body, the capillaries in the glomerulus do not lead directly to venules. Instead, they form another arteriole that branches into a second capillary network called the **peritubular capillaries.** These capillaries thread around the proximal and distal convoluted tubules and the loop of Henle. Molecules and ions that are reabsorbed from the filtrate are transferred indirectly between the nephron and the peritubular capillaries. First, the molecules or ions pass through the one-cell-thick wall of the tubule, then they diffuse through the interstitial fluid, and finally they pass into the capillary through its one-cell-thick wall.

Mammalian Nephrons Interact with Surrounding Kidney Structures to Produce Hyperosmotic Urine

In mammals, urine is hyperosmotic to body fluids. All other vertebrates except for a few aquatic bird species produce urine that is hypoosmotic (or isoosmotic) to body fluids. Production of hyperosmotic urine is a water-conserving adaptation involving an interaction between the activities of the mammalian nephrons and the highly ordered structure of the mammalian kidney. Three features underlie this interaction:

1. The arrangement of the loop of Henle, which descends through the medulla and returns to the cortex again.
2. Differences in the permeability of successive regions of the nephron, established by a specific group of membrane transport proteins in each region.
3. A gradient in the concentration of molecules and ions in the interstitial fluid of the kidney, which increases gradually from the renal cortex to the deepest levels of the renal medulla.

These features interact to conserve nutrients and water, balance salts, and concentrate wastes for excretion from the body.

Three processes are involved in forming urine: *glomerular filtration, tubular reabsorption,* and *tubular secretion.* These processes are described in the next two subsections.

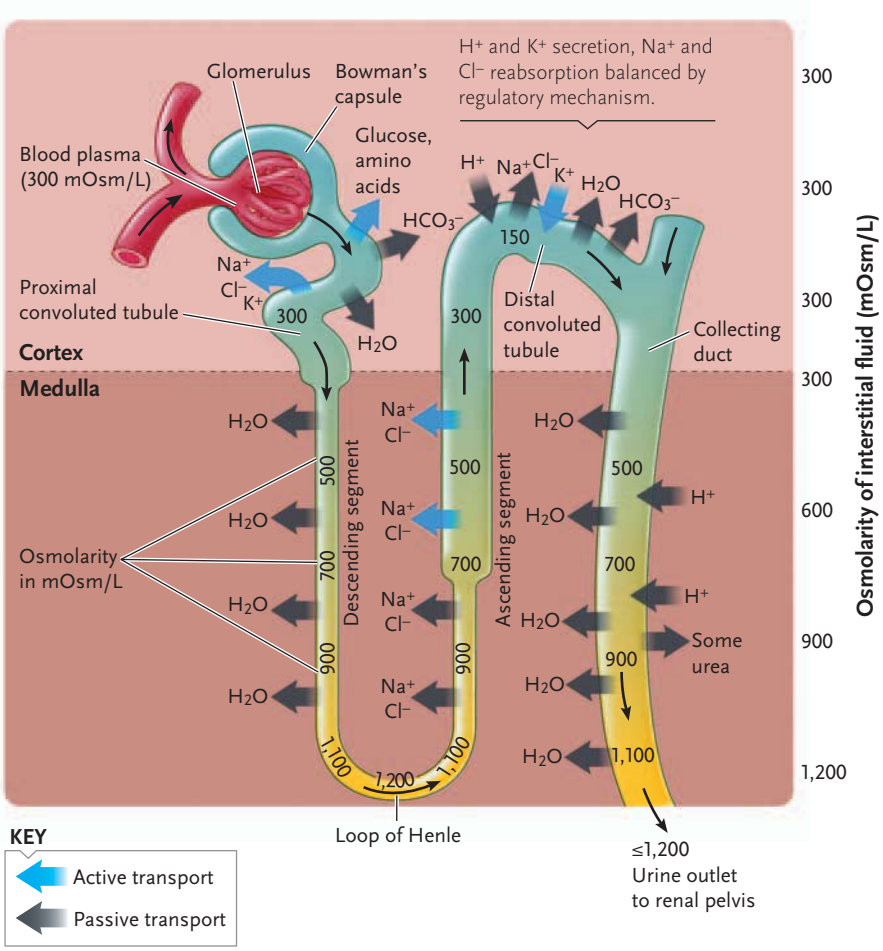

FIGURE 48.8 The movement of ions, water, and other molecules to and from nephrons and collecting tubules in the human kidney. Nephrons in other mammals and in birds work in similar fashion. The numbers are osmolarity values in mOsm/L.

Glomerular Filtration Begins the Process of Excretion

Glomerular filtration begins the process of excretion (shown in **Figure 48.8** and summarized in **Table 48.1**). The single layer of epithelial cells forming the glomerular capillaries is perforated by many pores that make the vessels much more permeable to water and solutes than other capillaries in the body. The higher pressure of the blood drives fluid containing ions, small nutrient molecules such as glucose and amino acids, and nitrogenous waste molecules (primarily urea) through the pores of the glomerular capillaries into Bowman's capsule. Blood cells and plasma proteins are too large to pass and are retained inside the capillaries.

The blood pressure driving fluid through the glomerular capillaries into Bowman's capsule is maintained because the diameter of the **afferent arteriole** delivering blood to the glomerulus is larger than that of the **efferent arteriole** that takes blood away from the glomerulus. That is, because more blood can enter the glomerulus through the afferent arteriole than can leave through the efferent arteriole, glomerular capillary pressure is maintained at a high level as a result of blood damming up in the capillaries.

In humans, Bowman's capsules collectively filter about 180 L (47.5 gallons) of fluid each day, from a daily total of 1,400 L (369.5 gallons) of blood that pass through the kidneys. The human body contains only about 2.75 L of blood plasma, meaning that the kidneys filter a fluid volume equivalent to 65 times the volume of the blood plasma each day. On average, more than 99% of the filtrate, mostly water, is reabsorbed in the nephrons, leaving about 1.5 L to be excreted daily as urine.

Reabsorption and Secretion Take Place in the Remainder of the Nephron

The fluid filtered into Bowman's capsule contains water, other small molecules, and ions at essentially the same concentrations as the blood plasma. As the filtrate flows through the tubules, substances of value are returned to the plasma in the peritubular capillaries (see Figure 48.7) through the selective process of tubular reabsorption. In addition, selective movement of substances from the blood of the peritubular capillaries into the tubules occurs by tubular secretion. Tubular secretion is a second avenue for substances to enter the tubules from the blood, the first being glomerular filtration. By the time the fluid reaches the distal end of

TABLE 48.1 Filtration, Reabsorption, and Secretion in Nephrons and Collecting Ducts

Segment	Location	Permeability and Movement	Osmolarity of Filtrate and Urine	Result of Passage
Bowman's capsule	Cortex	Water, ions, small nutrients, and nitrogenous wastes move through spaces between epithelia	300 mOsm/L, same as surrounding interstitial fluid	Water and small substances, but not proteins, pass into nephron
Proximal convoluted tubule	Cortex	Na^+ and K^+ actively reabsorbed, Cl^- follows; water leaves through aquaporins; HCO_3^- reabsorbed into plasma of peritubular capillaries; glucose, amino acids, and other nutrients actively reabsorbed	300 mOsm/L	67% of ions, 65% of water, 50% of urea, and all nutrients return to interstitial fluid; pH maintained
Descending segment of loop of Henle	Cortex into medulla	Water leaves through aquaporins; no movement of ions or urea	From 300 mOsm/L at top to 1,200 mOsm/L at bottom of loop	Additional water returned to interstitial fluid
Ascending segment of loop of Henle	Medulla into cortex	Na^+ and Cl^- actively transported out; no entry of water; no movement of urea	From 1,200 mOsm/L at bottom to 150 mOsm/L at top of loop	Additional ions returned to interstitial fluid
Distal convoluted tubule	Cortex	K^+ and Na^+ secreted via active transport into urine; Na^+ and Cl^- reabsorbed; water moves into urine through aquaporins; HCO_3^- reabsorbed into plasma of peritubular capillaries	From 150 mOsm/L at beginning to 300 mOsm/L at junction with collecting duct	Ion balance, pH balance
Collecting ducts	Cortex through medulla, empties into renal pelvis	Water moves out via aquaporins; no movement of ions; some urea leaves at bottom of duct	From 300 mOsm/L to 1,200 mOsm/L at junction with renal pelvis	More water and some urea returned to interstitial fluid; some H^+ added to urine

© Cengage Learning 2014

the tubules and passes through the collecting ducts, reabsorption out of the tubules and secretion into them have markedly altered the concentrations of all components of the filtrate.

THE PROXIMAL CONVOLUTED TUBULE Reabsorption of water, ions, and nutrients into the interstitial fluid is the main function of the proximal convoluted tubule. Na^+/K^+ pumps in the epithelium of the proximal convoluted tubule move Na^+ and K^+ from the filtrate into the interstitial fluid surrounding the tubule (see Figure 48.8). The movement of positive charges sets up a voltage gradient that causes Cl^- ions to be reabsorbed from within the tubule with the positive ions. Specific active transport proteins reabsorb essentially all the glucose, amino acids, and other nutrient molecules from the filtrate into the interstitial fluid, making the filtrate hypoosmotic to the interstitial fluid surrounding the tubule. As a result, water moves from the tubule into the interstitial fluid by osmosis. The osmotic movement is aided by *aquaporins,* transport proteins that form passages for water molecules in the transport epithelium of the tubule cells. (To review aquaporins, see Section 6.2 and *Unanswered Questions* for Chapter 6.) The nutrients and water that entered the interstitial fluid move into the peritubular capillaries.

Tubular secretion moves some substances into the tubule, notably detoxified poisons are transferred by passive diffusion (detoxification takes place in the liver). Small amounts of ammonia are also secreted into the tubule.

In all, the proximal convoluted tubule reabsorbs about 67% of the Na^+, K^+, and Cl^- ions, 65% of the water, 50% of the urea, and essentially all the glucose, amino acids, and other nutrient molecules in the filtrate. The ions, nutrients, and water reabsorbed by the tubule are transported into the interstitial fluid, and then into capillaries of the peritubular network. Although half of the urea is reabsorbed, the constant flow of filtrate through the tubules keeps the concentration of nitrogenous wastes low in body fluids.

The proximal convoluted tubule has structural specializations that fit its function. The epithelial cells that make up its walls are carpeted on their inner surface by a brush border of microvilli. Like the brush border of epithelial cells in the small intestine (see Section 47.3), these microvilli greatly increase the surface area available for reabsorption and secretion.

THE DESCENDING SEGMENT OF THE LOOP OF HENLE The loop of Henle has dual functions: (1) to recapture water in the descending segment; and (2) to reabsorb salts in the ascending segment.

The filtrate leaving the proximal convoluted tubule enters the descending segment of the loop of Henle, where water is

An Ore Spells Relief for Osmotic Stress

The osmolyte sorbitol is made from glucose in a reaction catalyzed by the enzyme *aldose reductase (AR)*. Placing renal cells in a hyperosmotic medium induces transcription of the AR gene.

Research Question

How does hyperosmotic stress activate the AR gene?

Experiments

To answer the question, Joan D. Ferraris and her colleagues at the National Institutes of Health in Bethesda, Maryland, cloned a DNA segment containing the AR gene and its upstream promoter and regulatory sequences from a rabbit genomic library (see Chapter 18) **(Figure A).** (Recall from Section 16.2 that the promoter, the sequence immediately upstream of the gene's RNA coding sequence, plays a basic role in initiating transcription of the gene, but does not contain regulatory sequences, which are located upstream of the promoter.)

The researchers then constructed a composite gene by fusing the upstream segment of the AR gene with the RNA coding sequence of the firefly luciferase gene **(Figure B).** The luciferase enzyme catalyzes a reaction that emits light as a product. By using light production as a measure of luciferase activity, the construct enabled the researchers to study the AR upstream region to identify the regulatory sequence required for activating transcription in cells exposed to a hyperosmotic medium.

The researchers transformed the composite gene into cultured rabbit renal cells, and then divided the cells into two groups. One group was placed in an isoosmotic medium (300 mOsm/L); the other group was placed in a medium made hyperosmotic (500 mOsm/L) by added NaCl. After a period of incubation, luciferase activity was measured in cell extracts. The cells in the hyperosmotic solution had several-fold higher luciferase activity than the cells in the isoosmotic solution, showing that the luciferase gene had been turned on under the high salt condition because of the presence of the regulatory sequence derived from the AR gene.

The next step was to identify the particular regulatory sequence. First, they identified the promoter of the AR gene by adding various lengths of fragments immediately upstream of the AR coding sequence to the luciferase gene. They found that a 208-bp sequence gave promoter activity **(Figure C);** that is, they saw a low level of transcription of luciferase in isoosmotic conditions, but that level of transcription did not change in hyperosmotic conditions. Next, the researchers broke the DNA upstream of the promoter into fragments, attached them one at a

© Cengage Learning 2014

reabsorbed. As this segment descends, it passes through regions of increasingly higher solute concentrations in the interstitial fluid of the medulla (see Figure 48.8). (The generation of this concentration gradient is described later.) As a result, more water moves out of the tubule by osmosis as the fluid travels through the descending segment.

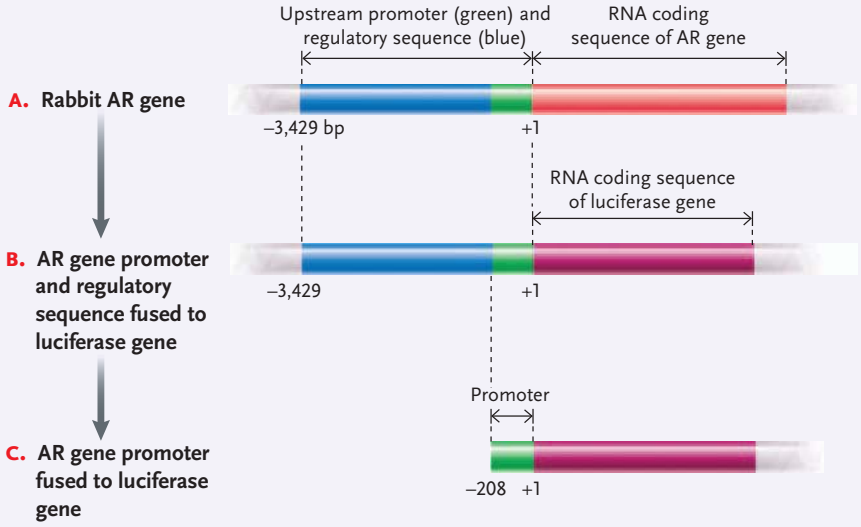
Aquaporins in the descending segment allow the rapid transport of water. The outward movement of water concentrates the molecules and ions inside the tubule, gradually increasing the osmolarity of the fluid to a peak of about 1,200 mOsm/L at the bottom of the loop. This is the same as the osmolarity of the interstitial fluid at the bottom of the medulla.

THE ASCENDING SEGMENT OF THE LOOP OF HENLE The fluid then moves into the ascending segment of the loop of Henle, where Na^+ and Cl^- are reabsorbed into the interstitial fluid. As this segment ascends, it passes through regions of gradually lessening osmolarity in the medulla (see Figure 48.8). The ascending segment has membrane proteins that transport salt ions, but no aquaporins. Because water is trapped in the ascending segment, the osmolarity of the urine is reduced as the salt ions move out of the tubule.

By the time the fluid reaches the cortex at the top of the ascending loop, its osmolarity has dropped to about 150 mOsm/L. During the travel of fluid around the entire loop of Henle, water, nutrients, and ions have been conserved and returned to body fluids, and the total volume of the filtrate in the nephron has been reduced greatly. Urea and other nitrogenous wastes have been concentrated in the filtrate. Little secretion occurs in either the descending or ascending segments of the loop of Henle.

THE DISTAL CONVOLUTED TUBULE Additional water is recovered by osmosis from the fluid in the distal convoluted tubule. In response to hormones triggered by changes in the body's salt concentrations (described in Section 48.4), a varying amount of K^+ is secreted into the fluid, and varying amounts of Na^+ and Cl^- ions are reabsorbed. Bicarbonate ions are reabsorbed from the filtrate as in the proximal tubule.

The amounts of urea and other nitrogenous wastes remain the same. By the time the fluid—now urine—enters the collecting ducts at the end of the nephron, it is isoosmotic with blood plasma (about 300 mOsm/L) but very different in composition.



THE COLLECTING DUCTS The collecting ducts concentrate the urine. These ducts, which are permeable to water but not salt ions, descend from the cortex through the medulla of the kidney. As the ducts descend, they encounter the gradient of increasing solute concentration in the interstitial fluid of the medulla. This increase makes water move osmotically out of the ducts and greatly increases the concentration of the urine, which can become as high as 1,200 mOsm/L at the bottom of the medulla. Near the bottom of the medulla, the walls of the collecting ducts contain passive urea transporters that allow a portion of this nitrogenous waste to pass from the duct into the interstitial fluid. This urea adds significantly to the concentration gradient of solutes in the medulla.

time to the promoter–luciferase gene construct, and tested them for luciferase expression in isoosmotic and hyperosmotic conditions. Eventually, they identified the minimal sequence that activates the luciferase gene in cells placed in hyperosmotic medium; it proved to be the sequence 5′-CGGAAAATCAC-3′, beginning 1,105 bp upstream of the site where transcription begins. The investigators termed the activating sequence an *osmotic response element (ORE)*.

Conclusion

Molecular experiments identified for the first time the regulatory sequence responsible for activating the AR gene under hyperosmotic conditions. The result was a first step in elucidating the molecular mechanism for how hyperosmotic stress regulates the expression of genes involved in responding to that stress.

THINK LIKE A SCIENTIST Given its location with respect to the site where transcription begins, in what gene regulatory element is the ORE (osmotic response element) likely to be?

Sources: J. D. Ferraris et al. 1994. Cloning, genomic organization, and osmotic response of the aldose reductase gene. *Proceedings of the National Academy of Sciences, USA* 91:10742–10746; J. D. Ferraris et al. 1996. ORE, a eukaryotic minimal essential osmotic response element. *Journal of Biological Chemistry* 271:18318–18321.

At its maximum value of 1,200 mOsm/L, reached when water conservation is at its maximum, the urine at the bottom of the collecting ducts is about four times more concentrated than body fluids. It can also be as low as 50 to 70 mOsm/L when very dilute urine is produced in response to conditions such as excessive water intake.

The hyperosomotic state of the interstitial fluid toward the bottom of the medulla would damage the medulla cells if they were not protected against osmotic water loss. The protection comes from high concentrations of otherwise inert organic molecules called *osmolytes* in the cytoplasm of these cells. The osmolytes, primarily a sugar alcohol called *sorbitol,* raise the osmolarity of the cells to match that of the surrounding interstitial fluid. *Insights from the Molecular Revolution* describes research that identified the molecular controls leading to sorbitol production in kidney medulla cells and other cells subjected to osmotic stress.

Urine flows from the end of the collecting ducts into the renal pelvis, and then through the ureters into the urinary bladder where it is stored. From the bladder, urine exits through the urethra to the outside.

Terrestrial Mammals Have Additional Water-Conserving Adaptations

Terrestrial mammals have other adaptations that complement the water-conserving activities of the kidneys. One is the location of the lungs deep inside the body, which reduces water loss by evaporation during breathing (see Section 46.1). Another is a body covering of keratinized skin. Skin is nearly impermeable so that it almost eliminates water loss by evaporation, except for the controlled loss through evaporation of sweat in mammals with sweat glands.

Water-conserving adaptations reach their greatest efficiency in desert rodents such as the kangaroo rat **(Figure 48.9).** The proportion of nephrons with long loops extending deep into the kidney medulla of kangaroo rats is very high, allowing them to excrete urine that is 20 times more concentrated than body fluids. Further, most of the water in the feces is absorbed in the large intestine and rectum. Lacking sweat glands, kangaroo rats lose little water by evaporation from the body surface. Much of the moisture in their breath is condensed and recycled by specialized passages in the nasal cavities. They stay in burrows during daytime, and come out to feed only at night.

About 90% of the kangaroo rat's daily water supply is generated from oxidative reactions in its cells. (Humans, by contrast, can make up only about 12% of their daily water needs from this source.) The remaining 10% of the kangaroo rat's water comes from its food. These structural and behavioral adaptations are so effective that a kangaroo rat can survive in the desert without ever drinking water.

Marine mammals, including whales, seals, and manatees, eat foods that are high in salt content and never drink fresh water. They are able to survive the high salt intake because they produce urine that is more concentrated than seawater. As a result, they are easily able to excrete all the excess salt they ingest in their diet.

STUDY BREAK 48.3

1. **Describe the structure of a human nephron from the proximal end to the distal end.**
2. **The urine entering the collecting ducts at the end of the nephron has an osmolarity essentially the same as that of fluids in other parts of the body. How is the urine subsequently made more concentrated?**

THINK OUTSIDE THE BOOK

On your own or collaboratively, research the symptoms and possible causes of chronic renal disease (also called chronic kidney disease). Then outline the hypothesis and research approach for a study of chronic renal disease that uses the rat as the experimental organism.

48.4 Regulation of Mammalian Kidney Function

Mammalian excretory functions are integrated into overall body functions by three primary control systems, which link kidney functions to blood pressure, to the osmolarity and pH of body fluids, and to the body's water balance:

- An autoregulation system located entirely within the kidney keeps glomerular filtration constant during variations in arterial blood pressure, as when we move from sitting to standing.
- Two hormonal control systems compensate for excessive loss of salt and body fluids and adjust the rate of water uptake in the kidneys to compensate for excessive water intake or loss. These two hormonal systems regulate interactions between the kidneys and the rest of the body.

The three systems work together, but we will discuss them separately.

An Autoregulation System Controls Glomerular Filtration Rate

An autoregulation system responds almost instantly to small variations in blood pressure to keep the glomerular filtration rate constant. Two mechanisms are involved in the autoregulation:

1. *Vascular control of blood pressure.* Increased blood pressure in the afferent arteriole is detected by receptors in the vessel. In response to the stretching, the smooth muscles of the arterial wall contract, which constricts the blood vessel, thereby constraining the blood flow to the glomerulus and reducing the glomerular filtration rate. In the opposite condition of reduced blood pressure in the arteriole, the receptors signal the blood vessel to dilate (expand), thereby increasing blood flow into the glomerulus and, therefore, glomerular filtration rate, even though arterial blood pressure has dropped.
2. *Feedback control from the distal convoluted tubule to the juxtaglomerular apparatus.* The **juxtaglomerular apparatus** (*juxta* = near) is located at a point where the distal convoluted tubule contacts the afferent arteriole carrying blood to the glomerulus **(Figure 48.10, inset).** The feedback control mechanism is triggered by salt concentration in the distal convoluted tubule. If the glomerular filtration rate increases above normal, more fluid than normal is filtered, and a higher salt concentration results in the distal convoluted tubule. Specialized tubule cells in the juxtaglomerular apparatus monitor the salt level of the fluid flowing past them in the tubule. If the salt level rises, those cells secrete chemical messengers that act locally (by paracrine regulation; see Section 42.1 and Figure 42.1) on the adjacent afferent arteriole, causing it to constrict. As a result, glomerular blood flow is reduced and glomerular filtration rate decreases to normal. If the glomerular filtration decreases below normal, the specialized tubule cells detect the lower salt level that results, secretion of the chemical messengers from those cells stops and the afferent arteriole dilates, thereby allowing an increase in the glomerular filtration rate.

The Renin-Angiotensin-Aldosterone System (RAAS) Responds to Na^+ by Triggering Na^+ Reabsorption

Major changes in blood volume and pressure occur when the body loses or gains Na^+ in excessive amounts. Excessive Na^+ loss may result from prolonged and heavy sweating, repeated vomiting, severe diarrhea, or insufficient Na^+ uptake in the diet. The Na^+ loss reduces the osmolarity of body fluids, which causes less

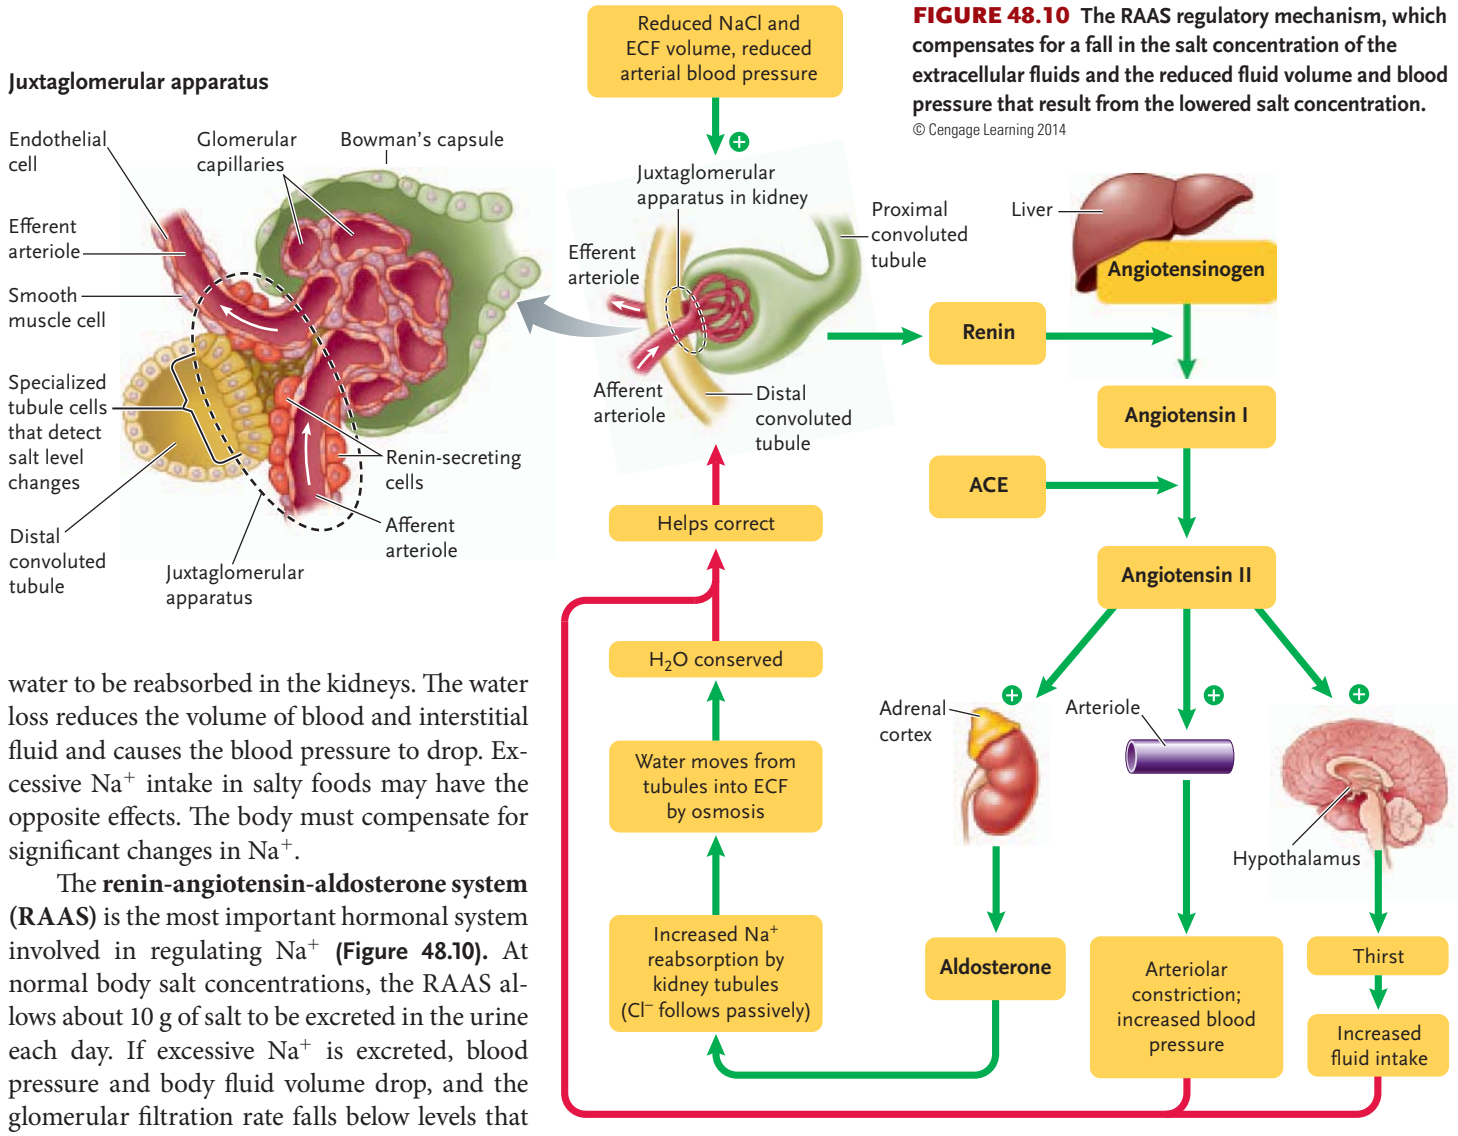

FIGURE 48.10 **The RAAS regulatory mechanism, which compensates for a fall in the salt concentration of the extracellular fluids and the reduced fluid volume and blood pressure that result from the lowered salt concentration.**

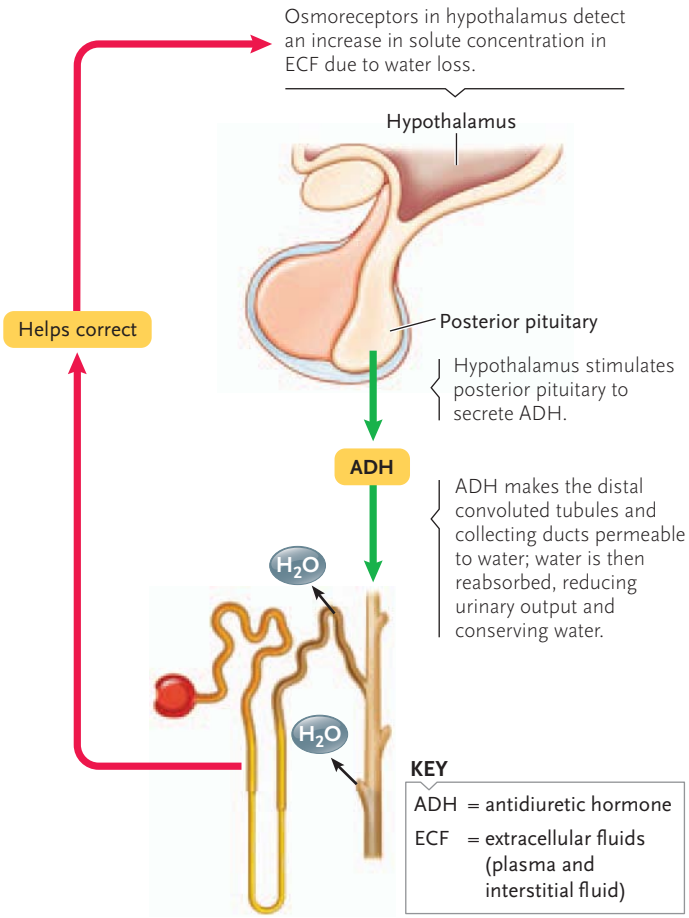
© Cengage Learning 2014

water to be reabsorbed in the kidneys. The water loss reduces the volume of blood and interstitial fluid and causes the blood pressure to drop. Excessive Na^+ intake in salty foods may have the opposite effects. The body must compensate for significant changes in Na^+.

The **renin-angiotensin-aldosterone system (RAAS)** is the most important hormonal system involved in regulating Na^+ **(Figure 48.10).** At normal body salt concentrations, the RAAS allows about 10 g of salt to be excreted in the urine each day. If excessive Na^+ is excreted, blood pressure and body fluid volume drop, and the glomerular filtration rate falls below levels that can be restored by the juxtaglomerular apparatus autoregulation. In response to this condition, the following events take place (see Figure 48.10):

- Cells in the juxtaglomerular apparatus secrete the enzyme **renin** into the bloodstream. (The RAAS also is activated to secrete renin when blood pressure or blood volume decreases independently of Na^+ levels, as in the case of a hemorrhage.)
- Renin cleaves the plasma protein *angiotensinogen* to produce **angiotensin I.**
- **Angiotensin-converting enzyme (ACE)** converts angiotensin I to **angiotensin II.**

Angiotensin II has three effects: (1) it raises blood pressure quickly by constricting arterioles in most parts of the body; (2) it stimulates synthesis of the steroid hormone **aldosterone** and its secretion from the adrenal cortex; and (3) it stimulates thirst so that more water is brought into the body. The aldosterone increases Na^+ reabsorption in the kidneys, which raises the osmolarity of body fluids. As a result, water moves from the tubules into the interstitial fluid, which conserves water. Angiotensin II may also stimulate secretion of **antidiuretic hormone (ADH)** (also called *vasopressin*) by the posterior pituitary (antidiuretic means "against urine output") (not shown in the figure). ADH increases water absorption in the kidneys. Overall, the combined effects of angiotensin act to return the blood pressure to normal.



In the opposite situation, when salt intake is too high, both body fluid volume and blood pressure rise above normal. Under these conditions, renin secretion is inhibited and, as a result, angiotensin production and aldosterone synthesis are not stimulated. The reduction in angiotensin lowers blood pressure by allowing arterioles to dilate; the reduction in aldosterone increases Na^+ loss in the urine by retarding the reabsorption of Na^+ and Cl^- from the kidney tubules.

Elevated blood pressure also stimulates specialized cells in the heart to release **atrial natriuretic factor (ANF),** a peptide hormone that inhibits renin release. ANF increases the filtration rate as well by dilating the arterioles that deliver blood to glomeruli and by inhibiting aldosterone release. As less Na^+ is reabsorbed and urine volume increases, both plasma volume and blood pressure return to normal.

The Antidiuretic Hormone (ADH) System Also Regulates Osmolarity and Water Balance

You have just learned that the ADH system may be stimulated by angiotensin II of the RAAS in response to an increase in Na^+. The control centers of the hypothalamus that regulate ADH secretion (and, therefore, urinary output) and thirst (and, therefore, drinking) function together. That is, both ADH secretion and thirst are stimulated by a bodily water deficit and suppressed by bodily water excess. Logically, the same conditions that require reduced urinary output to conserve water also cause the sensation of thirst to replace water.

The ADH system regulates osmolarity and water balance—and, therefore, urinary output—by increasing water reabsorption in the kidneys without changing the usual excretion of salt **(Figure 48.11).** *Osmoreceptors* in the hypothalamus that are located near the ADH-secreting cells and the thirst center monitor control ADH secretion. (An **osmoreceptor** is a sensory receptor that monitors the osmolarity of the extracellular fluid bathing it, which, in turn, reflects the concentration of the entire internal environment.) When the osmoreceptors detect an increase in osmolarity (too little water) and the need to conserve water increases, both ADH secretion and thirst are stimulated. As a result, reabsorption of water in the distal convoluted tubules and collecting ducts increases so that urinary output is reduced and water is conserved while, at the same time, water intake (drinking) is stimulated. These actions restore depleted water stocks, and dilute

FIGURE 48.12 **Experimental Research**

ADH-Stimulated Water Reabsorption in the Kidney Collecting Duct

Question: How does ADH cause water reabsorption in the kidney collecting ducts?

Experiment: The peptide hormone ADH causes the reabsorption of water in the kidney by increasing the number of aquaporin2 (AQP2) water channels in the plasma membrane of the collecting duct cells. AQP2 is the only aquaporin expressed exclusively in the collecting duct. Mark Knepper and his colleagues at the National Institutes of Health, Bethesda, Maryland, and the University of Aarhus, Denmark, investigated the mechanism by which ADH causes AQP2 to appear in the plasma membrane. They tested the "shuttle" hypothesis, which states that ADH induces the movement of AQP2 from intracellular vesicles (IVs) to the plasma membrane of cells on the lumen side of the collecting duct.

The researchers first attached sections of collecting duct from rat kidneys to a pipet and passed an ADH solution through the duct **(Figure 1).** They then counted the AQP2 in the IVs and in the plasma membrane of the lumen cells. To do this, they cut treated ducts into thin sections and added an antibody that specifically recognizes AQP2. The antibody had gold particles attached to it. Under an electron microscope, the electron-dense gold is easily visualized. Counting the gold particles therefore quantified the AQP2.

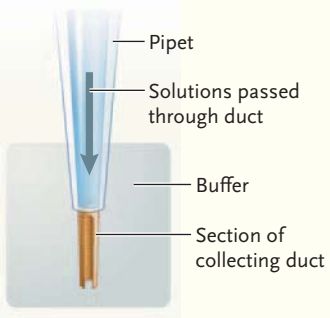

FIGURE 1

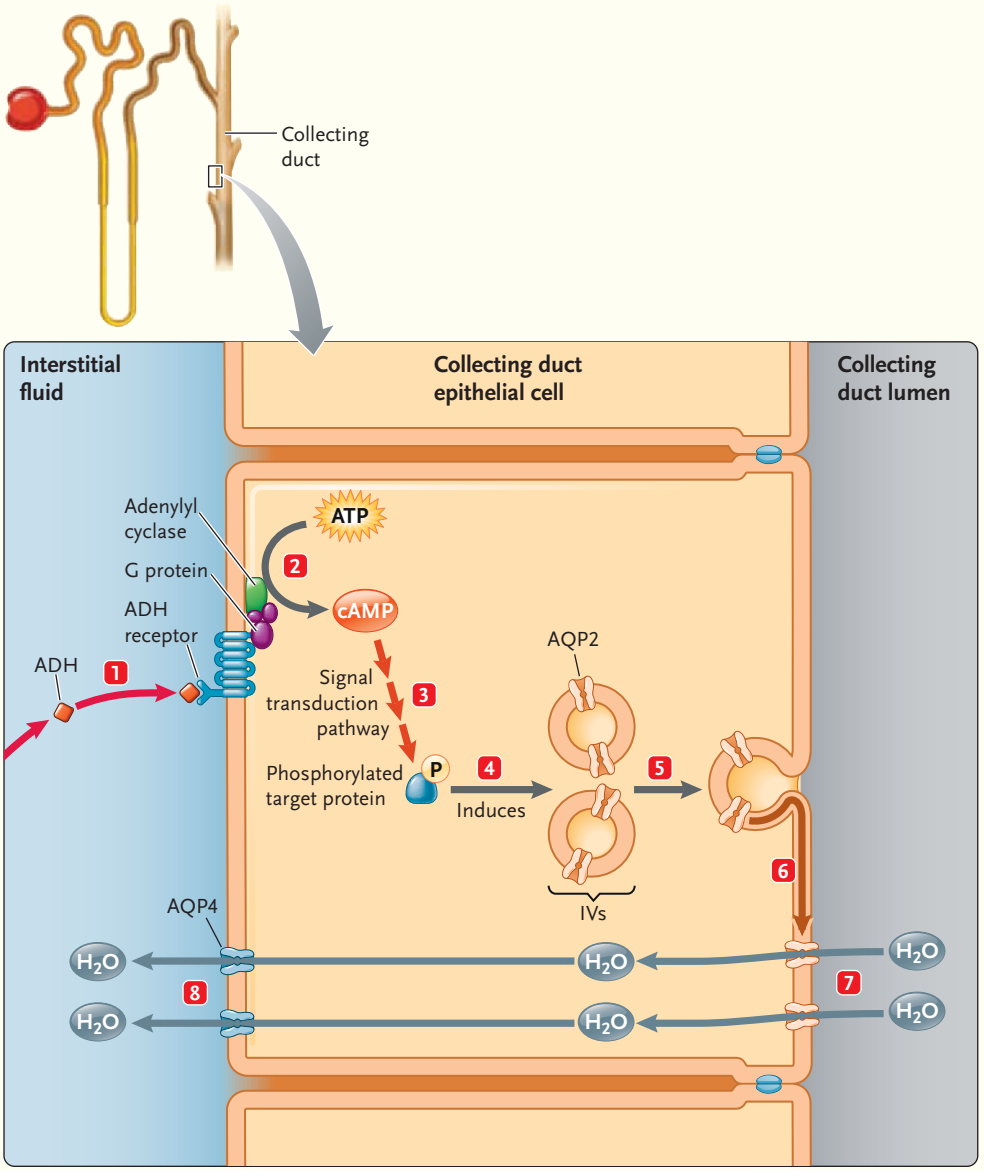
Results: The researchers measured the distribution of AQP2 in the absence of ADH, in the presence of ADH, and then after ADH had been washed away. Their results are expressed as the ratio of AQP2 in the plasma membrane of lumen cells to AQP2 in IVs:

Before ADH treatment: 0.32 ± 0.03

In presence of ADH: 0.38 ± 0.14



After ADH removal: 0.35 ± 0.04

Conclusion: ADH induces a change in distribution of AQP2, consistent with the shuttle hypothesis of AQP2 channels moving from IVs to the plasma membrane of lumen cells. The redistribution of AQP2 channels is reversible, as shown by the results after ADH removal.

Figure 2 shows the current molecular model for the ADH-induced redistribution of AQP2 channels in collecting duct epithelial cells.

1 ADH in the circulation passes through the capillary wall, diffuses through the interstitial fluid surrounding the collecting duct, and binds to the ADH G-protein–coupled receptor in the epithelial cell plasma membrane, activating it (see Section 7.4).

2 Activated receptor leads to activation of adenylyl cyclase, which produces cAMP from ATP.

3 cAMP triggers a signal transduction pathway (see Section 7.4) that leads to a phosphorylated target protein.

4 Phosphorylated target protein induces IVs with AQP2 channels in their membranes to move to plasma membrane of cells on lumen side of the collecting duct.

5 By exocytosis, the IVs fuse with the plasma membrane.

6 Completion of exocytosis results in AQP2 channels added to the plasma membrane.

7 Water from the collecting duct lumen is reasorbed through the AQP2 channels into the epithelial cells.

8 Water exits the epithelial cells via AQP4 channels in the plasma membrane on interstitial fluid side of the cell.

THINK LIKE A SCIENTIST In diabetes insipidus, the kidneys are unable to conserve water. One heritable form of the disease, central diabetes insipidus, can be treated by desmopressin, a synthetic replacement for ADH. Another heritable form of the disease, nephrogenic diabetes insipidus, does not respond to treatment with desmopressin. Hypothesize in which components shown in **Figure 2** might have been affected by the mutations in the two forms of the disease.

Source: S. Nielsen et al. 1995. Vasopressin increases water permeability of kidney collecting duct by inducing translocation of aquaporin-CD water channels to plasma membrane. *Proceedings of the National Academy of Sciences, USA* 92:1013–1017.

the solutes back to normal concentration. If, instead, there is excess water in the extracellular fluids, the osmolarity of those fluids drops below normal levels. The osmoreceptors are not stimulated so ADH secretion is reduced and this leads to increased urinary output. In addition, thirst is suppressed, reducing water intake.

Mechanistically, the action of ADH increases water reabsorption in the distal convoluted tubule and collecting ducts by promoting the insertion of more aquaporins into the epithelial membranes **(Figure 48.12).** Without ADH, water channels are retrieved from the distal convoluted tubule and collecting duct

epithelial membranes (endocytosis of plasma membrane to produce intracellular vesicles; see Figure 48.12), and water reabsorption is reduced significantly.

Although the RAAS and ADH systems interact to regulate the body's water balance over a wide range of conditions, their regulatory mechanisms cannot compensate for water losses for more than a few days if water is unavailable. Dehydration becomes fatal when water loss amounts to about 12% of the normal fluid volume of the body.

STUDY BREAK 48.4

Outline the roles of the RAAS and ADH system in regulating mammalian kidney function.

48.5 Kidney Function in Nonmammalian Vertebrates

Most nonmammalian vertebrates secrete hypoosmotic urine; only a few species of aquatic birds produce hyperosmotic urine. The particular adaptations that maintain osmolarity and water balance among these animals vary depending on whether retention of water or salts is the major issue.

Marine Fishes Conserve Water and Excrete Salts

Marine teleosts live in seawater, which is strongly hyperosmotic to their body fluids. As a result, they lose water continually to their environment by osmosis and must replace it by drinking continually **(Figure 48.13A).** The kidneys of marine teleosts play little role in regulating salt in their body fluids because they cannot produce hyperosmotic urine that would both remove salt and conserve water. Instead, excess Na^+, K^+, and Cl^- ions are eliminated from the body by specialized cells in the gills, called *chloride cells.* Those cells transport Cl^- actively into the surrounding seawater; in addition, the Na^+ and K^+ ions are transported actively to maintain electrical neutrality. Certain other ions in the ingested seawater, such as Ca^{2+} and Mg^{2+}, are removed by the kidneys in an isoosmotic urine. Some salt is taken in in food and swallowed water, and some salt is gained by diffusion into gill tissue. On balance, a marine teleost is able to retain most of the water it drinks and eliminate most of the salt, allowing its body fluids to remain hypoosmotic to the surrounding water with no need to secrete hyperosmotic urine. Nitrogenous wastes are released from the gills, primarily as ammonia, by simple diffusion. The kidneys play little role in nitrogenous-waste removal.

Sharks and rays have a different adaptation to seawater. The osmolarity of their body fluids is maintained close to that of seawater by retaining high levels of urea in body fluids, along with another nitrogenous waste, *trimethylamine oxide.* The match in osmolarity keeps sharks and rays from losing water to the surrounding sea by osmosis, and they do not have to drink seawater continually to maintain their water balance. Excess salts ingested with food are excreted in the kidney and by specialized secretory cells in a *rectal salt gland* located near the anal opening.

Freshwater Fishes and Amphibians Excrete Water and Conserve Salts

The body fluids of freshwater fishes and aquatic amphibians (no amphibians live in seawater) are hyperosmotic to the surrounding water, which usually ranges from about 1 to 10 mOsm/L. Water therefore moves osmotically into their tissues **(Figure 48.13B).** Such animals rarely drink, and they excrete large volumes of dilute urine to get rid of excess water. In freshwater fishes, salt ions lost with the urine and by diffusion out of the gill tissue are replaced by salt in foods and by active transport of Na^+ and K^+ into the body by the gills; Cl^- follows to maintain electrical neutrality. Aquatic amphibians obtain salt in the diet and by active transport

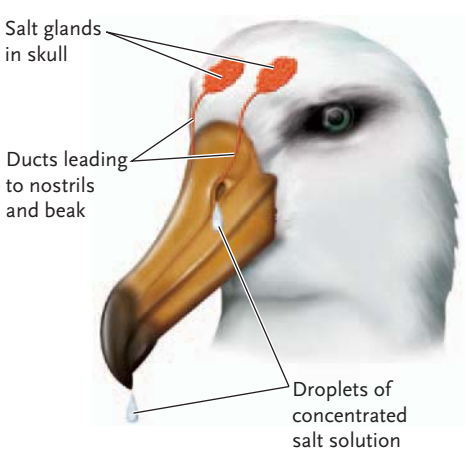
across the skin from the surrounding water. Nitrogenous wastes are excreted from the gills as ammonia in both freshwater fishes and aquatic amphibians.

Terrestrial amphibians must conserve both water and salt, which is obtained primarily in foods. In these animals, the kidneys secrete salt into the urine, causing water to enter the urine by osmosis. In the bladder, the salt is reclaimed by active transport and returned to body fluids. The water remains in the bladder, making the urine very dilute; during times of drought, it is reabsorbed as a water source. Terrestrial amphibians also have behavioral adaptations that help minimize water loss, such as seeking shaded, moist environments and remaining inactive during the day.

Larval amphibians, which are completely aquatic, excrete nitrogenous wastes from their gills as ammonia. Adult amphibians excrete nitrogenous wastes through their kidneys as urea.



Reptiles and Birds Excrete Uric Acid to Conserve Water

Terrestrial reptiles (lizards and snakes) conserve water by secreting nitrogenous wastes in the form of an almost water-free paste of uric acid crystals. Further water conservation occurs as the epithelial cells of the cloaca, the common exit for the digestive and excretory systems, absorb water from feces and urine before those wastes are excreted. Most birds conserve water by the same processes—they excrete nitrogenous wastes as uric acid and absorb water from the urine and feces in the cloaca. In reptiles, the scales covering the skin allow almost no water to escape through the body surface.

Reptiles and birds that live in or around seawater, including reptiles such as crocodilians, sea snakes, and sea turtles and birds such as seagulls, penguins, and pelicans, take in large quantities of salt with their food and rarely or never drink fresh water. These animals typically excrete excess salt through specialized *salt glands* located in the head **(Figure 48.14),** which remove salts from the blood by active transport. The salts are secreted to the environment as a water solution in which salts are two to three times more concentrated than in body fluids. The secretion exits through the nostrils of birds and lizards, through the mouth of marine snakes, and as salty tears from the eye sockets of sea turtles and crocodilians. Neural and hormonal controls, essentially the same as those regulating osmolarity in mammals, control the rate of fluid secretion and its salt concentration.

In sum, the adaptations described in this section permit excretion of toxic wastes and allow animals to maintain the salt concentration of body fluids at levels that keep cells from swelling or shrinking.

48.6 Introduction to Thermoregulation

Another vital challenge for animals is maintaining their internal environment at temperatures that can be tolerated by body cells. Animal cells can survive only within a temperature range from about 0°C to 45°C (32°F–113°F). Not far below 0°C, the lipid bilayer of a biological membrane changes from a fluid to a frozen gel, which disrupts vital cell functions, and ice crystals destroy the cell's organelles. As temperatures approach 45°C, most proteins and nucleic acids unfold from their functional form. Either condition leads quickly to cell death. Animals therefore usually maintain internal body temperatures somewhere within the 0°C to 45°C limits.

Temperature regulation—*thermoregulation*—is based on negative feedback pathways in which temperature receptors *(thermoreceptors)* detect changes from a temperature *set point.* Signals from the receptors trigger physiological and behavioral responses that return the temperature to the set point (thermoreceptors are discussed in Section 41.6; homeostatic control systems involving negative feedback mechanisms and set points are discussed in Section 38.4). All of the responses triggered by negative feedback mechanisms involve adjustments in the rate of heat-generating oxidative reactions within the body, coupled with adjustments in the rate of heat gain or loss at the body surface. The particular adaptations accomplishing these responses vary widely among species. And, although body temperature is regulated closely around a set point in all endotherms, the set point itself may vary over the course of a day and between seasons.

Thermoregulation Allows Animals to Reach Optimal Physiological Performance

Within the 0°C to 45°C range of tolerable temperatures, an animal's *organismal performance*—the rate and efficiency of its biochemical, physiological, and whole-body processes—varies

greatly. For example, the speed at which the Middle Eastern lizard *Agama stellio* can sprint is low when the animal's body temperature is cold, rises smoothly with body temperature until it levels to a fairly broad plateau, and then drops off dramatically with further increases in body temperature **(Figure 48.15).** The temperature range that provides good organismal performance varies from one species to another.

Animals Exchange Heat with Their Environments by Conduction, Convection, Radiation, and Evaporation

As part of thermoregulation, animals exchange heat with their environments. As with all physical objects, heat flows into animals if they are cooler than their surroundings and flows outward if they are warmer. This heat exchange occurs by four mechanisms: *conduction, convection, radiation,* and *evaporation* **(Figure 48.16).**

Conduction is the flow of heat between atoms or molecules in direct contact. An animal loses heat by conduction when it contacts a cooler object and gains heat when it contacts an object that is warmer. **Convection** is the transfer of heat from a body to a fluid, such as air or water, that passes over its surface. The movement maximizes heat transfer by replacing fluid that has absorbed or released heat with fluid at the original temperature. **Radiation** is the transfer of heat energy as electromagnetic radiation. Any object warmer than absolute zero (−273°C) radiates heat; as the object's temperature rises, the amount of heat it loses as radiation increases as well. Animals also gain heat through radiation, particularly by absorbing radiation from the sun. **Evaporation** is heat transfer through the energy required to change a liquid to a gas. Evaporation of water from a surface is an efficient way to transfer heat; when the water in sweat evaporates from the body surface, the body cools down because heat is being transferred to the evaporated water in the surrounding air.

FIGURE 48.16 Heat flow to (in red) and from (in blue) a runner on a hot, sunny day. Unlike conduction, convection, and evaporation, which take place through the kinetic movement of molecules, electromagnetic radiation is transmitted through space as waves of energy.

All animals gain or lose heat by a combination of these four mechanisms. If you run on a hot summer day, for example, you lose heat by the evaporation of sweat from the skin, by convection as air flows over the skin, and by outward infrared radiation. You gain heat from internal biochemical reactions (especially oxidations), by absorbing infrared and solar radiation, and by conduction as the feet contact the hot ground. To maintain a constant body temperature, the heat gained and lost through these pathways must balance.

Ectothermic and Endothermic Animals Rely on Different Heat Sources to Maintain Body Temperature

Different animals use one of two major strategies to balance heat gain and loss. Animals that obtain heat primarily from the external environment are **ectotherms** (*ecto* = outside); those obtaining most of their heat from internal physiological sources are **endotherms** (*endo* = inside). All ectotherms generate at least some heat from internal reactions, however, and endotherms can obtain heat from the environment under some circumstances.

Virtually all invertebrates, fishes, amphibians, and lizards and snakes are ectotherms. These animals are described popularly as cold-blooded, although the body temperature of some, such as an active lizard, may be as high as or higher than ours on a sunny day. Ectotherms regulate body temperature by controlling the rate of heat exchange with the environment. Through behavioral and physiological mechanisms, they adjust body temperature toward a level that allows optimal physiological performance. However, most ectotherms are unable to maintain optimal body temperature when the temperature of their surroundings departs too far from that optimum, particularly when environmental temperatures fall. As a result, the body temperatures of ectotherms fluctuate with environmental temperatures, and they typically are less active when it is cold. Nevertheless, ectotherms are highly successful, particularly in warm environments.

The endotherms—birds, mammals, some fishes, sea turtles, and some invertebrates—keep their bodies at an optimal temperature by regulating two processes: (1) the amount of heat generated by internal oxidative reactions; and (2) the amount of heat exchanged with the environment. Because endotherms use internal heat sources to maintain body temperature at optimal levels, they can remain active over a broader range of environmental temperatures than ectotherms, and thus inhabit a wider range of habitats. However, endotherms require a nearly constant supply of energy to maintain their

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

body temperatures. Because that energy is provided by food, endotherms typically consume much more food than ectotherms of equivalent size.

The difference between ectotherms and endotherms is reflected in their metabolic responses to environmental temperature **(Figure 48.17).** For example, the metabolic rate of a resting mouse *increases* steadily as the environmental temperature falls from 25°C to 10°C (77°F–50°F). This increase reflects the fact that to maintain a constant body temperature in a colder environment, endotherms must process progressively more food and generate more heat to compensate for their increased rate of heat loss. In this respect, an endotherm can be likened to a house in winter. To maintain a constant internal temperature, the homeowner must burn more oil or gas on a cold day than on a warm day.

By contrast, the metabolic rate of a resting lizard typically *decreases* steadily over the same temperature range. Because ectotherms do not maintain a constant body temperature, their biochemical and physiological functions, including oxidative reactions, slow down as environmental and body temperatures decrease. Thus, an ectotherm consumes and uses less energy when it is cold than when it is warm. This difference between ectotherms and endotherms is so fundamental that even samples of living tissue extracted from an ectotherm consume energy more slowly than equivalent samples from an endotherm.

Ectothermy and endothermy represent different strategies for coping with the variations in environmental temperature that all animals encounter; neither strategy is inherently superior to the other. Endotherms can remain fully active over a wide temperature range. Cold weather does not prevent them from foraging, mating, or escaping from predators, but it does increase their energy and food needs—and, to satisfy their need for food, they may not have the option of staying curled up safely in a warm burrow. Ectotherms do not have the capacity to be active when environmental temperatures drop too low; they move sluggishly and are unable to capture food or escape from predators. However, because their metabolic rates are lower under such circumstances, so are their food needs, and they do not have to look for food and expose themselves to danger to the extent that endotherms do.

In the next two sections, we examine in more detail how ectothermic and endothermic animals regulate their body temperatures.

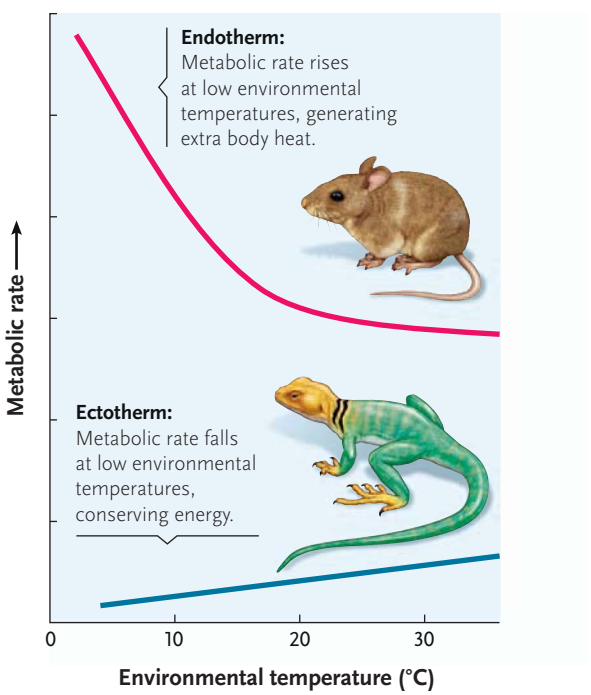

FIGURE 48.17 Metabolic responses of ectotherms and endotherms to cooling environmental temperatures. At any temperature, the metabolic rates of endotherms are always higher than those of ectotherms of comparable size.

STUDY BREAK 48.6

Distinguish between ectothermy and endothermy. Give one advantage and one disadvantage for each form of thermoregulation.

48.7 Ectothermy

Ectotherms vary widely in their ability to regulate internal body temperatures. For example, most aquatic invertebrates have such limited ability for thermoregulation that their body temperatures closely match those of the surrounding environment. These species live in or seek warm or temperate environments, where temperatures fall within a range that produces optimal physiological performance. Ectotherms with a greater ability for thermoregulation may occupy more varied habitats.

Ectotherms Are Found in All Invertebrate Groups

Most aquatic invertebrates are limited thermoregulators whose body temperature closely follows the temperature of their surroundings. However, even among these animals, some use behavioral responses to regulate body temperature. For example, a South American intertidal mollusk, *Echinolittorina peruviana,* is longer than it is wide. This animal orients itself as a means of thermoregulation. On sunny, summer days, it faces the sun, offering a smaller surface area for the sun's rays. On overcast summer days, or during the winter, it orients itself with a lateral side—which has the larger surface area—toward the sun's rays.

Invertebrates living in terrestrial habitats regulate body temperatures more closely. Many also use behavioral responses, such as moving between shaded and sunny regions, to regulate body temperature. Some winged arthropods, including bees, moths, butterflies, and dragonflies, use a combination of behavioral and heat-generating physiological mechanisms for thermoregulation. For example, in cool weather, these animals warm up before taking flight by vibrating the large flight muscles in the thorax, in a mechanism similar to shivering in humans.

Most Fishes, Amphibians, and Reptiles Are Ectotherms

Vertebrate ectotherms—fishes, amphibians, and reptiles (turtles, lizards, and snakes)—also vary widely in their ability for thermoregulation. Most aquatic species have a more limited thermoregulatory capacity than that found among terrestrial species, particularly the reptiles. Some fishes, however, are highly capable thermoregulators.

FISHES The body temperatures of most fishes remain within one or two degrees of their aquatic environment. However, many fishes use behavioral mechanisms to keep body temperatures at levels allowing good physiological performance. Freshwater species, for example, may use opportunities provided by the thermal stratification of lakes and ponds (see Figure 51.24). During hot summer days, they remain in deep, cool water, moving to the shallows to feed only during early morning and late evening when air and water temperatures fall.

AMPHIBIANS AND REPTILES The body temperatures of most amphibians also closely match environmental temperatures. Some terrestrial amphibians bask in the sun to raise their body temperature and seek shade to lower body temperature. However, basking can be dangerous to amphibians because they lose water rapidly through their permeable skin.

Thermoregulation is more pronounced among terrestrial reptiles. Some lizard species can maintain temperatures that are nearly as constant as those of endotherms. For small lizards, the most common behavioral thermoregulatory mechanism is shuttling between sunny (warmer) and shady (cooler) regions; in the deserts, lizards and other reptiles retreat into burrows during the hottest part of summer days. Some, such as the desert iguana *(Dipsosaurus dorsalis),* lose excess heat by *panting*—rapidly moving air in and out of the airways. The air movement increases heat loss by convection and by evaporation of water from the respiratory tract.

Lizards also frequently adjust their posture to foster heat exchange with the environment and control the angle of their body relative to the rays of the sun. Snakes and lizards can often be found on large rocks and on roads on chilly nights, taking advantage of the heat retained by the stone or concrete.

Ectotherms Can Compensate for Seasonal Variations in Environmental Temperature

Many ectotherms undergo physiological changes, called **thermal acclimatization,** in response to seasonal shifts in environmental temperature. These changes allow the animals to attain good physiological performance at both winter and summer temperatures.

For example, in the summer a bullhead catfish (*Ameiurus* species) can survive water temperatures as high as 36°C (97°F), but it cannot tolerate temperatures below 8°C (46°F). In the winter, however, the bullhead cannot survive water temperatures above 28°C (82°F), but can tolerate temperatures near 0°C (32°F).

Another acclimatizing change involves the phospholipids of biological membranes (see *Focus on Basic Research* in Chapter 6). For example, membrane phospholipids have higher proportions of double bonds in carp living in colder environments than in carp living in warmer environments. The higher proportion of double bonds makes it harder for the membrane to freeze. A higher proportion of cholesterol also protects membranes from freezing.

When seasonal temperatures fall below 0°C, some ectotherms add molecules to their body fluids that act as antifreeze molecules to depress their freezing point and retard ice crystal formation. For example, antifreeze proteins allow fishes such as the winter flounder to remain active in seawater as cold as −1.8°C (−9°F) (see *Insights from the Molecular Revolution* in Chapter 51).

Ectotherms thus control body temperature primarily by regulating heat exchange with the environment; internal-heat generating mechanisms contribute to the control mechanisms in some species, but are never the primary source of body heat. The opposite conditions occur among endotherms: although these animals also regulate heat exchange with the environment, their primary sources of body heat are internal.

STUDY BREAK 48.7

1. **Describe two mechanisms an ectothermic animal can use to regulate its temperature.**
2. **What is thermal acclimatization?**

48.8 Endothermy

Endotherms—mostly birds and mammals—have elaborate and extensive thermoregulatory adaptations. Highly specialized features of body structure interact with both physiological and behavioral mechanisms to keep the body temperature within a narrow range. Typically, the body temperatures of fully active individuals are held constant at levels between about 39°C and 42°C (102°F and 108°F) in birds, and 36°C and 39°C (97°F and 102°F) in mammals. These internal temperatures are maintained in the face of environmental temperatures that may range over much greater extremes, from as low as −42°C to as high as +48°C (−45°F to +120°F). Some highly specialized endotherms can even survive temperatures beyond these limits.

We begin by describing the basic homeostatic control systems that maintain body temperature, with primary emphasis on the human system. Later sections discuss variations in the responses of other mammals and of birds, and daily and seasonal variations in the temperature set point.

Information from Thermoreceptors Located in the Skin and Internal Structures Is Integrated in the Hypothalamus

Thermoreceptors (discussed in Section 41.6) are found in various locations in the human body, including the **integument**

(skin; introduced in Chapter 38), spinal cord, and hypothalamus. Current evidence suggests the existence of five thermoreceptor types, each active in specific temperature ranges, beginning at less than 8°C and extending to above 52°C. Signals from the thermoreceptors are integrated in the hypothalamus and other regions of the brain to bring about compensating physiological and behavioral responses **(Figure 48.18).** The responses keep body temperature close to the set point, which varies normally in humans between 35.5°C and 37.7°C (96.0°F and 99.9°F) for the head and trunk. The appendages typically vary more widely in temperature; in freezing weather, for example, our arms, hands, legs, and feet are typically cooler in temperature than the body core—and the ears and nose especially so.

The hypothalamus was identified as a major thermoreceptor and response integrator in mammals by experiments in which various regions of the brain were heated or cooled with a temperature probe. Within the brain, only the hypothalamus produced thermoregulatory responses such as shivering or panting.

RESPONSES WHEN CORE TEMPERATURE FALLS BELOW THE SET POINT When thermoreceptors signal a fall in core temperature below the set point, the hypothalamus triggers compensating responses by sending signals through the autonomic nervous system. Among the immediate responses is constriction of the arterioles in the skin (vasoconstriction), which reduces the flow of blood to capillary networks in the skin. The reduced flow cuts down the amount of heat delivered to the skin and lost from the body surface. The reduction in flow is most pronounced in the skin covering the extremities, where blood flow may be reduced by as much as 99% when core temperature falls.

Another immediate response is contraction of the smooth muscles erecting the hair shafts in mammals and feather shafts in birds, which traps air in pockets over the skin, reducing convective heat loss. The response is minimally effective in humans because hair is sparse on most parts of the body—it produces the goose bumps you experience when the weather gets chilly. However, in mammals with fur coats or in birds, erection of the hair or feather shafts significantly increases the thickness of the insulating layer that covers the skin.

Immediate behavioral responses triggered by a reduction in skin temperature also help reduce heat loss from the body. Mammals may reduce heat loss by moving to a warmer locale, curling into a ball, or huddling together.

If these immediate responses do not return body temperature to the set point, the hypothalamus triggers further responses, most notably the rhythmic tremors of skeletal muscle we know as shivering. The heat released by the muscle contractions and the oxidative reactions powering them can raise the total heat production of the body substantially. At the same time, the hypothalamus triggers secretion of epinephrine (from the adrenal medulla) and thyroid hormones (see Section 42.4). These hormones increase heat production by stimulating the oxidation of fats and other fuels. The generation of heat by oxidative mechanisms in nonmuscle tissue throughout the body is termed **nonshivering thermogenesis.**

In human newborn babies and many other mammals, the most intense heat generation by nonshivering thermogenesis takes place in a specialized **brown adipose tissue** (also called **brown fat**) that can produce heat rapidly. Heat is generated by a mechanism that uncouples electron transport from ATP production in mitochondria (see Section 8.4); the heat is transferred throughout the body by the blood. Animals that hibernate or are active in cold regions, as well as the young of many others, contain brown adipose tissue. In most mammals, brown adipose tissue is concentrated between the shoulders in the back and around the neck. In human newborn babies, this tissue accounts for about 5% of body weight. Typically the tissue shrinks as humans age, until it is absent or essentially so in most adults. However, if exposure to cold is ongoing, as is the case with male Finlanders who work outside during the year, significant amounts of the tissue remain.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

If none of these responses succeeds in raising body temperature to the set point, the result is **hypothermia,** a condition in which the core temperature falls below normal for a prolonged period. In humans, a drop in core temperature of only a few degrees affects brain function and leads to confusion; continued hypothermia can lead to coma and death (see *Why It Matters* in Chapter 38).

RESPONSES WHEN CORE TEMPERATURE RISES ABOVE THE SET POINT When core temperature rises above the set point, the hypothalamus sends signals through the autonomic system that trigger responses lowering body temperature (see Figure 38.10). As an immediate response, the signals relax smooth muscles of arterioles in the skin (vasodilation), increasing blood flow and with it, the heat lost from the body surface. In addition, in humans and other mammals with sweat glands, signals from the hypothalamus trigger the secretion of sweat, which absorbs heat as it evaporates from the surface of the skin.

Some endotherms, including dogs (which have sweat glands only on their feet) and many birds (which have no sweat glands), use panting as a major way to release heat (see Figure 38.10). These physiological changes are reinforced by behavioral responses such as seeking shade or a cool burrow, plunging into cold water, or taking a cold drink.

When the heat gain of the body is too great to be counteracted by these responses, **hyperthermia** results. An increase of only a few degrees above normal for a prolonged period is enough to disrupt vital biochemical reactions and damage brain cells. Most adult humans become unconscious if their body temperature reaches 41°C (106°F) and die if it goes above 43°C (110°F) for more than a few minutes.

The Skin Is an Organ of Heat Transfer in Birds and Mammals

The skin of birds and mammals is an organ of heat transfer. The arterioles delivering blood to the capillary networks of the skin constrict or dilate to control blood flow and, with it, the amount of heat transferred from the body core to the surface.

The outermost living tissue of human skin, the **epidermis,** consists of cells that grow and divide rapidly **(Figure 48.19),** becoming packed with fibers of a highly insoluble protein, *keratin* (see Section 5.3). When fully formed, the epidermal cells die and become compacted into a tough, nearly impermeable layer that limits water loss primarily to evaporation of the fluids secreted by the sweat glands.

The sweat glands and hair follicles are embedded in the layer below the epidermis. Called the **dermis,** it is packed with connective tissue fibers such as collagen, which resist compression, tearing, or puncture of the skin. The dermis also contains thermoreceptors and the dense networks of arterioles, capillaries, and venules that transfer heat between the skin and the environment.

The innermost layer of the skin, the **hypodermis,** contains larger blood vessels and additional reinforcing connective tissue. The hypodermis also contains an insulating layer of fatty tissue below the dermal capillary network, which ensures that heat flows between the body core and the surface primarily through the blood. The insulating layer is thickest in mammals that live in cold environments, such as whales, seals, walruses, and polar bears, in which it is known as *blubber.*

The Set Point Varies in Daily and Seasonal Rhythms in Many Birds and Mammals

The temperature set point in many birds and mammals varies in a regular cycle during the day. In some, the daily variations are relatively small and not obviously keyed to changes in environmental temperature. In others, larger variations are correlated with daily or seasonal temperature changes.

Camels undergo a daily variation of as much as 7°C (13°F) in set-point temperature. During the day, a camel's set point gradually resets upward, an adaptation that allows its body to absorb a large amount of heat. The heat absorption conserves water that would otherwise be lost by evaporation to keep the body at a lower set point. At night, when the desert is cooler, the thermostat resets again, allowing the body temperature to cool several degrees, releasing the excess heat absorbed during the day.

When the environmental temperature is cool, having a lowered temperature set point greatly reduces the energy required to maintain body temperature. In many animals, the lowered set point is accompanied by reductions in metabolic, nervous, and physical activity (including slower respiration and heartbeat), producing a sleeplike state known as **torpor.**

Many small animals and birds enter into **daily torpor,** a period of inactivity keyed to variations in daily temperature. Typically these animals expend more energy per unit of body

weight to keep warm than larger animals, because the ratio of body surface to volume increases as body size decreases. Hummingbirds, for example, feed actively during the daytime, when their set point is close to 40°C (104°F). During the cool of night, however, the set point drops to as low as 13°C (55°F); this allows the birds to conserve enough energy to survive overnight without feeding. Some nocturnal animals, including bats and small rodents such as deer mice, become torpid in cool locations during daylight hours when they do not actively feed. At night, their temperature set point rises and they become fully active **(Figure 48.20).**

FIGURE 48.20 Cycle of daily torpor in a deer mouse *(Peromyscus maniculatus).*
© Cengage Learning 2014

Many animals enter a prolonged state of torpor tied to the seasons, triggered in most cases by a change in day length that signals the transition between summer and winter. The importance of day length has been shown by laboratory experiments in which animals have been induced to enter seasonal torpor by changing the period of artificial light to match the winter or summer day length.

Extended torpor during winter, called **hibernation** (*hibernus* = relating to winter), greatly reduces metabolic expenditures when food is unobtainable. Typically, hibernators must store large quantities of fats to serve as energy reserves. The drop in body temperature during hibernation varies with the mammal. In some, such as hedgehogs, woodchucks, and squirrels, body temperature may fall by 20°C (36°F) or more. Body temperature even drops to near 0°C in some small hibernating mammals and, in the Arctic ground squirrel, the body supercools (goes to a below-freezing, unfrozen state) during hibernation, with body temperature dropping to about −3°C. Some ectotherms, including amphibians and reptiles living in northern latitudes and even some insects, also become torpid during winter.

Some mammals enter seasonal torpor during summer, called **estivation** (*aestivus* = relating to summer), when environmental temperatures are high and water is scarce. Some ground squirrels, for example, remain inactive in the cooler temperatures of their burrows during extreme summer heat. Many ectotherms, among them land snails, lungfishes, many toads and frogs, and some desert-living lizards, weather such climates by digging into the soil and entering a state of estivation that lasts throughout the hot dry season.

Some Animals Use Countercurrent Heat Exchangers to Retain Core Heat

Recall from Section 46.2 that many animals with internal gills use countercurrent exchange to maximize the amounts of O_2 and CO_2 exchanged with water. A countercurrent exchange system can also be used for heat exchange. **Figure 48.21** illustrates one type of *countercurrent heat exchanger.* Here, a set of arteries and veins is packed closely together in a region between the core and the periphery of the body, typically an extremity (one artery and one vein are shown in Figure 48.21). Warm blood from the core flows through arteries toward cold peripheral tissues and organs. In the countercurrent heat exchanger, that warm arterial blood flows next to cold blood from the body periphery that is in the veins. By conduction, heat moves from the artery to the vein and the now-warmer venous blood continues to the core.

Countercurrent heat exchanges of this type are found in many endotherms. In birds they are often in the legs, thereby limiting heat loss from the feet. In mammals, they are also often in the limbs; for example, in a dophin's fluke and flippers, and in the legs of an arctic wolf.

Another type of countercurrent exchange that helps to limit heat loss takes place in the nasal passages of birds and mammals. The air in the lungs of these animals is at 100% relative humidity because the cells of the lung capillaries must be

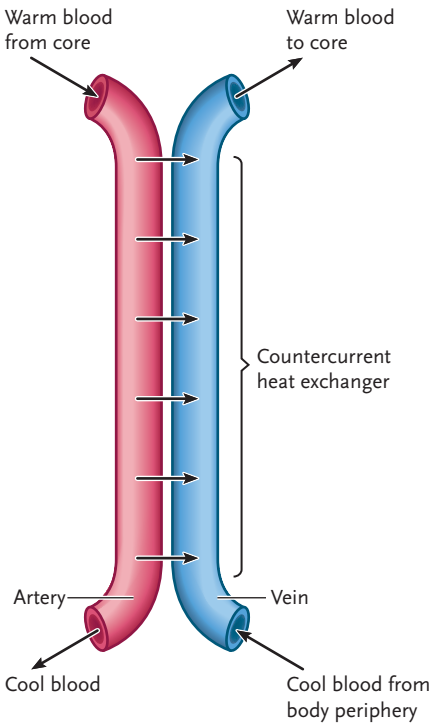

FIGURE 48.21 A countercurrent heat exchanger for conserving core heat.

moist to allow oxygen breathed in to pass into those cells and on into the pulmonary veins. The air expelled from the lungs therefore has the potential to cause significant water loss from the body. And, because the lung air is warm, there is the potential also for significant heat loss. An adaptation to limit water and heat loss is folds in the nasal cavity. These folds can be elaborate and represent a relatively large surface area. In outgoing breaths, some of the water in the air condenses on the nasal folds because the surfaces are cooler than those of the lung interior. Inhaled air is drier than the air leaving the lungs. The inhaled air evaporates some of the water on the nasal folds, which cools the folds for the next outgoing breath. This countercurrent exchange system involves opposing fluids separated by time rather than space as in the system discussed previously. This system is important for thermoregulation because it limits the loss of heat in expelled air. By this mechanism, mammals on average reclaim up to 45% of the water in expelled air, along with its heat content. Kangaroo rats reclaim up to 88% of their body water in this fashion.

STUDY BREAK 48.8

Describe how thermoreceptors and negative feedback pathways achieve temperature regulation in endotherms.

UNANSWERED QUESTIONS

How can we use genetics to understand how the kidney works in humans?

A variety of disorders of kidney function are inherited as Mendelian traits. For example, the disorder of renal growth known as polycystic kidney disease was recognized as a familial phenotype well before the structure of DNA was defined. Many other complex and common renal phenotypes (for example, blood pressure and susceptibility to the development of decreased kidney filtration function) also have genetic components.

The use of molecular cloning methods in the 1980s and 1990s led to enormous growth in our understanding of the specific transport proteins used by the kidney to fine-tune the extracellular environment. These discoveries were quickly followed by the elucidation of a large number of rare inherited disorders caused by mutations in the genes encoding many of these proteins. Careful observation of these human phenotypes, coupled with a biochemical understanding of the effects of these mutations, has in turn led to an improved understanding of basic renal physiology.

In the urine produced by a healthy kidney, protein is normally present only in very small amounts; little protein gets through the glomerular filtration barrier, and most of what does get through is reabsorbed in the renal tubule. By contrast, a large fraction of human kidney diseases are characterized by protein in the urine, a condition called proteinuria. Diabetic kidney disease, for example, the most common form of kidney disease in the Western world, is characterized by increased urine protein and the abnormal accumulation of extracellular protein in the renal glomerulus, leading to a gradual decline in kidney function.

For the past decade, most of my own laboratory's research has focused on inherited diseases of the renal glomerulus, using methods of molecular cloning (see Section 18.1) to identify disease genes. Mutations in the actin-regulatory proteins α-actinin-4 and INF2 both cause late onset proteinuria and slowly progressive kidney dysfunction. Based on our studies and the research of other labs, we believe that fine regulation of the actin cytoskeleton is critical to maintaining the complex architecture of glomerular podocytes, a specialized epithelial cell that forms the final part of the glomerular filter. When this architecture is disturbed, the podocytes become more easily injured.

Large amounts of protein (on the order of 3 g/day) are the central feature of a serious medical condition known as the nephrotic syndrome. By studying very early onset forms of the nephrotic syndrome, genes for proteins that are unique to the podocyte cell–cell junction have been shown to be mutated in these disorders. For example, the cell surface protein nephrin has been shown to play important structural and signaling functions. Despite the growing list of genes known to be important to normal filtering of the blood, much work needs to be done before we can answer the question of how the products of these genes interact to produce a functioning kidney.

Humans have many disadvantages as experimental organisms. We cannot do invasive experiments on them, we cannot do planned matings, and they take a long time to grow. Nonetheless, the careful study of renal phenotypes in humans followed by genetic analysis has led to a much better understanding of kidney disease and kidney function. It is important both for medicine and for understanding the kidney to use the information gained through genetic studies to inform biology.

THINK LIKE A SCIENTIST Kidney transplantation is a standard form of treatment for kidney failure. In some instances, the kidney disease that affected the original kidneys returns to involve the transplanted kidney. What does this say about the mechanism of the disease? What would this say about the mechanism of an inherited form of kidney disease?

Martin Pollak

Martin Pollak is Chief of Nephrology at the Beth Israel Deaconess Medical Center in Boston and Associate Professor of Medicine at Harvard Medical School. The focus of his laboratory is to learn more about the causes of kidney disease in patients and families by studying genetics. To learn more, visit http://www.fsgs.bwh.harvard.edu/index.html.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

48.1 Introduction to Osmoregulation and Excretion

- Solute concentration is measured as osmolarity in milliosmoles per liter of solution (mOsm/L). A solution can be comparatively hyperosmotic, hypoosmotic, or isoosmotic to another solution. Water moving from a region of higher osmolarity to a region of lower osmolarity across a selectively permeable membrane occurs by osmosis.
- Osmoconformers allow the osmolarity of their body fluids to match that of the environment. Osmoregulators keep the osmolarity of body fluids different from that of the environment.
- Molecules and ions must be removed from the body to keep cellular and extracellular fluids isoosmotic. In most animals, ECF is filtered through tubules formed from a transport epithelium and released to the exterior of the animal as urine (Figure 48.2).
- Nitrogenous wastes are excreted as ammonia, urea, or uric acid, or as a combination of these substances (Figure 48.3).

48.2 Osmoregulation and Excretion in Invertebrates

- Most marine invertebrates are osmoconformers; they expend little or no energy on maintaining water balance. Freshwater and terrestrial invertebrates are osmoregulators. They must expend energy to excrete water that moves into their cells by osmosis.
- The cells of the simplest marine invertebrates exchange water and solutes directly with the surrounding seawater. More complex invertebrates have specialized excretory tubules (Figures 48.4–48.6).

48.3 Osmoregulation and Excretion in Mammals

- In mammals and other vertebrates, excretory tubules are concentrated in the kidney.
- The mammalian excretory tubule, the nephron, has a proximal end at which filtration takes place, a middle region in which reabsorption and secretion occur, and a distal end that releases urine. A network of capillaries surrounding the nephron takes up ions and water and other molecules absorbed by the nephron. The urine leaving individual nephrons is processed further in collecting ducts and then pools in the renal pelvis. From there it flows through the ureter to the urinary bladder, and through the urethra to the exterior of the animal (Figure 48.7).
- Glomerular filtration, a process in plasma of the blood filters through the glomerular capillaries into Bowman's capsule, is the first step of excretion. By the process of tubular reabsorption in the proximal convoluted tubule and loop of Henle, substances of value (Na^+, Cl^-, K^+, water, HCO_3^-, and nutrients) are returned to the plasma as the filtrate flows through the nephron tubules. By the process of tubular secretion, selective movement of substances (such as detoxified poisons) takes place from the blood of the peritubular capillaries. Subsequently, the concentration of salts is balanced between the urine and the interstitial fluid surrounding the nephron, and more water is reabsorbed (Figure 48.8 and Table 48.1).

Animation: Human urinary system

Animation: Urine Formation

Animation: Tubular reabsorption

48.4 Regulation of Mammalian Kidney Function

- The kidney's autoregulation system responds rapidly to small variations in blood pressure so as to keep the glomerular filtration rate constant. The autoregulation system involves: (1) vascular control of blood pressure and (2) a feedback control mechanism between the tubule and specialized cells in the juxtaglomerular apparatus (Figure 48.10).
- When blood volume and blood pressure drop, the hormones of the renin-angiotensin-aldosterone system (RAAS) raise blood pressure by stimulating arteriole constriction and increasing NaCl reabsorption in the kidneys (Figure 48.10).
- ADH, which increases water reabsorption, is released from the pituitary when osmoreceptors detect an increase in the osmolarity of body fluids (Figures 48.11 and 48.12).

48.5 Kidney Function in Nonmammalian Vertebrates

- Marine teleosts continually drink seawater to replace body water lost by osmosis to their hyperosmotic environment. Excess salts and nitrogenous wastes are excreted by the gills (Figure 48.13A).
- The body fluids of sharks and rays are isoosmotic with seawater. They do not lose water by osmosis, and do not drink seawater. Excess salts are excreted in the kidney and by a rectal salt gland.
- Body fluids of freshwater fishes and amphibians are hyperosmotic to their environment, and these animals must excrete the excess water that enters by osmosis. Body salts are obtained from food and, in fishes, through the gills (Figure 46.13B). Nitrogenous wastes are excreted from the gills of fishes and larval amphibians as ammonia and through the kidneys of adult amphibians as urea.
- Reptiles and birds conserve water by secreting nitrogenous wastes as uric acid and by absorbing water from urine and feces in the cloaca.

Animation: Diffusion, osmosis, and countercurrent systems

48.6 Introduction to Thermoregulation

- Animals must maintain body temperature at a level that provides optimal physiological performance. Heat flows between animals and their environment by conduction, convection, radiation, and evaporation (Figures 48.15 and 48.16).
- Ectothermic animals obtain heat energy primarily from the environment; endothermic animals obtain heat energy primarily from internal reactions (Figure 48.17).

Animation: Control of human body temperature

48.7 Ectothermy

- Ectotherms obtain heat energy externally and control body temperature primarily by physiological or behavioral methods of regulating heat exchange with the environment.
- Many animals undergo thermal acclimatization, a structural or metabolic change in the limits of tolerable temperatures as the environment alternates between warm and cool seasons.

48.8 Endothermy

- Endotherms obtain heat energy primarily from internal reactions and maintain body temperature over a narrow range by balancing internal heat production against heat loss from the body surface.
- Internal heat production is controlled by negative feedback pathways triggered by thermoreceptors. When deviations from the temperature set point occur, signals from the receptors bring about compensating responses such as changes in blood flow to

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the body surface, sweating or panting, and behavioral modifications (Figure 48.18).

- The skin of endotherms is water-impermeable, reducing heat lost by direct evaporation of body fluids. The blood vessels of the skin regulate heat loss by constricting or dilating. A layer of insulating fatty tissue under the vessels limits losses to the heat carried by the blood. The hair of mammals and feathers of birds also insulate the skin. Erection of the hair or feathers reduces heat loss by thickening the insulating layer (Figure 48.19).
- The temperature set point in many birds and mammals varies in daily and seasonal patterns. During cooler conditions, a lowered set point is accompanied by torpor (Figure 48.20).
- Some animals use countercurrent heat exchangers to retain core heat. One form of exchanger is a set of arteries and veins arrayed close together in a region between the core and the body periphery. The opposing directions of fluid flow in the vessels allows heat to move from the warm blood in the arteries to warm up the cold blood in the veins which is heading toward the core. Another form of exchanger involves the nasal folds in birds and mammals. The folds provide an exchange mechanism to conserve body water and its heat content (Figure 48.21).

UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following statements about osmoregulation is true?
   a. In freshwater invertebrates, salts move out of the body into the water because the animal is hypoosmotic to the water.
   b. A marine teleost has to fight gaining water because it is isoosmotic to the sea.
   c. Most land animals are osmoconformers.
   d. Vertebrates are usually osmoregulators.
   e. Terrestrial animals can regulate their osmolarity without expending energy.
2. One role of tubules in excretion is to:
   a. absorb H^+ ions to buffer body fluids.
   b. transport proteins across transport epithelium.
   c. reabsorb glucose and amino acids.
   d. move toxic substances from the filtrate into the cells composing the transport tubules.
   e. filter by maintaining a lower pressure in the fluid outside the tubule than inside it.
3. Products of metabolism in humans, as in:
   a. terrestrial amphibians, can include urea, which requires more energy to produce than ammonia.
   b. birds and reptiles, can include uric acid, which is nontoxic and excreted as a paste.
   c. sharks, are primarily excreted as ammonia.
   d. hydra, must be isoosmotic with the water ingested.
   e. other mammals, cannot be water as water comes only from what they drink.
4. Filtration and/or excretion can be performed by:
   a. ciliated metanephridia in insects.
   b. protonephridia containing flame cells in flatworms.
   c. a nephron and bladder in insects.
   d. Malpighian tubules on the segments of earthworms.
   e. the hindgut, which reabsorbs Na^+ and K^+ into the hemolymph of earthworms.
5. A mammalian nephron contains the:
   a. Bowman's capsule, which delivers the filtrate to the glomerulus.
   b. Bowman's capsule, which filters fluids, 99% of which will be excreted.
   c. proximal convoluted tubule, which moves Na^+ and K^+ into the filtrate of the interstitial fluids.
   d. proximal convoluted tubule, which reabsorbs K^+, Na^+, Cl^-, and H_2O.
   e. proximal convoluted tubule, which lacks microvilli to ease fluid movement through it.
6. Which of the following correctly describes a part of kidney function?
   a. Collecting ducts dilute urine because they are permeable to salt but not water.
   b. In the ascending loop of Henle, Na^+ and Cl^- move into the tubules because the osmolarity of the filtrate is increased.
   c. The descending loop of Henle receives filtrate from the ascending loop.
   d. The distal convoluted tubule pumps water into the tubule by active transport.
   e. The renal pelvis receives urine from the collecting ducts and carries it to the ureters.
7. Which of the following is an example of autoregulation of kidney function?
   a. The RAAS regulates Na^+ by secreting renin when blood pressure or blood volume decreases.
   b. The ADH system regulates water balance by decreasing water reabsorption and increasing excretion of salt.
   c. Receptors in the juxtaglomerular apparatus detect a higher salt concentration in the distal convoluted tubule and trigger constriction of the afferent arteriole to reduce glomerular filtration rate.
   d. ANF is released by the kidney to increase renin release.
   e. Angiotensin II lowers blood pressure by constricting arterioles.
8. Deficient water levels in humans are prevented by:
   a. osmoreceptors in the hypothalamus that detect decreases in salt concentrations.
   b. the hypothalamus stimulating the posterior pituitary to secrete a hormone that allows the collecting ducts and distal convoluted tubules to be permeable to water.
   c. inhibiting ADH, which causes a rise in osmolarity of the ECF.
   d. producing dilute urine.
   e. drinking alcohol, which stimulates aldosterone to raise the osmolarity of body fluids.
9. Which best exemplifies ectothermy?
   a. The metabolic rate increases as the temperature decreases.
   b. Body temperature remains constant when environmental temperatures change.
   c. Food demand increases when temperatures drop.
   d. Virtually all invertebrate groups are ectotherms.
   e. No vertebrate groups are ectotherms.
10. Unique to endotherms is:
    a. torpor.
    b. thermal acclimatization.
    c. a nonchanging body temperature.
    d. response to seasonal temperature changes.
    e. thermoregulation by a hypothalamus.

Discuss the Concepts

1. A urinalysis reveals glucose, urea, hemoglobin, and sodium. Which of these substances are abnormal in urine, and why?
2. As a person ages, nephron tubules lose some of their ability to concentrate urine. What is the effect of this change?
3. Shivering increases air movement over the body surface. What effect does this air movement have on heat conservation in the shivering animal?
4. What heat transfer processes might account for the change in body temperature when a mammal's body temperature undergoes daily variations?

Design an Experiment

Design experiments to show the role of fluid consumption in thermoregulation during endurance exercise.

Interpret the Data

Products labeled as "organic" fill an increasing amount of space on supermarket shelves. What does that label mean? A food that carries the USDA's organic label must be produced without pesticides such as malathion and chlorpyrifos that conventional farmers typically use on fruits, vegetables, and grains.

Does eating organic food significantly affect the level of pesticide residues in a child's body? Chensheng Lu of Emory University used urine testing to find out. For 15 days, the urine of 23 children (ages 3–11) was monitored for breakdown products of pesticides. During the first 5 days (phase 1), children ate their standard, nonorganic diet. For the next 5 days (phase 2), they ate organic versions of the same types of foods and drinks. Then, for the final 5 days (phase 3), the children returned to their nonorganic diet. The results are shown in the **Table.**

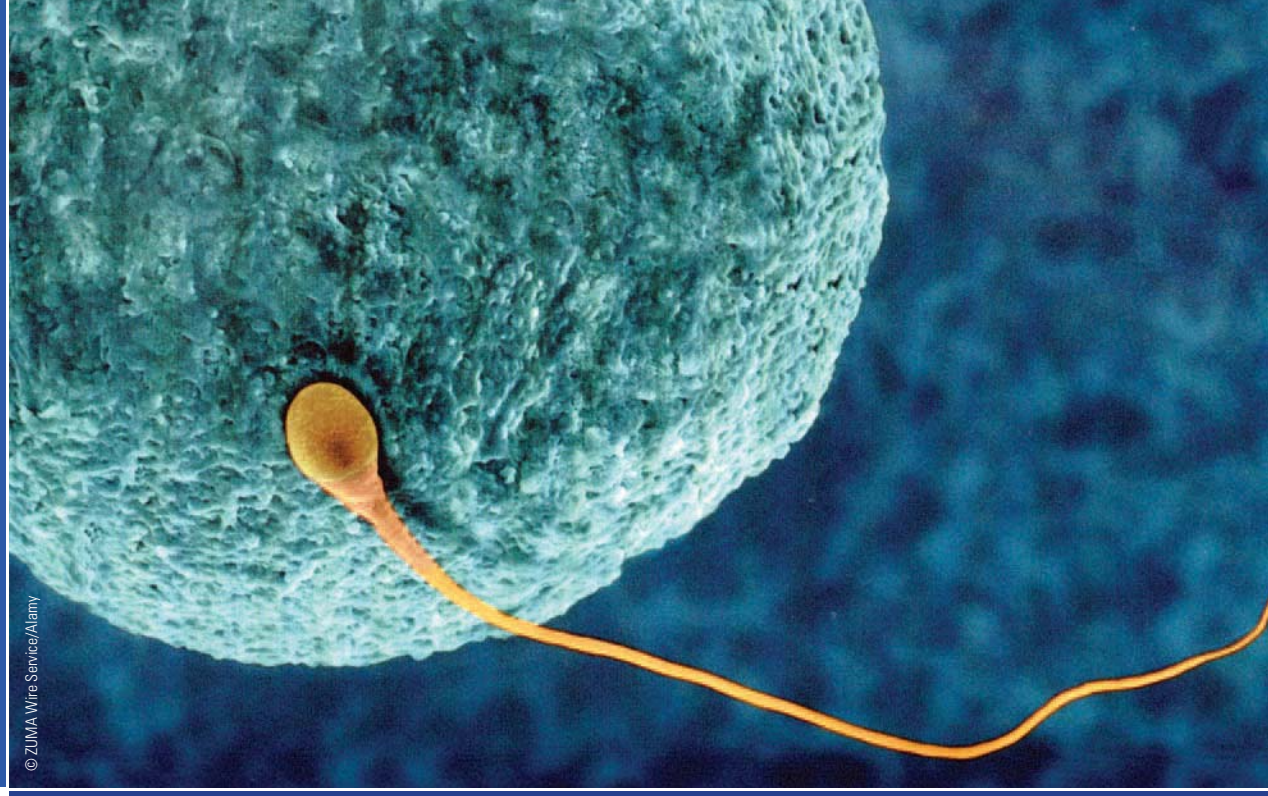
Levels of Metabolites (Breakdown Products) of Malathion and Chlorpyrifos in the Urine of Children Taking Part in a Study of Effects of an Organic Diet*

		Malathion metabolite		Chlorpyrifos metabolite	
Study phase	No. of samples	Mean (μg/L)	Maximum (μg/L)	Mean (μg/L)	Maximum (μg/L)
1. Nonorganic	87	2.9	96.5	7.2	31.1
2. Organic	116	0.3	7.4	1.7	17.1
3. Nonorganic	156	4.4	263.1	5.8	25.3

*The difference in the mean level of metabolites in the organic and inorganic phases of the study was statistically significant.

© Cengage Learning 2014

1. During which phase of the experiment did the children's urine contain the lowest level of the malathion metabolite?
2. During which phase of the experiment was the maximum level of the chlorpyrifos metabolite detected?
3. Did switching to an organic diet lower the amount of pesticide excreted by children?



Source: C. Lu et al. 2006. Organic diets significantly lower children's dietary exposure to organophosphorus pesticides. *Environmental Health Perspectives* 114:260–263.

Apply Evolutionary Thinking

Humans produce urea as an excretion product, whereas reptiles and birds produce uric acid. Indeed, human kidneys are not as efficient as those of reptiles and birds. What does this mean in an evolutionary sense?

Fertilization, the union of gametes such as the sperm and egg shown here, initiates development of a new individual.

STUDY OUTLINE

49.1 Animal Reproductive Modes: Asexual and Sexual Reproduction

49.2 Cellular Mechanisms of Sexual Reproduction

49.3 Sexual Reproduction in Humans

49.4 Methods for Preventing Pregnancy: Contraception

Animal Reproduction

Why it matters . . . It is seven days after the October full moon and night is falling. All the inhabitants of the Samoan island of Tutuila who have access to a boat are gathered on the island's large lagoon. Some hold lanterns and look into the water; others have nets at the ready. They are awaiting the palolo worm *(Eunice viridis)* **(Figure 49.1),** which has appeared in the water as the moon rises on this same night of the lunar year for as long as the islanders can remember.

The moon rises and the excitement of the crowd rises. Then, there they are, thousands of blue and green worms, squirming in the water like animated spaghetti. The boaters scoop up the worms by the netful and dump them into buckets. When the buckets are full, the islanders glide toward the shore where steaming pots are waiting, for palolo worms are a delicacy that the islanders savor only once a year. For the islanders, a night of feasting, singing, and dancing follows as they cook and eat the worms.

The worms that come to the surface to delight the islanders are not complete individuals. They are tail sections about 10 to 20 cm long that break from adults after they become filled with eggs or sperm (see Figure 49.1). The adults are polychaete annelids that live in burrows in coral reefs of the Samoan and Fiji islands. These annelids develop tail segments once a year, just after the October full moon. On the seventh night following the full moon, the tails break off and swim to the surface, where—if Samoans do not net them first—they disintegrate and release eggs and sperm by the millions. The anterior ends of the worms, safe in their burrows, survive to produce tails the next year.

The story of the palolo worm concerns the *reproductive cycle* of an animal. There is a biological clock in the worms, timed by periods of moonlight, that precisely sets both the appearance of the mating swarm and, indirectly, the appearance of the islanders with their boats. Most animals

show cycles in reproductive activity, and those cycles often are linked to the seasons.

The swarm of the palolo worms is only one of many adaptations that accomplish mating in animals. For animals that reproduce by eggs and sperm, the adaptations are as diverse as the number of species on Earth. This diversity allows individuals of the same species to find each other and unite eggs and sperm. Within the diversity, however, are underlying patterns that are shared by all animals.

Both the underlying patterns and the diversity of animal reproduction are the subjects of this chapter. We also discuss the development of eggs and sperm, and the union of egg and sperm that begins the development of a new individual. The next chapter continues with the events of development after eggs and sperm have united.

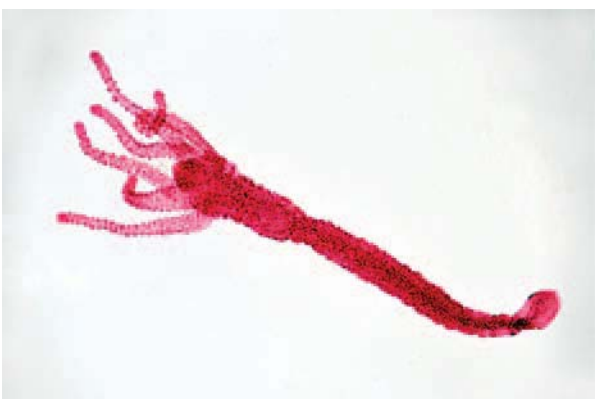
49.1 Animal Reproductive Modes: Asexual and Sexual Reproduction

Reproduction is part of a life cycle in which individuals grow, develop, and reproduce according to instructions encoded in DNA. Rather than survival of the individual, reproduction is the means of passing on the genes of an individual to new generations of the species. As such, it is among the most vital functions of living organisms.

Two basic modes of reproduction operate in the animal kingdom. In **asexual reproduction,** a single individual gives rise to offspring without fusion of **gametes** (egg and sperm); that is, there is no genetic input from another individual. In **sexual reproduction,** male and female parents produce offspring through the union of egg and sperm generated by meiosis (meiosis is discussed in Chapter 11).

Asexual Reproduction Produces Offspring with Genes from Only One Individual

Many aquatic invertebrates and some terrestrial annelids and insects reproduce asexually. Asexual reproduction is rare among vertebrates. In asexual reproduction, one or many cells of a parent develop directly into a new individual. In a few animals that undergo asexual reproduction, the cells taking part are genetically varied products of meiosis, but in most they are the products of mitosis. The offspring therefore are genetically identical to one another and to the parent; in other words, they are genetic clones of the parent. For this reason, asexual reproduction of this kind is also called **clonal reproduction.**



Genetic uniformity of offspring can be advantageous in environments that remain stable and uniform. Asexual reproduction tends to preserve gene combinations, producing individuals that are successful in such environments. Further, individuals do not have to expend energy to produce gametes or find a mate. Asexual reproduction can also bring reproductive advantages to individuals living in sparsely populated areas, or to sessile animals, which cannot move from place to place.

Asexual reproduction involving mitosis occurs in animals by three basic mechanisms: *fission, budding,* and *fragmentation.*

1. **Fission.** In **fission,** the parent separates into two or more offspring of approximately equal size. Planarians (flatworms), for instance, reproduce asexually by fission; depending on the species, they may divide by transverse or longitudinal fission.
2. **Budding.** In **budding,** a new individual grows and develops while attached to the parent. Sponges, tunicates, and some cnidarians reproduce asexually by this mechanism. The offspring may break free from the parent, or remain attached to form a *colony.* In the cnidarian *Hydra,* for example, an offspring buds and grows from one side of the parent's body and then detaches to become a separate individual **(Figure 49.2).**
3. **Fragmentation.** In **fragmentation,** pieces separate from the body of a parent and develop *(regenerate)* into new individuals. Many species of cnidarians, flatworms, annelids, and some echinoderms can reproduce by fragmentation.

Some animals produce offspring by the growth and development of an egg without fertilization. The offspring may be haploid or diploid depending on the species. This form of asexual reproduction is called **parthenogenesis** (*parthenos* = virgin, *genesis* = origin). Because the egg from which a parthenogenetic offspring is produced derives from meiosis in the female parent, the offspring are not genetically identical to the parent or to each other. (How chromosome segregation and genetic recombination during meiosis produce gametes with gene combinations different from the parent is described shortly.)

Parthenogenesis occurs in some invertebrates, including certain aphids, bees, and water fleas. In water fleas, for instance, the female can produce two types of eggs. One type of egg develops only if it is fertilized, whereas the other develops by parthenogenesis. The conditions set the switch for which form of reproduction occurs: sexual reproduction occurs when there is

environmental stress, whereas asexual reproduction occurs under favorable environmental conditions. The two types of environmental conditions, and, hence, the different reproductive cycles, tend to correlate with the seasons. In bees, haploid male drones are produced parthenogenetically from unfertilized eggs produced by reproductive females (queens) while new queens and sterile workers develop from fertilized eggs.

Parthenogenesis also occurs in some vertebrates, for example, in certain fish, salamanders, amphibians, lizards, and turkeys. In these animals, an egg, produced by meiosis, typically doubles its chromosomes to produce a diploid cell that begins development. In single-sex species where females have two identical sex chromosomes, the offspring are female, whereas in single-sex species where males have two identical sex chromosomes, the offspring are male. For instance, all whiptail lizards (*Cnemidophorus* species) are females, produced solely by parthenogenesis. These females go through the motions of mating and copulation with each other.

Sexual Reproduction Generates Diversity among Offspring

Animals reproduce sexually by the union of sperm and eggs produced by meiosis. The overriding advantage of sexual reproduction is the generation of genetic diversity among offspring. This diversity increases the chance that, in a changing environment, at least some offspring will grow and reproduce successfully. Diversity also increases the chance that offspring may be

able to live and reproduce in environments previously unoccupied by the species.

Two mechanisms that are part of meiosis give rise to the genetic diversity in eggs and sperm: *genetic recombination* (see Section 11.2) and the *independent assortment* of chromosomes of maternal and paternal origin (see Section 12.1). Genetic recombination mixes the alleles of parents into new combinations within chromosomes; independent assortment results in random combinations of maternal and paternal chromosomes in gamete nuclei. Additional variability is generated at fertilization when eggs and sperm from genetically different individuals fuse together at random to initiate the development of new individuals. To these sources of variability are added random DNA mutations, which are the ultimate source of variability for both sexual and asexual reproduction.

The disadvantages of sexual reproduction include the expenditure of energy and raw materials in producing gametes and finding mates, and producing fewer offspring per parent. The need to find mates, for instance, can expose animals to predation and takes time from finding food and shelter and caring for existing offspring. Concerning offspring number, consider a female that reproduces asexually. All of her progeny will be females, each of whom will produce more offspring by asexual reproduction. However, in sexual reproduction, one half of the offspring of a mating pair are females, and one-half are males (on average). Therefore, only one-half of the progeny produced by sexual reproduction of a female produce offspring for the following generation.

We turn now to the mechanisms of sexual reproduction, which include both cellular and whole-organism activities. The next section discusses cellular mechanisms.

STUDY BREAK 49.1

What are the advantages and disadvantages of asexual reproduction? Of sexual reproduction?

49.2 Cellular Mechanisms of Sexual Reproduction

The cellular mechanisms of sexual reproduction are **gametogenesis,** the formation of male and female gametes, and **fertilization,** the union of gametes that initiates development of a new individual. The pairing of a male and a female for the purpose of sexual reproduction is **mating.**

Gametogenesis Involves the Coordinated Events of Meiosis and Sperm and Egg Development

Gametes in most animals form from **germ cells,** a cell line that is set aside early in embryonic development and remains distinct from the other, **somatic cells** of the body. During development, the germ cells collect in specialized gamete-producing organs, the **gonads**—the **testes** (singular, *testis*) in males and **ovaries** in females. Mitotic divisions of the germ cells produce **spermatogonia** in males and **oogonia** in females; these are the cells that enter meiosis to give rise to gametes by **spermatogenesis** in males and **oogenesis** in females **(Figure 49.3).** In humans, each gamete has only one of 2^{23} possible combinations of parental chromosomes. In some animals, the germ cells also give rise to families of cells that assist gamete development.

Meiosis reduces the number of chromosomes from the diploid level characteristic of somatic cells of the species, in which there are two copies of each chromosome, to the haploid level of gametes, in which there is one copy of each chromosome. The fusion of a haploid sperm and egg during fertilization restores the diploid number of chromosomes and produces a **zygote,** the first cell of a new individual.

SPERMATOGENESIS Spermatogenesis produces mature, haploid sperm cells, also called **spermatozoa** (singular, *spermatozoon*) or simply *sperm* **(Figure 49.4).** The sperm of most animal species are motile cells, driven through a watery medium by the whiplike beating of a flagellum that extends from the posterior end of the cell. During maturation from spermatid to sperm, most of the cytoplasm is lost, except for mitochondria, which surround the base of a flagellum. These mitochondria produce the ATP used as the energy source for flagellar beating. At the head of the sperm, a specialized secretory vesicle, the **acrosome,** forms a cap over the nucleus. The acrosome contains enzymes and other proteins that help the sperm attach to and penetrate the surface coatings of an egg of the same species.

OOGENESIS Oogenesis produces mature, haploid egg cells, also called **ova** (singular, *ovum*) or simply *eggs.* The eggs of all ani-

mals are nonmotile cells, typically much larger than sperm of the same species. Whereas in spermatogenesis, all four products of meiosis develop into functional sperm, in oogenesis, only one of the cell products of meiosis develops into a functional egg **(Figure 49.5).** That egg retains almost all of the cytoplasm of the parent cell. The other products form nonfunctional cells called **polar bodies** (see Figure 49.3B). The unequal cytoplasmic divisions concentrate nutrients and other molecules required for development in the egg. In most species, the polar bodies eventually disintegrate and do not contribute to fertilization or embryonic development.

The oocytes of most animals do not complete meiosis until fertilization. In mammals, for example, oocytes stop developing at the end of the first meiotic prophase within a few weeks after a female is born. The oocytes remain in the ovary at this stage of development until the female is sexually mature. Then, one to several oocytes advance to the metaphase of the second meiotic division and are released from the ovary at intervals ranging from days to months, or at certain seasons, depending on the species. (In humans, some oocytes may therefore remain in prophase of the first meiotic division for perhaps 50 years until menopause.) As in other animals, meiosis is completed at fertilization to produce the fully mature egg. Mature eggs are the largest cell type of an animal species.

An egg typically has specialized features, which include: (1) stored nutrients and cytoplasmic determinants required for at least the early stages of embryonic development (see Section 16.4 for a discussion of cytoplasmic determinants); (2) egg coats of one or more kinds that protect the egg from mechanical injury and infection and, in some species, protect the embryo after fertilization; and (3) mechanisms that prevent the egg from being fertilized by more than one sperm cell (discussed shortly).

The amount of stored nutrients in an egg varies with the animal. Mammalian eggs are microscopic, containing few stored nutrients. In mammals, the embryo develops inside the mother and is supplied with nutrients by the mother's body. In contrast, the relatively large eggs of birds and reptiles contain all the nutrients required for complete embryonic development: the "yolk" contains the egg cell, and the "white" contains the nutrients. No matter what the size of an animal egg, however, most of the volume is cytoplasm, and the egg nucleus is microscopic or nearly so in all species.

FIGURE 49.5 **A mature hamster egg that has been fertilized.**

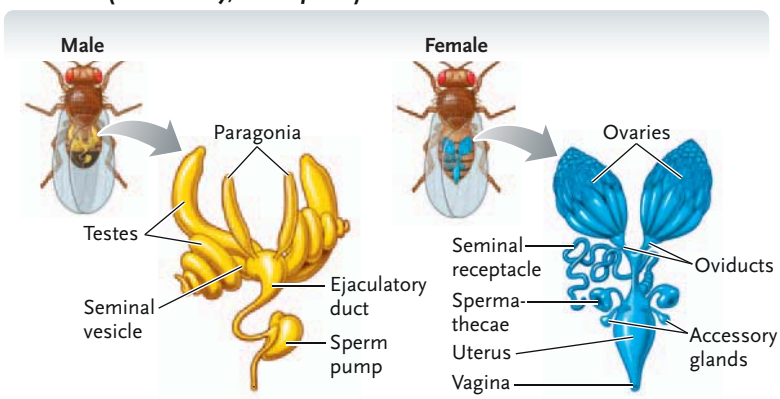
Egg coats are surface layers added during oocyte development or fertilization in many species. The **vitelline coat,** called the **zona pellucida** in mammals (see Figure 49.5) is a gel-like matrix of proteins, glycoproteins, or polysaccharides located immediately outside the plasma membrane of the egg cell. Insect eggs have additional outer protein coats that form a hard, water-impermeable layer for preventing desiccation. Amphibians and some echinoderms have an additional outer egg jelly layer instead of a tough protein coat that protects the egg from drying out (see Figure 49.8).

In birds, reptiles, and one group of egg-laying mammals, the **monotremes,** the egg white, a thick solution of proteins, surrounds the vitelline coat. Outside the white is the *shell* of the egg, flexible and leathery in reptiles and mineralized and brittle in birds. Both the egg white and the shell are added while the egg—fertilized or not—is in transit through the **oviduct,** the tube through which the egg moves from the ovary to the outside of the body. In mammals, the egg is surrounded by **follicle cells** during its development. These cells, which grow from ovarian tissue, nourish the developing egg. They also make up part of the zona pellucida while the egg is in the ovary, and remain as a protective layer after it is released.

Fertilization Requires an Internal or External Aquatic Medium

Eggs and sperm are delivered from the ovaries and testes to the site of fertilization by oviducts in females and by sperm ducts in males; in many species, external accessory sex organs participate in the delivery. **Figure 49.6** shows examples of invertebrate and vertebrate reproductive systems. The nonmotile eggs move through the oviducts on currents generated by the beating of cilia lining the oviducts, or by contractions of the oviducts or the body wall.

Depending on the species, fertilization may be *external,* taking place in a watery medium outside the body of both parents, or *internal,* taking place in a watery fluid inside the body of the female. In **external fertilization,** which occurs in most aquatic invertebrates, bony fishes, and amphibians, sperm and eggs are shed into the surrounding water. The sperm swim until they collide with an egg of the same species. The process is helped by synchronization of female and male gamete release, and by the enormous quantities of gametes released. In some animals, such as sea urchins and amphibians, the sperm are attracted to the egg by diffusible attractant molecules released by the egg.



Most amphibians, even terrestrial species such as toads, mate in an aquatic environment. Frogs typically mate by a reflex response called *amplexus,* in which the male clasps the fe-

male tightly around the body with his forelimbs **(Figure 49.7).** The embrace stimulates the female to shed a mass of eggs into the water through the **cloaca**—the cavity in reptiles, birds, amphibians, and many fishes into which both the intestinal and genital tracts empty. As the eggs are released, they are fertilized by sperm released by the male.

Internal fertilization takes place in invertebrates such as annelids, some arthropods, and some mollusks, and in vertebrates such as reptiles, birds, mammals, some fishes, and some salamanders. In these animals, the sperm are released by the male close to or inside the entrance of the reproductive tract of the female. The sperm swim through fluids in the reproductive tract until they reach and fertilize each egg. In some species, molecules released by the egg attract the sperm to its outer coats. The physical act involving the introduction of the male's accessory sex organ (for example, penis) into a female's accessory sex organ (for example, vagina) to accomplish internal fertilization is known as **copulation.** Internal fertilization makes terrestrial life possible by providing the aquatic medium required for fertilization inside the female's body without the danger of gametes drying by exposure to the air.

Male reptiles, birds, and mammals have accessory sex organs that place sperm directly inside the reproductive tract of females, where fertilization takes place. In reptiles and birds, sperm fertilize eggs as they are released from the ovary and travel through the oviducts, before the shell is added. In mammals, the male's penis delivers sperm into the female's vagina. Unlike the cloaca of the reptiles and birds, which has both sexual and excretory functions, the vagina is specialized for reproduction. The introduced sperm swim into the tubular oviducts containing the eggs, and fertilization takes place.

Fertilization Involves Fusion of a Sperm and an Egg, Which Activates the Egg for Development

Once a sperm touches the outer surface of an egg of the same species, receptor proteins in the sperm plasma membrane bind the sperm to the vitelline coat or zona pellucida. In most animals, only a sperm from the same species as the egg can recognize and bind to the egg surface.

Species recognition is highly important in animals that carry out external fertilization, because the water surrounding the egg may contain sperm of many different species. It is less important in internal fertilization, because structural adaptations and behavioral patterns of mating usually limit sperm transfer from males to females of the same species.

FERTILIZATION **Figure 49.8** shows the steps of fertilization in the sea urchin, a well-studied organism for invertebrate development and reproduction, and an often-used model for human fertility research. The steps are similar in other organisms. The attachment of sperm to egg triggers a rapid series of events starting with the **acrosomal reaction,** in which enzymes in the acrosome are released from the sperm and digest a path through the egg coats. The sperm, with its tail still beating, follows the path until its plasma membrane touches and fuses with the plasma membrane of the egg. Fusion introduces the sperm nucleus into the egg cytoplasm and activates the egg to complete meiosis and begin development.

EGG ACTIVATION AND BLOCKS TO POLYSPERMY *Polyspermy,* the phenomenon in which more than one sperm fertilizes an egg, can be prevented by two mechanisms: a *fast block* within seconds of fertilization, and a *slow block* within minutes.

In many invertebrate species, such as the sea urchin, the fusion of egg and sperm opens ion channels in the plasma membrane of the egg, spreading a wave of electrical depolarization over the egg surface, much like the nerve impulse traveling along a neuron. The depolarization alters the egg plasma membrane's potential from negative to positive so that it cannot fuse with any additional sperm. Because it occurs within a few seconds after fertilization, the barrier set up by the wave of depolarization is called the **fast block to polyspermy** (see Figure 49.8, step 5).

In vertebrates, the wave of membrane depolarization following sperm–egg fusion is not as pronounced, and does not prevent additional sperm from fusing with the egg. However, any additional sperm nuclei entering the egg cytoplasm usually break down and disappear, so that only the first sperm nucleus to enter fuses with the egg nucleus.

In both invertebrates and vertebrates, fusion of egg and sperm triggers the release of stored calcium (Ca^{2+}) ions from the endoplasmic reticulum of the egg into the cytosol. The Ca^{2+} ions activate control proteins and enzymes that initiate intense metabolic activity in the fertilized egg, including a rapid increase in cellular oxidations and synthesis of proteins and other molecules.

The Ca^{2+} ions also trigger the **cortical reaction,** in which **cortical granules,** secretory vesicles just under the plasma membrane of the egg, fuse with the membrane and release their contents to the outside by exocytosis (see Figure 49.8, step 7; the process of exocytosis is described in Section 6.5). Enzymes released from the cortical granules alter the egg coats within minutes after fertilization, so that no further sperm can attach and penetrate to the egg. Once this barrier, termed the **slow block to polyspermy,** is set up, no further sperm can reach the egg plasma membrane in any animal species.

After the sperm nucleus enters the egg cytoplasm, microtubules move the sperm and egg nuclei together in the egg cytoplasm and they fuse. The chromosomes of the egg and sperm nuclei then assemble together and enter mitosis. The subsequent, highly programmed events of embryonic development that convert the fertilized egg into an individual capable of independent existence are described in the next chapter.

Reproductive Systems May Be Oviparous or Viviparous in Animals with Internal Fertilization

In animals with internal fertilization, three major types of support for embryonic development have evolved: *oviparity,* meaning egg laying; *viviparity,* meaning giving birth to live offspring; and *ovoviparity,* meaning giving birth to live offspring that first hatch internally from eggs.

- **Oviparous** animals (*ovum* = egg, *parere* = to bring forth, to bear) lay eggs that contain the nutrients needed for development of the embryo outside the mother's body. Examples are insects, spiders, most reptiles, and birds. The only oviparous mammals are the *monotremes:* the echidnas (spiny anteaters—found in Australia and New Guinea) and the duck-billed platypus (*Ornithorhynchus anatinus*—found in Australia).
- **Viviparous** animals (*vivus* = alive) retain the embryo within the mother's body and nourish it during at least early embryo development. All mammals except the monotremes are viviparous. Viviparity is seen also in all other vertebrate groups except for the crocodiles, turtles, and birds. In viviparous animals, development of the embryo takes place in a specialized saclike organ, the **uterus** *(womb).* Among mammals, one group, called the *placental mammals* or *eutherians,* has a specialized temporary structure, the **placenta,** which connects the embryo to the uterus. The placenta facilitates the transfer of nutrients from the blood of the mother to the embryo and the movement of wastes in the opposite direction. Humans are an example of placental mammals. The other group of mammals, the *marsupials* or *metatherians,* originally were called nonplacental mammals because of a belief that they lacked a placenta. In fact, they do have a placenta, but it derives from a different tissue than that of eutherians and does not connect the embryo and the uterus. Instead it provides nutrients to the embryo from an attached membranous sac containing yolk for only the early stages of its development. In many metatherians, the embryo is then born at an early stage and crawls over the mother's fur to reach the **marsupium,** an abdominal pouch within which it attaches to nipples and continue its development. Kangaroos, koalas, wombats, and opossums are marsupials.
- **Ovoviviparous** animals retain fertilized eggs within the body and the embryo develops using the nutrients provided by the egg. There is no uterus or placenta involved. When development is complete, the eggs hatch inside the mother and the offspring are released to the exterior. Ovoviviparity is seen in some fishes, lizards, and amphibians, many snakes, and many invertebrates.

Hermaphroditism Is a Variation on Sexual Reproduction

Some animals have evolved modified mechanisms that they use as their normal sexual reproduction process. One of these mechanisms is **hermaphroditism** (from *Hermaphroditos,* the son of *Hermes* and *Aphrodite,* a Greek god and goddess), in which both mature egg-producing and mature sperm-producing tissue is present in the same individual. Most flatworms, earthworms, land snails, and numerous other invertebrates are hermaphroditic. In humans and other mammals, there are rare cases of individuals who have both testicular and ovarian tissues. They are not true hermaphrodites because they are not both male and female; rather, they are genetically either male or female, but with ambiguous genitalia. Hence, they are called *pseudohermaphrodites* rather than true hermaphrodites.

Most hermaphroditic animals do not fertilize themselves, because anatomical barriers prevent individuals from introducing sperm into their own body, or the egg and sperm mature at different times. The prevention of self-fertilization maintains the genetic variability of sexual reproduction.

Hermaphroditism takes two forms: **simultaneous hermaphroditism,** in which individuals develop functional ovaries and testes at the same time, and **sequential hermaphroditism,** in which individuals change from one sex to the other. The two earthworms shown in **Figure 49.9** provide a common example of simultaneous hermaphroditism. The only known vertebrate simultaneous hermaphrodites are hamlets (genus *Hypoplectrus*), a group of predatory sea basses. Sequential hermaphroditism is seen among a number of invertebrates (for example, the slipper shell *Crepidula fornicata,* a gastropod), and some ectothermic vertebrates, notably fishes

(for example, the clownfish, genus *Amphiprion*). In some species, the initial sex is male (as with the slipper shell and the clownfish), and in others it is female.

2. How is the slow block to polyspermy brought about?

THINK OUTSIDE THE BOOK

Use the Internet or research literature to outline a model for how hermaphroditism may have evolved.

49.3 Sexual Reproduction in Humans

Except for structural details, human reproduction is typical of that of eutherian (placental) mammals. Internally, these mammals have a pair of gonads, either ovaries or testes. The gonads have a dual function in mammals, as they do in all vertebrates: they both produce gametes and secrete hormones that are responsible for sexual development and mating behavior (see Section 42.4). Males have ducts that carry sperm from the testes to the exterior. Females have an oviduct that leads from each ovary to the uterus, in which fertilized eggs implant and proceed through embryonic development. Nutrients from the mother and wastes from the embryo are exchanged through the placenta. After birth, the newborn offspring is nourished with milk secreted by the mother's mammary glands.

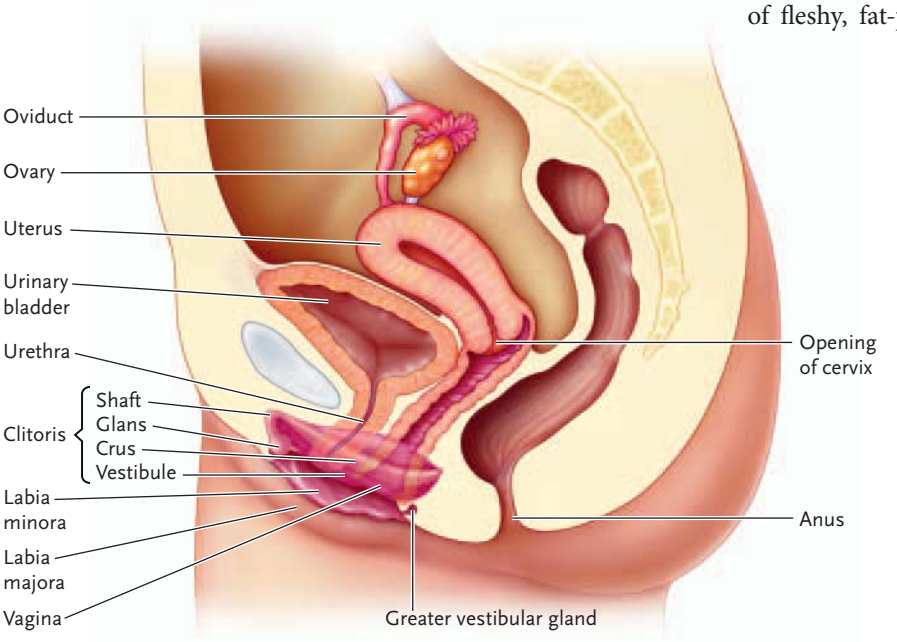

FIGURE 49.10 The reproductive organs of a human female.

© Cengage Learning 2014

In this section we survey reproductive structures and functions in humans as representative of eutherian mammals. Our story of human development continues in the next chapter, which traces the process from fertilization to birth.

Human Female Sexual Organs Function in Oocyte Production, Fertilization, and Embryonic Development

Human females have a pair of ovaries suspended in the abdominal cavity **(Figure 49.10).** An oviduct leads from each ovary to the uterus, which is a hollow, saclike organ with walls containing smooth muscle. The uterus is lined by the **endometrium,** which is formed by layers of connective tissue with embedded glands and is richly supplied with blood vessels. If an egg is fertilized and begins development, it must implant in the endometrium to continue developing. The lower end of the uterus, the **cervix,** opens into a muscular canal, the **vagina,** which leads to the exterior. Sperm enter the female reproductive tract via the vagina and, at birth, the baby passes from the uterus to the outside through the vagina.

At the birth of a female, each of her ovaries contains about 1 million oocytes, arrested at the end of the first meiotic prophase. Of these oocytes, about 200,000 to 400,000 survive until a female becomes sexually mature; about 400 are **ovulated**—released into the oviducts as immature eggs—during the lifetime of a woman. The egg is released into the abdominal cavity and is pulled into the nearby oviduct by the current produced by the beating of the cilia lining the oviduct. The cilia also propel the egg through the oviduct and into the uterus. Fertilization of the egg occurs in the oviduct.

The external female sex organs, collectively called the **vulva,** surround the opening of the vagina. Two folds of tissue, the **labia minora,** run from front to rear on either side of the opening to the vagina. These folds are partially covered by a pair of fleshy, fat-padded folds, the **labia majora,** which also run from front to rear on either side of the vagina. At the anterior end of the vulva, the labia minora join to partly cover the head of the **clitoris.** The rest of the clitoris is within the body. The clitoris contains erectile tissue and has the same embryonic origins as the penis. A pair of **greater vestibular glands,** with openings near the entrance to the vagina, secretes a mucus-rich fluid that lubricates the vulva. The opening of the urethra, which conducts urine from the bladder, is located between the clitoris and the vaginal opening. Most nerve endings associated with erotic sensations are concentrated in the clitoris, in the labia minora, and around the opening of the vagina. When a human female is born, a thin flap of tissue, the **hymen,** partially covers the opening of the vagina. This membrane, if it has not already been ruptured by physical exercise or other disturbances, is broken by the first sexual intercourse.

Ovulation in Human Females Occurs in a Monthly Cycle

Reproduction in human females is under neuroendocrine control, involving complex interactions between the hypothalamus, pituitary, ovaries, and uterus. Under this control, approximately every 28 days from puberty to menopause, a female releases an egg from one of her ovaries. The cyclic events in the ovary leading to ovulation are known as the **ovarian cycle.** This cycle is coordinated with the **uterine cycle,** or **menstrual cycle** (*menstruus* = monthly), events in the uterus that prepare it to receive the egg if fertilization occurs. While the cycle is commonly considered a monthly one, there is a lot of variation among human females with a range of about 15 to 45 days, and an average is about 28 to 29 days.

THE OVARIAN CYCLE The ovarian cycle produces a mature egg **(Figure 49.11).** The starting point for the cycle is a primary oocyte in prophase of meiosis division I. The beginning of the cycle is triggered by an increase in the release of **gonadotropin-releasing hormone (GnRH)** by the hypothalamus. This hormone stimulates the pituitary to release **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** into the bloodstream **(Figure 49.12A).** FSH stimulates 6 to 20 primary oocytes in the ovaries to be released from prophase of meiosis I and continue through the meiotic divisions. As the primary oocytes develop into secondary oocytes—which arrest in metaphase of meiosis II—they become surrounded by cells that form a **follicle** (day 2 of the cycle; **Figure 49.12B**). During this follicular phase, the follicle grows and develops and, at its largest size, becomes filled with fluid and may reach 12 to 15 mm in diameter. Usually only one follicle develops to maturity with release of the egg (secondary oocyte) by ovulation. If two or more follicles develop and their eggs are ovulated, multiple births of nonidentical siblings can result.

As the follicle enlarges, FSH and LH interact to stimulate the follicular cells to secrete **estrogens** (female sex hormones), primarily **estradiol** (see Section 42.4) **(Figure 49.12C).** Initially, the estrogens are secreted in low amounts; at this level, the estrogens have a *negative* feedback effect on the pituitary, inhibiting its secretion of FSH. As a result, FSH secretion declines briefly. However, estrogen secretion increases steadily, and its level peaks at about 12 days after follicle development begins (day 14 of cycle). The high estrogen level now has a *positive* feedback effect on the hypothalamus and pituitary, increasing the release of GnRH and stimulating the pituitary to release a burst of FSH and LH. The increased estrogen levels also convert the mucus secreted by the uterus to a thin and watery consistency, making it easier for sperm to swim through the uterus.

The burst in LH secretion stimulates the follicle cells to release enzymes that digest away the wall of the follicle, causing it to burst and release the egg (see Figure 49.12); this is ovulation. LH also initiates the last phase of the menstrual cycle, the *luteal phase.* That is, LH causes the follicle cells remaining at the surface of the ovary to grow into an enlarged, yellowish structure, the **corpus luteum** (*corpus* = body, *luteum* = yellow) (see Figure 49.11). Acting as an endocrine gland (see Section 42.1), the corpus luteum secretes several hormones: estrogens, large quan-

CLOSER LOOK **FIGURE 49.12** The ovarian and uterine (menstrual) cycles of a human female.

© Cengage Learning 2014

The ovarian cycle begins with an increase in the release of GnRH by the hypothalamus, which stimulates the release of FSH and LH from the anterior pituitary. The changes in concentrations of FSH and LH in the bloodstream play important roles in follicle development and ovulation.

In the follicular phase, FSH stimulates follicle growth. As the follicle enlarges, FSH and LH interact and stimulate cells of the follicle to secrete estrogens. Initially the estrogens inhibit secretion of FSH by the pituitary, causing a decrease in FSH concentration. When the estrogens reach a high concentration, they then stimulate the hypothalamus and pituitary to increase GnRH release, thereby stimulating the pituitary to produce a burst of LH and FSH. The burst in LH secretion causes ovulation and initiates the luteal phase, the development of the corpus luteum.

The concentrations of estrogens and progesterone are low during the follicular phase. The increase in estrogens late in that phase brings about ovulation and then their level drops. In the luteal phase, the corpus luteum secretes estrogens and large amounts of progesterone which stimulates growth of the uterine lining (the endometrium). In the absence of fertilization, the corpus luteum degenerates gradually and hormone levels fall bringing about menstruation.

The same hormones that control the ovarian cycle control the uterine cycle, which involves endometrium growth (proliferative phase), further uterine lining growth if there is no fertilization (the secretory phase), and break down of the endometrium (the menstrual phase).

SUMMARY The ovarian cycle produces an egg. First, GnRH released by the hypothalamus stimulates the anterior pituitary to release FSH and LH. FSH stimulates oocytes in the ovaries to initiate meiosis; one of them typically develops to maturity and becomes surrounded by cells that form a follicle. The follicle secretes estrogens, which stimulate an increase of FSH and LH concentrations in the blood. At about day 14, the LH stimulates the release of the egg from the follicle. The remainder of the follicle forms the corpus luteum, which secretes estrogens, progesterone, and inhibin.

THINK LIKE A SCIENTIST If the level of estrogens remains very low and does not increase as shown in the figure, what effect would that have on the menstrual cycle?

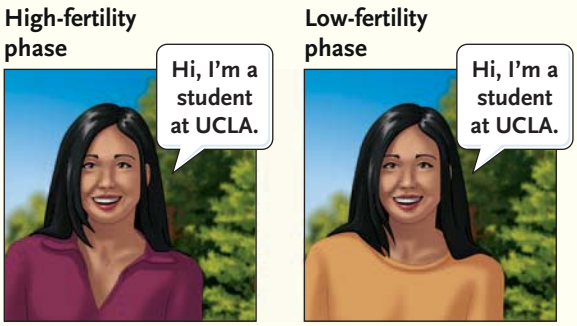

FIGURE 49.13 **Experimental Research**

Vocal Cues of Ovulation in Human Females

Question: Does the pitch of the female voice change in association with ovulation in human females?

Experiment: Primate females other than human females display well-characterized visual or olfactory cues that signal their reproductive state. Some research has documented particular cues associated with ovulation in humans; those cues relate to femininity and female attractiveness. Based on those observations, Gregory Bryant and Martie Haselton of the University of California, Los Angeles, hypothesized that vocal cues associated with female attractiveness would increase in frequency (pitch) over the menstrual cycle. A higher voice pitch is a signal associated with higher levels of female sex hormones, and correlates with being younger, both of which correlate with high fertility. To test their hypothesis, the researchers recruited 69 women with normal menstrual cycles and collected two sets of vocal samples from them saying "Hi, I'm a student at UCLA." One set was taken during a high-fertility phase of the cycle (at a time near ovulation) and the other set was taken during a low-fertility phase (at the luteal phase). The phase of the menstrual cycle at the time of vocal sampling was confirmed directly by hormonal tests. The samples were analyzed for the pitches of the voices and significant differences were determined using statistical methods.

Results: The average pitch of women's voices when the subjects said a simple sentence was significantly higher during the high-fertility phase of the menstrual cycle compared with during the low-fertility phase **(Figure).** The researchers confirmed in blind studies that the difference in frequency is readily detectable.

Average pitch = 211 Hz Average pitch = 206 Hz

Conclusion: The change in vocal pitch seen for high-fertility (approaching ovulation) versus low-fertility phases of the menstrual cycle is seen as evidence for a cyclic fertility cue in the female human voice. Potentially the cue signals to males that females are in a high-fertility state.

THINK LIKE A SCIENTIST If you wanted to determine whether vocal cues for ovulation is evolutionarily conserved in mammals, what experiment(s) would you do?

ties of **progesterone,** and **inhibin.** Progesterone, a female sex hormone, stimulates growth of the uterine lining and inhibits contractions of the uterus. Both progesterone and inhibin have a negative feedback effect on the hypothalamus and pituitary. Progesterone inhibits the secretion of GnRH. Without GnRH, the pituitary does not release FSH and LH. FSH secretion from the pituitary is also inhibited directly by inhibin. The fall in FSH and LH levels diminishes the signal for follicular growth, and no new follicles begin to grow in the ovary.

If fertilization does not occur, the corpus luteum gradually degenerates as cells are destroyed by phagocytosis and blood supply is cut off. By about 10 days after ovulation, little tissue remains, meaning that estrogen, progesterone, and inhibin are no longer secreted. In the absence of progesterone, *menstruation* begins (described in the next section). As progesterone and inhibin levels decrease, FSH and LH secretion is no longer inhibited, and a new monthly cycle begins.

THE UTERINE (MENSTRUAL) CYCLE The hormones that control the ovarian cycle also control the uterine (menstrual) cycle **(Figure 49.12D),** keeping the processes connected physiologically. Day 0 of the monthly cycle in the figure is the beginning of follicular development in the ovary (see Figure 49.12B); in the uterus, this correlates with the time at which menstrual flow begins.

Menstrual flow results from the breakdown of the thickened endometrium. Blood and tissue breakdown products are released from the uterus to the outside through the vagina. When the flow ceases, at day 4 to 5 of the cycle, the endometrium begins to grow again—this is the *proliferative phase.* As the endometrium gradually thickens, the oocytes in both ovaries begin to develop further, eventually leading to ovulation at about 14 days after the beginning of the cycle, as already described. If fertilization does not take place, the uterine lining continues to grow for another 14 days after ovulation—this is the *secretory phase.* At the end of that time, the absence of progesterone results in the contraction of arteries supplying blood to the uterine lining, shutting down the blood supply and causing the lining to disintegrate. The menstrual flow begins. Contractions of the uterus, no longer inhibited by progesterone, help expel the debris. Prostaglandins released by the degenerating endometrium add to the uterine contractions, making them severe enough to be felt as the pain of "cramps," and also sometimes causing other effects such as nausea, vomiting, and headaches.

Menstruation—the menstrual flow—occurs only in human females and our closest primate relatives, gorillas and chimpanzees. In other mammals, the uterine lining is completely reabsorbed if a fertilized egg does not implant during the period of reproductive activity. The uterine cycle in those mammals is called the *estrous* cycle.

Hormonal tests can show where a woman is in her menstrual cycle. In nonhuman primates, various cues inform the male of the reproductive state of a female. **Figure 49.13**

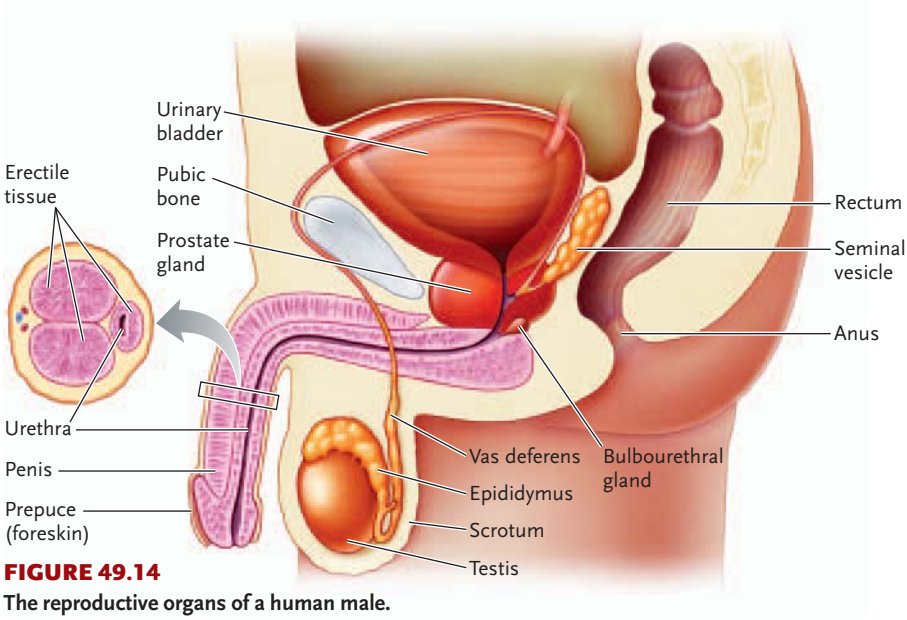
describes a research study demonstrating that vocal cues may signal the fertility state of human females.

Human Male Sexual Organs Function in Sperm Production and Delivery

Organs that produce and deliver sperm make up the male reproductive system **(Figure 49.14).** The testes are located outside the abdominal cavity. Sperm, which are produced by the testes, pass through tubules that enter the abdominal cavity and join with the urethra, the duct that carries urine from the bladder to an opening at the tip of the penis.



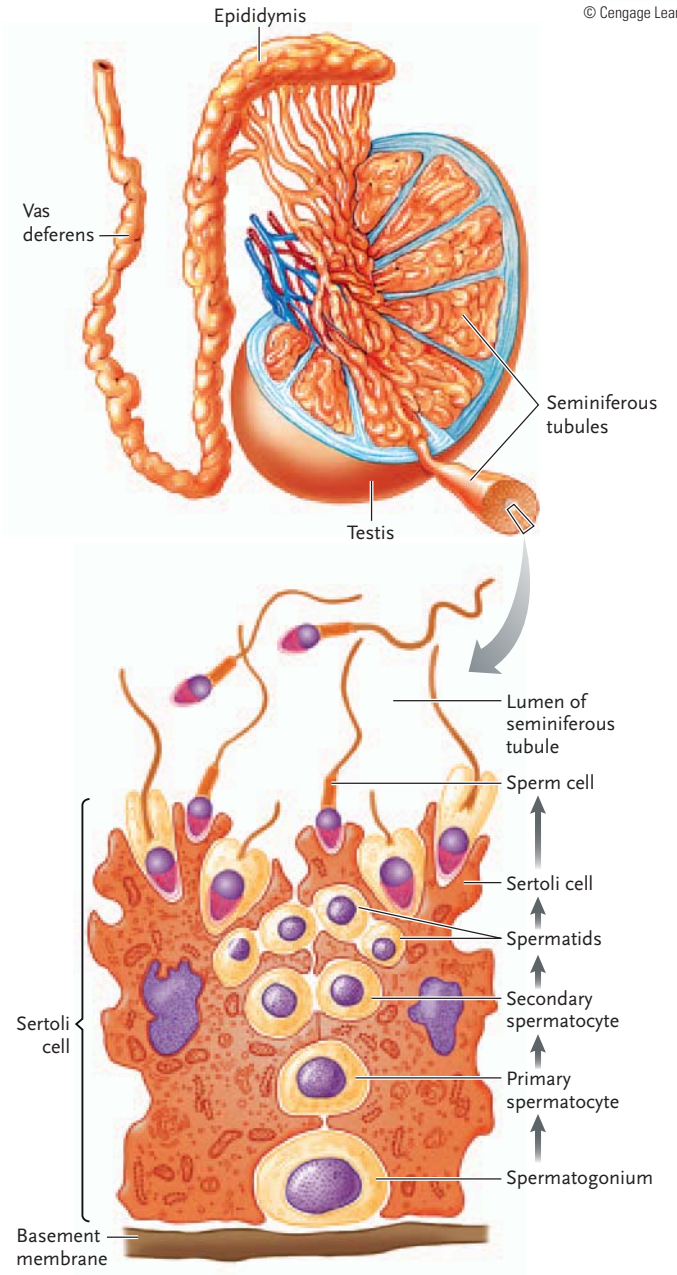


FIGURE 49.14
The reproductive organs of a human male.
© Cengage Learning 2014

MALE REPRODUCTIVE STRUCTURES Human males have a pair of testes, suspended in the baglike **scrotum.** Suspension in the scrotum keeps the testes cooler than the body core, at a temperature that provides an optimal environment for sperm development. Some land mammals such as elephants and monotremes have relatively low body temperatures and have internal testes (testes carried within the body). A testis is packed with about 125 m of **seminiferous tubules,** in which sperm proceed through all the stages of spermatogenesis **(Figure 49.15).** The entire process, from spermatogonium to sperm, takes about 9 to 10 weeks. The testes produce about 130 million sperm each day.

Supportive cells called **Sertoli cells** completely surround the developing spermatocytes in the seminiferous tubules. They supply nutrients to the spermatocytes and seal them off from the body's blood supply. Other cells located in the tissue surrounding the developing spermatocytes, the **Leydig cells,** produce the male sex hormones, known as **androgens,** particularly **testosterone** (see Figure 49.15 and Section 42.4).

Mature sperm flow from the seminiferous tubules into the **epididymis,** a coiled storage tubule attached to the surface of each testis. Rhythmic muscular contractions of the epididymis move the sperm into a thick-walled, muscular tube, the **vas deferens** (plural, *vasa deferentia*), which leads into the abdominal cavity. Just below the bladder, the vasa deferentia empty into the urethra. During ejaculation, muscular contractions force the sperm into the urethra and out of the penis. The sperm are activated and become motile as they come in contact with alkaline secretions added to the ejaculated fluid by accessory glands.

Most of the interior of the penis is filled with three cylinders of spongelike tissue that become filled with blood and

cause erection during sexual arousal. Although the human penis depends solely on engorgement of spongy tissue for erection, the males of many mammalian species, including bats, rodents, walruses, and most other primates, have a bone in the penis, the *baculum,* which helps maintain the penis in an erect state.

The penis ends in a soft, caplike structure, the **glans.** Most of the nerve endings producing erotic sensations are crowded into the glans and the region of the penile shaft just behind the glans. A loose fold of skin, the **prepuce** or **foreskin,** covers the glans (see Figure 49.14). In many cultures, the prepuce is removed for hygienic, religious, or other ritualistic reasons by the procedure called **circumcision** (*circum* = around, *caedere* = cut).

ACCESSORY GLANDS AND THE SEMEN About 150 million to 350 million sperm are released in a single ejaculation. Before they leave the body, these cells are mixed with the secretions of several accessory glands, forming the fluid known as **semen.** In humans, about two-thirds of the volume is produced by a pair of **seminal vesicles,** which secrete a thick, viscous liquid, the **seminal fluid,** into the vasa deferentia near the point where they join with the urethra. The seminal fluid contains prostaglandins that, when ejaculated into the female, trigger contractions of the female reproductive tract which help move the sperm into and through the uterus.

The large **prostate gland,** which surrounds the region where the vasa deferentia empty into the urethra, adds a thin, milky fluid to the semen. The alkaline prostate secretion, which makes up about one-third of the volume of the semen, raises the pH of the semen, and of the vagina, to about pH 6, the level of acidity best tolerated by sperm. The raised pH also activates motility of the sperm. As part of the prostate secretion, a fast-acting enzyme converts the semen to a thick gel when it is first ejaculated. The thickened consistency helps keep the semen from draining from the vagina when the penis is withdrawn. A second, slower-acting enzyme in the prostate secretion then gradually breaks down the semen clot and releases the sperm to swim freely in the female reproductive tract.

Finally, a pair of **bulbourethral glands** secretes a clear, mucus-rich fluid into the urethra before and during ejaculation. This fluid lubricates the tip of the penis and neutralizes the acidity of any residual urine in the urethra. In total, the secretions of the accessory glands make up more than 95% of the volume of semen; less than 5% is sperm.

Hormones Also Regulate Male Reproductive Functions

Many of the hormones regulating the menstrual cycle, including GnRH, FSH, LH, and inhibin, also regulate male reproductive functions. Testosterone, secreted by the Leydig cells in the testes, also plays a key role **(Figure 49.16).**

In sexually mature males, the hypothalamus secretes GnRH in brief pulses every 1 to 2 hours. The GnRH, in turn, stimulates the pituitary to secrete LH and FSH. LH stimulates the Leydig cells to secrete testosterone, which stimulates sperm production and controls the growth and function of male reproductive structures. FSH stimulates Sertoli cells to secrete a protein and other molecules that are required for spermatogenesis.

The concentrations of these hormones are maintained by feedback mechanisms. If the concentration of testosterone falls in the bloodstream, the hypothalamus responds by increasing GnRH secretion. If the concentration of testosterone rises too high, negative feedback mechanisms operate to return its concentration to an optimal level in the bloodstream (see Figure 49.16).

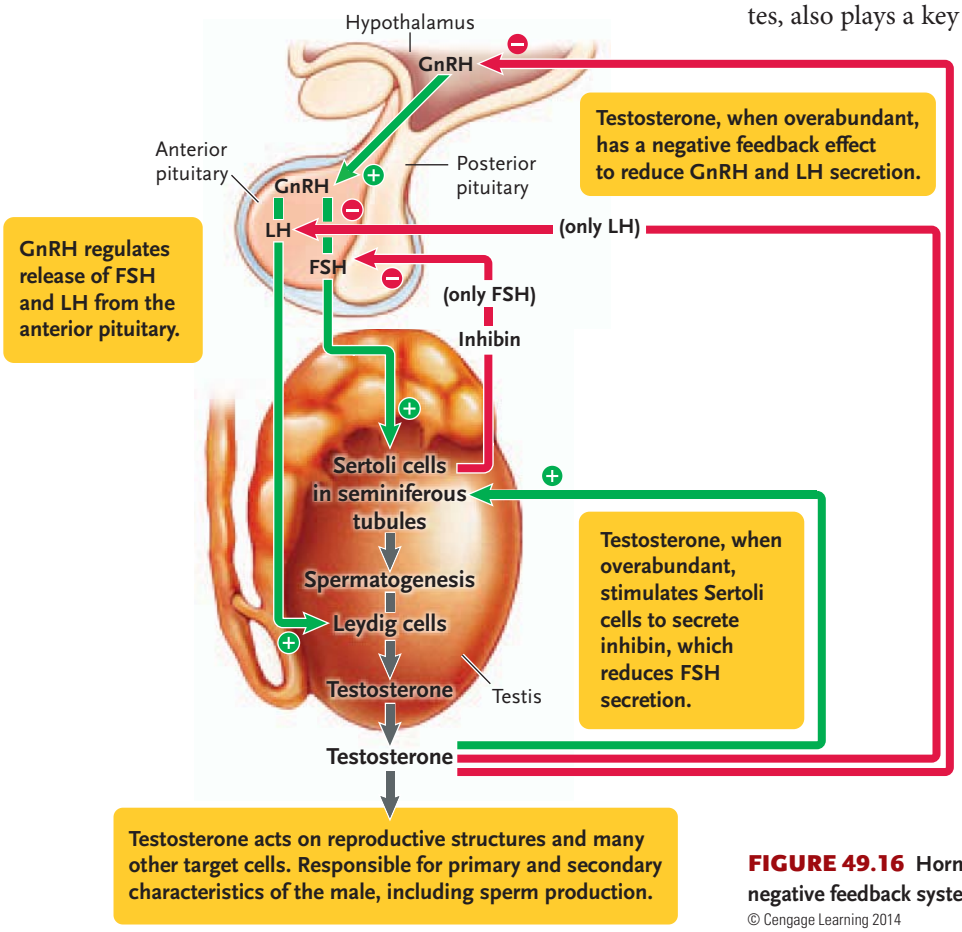

FIGURE 49.16 **Hormonal regulation of reproduction in the male, and the negative feedback systems controlling hormone levels.**

Human Copulation Follows a Typical Mammalian Pattern

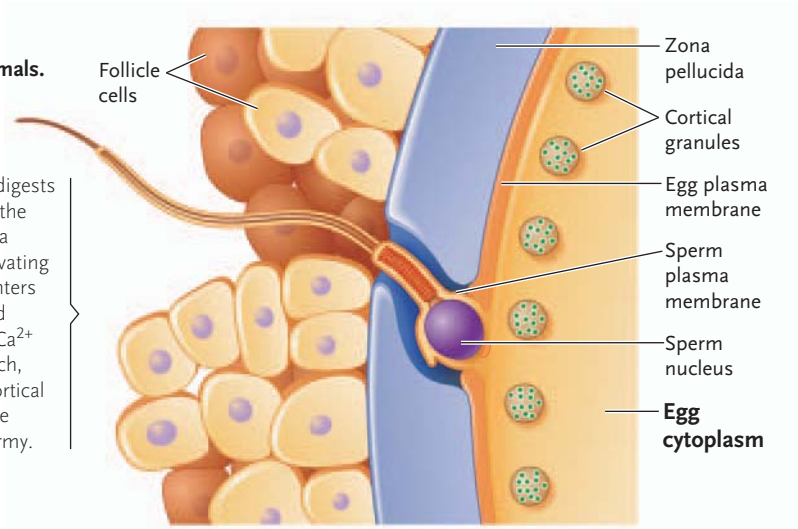
When the male is sexually aroused, the sphincter muscles controlling the flow of blood to the spongy erectile tissue of the penis relax, allowing the tissue to become engorged with blood. (The penis is a hydrostatic skeleton structure; see Section 43.2.) As the spongy tissue swells, it maintains the pressure by compressing and almost shutting off the veins draining blood from the penis. The engorgement produces an erection in which the penis lengthens, stiffens, and enlarges. During continued sexual arousal, lubricating fluid secreted by the bulbourethral glands may be released from the tip of the penis.

Female sexual arousal results in enlargement and erection of the clitoris, in a process analogous to erection of the penis in males. The labia minora also become engorged with blood and swell in size, and lubricating fluid is secreted onto the surfaces of the vulva by the greater vestibular glands. In addition to these changes, the nipples become erect by contraction of smooth muscle cells, and the breasts swell due to engorgement with blood.

Insertion of the penis into the vagina and the thrusting movements of copulation lead to the reflex actions of ejaculation, including spasmodic contractions of muscles surrounding the vasa deferentia, accessory glands, and urethra. During ejaculation, the sphincter muscles controlling the exit from the bladder close tightly, preventing urine from being released from the bladder and mixing with the ejaculate. Ejaculation is usually accompanied by *orgasm,* a sensation of intense physical pleasure that is the peak—climax—of excitement for sexual intercourse, followed by feelings of relaxation and gratification.

The motions of copulation stretch the vagina and stimulate the clitoris. The stretching and stimulation can also induce orgasm in females. The vaginal stretching also stimulates the hypothalamus to secrete oxytocin, which induces contractions of the uterus. The contractions keep the sperm in suspension and aid their movement through the reproductive tract. Uterine contractions are also induced by the prostaglandins in the semen.

Sperm reach the site of fertilization in the oviducts within 30 minutes after their ejaculation into the vagina. Of the millions of sperm released in a single ejaculation, only a few hundred actually reach the oviducts. After orgasm, the penis, clitoris, and labia minora gradually return to their unstimulated size. Females can experience additional orgasms within minutes or even seconds of a first orgasm, but most males enter a *refractory period* that lasts for 15 minutes or longer before they can regain an erection and have another orgasm.



A Human Egg Can Be Fertilized Only in the Oviduct

A human egg can be fertilized only during its passage through the third of the oviduct nearest the ovary. If the egg is not fertilized during the 12- to 24-hour period that it is in this location, it disintegrates and dies. However, sperm do not swim randomly for a chance encounter with the egg. Rather, they first swim up the cervical canal to reach the oviduct, and then are propelled up the oviduct by contractions of its smooth muscles. Further, researchers have found evidence that eggs release chemical attractant molecules that the sperm recognize, causing them to swim directly toward the egg. (*Insights from the Molecular Revolution* describes some of this research.)

To reach the egg, the fertilizing sperm uses enzymes in its plasma membranes to penetrate the layer of follicle cells surrounding the egg, and then by the acrosomal reaction dissolves a path through the zona pellucida coating the egg surface **(Figure 49.17).** As soon as the first sperm cell reaches the egg, the sperm and egg plasma membranes fuse, and the sperm cell enters the cytoplasm of the egg. Although only one sperm fertilizes the egg, the combined release of acrosomal enzymes from many sperm greatly increases the chance that a complete channel will be opened through the zona pellucida. Partly for this reason, a low sperm count is often a source of male infertility. Low sperm count has a number of causes, including infection, heat, frequent intercourse, smoking, and excess alcohol consumption.

The membrane fusion activates the egg. The sperm that has entered the egg releases nitric oxide, which stimulates the release of stored Ca^{2+} in the egg. The Ca^{2+} triggers cortical granule release to the outside of the egg. Enzymes from the cortical granules crosslink molecules in the zona pellucida, hardening it and sealing the channels opened by acrosomal enzymes. The enzymes also destroy the receptors that bind sperm to the surface of the zona pellucida. As a result, no further sperm can bind to the zona or reach the plasma membrane of the egg; this is the slow block to polyspermy. The Ca^{2+} also triggers the com-

FIGURE 49.17
Fertilization in mammals.
© Cengage Learning 2014

The fertilizing sperm digests a pathway to the egg; the sperm and egg plasma membranes fuse, activating the egg. The sperm enters the egg cytoplasm and stimulates release of Ca^{2+} stored in the egg, which, in turn, triggers the cortical reaction, leading to the slow block to polyspermy.

Egging on the Sperm

Odorants are aroma molecules that can be specifically recognized ("smelled") by receptor-based mechanisms. In vertebrates, more than a thousand genes encode odorant receptors, most of them olfactory receptors associated with the senses of smell and taste. However, odorant receptors are also located on cell types that do not function in taste and smell, including sperm.

Research Question

Do sperm odorant receptors function in sperm–egg attraction?

Experiments

Marc Spehr and his colleagues at Ruhr University Bochum performed a number of molecular experiments to answer the question. They first performed experiments that showed that testicular tissue contains two active odorant receptor genes. One gene was for hOR17-2 (hOR = *h*uman *o*lfactory *r*eceptor), which had been detected previously by others; and the other was for hOR17-4 (now called hOR1D2), which was not previously known to be active. They then molecularly cloned the gene for hOR17-4 and expressed it in cultured human embryonic kidney (HEK) cells. They found that an odorant chemical *bourgeonal* triggered a strong response in the genetically altered cells, but not in cells without the introduced gene. This result provided evidence that the product of the hOR17-4 gene does confer responsiveness to the odorant. They then tested untreated HEK cells for responsiveness to the odorant, and found that they did not respond, providing further evidence that the product of the odorant receptor gene was essential for the response.

In their final experiment, the researchers tested the response of human sperm cells in micropipettes to gradients of bourgeonal solutions.

Result

The sperm swam consistently toward the regions of highest concentration, and swam faster and more directly as the concentration increased. This experiment showed that human sperm can detect and respond to chemical attractants by swimming toward the source of the attractant.

Conclusion

An odorant receptor is on a sperm cell's surface and sperm will swim towards a chemical known to activate that receptor. Whether human eggs actually release such chemicals that act as sperm attractants remains to be determined. If so, the egg attractant detected by the hOR17-4 receptor is likely to resemble bourgeonal in chemical structure, because odorant receptors are highly specific in their responses.

As part of their research, the Spehr team found that another chemical, *undecanal,* strongly inhibits the binding of the hOR17-4 receptor to bourgeonal. With chemicals at hand that can both stimulate and eliminate sperm attraction, the system might provide a method for either contraception or procreation.

THINK LIKE A SCIENTIST A later study by other researchers demonstrated that male human subjects detected bourgeonal at significantly lower concentrations (mean value = 13 parts per billion) compared with female subjects (mean value = 26 parts per billion). What might this result mean?

Source: M. Spehr et al. 2003. Identification of a testicular odorant receptor mediating human sperm chemotaxis. *Science* 299:2054–2058.

pletion of meiosis of the egg (recall that, up to that point, it is a secondary oocyte arrested in meiosis II). The sperm and egg nuclei then fuse and the cell is now a zygote. Mitotic divisions of the zygote soon initiate embryonic development.

The first cell divisions of embryonic development take place while the fertilized egg is still in the oviduct. By about 7 days after ovulation, the embryo passes from the oviduct and implants in the uterine lining. During and after implantation, cells associated with the embryo secrete **human chorionic gonadotropin (hCG),** a hormone that keeps the corpus luteum in the ovary from breaking down. Excess hCG is excreted in the urine; its presence in urine or blood provides the basis of pregnancy tests.

The continued activity of the corpus luteum keeps estrogen and progesterone secretion at high levels, maintaining the uterine lining and preventing menstruation. The high progesterone level also thickens the mucus secreted by the uterus, forming a plug that seals the opening of the cervix from the vagina. The plug keeps bacteria, viruses, and sperm cells from further copulation from entering the uterus.

Later in development, about 10 weeks after implantation, the placenta takes over the secretion of progesterone, hCG secretion drops off, and the corpus luteum regresses. However, the corpus luteum continues to secrete the hormone *relaxin,* which inhibits contraction of the uterus until the time of birth is near.

Infertility Has Many Possible Causes

About 10% to 15% of couples in the United States are infertile. **Infertility** is defined as the inability for the female of the couple to get pregnant after 12 months of frequent, contraceptive-free intercourse. Infertility may result from a cause in either member of the couple, or a combination of factors involving both members of the couple.

MALE INFERTILITY Male infertility may result from a problem with the sperm or with the delivery of the sperm into the vagina. Problems with the sperm include low sperm concentration or altered sperm shape that affects mobility. For example, testosterone deficiency can lead to a reduced sperm count, and sexually transmitted diseases may temporarily affect sperm motility. In many cases, however, the root cause of low sperm count is not known. Problems with sperm delivery include sexual issues such as erectile dysfunction and blockage of the epididymis or ejaculatory ducts. Environmental factors such as a person's

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

health or lifestyle can also affect male fertility. Such factors include obesity, being underweight, malnutrition, emotional stress, alcohol or drug dependency, exposure to pesticides or other chemicals, and tobacco smoking.

FEMALE INFERTILITY Female infertility may result from any of a variety of causes including physical or hormonal changes. For example, inflammation of the Fallopian tubes (most frequently caused by *Chlamydia* infection) can cause damage, thereby affecting movement of the egg through the tube. Hormonal defects such as low levels of the hypothalamus–pituitary controlled LH and FSH, or certain medications, can block ovulation. Hormone deficiencies such as this can result from various perturbations of normal activity of the hypothalamus and pituitary, including tumors, injury, and excessive exercise. Many of the environmental factors that cause female infertility are the same as those that cause male infertility. In addition, female athletes with vigorous training regimens, such as cycling and running, may experience dysfunctions of their menstrual cycles, a condition called *athletic menstrual cycle irregularities.* The dysfunctions include amenorrhea (no menstrual periods) and cycles of normal length but without ovulation.

STUDY BREAK 49.3

Outline the roles of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in the ovarian cycle of a human female.

THINK OUTSIDE THE BOOK

The concept of athletic menstrual cycle irregularities was just introduced. Use the Internet or research literature to learn about possible hormonal differences in female athletes and to determine whether they might be involved in athletic menstrual cycle irregularities.

TABLE 49.1 Pregnancy Rates for Birth Control Methods

Method	Lowest Expected Rate of Pregnancy[a]	Typical-Use Rate of Pregnancy[b]
Rhythm method	1%–9%	25%
Withdrawal	4%	19%
Condom (male)	3%	14%
Condom (female)	5%	21%
Diaphragm and spermicidal jelly	6%	20%
Vasectomy (male sterilization)	0.1%	0.15%
Tubal ligation (female sterilization)	0.5%	0.5%
Contraceptive pill (combination estrogen/progestin)	0.1%	5%
Contraceptive pill (progestin only)	0.5%	5%
Implant (progestin)	0.09%	0.09%
Intrauterine device (IUD) (copper T)	0.6%	0.8%

[a]Rate of pregnancy when the birth control method was used correctly every time.

[b]Rate of pregnancy when the method was used typically, meaning that it may not have been always used correctly every time.

49.4 Methods for Preventing Pregnancy: Contraception

In human society, an unwanted pregnancy can be inconvenient at the least, or at the worst can have serious physical and social repercussions, particularly for the mother. Many methods exist for achieving **contraception**—the prevention of pregnancy—some old and others relatively new.

The oldest method of contraception is total abstinence from sex. Unfortunately, millions of years of animal evolution have stacked the cards against total abstinence by making the sex drive among the most powerful of compulsions. Millions of unwanted children attest to the failures of this method. Other methods of preventing pregnancy include techniques for: (1) preventing the sperm from reaching the site of fertilization; (2) preventing ovulation; or (3) interfering with implantation if fertilization does occur. **Table 49.1** lists the most common contraceptive techniques and their reliability, based on 1 year of use. You should refer to the table as we discuss each of the methods of contraception in the following sections. Note that, while we discuss each method individually, combinations of particular methods may be used to reduce further the chance of pregnancy.

Vasectomy and Tubal Ligation Are the Most Effective Methods for Preventing Fertilization

A natural technique for preventing fertilization is the *rhythm method,* which consists of avoiding intercourse during the time of the month when the egg can be fertilized. Because sperm can survive for as long as 5 days in the female reproductive tract, intercourse should be avoided from 5 days before ovulation and, for safety's sake, for another 4 or 5 days after ovulation. The method is difficult to apply because of the typical unpredictability of the time of ovulation (and the power of the sex drive).

Another natural method to prevent fertilization is *withdrawal*—starting sexual intercourse, but withdrawing

the penis before ejaculation. Unfortunately, once ejaculation begins, it proceeds as a series of reflexes that is extremely difficult to interrupt; in addition, some sperm may be present in lubrication produced before ejaculation.

The *condom,* a thin, close-fitting sheath of latex, lambskin, or polyurethane worn over the penis, is one of the traditional methods of preventing ejaculated sperm from entering the vagina. Condoms made from latex may also provide a barrier to the transmission of disease between sexual partners (condoms made from natural skin do not block viruses such as HIV). Pouchlike "female condoms," inserted into the vagina, prevent ejaculated sperm from entering the uterus.

The *diaphragm* is a cuplike rubber device that blocks the cervix in females. (The similar *cervical cap* is smaller and fits more closely over the cervix.) Typically a spermicidal jelly or cream is also used. To be most effective, a diaphragm and the spermicidal jelly must be inserted no more than an hour before intercourse, and left in place for the recommended time afterward.

The *intrauterine device (IUD)* is a small plastic or copper device inserted into the uterus just inside the cervix. The IUD remains in place as a long-term preventive measure; depending on the type, a single IUD is approved for 5 to 10 years of use. It is not completely clear how an IUD works; it is thought to cause a mild inflammation of the uterine lining that interferes with sperm function so that fertilization is less likely to occur. IUDs may also interfere with implantation of a fertilized egg but this may be a smaller contribution to their contraceptive effect. The IUD is effective as long as it is not deflected from its correct position in the uterus; unfortunately, this may happen without warning or the user's awareness. A few women also experience unpleasant side effects from the IUD such as cramps, uterine infections, or excessive menstrual bleeding.

Fertilization can also be prevented surgically, by cutting and closing off either the vasa deferentia in males or the oviducts in females. In *vasectomy,* the procedure for males, an incision is made in the scrotum and each vas deferens is severed and tied off. After vasectomy, the seminal fluid is still produced and ejaculated, but it does not contain sperm. In *tubal ligation,* the procedure for females, the oviducts are cut and tied off, or seared with heat (cauterized) to close them. The ligation prevents eggs from being fertilized or reaching the uterus. Neither vasectomy nor tubal ligation interferes with the production of sex hormones by the ovaries or testes, or results in any change in sexual behavior. Both operations are highly effective in preventing pregnancy. Although they can be reversed, the procedures are difficult and not always successful.

The Oral Contraceptive Pill Is the Most Effective Method for Preventing Ovulation

The primary method used to prevent ovulation is the *oral contraceptive pill,* or simply "the pill," containing a combination of estrogen and *progestin* (a synthetic form of progesterone) or progestin alone. In this highly effective method, the pill is taken daily for 20 to 21 days after the end of the menstrual flow and then stopped (placebo pills are taken for the remaining days of the cycle to maintain the routine of pill taking) to allow menstruation, and then the next month's course is begun. If pregnancy is desired, the pill is simply not taken after the menstrual flow.

The pill works by inhibiting the secretion of FSH and LH by the pituitary; without these hormones, ovulation does not occur. When the pill is stopped after 20 to 21 days, the resulting drop in progestin concentration causes the uterine lining to break down and initiates the menstrual flow. Since ovulation does not occur, fertilization and pregnancy are not possible.

Most pregnancies among women taking the pill result from failure to take it on schedule—often simply by forgetting to take the pill for a day or two at the wrong time of the month. Some women, about one in four, experience unpleasant side effects, such as nausea, tenderness of the breasts, irritability, nervousness, or changes in skin color or texture. Modern versions of the pill have almost eliminated the more serious side effects, such as increased incidence of breast cancer and formation of blood clots. However, cigarette smoking significantly increases the risk of heart attacks and strokes for women taking the pill. This risk increases with age and with the number of cigarettes smoked per day.

The Morning-After Pill Blocks Ovulation or Fertilization

Whatever the method of birth control, its effectiveness is improved if sex partners are highly motivated to avoid pregnancy, and careful in its use. The effectiveness of condoms, for example, is greatly improved if the penis is withdrawn immediately after ejaculation (before the semen has time to spread under the condom and leak into the vagina).

Another method used to prevent pregnancy is the so-called *emergency contraception pill,* commonly referred to as the "morning-after pill." These pills are administered after intercourse has occurred as a means to prevent pregnancy. A high-dosage synthetic progestin emergency contraception pill called Plan B is available in the United States without prescription to women who are 18 or older. This pill is highly effective if taken within 72 hours after unprotected sexual intercourse. Pregnancy tests do not work until significantly after this time. Research data show that Plan B works by blocking ovulation or fertilization. It may also inhibit implantation of a fertilized egg by altering the endometrium, but it has no effect if the process of implantation has begun.

Another emergency contraception pill is *mifepristone (RU-486),* which contains a molecule that binds to and blocks progesterone receptors in the uterine lining. The blockage prevents the lining from responding to progesterone and causes it to break down (that is, a menstrual period is initiated), taking with it any embryo that may have implanted. Mifepristone is

approved in the United States for terminating pregnancies up to 49 days postconception; the time period is longer in some foreign countries. It is available only by prescription.

In this chapter we have focused on animal reproduction up to the point of the fertilized egg. In the next chapter, we address the final stage of reproduction in sexually reproducing organisms, the development of a new individual from the fertilized egg.

STUDY BREAK 49.4

How does the oral contraceptive pill prevent pregnancy?

UNANSWERED QUESTIONS

What molecules are responsible for sperm recognition of egg coats?

Although fertilization is necessary for sexual reproduction, how sperm recognize eggs, particularly in mammals, has been an enigma. Fertilization success or failure may be attributed to how well complementary molecules on each gamete interact with each other. Furthermore, as discussed in Section 22.2, one of the prezygotic species-isolating mechanisms relies on the fact that gamete receptors from one species often do not recognize receptors from other species. However, in artificial environments (such as experimental situations), gametes from different species sometimes do recognize each other and form hybrids. These hybrids are usually explained by structural similarity of the molecules responsible for gamete recognition.

During fertilization in mammals, sperm must penetrate through several layers that surround the egg. Using motility and their own surface hyaluronidase, the sperm first move through the cumulus mass, a remnant of follicle cells (referred to as *cumulus cells*) and the sticky hyaluronate-containing matrix that cumulus cells produce. Next, the sperm bind to the zona pellucida, a tough acellular glycoprotein coat. In mammals, this coat is composed of three to four proteins, often referred to as ZP1, ZP2, ZP3, and ZP4. Mice, the mammal in which fertilization has been studied the most, produce ZP1, ZP2, and ZP3.

Starting in the 1980s, researchers have studied the function of zona pellucida glycoproteins. Early experiments studied the function of individual proteins using a competition assay. For this assay, zona pellucida proteins were dissolved and purified. Then, each was added individually to sperm to determine if it could occupy putative receptors on the plasma membrane of sperm cells and prevent the sperm from binding to cumulus-free eggs. Only ZP3 did this.

ZP3 also induces the acrosome reaction in sperm, which is necessary for sperm to penetrate the zona pellucida (discussed in Section 47.2). Subsequent research found that ZP3 bound to a form of the enzyme β-1,4-galactosyltransferase found on the sperm plasma membrane. Curiously, another ZP3 binding protein, sp56, was also found within the acrosome. These proteins may act sequentially to allow sperm to adhere to the zona pellucida (before and during or after the acrosome reaction).

Recent mouse genetic studies suggest that a more complex assembly of zona pellucida proteins is responsible for binding sperm. Other genetic studies indicate that additional receptors on sperm also contribute to sperm–zona pellucida adhesion. Further work is necessary to resolve the early biochemical data and the more recent results from genetic experiments. It is also important to clarify the role of other receptors that have been identified. Finally, recent evidence suggests that sperm begin the acrosome reaction in the cumulus cell mass prior to interaction with the zona pellucida. Regardless, it seems likely that fertilization includes a number or perhaps a sequence of molecular adhesive steps that must function properly for normal fertility and that there may be molecular redundancy in such a fundamental process.

How is membrane fusion regulated during the sperm acrosome reaction?

To release the acrosome, the outer acrosomal membrane fuses at hundreds of points with the plasma membrane overlying it. These fusion points expand, forming vesicles that are released, freeing the acrosomal contents. Acrosomal proteins are released in two phases. First, the more soluble acrosomal proteins are released. Then, acrosomal proteins that initially remained bound to a protein matrix within the acrosome are released. Regulated membrane fusion during secretion has been studied in most detail in neurons. In neurons, each secretory vesicle forms a single fusion point with the plasma membrane. Although membrane fusion during the acrosome reaction involves hundreds of fusion points, and secretory vesicles in somatic cells form just one, we found that proteins promoting membrane fusion in neuronal secretion at the synapse were also involved in the sperm acrosome reaction.

Proteins called SNAREs (from *S*oluble *N*-ethylmaleimide-sensitive factor *A*ttachment protein *RE*ceptor) promote membrane fusion in neuronal secretion. So-called "neuronal" SNAREs are also found in sperm near the acrosome. We have studied mice deficient in a protein called complexin that regulates SNARE function, and have found that sperm from these mice have defective acrosome reactions as well as markedly reduced fertility. Complexin appears to promote SNARE complex formation and then suspend the SNARE complex in an intermediate state in which membrane fusion can be completed readily by a Ca^{2+} influx into sperm.

Despite some molecular similarity to the neuronal process, membrane fusion in sperm is clearly unique. It is important to identify the important steps that prepare sperm for membrane fusion and to determine how SNARE function is regulated during the acrosome reaction. This should help understand sperm malfunctions that result in defects in the acrosome reaction, a frequent cause of male infertility.

THINK LIKE A SCIENTIST One of the procedures used in fertility clinics is called intracytoplasmic sperm injection (ICSI). A sperm is aspirated into a pipette, and the pipette is driven through the zona pellucida and egg membrane. The sperm is then injected directly into an egg, and the egg develops into an embryo. Predict the types of fertility problems for which this procedure could be used to produce offspring.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

49.1 Animal Reproductive Modes: Asexual and Sexual Reproduction

- In asexual reproduction, a single parent gives rise to offspring without genetic input from another individual. In sexual reproduction, offspring are produced by the union of gametes—eggs and sperm—from two parents.
- Asexual reproduction involving mitosis occurs in animals by fission, budding, or fragmentation (Figure 49.2). In parthenogenesis, a form of asexual reproduction, females produce eggs that develop without being fertilized.
- In sexual reproduction, genetic variability is produced by the meiotic processes of genetic recombination and independent assortment.

Animation: Spermatogenesis

49.2 Cellular Mechanisms of Sexual Reproduction

- Sexual reproduction includes two cellular processes, gametogenesis and fertilization, and a whole-organism process, mating. Gametogenesis is the formation of male and female gametes by meiotic cell division, followed by differentiation of the gametes; fertilization is the union of gametes that initiates development of new individuals (Figure 49.3).
- Gametogenesis takes place in the testes of males and in the ovaries of females. Sperm and eggs are delivered to the site of fertilization by sperm ducts in males and oviducts in females. External reproductive structures aid the delivery in many species.
- In male gametogenesis—spermatogenesis—each cell entering meiosis produces four haploid motile sperm cells. In female gametogenesis—oogenesis—each cell entering meiosis produces one haploid egg cell. The meiotic divisions of oogenesis concentrate almost all the cytoplasm in the single egg cell; the other division products are nonfunctional polar bodies (Figure 49.3).
- The egg contains stored nutrients and information required for at least the early stages of embryonic development. It is covered by one or more protective coats, and it has a mechanism that blocks additional sperm from entering after fertilization (Figure 49.5).
- Fertilization, which follows mating in most animals, may be external or internal. In external fertilization, sperm and eggs are shed into the surrounding water. In internal fertilization, sperm are released close to or inside the female reproductive ducts via copulation (Figure 49.6).
- When a sperm and egg touch during fertilization, their plasma membranes fuse, introducing the sperm nucleus into the egg cytoplasm. The sperm and egg nuclei then fuse to form a diploid zygote nucleus and initiate embryonic development (Figure 49.8).
- Oviparous animals lay eggs in which development of new individuals takes place outside the female's body. In viviparous animals, development takes place inside the female's body. In ovoviviparous animals, fertilized eggs are retained within the body while the embryo develops, the eggs hatch within the mother, and the offspring are then released from the body.
- In hermaphroditism, single individuals produce both mature egg-producing tissue and mature sperm-producing tissue (Figure 49.9).

Animation: Fertilization

49.3 Sexual Reproduction in Humans

- In females, eggs released from the ovaries travel through the oviducts to the uterus. The uterus opens into the vagina, the entrance for sperm and the exit for offspring during birth (Figure 49.10).
- The ovarian cycle produces an egg. The cycle begins with the release of GnRH by the hypothalamus, which stimulates the release of FSH and LH from the anterior pituitary. FSH stimulates oocytes in the ovaries to begin meiosis. One oocyte typically develops to maturity and is surrounded by cells that form a follicle (Figures 49.11 and 49.12).
- The enlarging follicle secretes estrogens, causing a burst in FSH and LH blood concentrations; at about day 14 of the cycle, the LH stimulates ovulation, the bursting of the follicle and the release of the egg. The remainder of the follicle forms the corpus luteum, which secretes estrogens, progesterone, and inhibin (Figures 49.11 and 49.12).
- Day 0 of the monthly uterine (menstrual) cycle correlates with the beginning of follicular development in the ovary and the beginning of the menstrual flow. Secretion of estrogen from the developing follicle stimulates the growth of a new endometrium. If fertilization does not occur, progesterone and inhibin maintain the endometrium until day 28 of the cycle, when the corpus luteum regresses. Without progesterone, the endometrium breaks down and is released as the menstrual flow (Figure 49.12).
- In males, sperm develop in seminiferous tubules in the testes and are released into the epididymis. When a male ejaculates, sperm travel from the epididymis to the vas deferens, and then through the urethra and the penis. The seminal vesicles, prostate gland, and bulbourethral glands add fluids to the sperm traveling to the outside (Figures 49.14 and 49.15).
- Sperm production in males is also controlled by LH and FSH. LH stimulates Leydig cells in the testes to secrete testosterone, which stimulates sperm production. FSH stimulates Sertoli cells in the testes to secrete molecules needed for spermatogenesis (Figure 49.16).
- During copulation, sperm are ejaculated into the vagina of the female. The sperm then swim through the female reproductive tract, aided by contractions of the oviduct and guided by molecules released by the egg. On contact with the egg in the oviduct, the acrosomes of sperm release enzymes that digest a path through the coats of the egg. When the fertilizing sperm contacts the egg, the sperm and egg plasma membranes fuse, releasing the sperm nucleus into the egg cytoplasm and activating the egg. The egg completes meiosis, and the sperm and egg nuclei fuse, producing the zygote (Figure 49.17).
- As the embryo implants, the hormone hCG sustains the corpus luteum, which continues to secrete estrogen and progesterone at high levels. These hormones maintain the uterine lining and prevent menstruation.
- Infertility has many causes, including physical problems, hormonal changes, or environmental factors.

49.4 Methods for Preventing Pregnancy: Contraception

- Methods of contraception work by preventing sperm from reaching the site of fertilization, by preventing ovulation, or by interfering with implantation (Table 49.1).
- Methods for preventing fertilization include the rhythm method, the condom, the diaphragm or cervical cap, the IUD, and a vasectomy or tubal ligation.
- The oral contraceptive pill prevents ovulation. It contains a combination of estrogen and the progesterone-like progestin, which inhibiting the secretion of FSH and LH and follicle formation.
- The morning-after pill blocks ovulation or fertilization, and may also inhibit implantation.

UNDERSTAND & APPLY

Test Your Knowledge

1. Asexual reproduction is most successful in:
   a. changing environments.
   b. sessile animals.
   c. densely settled populations.
   d. land animals.
   e. genetically varied individuals.
2. Which of the following processes does not increase genetic diversity?
   a. parthenogenesis
   b. random DNA mutations
   c. genetic recombination
   d. independent assortment
   e. random combinations of paternal and maternal chromosomes
3. Gametogenesis has parallel stages in egg and sperm formation. The stage in eggs that is equivalent to spermatids is the:
   a. primary oocyte.
   b. oogonium.
   c. ovum.
   d. ootid and polar bodies.
   e. secondary oocyte and polar body.
4. External fertilization provides a male with relative certainty of paternity and is found in:
   a. amphibians.
   b. birds.
   c. sharks.
   d. reptiles.
   e. mammals.
5. The slow block to polyspermy:
   a. is caused by a change in membrane potential from negative to positive.
   b. triggers the movement of Ca^{2+} from the cytosol to the endoplasmic reticulum.
   c. triggers a decrease in egg oxidation and protein synthesis.
   d. describes the fusion of egg and sperm nuclei.
   e. includes the fusion of cortical granules with the egg's plasma membrane.
6. Some placental animals provide nutrients to their embryos from an attached membranous yolk-containing sac. They are called:
   a. oviparous animals.
   b. ovoviviparous animals.
   c. metatherians.
   d. eutherians.
   e. mammals.
7. Which activity is a step in the ovarian cycle?
   a. FSH stimulates the pituitary to release GnRH.
   b. When FSH and LH levels fall, the corpus luteum shrinks and the uterine lining breaks down.
   c. Luteinizing hormone stimulates the uterus to make progesterone.
   d. Estrogen levels initially have a positive feedback effect on the pituitary, which is followed by higher estrogen levels causing negative feedback.
   e. A fully developed corpus luteum inhibits uterine lining growth.
8. During spermatogenesis in mammals, sperm travels from the:
   a. Sertoli cells past the epididymis and urethra, through the vas deferens to the prepuce.
   b. seminal vesicles past the prostate gland, through the glans and prepuce to the bulbourethral glands.
   c. vestibular glands past the Leydig cells, through the accessory glands and epididymis to the vas deferens.
   d. labia past the bulbourethral glands, through the vas deferens and urethra to the epididymis.
   e. seminiferous tubules past the Sertoli cells, through the epididymis and vas deferens to the urethra.
9. The secondary oocyte in humans is fertilized in the:
   a. uterus.
   b. vagina.
   c. oviduct.
   d. cervical canal.
   e. ovary.
10. The most effective method to prevent fertilization is:
    a. the oral contraceptive.
    b. the IUD.
    c. the morning-after pill.
    d. vasectomy in men and tubal ligation in women.
    e. the rhythm method.

Discuss the Concepts

1. Currently under development is an "antipregnancy vaccine" that stimulates a woman's immune system to develop antibodies against human chorionic gonadotropin (hCG). How would this method prevent pregnancy?
2. Men sometimes have reduced fertility because of *testicular varicoceles,* varicose veins in the testes in which blood pools. Based on what you now know of the conditions under which sperm develop properly, how do you think this condition might impair sperm development?
3. Spermatogenesis produces four sperm for each primary spermatocyte, but oogenesis produces only one egg for each primary oocyte. Why might these different outcomes be adaptive?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

4. Sertoli cells protect spermatocytes from attack by antibodies during their development in the human male. What structures might protect the oocyte and egg from attack by antibodies in the human female?
5. Compare the advantages and disadvantages of sexual and asexual reproduction for an aphid and a parasitic worm.
6. It may be possible to develop a birth control drug that would prevent conception by interfering with fertilization. Outline the design for such a drug and explain exactly how it would work. (There may be more than one design that, in theory, would be effective.)

Design an Experiment

Design experiments to determine if, and at what dose, vitamin E can decrease menstrual cramping significantly.

Interpret the Data

Contamination of water by agricultural chemicals affects the reproductive function of some animals. Are there effects on humans? Epidemiologist Shanna Swan and her colleagues studied sperm collected from men in four cities in the United States **(Table)**. The men were partners of women who had become pregnant and were visiting a prenatal clinic, so all were fertile. Of the four cities, Columbia, Missouri, is located in the county with the most farmlands. New York City represents an area with no agriculture.

Data from a Study of Sperm Collected from Men Who Were Partners of Pregnant Women Who Visited Prenatal Health Clinics in One of Four Cities

	Location of clinic			
	Columbia, Missouri	Los Angeles, California	Minneapolis, Minnesota	New York, New York
Average age	30.7	29.8	32.2	36.1
Percent nonsmokers	79.5	70.5	85.8	81.6
Percent with history of STD*	11.4	12.9	13.6	15.8
Sperm count (million/mL)	58.7	80.8	98.6	102.9
Percent motile sperm	48.2	54.5	52.1	56.4

*STD stands for sexually transmitted disease.

© Cengage Learning 2014

1. Where did researchers record the highest and lowest sperm counts?
2. In which cities did samples show the highest and lowest sperm motility (ability to move)?
3. Aging, smoking, and STDs adversely affect sperm. Could differences in any of these variables explain the regional differences in sperm count?
4. Do these data support the hypothesis that living near farmlands can adversely affect male reproductive function?

Source: S. Swan et al. 2003. Geographic differences in semen quality of fertile US males. *Environmental Health Perspectives* 111:414–420.

Apply Evolutionary Thinking

The nematode species *Caenorhabditis elegans* and *C. briggsae* are both hermaphroditic. Phylogenetic evidence indicates that the last common ancestor of these two species had a normal male–female mechanism of reproduction. What does this evidence suggest about their hermaphroditism?

50.4 Embryonic Development of Humans and Other Mammals

50.5 The Cellular Basis of Development

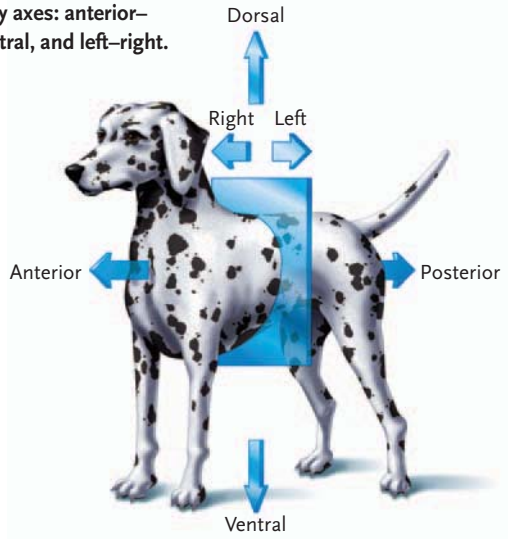
Animal Development

Why it matters . . . The uterine contractions announcing birth are taking place at shorter intervals and with greater intensity. The mother-to-be endures the discomfort and apprehension with the knowledge that the child that has been growing in her body will soon come into the world. It formed from a fertilized egg, about the size of a period on this page, and grew through a program of cell divisions, complex cell migrations, and molecular interactions.

Her baby's development required no conscious attention on her part: human development, like that of all animals, is programmed to proceed inexorably from fertilized egg to free-living offspring. Even childbirth is the result of programmed events that, once started, normally move to conclusion without requiring deliberate input from the mother.

Over the course of its development, the baby's body formed all the organ systems required for independent existence and, at its birth, they are already working to sustain its life. Most astonishing, perhaps, is the baby's brain. It formed from a tube of nerve tissue that bulged outward and enlarged, continually adding nerve cells and connecting them into complex circuits—all as part of the automated events of development. Still, the human brain is unique only in the degree of its complexity and integrative capacity; the brains of other mammals are basically similar and develop through the same embryonic pathways.

The baby enters the outside world passing head first through the cervix, and then the vagina. It is a girl, who with further luck and good care will continue developing through childhood, puberty, adult life, and old age, all through programs built into her DNA. As part of these passages, she may bring her own child into the world.



People have tried since ancient times to understand how development and birth take place. The scientific quest began with Aristotle, who observed chick development and correctly interpreted the functions of the placenta and umbilical cord in humans. The investigators who followed Aristotle concentrated on describing developmental changes in **morphology,** which is the

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

form or shape of an organism, or of a part of an organism. More recently, investigators began to trace the molecular underpinnings of the morphological events.

In this chapter we survey the results of these investigations. We take up the story of animal development where the previous chapter left off, with the fertilized egg. We continue with the early events leading from the fertilized egg to the primary tissues of the embryo, and then trace the development of organs from these tissues. Next, we describe human development as representative of the process in mammals. Then, we survey the cellular bases of these mechanisms. At the cellular level, the development of an adult animal from a fertilized egg involves cell division, in which more cells are produced by mitosis; **cell differentiation,** in which changes in gene expression establish cells with specialized structure and function; and **morphogenesis** ("form creation"), the generation of the body form of the animal as differentiated cells end up in their appropriate sites.

50.1 Mechanisms of Embryonic Development

Fertilization of an egg by a sperm cell produces a zygote. Embryonic development begins at this point and ultimately produces a free-living organism. All the instructions required for development are packed into the fertilized egg.

Developmental Information and Components for Growth Are Stored in the Fertilized Egg

Once the zygote is formed when egg and sperm nuclei fuse; mitotic divisions begin the developmental activity (see Section 49.2).

INFORMATION STORAGE IN THE EGG As introduced in Section 16.4, the initiation of development depends primarily on the DNA in the zygote nucleus, and on *cytoplasmic determinants,* that is, mRNA and protein molecules stored in the cytoplasm. Most of the mRNA and protein molecules are maternal in origin because the fertilizing sperm contributes essentially no cytoplasm to the zygote. The mRNAs and proteins direct the first stages of development up until the genes of the zygote become active.

OTHER COMPONENTS OF THE EGG In addition to cytoplasmic determinants, the egg cytoplasm also contains ribosomes and other cytoplasmic components required for protein synthesis and the early cell divisions of embryonic development. For example, the egg cytoplasm contains all the tubulin molecules required to form the spindles for early cell divisions. It also contains mitochondria, nutrients stored in granules in the yolk and in lipid droplets, and, in many animals, pigments that color the egg or regions of it.

Yolk contains nutrients. The eggs of insects, reptiles, and birds contain large amounts of yolk, which supplies all of the nutrients for development of the embryo. The eggs of placental mammals, in contrast, contain very little yolk, which supplies nutrients only for the earliest stages of development.

Depending on the species, the yolk may be concentrated at one end or in the center of the egg, or distributed evenly throughout the cytoplasm. Its distribution influences the rate and location of cell division during early embryonic development. Typically, cell division proceeds more slowly in the region of the egg containing the yolk. In the large, yolky eggs of birds and reptiles, cell division takes place only in a small, yolk-free patch at the surface of the egg.

Unequal distribution of yolk and other components in a mature egg is termed **polarity.** In most species, the egg nucleus is located toward one end of the egg. This end of the egg, called the **animal pole,** typically gives rise to surface structures and the anterior end of the embryo. The opposite end of the egg, the **vegetal pole,** typically gives rise to internal structures such as the gut and the posterior end of the embryo. Yolk, when unequally distributed in the egg cytoplasm, is most commonly concentrated in the vegetal half of the egg.

Fertilization of the egg launches the early events of development. As you follow these events, keep in mind that the developmental processes involved work together to produce the body plan of the adult. For a bilaterally symmetrical animal such as a human or a dog, for example, the adult must develop three body axes: the anterior–posterior axis, the dorsal–ventral (back–front) axis, and the left–right axis **(Figure 50.1).**

Cleavage, Gastrulation, and Organogenesis Are Early Events in Development

Soon after fertilization, the zygote begins **cleavage,** a series of mitotic divisions in which cycles of DNA replication and division occur *without* the production of new cytoplasm. As a result, the cytoplasm of the egg is partitioned into successively smaller cells without increasing the overall size or mass of the embryo **(Figure 50.2).** These cells are called **blastomeres** (*blastos* = bud or offshoot; *meros* = part or division). In the frog *Xenopus laevis,* for example, twelve cleavage divisions produce an embryo of about 4,000 cells.

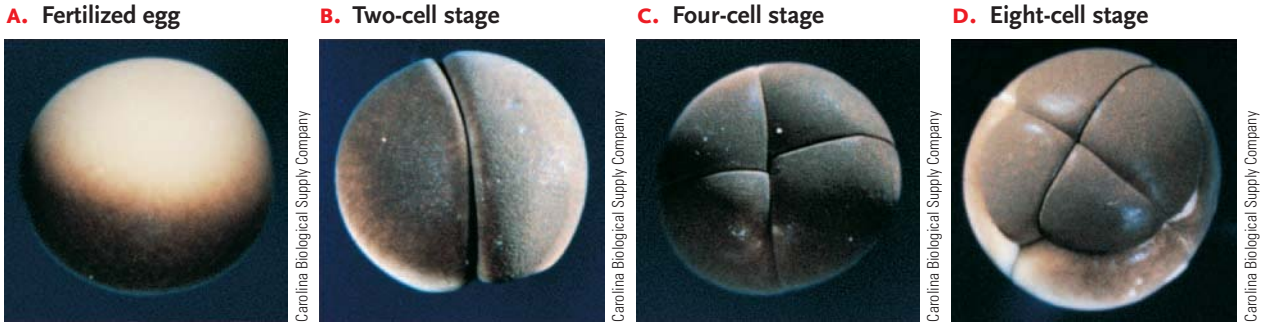

FIGURE 50.2 **The first three cleavage divisions of a frog embryo, which convert the fertilized egg into the eight-cell stage.** Note that the cleavage divisions cut the volume of the fertilized egg into successively smaller cells, called blastomeres.

Cleavage is the first of three major developmental processes that, with modifications, are common to the early development of most animals (described in detail for particular animals in the next section). Following cleavage, the second major process, **gastrulation,** produces an embryo with three distinct primary tissue layers. The third process, **organogenesis,** accomplishes the development of the major organ systems. At the end of organogenesis, the embryo has the body organization characteristic of its species. Gastrulation and organogenesis both involve the processes of cell division, cell migrations, and cell rearrangements. **Figure 50.3** outlines these stages in the life cycle of a frog.

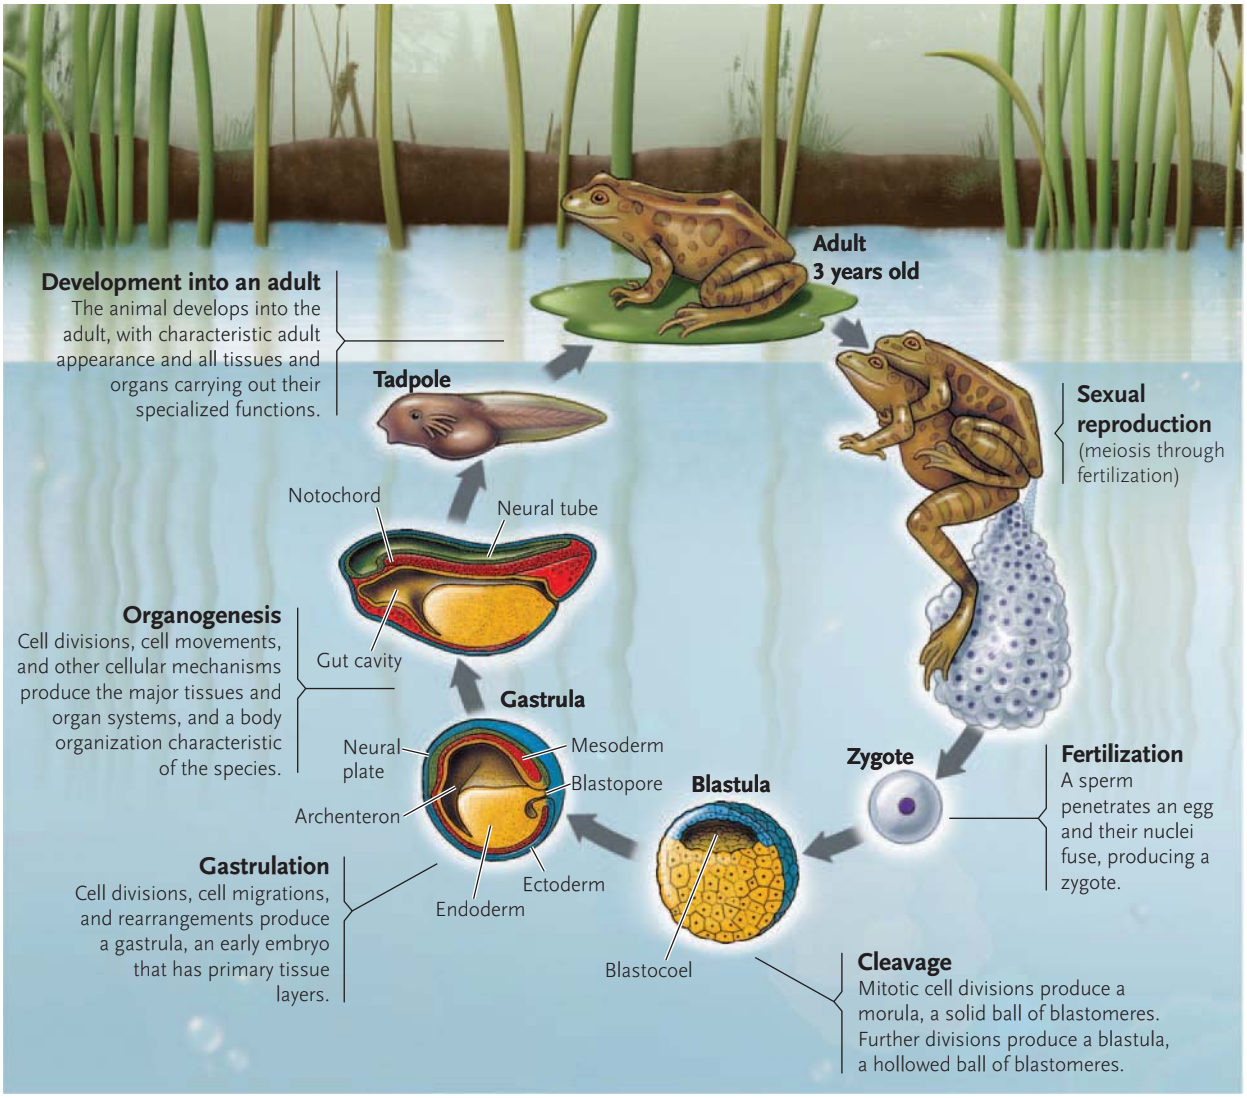

FIGURE 50.3 **Stages of animal development shown in a frog.**

The cleavage divisions lead to three successive developmental stages that are common to the early development of most animals. The first stage, called a **morula** (*morula* = mulberry), is a solid ball or layer of blastomeres. As cleavage divisions continue, the ball or layer hollows out to form the second stage, the **blastula** (*ula* = small), in which the blastomeres enclose a fluid-filled cavity, the **blastocoel** (*koilos* = hollow) (see Figure 50.3).

Once cleavage is complete, the blastomeres undergo extensive cellular rearrangements. This morphogenetic process is called **gastrulation,** and during the process the embryo is termed a **gastrula** (*gaster* = gut or belly) (see Figure 50.3). The details of gastrulation differ among animal groups, but the result is the same for all: some surface cells of the blastula move to an interior position, and three primary cell layers of the embryo are produced. The three layers are the **germ layers:** the outer **ectoderm** (*ecto* = outside; *derma* = skin), the inner **endoderm** (*endo* = inside), and the **mesoderm** (*meso* = middle) between the ectoderm and the endoderm. Gastrulation establishes body pattern; that is, each tissue and organ of the adult animal originates in one of the three primary cell layers of the gastrula **(Table 50.1).**

As gastrulation proceeds, embryonic cells begin to differentiate: they become recognizably different in biochemistry, structure, and function. The developmental potential of the cells also becomes more limited than that of the fertilized egg from which they originated. That is, although a fertilized egg is **totipotent,** meaning that it is capable of producing all the various types of cells of the adult, progressively the cells produced become more specialized. That is, totipotent cells give rise to **pluripotent** cells, which can give rise to most adult cell types, and then pluripotent cells give rise to **multipotent** cells, which give rise to cells with particular functions. Thus, for example, a multipotent mesoderm cell may develop into muscle or bone but not normally into outside skin or brain.

TABLE 50.1 Origins of Adult Tissues and Organs in the Three Primary Tissue Layers

Primary Tissue Layer	Adult Tissues and Organs
Ectoderm	Skin and its elaborations, including hair, feathers, scales, and nails; nervous system, including brain, spinal cord, and peripheral nerves; lens, retina, and cornea of eye; lining of mouth and anus; sweat glands, mammary glands, adrenal medulla, and tooth enamel
Mesoderm	Muscles; most of skeletal system, including bones and cartilage; circulatory system, including heart, blood vessels, and blood cells; internal reproductive organs; kidneys and outer walls of digestive tract
Endoderm	Lining of digestive tract, liver, pancreas, lining of respiratory tract, thyroid gland, lining of urethra, and urinary bladder

© Cengage Learning 2014

The restriction of developmental potential does not occur, as was once thought, because the cells have lost all their genes except those for the structure and function of the cell type they will become. Rather, except in rare instances, the differentiating cells all contain complete genomes of the organism, but each type of cell has a different program of gene expression. Several definitive experiments supporting this conclusion were carried out several decades ago by Robert Briggs and Thomas King of Lankenau Hospital Research Institute in Philadelphia (now Fox Chase Cancer Center) and extended by John B. Gurdon of the University of Cambridge, United Kingdom. In a typical experiment, the nucleus of a fertilized frog egg was destroyed by ultraviolet light. A micropipette was then used to transfer a nucleus from a fully differentiated tissue, intestinal epithelium, to the enucleated egg. Some of the eggs receiving the transplanted nuclei subsequently developed into normal tadpoles and adult frogs. This outcome was possible only if the differentiated intestinal cells still retained their full complement of genes. This conclusion was extended to mammals in 1997 when Ian Wilmut and his colleagues successfully cloned a sheep—Dolly—starting with an adult cell nucleus (see Section 18.2). The constancy of the genome during development was also discussed in Section 16.4.

A Number of Processes Are Responsible for Development

Development in all animals is accomplished by a number of processes that are under genetic control but are influenced to some extent by the environment (for example, temperature affects the rate of cell division). The processes are:

1. Mitotic cell divisions.
2. Cell migrations.
3. **Selective cell adhesions,** in which cells make and break specific connections to other cells or to the extracellular matrix.
4. **Induction,** in which one group of cells (the inducer cells) causes or influences another nearby group of cells (the responder cells) to follow a particular developmental pathway (see Section 16.4).
5. **Determination,** in which the developmental fate of a cell is set, and it is committed to becoming a particular cell type. Typically, determination is the result of induction.
6. **Differentiation,** which follows determination, establishes a cell-specific developmental program in cells. Differentiation results in cell types with clearly defined structures and functions.
7. **Apoptosis,** programmed cell death, in which tissues no longer required for continued development of the organism are removed.

Examples of these mechanisms in the examples of development are discussed in the following three sections.

STUDY BREAK 50.1

1. How do cleavage divisions differ from cell division in an adult organism?
2. What are the primary cell layers of the embryo, and what process is responsible for producing them?

50.2 Major Patterns of Cleavage and Gastrulation

With the principles of early embryonic development established, we describe cleavage and gastrulation in three animal groups that have been models in *embryology* (the study of embryos and their development): sea urchins, amphibians, and birds. Later in the chapter, we describe cleavage and gastrulation in humans and other mammals, which resemble the pattern in birds.

Sea Urchin Gastrulation Follows a Symmetrical Pattern That Reflects an Even Distribution of Yolk

The sea urchin is an echinoderm, a type of deuterostome (see Section 32.1). Cleavage divisions first produce a solid mass of blastomeres, the morula (**Figure 50.4,** step 1). Continued divisions produce a blastula containing about a thousand cells (step 2).

Gastrulation begins at the vegetal pole of the blastula. As a result of induction, some cells in the middle of that region become elongated and cylindrical, causing the region to flatten and thicken. Then, some cells break loose and migrate into the blastocoel (step 3). These cells, the *primary mesenchyme cells* (mesenchyme means "middle juice"), move around inside the blastocoel, making and breaking adhesions, until eventually they attach along the ventral sides of the blastocoel. These cells eventually become mesoderm cells (see step 7), from which the larval skeleton is produced. Next, the flattened vegetal pole of the blastula invaginates, pushing gradually into the interior (steps 4 and 5). The invaginated region is the **archenteron** (*arche* = beginning; *enteron* = intestine or gut), which is lined with future endoderm cells, and its opening at the vegetal pole end is the **blastopore.** The archenteron forms the primitive gut of the sea urchin embryo. *Secondary mesenchyme cells* form at the top of the archenteron. These cells also eventually become mesoderm cells.

The secondary mesenchyme cells send out extensions that stretch across the blastocoel and contact the inside of the ectoderm (step 6). These extensions make tight adhesions and then contract, pulling the invaginated cell layer inward and thereby eliminating most of the blastocoel.

At this point the embryo has two complete cell layers. The outer layer remaining from the original blastula surface makes up the ectoderm of the embryo. The second, inner

layer, derived from the cells forming the archenteron, makes up the endoderm. Mesodermal cells are also beginning to form a third layer, the mesoderm. Some are derived from the primary mesenchyme cells and others from the secondary mesenchyme cells that migrate into the space between ectoderm and endoderm (step 7). The mesodermal cells originating from secondary mesenchyme cells give rise to mesodermal organs of the sea urchin. When the mesoderm layer is complete, the embryo has three complete layers: ectoderm, mesoderm, and endoderm. At this point, cells within each layer begin to differentiate, as evidenced by the synthesis of different proteins in each layer.

As the ectoderm, mesoderm, and endoderm develop, the embryo lengthens into an ellipsoidal shape with the blastopore marking its posterior end. From this point on, organ systems differentiate through further cell division, cell migrations, selective cell adhesions, induction, and differentiation. The blastopore forms the anus; a mouth forms at the opposite, anterior end of the embryonic gut where the archenteron contacts and fuses with the ectoderm.

An archenteron and a blastopore are not present in the embryos of all organisms. For those that do have them, the blastopore gives rise to the anus or mouth of the embryo, depending on the animal group (see Section 31.2). In deuterostomes, which include echinoderms and chordates, the blastopore develops into the anus and the mouth forms at the opposite end of the embryonic gut formed by the archenteron. In the protostomes, which include annelids, arthropods, and mollusks, the blastopore develops into the mouth, and the anus forms at the opposite end of the embryonic gut.

Amphibian Cleavage and Gastrulation Are Influenced by an Unequal Distribution of Yolk

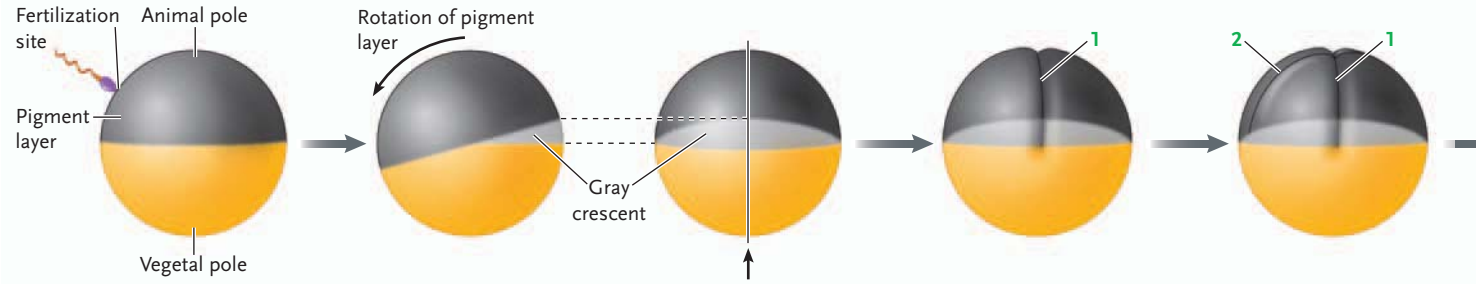
In amphibian eggs, such as those of frogs, yolk is concentrated in the vegetal half, which gives it a pale color. The animal half is darkly colored by a layer of pigment granules just below the surface. **Figure 50.5** shows the steps of fertilization and cleavage of a frog egg. The sperm typically fertilizes the egg in the animal half (step 1). After fertilization, the pigmented layer of cytoplasm rotates toward the site of sperm entry, exposing a crescent-shaped region of the underlying cytoplasm at the side opposite the point of sperm entry (step 2). This region, called the **gray crescent,** establishes the dorsal–ventral axis of the embryo, with the gray crescent marking the future dorsal side. The first cleavage division runs perpendicular to the long axis of the gray crescent and divides the crescent equally between the resulting two cells (step 3).

If one of the first two blastomeres does not receive gray crescent material, and the cells are separated experimentally, the cell without gray crescent divides to produce a disordered mass that stops developing. The cell receiving the gray crescent produces a normal embryo. Thus cytoplasmic material localized in the gray crescent is essential to normal development in frog embryos.

The second cleavage division is also in the vertical plane and at 90 degrees to the first cleavage division, producing the four-cell stage (step 4). At this point, the yolk in the vegetal half of the egg has slowed the progression of the first two cleavage furrows from going through that part of the egg. The third cleavage division is in the horizontal plane in the animal half of the egg and produces the eight-cell stage (step 5). By now the cleavage furrows of the first two cleavage divisions have continued all the way through the vegetal half of the egg. Embryo development continues with more divisions, first producing a morula (defined as a 16- to 64-cell stage in amphibians), and then a blastula (defined as at least 128 cells in amphibians) (step 6).

Gastrulation begins when cells from the animal pole move across the embryo surface and reach the region derived from the gray crescent (**Figure 50.6,** steps 1–2). This site is marked by a crescent-shaped depression rotated clockwise 90° called the **dorsal lip of the blastopore.** Cells changing shape and pushing inward from the surface in a process called **invagination** produce the depression. With continued inward migration of additional cells, the depression eventually forms a complete circle, which is the blastopore.

Cells now migrate into the blastopore by **involution,** a process in which the cells entering from the outer layer of the embryo spread over the internal surfaces of the remaining exterior cells (step 3). A consequence of involution is that the pigmented cell layer of the animal half expands to cover the entire surface of the embryo. The cells of the vegetal half are enclosed by the movement and show on the outside as a yolk plug in the blastopore (step 4). In amphibians, the blastopore gives rise to the anus.



Continued involution moves cells into the interior and upward (see steps 3 and 4), forming two layers that line the inside top half of the embryo. The uppermost of these layers is induced to become the dorsal mesoderm (see step 4). The layer beneath it, which contains cells originating from both the outer surface of the embryo and the yolky interior, becomes the endoderm (shown in yellow). The pigmented cells remaining at the surface of the embryo form the ectoderm (shown in blue). The ventral mesoderm begins to be induced near the vegetal pole.

As the mesoderm and endoderm form, the depression created by the inward cell migration gradually deepens and extends inward as the archenteron (see steps 3 and 4), which displaces the blastocoel. The cells of the three primary cell layers continue to increase in number by further cell migration and divisions as development proceeds.

During frog gastrulation, cells of the dorsal lip of the blastopore are inducer cells that control blastopore formation; if the cells in the dorsal lip are removed and transplanted elsewhere in the egg, they cause a second blastopore—and a second embryo—to form in this region (see Section 50.5).

The events of gastrulation in frogs thus include the same developmental processes as in sea urchins—cell divisions, cell migrations, selective adhesions, induction, and differentiation.

1 Fertilization. The animal pole contains yolk-free cytoplasm. The yolk is in the vegetal pole.

2 Pigment layer rotates toward site of fertilization, exposing some of underlying cytoplasm (the gray crescent).

3 Two-cell stage: First cleavage division (1) is in the vertical plane and divides the animal half into two, as well as dividing gray crescent equally between daughter cells. Yolk in the vegetal half slows the cleavage in that part of the egg.

4 Four-cell stage: Second cleavage division (2), also in the vertical plane, is at 90 degrees to that of the first division.

FIGURE 50.5 Fertilization and cleavage of a frog egg. The red numbers designate the cleavage divisions.

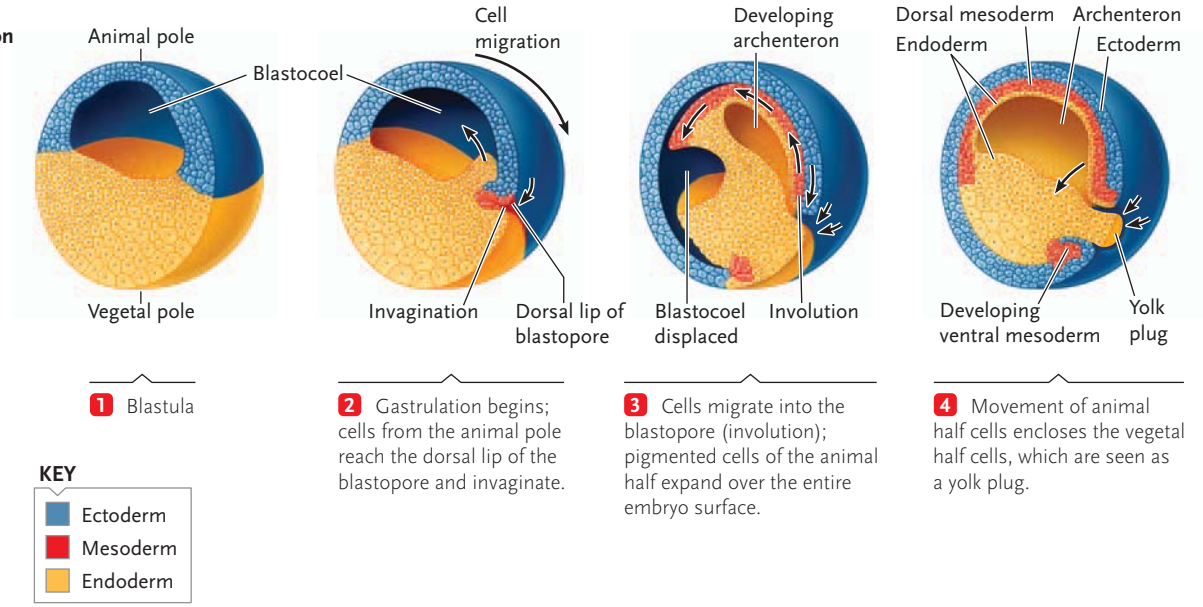
Gastrulation in Birds Proceeds at One Side of the Yolk

Gastrulation in amniotes (see Section 32.7) such as birds and reptiles is modified by the distribution of yolk, which occupies almost the entire volume of the egg. The portion of the cytoplasm that divides to give rise to the primary tissues of the embryo is confined to a thin layer at the egg surface. Although eggs of mammals (which are also amniotes) have little yolk, gastrulation follows a similar pattern, as discussed in Section 50.4.



CLEAVAGE AND GASTRULATION IN BIRDS The early cleavage divisions in birds produce a disclike layer of cells at the surface of the yolk called the **blastodisc** (**Figure 50.7,** step 1). When blastodisc formation is complete, the layer contains about 20,000 cells. The cells of the blastodisc then separate into two layers, called the **epiblast** (top layer) and **hypoblast** (bottom layer). The flattened cavity between them is the blastocoel (step 2).

Gastrulation begins as cells in the epiblast stream toward the midline of the blastodisc, thickening the epiblast in this region. The thickened layer—the **primitive streak**—begins forming in the posterior end of the embryo and extends toward the anterior end as more cells of the epiblast move into it (step 3). The primitive streak initially designates the future posterior end of the embryo, and by the time it has elongated fully, it has established the left and right sides of the embryo. The primitive streak forms on what will become the dorsal side of the embryo, with the ventral side below.

As the primitive streak forms, its midline sinks, forming the **primitive groove.** The primitive groove is a conduit for migrating cells to move into the blastocoel. The first cells to migrate through the primitive groove are epiblast cells (step 4), which will form the endoderm. Cells migrating laterally between the epiblast and the endoderm form the mesoderm. The epiblast cells left at the surface of the blastodisc form the ectoderm (see step 4). Thus all three of the primary tissue layers of

the chick embryo arise from the epiblast. Once the three layers are formed, gastrulation is complete.

Of the cells in the hypoblast, only a few near the posterior end of the embryo contribute directly to the embryo. These hypoblast cells form the *germ cells* that, later in development, migrate to the developing gonads and establish the cell line leading to eggs and sperm (see Section 49.2).

FORMATION OF EXTRAEMBRYONIC MEMBRANES Each primary tissue layer of a bird embryo extends outside the embryo to form four **extraembryonic membranes (Figure 50.8),** which conduct nutrients from the yolk to the embryo, exchange gases with the environment outside the egg, and store metabolic wastes removed from the embryo. The **yolk sac** consists of extensions of mesoderm and endoderm that enclose the yolk. Although the yolk sac remains connected to the gut of the embryo by a stalk, yolk does not directly enter the embryo by this route. Instead, it is absorbed by blood vessels in the membrane, which transport the nutrients to the embryo. The **chorion,** produced from ectoderm and mesoderm, is the outermost membrane, which surrounds the embryo and yolk sac completely, and lines the inside of the egg shell. This membrane exchanges oxygen and carbon dioxide with the environment through the shell of the egg. The **amnion** is the innermost membrane, which closes over the embryo to form the *amniotic cavity.* The cells of the amnion secrete *amniotic fluid* into the cavity, which bathes the embryo and provides an aquatic environment in which it can develop. Reptilian and mammalian embryos are also surrounded by an amnion and amniotic fluid. The adaptation of providing the embryo with an aquatic environment made the development of fully terrestrial vertebrates possible. The evolutionary importance of the amnion to the fully terrestrial vertebrates is recognized by classifying them together as amniotes (see Section 32.7). A membrane derived from mesoderm and endoderm that has bulged outward from the gut forms a sac called the **allantois.** This sac closely lines the chorion and fills much of the space between the chorion and the yolk sac. The allantois stores nitrogenous wastes (primarily uric acid) removed from the embryo. In addition, the part of the allantoic membrane that lines the chorion forms a rich bed of blood capillaries that is connected to the embryo by arteries and veins. This circulatory system delivers carbon dioxide to the chorion and picks up the oxygen that is absorbed through the shell and chorion.

50.3 From Gastrulation to Adult Body Structures: Organogenesis

Following gastrulation, organogenesis—the process by which the ectoderm, mesoderm, and endoderm develop into organs—gives rise to an individual with the body organization characteristic of its species. Organogenesis involves the same mechanisms used in gastrulation—cell division, cell migrations, selective cell adhesion, induction, and differentiation—plus an additional mechanism, *apoptosis,* in which certain cells are programmed to die (apoptosis is also discussed in Section 45.2 and later in this section). As with other aspects of development, the details of organogenesis differ among animal groups. The frog and the chick are used here as examples.

The Nervous System Develops from Ectoderm

In vertebrates, organogenesis begins with **neurulation,** the development of the nervous system from ectoderm. Preliminary to neurulation, cells of the dorsal mesoderm form the **notochord,** a solid rod of tissue that extends the length of the embryo under the dorsal ectoderm. Dorsal mesoderm cells under the ectoderm then induce the ectoderm cells above them to thicken and flatten into a longitudinal band called the **neural plate** (**Figure 50.9,** step 1).

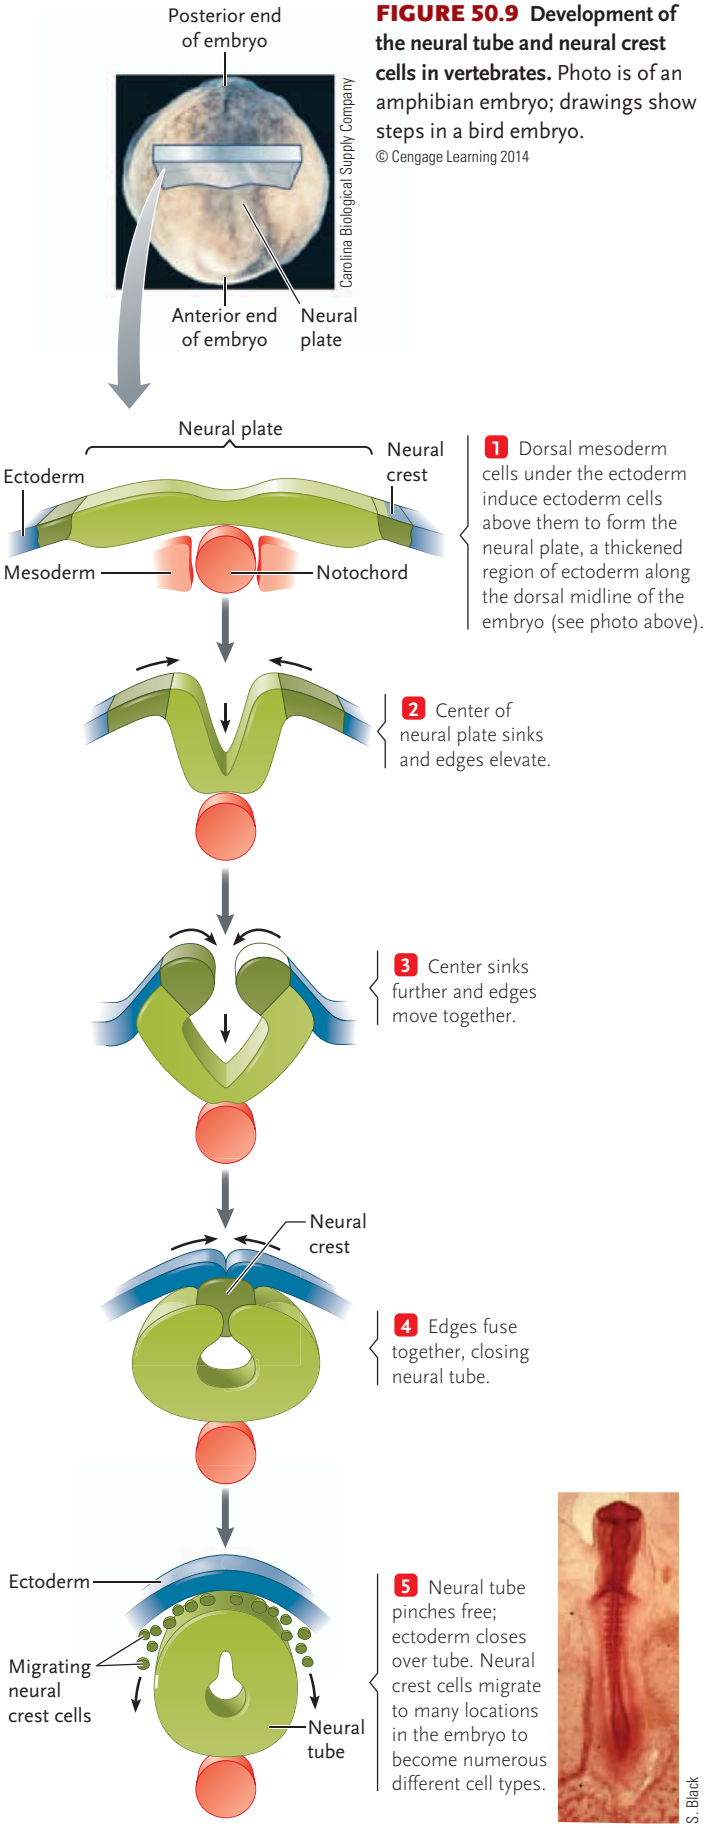

FIGURE 50.9 Development of the neural tube and neural crest cells in vertebrates. Photo is of an amphibian embryo; drawings show steps in a bird embryo.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Next, the neural plate sinks downward along its midline (step 2), creating a deep, longitudinal groove. At the same time, the edges elevate along the sides of the neural plate. The groove becomes deeper and the edges move together (step 3). Next, the edges fuse together and close over the center of the groove, converting the neural plate into a **neural tube** that runs the length of the embryo (step 4). The neural tube then pinches off from the overlying ectoderm, which closes over the tube (step 5). The ectoderm that comprises the neural tube is called *neural ectoderm* (colored light green in figures) to distinguish it from surface ectoderm (colored blue in figures). The central nervous system, including the brain and spinal cord, develops directly from the neural tube.

During formation of the neural tube, cells of the **neural crest**—the region where the neural tube pinches off from the ectoderm—migrate to many locations in the developing embryo and become numerous different types of cells that contribute to a variety of organ systems. Neural crest cells are also ectodermal cells; they are colored dark green in Figure 50.9. (The neural crest is one of the defining features of vertebrates.) Some cells develop into cranial nerves in the head; others contribute to the bones of the inner ear and skull, the cartilage of facial structures, and the teeth. Still others form ganglia of the autonomic nervous system, peripheral nerves leading from the spinal cord to body structures, and nerves of the developing gut. Neural crest cells also move to the skin, where they form pigment cells, and to the adrenal glands, where they form the medulla of the kidney. The migration of neural crest cells contributes to the development of all vertebrates.

Other structures differentiate in the embryo while the neural tube is forming. On either side of the notochord, the mesoderm separates into blocks of cells called **somites,** spaced one after the other along both sides of the notochord **(Figure 50.10).** The somites give rise to the vertebral column, the ribs, the repeating sets of muscles associated with the ribs and vertebral column, and muscles of the limbs. The mesoderm outside the somites, which extends around the primitive gut (lateral mesoderm in Figure 50.10), splits into two layers, one covering the surface of the gut, and the other lining the body wall. The space between the layers is the coelom of the adult (see Section 31.2).

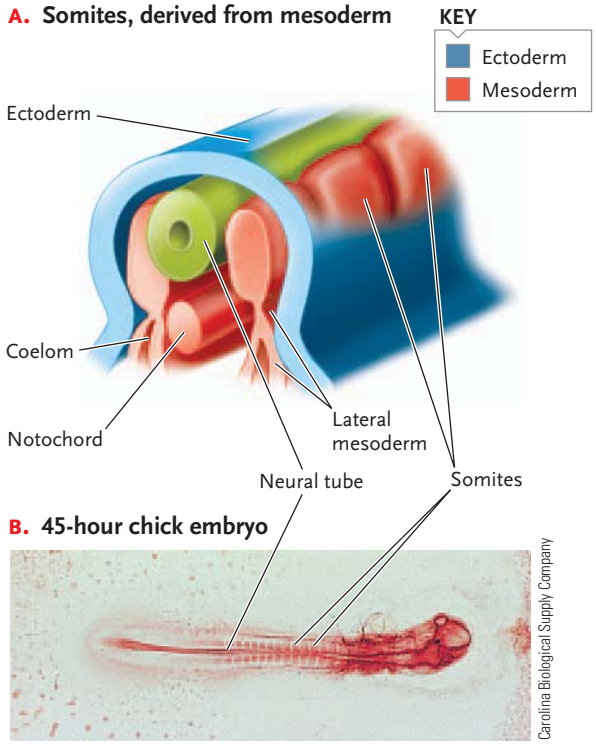

FIGURE 50.10 Later development of the mesoderm. (A) The somites develop into segmented structures such as the vertebrae, the ribs, and the musculature between the ribs. The lateral mesoderm gives rise to other structures, such as the heart and blood vessels and the linings of internal body cavities. **(B)** The somites in a 45-hour chick embryo.

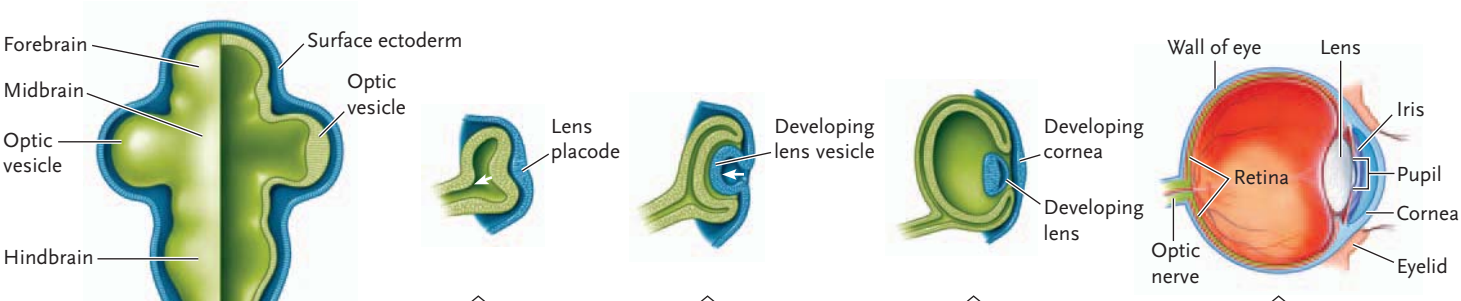
Sequential Inductions and Differentiation Are Central to Eye Development

We now discuss the development of the eye to show how cellular mechanisms interact in organogenesis. Eyes develop by the same pathway in all vertebrates.



The brain forms at the anterior end of the neural tube from a cluster of hollow vesicles that swell outward from the neural tube (**Figure 50.11,** step 1). One paired set of vesicles, the *optic vesicles,* develop into the eyes. The figure depicts the optic vesicles in the brain of a frog embryo; the morphology of the forebrain, midbrain, and hindbrain in embryos differs among vertebrates.

The optic vesicles are derived from a specific region of neural ectoderm in the neural plate. The simultaneous expression of a specific set of transcription factors—Pax6, Six3, and Rx1—in the most anterior tip of the neural plate is responsible for optic vesicle development. The optic vesicles grow outward and contact the overlying surface ectoderm, where they induce a series of developmental responses in both tissues. The outer surface of the optic vesicle thickens and flattens at the region of contact and then pushes inward, transforming the optic vesicle into a double-walled *optic cup,* which eventually becomes the retina. The optic cup induces the surface ectoderm to thicken into a disclike swelling, the *lens placode* (step 2). The center of the lens placode invaginates—sinks inward—toward the optic cup, and its edges eventually fuse together, forming a ball of ectodermal cells, the *lens vesicle* (step 3).

Ectoderm now closes over the lens vesicle, which then detaches from the surface ectoderm (step 4). The lens vesicle becomes the developing lens, the cells of which begin to synthesize *crystallins,* which are transparent, lens-specific proteins that collect into clear, glassy deposits. The lens cells finally lose their nuclei and form the elastic, crystal-clear lens.

As the developing lens invaginates, it induces the overlying surface ectoderm to begin differentiation into the cornea. First, the overlying ectoderm secretes layers of collagen. Neural crest cells then migrate into the collagen layers and form new layers of cells that eventually mature into the clear cornea. Relatively little is known about the development of the cornea, but the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

1 Expanding optic vesicle contacts overlying surface ectoderm; its outer wall thickens.

2 Outer wall of optic vesicle pushes inward, forming optic cup; overlying ectoderm thickens to form lens placode.

3 As optic cup deepens, lens placode invaginates and begins to pinch off, forming lens vesicle.

4 Ectoderm closes over lens vesicle, which then detaches from the surface cells. Neural crest cells migrate into the space between the now-developing lens and the epithelium-forming layers, which develop into the cornea.

5 Fully developed structures of vertebrate eye (human eye shown)

FIGURE 50.11 **Stages in the formation of the vertebrate eye from the optic vesicle of the brain and the surface ectoderm.** (The brain and spinal cord, colored light green, are derived from the neural tube, which consists of neural ectoderm.)

© Cengage Learning 2014

transcription factor Pax6 (see earlier discussion) is important for the process. The gene for Pax6 is not expressed in most tissues of adult mammals, but it is expressed in the adult cornea. The gene products that result from the action of Pax6 are important for healing wounds of the cornea.

Other cells contribute to accessory structures of the eye. For example, mesoderm and neural crest cells contribute to the reinforcing tissues in the wall of the eye and the muscles that move the eye. Figure 50.11, step 5, shows a fully developed vertebrate eye.

Many experiments have shown that the initial induction by the optic vesicle is necessary for development of the eye. For example, if an optic vesicle is removed before lens formation, the ectoderm fails to develop a lens placode and vesicle. Moreover, placing a removed optic vesicle under the ectoderm in other regions of the head causes a lens to form in the new location. Or, if the ectoderm over an optic vesicle is removed and ectoderm from elsewhere in the embryo is grafted in its place, a normal lens will develop in the grafted ectoderm, even though in its former location it would not differentiate into lens tissue.

Eye development also demonstrates differentiation. Ectoderm cells that are induced to form the lens of the eye synthesize crystallins; in other locations, ectoderm cells typically synthesize a different protein, *keratin,* as their predominant cell product. Keratin is a component of surface structures such as skin, hair, feathers, scales, and horns. In other words, as a response to induction by the optic vesicle, the genes of the ectoderm cells coding for crystallin are activated, whereas genes coding for keratin are not expressed.

STUDY BREAK 50.3

1. **What is the outcome of organogenesis?**
2. **What tissues or organs develop from the neural tube and neural crest cells?**

50.4 Embryonic Development of Humans and Other Mammals

The embryonic development of humans is representative of the placental mammals. In the uterus, the embryo is nourished by the placenta, which supplies oxygen and nutrients and carries away carbon dioxide and nitrogenous wastes.

Pregnancy or **gestation,** the period of mammalian development in the uterus, varies in different species. Larger mammals bearing larger young generally have longer gestation periods; for example, gestation takes 600 days in elephants and about 1 year in blue whales, versus 21 days in hamsters.

In humans, gestation takes about 38 weeks, which amounts to about 40 weeks from the beginning of the menstrual cycle in which fertilization takes place. Human gestation is divided into three **trimesters,** each approximately 3 months long.

The major developmental events in human gestation—cleavage, gastrulation, and organogenesis—take place during the first trimester. By the fourth week, the embryo's heart is beating, and by the end of the eighth week, the major organs and organ systems have formed. From this point until birth, the developing human is called a **fetus.** Only 5 cm long by the end of the first trimester, the fetus grows during the second and third trimesters to an average length of 50 cm and an average mass of 3.5 kg (or about 19.7 inches and 7.7 pounds). The period of gestation ends with birth.

Cleavage and Implantation Occupy the First 2 Weeks of Development

Human fertilization occurs when the egg is in the first third of the oviduct leading from the ovary to the uterus (see Section 49.3). After fertilization, cleavage divisions take place during passage of the developing embryo down the oviduct (also called the fallopian tube in mammals) and while it is still enclosed in the zona pellucida—the original coat of the egg **(Figure 50.12).**

By day 4, the morula, a 16- or 32-cell ball, has been produced. By the time the endometrium (uterine lining) is ready for implantation (about 7 days after ovulation; see Section 49.3), the morula has reached the uterus and has undergone further cell divisions and differentiation into a type of blastula called a **blastocyst,** which is a characteristic of mammalian development. At this time, the blastocyst is a single-cell-layered hollow ball that is made up of about 70 to 100 cells, and contains a fluid-filled cavity. The blastocoel, the fluid-filled cavity, has a dense mass of cells localized to one side called the **inner cell mass.** This inner cell mass gives rise to the embryo as well as the yolk sac, the allantois, and the amnion. The rest of the blastocyst becomes tissues that support the development of the embryo in the uterus. The outer single layer of cells of the blastocyst is the **trophoblast.**

Next, when the blastocyst has increased to an appropriate size, it breaks out of the zona pellucida and sticks to the endometrium on the side with the inner cell mass (**Figure 50.13,** step 1). Implantation begins when the trophoblast secretes proteases that digest pathways between endometrial cells. The trophoblast extends into the pathways, appearing like fingerlike projections into the endometrium. Continued digestion of endometrial cells generates a hole in the endometrium for the blastocyst and releases nutrients that the developing embryo can use.

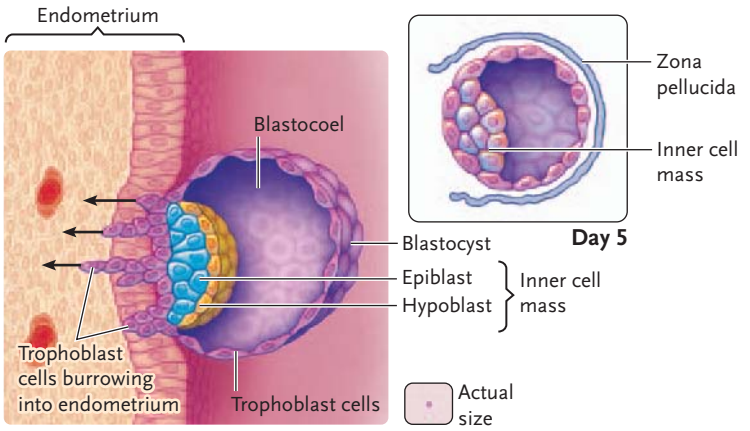
The inner cell mass of the burrowing blastocyst separates into the *embryonic disc,* which consists of two distinct cell layers (see Figure 50.13, step 1). The layer farther from the blastocoel is the *epiblast,* which gives rise to the embryo proper, and the layer nearer the blastocoel is the *hypoblast,* which gives rise to part of the extraembryonic membranes. When implantation is complete, the blastocyst has completely burrowed into the endometrium and is covered by a layer of endometrial cells (step 2).

Mammalian Gastrulation and Neurulation Resemble the Reptilian–Bird Pattern

Gastrulation proceeds as in birds (see Figure 50.7), with the formation of a primitive streak in the epiblast. Some epiblast cells remain in place, becoming the ectoderm, whereas others enter the streak to form the endoderm and mesoderm. The ectoderm, mesoderm, and endoderm are located initially in three layers; from this initial arrangement, the endoderm folds to form the primitive gut, and becomes surrounded with ectoderm and mesoderm. Neurulation in human and other mammalian embryos takes place essentially as in birds (see Figure 50.9).

Extraembryonic Membranes Give Rise to the Amnion and Part of the Placenta

Next, a layer of cells separates from the epiblast along its top margin (see Figure 50.13, step 2). The fluid-filled space created by the separation becomes the amniotic cavity, and the layer of ectodermal cells forming its roof becomes the amnion, the extraembryonic membrane surrounding the cavity. The amnion expands until eventually it surrounds the embryo completely and suspends it in amniotic fluid. As in birds, the hypoblast develops into the yolk sac. However, in mammals, the mesoderm of the yolk sac gives rise to the blood vessels in the embryonic portion of the placenta.



Although the amnion is expanding around the embryonic disc, blood-filled spaces form in maternal tissue, and trophoblast cells grow rapidly around both the embryo and amnion to form the chorion (step 3). Then, a connecting stalk forms between the embryonic disc and the chorion, while the chorion begins to grow into the endometrium as fingerlike extensions called **chorionic villi** (step 4). When complete, the chorionic villi greatly increase the surface area of the chorion. Where these villi grow into the endometrium is the area of the future placenta. As the chorion develops, mesodermal cells of the yolk sac grow into it and form a rich network of blood vessels, the embryonic circulation of the placenta. The expanding chorion stimulates the blood vessels of the endometrium to grow into the maternal circulation of the placenta (step 5).

Within the placenta of humans, apes, monkeys, and rodents, the maternal circulation opens into spaces in which the maternal blood bathes the trophoblast layers of the placenta (step 6). The fetal capillaries are positioned next to the trophoblast so that there can be as few as two cell layers separating the maternal and fetal blood. (Different types of placentas are found in other mammals.) The embryonic circulation remains closed, however, so that the embryonic and maternal blood do not mix directly. This prevents the mother from developing an immune reaction against cells of the embryo, which, because it is geneti-

CLOSER LOOK

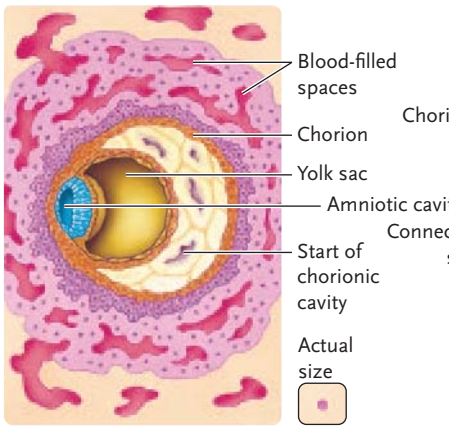

FIGURE 50.13 Implantation of a human blastocyst in the endometrium of the uterus and the establishment of the placenta.

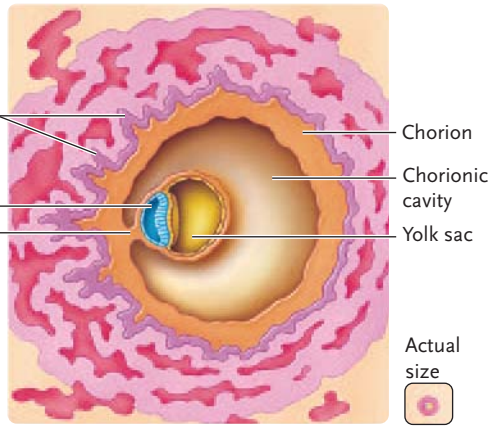
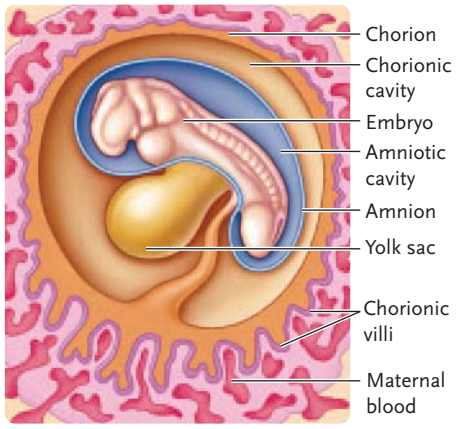
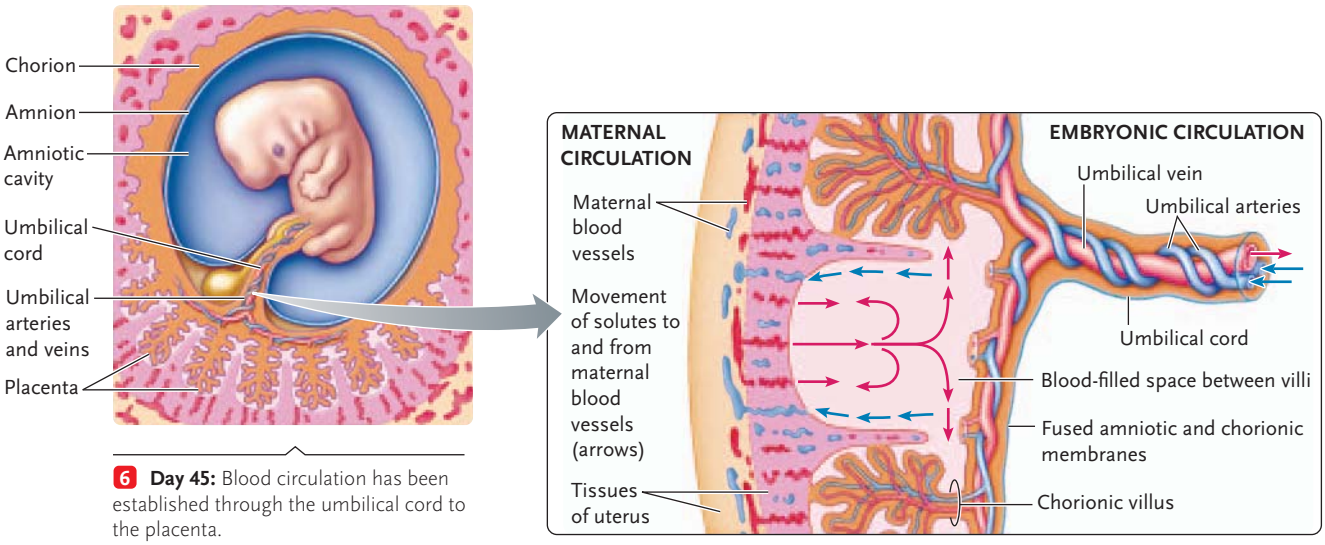


1 Days 6–7: Surface cells of the blastocyst attach to the endometrium and start to burrow into it. Implantation is under way.



2 Days 10–11: A layer of epiblast cells separates, producing the amniotic cavity. The cells above the cavity become the amnion, which eventually surrounds the embryo. The hypoblast begins to form around the yolk sac.



3 Day 12: Blood-filled spaces form in maternal tissue. The chorion forms, derived from trophoblast cells, and encloses the chorionic cavity.

4 Day 14: A connecting stalk has formed between the embryonic disk and chorion. Chorionic villi, which will be features of a placenta, start to form.

5 Day 25: The chorion continues to grow into the endometrium, producing the chorionic villi. The chorion growth stimulates blood vessels of the endometrium to grow into the maternal circulation of the placenta.

6 Day 45: Blood circulation has been established through the umbilical cord to the placenta.

SUMMARY Implantation of a human blastocyst in the endometrium occurs with the first two weeks of development. When implantation is complete, the embryonic disc (epiplast plus hypoblast) is connected to the chorion by a stalk, chorionic villi have started to form, and an amniotic cavity is present. As development continues, the placenta forms and blood circulation is established through the umbilical cord of the embryo and the placenta. The blood circulation of the embryo is kept separate from the maternal circulation.

THINK LIKE A SCIENTIST Why is it important to keep the circulation of the embryo and fetus separate from that of the mother?

FIGURE 50.14 The human embryo after 6 weeks (A) and 4 months (B) of development.

cally different from the mother, may be recognized as foreign by the mother's immune system. Eventually, the placenta and its blood circulation grow to cover about a quarter of the inner surface of the enlarged uterus and reach the size of a dinner plate.

As the embryonic blood circulation develops, this connecting stalk between the embryo and placenta develops into the **umbilical cord,** a long tissue with blood vessels linking the embryo and the placenta. The vessels in the umbilical cord are derived from the extraembryonic membrane, the *allantois.* They conduct blood between the embryo and the placenta (shown in the inset for Figure 50.13, step 6).

Within the placenta, nutrients and oxygen pass from the mother's circulation into the circulation of the embryo. Besides nutrients and oxygen, many other substances taken in by the mother—including alcohol, caffeine, drugs, and toxins in cigarette smoke—can pass from mother to embryo. Carbon dioxide and nitrogenous wastes pass from the embryo to the mother, and are disposed of by the mother's lungs and kidneys.

If the presence of a genetic disease such as cystic fibrosis or Down syndrome is suspected, tests can be carried out on cells removed from the embryonic portion of the placenta or from the amniotic fluid, which contains cells derived from the embryo. The test using cells of the placenta is called *chorionic villus sampling;* the test using cells derived from the amniotic fluid is called *amniocentesis* (see Section 13.4). Chorionic villus sampling can be carried out as early as the eighth week, compared with 14 weeks for amniocentesis. Both tests carry some degree of risk to the embryo.

Further Growth of the Fetus Culminates in Birth

By the end of its fourth week, a human embryo is 3 to 5 mm long, which is 250 to 500 times the size of the zygote. It has a tail and **pharyngeal arches,** which are embryonic features of all vertebrates. The pharyngeal arches contribute to the formation of the face, neck, mouth, larynx, and pharynx. After 6 weeks, the embryo is about 13 mm long and has a more humanlike appearance with, for example, eyes and developing limbs apparent **(Figure 50.14A).** At 16 weeks, the fetus's bones and muscle tissue continue to form, producing a more complete skeleton; its skin begins to form; its limbs with fingers and toes have developed; its organ systems have formed; and its sex is identifiable **(Figure 50.14B).** At birth the baby will have grown to about 3 times the length and 17 times the weight of the fetus at this stage.

Figure 50.15 shows the hormonal events and associated physical events of birth. As the period of fetal growth comes to a close, the fetus typically turns so that its head is downward, pressed against the cervix. A steep rise in the levels of estrogen secreted by the placenta at this time causes cells of the uterus to express the gene for the receptor of the hormone *oxytocin.* The receptors become inserted into the plasma membranes of those cells. Oxytocin—which is secreted by the pituitary gland—binds to its receptor, triggering the smooth muscle cells of the uterine wall to contract and begin the rhythmic contractions of labor. These contractions mark the beginning of **parturition** (*parturire* = to be in labor), the process of giving birth.

The contractions push the fetus further against the cervix and stretch its walls (step 1). In response, stretch receptors in the walls send nerve signals to the hypothalamus, which responds by stimulating the pituitary to secrete more oxytocin. In turn, the oxytocin stimulates more forceful contractions of the uterus, pressing the fetus more strongly against the cervix, and further stretching its walls. The positive feedback cycle continues, steadily increasing the strength of the uterine contractions.

As the contractions force the head of the fetus through the cervix (step 2), the amniotic membrane bursts, releasing the amniotic fluid. Usually, within 12 to 15 hours after the onset of uterine contractions, the head passes entirely through the cervix. Once the head is through, the rest of the body follows quickly and the entire fetus is forced through the vagina to the exterior, still connected to the placenta by the umbilical cord (step 3).

After the baby takes its first breath, the umbilical cord is cut and tied off by the birth attendant. Contractions of the uterus continue, expelling the placenta and any remnants of

the umbilical cord and embryonic membranes as the afterbirth. The short length of umbilical cord still attached to the infant dries and shrivels within a few days. Eventually, it separates entirely and leaves a scar, the **umbilicus** or navel, to mark its former site of attachment during embryonic development.

The Mother's Mammary Glands Become Active after Birth

Before birth of the fetus, estrogen and progesterone secreted by the placenta stimulate the growth of the mammary glands in the mother's breasts. However, the high levels of these hormones prevent the mammary glands from responding to *prolactin,* the hormone secreted by the pituitary that stimulates the glands to produce milk. After birth of the fetus and release of the placenta, the levels of estrogen and progesterone fall steeply in the mother's bloodstream, and the breasts begin to produce milk (stimulated by prolactin) and secrete it (stimulated by oxytocin).

Continued milk secretion depends on whether the infant is suckled by the mother. If the infant is suckled, stimulation of the nipples sends nerve impulses to the hypothalamus, which responds by signaling the pituitary to release a burst of prolactin and oxytocin. Hormonal stimulation of milk production and secretion continues as long as the infant is breastfed.

So far, we have followed the development of a generic human, but certain aspects of development differ depending on the offspring's sex. Next we look at the specifics of male and female development.

1 Contractions of the uterus press the head against the cervix, stretching the cervical opening.

2 The head of the fetus begins to pass through the cervix and vagina.

3 The placenta and umbilical cord will be forced out of the uterus as the "afterbirth."

A Gene on the Y Chromosome Determines the Development of Male or Female Sex Organs

The gonads and their ducts begin to develop during the fourth week of gestation. Until the seventh week, male and female embryos have the same set of internal structures derived from mesoderm, including a pair of gonads **(Figure 50.16A).** Each gonad is associated with two primitive ducts, the **Wolffian duct** (also called the *mesonephric duct*) and the **Müllerian duct** (also called the *paramesonephric duct*), which lead to a cloaca. At this time, the gonads are *bipotential:* they can develop into either male or female gonads.

The presence or absence of a Y chromosome determines whether the bipotential gonads and internal ducts develop into male or female gonads and their associated internal ducts. If the fetus has the XY combination of sex chromosomes, a single gene on the Y chromosome, *SRY (**S**ex-determining **R**egion of the **Y**),* becomes active in the seventh week. The protein encoded by the gene sets a molecular switch that causes the primitive gonads to develop into testes. The fetal testes then secrete two hormones, testosterone and the *anti-Müllerian hormone (AMH).* The testosterone stimulates development of the Wolffian ducts into the male reproductive tract, including the epididymis and vas deferens **(Figure 50.16B),** and seminal vesicles (see Figure 49.14). AMH causes the Müllerian ducts to degenerate and disappear. (*Insights from the Molecular Revolution* describes experiments that traced the activity of the *SRY* gene and its encoded protein in male development.) Testosterone additionally stimulates the development of the male genitalia.

If the fetus has the XX combination of chromosomes, no SRY protein is produced and the primitive gonads, under the influence of the estrogens and progesterone secreted by the placenta, develop into ovaries. The Müllerian ducts develop into the oviducts, uterus, and part of the vagina, and the Wolffian ducts degenerate and disappear **(Figure 50.16C).** The female sex hormones additionally stimulate the development of the female external genitalia.

Development Continues after Birth

Once fetal development is over, humans and other mammals, as well as most other animals, follow a prescribed course of further growth and development that leads to the adult, the sexually mature form of the species. In humans, the internal and external sexual organs mature and secondary sexual characteristics ap-

pear at puberty. Similar changes occur in most mammals. There are, in fact, many examples among different animal groups of developmental changes that take place after hatching or birth. In some cases, offspring hatch that are distinctly different in structure from the adult. Examples among invertebrates include insects such as *Drosophila* and butterflies, in which eggs hatch to produce larva that undergo metamorphosis into the adult. Frogs similarly hatch as tadpoles, which undergo metamorphosis to produce the adult.

We have now described embryonic development in animals from a morphological perspective. In the rest of the chapter, we focus on the cellular mechanisms that underlie development.

50.5 The Cellular Basis of Development

In the preceding sections, you learned about the processes of development from a mainly structural point of view. Underlying those developmental processes are specific cellular and molecular events. In this section, you will learn about some of the cellular events that underlie the stages of development. The genetic and molecular regulation of development was discussed in Section 16.4.

Cell Division Varies in Orientation and Rate during Embryonic Development

Recall from earlier in the chapter that *morphogenesis* is the generation of the body form as differentiated cells end up in their appropriate positions. In animals, morphogenesis occurs by changes in cell shape, cell position, and cell adhesion. For embryo morphogenesis, the *orientation* and *rate* of mitotic cell division have special significance. Regulation of these two features of mitotic cell division occurs at all stages of development.

The orientation of cell division refers to the angles at which daughter cells are added to older cells as development proceeds. Orientation is determined by the location of a furrow that separates the cytoplasm after mitotic division of the nucleus (furrowing is discussed in Section 10.2). The furrow forms in alignment with the spindle midpoint. Therefore, when the spindle is centrally positioned in the cell, the furrow leads to symmetrical division of the cell. However, when the spindle is displaced to one end of the cell, the furrow leads to asymmetrical division of the cell into a smaller and a larger cell. Little is known about how spindle positioning is regulated.

The rate of cell division primarily reflects the time spent in the G_1 period of interphase (see Section 10.2); once DNA replication begins, the rest of the cell cycle is usually of uniform length in all cells of the same species. As an embryo develops and cells differentiate, the time spent in interphase increases and varies in length in different cell types. Therefore, different cell types proliferate at various rates, giving rise to tissues and organs with different cell numbers. Ultimately, the rate of cell division is under genetic control.

Frog egg cleavage provides examples of how both changes in orientation and rate of mitotic division affect development. The first two cleavages start at the animal pole and extend to the vegetal pole, producing four equal blastomeres (see Figure 50.2). The third cleavage occurs equatorially. However, because there is yolk in the vegetal region of the embryo, this cleavage furrow forms not at the equator but up higher toward the animal pole. The result is an eight-cell embryo with four small blastomeres in the animal region of the embryo, and four large blastomeres in the vegetal region. All the blastomeres then divide at the same rate up until the twelfth division. Thereafter, blastomeres in the animal region divide rapidly whereas blastomeres in the vegetal region divide more slowly because division is inhibited by yolk. As a result, the animal region becomes filled with many small cells, whereas the vegetal region contains a relatively small number of yolk-filled blastomeres.

Turning on Male Development

The switch to male development in mammalian embryos is triggered by the SRY protein encoded by the *SRY* gene on the Y chromosome. Individuals with an inactive SRY protein due to a mutation in the *SRY* gene develop into females, even though they have the XY combination of sex chromosomes. The mutant SRY proteins have changes in single amino acids or have a missing segment. All the single amino acid changes are concentrated in a region of the SRY protein known as the *HMG box,* which can bind to DNA. This discovery suggested that SRY is a regulatory protein that binds to regulatory sequences of genes such as *AMH,* which encodes the anti-Müllerian hormone, and turns on expression of those genes.

Research Question

Does SRY regulate the expression of the *AMH* directly?

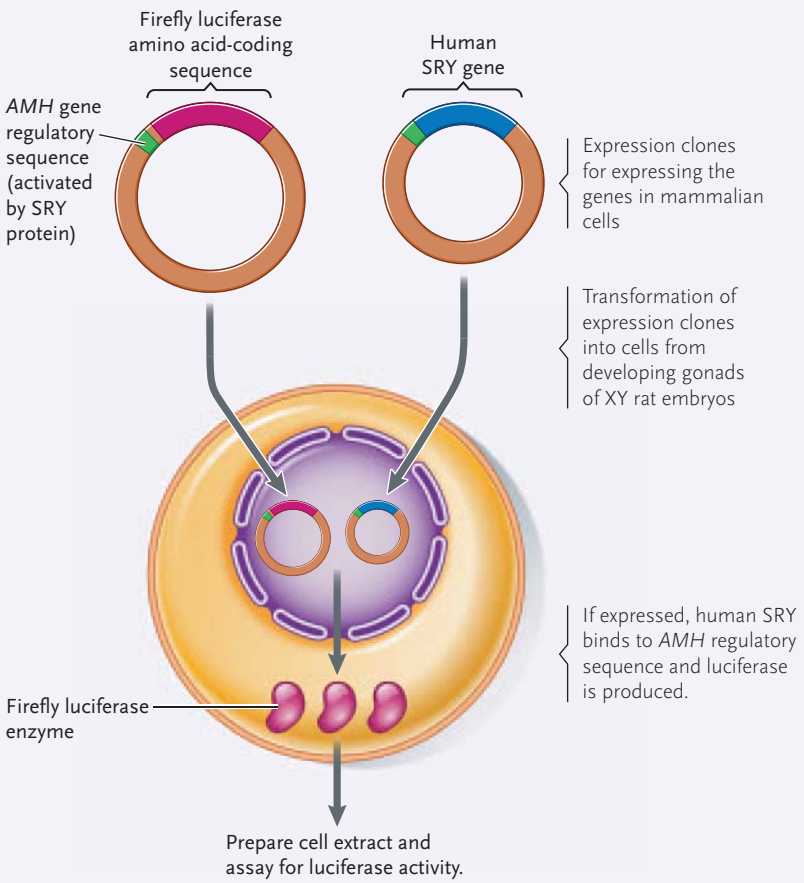
Experiment

A group of investigators led by Michael Weiss at the Harvard Medical School and Massachusetts General Hospital in Boston tested whether SRY turns on the *AMH* gene directly.

For their experiments, the researchers attached the regulatory sequences that control transcription of the *AMH* gene to the amino acid-coding sequence of a gene encoding firefly luciferase **(Figure).** Firefly luciferase is an enzyme that catalyzes a reaction with the substrate luciferin to produce light (see *Insights from the Molecular Revolution,* Chapter 42). If SRY binds to the *AMH* gene regulatory sequence of the constructed gene and activates transcription, translation of the resulting mRNA produces luciferase. Luciferase activity is measured in cell extracts; the quantification of the amount of light produced in the reaction indicates the degree of activation of transcription caused by SRY. The data are then extrapolated to the effects of SRY on the complete *AMH* gene.

The researchers introduced the composite *AMH*–luciferase gene into embryonic cells removed from the developing gonads of XY rat embryos. A normal human *SRY* gene was then introduced into the gonad cells containing the artificial gene, and luciferase activity was measured.

Results



High luciferase activity was seen, confirming that the normal SRY protein activates the *AMH* gene. The experiment was repeated with a mutant *SRY* gene isolated from a human patient who had developed into a female even though she had the XY combination of sex chromosomes. The mutation involved altered a single amino acid in the HMG box of the SRY protein. When her *SRY* gene was added to the embryonic rat gonad cells, there was no luciferase activity, indicating that her altered SRY protein could not turn on the *AMH* gene.

Conclusions

Adding a normal SRY protein to the *AMH* gene in a test tube showed that the protein binds directly to the gene. Tests with DNA-digesting enzymes showed that combination with SRY protects a segment of the regulatory sequence of the *AMH* gene from attack by the enzymes. This protection indicated that SRY binds this sequence, as expected for a regulatory protein.

THINK LIKE A SCIENTIST The experiments described involved missense mutations in the HMG box-encoding region of the *SRY* gene. (Types of mutations are described in Section 15.5). Predict what result would have been obtained in this experiment with: (a) a nonsense mutation in the *SRY* gene upstream of the HMG-box encoding region; (b) a nonsense mutation downstream of that region; and (c) a frameshift mutation upstream of that region.

Cell-Shape Changes and Cell Migrations Play Important Roles in Development

We have seen that embryonic cells undergo changes in shape that generate cell migrations, such as the infolding of surface layers to produce endoderm or mesoderm. Entire cells also migrate during the embryonic growth of animals, both singly and in groups. Both the shape changes and the whole-cell migrations are produced by microtubules (powered by dyneins and kinesins) and microfilaments (powered by myosins) (see Section 5.3). Cell migrations are also produced by changes in the rate of growth or by the breakdown of microtubules and microfilaments. Generally speaking, changes in both cell shape and cell migration play important roles in cleavage, gastrulation, and organogenesis.

CHANGES IN CELL SHAPE Changes in cell shape typically result from reorganization of the cytoskeleton. For example, during the development of the neural plate in frogs (see Figure 50.9), the ectoderm flattens and thickens; that is, microtubules within cells in the ectoderm layer lengthen and slide farther apart, causing the cells to transition from a cubelike to a columnar shape **(Figure 50.17A).**

Once formed, the neural plate sinks downward along its midline as a result of a change in cell shape from columnar to wedgelike **(Figure 50.17B).** As the tops of the cells narrow, the entire cell layer is forced inward—it invaginates. How does this occur? Each wedge-shaped cell contains a group of microfilaments arranged in a circle at its top. The microfilaments slide over each other, tightening the ring like a drawstring and narrowing the top of the cell.

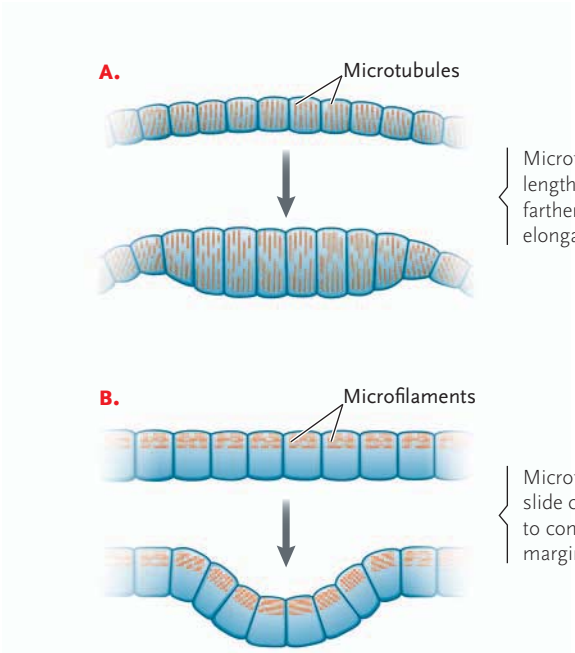

FIGURE 50.17 **The roles of microtubules (A) and microfilaments (B) in the changes in cell shape that produce developmental movements, such as neural plate formation.**

© Cengage Learning 2014

WHOLE-CELL MIGRATIONS Among the most striking examples of whole-cell migrations in embryonic development are the migrations of cells during gastrulation to form the three germ layers, that is, the ectoderm, mesoderm, and endoderm, and the often long-distance migrations of neural crest cells. These whole-cell migrations involve the coordinated activity of microtubules and microfilaments and large-scale reorganization of the cytoskeleton.

Cell migration proceeds in four stages:

1. *Polarization.* The front and back ends of a cell becomes defined by a polarization process. Polarization is triggered either by diffusible signals or by signals from the extracellular matrix (ECM). In response to a polarizing signal, the cell reorganizes its cytoskeleton so that the cell has a front and a back end.
2. *Protrusion of the front end of the cell.* Actin microfilaments assemble into long, parallel bundles, causing the front end of the cell to protrude.
3. *Adhesion.* In order to migrate, a cell must be anchored to a substrate that it can push on. Therefore, the cell at this stage adheres to the surrounding extracellular matrix. (Some molecular aspects of the adhesion process are described later.)
4. *Release of rear adhesion, and forward migration to a new adhesion point.* Adhesion of the cell to the substrate at its rear end are released, and the cell migrates forward and adheres to a new attachment point. Repetition of this stage results in continued forward movement in a fashion somewhat resembling how an amoeba moves (see Section 5.3 and Figure 6.15).

How do the cells know where to go? Typically, cells migrate over the surface of stationary cells in one of the embryo's layers. In many developmental systems, migrating cells follow tracks formed by molecules of the extracellular matrix that is secreted by the cells along the route over which they travel. An important track molecule is *fibronectin,* a fibrous, elongated glycoprotein of the extracellular matrix. Migrating cells can recognize and adhere to the fibronectin; in response, internal changes in the cells trigger movement in a direction based on the alignment of the fibronectin molecules. For instance, paths of fibronectin guide primordial germ cells to the gonads, and cells of the heart to the midline of the embryo. Experiments in which the formation of fibronectin pathways was prevented have shown how crucial those pathways are for embryonic development. For example, gastrulation does not occur in amphibians lacking fibronectin, and in mammals, mesoderm and neural tube development is defective in the absence of fibronectin.

Some migrating cells follow concentration gradients instead of molecular tracks. The gradients are created by the diffusion of molecules (often proteins) released by cells in one part of an embryo. Cells with receptors for the diffusing molecule follow the gradient toward its source, or move away from the source.

Selective Cell Adhesions Underlie Cell Migrations

Selective cell adhesion, the ability of an embryonic cell to make and break specific connections to other cells, is closely related to cell migration. As development proceeds, many cells break their initial adhesions and move, forming new adhesions in different locations. Final cell adhesions hold the embryo in its correct shape and form. Junctions of various kinds, including tight, anchoring, and gap junctions, reinforce the final adhesions (see Section 5.5).

The selective nature of cell adhesions was first demonstrated in a classic experiment by Johannes Holtfreter of the University of Rochester and his student P. L. Townes. The researchers removed pieces of ectoderm, mesoderm, and endoderm from living amphibian embryos in the neurulation stage, separated them into individual cells, and added the cells in various combinations to a culture medium. Initially the cells clumped together at random into a ball. After a few hours, they sorted themselves out and moved into arrangements resembling their normal locations in the gastrula **(Figure 50.18).**

Further research has identified many cell surface proteins responsible for selective cell adhesions, including **cell adhesion molecules** (CAMs; see Section 5.5) and **cadherins** *(calcium-dependent adhesion molecules).* As cells develop, different types of CAMs or cadherins may appear or disappear from their surfaces as they make and break cell adhesions. The changes reflect alterations in gene activity, often in response to molecular signals arriving from other cells. For example, in the neural plate stage of neurulation in the frog (see Figure 50.9), N-cadherin is on neural plate cells, keeping those cells together, whereas E-cadherin is on the adjacent ectodermal cells, keeping those cells together. The neural tube is produced when the neural plate cells separate from the ectodermal cells, whereas both cell types retain their respective cadherin type. The neural crest cells have neither cadherin bound to them, so they do not bind to each other and they disperse (as described earlier). However, if N-cadherin is expressed in the ectodermal cells through experimental manipulation, the forming neural tube does not separate from the flanking ectodermal cells because all of the cells are held together by N-cadherin.

As they begin to disperse, neural crest cells produce *integrins,* which insert into the plasma membrane. Recall from Section 5.5 that integrins are receptor proteins that span the plasma membrane. On the cytoplasmic side, integrins bind to actin microfilaments of the cytoskeleton. Integrins function to integrate changes outside and inside the cell by communicating changes in the extracellular matrix to the cytoskeleton. In the example here, the integrin receptors of the neural crest cells interact with proteins in the extracellular matrix in a way that causes cytoskeletal changes. The cytoskeletal changes move the cells along their migration pathways. More generally, integrins are involved in many key developmental processes.

The development of a new organism involves the cell shape changes, cell migrations, and cell adhesions we have just discussed and, in addition, the programmed emergence of particular types of cells, or cell lineages, as we will see next.

Fate Mapping Maps Adult Structures onto Regions of the Embryos from Which They Developed

From the early days of studying development, embryologists have focused on describing not only how embryos form and develop, but exactly how adult tissues and organs are produced from the cells of the embryo. Thus, an important goal in embryology is to trace cell lineages from embryo to adult. For most organisms, it is not possible to trace lineages at the individual cell level, primarily because of the complexity of the developmental process and the typical opacity of embryos. However, it has been possible to map adult or larval structures onto the region of the embryo from which each structure developed. This type of study is called *fate mapping,* and the result is called a **fate map.** Experimentally, fate mapping is done by following development of living embryos under the microscope, either using species in which the embryo is transparent, or by marking cells so they can be followed. Cells may be marked with vital dyes (dyes that do not kill cells), fluorescent dyes, or radioactive labels. Fate maps have been produced for a number of organisms, including the chick, *Xenopus,* and *Drosophila.*

In most cases a fate map is not detailed enough to relate how particular cells in the embryo gave rise to cells of the adult. The exception is the fate map of the nematode *Caenorhabditis elegans,* an organism that has a fixed, reproducible developmental pattern. This animal has a transparent body, and scientists have been able to map the fate—trace the **cell lineage**—of every somatic and germ-line cell as the zygote divides and the resulting embryo differentiates into the 959-cell adult hermaphrodite or the 1,031-cell adult male **(Figure 50.19).** All somatic cells of the adult can be traced from five somatic *founder cells* produced during early development. Knowing the cell lineages of *C. elegans* has been a valuable tool for research into the genetic and molecular control of development in this organism, for mutants affecting development have an easily visible effect. Among the results of such studies, we have learned that not only are proteins encoded by regulatory genes involved in the control of development, but so are some miRNAs. For example, genetic manipulation makes it possible to knock out the functions of specific miRNA-coding genes. For most miRNA-coding genes, the knockouts do not affect development. However, for a few of the miRNA-coding genes, the knockouts cause defects in the timing of development.

Induction Depends on Molecular Signals Made by Inducing Cells

Recall from Section 50.1 that induction is the process by which a group of cells (the inducer cells) causes or influences a nearby group of cells (the responder cells) to follow a particular developmental pathway. Recall also that induction is the major pro-

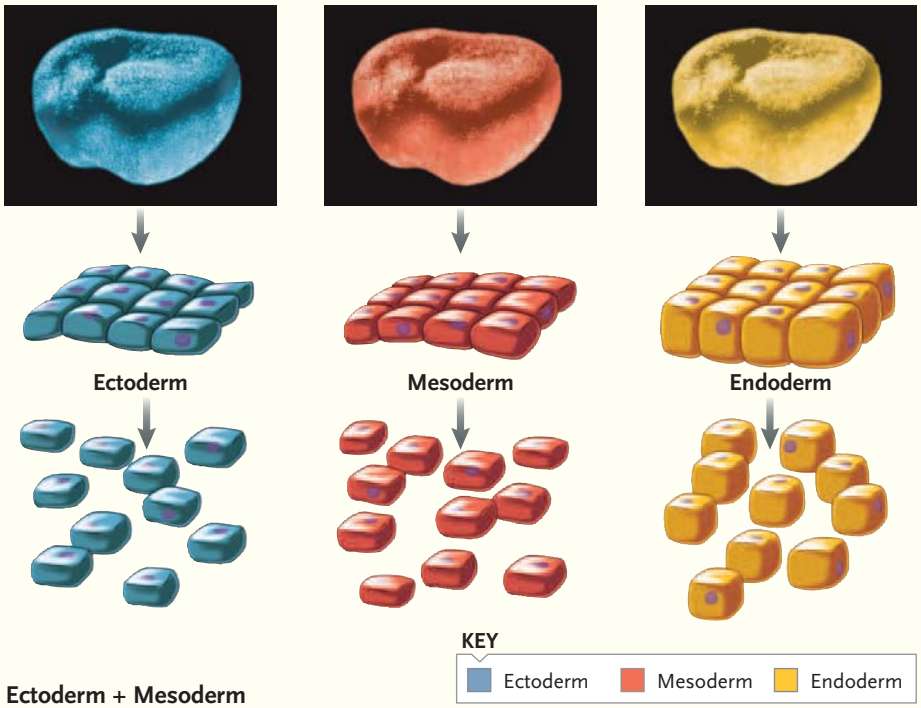
Demonstrating the Selective Adhesion Properties of Cells



Question: Do cells make specific connections to other cells?

Experiment: Johannes Holtfreter and P. L. Townes demonstrated that cells make specific connections to other cells, meaning that cells have selective adhesion properties.

1. Holtfreter and Townes separated ectoderm, mesoderm, and endoderm tissue from amphibian embryos soon after the neural tube had formed. They used embryos from amphibian species that had cells of different colors and sizes, enabling them to follow under the microscope where each cell type ended up. (The colors shown here are for illustrative purposes only.)

2. The researchers placed the tissues individually in alkaline solutions, which caused the tissues to break down into single cells.

3. Holtfreter and Townes combined suspensions of single cells in various ways. Shown here are ectoderm + mesoderm, and ectoderm + mesoderm + endoderm. When the pH was returned to neutrality, the cells formed aggregates. Through a microscope, the researchers followed what happened to the aggregates.

Results: In time the reaggregated cells sorted themselves with respect to cell type; that is, instead of the cell types remaining mixed, each cell type became separated spatially. In the ectoderm + mesoderm mixture, the ectoderm moved to the periphery of the aggregate, surrounding mesoderm cells in the center. In no case did the two cell types remain randomly mixed. In the ectoderm + mesoderm + endoderm mixture, cell sorting in the aggregates generated cell positions reflecting the positions of the cell types in the embryo. That is, the endoderm cells separated from the ectoderm and mesoderm cells and became surrounded by them. In the end, the ectoderm cells were located on the periphery, the endoderm cells were internal, and the mesoderm cells were between the other two cell types.

Conclusion: Holtfreter interpreted the results to mean that cells have selective affinity for each other—cells have selective adhesion properties. Specifically, he proposed that ectoderm cells have positive affinity for mesoderm cells but negative affinity for endoderm cells, whereas mesoderm cells have positive affinity for both ectoderm cells and endoderm cells. In modern terms, these properties result from cell surface molecules that give cells specific adhesion properties.

THINK LIKE A SCIENTIST As the main text discusses, subsequent research identified cadherins as one type of cell surface proteins responsible for selective cell adhesions. Suppose you have a cloned cDNA for a cadherin, which is proposed to be one type of cell surface protein responsible for selective cell adhesions. How could you use that cloned cDNA to test directly whether or not it has that role?

cess responsible for determination, in which the developmental fate of a cell is set, and that induction occurs when signal molecules interact with surface receptors on the responding cells, typically triggering changes in gene activity.

A German scientist, Hans Spemann of the University of Freiburg, carried out the first experiments identifying induction in embryos in the 1920s. He and his doctoral student, Hilde Mangold, found that if the dorsal lip of a newt embryo was removed and grafted into a different position on another newt embryo, on the ventral side for instance, cells moving inward from the dorsal lip induced a neural plate, a neural tube, and eventually an entire embryo to form in the new location **(Figure 50.20).** On the basis of his pioneering research, Spemann proposed that the dorsal lip is an *organizer,* acting on other cells to alter their course of development. This action is now known as *induction,* and the cells responsible for induction are known generally as inducer cells. Spemann received the Nobel Prize in 1935 for his research. (In 1924, the year their research paper was published, Mangold died in an accident when her kitchen gasoline heater exploded. She would likely have also received the Nobel Prize, but they are never awarded posthumously.)

Induction in development typically involves paracrine signaling, meaning that the inducer molecule secreted by the inducer cell changes the cellular behavior of responder cells that are located nearby the inducer cells (see Section 42.1). For a cell to respond to the inducer molecule, it must have a receptor for that molecule. In addition, the responder cell must be able to respond to the specific inducer, a condition called *competence.* That is, simply having a receptor is not sufficient to generate a response; in addition, the responder cell must be expressing a genetic program that makes it competent to respond. Induction by the optic vesicle, discussed earlier in this chapter (see Figure 50.11), provides an example. You learned in the earlier discussion that transplanting the optic vesicle under ectoderm in other regions of the head induces a lens to form in the new location. However, if the optic vesicle is placed under ectoderm in areas other than the head, lens tissue does not develop. The interpretation is that only head ectoderm is competent to respond to the signals from the optic vesicle and produce a lens.

Tissues responding to inducing signals may themselves become inducers as development proceeds. For instance, once the lens has formed as a result of the induction events discussed above, the lens itself induces other tissues. In this particular example, the optic vesicle becomes a responder tissue for inducer molecules secreted by the lens. As a result, the optic vesicle becomes the optic cup (see Figure 50.11, step 2) and then the wall of the optic cup differentiates into the layers of the retina.

Differentiation Produces Specialized Cells without Loss of Genes

Differentiation is the process by which cells that have committed to a particular developmental fate by the determination process (see Section 50.1) now develop into specialized cell types with distinct structures and functions. As part of differentiation, cells concentrate on the production of molecules characteristic of the specific types. For example, 80% to 90% of the total protein that lens cells synthesize is crystallin.

Research into differentiation confirmed that as cells specialize, they retain all the genes of the original egg cell; except in rare instances, differentiation does not occur through selective gene loss. Several definitive experiments supporting this conclusion were carried out several decades ago by Robert Briggs and Thomas King of Lankenau Hospital Research Institute in Phila-

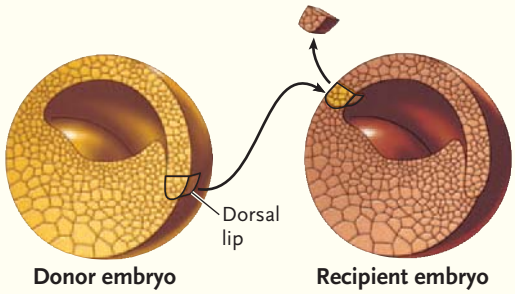

FIGURE 50.20 **Experimental Research**

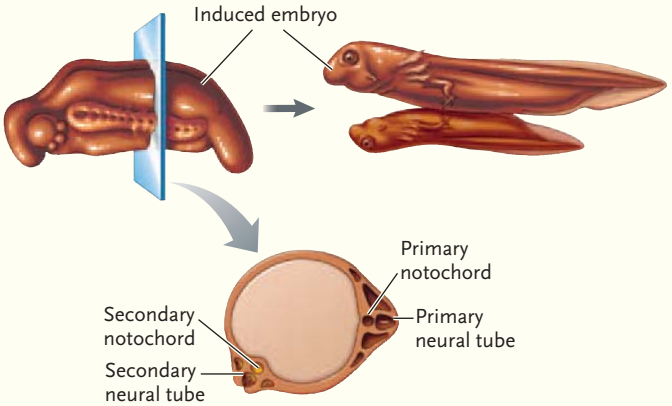
Spemann and Mangold's Experiment Demonstrating Induction in Embryos



Question: Does induction occur in embryonic development?

Experiment: Hans Spemann and Hilde Mangold performed transplantation experiments with newt embryos.

1. The researchers grafted the dorsal lip of the blastopore from one newt embryo and onto a different position—the ventral side—of another embryo. The two embryos were from different newt species that differed in pigmentation, allowing the fate of the transplanted tissue to be followed easily during development.

2. The embryo with the transplant was allowed to develop.

Result: At the ventral location on the recipient embryo where the dorsal lip of the blastopore was grafted, another embryo developed simultaneously with the recipient embryo. Eventually, two mature embryos were produced attached on their ventral surfaces.

Conclusion: The grafted dorsal lip of the blastopore induced a second gastrulation and subsequent development in the ventral region of the recipient embryo. The result demonstrated the ability of particular cells to induce the specific development of other cells.

THINK LIKE A SCIENTIST As a preliminary step, you transplanted cells from the upper tip of the primitive streak from one gastrulating chick embryo to an off-center site in another gastrulating chick embryo. The result was that, at the site of transplantation, a second set of dorsal structures formed in addition to the dorsal structures formed as a result of the recipient's primitive streak. The conclusion from this experiment is that the tip of the primitive streak induces dorsal structures. Now, if you transplant a primitive streak tip from a donor duck embryo to a recipient chick embryo, a second set of dorsal structures is also induced. Are these dorsal structures formed from duck cells or chick cells?

delphia (now Fox Chase Cancer Center), and extended by John B. Gurdon of the University of Cambridge, United Kingdom. In a typical experiment, the nucleus of a fertilized frog egg was destroyed by ultraviolet light. A micropipette was then used to transfer a nucleus from a fully differentiated tissue, intestinal epithelium, to the enucleated egg. Some of the eggs receiving the transplanted nuclei subsequently developed into normal tadpoles and adult frogs. This outcome was possible only if the differentiated intestinal cells still retained their full complement of genes. This conclusion was extended to mammals in 1997 when Ian Wilmut and his colleagues successfully cloned a sheep—Dolly—starting with an adult cell nucleus. (This experiment is described in Section 18.2.)

Apoptosis Is a Normal Part of Development

Induction and differentiation build complex, specialized organs from the three fundamental tissue types. Complementing these processes is *apoptosis*—a type of programmed cell death—a process that removes cells in a regulated way at a specific point in development. Apoptosis is an active process that is a normal part of development in animals. Programmed cell death processes have also been identified in plants (see Chapter 37). We focus here on animal development. (Apoptosis is also involved in removing cells that are damaged beyond repair, or cells that are infected with viruses. Those roles for apoptosis are not part of animal development and are not discussed here.)

An example of apoptosis is afforded by the nematode worm, *C. elegans*. In the worm, division of the fertilized egg eventually generates 1,090 cells, of which exactly 131 die by apoptosis at prescribed times to produce the 959 cells characteristic of an adult hermaphrodite. (*C. elegans* cell fates are summarized earlier in this section; see Figure 50.19.) In humans, for example, a developing fetus in the uterus produces about three times more neurons than is found at birth; the others are destroyed by apoptosis. Numerous other examples of apoptosis occur in animal development, including controlling the number

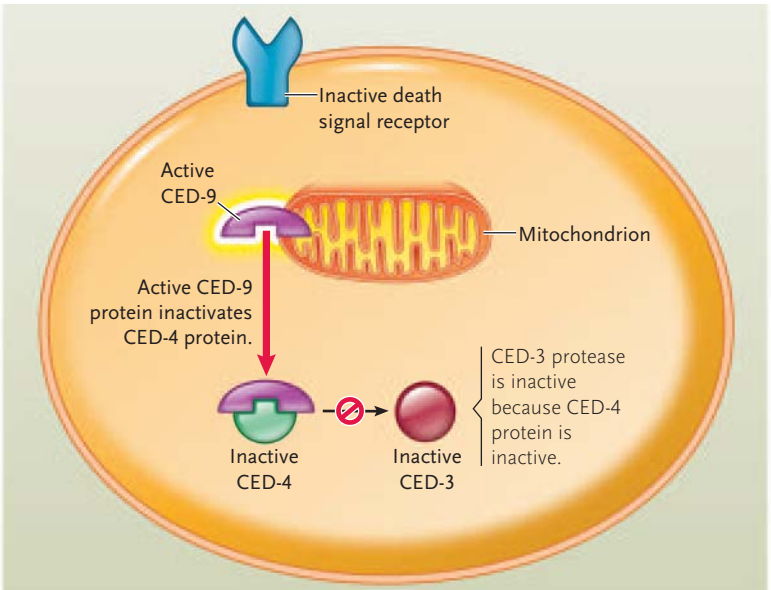
of cells in particular tissues (such as neurons), generating complex organs (such as the heart and the retina), and removing structures not needed (such as mammary tissue in male mammals, the tails of frogs, and tissue to create the vaginal opening) and controlling the spacing and orientation of tissues (such as neuron spacing and orientation and the spaces between digits [fingers and toes]). Considering the last example, in early development, tissue fills in the spaces between what will become the digits. The removal of that tissue—webbing—by apoptosis generates the free digits found later in development (see later discussion for more details about this example).

Apoptosis is characterized by specific morphological changes in cells. These changes include: (1) cell shrinkage, which can also result in a loss of cell-to-cell contact; (2) degradation of chromatin (which includes the DNA); (3) blebbing (production of small bulges) of the cell membrane; and (4) phagocytosis of the whole cell by macrophages, or fragmentation of the cell, followed by phagocytosis of the fragments.

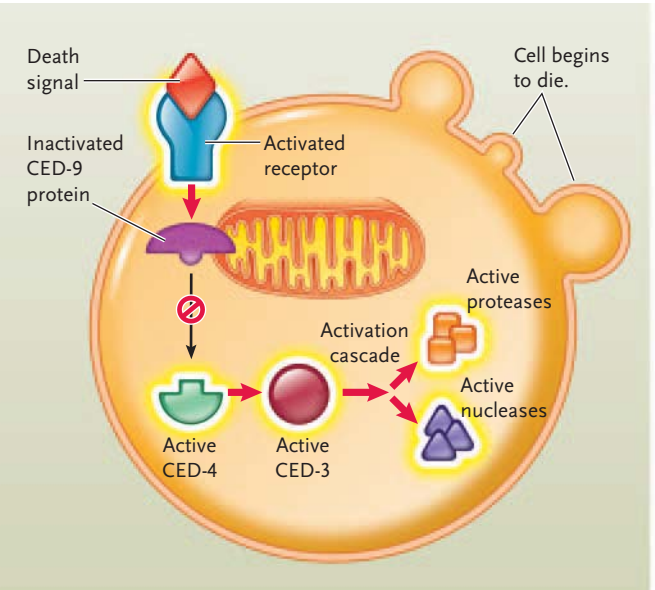


C. elegans was the model organism for genetic research that first delineated a pathway for apoptosis, a death pathway if you will. (Sydney Brenner, H. Robert Hurvitz, and John Sulson received a Nobel Prize in 2002 for this research on the "genetic regulation of organ development and programmed cell death.") The molecular basis of apoptosis involves a molecule called a death signal that binds to a receptor in the plasma membrane of a cell targeted for apoptosis. Binding of the death signal to the receptor activates it and, by signal transduction (see Chapter 7), leads to the activation of cellular proteins that kill the cell. In the absence of the death signal, the killing proteins remain inactive. Let us step through the two situations:

In the absence of a death signal, the membrane receptor is inactive **(Figure 50.21A).** This allows a protein associated with the outer mitochondrial membrane, CED-9 (encoded by the *ced-9 cell d*eath gene) to bind to and inactivate CED-4 (encoded by the *ced-4* gene). CED-4 in active form is required to activate the CED-3 protein (encoded by the *ced-3* gene), which is a protease of a class of proteases called *caspases.* Active CED-3 caspase is needed to turn on the cell death program. But here, in the absence of a death signal, CED-9 inactivates CED-4 which then cannot activate CED-4, so no apoptosis occurs. Cells with molecular switches set in this way are those that normally survive to form the adult nematode.

Binding of a death signal to the receptor activates the receptor and the events that follow are typical of signal transduction pathways **(Figure 50.21B)** (see Sections 7.1–7.4). In this case, activation of the receptor leads to inactivation of CED-9. Because CED-9 no longer inhibits CED-4, CED-4 is active and, in turn, it activates the CED-3 protease. Activated CED-3 initiates a cascade of reactions, including the activation of other caspase proteases, and nucleases that degrade cell structures and chromosomes as part of the cell death program.

Homologs of the CED-3, CED-4, and CED-9 proteins are involved in the apoptosis pathway that is common to all ani-



A. No death signal

© Cengage Learning 2014

Apoptosis is inhibited as long as CED-9 protein is active; cell remains alive.

B. Death signal

When a death signal binds to the death signal receptor, it activates the receptor, which leads to inactivation of CED-9 protein. As a result, CED-4 protein is no longer inhibited and becomes active, activating CED-3 protease. Active CED-3 triggers a cascade of activations producing active caspase proteases and nucleases, which cause the changes seen in apoptotic cells and lead eventually to cell death.

FIGURE 50.21 The molecular basis of apoptosis in the nematode, *C. elegans*. (A) In the absence of a death signal, no apoptosis occurs. **(B)** In the presence of a death signal, activation of CED-4 and CED-3 proteins triggers a pathway that leads to death of the cell.

mals that have been studied. Genetic studies have demonstrated their importance in development. For instance, worms deficient in CED-4 have 15% more cells than normal worms, yet they are viable. However, mice with deletions of their *ced-4* homologs late in embryonic development exhibit severe head and face anomalies and brain overgrowth. Mice with deletions of their *ced-3* homologs die around birth due to massive cell overgrowth in their nervous systems.

Let us consider the example of the role of apoptosis in the formation of digits in tetrapods in a little more detail. Some tetrapods, such as humans, mice, and chickens have separated digits, whereas others, such as ducks and a number of other bird species, frogs, bats, and otters, have webbing between digits. In all cases, early development produces a primordial limb with connected digits. The removal or not of the webbing by apoptosis then is under genetic control. Consider the chicken and the duck, which have highly similar feet except for the webbing in the duck. During development of the feet, bone morphogenic proteins (BMPs) are expressed in the tissue between the digits in both birds. BMPs signal the apoptosis events that result in the removal of the tissue between the digits, and those events produce the separated digits we see in the chicken. In the development of the duck foot, however, a protein called Gremlin is expressed in the tissue between the digits that inhibits the action of the BMPs. As a result, the duck has webbed feet. We can interpret these molecular data to mean that the evolution of web-footed birds likely involved the inhibition of BMP-mediated apoptosis in the tissue between the developing digits. The inhibition of BMP-mediated apoptosis by Gremlin is also involved in the development of the wing of the bat; the wing is webbing between the digits of the forefeet.

Recent research is showing that miRNAs are involved in apoptosis and, in fact, may be critical for its regulation in a number of developing tissues. For instance, in the frog, *Xenopus,* a particular miRNA is expressed during eye development in the neural layer of the retina and is required for correct formation of the eye structure. Inhibition of that miRNA results in a reduction in eye size, and that reduction occurs because of a significant increase in apoptosis in the retina. Research has shown that the miRNA involved negatively regulates the *ced-4* homolog, confirming its direct role in the regulation of apoptosis during normal development.

THINK OUTSIDE THE BOOK

Use the Internet or research literature to outline evidence associating an increase in the level of N-cadherin with breast cancer.

UNANSWERED QUESTIONS

How do cells that comprise animals know what sex an animal should be as it grows up?

This should be an easy question to answer, because we know that in mammals it is the presence of the Y chromosome (containing the gene *SRY* discussed earlier in this chapter) that determines the development of testes in males. Testes then secrete testosterone and anti-Müllerian hormone (AMH), which stimulate Wolffian duct development and Müllerian duct regression. In females, ovaries develop because of the absence of SRY protein and the Müllerian ducts form. Steroid hormones secreted from the gonads then act to differentiate other tissues, including the brain. However, in nature there are many reports of animals that are gynandromorphic; that is, they have both female and male characteristics. These animals can be either bilaterally symmetrical or mosaics (containing a mix of male and female cells). Gynandromorphs have been seen in chickens, song birds, blue crabs, spiders, and insects, including butterflies and carpenter bees, as well as others. Some gynandromorphs that have been well studied include a song bird, the gynandromorphic Australian zebra finch, which had a testis and male plumage on the right side of the body and an ovary and female plumage on the left side of the body. Avian sex determination is chromosomal, and birds have a *ZW* sex-determination system that is reversed compared to the mammalian *XY* system. Female birds have heterogametic chromosomes *(ZW)* and males have homogametic chromosomes *(ZZ),* and the sex-determining gene in birds is the *Z*-linked DMRT1 gene. The gynandromorphic zebra finch was studied by Dr. Arthur P. Arnold at the University of California, Los Angeles, where he and a team of researchers determined that the right side of the brain of the bird contained no *W* sex chromosomes while the left side contained both *Z* and *W* chromosomes. The fact that these animals develop naturally indicates that there are still many unanswered questions about sexual differentiation. What is not yet known is if the sex imposed on a developing cell comes entirely from hormonal signals originating from the outside of the cell, or if there are also signals coming from within the cells from the cell's own genome. Also, in vertebrates, how do sex chromosomes, acting on individual cells, play a role in the differences that develop between male and female tissues, including the brain?

What initiates childbirth?

You learned in this chapter that a series of hormonal and physical events are associated with childbirth. There is an increase in the secretion of oxytocin from the posterior pituitary gland and oxytocin receptors are found in the smooth muscle cells of the uterine wall. Oxytocin stimulates the muscle to begin the rhythmic contractions of labor marking the beginning of birth or parturition. This process has been well studied, but the initiation of labor is a complex process that has yet to be fully explained. What fetal-derived signals lead to the initiation of labor? How do these signals play a role in preterm labor? What roles do signals, such as prostaglandins, from the placenta play in regulating the timing of birth? What roles do the fetal hypothalamus and adrenal glands play in initiating childbirth? What roles do hormones, such as estradiol from the mother, or cortisol and corticotropin-releasing factor from the fetus, play in sending the signals to begin the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

process of parturition? One researcher who is making strides in this area is Louis J. Muglia M.D., Ph.D., from Washington University School of Medicine in St. Louis, Missouri. Dr. Muglia has been researching the timing of birth and the challenges to prevent premature births. His research has demonstrated that prostaglandins are essential for the initiation of parturition, and he has determined that the regulation of COX-1 is important for the initiation of parturition in mice. COX-1 (cyclooxygenase-1) is a protein that acts as an enzyme to speed up the production of prostaglandins in the stomach and the expression of the *COX-1* gene increases in the uterus during pregnancy. Identifying regulatory factors, such as COX-1, may provide critical information into timing the onset of parturition.

THINK LIKE A SCIENTIST Based on the first unanswered question, do you think there are mammals that are gynandromophs? Does your answer to this question alter the significance of the research?

Courtesy of Laura Caruth

Laura Carruth, an assistant professor of biology at Georgia State University, studies the genetic and hormonal factors that lead to sex differences in brain development. Her work focuses on model systems in songbirds (the Australian zebra finch) and mice. To learn more about Dr. Carruth's research, go to http://www2.gsu.edu/~wwwllc/.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

50.1 Mechanisms of Embryonic Development

- Developmental information is stored in both the nucleus and cytoplasm of the fertilized egg. The mRNA and protein molecules that direct the first stages of development are the cytoplasmic determinants.
- The unequal distribution of yolk and other components makes eggs polar. The animal pole typically gives rise to surface structures and the anterior end of the embryo, whereas the vegetal pole typically gives rise to internal structures of the embryo such as the gut (Figure 50.2).
- Following fertilization, cleavage divisions produce the morula. The morula hollows out to form the blastula, which develops into the gastrula, the stage in which rearrangements of cells produce the ectoderm, mesoderm, and endoderm. Gastrulation establishes the body pattern, in that the organs and other structures of embryo arise from these three tissue layers (Figure 50.3; Table 50.1).
- Development proceeds as a result of cell division, cell movements, selective adhesions, induction, determination, and differentiation.

Animation: Body Planes

Animation: Leopard frog life cycle

50.2 Major Patterns of Cleavage and Gastrulation

- In sea urchin eggs, yolk is distributed evenly. As a result, cleavage divisions take place at the same rate in all regions of the embryo, and gastrulation follows a symmetrical pattern (Figure 50.4).
- In amphibian eggs, yolk is distributed unequally, with most in the vegetal pole. As a result, the rate of cell division is more rapid in the animal pole, and gastrulation shows an asymmetrical pattern (Figures 50.5 and 50.6).
- In bird and reptile embryos, the cleavage divisions give rise to a flat disc of cells at the top of the yolk, which divides into the epiblast and the hypoblast. In gastrulation, cells of the epiblast migrate to the interior to form the endoderm and the mesoderm. The epiblast cells left at the surface form the ectoderm (Figure 50.7).
- In birds and reptiles, the yolk sac, chorion, amnion, and allantoic membrane form from extensions of the primary tissue layers. These extraembryonic membranes conduct nutrients from the yolk to the embryo, exchange gases with the environment, and store metabolic wastes (Figure 50.8).

Animation: Process of gastrulation

Animation: Structure of the placenta

50.3 From Gastrulation to Adult Body Structures: Organogenesis

- In organogenesis, the three primary tissues give rise to the tissues and organs of the embryo. Organogenesis begins with neurulation, the development of the nervous system from ectoderm (Figures 50.9 and 50.10).
- The mesoderm splits into somites, which give rise to the vertebral column and to the muscles of the ribs, vertebral column, and limbs (Figure 50.10).
- Development of the eye from optic vesicles is illustrative of the inductions and differentiations common to organogenesis in vertebrates (Figure 50.11).

50.4 Embryonic Development of Humans and Other Mammals

- In humans, as in other placental mammals, cleavage divisions produce a morula that differentiates into a blastocyst. The blastocyst implants into the endometrium of the uterus, and its inner cell mass separates into the epiblast and hypoblast. The epiblast produces the ectoderm, mesoderm, and endoderm of the embryo (Figures 50.12 and 50.13, steps 1–2).
- Gastrulation, neurulation, differentiation of cell layers, and formation of extraembryonic membranes occur by mechanisms similar to those of bird and reptile embryos. Differentiation of ectoderm, mesoderm, and endoderm into their final tissues and organs is also similar in birds and reptiles.
- Extraembryonic membranes form in mammals by processes that are also similar to the reptilian–bird pattern. However, some of the membranes have altered functions, reflecting the minimal amount of yolk in mammalian embryos, and maintenance of the embryo by the placenta (Figure 50.13, steps 3–5).
- The placenta is connected to the embryo by the umbilical cord, which conducts blood between the embryo and the placenta (Figure 50.13, step 6).
- Fetal growth proceeds until birth, when the fetus is forced from the uterine cavity and through the vagina by contractions of the uterus, stimulated by oxytocin (Figures 50.14 and 50.15).
- The mother's mammary glands secrete milk once the offspring is born. Suckling by the offspring stimulates prolactin and oxytocin release from the pituitary, which stimulates milk production and secretion from the glands, respectively.

- Embryos develop internal male or female sex organs from the same primitive structures. The presence or absence of a Y chromosome, which carries the key *SRY* gene, determines whether the internal structures develop into male or female sexual organs (Figure 50.16).
- Most animals continue development after hatching or birth, leading to the adult, the sexually mature form of the species.

Animation: Cleavage and implantation

Animation: Female reproductive system

50.5 The Cellular Basis of Development

- Development in animals involves the regulation of specific cellular events, including cell division, cell migration, and cell adhesion.
- Cell division in development varies in orientation and rate.
- Cell movements in development occur through changes in cell shape or the migrations of entire cells. Shape changes are produced by microtubules or microfilaments. Cell migrations involve the activity of microtubules and microfilaments and large-scale reorganization of the cytoskeleton. The four stages of cell migration are polarization, protrusion of the front end of the cell, adhesion, and then release of adhesion at the rear of the cell and forward migration to a new adhesion point. In many developmental systems, migrating cells follow tracks formed by molecules of the extracellular matrix (Figure 50.17).
- Selective cell adhesions, which depend on surface glycoproteins including CAMs and cadherins, underlie many cell movements. The final cell adhesions hold the embryo in its correct shape and form (Figure 50.18).
- For some organisms, the origins of adult or larval structures have been mapped to regions of the embryo from which each structure derived (Figure 50.19).
- Induction results from the effects of signaling molecules of the inducing cells on the responder cells that are nearby the inducer cells. To change its cellular behavior, the responder cell must have a receptor for the inducer molecule and it must be competent to respond (Figure 50.20).
- In differentiation, cells change from embryonic form to specialized types with distinct structures and functions. Differentiation occurs by differential gene activation.
- Apoptosis—a type of programmed cell death—plays an important role in normal development by removing tissues present during development but not in the adult tissue or organ (Figure 50.21).

Test Your Knowledge

1. Major contributors to the axes of the animal body are the:
   a. sperm and egg cytoplasm.
   b. sperm and egg chromosomes.
   c. ribosomes and mitochondria.
   d. egg nucleus and yolk.
   e. pigments.
2. The process by which cells undergo mitosis without a corresponding increase in cytoplasm is called:
   a. polarity.
   b. cleavage.
   c. gastrulation.
   d. organogenesis.
   e. induction.
3. Which of the following mechanisms does *not* contribute to zygote development?
   a. meiosis
   b. mitosis
   c. selective cell adhesions
   d. determination
   e. induction
4. A major event during gastrulation is:
   a. the outward movement of cells at the dorsal lip of the blastopore.
   b. the displacement of the archenteron by the blastocoel.
   c. the formation of the coelom from the endoderm.
   d. the extension of ectoderm and endoderm to form the yolk sac.
   e. the development of ectoderm to form epidermal and neural tissues.
5. The presence of the gray crescent in a frog embryo:
   a. corresponds to the location of the future mouth.
   b. corresponds to the location of sperm entry into the egg.
   c. will cause the formation of a disordered mass of cells.
   d. contains concentrated amounts of darkly colored pigment granules from the animal pole.
   e. indicates that the egg has been fertilized.
6. To contribute to the formation of a nervous system:
   a. the neural crest develops into motor neurons.
   b. the neural tube is converted into a neural plate.
   c. the notochord induces the overlying ectoderm to become a neural plate.
   d. the roof of the archenteron induces the formation of the neural tube.
   e. somites give rise to the autonomic nervous system.
7. In mammalian development:
   a. the morula develops into a trophoblast.
   b. the chorionic villi allow the blastocyst to move down the oviduct.
   c. the allantois takes over the work of the amnion.
   d. the pharyngeal arches transform into the pharynx, larynx, and nasal cavities.
   e. prolactin stimulates parturition.
8. In the development of the female sex organs:
   a. all ducts in the 7-week embryo become Wolffian ducts.
   b. the *SRY* gene is activated.
   c. anti-Müllerian hormone is secreted.
   d. the Müllerian ducts develop into oviducts.
   e. the mother secretes oxytocin.
9. In the embryonic development of the eye:
   a. the optic vesicle cells permanently adhere to each other to prevent movement, whereas the optic cup cells are very motile.
   b. signals from the optic cup trigger surface receptors on the lens placode.
   c. gradients determine that the ectoderm overlying the lens vesicle develops into the optic vesicle.
   d. microtubules powered by myosins and microfilaments powered by dyneins move the eye components around in the head region.
   e. cadherins function in the presence of calcium to allow the lens placode and optic cup to break apart.

10. Which of the following statements about development is incorrect?
    a. As microtubules lengthen and slide apart, the shape of cells within the ectoderm changes.
    b. The extracellular matrix molecule fibronectin guides the movement of cells during development.
    c. The furrow formed during mitosis of cells in the developing embryo is centrally located to ensure all cells divide symmetrically.
    d. Cell surface cadherins regulate the ability of developing cells to adhere to one another.
    e. Integrins are responsible for transmitting information from the extracellular matrix to the cytoskeleton.

Discuss the Concepts

1. Experimentally, it is possible to divide an amphibian egg so that the gray crescent is wholly within one of the two cells formed. If the two cells are separated, only the cell with the gray crescent will form an embryo with a long axis, notochord, nerve cord, and back musculature. The other forms a shapeless mass of immature gut and blood cells. Propose an explanation of these outcomes.
2. Developmental biologist Lewis Wolpert once observed that "it is not birth, marriage or death, but gastrulation which is truly the most important time in your life." In what sense is he correct?
3. Arguably, in sexually reproducing animals, development begins when eggs and sperm form in the parents. In a paragraph, explain the rationale for this idea.
4. Investigators discovered a *Drosophila* protein that triggers development of the nerve cord on the ventral side of the embryos. When an mRNA encoding the protein was injected into cells on the ventral side of *Xenopus* embryos, dorsal structures were formed on the ventral side, including incomplete heads. What do these findings suggest about the evolution of embryonic development?

Design an Experiment

You learned in this chapter about the molecular basis of apoptosis in the nematode worm, *C. elegans*. In humans, the *BCL2* gene is a homolog of the worm *ced-9* gene. What experiment would convince you that the human BCL2 protein is functional homologous to the worm CED-9 protein?

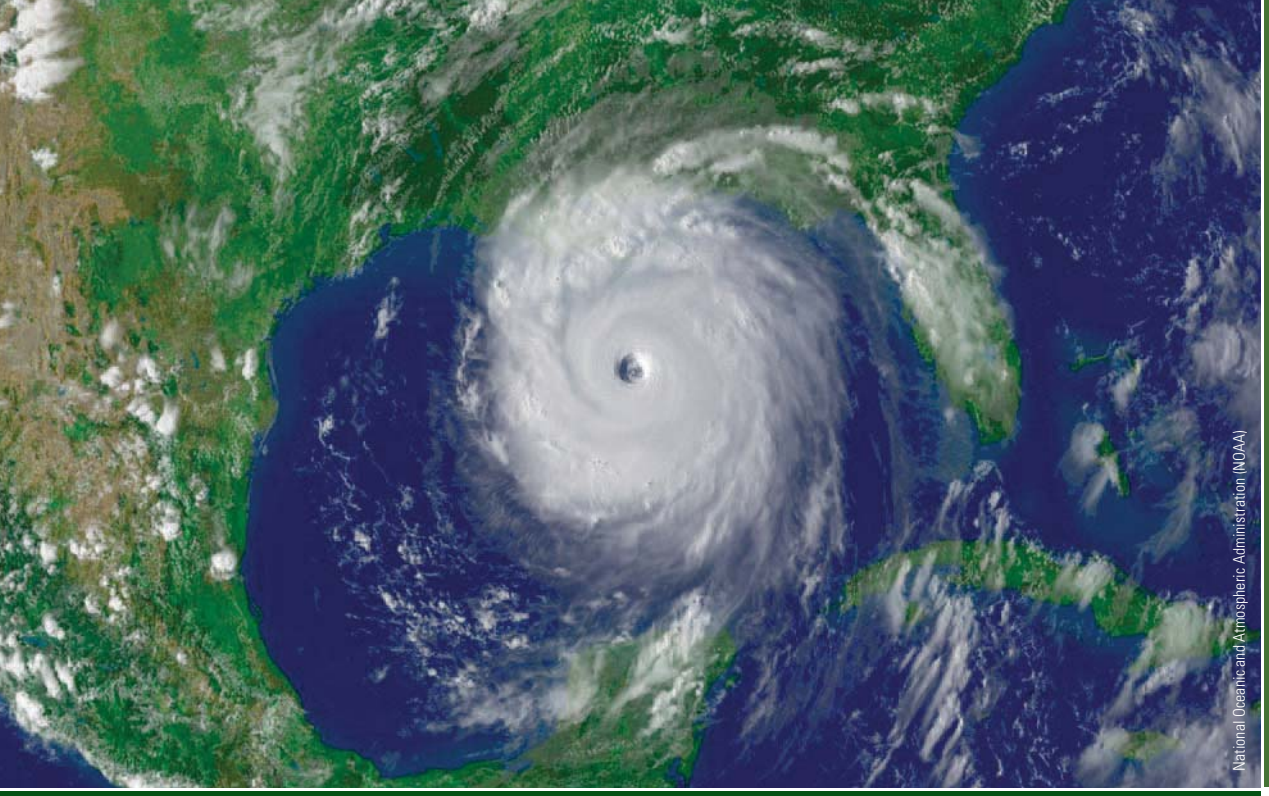
Interpret the Data

People considering fertility treatments should be aware that such treatments raise the risk of multiple births and that multiple pregnancies are associated with an increased risk of some birth defects. The **Table** shows the results of Yiwei Tang's study of birth defects reported in Florida from 1996 to 2000. Tang compared the incidence of various defects among single and multiple births. She calculated the relative risk for each type of defect based on type of birth, and corrected for other differences that might increase risk: maternal age, income, race, previous adverse pregnancy experience, education, Medicaid participation during pregnancy, and the infant's sex and number of siblings. A relative risk of less than 1 means a defect occurs less often with multiple births than single births. A relative risk of greater than 1 means that multiples are more likely to have a defect.

Prevalence, per 10,000 Live Births, of Various Types of Birth Defects among Multiple and Single Births

	Prevalence of defect		Relative
	Multiples	Singles	Risk
Total birth defects	358.50	250.54	1.46
Central nervous system defects	40.75	18.89	2.23
Chromosomal defects	15.15	14.20	0.93
Gastrointestinal defects	28.13	23.44	1.37
Genital/urinary defects	72.85	58.16	1.31
Heart defects	189.71	113.89	1.65
Musculoskeletal defects	20.92	25.87	0.92
Fetal alcohol syndrome	4.33	3.63	1.03
Oral defects	19.84	15.48	1.29

© Cengage Learning 2014



1. What was the most common type of birth defect in the single-birth group?
2. Was that defect more or less common in the multiple-birth group than among single births?
3. Tang found that multiples have more than twice the risk of single newborns for one type of defect. Which type?
4. Does a multiple pregnancy increase the relative risk of chromosomal defects in offspring?

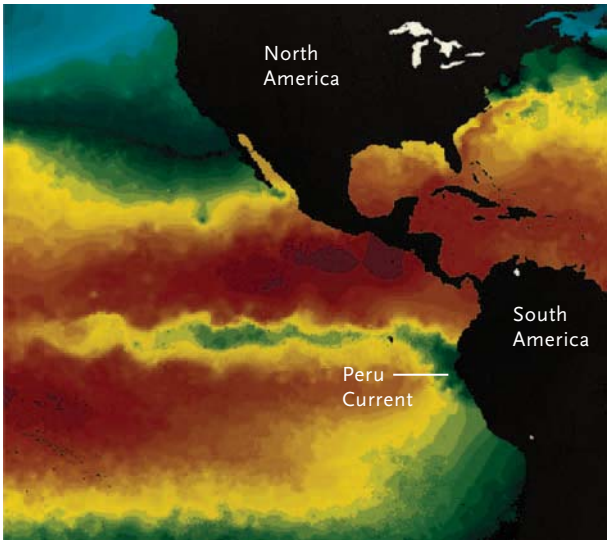
Ecology and the Biosphere

STUDY OUTLINE

51.1 The Science of Ecology
51.2 Environmental Diversity of the Biosphere
51.3 Organismal Responses to Environmental Variation and Climate Change
51.4 Terrestrial Biomes
51.5 Freshwater Environments
51.6 Marine Environments

Why it matters . . . The winter of 1997 to 1998 was one for the books. Record rainfall caused mudslides in California and flooding along the normally arid coast of Ecuador and Peru. But the annual rains never arrived in Asia and Australia, and fires consumed tropical rainforests in Indonesia and Malaysia. What caused these major climatic dislocations? Every 3 to 7 years, interactions between the upper layers of the Pacific Ocean and the atmosphere produce El Niño, a climatic event with global consequences **(Figure 51.1).** The 1997 to 1998 El Niño altered weather patterns worldwide, killing more than 2,000 people and causing at least $30 billion in property damage.

In most years, air flows from a high pressure system over the eastern Pacific toward a low pressure system over the western Pacific. These winds move surface water from east to west and bring heavy rains to parts of Asia and Australia. Winds also usually blow from the poles toward the equator along the western sides of continents, and Earth's rotation causes these winds to push ocean surface water westward, away from the coast. The displaced surface water is replaced by cold, deep, nutrient-rich water carried by vertical currents called *upwellings* (Figure 51.1A). The nutrients support complex marine food webs in the shallow water above the continental shelf. For example, the Peru Current along the west coast of South America once supported a rich anchovy fishery.



Ocean currents vary seasonally, however, and in late December or early January, a warm, nutrient-poor current flows eastward along the equator and then north and south along the coastlines of Central and South America. Peruvian fishermen call this warm current El Niño (Spanish for "the child"), because it reaches their coast around Christmas. It usually persists for only a few weeks.

In strong El Niño years, however, atmospheric pressure systems change over the Pacific, altering the prevailing winds and ocean currents. Equatorial winds weaken; surface currents reverse direction, flowing from west to east; and a huge pool of warm ocean water accumulates in

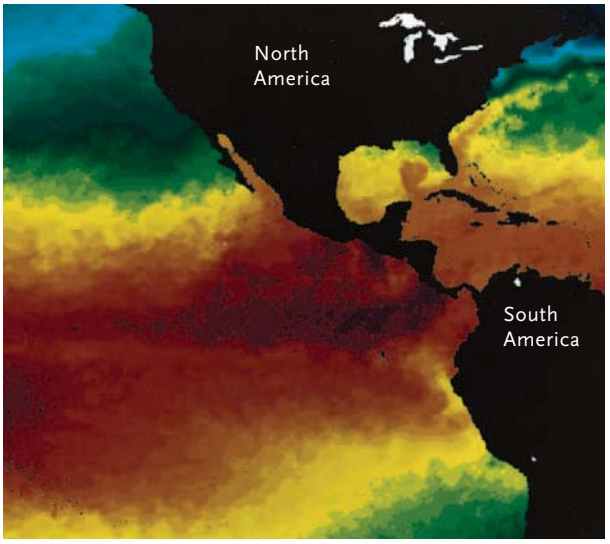

FIGURE 51.1
El Niño and Pacific Ocean currents.

A. Usual pattern of Pacific Ocean currents

In most years, the powerful Peru Current carries cold water from the ocean bottom to the surface off the west coast of South America. The cold surface water then flows westward along the equator toward a large pool of warm water in the western Pacific Ocean. In this satellite photo taken on May 31, 1988, dark red indicates the warmest water and dark green the coldest upwelled water.

B. Pacific Ocean currents in an El Niño year

NASA

During an El Niño event, equatorial winds reverse directions and warm surface water flows eastward along the equator from the western Pacific Ocean toward South America. In this satellite photo taken on May 13, 1992, the warm water (orange) reached the west coast of South America, suppressing the upwelling of cold water by the Peru Current.

the eastern Pacific. During these shifts, the heavy rain that usually falls on Asia and Australia is instead delivered to the central and eastern Pacific. Thus, in strong El Niño years, Asia and Australia receive less rain than usual, and the west coasts of the Americas receive more. In the United States, winter temperatures are unusually high in the north central states and unusually low in the southern states.

El Niño episodes also alter sea surface temperature. When the warm current flowing from west to east reaches the continental shelf, it displaces the cold water of the Peru Current and prevents the usual upwelling (Figure 51.1B). These changes in ocean currents have catastrophic effects on marine life. Lacking sufficient nutrients, phytoplankton (that is, tiny floating photosynthetic organisms) die, followed by fishes that eat phytoplankton, and seabirds that eat fishes. In combination with overfishing, the El Niño of 1972 drove the Peruvian anchovy population to the brink of extinction.

Some El Niño years are followed by a weather pattern called La Niña: the low pressure system over the western Pacific is accentuated, pulling air and ocean surface water from east to west. Low ocean surface temperatures extend from the coast of South America to Samoa. La Niña's effect on winter weather is opposite that of El Niño: parts of Asia and Australia are unusually wet; the northern United States experiences periods of cold, wet weather, whereas the southern region is unusually warm and dry.

El Niño and La Niña are two extremes of a global climate cycle called the El Niño Southern Oscillation, or ENSO (the name refers to fluctuations in air pressure over the tropical Pacific). ENSO, a product of large-scale interactions between the ocean and atmosphere, has a major impact on the **biosphere,** which comprises all organisms on Earth and the places where they live.

The devastation induced by severe El Niño and La Niña events introduces our unit on **ecology,** the study of interactions between organisms and their environments. All environments have both **biotic** ("biological") and **abiotic** ("nonbiological") components. The biotic environment includes all the organisms found in a particular place; the abiotic environment includes temperature, moisture, soil chemistry, and other physical factors. In addition to living organisms, the biosphere includes three abiotic components, which surround Earth's geological bulk like a skin. The **hydrosphere** encompasses all the water, including oceans and polar ice caps. The **lithosphere** includes the rocks, sediments, and soils of the crust. Finally, the **atmosphere** includes gases and airborne particles that envelop the planet.

In this chapter, we survey the biosphere with a wide-angle lens. After first describing how ecologists study the relationships between organisms and their environments, we examine Earth's environmental diversity as well as some mechanisms—the products of evolution—that allow organisms to cope with environmental variations in space and time. We then consider how variations in the physical environment influence the large-scale distributions of organisms on land, in fresh water, and in the sea.

51.1 The Science of Ecology

The subject matter of ecology is so vast and so diverse that ecological research is often linked to work in genetics, physiology, anatomy, behavior, paleontology, and evolution as well as

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

geology, geography, and environmental science. The connections between research in ecology and evolution are especially strong, because organisms exhibit evolutionary responses to their ecological relationships, and because ecological relationships change as organisms evolve. Moreover, many ecological phenomena occur over huge areas and long time spans. Thus, ecologists must devise clever ways to determine how environments influence organisms, how organisms respond to environmental factors, and how organisms change the environments in which they live.

Today, the science of ecology encompasses two related disciplines. The major research questions of *basic ecology* relate to the distribution and abundance of species and how they interact with each other and with the physical environment. Using these data as a baseline, workers in *applied ecology* develop conservation plans and amelioration programs to limit, repair, and mitigate ecological damage caused by human activities. Research in applied ecology overlaps to some extent with that in environmental science, but the latter discipline also encompasses perspectives from the social sciences, such as economics and political science.

Ecologists Study Levels of Organization Ranging from Individual Organisms to the Biosphere

Ecology can be divided into five increasingly complex and inclusive levels of organization. In **organismal ecology,** researchers study the genetic, biochemical, physiological, morphological, and behavioral adaptations of organisms to the abiotic environment. We have described many such adaptations in Units V and VI; we describe the evolution of animal behavior in Chapter 56.

Population ecology, the subject of Chapter 52, focuses on **populations,** groups of individuals of the same species that live together. Population ecologists study how the size and other characteristics of populations change in space and time. Research in **community ecology,** discussed in Chapter 53, examines groups of populations that occur together in one area. Community ecologists study interactions between species, analyzing how predation, competition, and environmental disturbances influence a community's development, organization, and structure. Ecologists studying **ecosystem ecology,** considered in Chapter 54, explore the cycling of nutrients and the flow of energy between the biotic components of an ecological community and the abiotic environment. Finally, the largest-scale ecological studies focus on the biosphere, which we consider in this chapter. We discuss biodiversity and conservation biology in Chapter 55.

Ecologists Test Hypotheses with Observational and Experimental Data

Ecology has its roots in descriptive natural-history studies that date back to the ancient Greeks. Modern ecology was born in 1870 when the German biologist Ernst Haeckel coined the term *Oekologie* (*oikos* = house). Contemporary researchers still gather descriptive information about ecological relationships; these observations often provide the background for more analytical studies.

Most ecologists create hypotheses about ecological relationships and how they change through time or differ from place to place. Like other scientists, some ecologists formalize these ideas in mathematical models that express clearly defined, but hypothetical, relationships among important variables in a system. Manipulation of a model, usually with the help of a computer, can allow researchers to ask what would happen if some of the variables or their relationships change. Thus, researchers can simulate natural events and large-scale experiments before investing time, energy, and money in field and laboratory work. Bear in mind, however, that mathematical models are no better than the ideas and assumptions they embody, and useful models are constructed only after basic observations define the relevant variables.

Ecologists often conduct field or laboratory studies to test the predictions of their hypotheses. In controlled experiments, researchers compare data from an experimental treatment (in which one or more variables are artificially manipulated) with data from a control (in which nothing is changed). Sometimes the distributions of species create "natural experiments," eliminating the need to manipulate variables. Studies of how islands of different sizes harbor different numbers of bird species (described in Section 53.7) provide an example of a natural experiment.

STUDY BREAK 51.1

1. **Why are studies of ecosystems more "inclusive" than studies of populations?**
2. **In what ways are mathematical models useful in ecological research?**

51.2 Environmental Diversity of the Biosphere

Numerous abiotic factors—sunlight, temperature, humidity, wind speed, cloud cover, and rainfall—contribute to a region's **climate,** the weather conditions prevailing over an extended period of time. Climates vary on global, regional, and local scales, and they undergo seasonal changes almost everywhere. As you will discover as you read this chapter, variations in climate over space and time influence the lives of all organisms.

Variations in Incoming Solar Radiation Create Global Climate Patterns

A global pattern of environmental diversity results from latitudinal variation in incoming solar radiation, Earth's rotation on its axis, and its orbit around the sun.

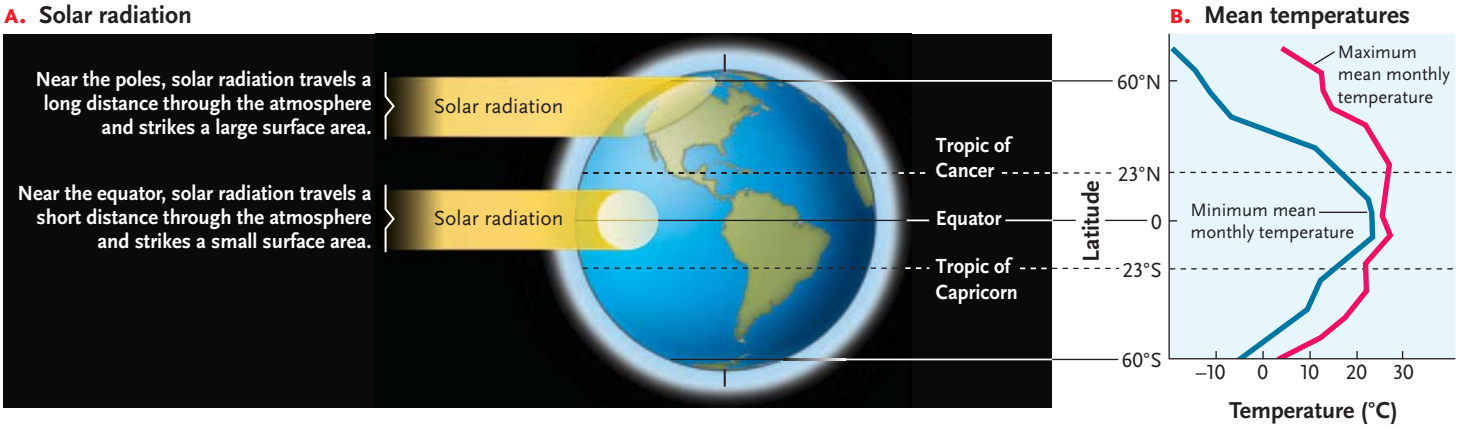

FIGURE 51.2 **Latitudinal variation in solar radiation and temperature.** **(A)** Solar radiation is more intense near the equator than near the poles. **(B)** Minimum and maximum mean monthly temperatures—as well as the range of mean monthly temperatures—vary with latitude.

© Cengage Learning 2014

SOLAR RADIATION Earth's spherical shape causes the intensity of incoming solar radiation to vary from the equator to the poles **(Figure 51.2).** When sunlight strikes Earth directly at a 90° angle, as it does near the equator, it travels the shortest possible distance through the radiation-absorbing atmosphere and falls on the smallest possible surface area (Figure 51.2A). When sunlight arrives at an oblique angle, as it does near the poles, it travels a longer distance through the atmosphere and shines on a larger area. Thus, solar radiation is more concentrated near the equator than it is at higher latitudes, causing latitudinal variation in temperature (Figure 51.2B).

SEASONALITY Earth is tilted on its axis at a fixed position of 23.5° from the perpendicular to the plane on which it orbits the sun **(Figure 51.3).** This tilt produces seasonal variation in the duration and intensity of incoming solar radiation. The Northern Hemisphere receives its maximum illumination—and the Southern Hemisphere its minimum—on the June solstice (around June 22), when the sun shines directly over the Tropic of Cancer (23.5° N latitude). The reverse is true on the December solstice (around December 22), when the sun shines directly over the Tropic of Capricorn (23.5° S latitude). Twice each year, on the vernal and autumnal equinoxes (around March 21 and September 23, respectively), the sun shines directly over the equator.

Earth's tilt is permanent, and only the **tropics**—the latitudes between the Tropics of Cancer and Capricorn—ever receive solar radiation from directly overhead. Tropical regions experience only small seasonal changes in temperature and day length: environmental temperature is high, and days last approximately 12 hours throughout the year. (Tropical seasonality is reflected in the alternation of wet and dry periods rather than warm and cold seasons.) Seasonal variation in temperature and day length increases steadily toward the poles. Polar winters are long and cold with periods of continuous darkness, and polar summers are short with periods of continuous light.

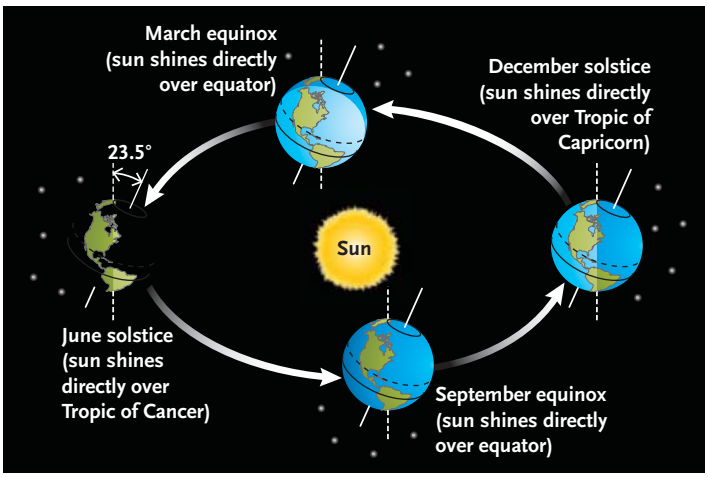

FIGURE 51.3 **Seasonal variation in solar radiation.** Earth's fixed tilt on its axis causes the Northern Hemisphere to receive more sunlight in June and the Southern Hemisphere to receive more in December. These differences are reflected in seasonal variations in day length and temperature, which are more pronounced at the poles than at the equator.

© Cengage Learning 2014

AIR CIRCULATION Sunlight warms air masses, causing them to expand, lose pressure, and rise in the atmosphere. The unequal heating of air at different latitudes initiates global air movements, producing three circulation cells in each hemisphere **(Figure 51.4).** Warm equatorial air masses rise to high altitude before spreading north and south. They eventually sink back to Earth at about 30° N and S latitude. At low altitude, some air masses flow back toward the equator, completing low-latitude circulation cells. Others flow toward the poles, rise at 60° latitude, and divide at high altitude. Some air flows toward the equator, completing the pair of middle-latitude circulation cells. The rest moves toward the poles, where it descends and flows toward the equator, forming the polar circulation cells.

The flow of air masses at low altitude creates winds near the planet's surface. But the surface rotates beneath the atmosphere, moving rapidly near the equator, where Earth's diameter is greatest, and slowly near the poles. Latitudinal variation in the speed of rotation deflects the movement of the rising and sinking air masses from a strictly north–south path into belts of easterly and westerly winds (see the right side of Figure 51.4);

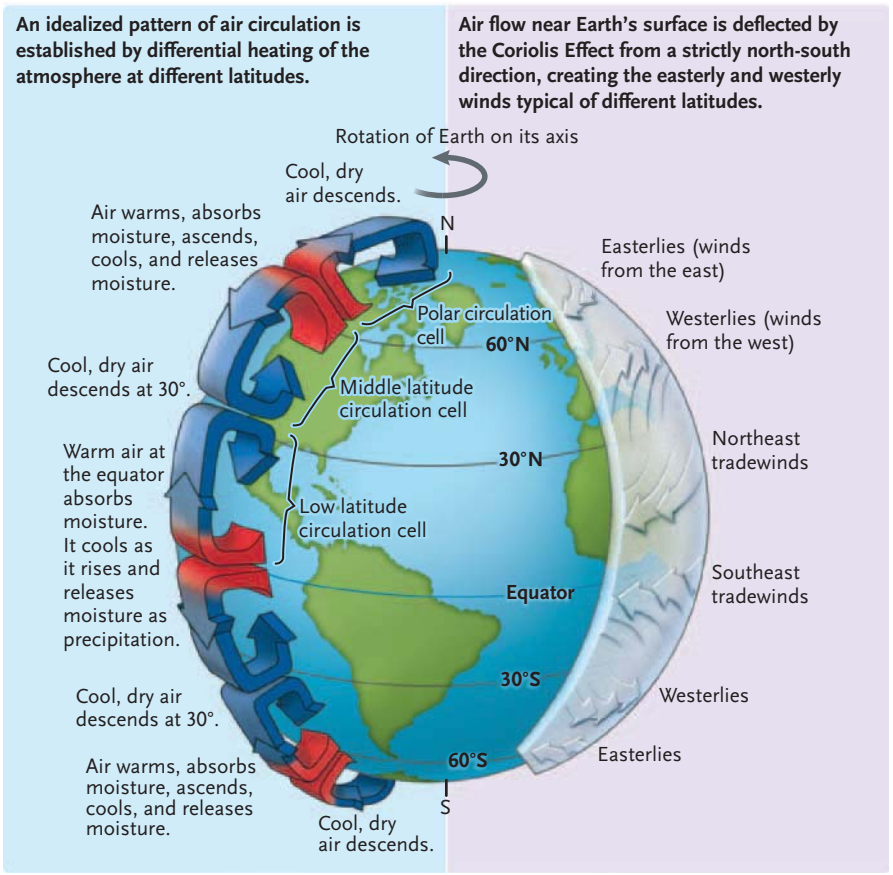

FIGURE 51.4 **Global air circulation.** Latitudinal variations in the intensity of solar radiation cause equatorial air masses to warm and rise, initiating a global pattern of air movement in three circulation cells in each hemisphere. Air masses moving near Earth's surface are deflected from a strictly north–south flow by the planet's rotation, creating easterly and westerly winds.

© Cengage Learning 2014

this deflection is called the Coriolis Effect. Winds near the equator are called the trade winds; those further from the equator are the temperate (that is, between roughly 23° and 66° latitude) westerlies and easterlies, named for the direction from which they blow.

PRECIPITATION Differences in solar radiation and global air circulation create latitudinal variations in rainfall **(Figure 51.5).** Warm air holds more water vapor than cool air does. As air near the equator heats up, it absorbs water, primarily from the oceans. However, the warm air masses expand as they rise, and their heat energy is distributed over a larger volume, causing their temperature to drop. A decrease in temperature without the actual *loss* of heat energy is called

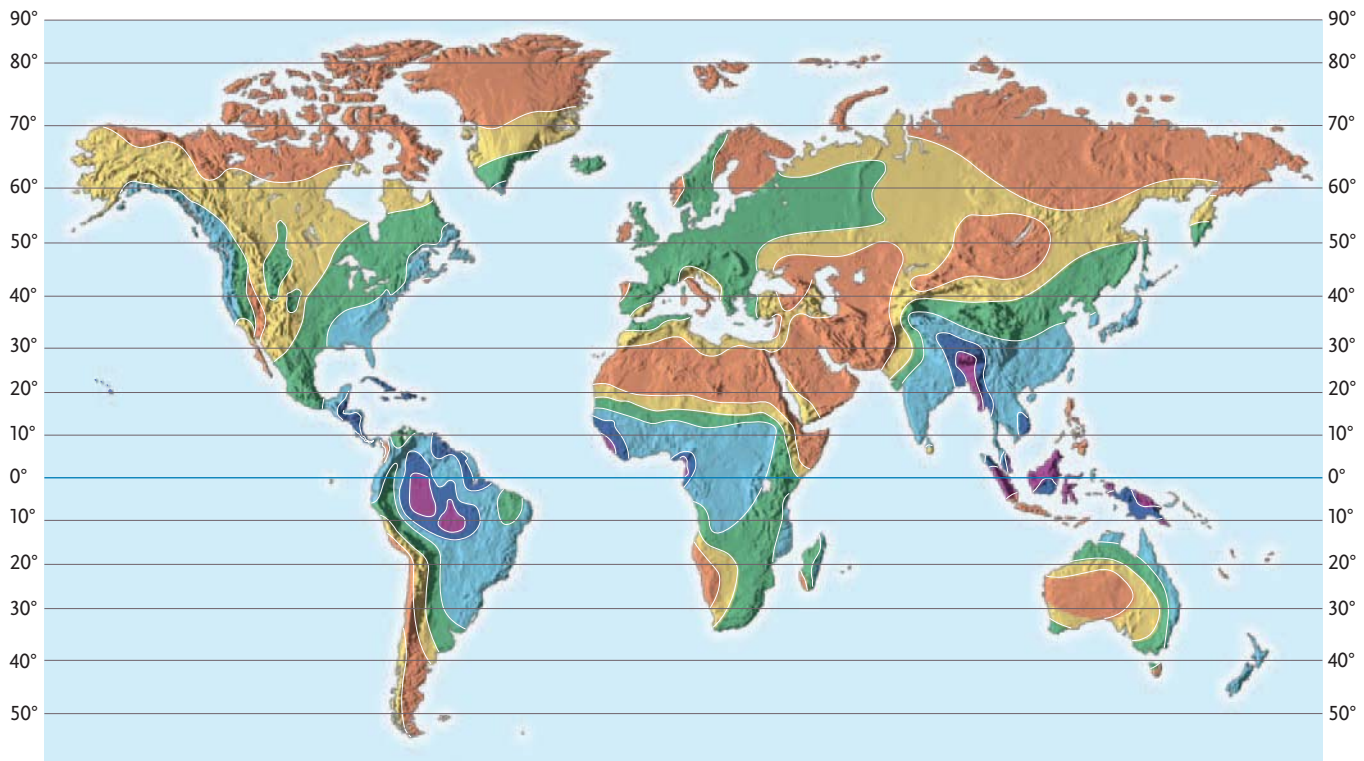

FIGURE 51.5 **Variations in precipitation.** The tropics receive high annual rainfall, whereas regions near 30° latitude are usually dry. Local topographic features and ocean currents also influence precipitation patterns.

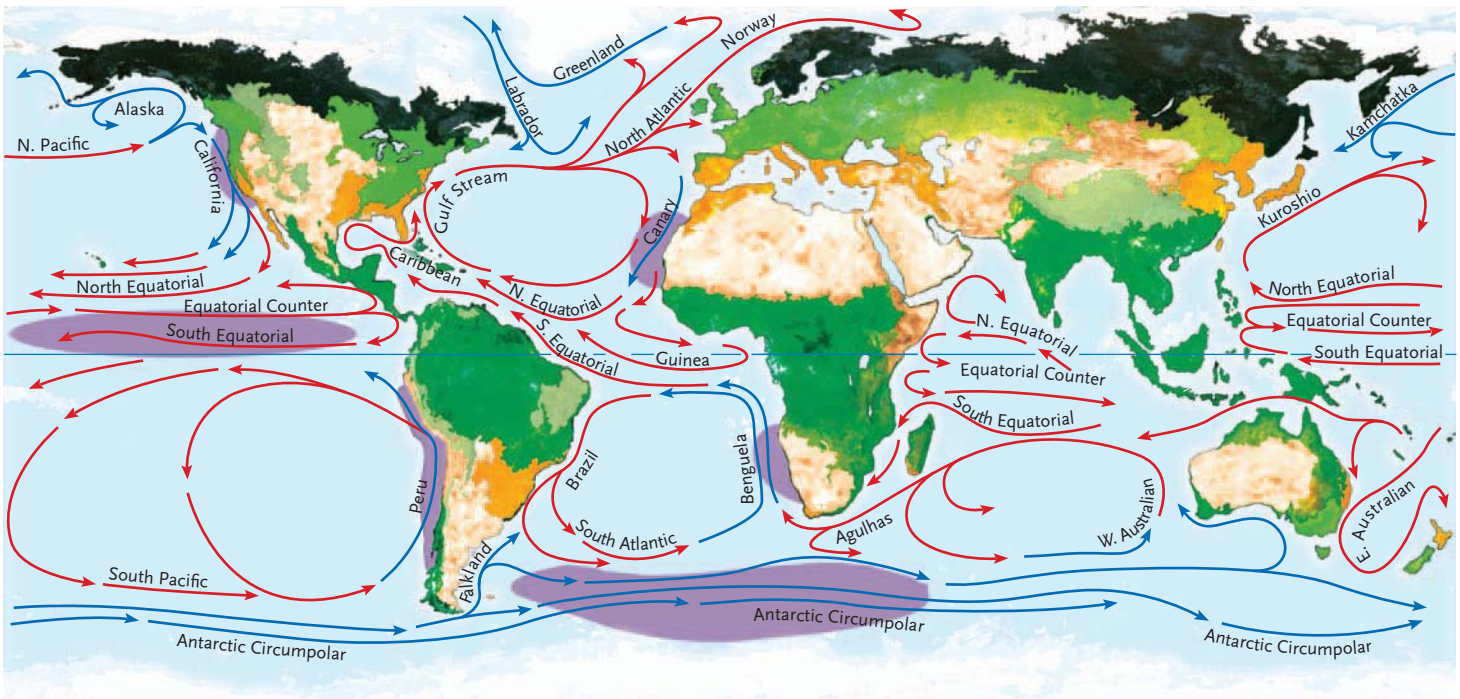
adiabatic cooling. After cooling adiabatically, the rising air masses release moisture as rain (see labels on the left side of Figure 51.4). Torrential rainfall is characteristic of warm equatorial regions, where rising, moisture-laden air masses cool as they reach high altitude.

As cool, dry air masses descend at 30° latitude, increased air pressure at low altitude compresses them, concentrating their heat energy, raising their temperature, and increasing their capacity to hold moisture. The descending air masses absorb water from the land, so these latitudes are typically dry. Some air masses continue moving toward the poles in the lower atmosphere. When they rise at 60° latitude, they cool adiabatically and release precipitation (see Figure 51.4), creating moist habitats in the northern and southern temperate zones.

OCEAN CURRENTS Latitudinal variations in solar radiation also warm the oceans' surface water unevenly. Because the volume of water increases as it warms, sea level is about 8 cm higher at the equator than at the poles. The volume of water associated with this "slope" is enough to cause surface water to move in response to gravity. The trade winds and temperate westerlies also contribute to the mass flow of water at the ocean surface. Thus, surface water flows in the direction of prevailing winds, forming major currents. Earth's rotation, the positions of landmasses, and the shapes of ocean basins also influence their movement.



Oceanic circulation is generally clockwise in the Northern Hemisphere and counterclockwise in the Southern **(Figure 51.6).** The trade winds push surface water toward the equator and westward until it contacts the eastern edge of a continent. Swift, narrow, and deep currents of warm, nutrient-poor water run toward the poles, parallel to the east coasts of continents. For example, the Gulf Stream flows northward along the east coast of North America, carrying warm water toward northwestern Europe. Cold water returns from the poles toward the equator in slow, broad, and shallow currents, such as the Peru Current, that parallel the west coasts of continents.

Regional and Local Effects Overlay Global Climate Patterns

Although global and seasonal patterns determine a site's climate, regional and local effects also influence abiotic conditions.

PROXIMITY TO THE OCEAN Currents running along seacoasts exchange heat with air masses flowing above them, moderating the temperature over nearby land. Breezes often blow from the sea toward the land during the day and in the opposite direction at night **(Figure 51.7).** These local effects sometimes override latitudinal variations in temperature. For example, the climate in London is much milder than that in Minneapolis, even though Minneapolis is slightly further south. Minneapolis has a **continental climate** that is not moderated by the distant ocean, but London has a **maritime climate** that is tempered by winds crossing the nearby North Atlantic Current.

Ocean currents also affect moisture conditions in coastal habitats. For example, air masses absorb water as they move

KEY

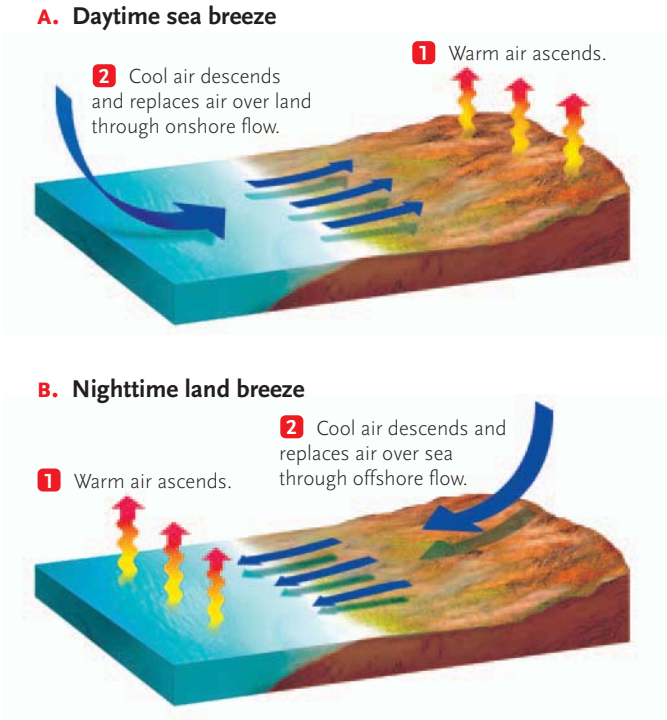

FIGURE 51.7 **Sea breezes and land breezes.** **(A)** On a summer afternoon, when the land is warmer than the adjacent ocean, warm air rises over the land, and a cool sea breeze blows inland from the ocean. **(B)** At night, when the ocean is warmer than the land, the pattern is reversed.

© Cengage Learning 2014

from west to east across the Pacific Ocean. They cool as they cross the cold California Current, and when they reach land in northern California and Oregon during winter, their water vapor condenses into heavy fog and rain. During summer, however, land is warmer than the adjacent ocean. The air masses heat up as they cross the land, and they accumulate water, creating dry conditions.

Some regions experience **monsoon cycles** caused by seasonal reversals of wind direction. In the North American southwest, for example, summer heat causes air masses over land to rise, creating a zone of low pressure. Moist air from the nearby Gulf of California flows inland, where it rises and cools adiabatically, releasing substantial precipitation. Summer monsoon rains deliver one-third to one-half of the annual rainfall in Arizona and New Mexico. During the winter, when land is cooler than the nearby ocean, low-pressure systems form over the ocean, and winds blow from the land to the sea; thus, winters in the southwest are generally dry. Seasonal monsoon cycles also deliver torrential rainfall to parts of Africa, Asia, and South America.

THE EFFECTS OF TOPOGRAPHY Mountains, valleys, and other topographic features also influence regional climates. In the Northern Hemisphere, south-facing slopes are warmer and drier than north-facing slopes because they receive more solar radiation. In addition, adiabatic cooling causes air temperature to decline 3° to 6°C for every 1,000 m increase in altitude.

Mountains also establish regional and local rainfall patterns. For example, after a warm air mass picks up moisture from the Pacific Ocean, it moves inland and reaches the Sierra Nevada, which parallels the California coast. As it rises to cross the mountains, the air cools adiabatically and loses moisture, releasing heavy rainfall on the windward side **(Figure 51.8).** After the now-dry air crosses the peaks, it descends and warms, absorbing moisture and forming a **rain shadow.** Habitats on the leeward side of mountains, such as the Great Basin Desert in western North America, are typically drier than those on the windward side.

MICROCLIMATE Although climate influences the overall distributions of organisms, the abiotic conditions that immediately surround them—the **microclimate**—have the greatest effect on survival and reproduction. For example, a fallen log on the forest floor creates a microclimate in the underlying soil that is shadier, cooler, and moister than surrounding soil exposed to sun and wind. Many animals, including some insects, worms, salamanders, and snakes, occupy these sheltered sites and avoid the effects of prolonged exposure to the elements.

STUDY BREAK 51.2

1. How does Earth's spherical shape influence temperature and air movements at different latitudes?
2. What causes seasonality of the climate in the temperate zone?
3. Why do dry conditions occur at 30° N and S latitude?
4. Briefly describe how mountains influence local precipitation.

Frozen Fish? Not if they have antifreeze proteins

Polar-dwelling fishes, such as winter flounder, Alaskan plaice, and Arctic sculpin, have "antifreeze proteins" that prevent their bodies from freezing into solid ice at the extremely low environmental temperatures they encounter. As ice crystals begin to form within a fish's cells and tissues, the antifreeze proteins bind to the crystals and cover them with a protein coat that prevents further crystal growth and fusion. As a result, the fishes freeze only to an ultrafine slush that allows continued activity, including movement and feeding. The antifreeze proteins are small molecules containing between 30 and 50 amino acids.

Research Question

How do antifreeze proteins bind to ice crystals?

Experiment

Frank Sicheri and D. S. C. Yang at McMaster University in Hamilton, Ontario, and the Bio-Crystallography Laboratory of the VA Medical Center in Pittsburgh, Pennsylvania, sought a molecular answer to the question. They used X-ray crystallography (a technique like X-ray diffraction, described in Section 14.2, but applied to crystals) to work out the molecular structure of the antifreeze protein from the winter flounder *(Pseudopleuronectes americanus)*. They grew protein crystals in a solution at 4°C and then examined them by X-ray crystallography at 4°C and −180°C.

Conclusion

The X-ray crystallography data indicated that the 37 amino acids of the antifreeze protein wind into a single, linear alpha helix (see Section 3.4). Along one side of the helix, side groups of two polar amino acids, threonine and asparagine, extend from the surface at four evenly spaced locations in a flat plane, one at either end of the molecule and two within the helix. Sicheri and Yang propose that these locations, which are spaced 1.65 nm apart, are *ice-binding motifs*. The four motifs would fit nicely to the tips of ridges formed by water molecules on the surface of an ice crystal, which are spaced at intervals of 1.67 nm **(Figure).** Hydrogen bonds between the polar amino acid side groups and water molecules along the ridges would hold the proteins tightly to the surface of the ice crystal. The tight fit would prevent more water molecules from adding to the ice surface and thereby prevent further crystal growth.

Understanding how the fish antifreeze proteins work is not just a fascinating scientific issue. The description and characterization of the antifreeze proteins could lead to medical and industrial applications in situations where procedures and equipment must tolerate freezing conditions. In fact, the U.S. Food and Drug Administration allows the use of an antifreeze protein—originally discovered in an arctic fish, but now produced by genetically engineered yeast—as an ingredient in ice cream to enhance its creamy texture.

THINK LIKE A SCIENTIST Would you expect to find antifreeze proteins in fish species that live in the tropics?

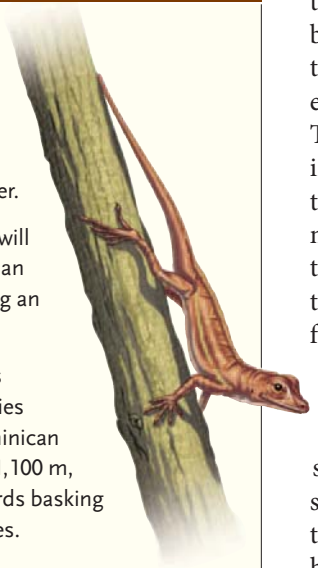
THINK OUTSIDE THE BOOK

Using weather records for your community, characterize the climate in the area where you live. How do seasonal variations in temperature, precipitation, and day length compare to those observed at the poles and at the equator?

51.3 Organismal Responses to Environmental Variation and Climate Change

Daily and seasonal variations in physical factors have profound effects on the biology of individual organisms. Moreover, large-scale variations in environmental conditions, including those caused by global climate change, often influence the distributions of populations.

Organisms Use Homeostatic Responses to Cope with Environmental Variation



Many animals exhibit diverse homeostatic responses—biochemical, behavioral, physiological, and morphological—that enable them to maintain relatively constant conditions within their cells and tissues. Although the ability to use these responses almost certainly has a genetic basis, only some responses to environmental variation are *obligate* (that is, must always be used). *Insights from the Molecular Revolution* describes one such evolutionary response at the biochemical level. Many behavioral and physiological responses are *facultative*. In other words, animals may use them or not, as their immediate conditions demand. Here we provide two brief examples of facultative behavioral and physiological responses to variations in environmental temperature through space and time.

Like many ectothermic animals, lizards often use behaviors to regulate body temperature (see Figure 1.15 and Section 48.6).

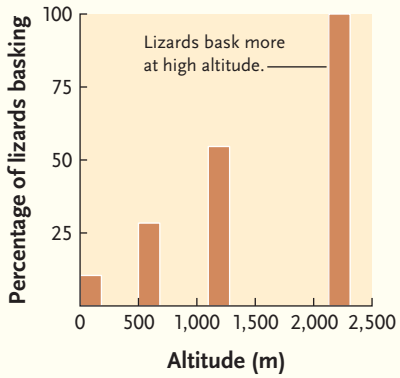
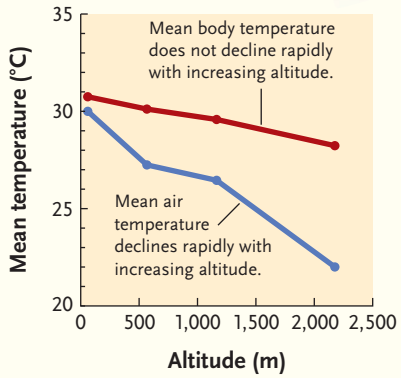
FIGURE 51.9 **Observational Research**



How Do Lizards Compensate for Altitudinal Variation in Environmental Temperature?



Hypothesis: Lizards living at high altitude can use behaviors to compensate for the low environmental temperatures they encounter.

Prediction: The percentage of lizards observed basking in the sun will increase with altitude, and mean air temperatures will vary more than mean lizard body temperatures among study sites distributed along an altitudinal gradient.

Method: Hertz and Huey measured the basking behavior as well as air temperatures and body temperatures of two closely related species of *Anolis* lizards distributed along an altitudinal gradient in the Dominican Republic. They surveyed populations of lizards at sea level, 550 m, 1,100 m, and 2,200 m elevation. They then compared the percentages of lizards basking and the mean air and lizard body temperatures at the four study sites.

Result: The percentage of lizards basking increased steadily with altitude. Mean air temperature differed by as much as 8°C among study sites, but mean body temperature differed by only 2°C.

Conclusion: Lizards living at high altitude bask in patches of sun more frequently, partially compensating for the low environmental temperatures in their habitats.

THINK LIKE A SCIENTIST If global climate change caused air temperatures in the habitats occupied by these lizards to increase, how would you expect the lizards' behavior to change?

Source: P. E. Hertz and R. B. Huey. 1981. Compensation for altitudinal variation in the thermal environment by some *Anolis* lizards on Hispaniola. *Ecology* 62:515–521.

They commonly bask in sunny spots to raise body temperature and seek shaded places to cool off. Many *Anolis* lizard species (see *Focus on Research Organisms* in Chapter 32) are distributed over broad altitudinal ranges, and populations living at high altitude encounter cooler environments than do those at low altitude. While they were graduate students at Harvard University, Paul E. Hertz, now of Barnard College, and Raymond B. Huey, now of the University of Washington, hypothesized that *Anolis* populations living at cool, high altitudes would bask more frequently than those living at warm, low altitudes. Hertz and Huey tested their hypothesis by observing *Anolis cybotes* and its close relative *Anolis shrevei* along an altitudinal gradient in the Dominican Republic **(Figure 51.9).** Their results indicate that basking frequency increases steadily with altitude. Moreover, the body temperatures of the lizards vary much less with altitude than do air temperatures at the same localities. The researchers therefore concluded that increased basking frequency by lizards at high altitude partially compensates for the lower environmental temperatures they encounter.

The state of extreme physiological sluggishness called *torpor* is a facultative response to daily variations in environmental temperature. Endothermic animals use the heat generated by the metabolic breakdown of food to maintain high body temperature (see Section 48.6). However, small endotherms, such as hummingbirds, have a large relative surface area through which they lose body heat. When environmental temperature is low, they may lose heat faster than they can generate it, risking the total depletion of their energy reserves and death by starvation. The problem is particularly acute at night, when hummingbirds cannot feed to replenish their energy stores. F. Reed Hainsworth and Larry Wolf of Syracuse University discovered that the purple-throated carib *(Eulampis jugularis),* a West Indian hummingbird, often becomes torpid at night, lowering its body temperature from 40° to 20°C. Because torpor reduces the temperature difference between their bodies and the environment, torpid birds lose heat less rapidly. At the nighttime environmental temperatures they usually encounter, the torpid hummingbirds may use 80% less energy than they would if they had not entered a temporarily dormant state.

Global Climate Change Affects the Ecology of Many Organisms

As described in Section 54.4, virtually all scientists agree that Earth's atmosphere and oceans are getting steadily warmer. What effect will rapid global climate change have on biological systems? Biologists hypothesize that, on the spatial scale of the biosphere, rising temperatures will affect the geographical distributions of populations, species, and communities. Models of climate change predict that the distributions of polar species will contract to even higher latitudes, the ranges of temperate

and tropical species will expand or shift toward the poles, and lowland species will move to higher elevations. The models also predict that global warming will change the timing of important biological events. For example, plants whose flowering is triggered by warm springtime temperatures will flower earlier in the season; similarly, migratory animals will return from their wintering grounds and begin reproducing earlier in the year.

Camille Parmesan of the University of Texas at Austin and Gary Yohe of Wesleyan University tested these predictions with a massive literature review. They surveyed studies of changes in the geographical distributions and timing of springtime activities in a wide variety of herbaceous plants, trees, invertebrates, and vertebrates over roughly the past century. Their analysis, published in 2003, suggested that the geographical ranges of 99 species of butterflies, birds, and alpine herbs in the Northern Hemisphere have shifted dramatically into habitats that had previously been too cold for them. Some species have expanded their distributions northward an average of 6.1 km per decade. Other species have shifted their distributions to higher altitude, an average of 6.1 m per decade. Their analysis also indicated that for 172 diverse species (including plants, butterflies, amphibians, and birds) springtime growth and reproduction have occurred on average 2.3 days earlier per decade. If these trends continue at the same rate, spring flowering and animal reproduction will occur one full month earlier in the year 2130 than it did in 2000.

A parallel analysis of less detailed data on 677 species of plants and animals suggested that 62% of the species surveyed showed trends toward earlier flowering, breeding, or growth. And for 434 species in which researchers documented a change in geographical distribution, 80% of the shifts were in the direction predicted by climate change models.

Climate warming is also changing the combinations of species that occur together within ecological communities. For example, in a paper published in 2008, Craig Moritz of the University of California, Berkeley, and his colleagues from Berkeley and Colorado State University compared the elevational distributions of small mammals in Yosemite National Park to data compiled a century earlier by naturalist Joseph Grinnell. The minimum temperatures recorded at Yosemite have increased about 3°C over the last century, reflecting the worldwide trend of global warming. The distributions of half of the 28 species they monitored had shifted upward an average of 500 m. Some species that had occupied low elevation sites expanded their ranges to include higher elevations. By contrast, some species that had lived only at middle and high elevation sites no longer live at middle elevations; their distributions are now restricted to higher elevations. As a result of these shifts in species distributions, different combinations of small mammals now occupy middle and high elevation sites in the park, and some species that live at high elevation may face extinction as environmental temperatures continue to rise and other species expand upward into their habitats **(Figure 51.10).**

The effects of global climate change are not restricted to terrestrial environments. Ocean temperatures are also rising, and these changes are reflected in the distributions of marine species. For example, among invertebrates and fishes on the California coast, cold-adapted species have become less abundant and warm-adapted species more abundant. Comparable changes have been noted in other communities from Antarctica to the Arctic.

Dr. Mark Chappell

FIGURE 51.10 Endangered by climate change. The elevational range of the alpine chipmunk *(Tamius alpinus)* has shifted more than 600 m upward in the last 100 years, confining its populations to relatively small areas high in the Sierra Nevada of California.

The geographical distributions of species and ecological communities have often changed with climate shifts over evolutionary time, but the rate of global warming has accelerated in your lifetime. As you will discover as you read Chapters 53 and 54, the factors that govern the structures of communities and ecosystems are complex, and scientists are far from being able to predict all of the consequences of these changes in detail. In the next section, we describe how today's climate affects species and community distributions on a biosphere-wide scale. You can be certain that biology texts in the twenty-second century will paint a very different portrait of these large-scale associations.

51.4 Terrestrial Biomes

In Section 23.3 we described how convergent evolution produces morphological and physiological similarities in species that occupy similar environments. Early in the twentieth century, two American ecologists, Frederic Clements of the Carnegie Institution in Washington and Victor Shelford of the University of Illinois, generalized this observation by defining the **biome** as a vegetation type plus its associated microorganisms, fungi, and animals. Although vegetation is superficially similar throughout a biome, the particular species within it vary from place to place. For example, in eastern North America, the temperate deciduous forest biome includes beech-maple forests in the north and oak-hickory forests in the south. Before surveying eight major terrestrial biomes—*tropical forests, savannas, deserts, chaparral, temperate grasslands, temperate deciduous forests, evergreen coniferous forests,* and *tundra*—we consider how environmental factors influence their overall distribution.

CLOSER LOOK **FIGURE 51.11** Distribution of biomes on a climograph.

SUMMARY Each of the major terrestrial biomes occupies a characteristic combination of temperature and moisture conditions.

THINK LIKE A SCIENTIST Will the effects of global warming change the distribution of biomes on the climograph?

© Cengage Learning 2014

Environmental Variation Governs the Distribution of Terrestrial Biomes

Because organisms—and the communities they form—are sensitive to abiotic factors, climate is the main determinant of biome distribution. A **climograph** portrays the particular combination of temperature and rainfall conditions where each terrestrial biome occurs **(Figure 51.11).** For example, some deserts, grasslands, savannas, and tropical forests occur in areas that have comparable mean annual temperatures but vastly different rainfall. Conversely, some biomes, such as boreal forests, temperate deciduous forests, and savannas, are found under similar moisture conditions but different temperature regimes.

Although the climograph provides a general portrait of the temperature and moisture conditions where the different biomes occur, it does not address the details of environmental variation. For example, the climograph includes only mean annual temperature and rainfall, not seasonal variation in these factors. Two regions may have the same mean temperature even though one experiences blazingly hot summers and bitterly cold winters and the other has moderate temperature throughout the year; we would expect them to harbor different organisms. Moreover, the distributions of communities are also influenced by nonclimatic factors, such as regional variations in soil structure and mineral composition (see Section 35.2).

Because temperature and rainfall exhibit latitudinal patterns (displayed in Figures 51.2 and 51.5), the distributions of some terrestrial biomes appear as bands on a world map **(Figure 51.12).** But regional and local climatic variations influence these broad patterns. For example, chaparral is common in certain coastal habitats, whereas grasslands occur further inland at similar latitudes. Comparable bands of distinct vegetation form on mountainsides because temperature and moisture conditions also change with altitude.

Tropical Forests Include Earth's Most Species-Rich Communities

Three types of **tropical forests**—rainforest, deciduous forest, and montane forest—sweep across the parts of Africa, Asia, Australia, and Central and South America that receive intense solar radiation and heavy rainfall.

Tropical rainforests grow where some rain falls every month, mean annual rainfall exceeds 250 cm, mean annual temperature is at least 25°C, and humidity is above 80%. Limited by neither temperature nor water, the productivity of a tropical rainforest is exceptionally high (see Section 54.1). Trees replace their leaves throughout the year, producing a continuous rain of detritus that ants, land crabs, and other scavengers quickly consume. Decomposition is rapid in the hot, moist environment, and almost no litter accumulates on the ground. Because nutrients released by decomposition are promptly absorbed by vegetation or leached by rain, soil in tropical rainforests is nutrient-poor, with low humus content (see Section 35.2).

Tropical rainforests are usually layered (see Figure 53.19). The crowns of tall trees form a dense, tangled canopy that intercepts most incoming sunlight 40 to 45 m above the ground **(Figure 51.13).** Even the largest trees grow only shallow roots in the thin soil, but many have wide *buttresses,* woody lateral extensions of their trunks, that stabilize them in the ground. Shade-tolerant shrubs and small trees form understory layers below the canopy. The woody stems of lianas climb through both layers, and epiphytes, such as bromeliads and orchids, cover the

trunks and branches of trees, especially in sunlit openings. In mature rainforests, the ground is surprisingly bare of leafy vegetation, because very little sunlight reaches the forest floor.

Tropical rainforests probably harbor more plant and animal species than all other terrestrial biomes combined. Ecologists have proposed numerous hypotheses to explain both the evolution and maintenance of the large number of species living in these communities (see Section 53.7), but no single hypothesis explains the pattern adequately. In fact, we do not even have a complete species list for any rainforest community, largely because most animals live in the highly productive canopy, which ecologists have only recently begun to study in detail (see *Focus on Basic Research*). The most extensive tracts of tropical rainforest occur in South America, central and western Africa, and Southeast Asia. Unfortunately, they are being cleared at an alarming rate (see Chapter 55); some experts predict that this biome will all but disappear before the middle of the twenty-first century.

Habitats centered at 20° north and south of the equator experience a pronounced summer rainy season and winter dry season. **Tropical deciduous forests** occur where winter drought reduces photosynthesis, and most trees drop their leaves. For example, the monsoon forests of Southeast Asia, which harbor teak and other tropical hardwoods, are as lush as tropical rainforests in the rainy season; but many trees are bare in the dry season.

Exploring the Rainforest Canopy

Biological diversity in tropical rainforests has fascinated naturalists for centuries. Sadly, most of its organisms live beyond our reach. The forest canopy extends from 9 or 10 m above the ground to heights as great as 45 m, making the canopy inaccessible and largely unexplored. Early ecologists were able to study canopy-dwelling species only when they found a fallen tree or followed loggers into the forest. In the 1930s, a clever botanist trained monkeys to retrieve plants from the canopy, but these efforts provided little data about the ecological interactions that govern life in the treetops.

Many ecologists still study canopy-dwelling organisms from the safety of the ground. Binoculars provide a good view of fairly large vertebrates. And a hike along a ridgetop can provide a canopy-level view of trees growing in an adjacent valley or ravine. Some researchers use ropes to hoist nets or traps into the canopy, lowering them periodically to see what they have caught. Others spray a fog of insecticide into the canopy to kill small invertebrates, which then rain down onto plastic sheets spread below the trees. These ground-based techniques have led to the discovery of hundreds—perhaps thousands—of new arthropod species. Ecologists now collect huge samples of arthropods to study the species composition and structure of communities and to monitor changes in these communities over time. But distant observations and mass sampling techniques don't provide detailed data about which insects are feeding on a tree, how often hummingbirds pollinate a flower, or when a tiny lizard hunts its prey.

Today many ecologists routinely risk life and limb to collect detailed ecological data in the rainforest canopy. They climb trees and crawl along stout branches. Many build stable observation decks with walkways, allowing study on either side of the "trail" **(Figure).**

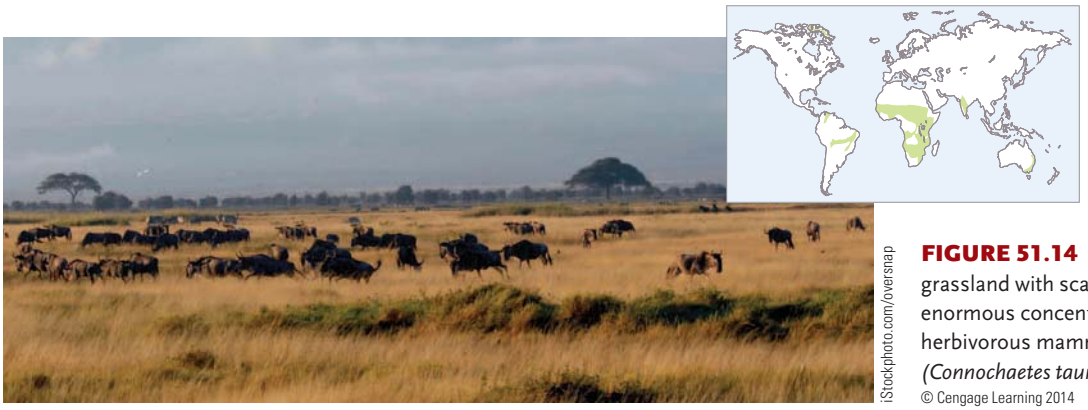
What does this newfound access to the rainforest canopy add to our knowledge of organisms that live there? Researchers can measure the physical environment of the canopy and observe the physiological and behavioral adaptations of its plants and animals. For example, researchers are gathering data on the feeding habits and behavior of small animals that never venture to the ground, such as fruit-eating bats and birds. When coupled with information about the movement patterns of these animals, the data provide insight into the dispersal of seeds in the fruits. And an understanding of seed dispersal provides information for studies of the population ecology of rainforest trees.

Canopy ecologists have also discovered fascinating relationships between plants and their animal pollinators. For example, Donald Perry, a freelance biologist, discovered that birds are attracted to the sweet nectar of the vine *Norantea sessilis.* Feeding birds step on the vine's sturdy flowers; their feet become covered with the plant's pollen, which is embedded in a gummy substance. When the birds visit another vine of the same species, they transfer the pollen to that plant's flowers, providing cross-pollination, which appears to be necessary for the vine's reproduction.

Nalini M. Nadkarni

FIGURE **A platform in the canopy of a tropical rainforest in Costa Rica provides a comfortable perch for Donald Perry to survey the pollinating activity of birds and bees.**

Research in the tropical rainforest canopy promises exciting discoveries about ecological relationships in this unique biome, which is the most threatened on Earth (see Chapter 55). Such research is essential for developing a public appreciation of tropical forests and for creating conservation plans to preserve them.



High altitudes in the tropics support distinctive **tropical montane forests,** or "cloud forests," which are frequently enveloped in mist. The trees, often no more than 3 m tall, are densely covered with epiphytes, which thrive in the moisture-laden air. Cloud-forest plants grow slowly because productivity is limited by low temperatures, high humidity (making transpiration difficult), and sunlight-blocking clouds.

Savannas Grow Where Moderate Rainfall Is Highly Seasonal

Grasslands with scattered trees, the biome called **savanna,** grow in areas adjacent to tropical deciduous forests **(Figure 51.14).** Seasonality in tropical and subtropical savannas is determined by the availability of water; although annual rainfall averages 90 to 150 cm, droughts typically last for months. Grasses are successful in semiarid conditions because their shallow roots harvest water efficiently. With the onset of seasonal rains, they grow quickly, reaching a height of 2 to 3 m. During the dry season, grasses die back and frequently burn, but their underground parts remain alive and resprout when water again becomes available. Shrubby trees outcompete grasses in moist, low-lying areas or on rocky ground, but periodic fires and grazing mammals eliminate most trees as seedlings.

The largest savannas stretch across eastern and southern Africa; smaller patches occur in India, Australia, and South America. African savannas are home to large herbivorous mammals, including antelopes, zebras, giraffes, and elephants,

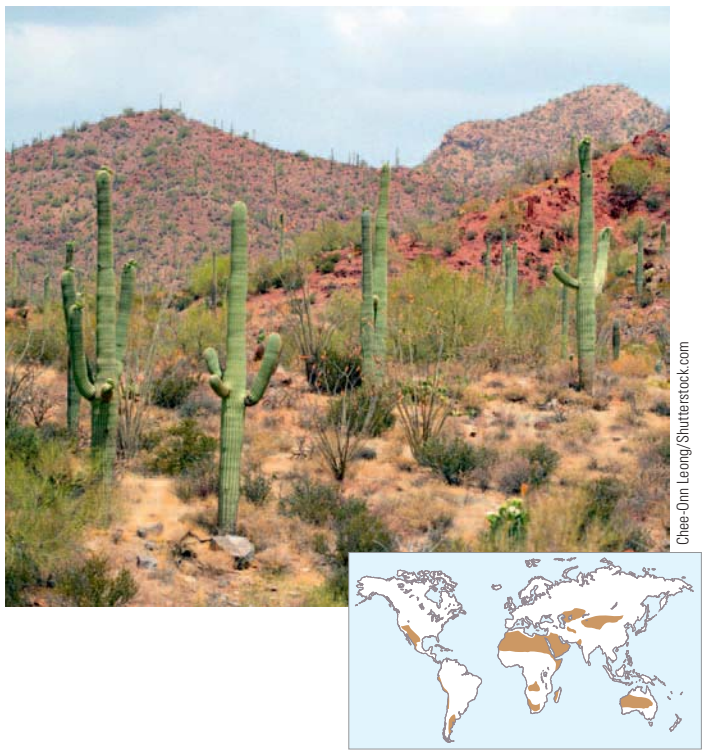
© Cengage Learning 2014

some of which fall prey to savanna predators, such as lions, leopards, cheetahs, and wild dogs. Grazing mammals follow the seasonal cycle of grasses, migrating away from dry areas to greener pastures.

Thorn forests grow at the arid borders of true savanna, where large mammals are less abundant. Grasses and other plants that store energy in large underground root systems grow among scrubby trees. Thorn forests are also highly seasonal, growing dramatically in the rainy season and dying back during the annual dry season, which may last for 8 to 9 months.

Deserts Develop Where Little Precipitation Falls

Deserts form where rainfall averages less than 25 cm per year. The hot deserts of the American Southwest, northern Chile, Australia, northern and southern Africa, and Arabia occur near 30° latitude, where descending air masses create very dry conditions. Cool deserts, such as the Gobi and Kyzyl-Kum of Asia and the Great Basin of North America, form in massive rain shadows at higher latitudes.



Desert conditions are often extreme. Rainfall arrives infrequently in heavy, brief pulses; and sudden runoff erodes topsoil, which often has high mineral content but little organic matter. Dry air and scant cloud cover allow most sunlight to reach the ground, raising daytime air and ground temperatures as high as 45°C and 70°C, respectively. At night, the surface loses heat quickly; in some deserts, temperatures drop below freezing in winter.

Desert vegetation is always sparse because arid environments do not favor large, leafy plants. Some deserts, such as the Namib of Africa and the Atacama-Sechura of South America, receive so little rainfall that large areas are practically devoid of vegetation. By contrast, the hot Sonoran Desert in northern Mexico, southeastern California, and southern Arizona harbors a diverse flora, including deep-rooted shrubs and shallow-rooted cacti **(Figure 51.15).** Mesquite and cottonwood trees grow long taproots into the permanent water supply below streambeds. Perennial plants often protect their tissues from herbivores with spines or toxic chemicals, and many use CAM photosynthesis to conserve water (see Section 9.4). After seasonal rains, annual plants germinate, mature, flower, and produce seeds before brutally dry conditions resume.

Deserts also support abundant animals, most of them fairly small. Ants, birds, and rodents often subsist on seeds. Some seed-eating mammals survive on the water they extract from food. Insects, some lizards, and mammals consume the sparse vegetation. Scorpions, lizards, and birds feed primarily on insects; and snakes, owls, and foxes prey on other animals. Most desert animals avoid the midday heat and dehydrating conditions; many retreat into underground burrows, where water vapor from their respiration cools and moistens the air. Many species are nocturnal or active only in the early morning and late afternoon.

John C. Cunningham/Visuals Unlimited

FIGURE 51.16 Chaparral. Chaparral covers broad expanses of hills in coastal areas of central and southern California.
© Cengage Learning 2014

Chaparral Grows Where Winters Are Cool and Wet and Summers Are Hot and Dry

A scrubby mix of short trees and low shrubs called **chaparral** dominates narrow sections of coastal land between 30° and 40° latitude, where winters are cool and wet and summers hot and dry. Seasonal rainfall averages only 25 to 60 cm per year. Chaparral occurs in central and southern California, central Chile, southwestern Australia, southern Africa, and the Mediterranean region.

Chaparral shrubs are dense, with hard, tough, evergreen leaves **(Figure 51.16).** They grow woody stems above ground and large root systems in the soil. Many species, such as sages (genus *Salvia*), produce toxic, aromatic compounds that inhibit the germination and growth of other plants. Just after the winter rains, the shrubs are covered with new leaves and flowers, and the vegetation teems with insects and breeding birds. During the hot, dry summers, however, most plants are dormant, and lightning sparks frequent fires. The aromatic oils and resins of many species, such as eucalyptus, make them highly flammable. Their aboveground parts burn swiftly, but they quickly resprout from large root crowns. Other species release seeds from fire-resistant cones or pods, and their seedlings grow in ash-enriched soil.

Temperate Grasslands Are Subject to Periodic Disturbance

Temperate grasslands include the prairies of North America, the steppes of central Asia, the pampas of South America, and the veldt of southern Africa. They stretch across the interiors of continents, where winters are cold and snowy and summers are warm and fairly dry. Only 25 to 100 cm of rain falls unevenly through the year. Temperate grasslands are in a near-constant state of flux: seasonal drought, periodic fires, and grazing by mammals destroy the seedlings of shrubs and trees, preventing them from displacing perennial grasses and herbaceous plants (see Section 53.6). Grassland soil is rich in organic matter because the aboveground parts of most plants die and decompose annually.

In North America, shortgrass prairie **(Figure 51.17A)** covers much of the west, where winds are strong, rainfall light and infrequent, and evaporation rapid. Drought-tolerant perennials have deep roots, and their underground rhizomes, which store energy, resprout quickly after a fire. Tallgrass prairie **(Figure 51.17B)** once occupied moister regions to the east of the shortgrass prairie. It boasted an abundance of legumes and sunflowers, often 3 m tall, but most of it was converted to farmland long ago; small patches still exist in nature preserves and in glades within eastern deciduous forests.

North American grasslands are still occupied by large grazing mammals, including pronghorns and bison, which once numbered in the millions. The most familiar burrowing mammal is the prairie dog, a rodent, but pocket gophers, ground squirrels, and jackrabbits are also common. Wolves were the primary large predators until they were hunted nearly to extinction. Coyotes, foxes, ferrets, hawks, and owls still take small prey today.

Summer

Thomas E. Hemmerly

Winter

Thomas E. Hemmerly

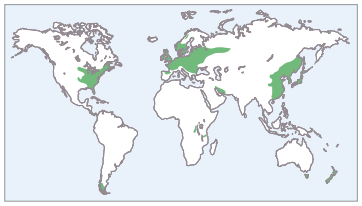

FIGURE 51.18 Temperate deciduous forest. Seasonal variations in temperature and water change the character of this forest south of Nashville, Tennessee.

© Cengage Learning 2014

Temperate Deciduous Forests Experience Seasonal Dormancy

At temperate latitudes, with warm summers, cold winters, and annual precipitation between 75 and 250 cm, **temperate deciduous forests** grow at low to middle altitudes. In winter, low temperatures reduce photosynthetic rates, and snow and ice can damage leaves. Thus, most plants shed their leaves and grow new ones in spring **(Figure 51.18).** The thick layer of leaf litter, which releases mineral nutrients as it decomposes, enriches the soil. Decomposition is slow, however, because the growing season is only about 7 months long.

Temperate deciduous forests harbor fewer species than tropical forests. Trees form a canopy 10 to 35 m high, and woody shrubs form an understory below it. Herbaceous plants and a ground layer of mosses or liverworts grow below the shrubs. Many herbaceous plants, including some terrestrial orchids, flower early in spring, before trees produce sunlight-blocking leaves; others flower near the end of the growing season.

Forests of ash, beech, birch, chestnut, elm, and oak stretched unbroken across eastern North America, Europe, and eastern Asia before farmers cleared the land. In North America, introduced diseases and insects have nearly eliminated the once dominant species, such as American chestnut and American elm. Today, beech, birch, and maple predominate in the Northeast; oak–hickory forests dominate farther south and west; and oak woodlands merge into tallgrass prairie to the west. Before the arrival of Europeans, deer, bison, bears, and pumas roamed the forests with many smaller species of animals. Today, small mammals such as voles, mice, chipmunks, squirrels, rabbits, opossums, and raccoons predominate, although deer and bears—species that thrive in habitats that have been disturbed by human activities—have recently surged in abundance.

Evergreen Coniferous Forests Predominate at High Northern Latitudes

The **boreal forest,** or **taiga** (Russian for "swamp forest"), is a circumpolar expanse of evergreen coniferous trees in Europe, Asia, and North America **(Figure 51.19).** Snow blankets the ground during long and extremely cold winters, but most precipitation falls during the short summer. In the northernmost taiga, plants grow quickly during long (18-hour) summer days.

Stands of white spruce and balsam fir dominate North America's boreal forest. Their needle-shaped leaves have a thick cuticle and recessed stomata that conserve water during winter, when groundwater is frozen. Fallen needles acidify the thin soil, which speeds the leaching of most nutrients, and few shrubs and herbaceous plants grow beneath the conifers. Lightning-sparked fires are common; some deciduous trees grow in areas opened by fire, but conifers eventually replace them. Cold streams, marshes, ponds, and lakes often dot the landscape; at flat, poorly drained sites, peat mosses, shrubs, and stunted trees dominate acidic bogs, called muskegs.

Most taiga is relatively undisturbed by humans, and it still harbors its native animals. Moose, elk, and deer are the dominant large herbivores. Hare as well as squirrels, porcupines, and other rodents also feed on plants. Some small animals are active all winter in runways they dig beneath the snow. Wolves, lynx, and wolverines prey on herbivores. Grizzly bears and black bears roam the forest, devouring seeds, berries, fishes, and small animals. Mosquitoes, black flies, and gnats are superabundant near bogs and lakes in summer.

Other types of coniferous forests grow in more southerly coastal lowlands where winters are mild and wet and the summers are cool. For example, a **temperate rainforest,** supported by heavy rain and fog, parallels the North American coast from

Alaska into northern California. In western Washington State, the rainforest on the Olympic Peninsula receives 500 cm of rainfall per year, as much as some tropical forests. This temperate rainforest harbors some of the world's tallest trees, including Douglas fir and Sitka spruce to the north and coast redwoods to the south.

Tundra Comprises a Vast, Treeless Plain in the Northernmost Habitats

The treeless **arctic tundra** stretches from the boreal forests to the polar ice cap in Europe, Asia, and North America. Covering almost 5% of the land, this biome is windswept and wet. Winter temperatures are consistently below freezing. The 2-month summer is so cool that only the topmost layer of soil ever thaws, leaving the ground below perpetually frozen; in some areas, this **permafrost** is more than 500 m thick. Although less than 25 cm of precipitation falls each year, evaporation is slow, and permafrost is impermeable; thus, low-lying soil remains permanently waterlogged, forming bogs **(Figure 51.20A).** Anaerobic conditions and low temperatures retard decomposition, and soggy masses of detritus accumulate.

Plants in the tundra are short because the weak sunlight and minimal growing season provide barely enough energy and warmth for photosynthetic activity; moreover, strong winter winds shred any plants with a high profile. The vegetation consists of low-growing lichens, mosses, grasses, perennial herbs, dwarf shrubs, and a few stunted trees, usually less than 1 m tall. During summer's nearly continuous sunlight, plants flower profusely, and their fruits ripen fast.

Some animals, including herbivorous arctic hares, lemmings, and willow ptarmigans, as well as predatory snowy owls, wolves, foxes, and lynx, are permanent tundra residents. In summer, herds of herbivorous musk oxen, caribou, and reindeer migrate there from boreal forests, and migratory shorebirds and waterfowl arrive to breed. Flying insects abound in summer, especially mosquitoes and black flies, which reproduce in boggy habitats.

A similar biome, called **alpine tundra,** occurs on high mountaintops throughout the world **(Figure 51.20B).** Dominant plants form cushions and mats that withstand the buffeting of strong winds. Winter temperatures are well below freezing, and shaded patches of snow persist even in summer. The thin, fast-draining soil is nutrient-poor, and photosynthetic activity is low.

1. Which terrestrial biomes occur in habitats that receive the most rainfall?
2. Which terrestrial biomes are renewed by periodic fires?
3. Which terrestrial biomes have the tallest vegetation? Which ones have the shortest?
4. In which terrestrial biomes are the trees usually evergreen?

THINK OUTSIDE THE BOOK

What biome surrounds the community where you live? If you live in a city, how might you define an urban biome? How far would you need to travel to be in a different biome?

51.5 Freshwater Environments

Biomes are traditionally defined for terrestrial environments. Their aquatic counterparts comprise several distinctive habitats in either freshwater or marine environments. In freshwater environments, water with a salt concentration below 0.5% accumulates or moves through a landscape. Ecologists distinguish between *lotic* systems, where water flows through channels, and *lentic* systems, where water stands in an open basin. All freshwater environments interact with the surrounding terrestrial habitats, because runoff from the land carries a nearly constant input of nutrients. Highly productive **wetlands** often occur at the borders of freshwater environments. These marshes and swamps may harbor an astounding array of microorganisms, algae, plants, invertebrates, and vertebrates.

Streams and Rivers Carry Water Downhill to a Lake or Sea

Flowing-water environments start as seeps on high ground. As the water flows downhill, it collects into nar-

FIGURE 51.21 Stream and river habitats. (A) In streams, such as this one in Virginia, water flows quickly through narrow channels, often with a rocky bottom. **(B)** In rivers, like the Rio Napo in Ecuador, water flows more slowly through broad channels, and suspended sediments often make the water murky.

row streams, which merge to form wide rivers **(Figure 51.21).** Streams and rivers include three habitats. *Riffles* are shallow, fast-moving, turbulent stretches over a rough bottom of pebbles or rocks. *Pools* are deep, slow-moving areas with a smooth sand or mud bottom. *Runs* are deep, fast-moving stretches over smooth bedrock or sand. Streams generally have high flow rate, low volume, and lots of riffles and pools. As they merge into rivers, flow rate declines, but flow volume increases, and runs and pools predominate. Flow rate and volume also vary seasonally with the rate of water input from rainfall and snowmelt and geographically with altitude and topography.

Physical factors change over the length of a flowing-water system. The concentration of suspended particulate material is low in streams, but high in rivers, which are often turbid with silt. Temperature also rises as water flows downstream to warmer lowland habitats. Because oxygen is more soluble in cold water than in warm water, dissolved oxygen is usually higher in streams than in rivers. Erosion of the streambed and surrounding land provides the solute content of flowing water. Today, agricultural runoff and industrial and municipal wastes provide major input. In unpolluted streams, organic detritus provides more than 95% of the nutrients and energy entering aquatic food webs. This input is particularly important in streams flowing through dense forests, where vegetation blocks the sunlight necessary for photosynthesis.

The flow of water affects every aspect of life in streams and rivers. In swift-moving riffles, primary producers cling permanently to fixed substrates, because phytoplankton are swept away by the current. Insect larvae and other invertebrates attach to the undersides of rocks; many species have a flattened shape to maintain a low profile in the current. By contrast, large rivers have dense populations of algae and cyanobacteria, which attach to rocks and other substrates (that is, surfaces to which organisms can adhere), and rooted aquatic plants at the river's edge.

Lakes Are Bodies of Standing Water That Accumulate in Basins

Lakes and other standing-water biomes are generally fed by rainfall and by streams and rivers that carry water from surrounding lands **(Figure 51.22).** Because the availability of light affects photosynthesis by a lake's phytoplankton and plants, ecologists often distinguish between the **photic zone** of a lake, the surface water that sunlight penetrates, and the deeper **aphotic zone,** which is darker.

LAKE ZONATION Every lake includes zones, defined by depth and distance from the shore, that provide distinctive environments **(Figure 51.23).** In the **littoral zone,** the shallow water near the shore, sunlight penetrates to the bottom. Enriched by nutrients made available by decomposers and runoff, the littoral zone has high photosynthetic activity and is occupied by many species. Rooted aquatic plants, such as cattails and water lilies, grow above the surface, and "floating aquatics," such as duckweed, are common. Submerged vegetation harbors a rich community of microorganisms, epiphytes, and invertebrates. Numerous animals—insects, worms, snails, crayfish, fishes, frogs, turtles, and water birds—use the littoral zone to feed and reproduce.

The **limnetic zone,** the sunlit water beyond the littoral, supports plankton communities: the primary photosynthesizers are phytoplankton—cyanobacteria, diatoms, and green algae; they are eaten by zooplankton—rotifers, copepods, and other tiny heterotrophs. Small fishes, which feed on plankton, are themselves consumed by larger fishes, such as bass.

Photosynthesis is impossible, however, in the **profundal zone,** the perpetually dark water below the limnetic zone. Nev-

ertheless, a constant rain of detritus from the limnetic zone supports a community of bacterial decomposers and animals that feed on dead or dying material, including worms, clams, insect larvae, and catfish.

SEASONAL CHANGES IN TEMPERATE LAKES In temperate areas, seasonal temperature variations induce changes in the vertical zonation of lakes **(Figure 51.24).** Like other liquids, water gets denser as it cools. But water has a unique property: it reaches maximum density at 4°C, with the density declining as it gets colder. Thus, water at 4°C sinks below water that is either warmer or colder; ice floats because it is less dense than very cold water.

During winter, ice forms on the surface of temperate zone lakes. Water temperature varies from near freezing just below the ice to 4°C at the bottom. Differences in the density of water at 0° and 4°C maintain this thermal stratification. In spring, as the ice melts, the warmer, denser water sinks; and the surface temperature gradually rises to 4°C. For a brief time, the temperature is uniform at all depths. Winds blowing across the lake create vertical currents that cause a **spring overturn,** mixing surface water with deep water. Oxygen at the surface moves to the bottom, and nutrients from the bottom move to the surface.

By midsummer, sunlight heats the top layer of the limnetic zone, called the **epilimnion,** to temperatures above 4°C. In large lakes, the epilimnion may be more than 10 m deep. In the deep water of the lake's profundal zone, called the **hypolimnion,** the temperature remains near 4°C. However, at the boundary between the epilimnion and the hypolimnion, water temperature changes abruptly over a narrow depth range, called the **thermocline.** The thermocline prevents vertical mixing because warm surface water floats above the thermocline, and cool deep water stays below it. During summer, nutrient-rich

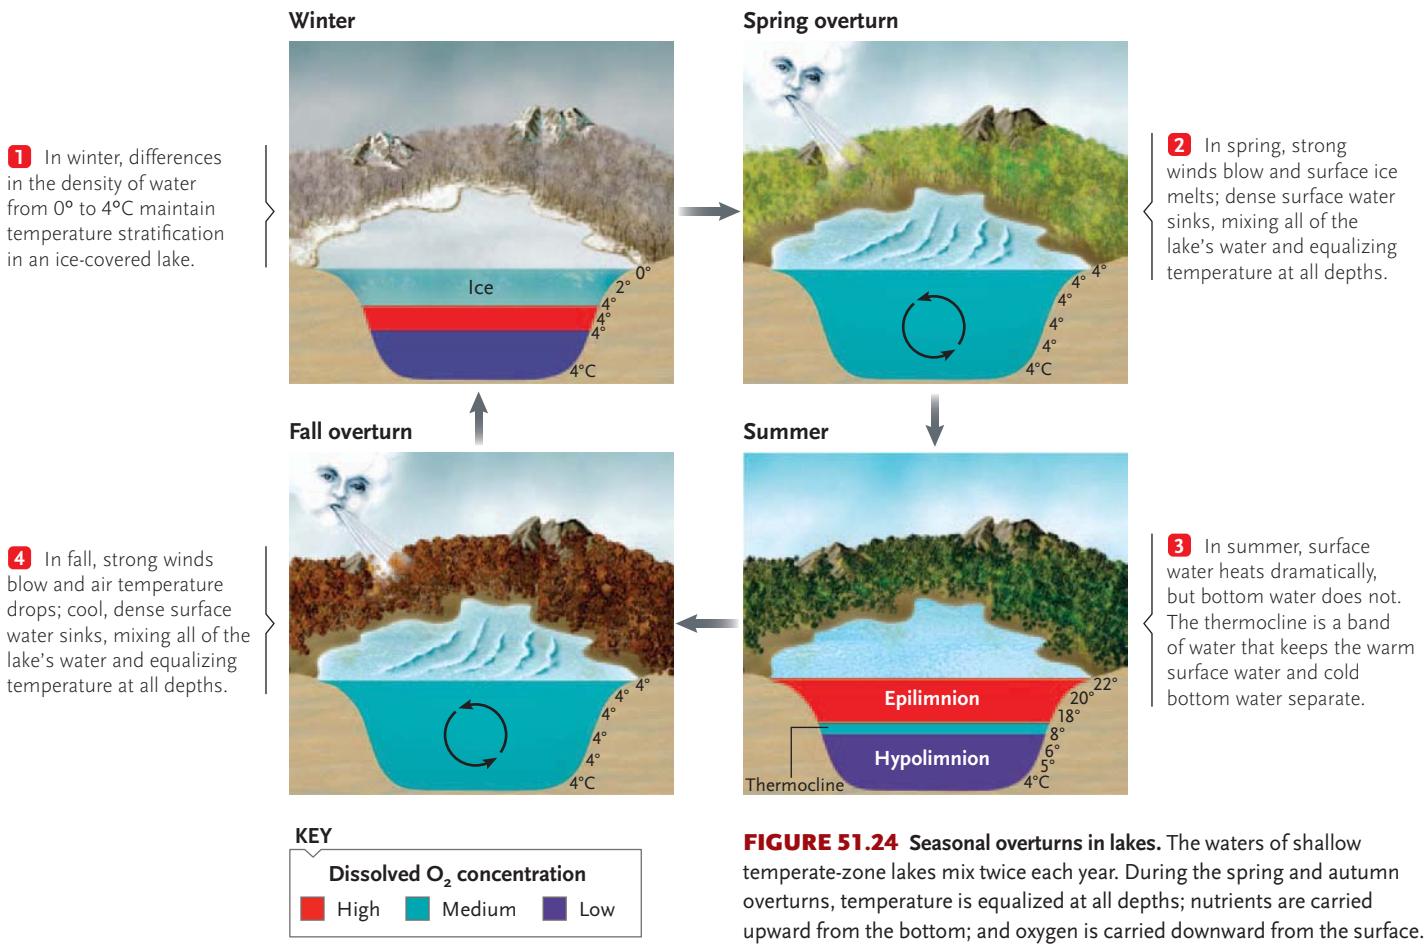

FIGURE 51.24 **Seasonal overturns in lakes.** The waters of shallow temperate-zone lakes mix twice each year. During the spring and autumn overturns, temperature is equalized at all depths; nutrients are carried upward from the bottom; and oxygen is carried downward from the surface.

FIGURE 51.25 **Experimental Research**

What Causes Lake Eutrophication?

Question: Does the addition of excess phosphorus to a lake encourage the growth of phytoplankton, such as cyanobacteria?

Experiment: Schindler and his colleagues experimentally separated the two basins of a lake in Ontario, Canada, with a plastic curtain. The researchers added phosphates to one basin and used the other basin as a control.

Results: Within two months, the artificially enriched basin (in the upper left of the photo) sported a pale green bloom of cyanobacteria, a sure sign of eutrophication; the control basin remained oligotrophic and crystal clear.

D. W. Schindler. *Science* 184:897–899.

Conclusion: The addition of excess phosphorus to a lake encourages blooms of cyanobacteria, causing the lake to change from oligotrophic to eutrophic.

THINK LIKE A SCIENTIST Why do new housing developments on hilly ground often pose a danger to nearby lakes?

detritus sinks to the bottom of the lake, where decomposition depletes the oxygen dissolved in the hypolimnion. In autumn, declining sunlight and winds cause the epilimnion to cool, and as the water becomes denser, it sinks, eliminating the thermocline. Winds then mix the water vertically once again during an **autumn overturn,** and dissolved gases and nutrients are equalized at all depths.

Photosynthetic activity in the limnetic zone varies with the seasonal overturns. In spring, increased sunlight, warm temperatures, and the sudden availability of nutrients induce a bloom of photosynthesis and growth. As the season progresses and the thermocline prevents vertical mixing, nutrient levels dwindle in the epilimnion, and photosynthetic activity declines. By late summer, nutrient shortages limit photosynthesis. After the autumn overturn, nutrient cycling drives a short burst of productivity. But as days get shorter and temperature declines, productivity remains low until spring.

TROPHIC NATURE OF LAKES Ecologists classify lakes by their nutrient content and rates of photosynthetic activity. **Oligotrophic lakes** are poor in nutrients and organic matter, but rich in oxygen. Their low productivity keeps the water crystal clear, making them popular recreational sites. By contrast, **eutrophic lakes** are rich in nutrients and organic matter. The decomposition of organic matter depletes oxygen in the hypolimnion when the lake is stratified, and high productivity in the epilimnion often chokes the water with seasonal blooms of cyanobacteria and filamentous algae. Eutrophic lakes are often thick and "soupy," making them unattractive for recreation. Over long periods of time, as sediments accumulate, lakes naturally change from oligotrophic to eutrophic; their basins eventually fill with sediments, and terrestrial plants invade.

The addition of nutrients to a lake often disrupts its trophic condition (see *Why It Matters* for Chapter 54). In a classic experiment conducted in the late 1960s, David Schindler and his colleagues at The Experimental Lakes Project in Ontario, Canada, experimentally separated the two basins of a lake with a plastic curtain. The researchers added phosphates to one basin and used the other basin as a control. Within 2 months, the artificially enriched basin sported a bloom of cyanobacteria, a sign of eutrophication; the control basin remained oligotrophic and crystal clear **(Figure 51.25).**

51.6 Marine Environments

Marine environments, in which salinity (salt concentration) averages about 3%, cover nearly three-fourths of Earth's surface and account for a large fraction of its photosynthetic activity. They also mediate important global processes: marine phytoplankton process large amounts of carbon dioxide, generating oxygen and moderating a major cause of global climate change (see Chapter 54).

As with standing freshwater environments, depth and distance from shore govern the physical characteristics of marine habitats. Ecologists describe ocean zonation in several ways **(Figure 51.26),** including the distinction between the photic and aphotic zones. Another major distinction is between the **pelagic province,** the water, and the **benthic province,** the bottom sediments. The pelagic province includes the **neritic zone,** the shallow water above the continental shelves, and the **oceanic zone,** the deep water beyond them. The benthic province is divided into the **intertidal zone,** the shoreline that is alternately sub-

merged and exposed by tides, and the **abyssal zone,** the bottom sediments that lie permanently below deeper water. Here we describe five marine environments—*estuaries, rocky and sandy coasts, continental shelves and oceanic banks, open ocean,* and *benthic regions*—that represent particular associations of organisms occupying different marine zones and provinces.

Estuaries Form Where Rivers Meet the Sea

Estuaries are coastal regions where seawater mixes with fresh water from rivers, streams, and runoff **(Figure 51.27).** Salinity is low where fresh water enters the estuary and high on the tidal side. After heavy rainfall, fresh water floods into the habitat, reducing salinity and raising water temperature. At high tide, cold, salty water flows in from the sea. All estuarine organisms must tolerate these variable conditions.

Variations in local topography influence an estuary's physical features. Chesapeake Bay in Maryland, Mobile Bay in Alabama, and San Francisco Bay in California are broad, shallow estuaries. The estuaries in Alaska and British Columbia are narrow and deep, as are Norway's fjords. Many estuaries are bordered by **salt marshes,** tidal wetlands dominated by emergent grasses and reeds (Figure 51.27A). In tropical estuaries, the roots of densely packed mangrove trees penetrate the muddy bottom, accumulating sediments and slowly adding land to the shoreline (Figure 51.27B).

The constant input of nutrients and removal of wastes by the tides contribute to exceptionally high productivity in estuaries. The most common photosynthetic organisms include phytoplankton, salt-tolerant grasses and reeds that can withstand submergence at high tide, and algae that grow in mud and on plant surfaces. Roots and stems trap organic matter, which decomposes. The detritus (and bacteria clinging to it) supports nematodes, snails, crabs, and fishes; suspension-feeding mollusks and arthropods capture edible particles in the slowly moving water. Many marine arthropods and fishes breed in calm, shallow estuaries, where their young find abundant food and refuge from predators in the complex vegetation. Migratory birds use estuaries as rest stops, and shore birds and waterfowl use their muddy bottoms as rich feeding grounds, particularly at low tide.

Rocky and Sandy Coasts Experience Cyclic Periods of Exposure and Submergence

The intertidal zone, the area between low and high tide marks, is one of the most stressful habitats on Earth. On rocky shores, residents are battered by waves and floating debris. Sessile species, such as mussels and barnacles, attach to substrates with special structures or cement. Motile species, such as limpets and sea stars, simply hang on to rocks. Organisms that live high on the shore dry out at low tide, freeze in winter, and bake in summer. Exposed animals often seal themselves inside shells, and intertidal algae have thick polysaccharide coats that adsorb water and prevent dehydration.

FIGURE 51.28 Vertical zonation in the intertidal. A rocky shore in the Pacific Northwest clearly exhibits vertical zonation. The distance between low and high tide marks on this rocky shore is about 3 m.

Biotic interactions also take their toll. Organisms throughout the intertidal zone compete for attachment sites to avoid being washed away (see Figure 53.12). At low tide, predatory birds and mammals attack from above; at high tide, predatory fishes move in from the sea. Because the tides often scour detritus from the rocky intertidal, communities on rocky shores are largely supported by the photosynthetic algae and phytoplankton.

Rocky shores often have three zones **(Figure 51.28).** The *upper intertidal* is submerged only during the highest tide of the lunar cycle. It is sparsely populated by barnacles, sturdy algae, and grazing and predatory snails. The *middle intertidal* is submerged daily during the highest regular tide and exposed during the lowest. Its tide pools are occupied by red, brown, and green algae, grazing and predatory mollusks, sponges, sea anemones, worms from several phyla, hermit crabs, echinoderms, and small fishes. Biodiversity is greatest in the *lower intertidal,* which is exposed only during the lowest tide of the lunar cycle. It is occupied by dense beds of algae, tunicates, echinoderms, other invertebrates, and fishes.

Sandy shores are composed of loose sediments that waves and currents constantly rearrange. Large plants and algae cannot grow on such unstable substrates, but organic debris imported from off shore or from nearby land supports animals that feed on detritus. Animals live in burrows, which they must frequently repair as the substrate shifts. Crabs and shorebirds live as scavengers or predators above the high tide mark. At night, beach hoppers and ghost crabs leave their burrows, seeking food. Marine worms, clams, crabs, and other invertebrates live in the sand between the high and low tide marks.

Light Penetrates the Shallow Water over Continental Shelves and Oceanic Banks

The neritic zone includes the shallow water over continental shelves and oceanic banks, underwater landmasses that rise to within 300 m of the surface. Although small in area, the neritic zone is highly productive and species-rich **(Figure 51.29).** Runoff from the land brings a steady inflow of nutrients, and upwelling (that is, vertical currents) and waves circulate nutrients from the bottom to the photic zone.

In temperate regions, giant kelp forests, which are among the most productive ecosystems, occupy some continental shelves and banks (Figure 51.29A). Kelp are enormous algae that attach to the bottom with giant holdfasts; their stipes ("stems") reach upward with fronds fanning out into the water. Sea anemones, snails, echinoderms, lobsters, and other invertebrates live in the kelp, where fishes and other predators consume them. Even where kelp does not grow, continental shelves and banks teem with life. Most of the important fisheries in the temperate zone occur there.

In the tropics, the warm but nutrient-poor water above continental shelves is often occupied by **coral reefs** (Figure 51.29B). Sunlight penetrates the clear water all the way to the bottom. Photosynthetic dinoflagellates, living as endosymbionts of the coral animals (see Section 27.2), and coralline algae are largely responsible for the photosynthesis that takes place there. Coral animals also feed on microscopic organisms and suspended particles. The reefs are the remains of corals, algae, and other organisms, and their structural complexity rivals that of tropical rainforests. Tides and currents carve ledges and caverns. Storms frequently disturb the reefs, creating openings in which new coral colonies can grow (see Section 53.5). A reef may be festooned with as many as 750 species of corals and a dizzying variety of algae. The diversity of coral skeletons provides a complex structure that is used by invertebrates from nearly every phylum and by a host of herbivorous and carnivorous fishes.

In the Open Ocean, Photosynthesis Occurs Only in the Sunlit Upper Layers

The oceanic zone lies beyond the continental shelves. Though generally low in nutrients, it is locally enriched by runoff from land and by upwelling bottom waters. The open ocean is typically cold, except in the tropics. The surface water is illuminated by sunlight, which warms it somewhat and allows photosynthesis. Most photosynthesis is undertaken in the top 50 m, however, because seawater filters light. Photosynthetic activity varies seasonally, as it does on land.

"Pastures" of phytoplankton are eaten by zooplankton, including copepods, shrimplike krill, small worms, cnidarians, and the larvae of invertebrates and fishes. Consumers that can actively swim against the currents, such as squids, fishes, marine turtles, and whales, are called **nekton (Figure 51.30).** Some consumers feed on plankton, and some prey on other nekton. Low light levels in water between about 50 and 600 m allow little photosynthesis, but many fishes and some mobile invertebrates are active at these depths, traveling into the sunlit zone to feed on organisms near the surface.

No sunlight ever penetrates the deepest part of the oceanic zone, below 600 m. Some of these abyssal regions, such as the Marianas Trench, are more than 9 km below the surface. Scientists have explored the deepest water in the ocean only during the past few decades, but we know that it is a cold (2°–3°C), dark environment, where organisms live under tremendous pressure from the ocean above. Abyssal communities are surprisingly diverse, although population densities tend to be low. The denizens of the abyssal zone include invertebrates, bony fishes, and sharks. Some fishes and invertebrates are bioluminescent, producing spots of light that may serve for communication or as lures to entice prey within reach of their large jaws **(Figure 51.31).**

The Benthic Province Includes the Rocks and Sediments of the Ocean Bottom

The benthic province extends from the intertidal zone to the deep-sea trenches. In the oceanic zone, bottom sediments are composed of soft mud, fine particles of silt, detritus, and the shells of dead microscopic organisms. Species living in and on the bottom are collectively called **benthos.** Sunlight never strikes the benthic province of the open ocean, which is inhabited by bacteria, fungi, and a variety of animals. Sessile invertebrates, such as sponges, sea anemones, and clams, live amidst the sediments, and many motile animals, including worms, mollusks, crustaceans, echinoderms, and fishes, feed on the organic remains that sink from pelagic communities.

In 1976, researchers found communities thriving near hydrothermal vents at a depth of 3,000 m near the Galápagos Rift, a volcanically active boundary between two crustal plates. Near-freezing water seeps into fissures where it is heated to temperatures of 350°C or higher. Pressure forces the heated water upward, and minerals are leached from porous rocks as the water spews out through vents in the seafloor. This hydrothermal outpouring releases hydrogen sulfide, which chemosynthetic bacteria use as an energy source to fix carbon dioxide, just as plants and algae use sunlight for photosynthesis.

Some of these bacteria live as endosymbionts of giant clams and tube-dwelling worms **(Figure 51.32).** Worms in the genus *Riftia* lack digestive systems, subsisting entirely on the organic compounds produced by their chemosynthetic partners, which are so numerous that they account for up to half of

FIGURE 51.32 Deep benthos. Giant tube-dwelling worms *(Riftia)* and their chemosynthetic bacterial endosymbionts are common in hydrothermal vent communities on the deep ocean floor.

the worms' body weight. The worms' blood contains both hemoglobin and sulfide-binding proteins, which deliver oxygen and sulfides to the bacteria.

Deep-sea communities also include sea anemones, crustaceans, and fishes. Researchers have located hydrothermal vent ecosystems in the South Pacific, near Easter Island; the North Pacific, off the coast of British Columbia; the Gulf of California, about 150 miles south of the tip of Baja California, Mexico; and the Atlantic.

Recent research in the deepest reaches of the ocean reveals that communities also exist in areas far from hydrothermal vents. These "cold seep" communities thrive on broad expanses of the seafloor, where extremely salty water percolates upward from the underlying rocks and sediment, carrying abundant minerals, hydrogen sulfide, and methane to areas that are accessible to organisms. Chemosynthetic bacteria, which grow in large mats, can metabolize these molecules, serving as a food source for animal communities that include sponges, worms, and bivalve mollusks.

3. **Which marine regions receive abundant energy input from sunlight?**
4. **What is the source of nutrients and energy for the benthos of the oceanic zone?**
5. **What organisms are responsible for the synthesis of organic compounds in hydrothermal vent and cold seep communities, and how do they differ from those in the photic zone?**

UNANSWERED QUESTIONS

How will biomes change in response to anthropogenic (human-induced) global warming?

Will biomes remain largely intact and simply shift their geographical distributions northward or upward (to higher altitudes)? Or will the biomes we recognize today become disrupted, and new biomes arise as species associate in different combinations? Parmesan and Yohe estimated that 59% of wild species around the world have already shown some change in their geographical distributions in response to the relatively small level of global warming—a 0.7°C rise in average temperature—over the past 100 years. Documented responses to global warming vary from species to species, however. For example, only 20% of butterfly species in Spain, France, and North Africa have shifted their southern range boundaries northward, but 70% of butterfly species in the United Kingdom and Scandinavia have expanded their northern range borders further northward, sometimes by as much as 300 km over the past 30 years.

Thus, although the distributions of some species appear stable, the ranges of others are showing strong responses to global warming. At least two hypotheses may explain these patterns. First, some species may be stressed by rising temperatures but have not yet shown a measurable response. Second, the geographical distributions of some species may not be governed primarily by climate. Whatever the reason, the fact that we observe large variation in the response of different species suggests that not all species in a community are moving together. Thus, the existing communities of birds, butterflies, and trees are being disrupted—with some species moving and others not. Biologists have also noted differences in the response of different taxonomic groups. Butterflies in Europe and North America seem to be shifting their distributions northward and upward at about the same rate that temperatures are changing, but plants appear to lag behind. Alpine herbs in Switzerland, for example, have shifted their distributions upward at about half the rate that one might expect from the rate of regional warming, and it was not until 30 years after warming began that tree seedlings in Sweden started to colonize alpine habitats at higher elevations, shifting the treeline upward.

Even bigger questions remain. Will the vegetation that currently lives in the tropics expand into what is now the temperate zone and cover more of the planet? Some studies suggest that tropical lowland trees are already at their physiological limit—already showing signs of stress by shutting down photosynthesis on the hottest and driest days. Furthermore, climate model projections from a 2007 report of the Intergovernmental Panel on Climate Change consistently show substantial drying as well as warming in middle latitudes. If this projection is correct, many plants and animals now living in the wet tropics will be unable to shift northward into what may become an extreme desert climate. And what will happen to the arctic tundra? Researchers have already collected strong evidence that shrubs and trees are encroaching northward into the tundra of Alaska and Canada. The permafrost is melting, and the soil is drying. How do these observed changes in plant and animal distributions relate to the future? Human activity has already caused Earth's

mean annual temperature to rise by 0.7°C in the past 100 years. Climate model projections suggest that further increases between 1.8°C and 4.0°C are likely; some models suggest the rise will be over 6.0°C. Can the tundra biome survive even the lowest projections—more than twice the warming it has already experienced?

How will evolution shape the ways that wild species respond to climate change? Which groups of organisms are likely to adapt, and which are likely to become extinct?

Populations are evolving all the time in response to changing selection regimes. Global warming is one of many human-driven environmental changes that could foster genetic change. Biologists have known for decades that organisms are locally adapted to the climatic conditions under which they routinely live. Scientists have documented local genetic changes toward more warm-adapted genotypes in fruit flies, mosquitoes, and the algal symbionts of corals. Do the observed genetic changes suggest that these species are adapting to anthropogenic global warming? Will other species follow suit? The fossil record suggests that during the Pleistocene glaciations, when Earth's temperature shifted between glacial periods (4°–8°C colder than now) and interglacial periods (today's temperatures), very few species became extinct and few experienced substantial morphological evolution. But, before the Pleistocene, Earth was much hotter than it is today, and the atmosphere had higher levels of CO_2. During the transition from these very warm, high CO_2 conditions to the colder, low CO_2 conditions of the Pleistocene, a large proportion of species became extinct. To how much climate change can organisms adapt? At what point is climate change extreme enough that species come to the limit of their genetic variation, can no longer adapt, and become extinct?

THINK LIKE A SCIENTIST Given what you have learned about the effects of climate change on species' distributions, in which types of habitats or geographic regions should we witness the most dramatic loss of species in the near future?

Camille Parmesan

Camille Parmesan is an associate professor in the Section of Integrative Biology at the University of Texas at Austin. Her recent work has focused on current impacts of climate change on wildlife, and especially on butterfly range shifts. REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

51.1 The Science of Ecology

- Ecology is the study of the interactions between organisms and their environments. Basic ecology focuses on undisturbed natural systems, whereas applied ecology considers the effects of human disturbance.
- Ecologists conduct research at five levels of organization: organisms, populations, communities, ecosystems, and the biosphere.
- Ecologists test hypotheses about ecological relationships with experimental or observational data. They sometimes frame hypotheses in mathematical models.

51.2 Environmental Diversity of the Biosphere

- The biosphere encompasses all the regions on Earth where organisms live, including the atmosphere, hydrosphere, and lithosphere.
- Latitudinal variations in solar radiation establish global climate patterns (Figure 51.2). Earth's tilt on its axis causes seasonal variation in solar radiation and climate (Figure 51.3). Seasonal variations in day length and temperature increase steadily from tropical latitudes toward the poles.
- Unequal heating of the atmosphere causes air masses to flow in circulation cells that create worldwide wind and precipitation patterns (Figures 51.4 and 51.5). Ocean currents generally flow clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere (Figure 51.6).
- The oceans and local topographical features influence regional and local climates. Proximity to the ocean has a moderating effect on terrestrial climates (Figure 51.7). Habitats are generally wetter on the windward sides of mountains than on the leeward sides (Figure 51.8).

Animation: Air circulation and climate

Animation: Rain shadow effect

Animation: Sea Breeze

Animation: Coastal upwelling

51.3 Organismal Responses to Environmental Variation and Climate Change

- Organisms use homeostatic responses to cope with environmental variation. Animals often use facultative behavioral and physiological mechanisms to respond to environmental temperature (Figure 51.9).
- Global climate change is affecting the ecology of many organisms. Many species are experiencing changes in their geographical ranges or in the timing of their reproduction (Figure 51.10).

Animation: Disruptive selection among African finches

51.4 Terrestrial Biomes

- Biomes are general types of vegetation and other associated organisms. Climate is the major determinant of terrestrial biome distributions (Figures 51.11 and 51.12).
- Tropical forest occurs at low latitudes where seasonality is determined by variations in rainfall rather than by day length and temperature (Figure 51.13). Tropical rainforests are the most species-rich terrestrial biome, but they grow on nutrient-poor soils.
- Savanna is tropical and subtropical grassland with scattered trees (Figure 51.14). Long dry seasons, fires, and grazing by large mammals prevent trees from replacing perennial grasses.
- Deserts form in arid regions where precipitation is low and temperature varies widely on a daily and seasonal basis (Figure 51.15).
- Chaparral is a coastal biome dominated by dense, woody shrubs and trees that resprout after periodic fires (Figure 51.16). Chaparral occurs where winters are mild and wet and summers hot and dry.
- Temperate grassland grows where winters are cold, summers are warm, and rainfall is moderate (Figure 51.17). Tree seedlings are eliminated from grasslands by droughts, periodic fires, and grazing by mammals. Grassland soils are rich and deep.
- Temperate deciduous forest flourishes at middle latitudes with abundant rainfall. The seasonality of the climate is reflected in the annual loss and regrowth of leaves (Figure 51.18).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The boreal forest, or taiga, includes dense stands of coniferous trees at high latitudes, where winters are long and cold (Figure 51.19).
- Tundra is the northernmost biome, where plants grow in shallow topsoil over a layer of permafrost (Figure 51.20). The brief growing season and winter winds cause tundra plants to be very short.

51.5 Freshwater Environments

- Freshwater environments include both flowing-water and standing-water systems.
- The physical characteristics of flowing-water environments change from the headwaters of a stream to the mouth of a river (Figure 51.21).
- The physical characteristics of standing-water environments change with the depth of water and distance from shore (Figures 51.22 and 51.23). Lakes exhibit marked vertical zonation and, in the temperate zone, undergo a seasonal mixing of their waters (Figure 51.24). Lakes are generally classified by their nutrient status and productivity (Figure 51.25).

Animation: Lake zonation

51.6 Marine Environments

- The oceans exhibit marked zonation based on water depth and distance from shore (Figure 51.26).
- Estuaries are highly productive tidal environments where rivers provide a constant input of nutrients and freshwater, and the tides carry away wastes (Figure 51.27).
- The intertidal zone is a stressful environment that is alternately submerged and exposed (Figure 51.28).
- Highly productive and diverse shallow-water communities thrive on continental shelves and oceanic banks. Kelp forests predominate at high latitudes, whereas coral reefs occur in the tropics (Figure 51.29).
- The open ocean is highly stratified because photosynthesis is possible only in the uppermost 50 m of water. Plankton are the primary producers in the uppermost layers (Figure 51.30). The deep sea includes many predatory species (Figure 51.31).
- Organisms of the sea floor occupy the benthic province. Falling detritus supports most benthic communities, but chemosynthetic bacteria support communities near deep-sea hydrothermal vents (Figure 51.32) and cold seeps.

Animation: Oceanic zones

UNDERSTAND & APPLY

Test Your Knowledge

1. The lithosphere includes all:
   a. oceans.
   b. ice caps.
   c. rocks, soils, and sediments.
   d. gases and airborne particles.
   e. places where organisms live.
2. Earth's 23.5° tilt on its axis directly causes:
   a. latitudinal variation in average annual rainfall.
   b. ocean currents to rotate clockwise in the Northern Hemisphere.
   c. microclimates to vary dramatically over short distances.
   d. low rainfall on the leeward side of mountain ranges.
   e. seasonal variation in the amount of solar radiation.
3. Adiabatic cooling causes rising air masses to:
   a. absorb moisture from Earth's surface.
   b. release precipitation.
   c. change the direction of the El Niño current.
   d. flow toward the equator from the poles.
   e. be deflected from a strictly northward or southward flow.
4. The term "rain shadow" describes the:
   a. low rainfall that is typical on the leeward side of mountains.
   b. low rainfall that is typical at 30° latitude.
   c. high rainfall that is typical on the windward side of mountains.
   d. blocking of rain by vegetation in dense tropical forests.
   e. low rainfall that is typical in the interior of continents.
5. The major climatic factors that govern the distributions of terrestrial biomes are:
   a. temperature only.
   b. rainfall only.
   c. wind speed only.
   d. temperature and rainfall.
   e. temperature, rainfall, and wind speed.
6. Which biome experiences the highest annual rainfall?
   a. tropical rainforest
   b. tropical savanna
   c. chaparral
   d. temperature grassland
   e. arctic tundra
7. From which biome are trees excluded by periodic fires and grazing herbivores?
   a. tropical rainforest
   b. thorn forest
   c. chaparral
   d. temperate grassland
   e. arctic tundra
8. The major source of nutrients in the headwaters of a small stream is from:
   a. dead leaves and other organic matter from adjacent land.
   b. photosynthesis by phytoplankton.
   c. photosynthesis by floating aquatic plants.
   d. the activity of chemoautotrophic bacteria.
   e. minerals from the underlying bedrock.
9. During the spring overturn in a temperate zone lake:
   a. oxygen is carried from the surface to the bottom, and nutrients are carried from the bottom to the surface.
   b. nutrients are carried from the surface to the bottom, and oxygen is carried from the bottom to the surface.
   c. nutrients and oxygen are carried from the bottom waters to the surface waters.
   d. nutrients and oxygen are carried from the surface waters to the bottom waters.
   e. oxygen concentration remains constant at all depths, and nutrients sink to the bottom.

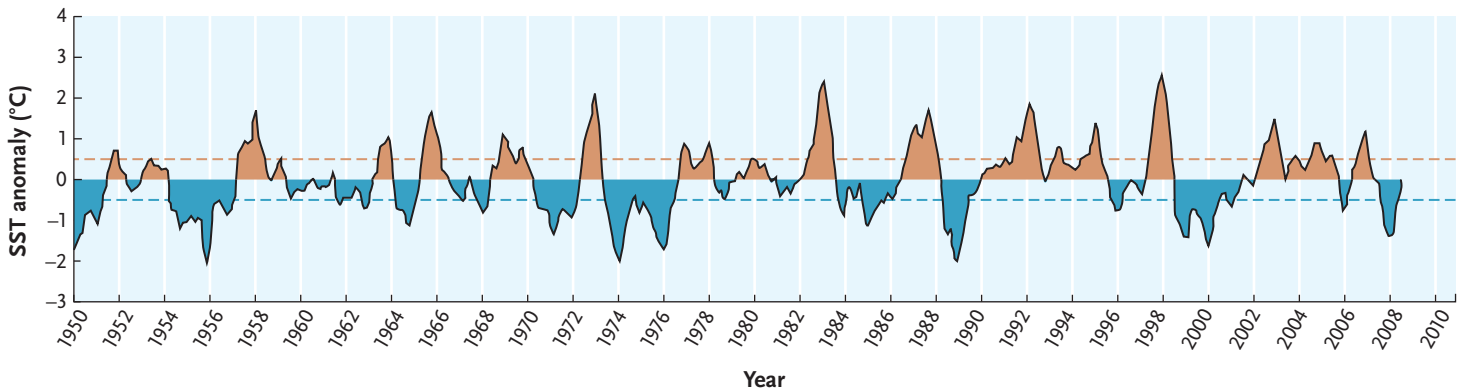
10. In which habitat must organisms adjust regularly to changing salinity?
    a. salt marsh
    b. coral reef
    c. benthic province
    d. estuary
    e. riffle

Discuss the Concepts

1. Temperate grassland and chaparral often burn in lightning-induced fires, which stimulate the germination of seeds and regrowth of existing vegetation. Do you think that companies or the government should sell fire insurance to people who build expensive homes in places where periodic fires are virtually inevitable?
2. Boreal forests generally harbor many fewer species of trees than tropical forests do. Develop three hypotheses to explain this pattern. What data would you collect to test your hypotheses?
3. Many regions have been developed for agriculture, industry, and human habitation. Have our activities created new biomes? What physical environments are created by development, and what plants and animals occupy developed areas?

Design an Experiment

Design an experiment to test the hypothesis that streams receive much of their nutrients and energy from material that falls into them from overhanging vegetation.



Apply Evolutionary Thinking

If the geographical ranges of species change in response to global warming, what new selection pressures will organisms face as they move into ecological communities where they have not previously occurred? Your answer should address the effects of novel species interactions as well as the effects of encountering different physical environments.

Interpret the Data

Climate scientists at NOAA, the National Oceanographic and Atmospheric Administration, collect data about sea surface temperature (SST) and atmospheric conditions to predict El Niño and La Niña events before they occur. Researchers then calculate SST anomalies, the differences between current SSTs and historical averages. *Positive* anomalies of 0.5°C or more indicate that surface waters are much warmer than usual, a sign that El Niño is coming. *Negative* anomalies of 0.5°C or more indicate that surface waters are much cooler than usual, a sign of an upcoming La Niña. Anomalies that are within 0.5°C of average SSTs are identified as neutral conditions. The accompanying **Figure** presents SST anomalies in the eastern Pacific Ocean from 1950 through 2008.

1. How many times have SSTs predicted a likely El Niño event or a likely La Niña event over the time represented in the graph?
2. Are all SST anomalies of equal magnitude and duration?
3. Is there a fixed pattern in the distribution of El Niño and La Niña events? In other words, does one type of event *always* follow the other?

52.1 Population Characteristics
52.2 Demography
52.3 The Evolution of Life Histories
52.4 Models of Population Growth
52.5 Population Dynamics
52.6 Human Population Growth

Population Ecology

Why it matters . . . When humans immigrate to new places, they often transport familiar plants and animals from home, introducing them into their new gardens, fields, and forests. Some organisms fail to survive in the new environments. But other species—like the European starlings *(Sturnus vulgaris)* and house sparrows *(Passer domesticus)* that are now so common in North America—flourish, and sometimes become pests.

In 1859, an Australian rancher released a few pairs of European rabbits *(Oryctolagus cuniculus)* for sport hunting in the state of Victoria. The rabbits bred rapidly, sometimes producing litters of four or five offspring every month. They had no natural predators in Australia, and by 1900, an estimated 20 million rabbits had overrun much of the continent. Their advance was limited only by extreme climates, clay soil, and lack of food or water. The rabbits destroyed natural vegetation and the pastures that supported a large sheep industry. The government tried in vain to poison the rabbits. Ranchers introduced predators, hoping that they would eat rabbits faster than the rabbits could reproduce. But the rabbits continued to multiply. Eventually, the government built a "rabbit-proof fence" that stretched more than 3,200 km (2,000 miles) to keep the rabbits out of the rich pasture lands in Western Australia **(Figure 52.1).**

In 1950, scientists tackled the devastating problems caused by the introduced rabbits. Biologists collected myxoma virus (a relative of smallpox) from infected rabbits in South America and released it among the European rabbits in Australia. The virus was lethal to European rabbits, which had never evolved resistance to it. The first epidemic of myxomatosis killed more than 99% of infected rabbits. But in the following season, the virus killed only 90% of infected rabbits, and within a few years, the virus was killing only half the rabbits it infected. Clearly, some rabbits were becoming more resistant to the virus. Resistant rabbits survived and reproduced, comprising a larger percentage of the population over time (see Section 21.3 to review

FIGURE 52.1 Introduced organisms. European rabbits multiplied so rapidly and destroyed so much vegetation in Australia that the government built a fence across the country to prevent their spread.

natural selection). Subsequent research showed that the virus had also become less virulent. Today, wildlife-control agents develop and release more deadly viruses to control the rabbit population.

This brief history of an introduced population identifies several questions about **population dynamics**—how the characteristics of populations change through time and vary from place to place—that we consider in this chapter. For example, why do some populations, like the rabbits in Australia, grow explosively, whereas others maintain reasonably stable numbers over long periods of time? How do interactions with abiotic and biotic factors in the environment influence the characteristics of populations? Finally, how do populations respond evolutionarily to their interactions with the environment?

52.1 Population Characteristics

Populations have characteristics that transcend those of the individuals they comprise. For example, every population has a **geographical range,** the overall spatial boundaries within which it lives. Geographical ranges vary enormously. A population of snails might inhabit a small tidepool, whereas a population of marine phytoplankton might occupy an area that is orders of magnitude larger. Every population also occupies a **habitat,** the specific environment in which it lives, as characterized by its biotic and abiotic features. Ecologists also measure other population characteristics, such as size, distribution in space, and age structure.

A Population's Size and Density Determine the Amount of Resources It Uses

Population size is simply the number of individuals in a population at a specified time. **Population density** is the number of individuals per unit area or per unit volume of habitat. Species with large body sizes generally have lower population densities than species with smaller body sizes **(Figure 52.2).** Although population size and density are related measures, knowing a population's density provides more information about its relationship to the resources it uses. For example, if a population of 200 oak trees occupies 1 hectare (10,000 m^2), its population density is 200/10,000 m^2 or one tree per 50 m^2. But if a population of 200 oaks is spread over 5 hectares, its density is one tree per 250 m^2. Clearly, the second population is less dense than the first, and its members will have greater access to sunlight, water, and other resources.

Ecologists measure population size and density to monitor and manage populations of endangered species, economically important species, and agricultural pests. For large-bodied species, a simple head count provides accurate information. For example, ecologists survey the size and density of African bush elephant *(Loxodonta africana)* populations by flying over herds and counting individuals. Researchers use a variation on that technique to estimate population size in tiny organisms that live at high population densities. To estimate the density of aquatic phytoplankton, for example, you might collect water samples of known volume from representative areas in a lake and use a microscope to count the organisms; you could then extrapolate their population size and density based on the estimated volume of the entire lake. In other cases, researchers use the mark-release-recapture sampling technique **(Figure 52.3).**

Populations Differ in How They Are Distributed in Space

Populations also vary in their **dispersion,** the spatial distribution of individuals within the geographical range. Ecologists define three theoretical patterns of dispersion: *random, clumped,* and *uniform* **(Figure 52.4).**

For some populations, environmental conditions don't vary much within a habitat, and individuals are neither attracted to nor repelled by others of their species. These populations exhibit **random dispersion,** which has a formal statistical definition that serves as a theoretical baseline for assessing whether organisms are clumped or uniformly distributed. In cases of random dispersion, individuals are distributed unpre-

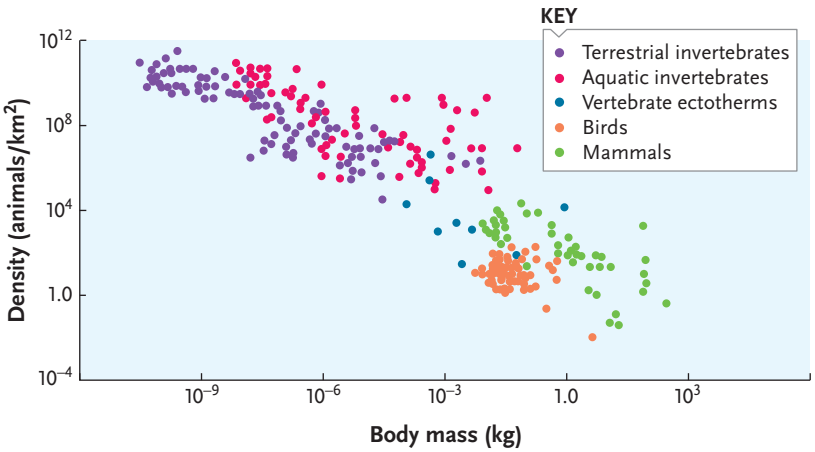

FIGURE 52.2 Population density and body size. Population density generally declines with increasing body size among animal species. Similar trends exist for other types of organisms.

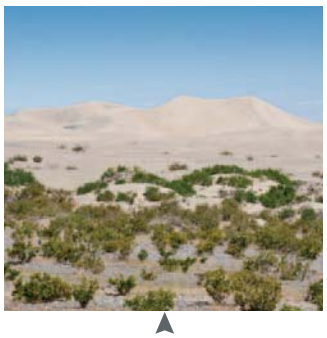
FIGURE 52.3 **Research Method**

Using Mark-Release-Recapture to Estimate Population Size

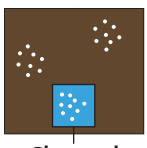
Purpose: Ecologists use the mark-release-recapture technique to estimate the population size of mobile animals that live within a restricted geographic range.

Protocol: A sample of organisms is captured, marked in some permanent but harmless way, and released. Insects and reptiles are marked with ink or paint, birds with rings on their legs, and mammals with ear tags or collars. Some time later, a second sample of organisms is captured, and the researcher notes what proportion of the second sample carries the mark. That proportion tells us what percentage of the total population was captured and marked at the first sampling. The total population size is estimated as (number marked) × (number in the second sample/number of marked recaptures).



Michael C. Singer, University of Texas

Interpreting the Results: Imagine that you capture 120 butterflies, mark each with a black spot on its wing, and release them. A week later, you capture a second sample of 150 butterflies, and find that 30 of them have the black mark. Thus, you had marked one out of every five butterflies (30/150) on your first field trip. Because you captured 120 individuals on that first excursion, you would estimate that the total population size is 120 × (150/30) = 600 butterflies.



The technique is based on several assumptions that are critical to its accuracy: (1) that being marked has no effect on survival; (2) that marked and unmarked animals mix randomly in the population; (3) that no migration into or out of the population takes place during the estimating period; and (4) that marked individuals are just as likely to be captured as unmarked individuals. (Sometimes animals become "trap shy" or "trap happy," a violation of the fourth assumption.)

Clumped

A clumped dispersion pattern is one in which individuals are grouped more closely to each other than if they are randomly dispersed.

Random

A random dispersion pattern, in which organisms are distributed independently of each other, serves as a statistical yardstick for evaluating other dispersion patterns.

Uniform

A uniform dispersion pattern is one in which individuals are more widely separated from each other than they are if they are randomly dispersed.

dictably. Some spiders, burrowing clams, and rainforest trees exhibit random dispersion.

Three reasons explain why a **clumped dispersion**—with individuals grouped together—is extremely common in nature. First, suitable conditions often have a patchy distribution. For example, certain pasture plants may be clumped in small, scattered areas where cowpats fell months before, locally enriching the soil. Second, some animals live in social groups (see Section 56.7). Mates are easy to locate within groups, and individuals may cooperate in rearing offspring, feeding, or defending themselves from predators. Third, some organisms are clumped because of their reproductive pattern. Plants and animals that produce asexual clones, such as aspen trees and sea anemones, often occur in large aggregations (see Chapters 36 and 49). In other species, seeds, eggs, or larvae lack dispersal mechanisms, and offspring grow near their parents.

When the individuals in a population repel each other because resources are in short supply, they tend to be evenly spaced in their habitat, a pattern called **uniform dispersion.** For example, creosote bushes *(Larrea tridentata)* are uniformly distributed in the dry scrub deserts of the American Southwest. Mature bushes deplete the surrounding soil of water and secrete toxic chemicals, making it impossible for seedlings to grow. Moreover, seed-eating ants and rodents that live at the base of mature bushes consume any seeds that fall nearby. Territorial behavior, the defense of an area and its resources, produces uniform dispersion in animals (see Section 56.4).

Whether the spatial distribution of a population appears to be random, clumped, or uniform depends partly on how large an area an ecologist studies. Oak seedlings may be randomly dispersed on a spatial scale of a few square meters, but over an entire mixed hardwood forest, they are clumped under the parent trees.

FIGURE 52.4 **Dispersion patterns.** Schooling fishes, like these Maldives bulleyes *(Priacanthus hamrur)* from the Indian Ocean, exhibit a clumped pattern of dispersion. A random pattern of dispersion, which is fairly rare in nature, occurs in organisms that are neither attracted to nor repelled by each other. Creosote bushes *(Larrea tridentata)* in Death Valley, California, exhibit uniform dispersion.

In addition, the dispersion of animal populations often varies through time in response to natural environmental rhythms. Few habitats provide a constant supply of resources throughout the year, and many animals move from one habitat to another on a seasonal cycle. For example, tropical birds and mammals are often widely dispersed in deciduous forests during the wet season. But during the dry season, they crowd into narrow "gallery forests" along watercourses where evergreen trees provide food and shelter.

A Population's Age Structure, Generation Time, and Sex Ratio Influence How Quickly It Will Grow

All populations have an **age structure,** a statistical description of the relative numbers of individuals in each age class (see Section 52.6). Individuals can be roughly categorized as prereproductive (younger than the age of sexual maturity), reproductive, or postreproductive (older than the maximum age of reproduction). A population's age structure reflects its recent growth history and predicts its future growth potential. Populations that include many prereproductive individuals grew rapidly in the recent past and will continue to grow larger as the young individuals mature and reproduce.

Another characteristic that influences a population's growth is its **generation time,** the average time between the birth of an organism and the birth of its offspring. Generation time is usually short in species that reach sexual maturity at a small body size **(Figure 52.5).** Their populations often grow rapidly because of the speedy accumulation of reproductive individuals.

Populations also vary in their **sex ratio,** the relative proportions of males and females. In general, the number of females in a population has a bigger impact on population growth than the number of males because only females actually produce offspring. Moreover, in many species, one male can mate with several females, and the number of males may have little effect on the population's reproductive output. In northern elephant seals *(Mirounga angustirostris),* for example, mature bulls fight for dominance on the beaches where the seals mate, and only a few males may ultimately inseminate a hundred or more females. Thus, the presence of other males in the group has little effect on the size of future generations. However, in animals that form lifelong pair bonds, such as geese and swans, the number of males does influence reproduction in the population.

Population ecologists often try to determine the proportion of individuals in a population that are reproducing. This issue is particularly relevant to the conservation of any species in which individuals are rare or widely dispersed in the habitat (see Section 55.5). As *Insights from the Molecular Revolution* describes, ecologists now use DNA analysis to address this question. In the next section, we consider factors that influence the age structure of a population and its potential for future growth.

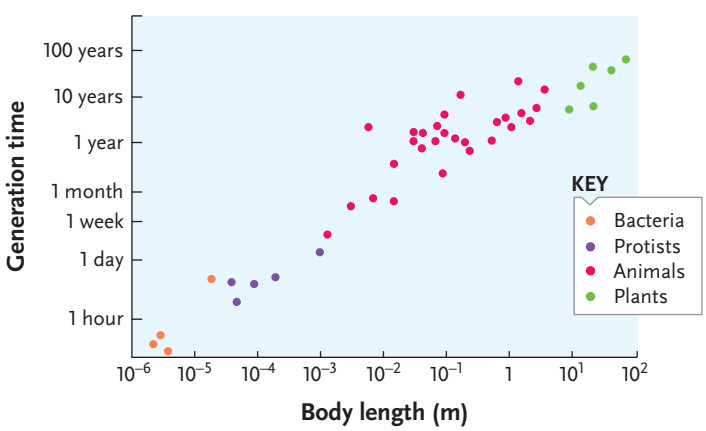

FIGURE 52.5 Generation time and body size. Generation time increases with body size among bacteria, protists, plants, and animals. The logarithmic scale on both axes compresses the data into a straight line.

STUDY BREAK 52.1

1. What is the difference between a population's size and its density?
2. What do the three patterns of dispersion imply about the relationships between individuals in a population?

THINK OUTSIDE THE BOOK

Try to estimate the size of a population of plants or animals that live near your home or campus. Start by defining the boundaries of the population, identify the method you would use, and then make the estimate. How does the type of organism you are studying affect the accuracy of your estimate?

52.2 Demography

Populations grow larger through the birth of individuals and the **immigration** (movement into the population) of organisms from neighboring populations. Conversely, death and **emigration** (movement out of the population) reduce population size. **Demography** is the statistical study of the processes that change a population's size and density through time.

Ecologists use demographic analysis to predict a population's future growth. For human populations, these data help governments anticipate the need for social services such as schools and hospitals. Demographic data also allow conservation ecologists to develop plans to protect endangered species. For example, demographic data on the northern spotted owl *(Strix occidentalis caurina)* helped convince the courts to restrict logging in the owl's primary habitat, the old growth forests of the Pacific Northwest. *Life tables* and *survivorship curves* are among the tools ecologists use to analyze demographic data.

Asocial Armadillos: Can armadillo reproductive patterns explain the expansion of their range?

Relatively little is known about the behavior of nine-banded armadillos (*Dasypus novemcinctus,* pictured in Figure 20.6). They are slow moving and solitary animals, yet they have spread from Mexico and southern Texas through most of the southern United States in only 100 years.

Research Question

Given their almost completely asocial behavior, what proportion of an armadillo population successfully mates? And, given their slow movements, how did they expand their range?

Experiment

Paulo A. Prodöhl and his colleagues at the University of Georgia, University of Washington, and Valdosta State University used molecular techniques to answer these questions. Their previous work had identified seven short tandem repeat (STR) loci in the armadillo genome. An STR locus consists of a segment of a chromosome with a short sequence repeated in series (see Section 18.2). In this case, the loci are approximately 200 bp long with 2-bp and 4-bp repeated sequences. Alleles of each locus vary in length because they differ in the number of copies of the repeated sequences. Because alleles of STR loci are inherited in the same way as alleles of genes, the researchers could trace parentage and migration patterns by comparing the allelic variations of the STR loci, in a manner analogous to human DNA fingerprinting.

Researchers collected small tissue samples from the ears of 290 armadillos living in the Tall Timbers Research Station near Tallahassee, Florida. They extracted genomic DNA from the tissue sample and used the polymerase chain reaction (PCR) to amplify alleles for each of the seven STR loci. They used gel electrophoresis to determine the sizes of the fragments amplified by PCR. The molecular techniques involved are discussed in Chapter 18.

Results

The investigators determined the relatedness of juveniles and adults using statistical methods to compare the gel patterns produced by their DNA **(Figure).** Adult males and females with gel patterns most similar to those of a given juvenile were considered to be its parents. When the data identified more than two possible parents, the male and female living closest to a juvenile were scored as the most likely candidates. These techniques allowed the investigators to assign parents to 69 juveniles. Only seven juveniles could not be assigned parents, possibly because the parents had died, avoided capture, or emigrated from the population.

Conclusion

The results from four years of study suggest that 36% to 46% of adult armadillos reproduced at least once, despite their asocial habits—a moderately successful reproductive rate. In general, parents and offspring lived between 800 and 1,500 m of each other, and individuals were usually recaptured within a 200-m radius of the same spot from season to season and from one year to the next. Thus, migration appears to be very limited, leaving the basis of their rapid spread unexplained.

THINK LIKE A SCIENTIST When the data on STR loci identified more than one possible set of parents for a juvenile armadillo in the sample, the researchers scored the adult male and female living closest to the juvenile as its probable parents. What effect might this assumption have on the estimate of how far an individual armadillo might move in its lifetime.

Source: P. A. Prodöhl et al. 1998. Genetic maternity and paternity in a local population of armadillos assessed by microsatellite DNA markers and field data. *American Naturalist* 151:7–19.

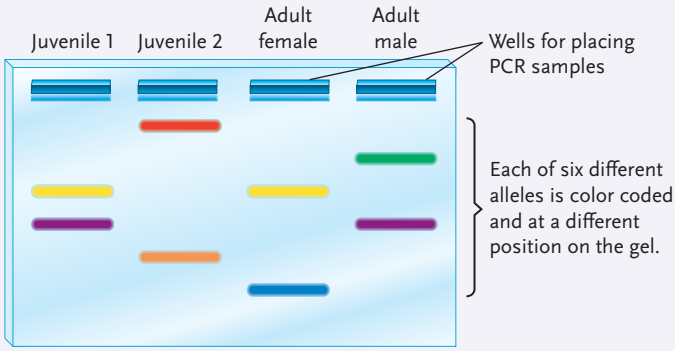

FIGURE Theoretical gel electrophoresis result for STR alleles at one locus for two juveniles and an adult female and male. Juvenile 1 could be the offspring of the two adults because its two alleles match alleles present in the two parents. However, Juvenile 2 could not be the offspring of these two parents because neither of its alleles could have come from those two adults.

Life Tables Summarize a Population's Survival and Reproductive Rates

Although every species has a characteristic life span, few individuals survive to the maximum age possible. Mortality results from starvation, disease, accidents, predation, or the inability to find a suitable habitat. Life insurance companies first developed techniques for measuring mortality rates, but ecologists adapted these approaches to the study of nonhuman populations.

A **life table** summarizes the demographic characteristics of a population **(Table 52.1).** To collect life-table data for short-lived organisms, demographers typically mark a **cohort,** a group of individuals of similar age, at birth and monitor their survival until all members of the cohort die. For organisms that live more than a few years, a researcher might sample the population for one or two years, recording the ages at which individuals die, and then extrapolate those results over the species' life span.

In any life table, the life span of the organisms is divided into age intervals of convenient length: days, weeks, or months for short-lived species; years or groups of years for longer-lived species. Mortality can be expressed in two complementary ways. **Age-specific mortality** is the proportion of individuals

alive at the start of an age interval that died during that age interval. Its more cheerful reflection, **age-specific survivorship,** is the proportion of individuals alive at the start of an age interval that survived until the start of the next age interval. Thus, in Table 52.1, the age-specific mortality rate during the three-to-six-month age interval is 195/722 = 0.270, and the age-specific survivorship rate is 527/722 = 0.730. For any age interval, the sum of age-specific mortality and age-specific survivorship always equals 1. Life tables also summarize the proportion of the cohort that survived to a particular age, a statistic that identifies the probability that any randomly selected newborn will still be alive at that age. For the 3-to-6-month age interval in Table 52.1, this probability is 722/843 = 0.856.

Life tables also include data on **age-specific fecundity,** the average number of offspring produced by surviving females during each age interval. Table 52.1 shows, for example, that plants in the 3-to-6-month age interval each produced an average of 300 seeds. In some species, including humans, fecundity is highest in individuals of intermediate age. Younger individuals have not yet reached sexual maturity, and older individuals are past their reproductive prime. However, in some plants and animals, fecundity increases steadily with age.

Survivorship Curves Depict Changes in Survival Rate over the Life Span

Survivorship data are depicted graphically in a **survivorship curve,** which displays the rate of survival for individuals over the species' average life span. Ecologists have identified three generalized survivorship curves (blue lines in **Figure 52.6**), al-

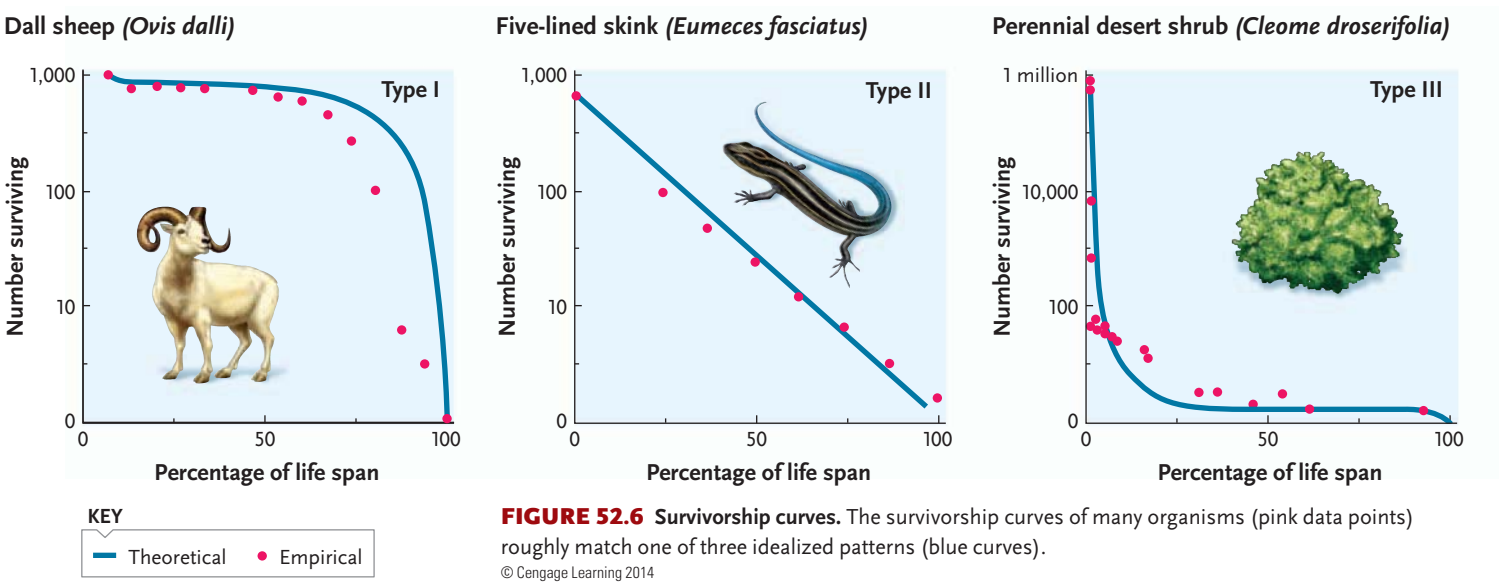

FIGURE 52.6 **Survivorship curves.** The survivorship curves of many organisms (pink data points) roughly match one of three idealized patterns (blue curves).

though most organisms exhibit survivorship patterns that fall between these idealized patterns.

Type I curves reflect high survivorship until late in life, when mortality takes a great toll. Type I curves are typical of large animals that produce few young and provide them with extended care, which reduces juvenile mortality. For example, large mammals, such as the Dall's sheep *(Ovis dalli),* produce only one or two offspring at a time and nurture them through their vulnerable first year.

Type II curves reflect a relatively constant rate of mortality in all age classes, a pattern that produces steadily declining survivorship. Many lizards, such as the five-lined skink *(Eumeces fasciatus),* as well as songbirds and small mammals, face a constant probability of mortality from predation, disease, and starvation.

Type III curves reflect high juvenile mortality, followed by a period of low mortality once the offspring reach a critical age and size. For example, *Cleome droserifolia,* a desert shrub from the Middle East, experiences extraordinarily high mortality in its seed and seedling stages. Researchers estimate that for every million seeds produced, fewer than 1,000 germinate, and only about 40 individuals survive their first year. Once a plant becomes established, however, its likelihood of future survival is higher, and the survivorship curve flattens out. Many plants, insects, marine invertebrates, and fishes exhibit type III survivorship.

52.3 The Evolution of Life Histories

The analysis of life tables reveals how natural selection has produced different **life histories**—the lifetime patterns of growth, maturation, and reproduction—that maximize the number of surviving offspring an individual produces.

Organisms Face Trade-Offs in Their Allocation of Resources

Every organism is constrained by a finite **energy budget,** the total amount of energy that it can accumulate and use to fuel its activities. An organism's energy budget is like a savings account. When the individual accumulates more energy than it needs, it makes deposits to this account—energy is stored as starch, glycogen, or fat. When it expends more energy than it harvests, it makes withdrawals from its energy stores. But unlike a bank account, an organism's energy budget cannot be overdrawn, and no loans against future "earnings" are possible.

Organisms use the energy they harvest for three broadly defined functions: maintenance (the preservation of good physiological condition), growth, and reproduction. And when an organism devotes energy to any one of these functions, the balance in its energy budget is reduced, leaving less energy for the other functions.

Life History Patterns Vary Dramatically among Species

A fish, a deciduous tree, and a mammal illustrate the dramatic variations that exist in life history patterns **(Figure 52.7).** Larval coho salmon *(Oncorhynchus kisutch)* hatch in the headwaters of a stream, where they feed and grow for about a year before assuming their adult body form. After swimming downstream to the ocean, they remain at sea for a year or two, feeding voraciously and growing rapidly. Eventually, salmon use sun-compass, geomagnetic, and chemical cues to return to the rivers and streams where they hatched. The fishes swim upstream, and each female lays hundreds or thousands of relatively small eggs. After spending all of their energy reserves on the upstream journey and reproduction, their condition deteriorates and they die.

Most deciduous trees in the temperate zone, such as oaks (genus *Quercus*), begin their lives as seeds in late summer. The seeds remain metabolically inactive until the following spring or a later year. After germinating, trees collect nutrients and energy and continue to grow throughout their lives. Once they achieve a critical size, they may produce thousands of seeds annually for many years. Thus, growth and

reproduction occur simultaneously through much of the trees' life.

European red deer *(Cervus elaphus)* are born in spring, and young remain with their mothers for an extended period, nursing and growing rapidly. After weaning, they feed on their own. Female red deer begin to breed after reaching adult size in their third year, producing one or two offspring annually until they are about 16 years old, when they reach their maximum life span and die.

How can we summarize the similarities and differences in the life histories of these organisms? All three species harvest energy throughout their lives. Salmon and deciduous trees continue to grow until old age, whereas deer reach adult size fairly early in life. Salmon produce many offspring in a single reproductive episode, whereas deciduous trees and deer reproduce repeatedly. However, most trees produce thousands of seeds annually, whereas deer produce only one or two young each spring.

What factors have produced these variations in life history patterns? Life history traits—like all population characteristics—are modified by natural selection. Thus, organisms exhibit evolutionary adaptations that increase the fitness of individuals. Each species' life history is, in fact, a highly integrated "strategy"—not in the human sense of planning ahead, but as a suite of selection-driven adaptations.

Ecologists Analyze the Individual Components of Life Histories

In analyzing life histories, ecologists often compare the number of offspring produced with the amount of care provided to each. They also consider the number of reproductive episodes in the organism's lifetime, and the age at which it first reproduces. Because these characteristics evolve together, a change in one trait is likely to influence the success of the others.

FECUNDITY VERSUS PARENTAL CARE

If a female has a fixed amount of energy for reproduction, she can package that energy in various ways. By way of illustration, a female duck with 1,000 units of energy for reproduction might lay 10 eggs that each contain 100 units of energy. A salmon, which has higher fecundity, might lay 1,000 eggs, each endowed with 1 unit of energy. The amount of energy invested in each offspring *before* it is born represents the **passive parental care** that the female provides. Passive parental care is provided through yolk in an egg, endosperm in a seed, or, in mammals, nutrients that cross the placenta.

Many animals, especially birds and mammals, also provide **active parental care** to offspring *after* their birth. In general, species that produce many offspring in a reproductive episode—such as the coho salmon—provide relatively little active parental care *to each offspring*. In fact, female coho salmon, which produce 2,400 to 4,500 eggs, die before their eggs even hatch. Conversely, species that produce only a few offspring at a time—such as the European red deer—provide a lot of care to each. A red deer doe nurses its single fawn for up to 8 months before weaning it.

ONE REPRODUCTIVE EPISODE VERSUS SEVERAL

A second life history characteristic adjusted by natural selection is the number of reproductive episodes in an organism's lifetime. Some organisms, like the coho salmon, devote all of their stored energy to a single reproductive event. Any adult that survives the upstream migration is likely to leave some surviving offspring. Other species, such as deciduous trees and red deer, reproduce multiple times. In contrast to salmon, individuals of these species devote only some of their energy budget to reproduction at any time, with the balance allocated to maintenance and growth. Moreover, in some plants, invertebrates, fishes, and reptiles, larger individuals produce more offspring than small ones do. Thus, one advantage of using only part of the energy budget for reproduction is that continued growth may result in greater fecundity at a later age. However, if an organism does not survive until the next breeding season, the potential advantage of putting energy into maintenance and growth is lost.

EARLY REPRODUCTION VERSUS LATE REPRODUCTION

Individuals that first reproduce at the earliest possible age may stand a good chance of leaving some surviving offspring. But the energy devoted to reproduction is no longer available for maintenance and growth. Thus, early reproducers may be smaller and less healthy than individuals that delay reproduction in favor of these other functions. Conversely, an individual that delays reproduction may increase its chance of survival and its future fecundity by becoming larger or more experienced. But there is always some chance that it will die before the next breeding season, leaving no offspring at all. Thus, a finite energy budget and the risk of mortality establish a trade-off in the timing of first reproduction. Mathematical models suggest that delayed reproduction will be favored by natural selection if a sexually mature individual has a good chance of surviving to an older age, if organisms grow larger as they age, and if larger organisms have higher fecundity. Early reproduction will be favored if adult survival rates are low, if animals don't grow larger as they age, or if larger size does not increase fecundity.

Life history characteristics not only vary from one species to another, but they also vary among populations of a single species. *Focus on Basic Research* describes how predation influences life history characteristics in natural populations of guppies *(Poecilia reticulata)* in Trinidad.

The Evolution of Life History Traits in Guppies

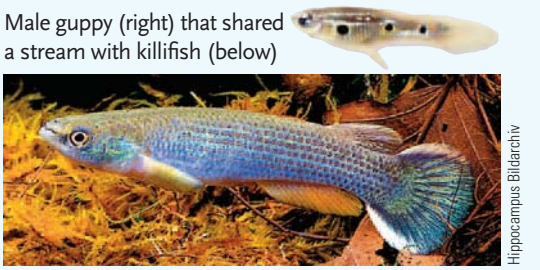
Some years ago, drenched with sweat and with fishnets in hand, two ecologists were engaged in fieldwork on the Caribbean island of Trinidad **(Figure A).** They were after guppies *(Poecilia reticulata)*—small fish that bear live young in shallow mountain streams. John Endler and David Reznick, then of the University of California, Santa Barbara, were studying the environmental variables that influence the evolution of life history patterns in guppies.

Male guppies are easy to distinguish from females. Males, which stop growing at sexual maturity, are smaller, and their scales have bright colors that serve as visual signals in intricate courtship displays. The drably colored females continue to grow larger throughout their lives.

David Reznick/University of California, Riverside

FIGURE A **David Reznick surveys a shallow stream in the mountains of Trinidad.**

In the mountains of Trinidad, guppies living in different streams—and even in different parts of the same stream—are eaten by one of two other fish species **(Figure B).** In some streams, a large pike-cichlid *(Crenicichla alta)* prefers mature guppies and tends not to spend time hunting small, immature ones. In other streams, a small killifish *(Rivulus hartii)* preys on immature guppies but does not have much success with the larger adults.



Reznick and Endler found that the life history patterns of guppies vary among streams with different predators. In streams with pike-cichlids, both male and female guppies mature faster and begin to reproduce at a smaller size and a younger age than their counterparts in streams where killifish live **(Figure C).** In addition, female guppies from pike-cichlid streams reproduce more often and produce smaller and more numerous young **(Figure D).** These differences allow guppies to avoid some predation. Those in pike-cichlid streams begin to reproduce when they are smaller than the size preferred by that predator. And those from killifish streams grow quickly to a size that is too large to be consumed by killifish.

FIGURE B **Male guppies from streams where pike-cichlids live (top) are smaller, more streamlined, and have duller colors than those from streams where killifish live (bottom).** The pike-cichlid prefers to eat large guppies, and the killifish feeds on small guppies. Guppies are shown approximately life-size; adult pike-cichlids grow to 16 cm in length, and adult killifish grow to 10 cm.

52.4 Models of Population Growth

We now examine mathematical models of population growth that describe very different responses to changes in a population's density. *Geometric* and *exponential* models apply when populations experience unlimited growth. The *logistic* model applies when population growth is limited, often because available resources are finite. These simple models are tools that help ecologists refine their hypotheses, but neither provides entirely accurate predictions of population growth in nature. In the simplest versions of these models, ecologists define births as the production of offspring by any form of reproduction, and ignore the effects of immigration and emigration.

Geometric and Exponential Models Describe Population Growth without Limitation

Sometimes populations increase in size for a period of time with no apparent limits on their growth. In models of unlimited population growth, population size increases steadily by a constant ratio **(Figure 52.8).** Bacterial populations provide the most obvious examples, but multicellular organisms also sometimes exhibit exponential population growth.

GEOMETRIC POPULATION GROWTH Bacteria reproduce by binary fission: a parent cell divides in half, producing two daughter cells, which each divide to produce two granddaughter cells. Generation time in a bacterial population is simply the time between successive cell divisions. And if no bacteria in the population die, the population doubles in size each generation. This pattern of population growth is described as "geometric," because the population grows by a constant multiplier every generation; in our example of binary fission in bacteria, the multiplier is 2.

Bacterial populations grow quickly under ideal temperatures and with unlimited space and food. Consider a laboratory population of the human intestinal bacterium *Escherichia coli,* for which the generation time can be as short as 20 minutes. If we start with a population of one bacterium, the population doubles to two cells after one generation, to four cells after two generations, and to eight cells after three generations

Although these life history differences were correlated with the distributions of the two predatory fishes, they might result from some other, unknown differences between the streams. Endler and Reznick investigated this possibility with controlled laboratory experiments. They shipped groups of guppies to California, where they bred guppies from each kind of stream for two generations. Both experimental populations were raised under identical conditions in the absence of predation. Even when predators were absent, the two experimental populations retained their life history differences. These results provided evidence of a heritable genetic basis for the observed life history differences.

Endler and Reznick also examined the role of predators in the *evolution* of the size differences. They raised guppies for many generations in the laboratory under three experimental conditions—some alone, some with killifish, and some with pike-cichlids. As predicted, the guppy lineage that was subjected to predation by killifish became larger at maturity. Individuals that were small at maturity were frequently eaten, and their reproduction was limited. The lineage that was raised with pike-cichlids showed a trend toward earlier maturity. Individuals that matured at a larger size faced a greater likelihood of being eaten before they had reproduced.

Finally, when they first visited Trinidad, Endler and Reznick had introduced guppies from a pike-cichlid stream into another stream that contained killifish but no pike-cichlids or guppies. Eleven years later, the introduced guppy population had changed. As the researchers predicted, the guppies had become larger in size and reproduced more slowly, characteristics that are typical of natural guppy populations that live and die with killifish.

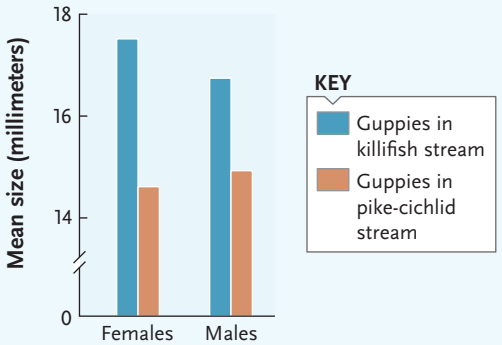

FIGURE C **Guppies in streams occupied by pike-cichlids are smaller than those in streams occupied by killifish.**

(Figure 52.8A). After only eight hours, or 24 generations, the population will number more than 16 million. And after a single day, or 72 generations, the population will number nearly 5×10^{21} cells. Although other bacteria grow more slowly than *E. coli,* it is no wonder that pathogenic bacteria, such as those causing cholera or plague, can quickly overtake the defenses of an infected animal.

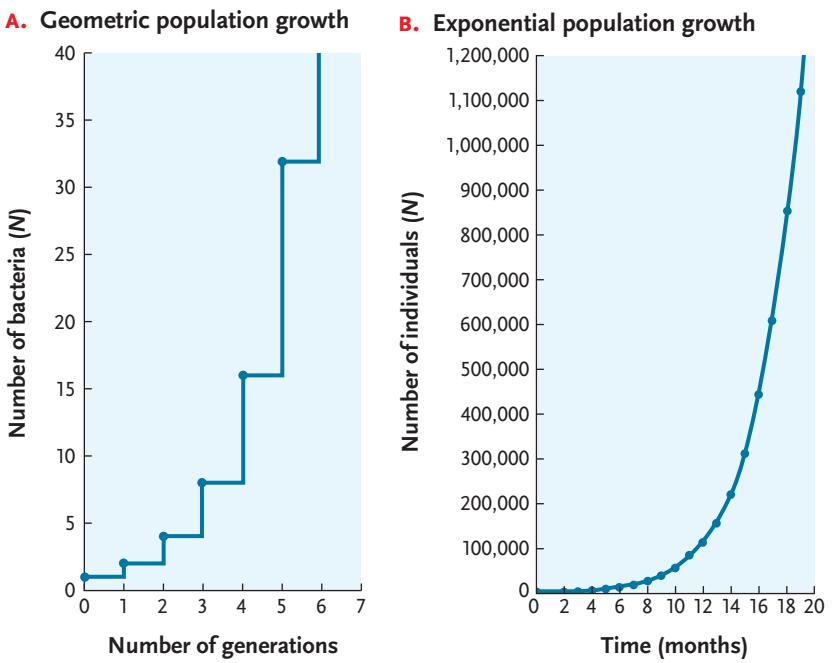

FIGURE 52.8 **Changes in population size predicted by two models of unlimited population growth. (A)** If all members of a bacterial population divide simultaneously, a plot of population size over time forms a stair-stepped curve in which the steps get larger as the number of dividing cells increases. **(B)** Exponential population growth produces a J-shaped curve of population size plotted against time. Although the per capita growth rate r remains constant, the increase in population size gets larger every month because more individuals are reproducing.

EXPONENTIAL POPULATION GROWTH IN OTHER ORGANISMS

By contrast to bacteria, many plants and animals live side-by-side with their offspring. In these populations, births increase a population's size and deaths decrease it. Over a given time period:

Change in population size =
Number of births − Number of deaths

We express this relationship mathematically by defining N as the population size; ΔN (pronounced "delta N") as the change in population size; Δt as the time period during which the change occurs; and B and D as the absolute numbers of births and deaths, respectively, *during that time period.* Thus, $\Delta N/\Delta t$ symbolizes the change in population size over time, and

$$\Delta N/\Delta t = B - D$$

The preceding equation applies to any population for which we know the exact numbers of births and deaths.

Ecologists usually express births and deaths as *per capita* (per individual) rates, allowing them to apply the model to a population of any size. The per capita birth rate, symbolized *b,* is simply the number of births in the population during the specified time period divided by the population size: $b = (B/N)$. Similarly, the per capita death rate, *d,* is the number of deaths divided by the population size: $d = (D/N)$. If, for example, in a population of 2,000 field mice, 1,000 mice are born and 200 mice die during one month, then $b = 1{,}000/2{,}000 = 0.5$ births per individual per month, and $d = 200/2{,}000 = 0.1$ deaths per individual per month. Of course, no mouse can give birth to half an offspring, and no individual can die one-tenth of a death. But these rates tell us the per capita birth and death rates *averaged over all mice in the population.* Per capita birth and death rates are always expressed over a specified time period. For long-lived organisms, such as humans, time is measured in years; for short-lived organisms, such as fruit flies, time is measured in days. We can calculate per capita birth and death rates from data in a life table.

We can now revise the population growth equation to use per capita birth and death rates instead of the actual numbers of births and deaths. The change in a population's size during a given time period ($\Delta N/\Delta t$) depends on the per capita birth and death rates, as well as on the number of individuals in the population. Mathematically, we can write

$$\Delta N/\Delta t = B - D = bN - dN = (b - d)N$$

or, in the notation of calculus,

$$dN/dt = (b - d)N$$

This equation describes the **exponential model of population growth.** (Note that in calculus, dN/dt is the notation for the population growth rate; the "d" in dN/dt is *not* the same "d" that we use to symbolize the per capita death rate.)

The difference between the per capita birth rate and the per capita death rate, $b - d$, is the **per capita growth rate** of the population, symbolized by *r.* Like b and d, r is always expressed per individual per unit time. Using the per capita growth rate, r, in place of $(b - d)$, the exponential growth equation is written

$$dN/dt = rN$$

If the birth rate exceeds the death rate, r has a positive value ($r > 0$), and the population is growing. In our example with field mice, $r = 0.5 - 0.1 = 0.4$ mice per mouse per month. If the birth rate is lower than the death rate, however, r has a negative value ($r < 0$), and the population is getting smaller. In populations where the birth rate equals the death rate, $r = 0$, and the population's size is not changing—a situation known as **zero population growth,** or ZPG. Even under conditions of ZPG, births and deaths still occur, but the numbers of births and deaths cancel out.

As long as a population's per capita growth rate is positive ($r > 0$), the population will increase in size. In our hypothetical population of field mice, we started with $N = 2{,}000$ mice, and calculated a per capita growth rate of 0.4 mice per individual per month. In the first month, the population grows by $0.4 \times 2{,}000 = 800$ mice. At the start of the second month, $N = 2{,}800$ and r still $= 0.4$. Thus, in the second month, the population grows by $0.4 \times 2{,}800 = 1{,}120$ mice. Notice that even though r remains constant, the *increase* in population size gets larger each month simply because more individuals are reproducing. In less than two years, the mouse population will grow to more than 1 million. A graph of exponential population growth has a characteristic J shape, getting steeper through time (Figure 52.8B). The population grows at an ever-increasing pace because the change in a population's size depends on the number of individuals in the population as well as its per capita growth rate.

POPULATION GROWTH UNDER IDEAL CONDITIONS

Imagine a hypothetical population living in an ideal environment—one with unlimited food and shelter, no predators, parasites, or disease, and a comfortable abiotic environment. Under such circumstances, which are admittedly unrealistic, the per capita birth rate is very high, the per capita death rate is very low, and the per capita growth rate, *r,* is as high as it can possibly be. This maximum per capita growth rate, symbolized r_{max}, is the population's **intrinsic rate of increase.** Under these ideal conditions, the exponential growth equation is

$$dN/dt = r_{max}N$$

When populations are growing at their intrinsic rate of increase, population size increases very rapidly. Across a wide variety of bacteria, protists, and animals, r_{max} varies inversely with generation time: species with short generation time (that is, those that mature quickly) have higher intrinsic rates of increase than those with long generation time **(Figure 52.9).**

The Logistic Model Describes Population Growth When Resources Are Limited

The geometric and exponential models predict unlimited population growth. But we know from even casual observations that the population sizes of most species are somehow limited—we are

not knee-deep in bacteria, rosebushes, or garter snakes. What factors limit the growth of populations? As a population gets larger, it uses more vital resources, and a shortage of resources may eventually develop. As a result, individuals may have less energy available for maintenance and reproduction, causing per capita birth rates to decrease and per capita death rates to increase. Changes in these rates reduce the population's per capita growth rate, causing population growth to slow down or to stop altogether.

THE LOGISTIC MODEL Environments provide enough resources to sustain only a finite population of any species. The maximum number of individuals that an environment can support indefinitely is termed its **carrying capacity,** symbolized *K*. The carrying capacity, which is defined for each population, is a property of the environment, and it varies from one habitat to another and in a single habitat through time. For example, the spring and summer flush of insects in temperate habitats supports large populations of insectivorous birds. But fewer insects are available in autumn and winter, causing a seasonal decline in the carrying capacity for birds. Many birds then migrate to habitats that provide more food and better weather.

The **logistic model of population growth** assumes that a population's per capita growth rate, *r,* decreases as the population gets larger **(Figure 52.10A).** In other words, population growth slows as the population size approaches the carrying capacity. The mathematical expression $(K - N)$ tells us how many individuals can be added to a population before it reaches carrying capacity. And the expression $(K - N)/K$ indicates what *percentage* of the carrying capacity is still available.

To create the logistic model, we factor the impact of carrying capacity into the exponential model by letting $r = r_{max}(K - N)/K$. This calculation reduces the per capita growth rate r from its maximum value (r_{max}) as N increases:

$$dN/dt = r_{max}N(K - N)/K$$

The calculation of how r varies with population size is straightforward **(Table 52.2).** In a very small population (N is much smaller than K), plenty of resources are still available; the value of $(K - N)/K$ is close to 1, and the per capita growth rate r is therefore close to the maximum possible (r_{max}). Under these conditions, population growth is close to exponential. If a population is large (N is close to K), few additional resources are available, the value of $(K - N)/K$ is small, and the per capita growth rate r is very low. When the size of the population exactly equals the carrying capacity, $(K - N)/K$ becomes zero, and so does the population growth rate—the situation defined as ZPG.

The logistic model of population growth predicts an S-shaped graph of population size over time, with the popula-

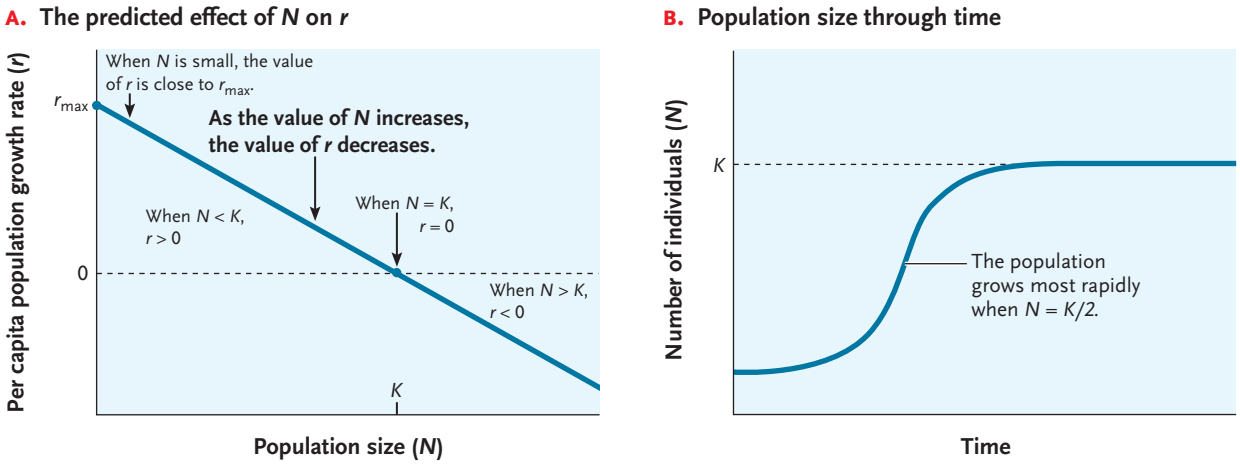

FIGURE 52.10 **The logistic model of population growth. (A)** The logistic model assumes that the per capita population growth rate *r* decreases linearly as population size (*N*) increases. **(B)** The logistic model predicts that population size increases quickly at first, but then slowly approaches the carrying capacity (*K*).

tion slowly approaching its carrying capacity and remaining at that level **(Figure 52.10B).** According to this model, the population grows slowly when the population size is small, because there are few individuals reproducing. It also grows slowly when the population size is large because the per capita population growth rate is low. The population grows quickly (dN/dt is highest) at intermediate population sizes, when a sizable number of individuals are breeding and the per capita population growth rate r is still fairly high (see Table 52.2).

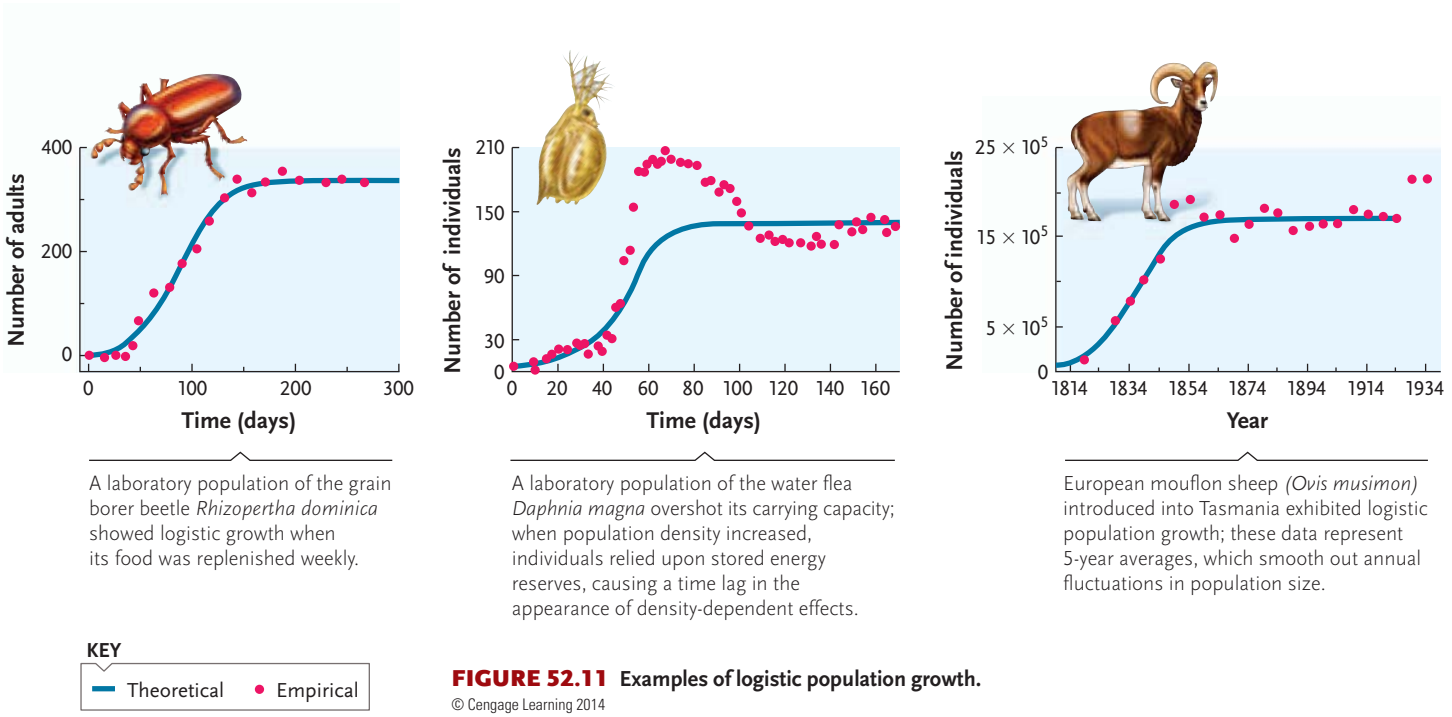
INTRASPECIFIC COMPETITION The logistic model assumes that vital resources become increasingly limited as a population grows larger. Thus, the model is a mathematical portrait of **intraspecific** (within species) **competition,** the dependence of two or more individuals in a population on the same limiting resource. For animals, limiting resources can be food, water, nesting sites, refuges from predators, and, for sessile species (those permanently attached to a surface), space. For plants, sunlight, water, inorganic nutrients, and growing space can be limiting. The pattern of uniform dispersion described earlier often reflects intraspecific competition for limited resources.

In some very dense populations, the accumulation of poisonous waste products may also reduce survivorship and reproduction. Most natural populations live in open systems where wastes are consumed by other organisms or flushed away. But the buildup of toxic wastes is common in laboratory cultures of microorganisms. For example, yeast cells ferment sugar and produce ethanol as a waste product. Thus, the alcohol content of wine rarely exceeds 13% by volume, the ethanol concentration that poisons winemaking yeasts.

LOGISTIC GROWTH IN THE LABORATORY AND IN NATURE How well do species conform to the predictions of the logistic model? In simple laboratory cultures, relatively small organisms, such as *Paramecium,* some crustaceans, and flour beetles, often show an S-shaped pattern of population growth. Moreover, large animals that have been introduced into new environments sometimes exhibit a pattern of population growth that matches the predictions of the logistic model **(Figure 52.11).**

Nevertheless, some assumptions of the logistic model are unrealistic. For example, the model predicts that survivorship and fecundity respond immediately to changes in a population's density. But many organisms exhibit a delayed response, called a **time lag.** Some time lags occur because fecundity is usually determined by the availability of resources at some time in the past, when individuals were adding yolk to eggs or endosperm to seeds. Moreover, when food resources become scarce, individuals may use stored energy reserves to survive and reproduce, and the effects of crowding may not be felt until those reserves are depleted. As a result, the population size may temporarily overshoot its carrying capacity (Figure 52.11, center). Deaths may then outnumber births, causing the population size to drop below the carrying capacity, at least temporarily. Time lags can cause a population to oscillate around its carrying capacity.

Another unrealistic assumption of the logistic model is that the addition of new individuals to a population always decreases survivorship and fecundity, no matter how small the population is. But in small populations, modest population growth probably doesn't have much effect on these processes. In fact, most organisms probably require a minimum population density to survive and reproduce. For example, some plants flourish in small clumps that buffer them from physical stresses, whereas a single individual living in the open would suffer adverse effects. And in some animal populations, a minimum population density is necessary for individuals to find mates—an important issue in conservation biology (see Chapter 55).



STUDY BREAK 52.4

1. How does the prediction of the exponential model of population growth differ from that of the logistic model?
2. What is carrying capacity? Is it a property of a habitat or of a population?
3. What is a time lag?

52.5 Population Dynamics

Long-term studies on many species have shown that the size, density, age structure, and geographical ranges of most populations change somewhat from season to season and from year to year. As you have seen, some populations experience dramatic variations in size and other characteristics through time,

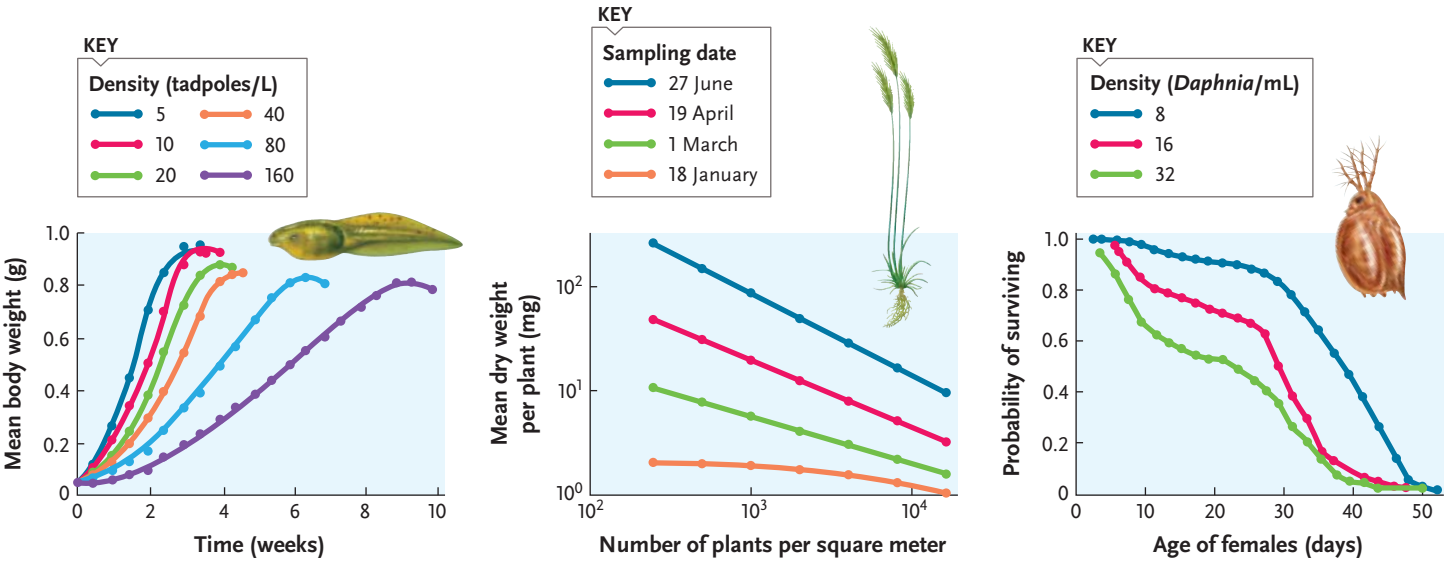
A laboratory population of the grain borer beetle *Rhizopertha dominica* showed logistic growth when its food was replenished weekly.

A laboratory population of the water flea *Daphnia magna* overshot its carrying capacity; when population density increased, individuals relied upon stored energy reserves, causing a time lag in the appearance of density-dependent effects.

European mouflon sheep *(Ovis musimon)* introduced into Tasmania exhibited logistic population growth; these data represent 5-year averages, which smooth out annual fluctuations in population size.

FIGURE 52.11 Examples of logistic population growth.



© Cengage Learning 2014

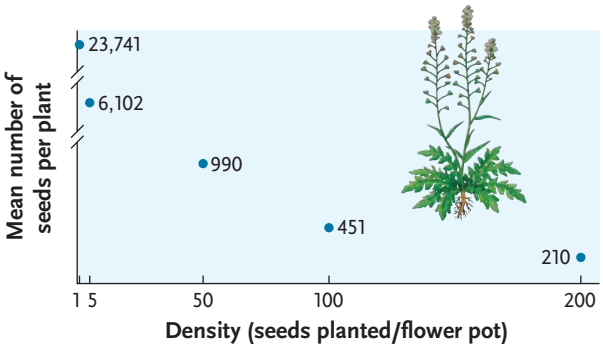
whereas other populations appear to be much more stable. What environmental factors influence these aspects of population dynamics? Why do these characteristics fluctuate more in some populations than in others?

Density-Dependent Factors Often Regulate Population Size

Many factors that affect population dynamics are **density-dependent:** their influence increases or decreases with the density of the population. Examples of density-dependent environmental factors include intraspecific competition and predation. The logistic model includes the effects of density-dependence in its assumption that per capita birth and death rates change with a population's density.

THE EFFECTS OF CROWDING Numerous laboratory and field studies show that crowding (high population density) decreases the individual growth rate, adult size, and survival of plants and animals **(Figure 52.12).** Organisms living in extremely dense populations are unable to harvest enough resources; they grow slowly and tend to be small, weak, and less likely to survive.

Tadpoles of the frog *Rana tigrina* grew faster and reached larger adult body size at low densities than at high densities.



The size of the annual dune grass *Vulpia fasciculata* decreased markedly when plants were grown at high density. Density effects became more accentuated through time, as the plants grew larger (indicated by the progressively steeper slopes of the lines).

The water flea *Daphnia pulex* had higher survivorship at a density of 8/mL than at densities of 16/mL or 32/mL.

FIGURE 52.14 **A swarm of locusts.** Migratory locusts *(Locusta migratoria)*, moving across an African landscape, can devour their own weight in plant material every day.

Gardeners understand this relationship, thinning their plants to a density that maximizes the number of vigorous individuals.

Crowding also has a negative effect on reproduction **(Figure 52.13).** When resources are in short supply, each individual has less energy available for reproduction after meeting its basic maintenance needs. Hence, females in crowded populations produce either fewer offspring or smaller offspring that are less likely to survive.

In some species, crowding stimulates developmental and behavioral changes that may influence the density of a population. For example, migratory locusts *(Locusta migratoria)* can develop into either solitary or migratory forms in the same population. Migratory individuals have longer wings and more body fat, characteristics that allow them to disperse great distances. High population density increases the frequency of the migratory form, and huge numbers of locusts move away from the area of high density **(Figure 52.14),** reducing the size of the original population.

These studies confirm the assumptions of the logistic equation, but they don't prove that natural populations are regulated by density-dependent factors. A convincing demonstration requires experimental evidence that an increase in population density causes population size to decrease, and that a decrease in density causes it to increase. In one study conducted in the 1960s, Robert Eisenberg of the University of Michigan experimentally increased the numbers of aquatic snails in some ponds, decreased them in others, and maintained natural densities in control ponds. Although adult survivorship did not differ between experimental and control treatments, snails in the high-density ponds produced fewer eggs, and those in the low-density ponds produced more eggs than those living at the control density. In addition, the survival rates of young snails declined as density increased. After four months, the densities in the two experimental groups converged on those in the control, providing strong evidence of density-dependent population regulation.

OTHER DENSITY-DEPENDENT FACTORS

Our discussion of the logistic equation described intraspecific competition as the primary density-dependent factor regulating population size. Competition between populations of different species also exerts density-dependent effects on population growth, a topic we consider in Section 53.1.

Predation can also cause density-dependent population regulation. As a particular prey species becomes more numerous, predators may consume more of it because it is easier to find and catch. Once a prey species has exceeded a threshold density, predators may consume a *larger percentage* of the prey population, which is a density-dependent effect (see Figure 21.16). For example, on rocky shores in California, sea stars concentrate their feeding on the most abundant of several invertebrate species. When one prey species becomes common, predators feed on it disproportionately, drastically reducing its numbers.

Like predation, parasitism and disease cause density-dependent regulation of plant and animal populations. Infectious microorganisms spread quickly in a crowded population. In addition, if individuals crowded together are weak or malnourished, they are more susceptible to infection and may die from diseases that healthy organisms would survive.

Global Climate Change Is Increasing the Impact of Density-Independent Factors

Some populations are affected by **density-independent** factors, which reduce population size regardless of its density. If an insect population is not physiologically adapted to high temperature, a sudden hot spell may kill 80% of the insects whether they number 100 or 100,000. Fires, earthquakes, storms, and other natural disturbances may contribute directly or indirectly to density-independent mortality. But because such factors do not cause a population to fluctuate around its carrying capacity, density-independent factors do not *regulate* population size, although they may reduce it.

For many years, ecologists have recognized the strong effects of density-independent factors on populations of small-bodied species that cannot buffer themselves against environmental change. Their populations grow exponentially for a time, but shifts in climate or random events cause high mortality before populations reach a size at which density-dependent factors regulate their numbers. When conditions improve, populations grow exponentially—at least until another density-independent factor causes them to crash again. For example, a small Australian insect, *Thrips imaginis,* feeds on pollen and flowers of plants in the rose family; they are frequently abundant enough to damage the blooms. *Thrips* populations grow exponentially in spring, when many flowers are available and the weather is warm and moist **(Figure 52.15).** But populations crash predictably during summer because *Thrips* do not tolerate extremely hot and dry conditions. After the crash, a few individuals survive in remaining flowers, forming the stock from which the population grows exponentially the following spring.

Recent research on the effects of global climate change suggests that the very rapid warming observed since the middle of the twentieth century (see Chapter 54) has also had a significant impact on the population ecology of large, long-lived or-

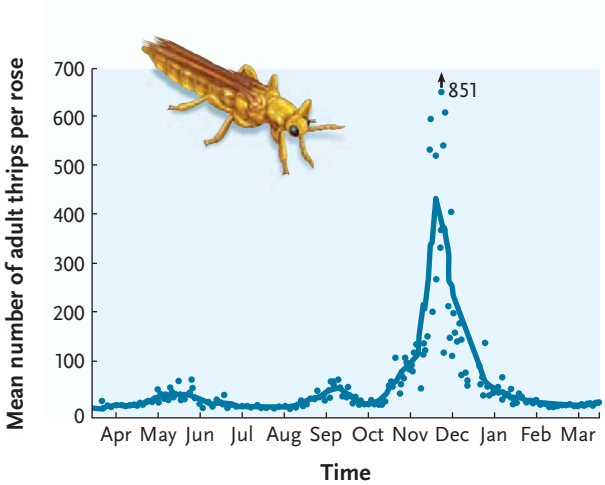

FIGURE 52.15 Booms and busts in a *Thrips* population. Populations of the Australian insect *Thrips imaginis* grow exponentially when conditions are favorable during spring (which begins in September in the southern hemisphere). The populations crash in summer, however, when hot and dry conditions cause high mortality.

FIGURE 52.16 Global climate change and mortality in trees. Like other conifers in western North America, red fir trees *(Abies magnifica)* in Sequoia National Park, California, have experienced increased mortality, almost certainly as a result of climate warming.

ganisms. For example, in 2009, Phillip J. van Mantgem of the U.S. Geological Survey and colleagues from seven other institutions published an analysis of data collected between 1955 and 2007 in undisturbed coniferous forests of western North America. Their survey, which included 76 stands of trees between 200 and 1,000 years old, revealed that average mortality rates had increased 4% per year; the increase was most apparent in the Pacific Northwest, where mortality rates doubled in as little as 17 years **(Figure 52.16).** Increased mortality was evident at all elevations and in trees of all species, sizes, and ages. After considering several possible causes of the increased mortality, the researchers concluded that climate warming—about 0.5°C per decade in western North America—and the concomitant lengthening of summer droughts was the major contributing factor. The extended droughts not only prevent tree seedlings from establishing themselves and renewing the forests, but they also limit the photosynthetic activity of established trees and leave them more vulnerable to infestation by insect and fungal pests. These environmental stresses may lead to the large-scale death of western North American forests.

Interacting Environmental Factors Influence Population Dynamics in Complex Ways

Sometimes several density-dependent factors influence a population at the same time. For example, on small islands in the West Indies, the spider *Metepeira datona* is rare wherever lizards (*Ameiva festiva, Anolis carolinensis,* and *Anolis sagrei*) are abundant, but common where the lizards are rare or absent. To test whether the presence of lizards limits the abundance of spiders, David Spiller and Tom Schoener of the University of Cali-

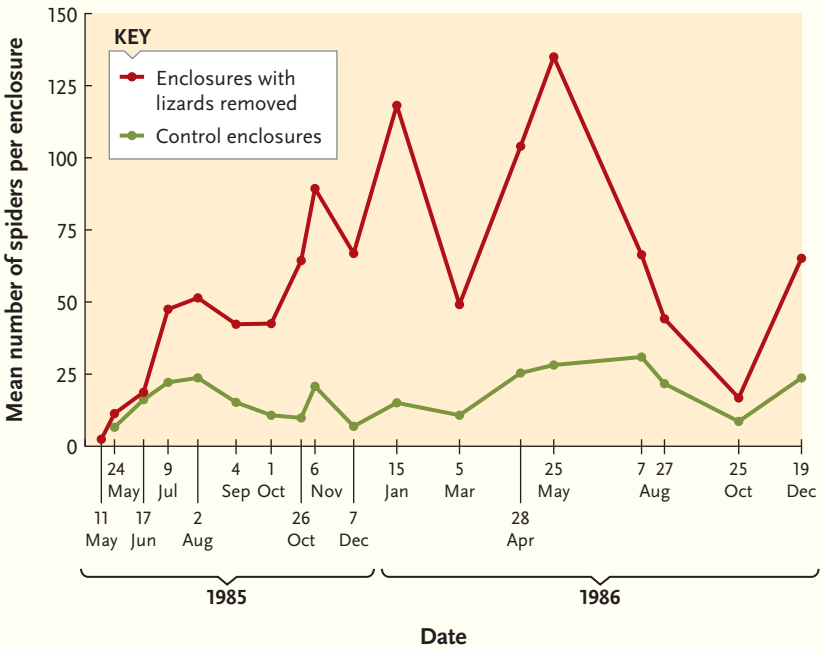

FIGURE 52.17 **Experimental Research**

Evaluating Density-Dependent Interactions between Species

Question: Does the population density of lizards on Caribbean islands have any effect on the population density of spiders?

Experiment: Spiller and Schoener built fences around a series of study plots on a small island in the Bahamas. They excluded all individuals of three lizard species from the experimental plots, but left resident lizards undisturbed in the control plots. They then made monthly measurements of population densities of the web-building spider *Metepeira datona* in both experimental plots and control plots.

Results: Over the 20-month course of the experiment, spider densities were as much as five times higher in the experimental plots than in the control plots.

D. A. Spiller and T. W. Schoener. 1998. An experimental study of the effects of lizards on web-spider communities. *Ecological Monographs* 58:57–77. Ecological monographs by ECOLOGICAL SOCIETY OF AMERICA Copyright 1988. Reproduced with permission of ECOLOGICAL SOCIETY OF AMERICA in the format Textbook via Copyright Clearance Center.

Conclusion: Spiller and Schoener concluded that the presence of lizards has a large impact on spider populations. The lizards not only compete with the spiders for insect food, but they also appear to prey on the spiders.

THINK LIKE A SCIENTIST If you look closely at the graph, you will notice that the numbers of spiders in control enclosures and in enclosures with lizards removed sometimes increase or decrease at roughly the same time. What factors might account for these parallel changes in spider numbers?

Source: D. A. Spiller and T. W. Schoener. 1998. An experimental study of the effects of lizards on web-spider communities. *Ecological Monographs* 58:57–77.

fornia, Davis, built screened fences around plots on islands where these species occur. They eliminated lizards from experimental plots, but left them in control plots. After two years, spider populations in some experimental plots were five times denser than those in control plots **(Figure 52.17).** In this case, lizards had two density-dependent effects on spider populations: they preyed upon spiders, and they competed with them for food.

Density-dependent factors can also interact with density-independent factors, limiting population growth. For example, food shortage caused by high population density (a density-dependent factor) may lead to malnourishment; in turn, malnourished individuals may be more likely to succumb to the stress of extreme weather (a density-independent factor).

Populations can also be affected by density-independent factors in a density-dependent manner. For example, animals often retreat into shelters to escape environmental stresses, such as floods or severe heat. If a population is small, most individuals can fit into a limited number of available refuges. But if a population is large, only a small proportion will find suitable shelter; the larger the population is, the greater the percentage of individuals that will experience the stress. Thus, although the density-independent effects of weather limit *Thrips* populations, it is the availability of flowers in summer—clearly a density-dependent factor—that regulates the size of the *Thrips* stock from which the population grows the following spring. Hence, both types of factors influence the size of *Thrips* populations.

Life History Characteristics Govern Fluctuations in Population Size through Time

Even casual observation reveals tremendous variation in how rapidly population size changes in different species. For example, new weeds often appear in a vegetable garden overnight, whereas the number of oak trees in a forest may remain relatively stable for years. Why do some species have the potential for explosive population growth, but others do not? The answer lies in how natural selection has molded life history strategies that are adapted to different ecological conditions. Ecologists describe two divergent life history patterns—***r*-selected** species and ***K*-selected** species—with very different characteristics **(Table 52.3, Figure 52.18).** These strategies represent extremes on a continuum of possible patterns, and the life histories of most species actually fall somewhere between them.

Species with an *r*-selected life history are adapted to function well in rapidly changing environments. They are generally small, have short generation times, and produce numerous, tiny offspring, often in a single reproductive event. The offspring receive little or no parental care of any kind. Because species with short generation times tend to have high r_{max} (see Figure 52.9), their populations grow exponentially when envi-

FIGURE 52.18 Life history differences. (A) An *r*-selected species, like quinoa *(Chenopodium quinoa)*, matures in one growing season and produces many tiny seeds, which were a traditional food staple for the indigenous people of North and South America. **(B)** A *K*-selected species, like the coconut palm *(Cocos nucifera)*, grows slowly and produces a few large seeds repeatedly during its long life.

ronmental conditions are favorable—hence the name *r*-selected. Although their numerous offspring disperse and rapidly colonize available habitats, most die before reaching sexual maturity (Type III survivorship). Thus, the success of an *r*-selected life history depends on flooding the environment with a *large quantity* of young, only a few of which may be successful.

Because they have small body size, *r*-selected species lack physiological mechanisms to buffer them from environmental variation. Thus, as described earlier for the Australian thrips living in roses, survivorship and fecundity are often greatly influenced by density-independent factors, and population size fluctuates markedly. In good years, survivorship and fecundity may be high, and the population explodes. In bad years, survivorship and fecundity may be low, and the population crashes. Populations of *r*-selected species are often so greatly reduced by changes in abiotic environmental factors, such as temperature or moisture, that they never grow large enough to face a shortage of limiting resources. Thus, the carrying capacity for the species cannot be estimated, and changes in their population size cannot be described by the logistic model of population growth.

By contrast, *K*-selected species thrive in more stable environments. They are generally large, have long generation times, and produce offspring repeatedly during their lifetimes. Their offspring receive substantial parental care, either as energy reserves in an egg or seed or as active care, ensuring that most survive the early stages of life (Type I or Type II survivorship). Because *K*-selected species typically have a low r_{max}, their populations often grow slowly. The success of a *K*-selected life history therefore depends on the production of a relatively small number of *high quality* offspring that join an already well-established population.

The large body size of *K*-selected species allows them to use behavioral and physiological mechanisms to buffer themselves against environmental change, so that survivorship and fecundity do not fluctuate wildly in response to environmental variations. Instead, their populations are often affected by density-dependent factors, which regulate population size near the carrying capacity for the species—hence the name *K*-selected. For these species, natural selection has favored life history characteristics that result in stable population sizes: the production of relatively few offspring, extensive parental care, good competitive ability, a long life span, and repeated reproductions. Many large terrestrial vertebrates are examples of *K*-selected species.

Metapopulation Structure Allows Local Populations to Exchange Individuals

Although the models of population growth discussed earlier ignore the effects of immigration and emigration, individuals frequently disperse from one local population to another. To describe the dynamics of such movements, ecologists define a **metapopulation** as a group of neighboring populations that exchange individuals. All local populations within a metapopulation are not equal; they often differ in size, population growth rates, the suitability of their habitats, their exposure to predators, and other factors. Moreover, some may decline steadily (even to extinction), while others may increase.

Under favorable circumstances, a population may produce numerous offspring, some of which emigrate and join nearby populations, where they breed, providing a genetic connection between local populations (see the discussion of gene flow in

Do Immigrants from Source Populations Prevent Extinction of Sink Populations of the Bay Checkerspot Butterfly?

Paul Ehrlich

Map of serpentine habitat patches near Morgan Hill

Hypothesis: Populations of the bay checkerspot butterfly *(Euphydryas editha bayensis)* living on small patches of suitable habitat are "sink" populations that frequently become extinct. Populations in large habitat patches can serve as a "source" of individuals to recolonize small habitat patches nearby.

Prediction: Because the bay checkerspot butterfly is a weak flyer, small patches of suitable habitat that are close to a large source population will be recolonized frequently. Patches of suitable habitat that are far from a large source population will be recolonized only rarely.

Method: Susan Harrison, Dennis D. Murphy, and Paul R. Ehrlich of Stanford University surveyed 59 small patches of serpentine grassland near San Jose, California, in 1986 and 1987. They estimated the "quality" of each patch based on the presence or absence of food plants on which bay checkerspots depend and on aspects of the physical environment that are important to these butterflies. They also measured the distance of each patch from Morgan Hill, a very large patch of suitable habitat that had sustained a bay checkerspot population for many years. In patches where they found butterflies, they estimated bay checkerspot population sizes.

Results: A complex statistical analysis revealed that both distance from the Morgan Hill population and habitat patch quality were important factors in determining whether bay checkerspots would be present or absent in small habitat patches. The authors noted that only the nine high-quality habitat patches near Morgan Hill (red on the map) were occupied by bay checkerspots. Of 50 unoccupied habitat patches, 6 were near Morgan Hill but of low quality; 18 were of high quality but far from Morgan Hill; and 26 were too far from Morgan Hill and of too low quality to support a population of bay checkerspots.

Conclusion: Populations of bay checkerspot butterflies that occupy large patches of suitable habitat serve as source populations for individuals that recolonize small patches of suitable habitat where butterfly populations frequently become extinct. However, because the bay checkerspot is a weak flyer, it recolonizes small patches of suitable habitat only if they are close to a source population.

THINK LIKE A SCIENTIST What impact would residential and commercial development have on metapopulations of Bay checkerspot butterflies?

Source: S. Harrison et al. 1988. Distribution of the bay checkerspot butterfly, *Euphydryas editha bayensis:* Evidence for a metapopulations model. *The American Naturalist* 132:360–382.

Section 21.3). Thus, dispersal and gene flow between local populations maintain the metapopulation.

Populations that are either stable or increasing in size are described as **source populations** because they are a possible source of immigrants to other populations. Those that decline in size are called **sink populations** because they receive available immigrants. Individuals usually move from source populations to sink populations, and sink populations persist because they receive immigrants from source populations in the metapopulation.

The bay checkerspot butterfly, *Euphydryas editha bayensis* **(Figure 52.19),** provides an example of metapopulation dynamics. This species is restricted to serpentine grassland in the San Francisco Bay area (see Figure 53.18) because its larvae eat plants that grow only in that community. Human disturbance has fragmented much of the butterfly's natural habitat into patches of varying size, each of which may support a local butterfly population. The life cycle of these butterflies is always a race against time, because the larvae must feed and mature before dry summer weather kills their food plants. Populations in small patches often become extinct, but those occupying larger patches, where food plants stay alive longer, generally survive the seasonal drought. (Global climate warming has exacerbated the problem in recent years, causing food plants to die earlier in the season—and pushing the butterfly to the brink of extinction.) Butterfly populations in larger habitat patches still serve as source populations for emigrants that repopulate small habitat patches the following year. But the bay checkerspot is a poor flyer, and it cannot disperse long distances. Thus, small patches of suitable habitat harbor bay checkerspots only if they are close to a larger patch that serves as a source.

Some Species Exhibit Regular Cycles in Population Size

The population densities of many insects, birds, and mammals in the northern hemisphere fluctuate between species-specific lows and highs in a multiyear cycle. Arctic populations of small rodents vary in size over a four-year cycle, whereas snowshoe hares, ruffed grouse, and lynxes have 10-year cycles. Ecologists documented such cyclic fluctuations more than a century ago, but none of the general hypotheses so far proposed explains the cycles in all species. The availability and quality of food, the abundance of predators, the prevalence of disease-causing microorganisms, and variations in weather may influence population growth. Furthermore, a cycling population's food supply and predators are themselves influenced by the population's size.

Theories of *intrinsic control* suggest that as an animal population grows, individuals undergo hormonal changes that increase aggressiveness, reduce reproduction, and foster dispersal to other areas. The dispersal phase of the cycle may be dramatic. For example, when populations of the Norway lemming *(Lemmus lemmus),* a rodent that lives in the Scandinavian arctic, reach their peak density, aggressive interactions drive younger and weaker individuals away from their place of birth. The exodus of many thousands of lemmings, scrambling over rocks and even cliffs, was sometimes incorrectly portrayed in nature films as a suicidal mass migration. Researchers do not yet know how widespread these hormonal and behavioral changes are among different species or exactly what regulates them.

Other explanations focus on *extrinsic control,* such as the relationship between a cycling species and its food or predators. A dense population may exhaust its food supply, increasing mortality and decreasing reproduction. But experimental food supplementation does not always prevent a decline in mammal populations, indicating that other factors are also at work.

Some mathematical models as well as some laboratory experiments on protists or small arthropods suggest that the cycles of predators and their prey are induced by time lags in each population's response to changes in density of the other **(Figure 52.20).** In the past, the 10-year cycles of snowshoe hares *(Lepus americanus)* and their feline predators, Canada lynxes *(Lynx canadensis),* were often cited as a classic example of such an interaction. But ecological relationships are often complex, and recent research has cast doubt on this straightforward explanation. Hare populations exhibit a 10-year fluctuation even on islands where lynxes are absent. Thus, the lynx cannot be solely responsible for the hare's cycle, although cycles in the hare populations may trigger cycles in populations of their predators.

Charles Krebs and his colleagues at the University of British Columbia studied hare and lynx interactions with a large-scale, multiyear experiment in the southern Yukon. They fenced experimental areas where they added food for the hares, excluded mammalian predators, or applied both experimental treatments; unmanipulated plots served as controls. Where mammalian predators were excluded, hare densities approximately doubled relative to the controls. Where food was added, hare densities tripled. But in plots where predators were excluded *and* food was added, the hare densities increased 11-fold. Krebs and his colleagues concluded that neither food availability nor predation alone is solely responsible for arctic hare population cycles; instead, complex interactions between the hares, their food plants, and their predators create the cyclic fluctuations in hare population size.

STUDY BREAK 52.5

1. **How can you tell whether an environmental factor causes density-dependent or density-independent effects on a population?**
2. **Are the effects of infectious diseases on populations more likely to be density-dependent or density-independent?**

52.6 Human Population Growth

How do human populations compare with those of other species we have studied? The worldwide human population surpassed 7 billion in 2011, and it is projected to reach 9 billion by 2050. Like many other species, most humans live in discrete populations, which vary in their demographic traits and access to resources. Although many of us live comfortably, more than a billion people are malnourished or starving, lack clean drinking water, and live without adequate shelter or health care. Even if it were possible to double the food supply, increased agricultural production would inevitably increase pollution and contribute to spoiled croplands, deforestation, and desertification, which are described in Chapter 55.

Human Populations Have Sidestepped the Usual Density-Dependent Controls

For most of human history, our population grew slowly; but over the past two centuries, the worldwide human population has grown exponentially **(Figure 52.21).** Demographers have identified three ways in which humans have avoided the effects of density-dependent regulating factors.

First, humans have expanded their geographical range into virtually every terrestrial habitat on Earth. Our early ancestors lived in tropical and subtropical grasslands, but by 40,000 years ago, they had dispersed through much of the world (see Section 32.13). Their success resulted from their ability to solve ecological problems by building fires, assembling shelters, making clothing and tools, and planning community hunts. Vital survival skills spread from generation to generation and from one population to another because language allowed the communication of complex ideas and knowledge.

Second, humans have increased the carrying capacities of habitats they occupy. About 11,000 years ago, many populations shifted from hunting and gathering to agriculture. They cultivated wild grasses, diverted water to irrigate crops, and used do-

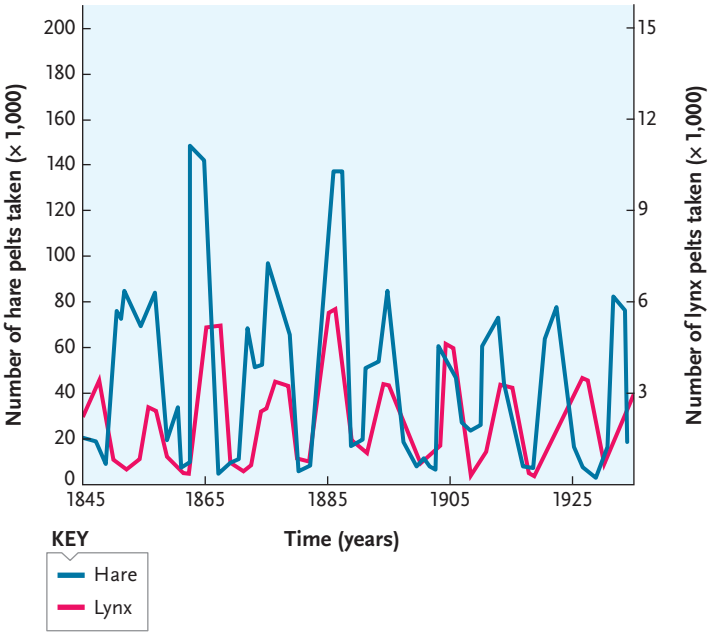
Predator–prey interactions may contribute to density-dependent regulation of both populations.



A. Predictions of a predator–prey model

A mathematical model predicts cycles in the numbers of predators and prey because of time lags in each species' responses to changes in the density of the other. (Predator population size is exaggerated in this graph: predators are usually less common than prey.)

B. Lynx and hare population sizes through time

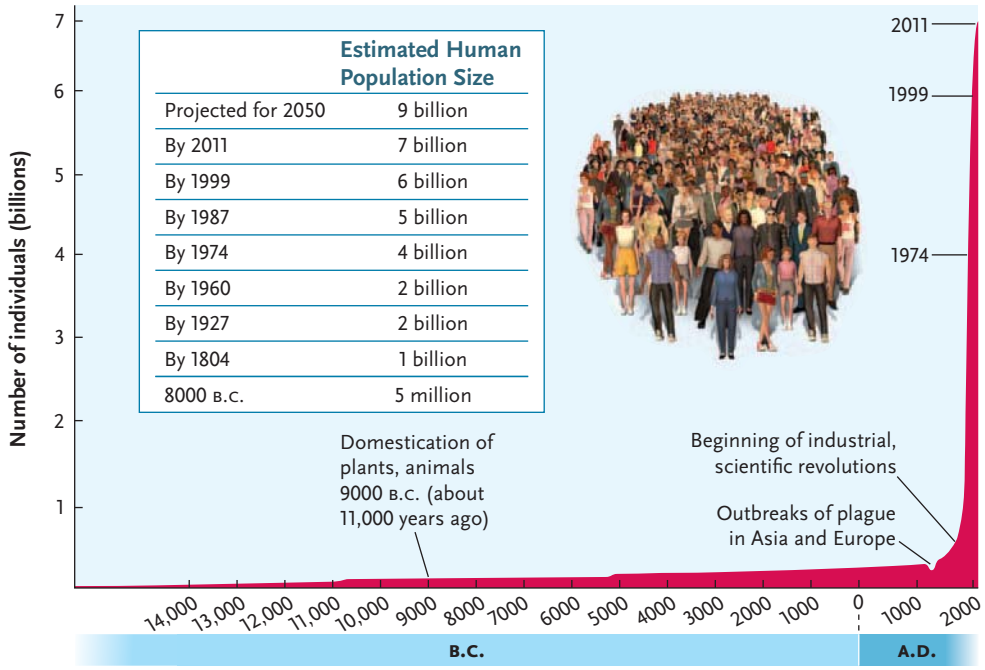
The interaction between the Canada lynx (*Lynx canadensis*) and the snowshoe hare (*Lepus americanus*) was often described as a cyclic predator–prey interaction. The abundances of lynx and hare are based on counts of pelts that trappers sold to Hudson's Bay Company over a 90-year period.

Tom Brakefield/Getty Images

SUMMARY As the graph in **(B)** illustrates, the number of predators (lynx) often rises and falls with the number of their prey (hare), but the timing of changes in the predator and prey population sizes does not match the predictions of the mathematical model precisely. Recent research has shown that population cycles in snowshoe hares are caused by complex interactions between the hare, its food plants, and its predators.

THINK LIKE A SCIENTIST What is the approximate length of the population cycles of lynx and hare? According to the data in the graph, in which years did the population size of lynx increase almost instantaneously after an increase in the hare population? In which years did the lynx population size increase some time after an increase in the hare population?

© Cengage Learning 2014



mesticated animals for food and labor. Such innovations increased the availability of food, raising both the carrying capacity and the population growth rate. In the mid-eighteenth century, people harnessed the energy in fossil fuels, and industrialization began in Western Europe and North America. Food supplies and the carrying capacity increased again, at least in the industrialized countries, through the use of synthetic fertilizers, pesticides, and efficient methods of transportation and food distribution.

Third, advances in public health have reduced the effects of critical population-limiting factors such as malnutrition, contagious diseases, and poor hygiene. Over the past 300 years, modern plumbing and sewage treatment, improvements in food handling and processing, and medical discoveries have reduced death rates sharply. Births now greatly exceed deaths, especially in less industrialized countries, resulting in rapid population growth.

Age Structure and Economic Development May Now Control Our Population Growth

Where have our migrations and technological developments taken us? It took almost 3 *million* years for the human population to reach 1 billion, 123 years to reach the second billion, and only 12 years to jump from 6 billion to 7 billion (see the inset table in Figure 52.21). Rapid population growth may now be an inevitable consequence of our age structure and economic development.

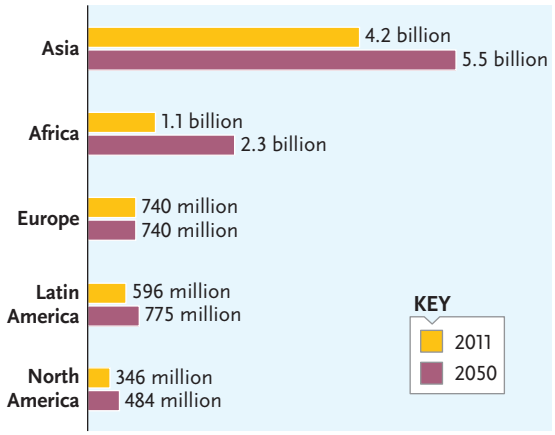

FIGURE 52.22 Local variation in human population growth rates. **(A)** Average annual population growth rates varied among countries in 2011. **(B)** In some regions, the population is projected to increase greatly by 2050; the population of Europe will likely remain unchanged. Source: Population Reference Bureau, Washington, D.C.

A. Mean annual population growth rates, 2011

B. Actual and projected population sizes for major world regions

POPULATION GROWTH AND AGE STRUCTURE On a worldwide scale, the annual growth rate for the human population averaged roughly 1.2% ($r = 0.012$ new individuals per individual per year) between 2001 and 2011. Population experts expect that rate to decline, but even so, the human population will continue to grow at least until 2050.

The annual population growth rates of individual nations vary widely, however, ranging from slightly below 0% (that is, the population is getting smaller) to 3.6% in 2009 **(Figure 52.22A).** The industrialized countries of Western Europe have achieved nearly zero population growth, and in some cases negative growth, but other countries—notably those in Africa, Latin America, and Asia—will experience huge increases over the next 15 to 40 years **(Figure 52.22B).**

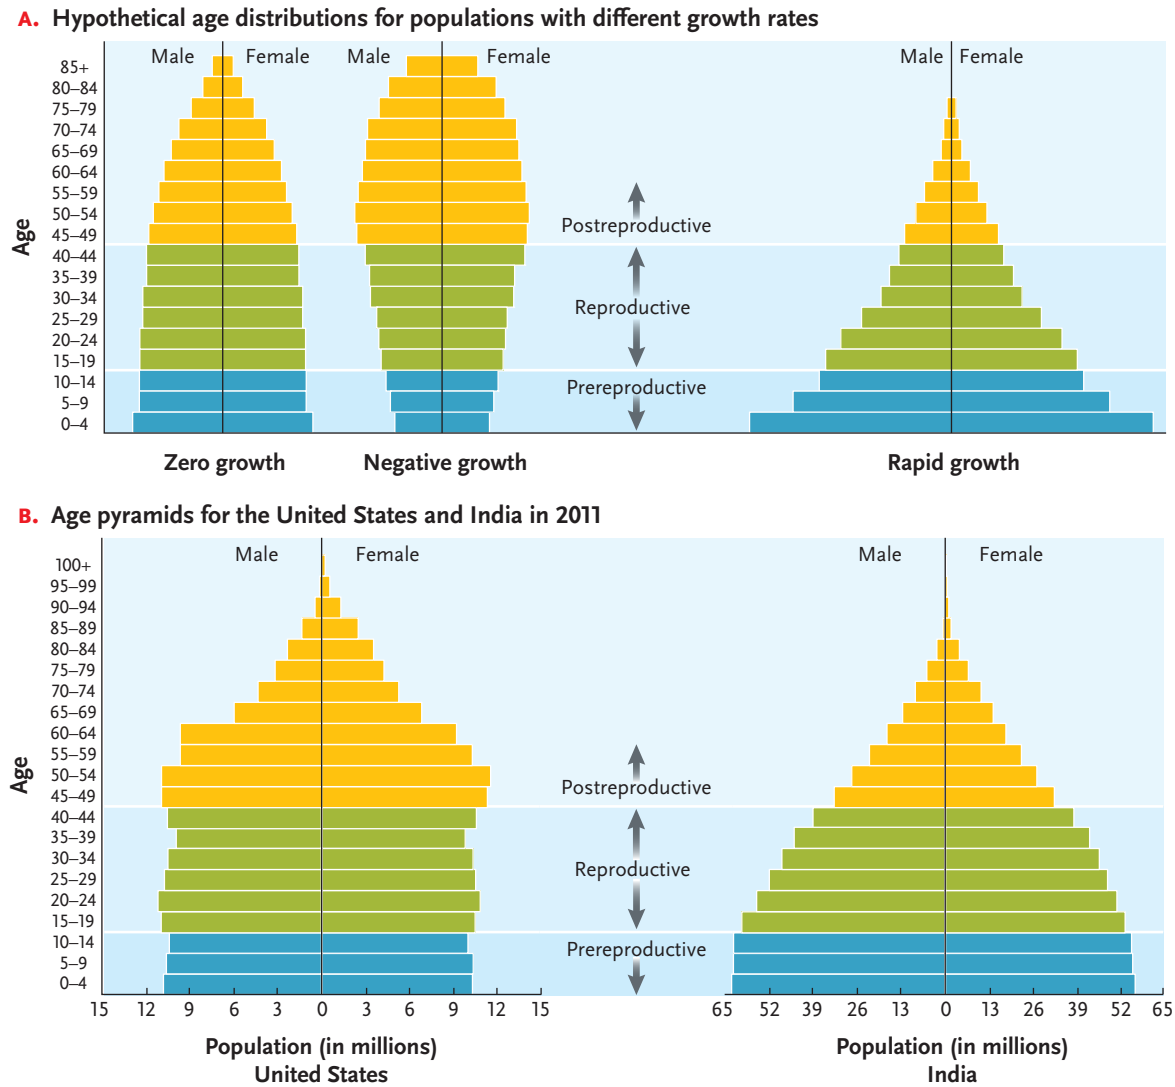

FIGURE 52.23 **Age-structure diagrams. (A)** Hypothetical age-structure diagrams differ for countries with zero, negative, and rapid population growth rates. The width of each bar represents the proportion of the population in each age class. **(B)** Age-structure diagrams for the United States and India in 2011 (measured in millions of people) suggest that these countries will experience different population growth rates in the near future.

Source: U.S. Census Bureau, International Data Base

For all long-lived species, differences in age structure are a major determinant of differences in population growth rates **(Figure 52.23).** The uniform age structure of countries with zero growth—with approximately equal numbers of people of reproductive and prereproductive ages—suggests that individuals have just been replacing themselves and that these populations will not experience a growth spurt when today's children mature. By contrast, the narrow-based age structure of countries with negative growth illustrates a continuing decrease in population size. Reproductives have been producing very few offspring, and the small group of prereproductives may not even replace themselves. Countries with rapid growth have a broad-based age structure, with many youngsters born during the previous 15 years. Worldwide, more than one-quarter of the human population falls within this prereproductive base. This age class will soon reach sexual maturity. Even if each woman produces only two offspring, populations will continue to grow rapidly because so many individuals are reproducing.

The age structure of the United States falls between those for countries with zero growth and countries with rapid growth. The average number of children per family has declined to the two that are necessary to replace their parents in the population. Nevertheless, the U.S. population will continue to grow slowly for the next couple of generations largely because of continued immigration.

POPULATION GROWTH AND ECONOMIC DEVELOPMENT

The relationship between a country's population growth and its economic development can be depicted by the **demographic transition model (Figure 52.24).** This model describes historical

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).

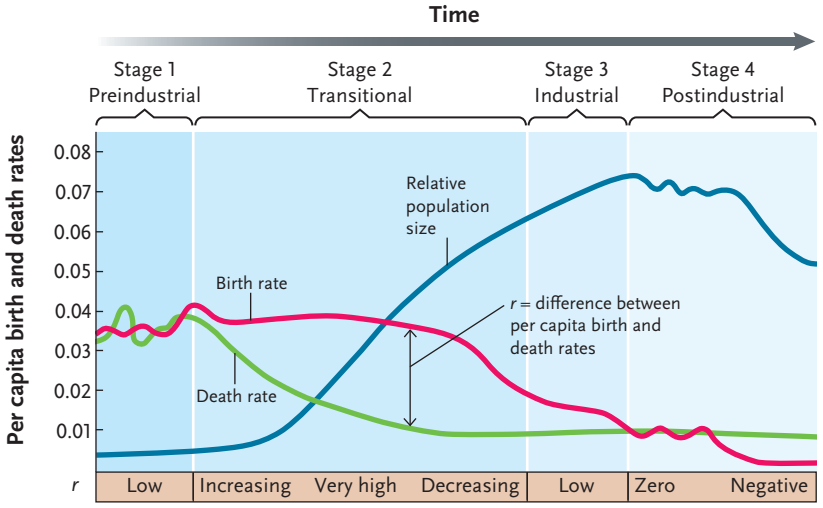

FIGURE 52.24 The demographic transition. The demographic transition model describes changes in the birth and death rates and relative population size as a country passes through four stages of economic development. The bottom bar describes the net population growth rate, *r*.

© Cengage Learning 2014

changes in demographic patterns in the industrialized countries of Western Europe; we do not know if it accurately predicts the future for developing nations today.

According to this model, during a country's *preindustrial* stage, birth and death rates are high, and the population grows slowly. Industrialization begins a *transitional* stage, when food production rises, and health care and sanitation improve. The death rate declines, resulting in an increased rate of population growth. Later, as living conditions improve, the birth rate also declines, causing the population growth rate to drop. When the *industrial* stage is in full swing, population growth slows dramatically. People move from the countryside to cities, and urban couples often choose to accumulate material goods instead of having large families. Zero population growth is reached in the *postindustrial* stage. Eventually, the birth rate falls below the death rate, *r* falls below zero, and population size begins to decrease.

Today, the United States, Canada, Australia, Japan, Russia, and most of Western Europe are in the industrial stage. Their growth rates have already decreased or are slowly decreasing. In some Western European countries, birth rates are lower than death rates, and populations are getting smaller, indicating their entry into the postindustrial stage. Many less industrialized countries are in the transitional stage, but they may not have enough skilled workers or enough capital to make the transition to an industrialized economy. Thus, many poorer nations may be stuck in the transitional stage.

LIMITING POPULATION GROWTH Most governments realize that increased population size is now a major factor causing resource depletion, excessive pollution, and an overall decline in the quality of life. The principles of population ecology demonstrate that a slowing of population growth—or an actual decline in population size—can be achieved only by decreasing the birth rate or increasing the death rate. And because increasing mortality is neither a rational nor humane means of population control, most governments are attempting to lower birth rates with **family planning programs.** These programs educate people about ways to produce an optimal family size on an economically feasible schedule. Programs vary in their details, but all provide information on methods of birth control (see Section 49.4). When thoughtfully developed and carefully administered, family planning programs cause birth rates to decline significantly.

All species face limits to their population growth. We have postponed the action of most factors that limit population growth, but no amount of invention can expand the ultimate limits set by resource depletion and a damaged environment. We now face two options for limiting human population growth: we can make a global effort to limit our population growth, or we can wait until the environment does it for us.

STUDY BREAK 52.6

1. **How have humans sidestepped the controls that regulate populations of other organisms?**
2. **How does the age structure of a population influence its future population growth?**

UNANSWERED QUESTIONS

Are there universal governing principles in population ecology, similar to the laws of physical sciences? Or is the natural world so complex that each population must be considered individually, leaving us with just a series of case studies?

These types of broad questions motivated the founders of modern ecological studies, such as G. Evelyn Hutchinson and Robert MacArthur. Many ecologists have attempted to codify aspects of population ecology in terms of specific principles, sometimes imposing artificial dichotomies in the process. For example, this chapter considered whether or not natural populations are subject to either density-dependent or density-independent regulation. Ecologists have also attempted to uncover basic patterns in community ecology, which are described in the next chapter. We do know that some general principles are often important in governing the structure of populations or natural communities but, as yet, we cannot apply any of them to a specific system without also including a detailed study of that system.

What is the importance of scale in ecology?

Although an individual population can be a meaningful object of study, ecologists often collect data from multiple populations of the same species to compare results among the "replicates." However, although the separate populations may appear to be replicates, they are often quite different in appearance, age structure, life history, or other characteristics. Ecologists confronted with such variation might seek explanations in the differences between the populations' environments, including both abiotic and biotic factors. However, such local variation may also be attributable to the larger context, such as the landscape or surrounding communities.

One important manifestation of this question applies to how the populations of a species are distributed in space. In many cases, discrete populations are widely separated from one another. Such separation is easy to imagine in terms of fish that live in lakes or organisms that live on islands, but it also applies in a diversity of other organisms. For example, many plants and animals, like the Bay checkerspot butterflies discussed in this chapter, are found only on chemically distinct patches of soil that are distributed like islands across a terrestrial environment. Many lizards live in rock outcrops that dot the landscape. Other organisms live on cool, wet mountaintops surrounded by desert. Such isolation is often exaggerated by human modification of the landscape, which progressively fragments and isolates habitable environments from one another. How does such subdivision change the dynamics of the individual populations? How does it change the way they evolve? These are questions that have challenged population and evolutionary biologists for decades. The effects of humans on the environment are making the answers to these questions more than a theoretical concern.

What is the importance of evolution in ecological interactions?

Most research in ecology, ranging from formal models of population growth and regulation to empirical studies, treats populations as if they were unchanging—as if they were not evolving. This implicit perspective does not deny that evolution is happening, but treats it as if it happens on such a long time scale that it need not be considered in contemporary studies. However, many recent studies have shown that populations may evolve quickly, often on a year-to-year basis. If this observation is generally true, then ecological studies that do not include evolutionary change may be compromised. For example, the monitoring and management of commercially exploited fish populations are based entirely on models of population growth, demography, and life histories similar to those considered in this chapter. Commercial fisheries often capture a large proportion of a population every year, focusing on the largest adults. Although research has clearly shown that these practices are likely to select for earlier maturity at a smaller size, these findings have not yet been incorporated into fisheries-management policy. More generally, ecologists have not yet included sufficient emphasis on the interaction between evolution as it occurs on the scale of our day-to-day existence and the modeling and empirical study of ecological processes.

THINK LIKE A SCIENTIST

1. Why do you think the mathematical models describing population growth introduced in this chapter are not considered biological laws?
2. Considering life table data, why do you think population ecologists often "ignore" evolutionary change? How can molecular biology be used to incorporate evolution into population level studies?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

52.1 Population Characteristics

- A population's size and density can be measured directly or with sampling techniques (Figures 52.2 and 52.3).
- Organisms within a population may be clumped, uniformly distributed, or randomly distributed within their habitat (Figure 52.4). Clumped dispersion is the most common, but animals may change their dispersion pattern seasonally.
- The relative numbers of individuals of different ages determine a population's age structure. Generation time is the average time between an individual's birth and the birth of its offspring (Figure 52.5). A population's sex ratio is the relative proportion of males and females.

52.2 Demography

- Demography is the study of the survivorship, reproduction, immigration, and emigration patterns that influence population characteristics.
- Life tables summarize age-specific mortality, survivorship, and age-specific fecundity of surviving individuals (Table 52.1).
- Survivorship curves depict a population's survival pattern over its life span. Ecologists define three general patterns of survivorship: high survivorship until late in life, a constant mortality level at all ages, and high juvenile mortality (Figure 52.6).

Animation: Life history patterns

52.3 The Evolution of Life Histories

- An organism's energy budget mandates trade-offs in the allocation of energy to maintenance, growth, and reproduction (Figure 52.7).
- Natural selection has molded several interacting components of life history variation based upon the allocation of resources to growth, maintenance, and reproduction: the trade-off between fecundity and parental care; whether to reproduce once versus multiple times; and the age of first reproduction.

Animation: Guppy characteristics

52.4 Models of Population Growth

- Bacteria reproduce by binary fission, and their populations double in size each generation (Figure 52.8A).
- The exponential growth model, $dN/dt = rN$, describes unlimited population growth. A graph of exponential growth is J-shaped (Figure 52.8B).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The maximum population growth rates of populations, symbolized r_{max}, vary inversely with their generation times (Figure 52.9).
- The logistic model, $dN/dt = r_{max}N(K - N/K)$, includes the effects of resource limitation. The carrying capacity, *K,* is the maximum population size that an environment can sustain. The per capita population growth rate, *r,* decreases as *N* approaches *K.* A graph of logistic growth is S-shaped (Figure 52.10, Table 52.2).
- Some populations exhibit logistic growth in the laboratory and in nature, but time lags in response to increased density may cause *N* to oscillate around *K* (Figure 52.11).

Animation: Exponential Population Growth in Mice

Animation: Patterns of Population Growth

52.5 Population Dynamics

- Density-dependent factors regulate population size by reducing individual growth rates, adult size, survivorship, and fecundity (Figures 52.12 and 52.13). Competition within populations or between species, predator–prey interactions, parasites, and infectious diseases can cause density-dependent population regulation (Figure 52.14).
- Abiotic environmental factors, which affect a population regardless of its size, cause density-independent limitation of population size (Figure 52.15).
- Global climate change is exaggerating the effects of density-independent factors on populations of large, long-lived organisms (Figure 52.16).
- Interactions between density-dependent and density-independent factors often influence population size (Figure 52.17).
- The life history patterns of most organisms fall between two extremes: *r*-selected species and *K*-selected species (Figure 52.18). They differ in many life history characteristics (Table 52.3).
- Within metapopulations, sink populations are often replenished by individuals dispersing from a source population (Figure 52.19).
- Some animal populations exhibit cyclic fluctuations in size (Figure 52.20). No general model has successfully explained all population cycles.

52.6 Human Population Growth

- Human populations have sidestepped density-dependent population regulation by expanding into most terrestrial habitats, increasing carrying capacity, and reducing death rates with improved medical care and sanitation (Figures 52.21 and 52.22).
- Age structure may now control human population growth rates (Figure 52.23). In countries with large numbers of young people, populations will continue to grow rapidly as they reach sexual maturity. The populations of countries with a uniform age structure will not experience much growth in the foreseeable future.
- The demographic transition model describes the influence of economic development on population growth (Figure 52.24).
- Many governments encourage population control through family planning programs.

UNDERSTAND & APPLY

Test Your Knowledge

1. Ecologists sometimes use mathematical models to:
   a. avoid conducting laboratory studies or field work.
   b. simulate natural events before conducting detailed field studies.
   c. make basic observations about ecological relationships in nature.
   d. collect survivorship and fecundity data to construct life tables.
   e. determine the geographical ranges of populations.
2. The number of individuals per unit area or volume of habitat is called the population's:
   a. geographical range.
   b. dispersion pattern.
   c. density.
   d. size.
   e. age structure.
3. One day you caught and marked 90 butterflies in a population. A week later, you returned to the population and caught 80 butterflies, including 16 that had been marked previously. What is the size of the butterfly population?
   a. 170
   b. 450
   c. 154
   d. 186
   e. 106
4. A uniform dispersion pattern implies that members of a population:
   a. cooperate in rearing their offspring.
   b. work together to escape from predators.
   c. use resources that are patchily distributed.
   d. may experience intraspecific competition for vital resources.
   e. have no ecological interactions with each other.
5. The model of exponential population growth predicts that the per capita population growth rate *r:*
   a. does not change as a population gets larger.
   b. gets larger as a population gets larger.
   c. gets smaller as a population gets larger.
   d. is always at its maximum level (r_{max}).
   e. fluctuates on a regular cycle.
6. A population of 1,000 individuals experiences 462 births and 380 deaths in 1 year. What is the value of *r* for this population?
   a. 0.842/individual/year
   b. 0.462/individual/year
   c. 0.380/individual/year
   d. 0.820/individual/year
   e. 0.082/individual/year
7. According to the logistic model of population growth, the absolute number of individuals by which a population grows during a given time period:
   a. gets steadily larger as the population size increases.
   b. gets steadily smaller as the population size increases.
   c. remains constant as the population size increases.
   d. is highest when the population is at an intermediate size.
   e. fluctuates on a regular cycle.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

8. Which example might reflect density-dependent regulation of population size?
   a. An exterminator uses a pesticide to eliminate carpenter ants from a home.
   b. Mosquitoes disappear from an area after the first frost.
   c. The lawn dies after a month-long drought.
   d. Storms blow over and kill all the willow trees along a lake.
   e. The size of a clam population declines as the number of predatory herring gulls explodes.
9. A *K*-selected species is likely to exhibit:
   a. a Type I survivorship curve and a short generation time.
   b. a Type II survivorship curve and a short generation time.
   c. a Type III survivorship curve and a short generation time.
   d. a Type I survivorship curve and a long generation time.
   e. a Type II survivorship curve and a long generation time.
10. One reason why human populations have been able to sidestep the factors that usually control population growth is that:
   a. the carrying capacity for humans has remained constant since humans first evolved.
   b. agriculture and industrialization have increased the carrying capacity for our species.
   c. the population growth rate (*r*) for the human population has always been small.
   d. the age structure of human populations has no impact on its population growth.
   e. plagues have killed off large numbers of humans at certain times in the past.

Discuss the Concepts

1. Choose an animal or plant species that lives in your environment and identify the density-dependent and density-independent factors that might influence its population size. How could you demonstrate conclusively that the factors are either density-dependent or density-independent?
2. Many city-dwellers have noted that the density of cockroaches in apartment kitchens appears to vary with the habits of the occupants: people who wrap food carefully and clean their kitchen frequently tend to have fewer arthropod roommates than those who leave food on kitchen counters and clean less often. Interpret these observations from the viewpoint of a population ecologist.
3. How could you define the worldwide carrying capacity for humans? What factors would you have to take into account?

Design an Experiment

Design an experiment using fruit flies or some other small laboratory animal to test the hypothesis that delaying the age of first reproduction will decrease a population's per capita birth rate. Your experimental design should include experimental and control groups as well as details about your experimental methods and the data you would collect.

Interpret the Data

Gregory M. Erickson of Florida State University and colleagues from Florida State and the University of Alberta analyzed a fossil assemblage of 22 individuals of *Albertosaurus sarcophagus,* a relative of *Tyrannosaurus rex.* All 22 had died at roughly the same time—but at different ages—perhaps because of a drought or starvation. They used growth lines present in the fossilized leg bones to determine the age at death of each specimen. They had no data for very young individuals, and assumed a 60% mortality rate between birth and age two. The researchers constructed the following **Table** extrapolated to an initial cohort of 1,000 individuals:

Age (years)	Number Surviving	Age (years)	Number Surviving
0	1,000	15	218
1	___	16	182
2	400	17	164
3	___	18	127
4	382	19	109
5	___	20	73
6	364	21	56
7	___	22	___
8	345	23	36
9	327	24	___
10	___	25	___
11	309	26	___
12	291	27	___
13	273	28	18
14	255		

© Cengage Learning 2014

Did this population of animals exhibit a Type I, Type II, or Type III survivorship pattern—or something intermediate? What does the life table tell you about the age at which *Albertosaurus sarcophagus* was most vulnerable to the factors causing mortality?

Population Interactions and Community Ecology

Why it matters . . . In some open woodlands in Central America, flocks of chestnut-headed oropendolas *(Psarocolius wagleri),* members of the blackbird family, build hanging nests in isolated trees **(Figure 53.1).** Female giant cowbirds *(Molothrus oryzivorus)* often bully their way into a colony, laying an egg or two in each oropendola nest. Cowbirds are *brood parasites* on oropendolas, tricking them into caring for cowbird young. The cowbird chicks grow faster than oropendola chicks, and they consume much of the food that the oropendolas bring to their own offspring. Because cowbird chicks take food away from their oropendola nest mates, we might expect adult oropendolas to eject cowbird eggs and chicks from their nests—but often they don't.

Why do some oropendolas care for offspring that are not their own? In an ingenious study conducted in the 1960s, Neal Smith of the Smithsonian Tropical Research Institute determined that cowbird chicks could actually increase the number of offspring that some oropendolas raise. Oropendola chicks are frequently parasitized by botfly larvae, which feed on their flesh. The aggressive cowbird chicks snap at adult botflies and pick fly larvae off their nest mates. Although cowbird chicks eat food meant for oropendola chicks, they also protect them from potentially lethal parasites; twice as many young oropendolas survive in nests with cowbird chicks as in nests without them.

In other areas of Central America, oropendolas build nests near the hives of bees or wasps. These oropendolas chase cowbirds from their colonies, and when a cowbird does manage to sneak an egg into one of their nests, the oropendolas frequently eject it. Why do oropendolas in these colonies reject cowbird eggs? Smith determined that the swarms of bees and wasps keep botflies

FIGURE 53.1 Potential victims of brood parasitism. Chestnut-headed oropendolas *(Psarocolius wagleri)* rear their young in elaborate hanging nests. Some populations of oropendolas are subject to brood parasitism by giant cowbirds *(Molothrus oryzivorus)*.

away from the oropendola colonies. At these sites, twice as many oropendola chicks survive in nests without cowbirds as in those that include them. Thus the oropendolas derive no benefit from having cowbird chicks in their nests, and natural selection has favored discriminating behavior in oropendolas that nest near bees and wasps.

The story of the oropendolas, cowbirds, botflies, bees, and wasps provides an example of the population interactions that characterize life in an **ecological community,** an assemblage of species living in the same place. As this story reveals, the presence or absence of certain species may alter the effects of such interactions in almost unimaginably complex ways. We begin this chapter with a description of some of the many ways that populations in a community interact. We then examine how population interactions and other factors, such as the kinds of species present and the relative numbers of each species, influence a community's characteristics.

53.1 Population Interactions

Interactions between populations usually provide benefits or cause harm to the interacting organisms, as compared with organisms that are not engaged in the interaction **(Table 53.1).** Because interactions with other species often affect the survival and reproduction of individuals, many of the relationships that we witness today are the products of long-term evolutionary

TABLE 53.1 Population Interactions and Their Effects

Interaction	Effects on Interacting Populations	
Predation	+/−	Predators gain nutrients and energy; prey are killed or injured.
Herbivory	+/−	Herbivores gain nutrients and energy; plants are killed or injured.
Parasitism	+/−	Parasites gain nutrients and energy; hosts are injured or killed.
Competition	−/−	Both competing populations lose access to some resources.
Commensalism	+/0	One population benefits; the other population is unaffected.
Mutualism	+/+	Both populations benefit.

modification. Before examining several general types of population interactions, we briefly consider how natural selection has shaped the relationships between interacting species.

Coevolution Produces Reciprocal Adaptations in Species That Interact Ecologically

Population interactions change constantly. New adaptations that evolve in one species exert selection pressure on another, which then evolves adaptations that exert selection pressure on the first. The evolution of genetically based, reciprocal adaptations in two or more interacting species is described as **coevolution.**

Some coevolutionary relationships are straightforward. For example, ecologists describe the coevolutionary interactions between some predators and their prey as a race in which each species evolves adaptations that temporarily allow it to outpace the other. When antelope populations suffer predation by cheetahs, natural selection fosters the evolution of faster speed in the antelopes. Cheetahs then experience selection for increased speed so that they can overtake and capture antelopes. Other coevolved interactions provide benefits to both partners. For example, the flower structures of different monkey-flower species have evolved characteristics that allow them to be visited by either bees or hummingbirds (see Figure 22.7).

Although one can hypothesize a coevolutionary relationship between any two interacting species, documenting the evolution of reciprocal adaptations is difficult. As our introductory story about oropendolas and their parasites illustrated, coevolutionary interactions often involve more than two species. Indeed, most organisms experience complex interactions with numerous other species in their communities, and the simple portrayal of coevolution as taking place between two species rarely does justice to the complexity of these relationships.

Predation and Herbivory Define Many Relationships in Ecological Communities

Because animals acquire nutrients and energy by consuming other organisms, **predation** (the interaction between predatory animals and the animal prey they consume) and **herbivory** (the interaction between herbivorous animals and the plants they eat) are often the most conspicuous relationships in ecological communities.

ADAPTATIONS FOR FEEDING Both predators and herbivores have evolved remarkable characteristics that allow them to feed effectively. Carnivores use sensory systems to locate animal prey and specialized behaviors and anatomical structures to capture and consume it. For example, a rattlesnake (genus *Crotalus*) uses heat sensors on its head (see Figure 41.22) and chemical sensors in the roof of its mouth to find rats or other endothermic prey. Its hollow fangs inject toxins that kill the prey and begin to digest its tissues even before the snake consumes it. And elastic ligaments connecting the bones of its jaws and skull allow a snake to swallow prey that is larger than its head. Herbivores have comparable adaptations for locating and processing their food plants. Insects use chemical sensors on their legs and heads to identify edible plants and sharp mandibles or sucking mouthparts to consume plant tissues or sap. Herbivorous mammals have specialized teeth to harvest and grind tough vegetation (see Section 47.5).

All animals must select their diets from a variety of potential food items. Some species, described as *specialists,* feed on one or just a few types of food. Among birds, for example, the Everglades kite *(Rostrhamus sociabilis)* consumes just one prey species, the apple snail *(Pomacea paludosa).* Other species, described as *generalists,* have broader tastes. Crows (genus *Corvus*) consume food ranging from grains to insects to carrion.

How does an animal select what food to eat? Some mathematical models, collectively described as **optimal foraging theory,** predict that an animal's diet is a compromise between the costs and benefits associated with different types and sizes of food. Assuming that animals try to maximize their energy intake in a given feeding time, their diets should be determined by the time and energy it takes to pursue, capture, and consume a particular kind of food compared with the energy that food provides. For example, a cougar *(Puma concolor)* will invest more time and energy hunting a mountain goat *(Oreamnos americanus)* than a jackrabbit *(Lepus townsendii),* but the payoff for the cougar is a bigger meal.

Food abundance also affects food choice. When prey are scarce, animals often take what they can get, settling for food that has a low benefit-to-cost ratio. But when food is abundant, they may specialize, selecting types that provide the largest energetic return. Bluegill sunfish *(Lepomis macrochirus),* for example, feed on *Daphnia* and other small crustaceans. When crustacean density is high, the fish hunt mostly large *Daphnia,*

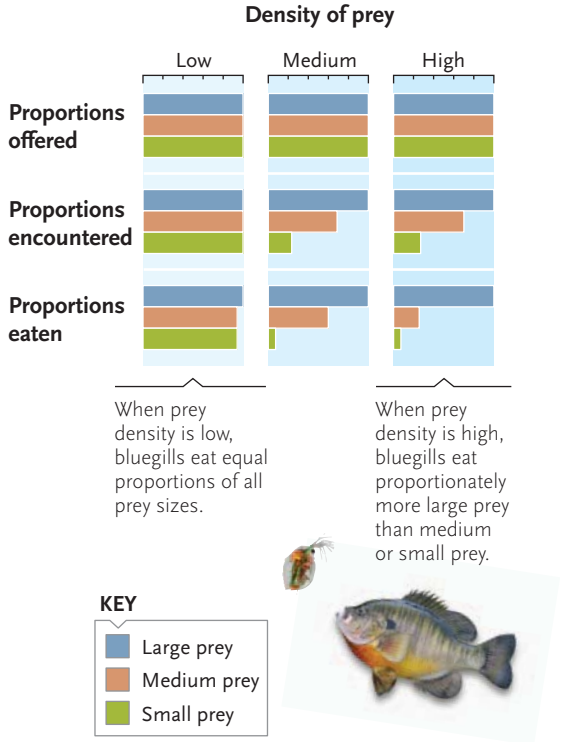

FIGURE 53.2 An experiment demonstrating that prey density affects predator food choice. Researchers tested the food-size preferences of captive bluegill sunfish *(Lepomis macrochirus)* by offering them equal numbers of small, medium, and large-sized prey *(Daphnia magna)* at three different prey densities. Because large prey are the easiest to find, bluegills encountered them more frequently than small or medium-sized prey, especially at the highest prey density. The bluegills' selection of prey varied with prey density; they strongly preferred large prey when prey of all sizes were abundant.

(*Daphnia,* Lebendkulturen.de/Shutterstock.com; bluegill, © iStockphoto.com/George Peters)

© Cengage Learning 2014

which provide more energy for their effort; but when prey density is low, bluegills feed on *Daphnia* of all sizes **(Figure 53.2).**

DEFENSES AGAINST HERBIVORY AND PREDATION Because herbivory and predation have a negative impact on the organisms being consumed, plants and animals have evolved mechanisms to avoid being eaten. Some plants use spines, thorns, and irritating hairs to protect themselves from herbivores. Many plant tissues also contain poisonous chemicals that deter herbivores from feeding. For example, plants in the milkweed family (Asclepiadaceae) exude a milky, irritating sap that contains cardiac glycosides, even small amounts of which are toxic to vertebrate heart muscle. Other compounds mimic the structure of insect hormones, disrupting the development of insects that consume them. Most of these poisonous compounds are volatile, giving plants their typical aromas; some herbivores have coevolved the ability to recognize these odors and avoid the toxic plants. Recent research indicates that some plants increase their production of toxic compounds in response to herbivore feeding. For example, potato and tomato plants that have been damaged by herbivores produce higher levels of protease-

inhibiting chemicals; these compounds prevent herbivores from digesting proteins they have just consumed, reducing the food value of these plant tissues.

Many animals have evolved an appearance that provides a passive defense against predation **(Figure 53.3).** Caterpillars that look like bird droppings, for example, may not attract much attention from a hungry predator. And as you learned in Chapter 1 (see Figure 1.9), **cryptic coloration** helps some prey (as well as some predators) to blend in with their surroundings.

Once discovered by a predator, many animals first try to run away. When cornered, they may try to startle or intimidate the predator with a display that increases their apparent size or ferocity **(Figure 53.4).** Such a display might confuse the predator just long enough to allow the potential victim to escape. Other species seek shelter in protected sites. For example, flexible-shelled African pancake tortoises *(Malacochersus tornieri)* retreat into rocky crevices and puff themselves up with air, becoming so tightly wedged between rocks that predators cannot extract them.

Other animals defend themselves actively. North American porcupines (genus *Erethizon*) release hairs modified into sharp, barbed quills that stick in a predator's mouth, causing severe pain and swelling. Other species fight back by biting, charging, or kicking an attacking predator. Chemical defenses also provide effective protection. Skunks release a noxious spray when threatened, and some frogs and toads produce neurotoxic skin secretions that paralyze and kill mammals. Some insects even protect themselves with poisons acquired from plants. The caterpillars of monarch butterflies *(Danaus plexippus)* are immune to the cardiac glycosides in the milkweed leaves they eat. They store these chemicals at high concentration, even through metamorphosis, making adult monarchs poisonous to vertebrate predators.

Poisonous or repellant species often advertise their unpalatability with bright, contrasting patterns, called **aposematic coloration (Figure 53.5).** Although a predator might attack a black-and-white skunk, a yellow-banded wasp, or an orange monarch butterfly once, it quickly learns to associate the gaudy color pattern with pain, illness, or severe indigestion—and rarely attacks these easily recognized animals again.

Mimicry, in which one species evolves an appearance resembling that of another **(Figure 53.6),** is also a form of defense. In **Batesian mimicry,** named for English naturalist Henry W. Bates, a palatable or harmless species, the **mimic,** resembles an unpalatable or poisonous one, the **model.** Any predator that eats the poisonous model will subsequently avoid other organisms that resemble it. In **Müllerian mimicry,** named for German zoologist Fritz Müller, two or more unpalatable species share a similar appearance, which reinforces the lesson learned by a predator that attacks any species in the mimicry complex.

Despite the effectiveness of many antipredator defenses, coevolution has often molded the responses of predators to overcome them. For example, when threatened by a predator, the pinacate beetle *(Eleodes longicollis)* raises its rear end and

sprays a noxious chemical from a gland at the tip of its abdomen. Although this behavior deters many would-be predators, grasshopper mice (genus *Onychomys*) of the American southwest circumvent this defense: they grab the beetles, shove their abdomens into the ground, rendering the beetle's spray ineffective, and then eat the beetles head first **(Figure 53.7).**

Interspecific Competition Occurs When Different Species Depend on the Same Limiting Resources

Populations of different species often use the same limiting resources, causing **interspecific competition** (competition *between* species). The competing populations may experience increased mortality and decreased reproduction, responses that are similar to the effects of intraspecific competition (see Section 53.4). Interspecific competition reduces the size and population growth rate of one or more of the competing populations.

Community ecologists identify two main forms of interspecific competition. In **interference competition,** individuals of one species harm individuals of another species directly. Animals may fight for access to resources, as when lions chase smaller scavengers like hyenas and jackals from their kills. Similarly, many plant species, including creosote bushes (see Figure 52.4), release toxic chemicals that prevent other plants from growing nearby. In **exploitative competition,** two or more populations use ("exploit") the same limiting resource. The presence of one species reduces resource availability for the others, even in the absence of snout-to-snout or root-to-root confrontations. For example, in the deserts of the American Southwest, many bird and ant species feed largely on seeds. Thus, each seed-eating species may deplete the food supply available to others.

FIGURE 53.7 **Coevolution of predators and prey. (A)** When disturbed by a predator, the pinacate beetle sprays a noxious chemical from its posterior end. **(B)** Grasshopper mice overcome this defense by shoving a beetle's rear end into the soil and dining on its head first.

COMPETITIVE EXCLUSION In the 1920s, the Russian mathematician Alfred J. Lotka and the Italian biologist Vito Volterra independently proposed a model of interspecific competition, modifying the logistic equation (see Section 50.4) to describe the effects of competition between two species. In their model, an increase in the size of one population reduces the population growth rate (r) of the other.

A Russian biologist, G. F. Gause, tested this general model experimentally in the 1930s, using species that might compete with each other for resources in a simple laboratory system. He grew cultures of two *Paramecium* species (ciliate "protists") under constant laboratory conditions, regularly renewing food and removing wastes. Both species fed on bacteria suspended in the culture medium. When grown alone, each species exhibited logistic growth. When grown together in the same dish, however, *Paramecium aurelia* persisted at high density, but *Paramecium caudatum* was nearly eliminated **(Figure 53.8).** These results inspired Gause to define the **competitive exclusion principle:** populations of two or more species cannot coexist indefinitely if they rely on the same limiting resources and exploit them in the same way. One species is inevitably more successful, harvesting resources more efficiently and producing more offspring than the other.

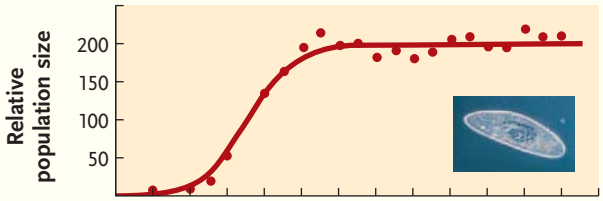
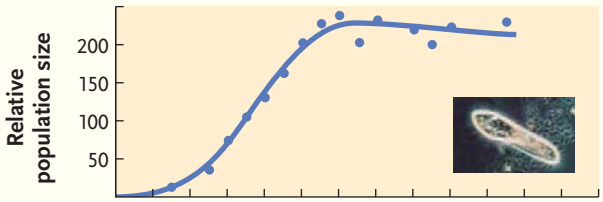
FIGURE 53.8 Experimental Research



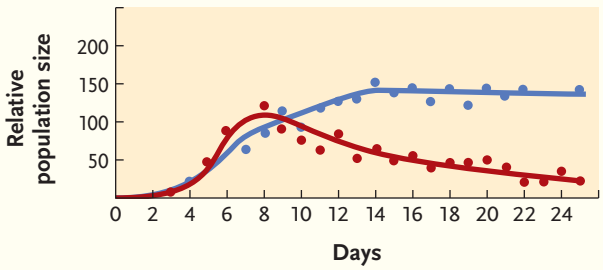
Gause's Experiments on Interspecific Competition in *Paramecium*

Question: Can two species of *Paramecium* coexist in a simple laboratory environment?



Experiment: Gause grew populations of two species, *Paramecium aurelia* and *Paramecium caudatum,* alone (single species cultures) or together (mixed cultures) in small bottles in his laboratory. To determine whether the growth of these populations followed the predictions of the logistic equation, Gause had to maintain a reasonably constant carrying capacity in each culture. Thus, he fed the cultures a broth of bacteria, and he eliminated their waste products (by centrifuging the cultures and removing some of the culture medium) on a regular schedule. He then monitored their population sizes through time.

Results: When grown separately, *P. caudatum* **(A)** and *P. aurelia* **(B)** each exhibited logistic population growth. But when the two species were grown together in a mixed culture **(C),** *P. aurelia* persisted and *P. caudatum* was nearly eliminated from the culture.



A. *P. caudatum* alone

B. *P. aurelia* alone

C. Mixed culture

Conclusion: Because one species was almost always eliminated from mixed species cultures, Gause formulated the competitive exclusion principle: populations of two or more species cannot coexist indefinitely if they rely on the same limiting resources and exploit them in the same way.

THINK LIKE A SCIENTIST The results of this study suggest that when the two species are grown together in mixed culture, *P. aurelia* persists and *P. caudatum* becomes extinct. But does the presence of *P. caudatum* appear to have any effect on *P. aurelia* in the mixed cultures?

THE NICHE CONCEPT Ecologists developed the concept of the **ecological niche** as a tool for visualizing resource use and the potential for interspecific competition in nature. We define a population's niche by the resources it uses and the environmental conditions it requires over its lifetime. In this context, the niche includes food, shelter, and nutrients as well as abiotic conditions, such as light intensity and temperature, which cannot be depleted. In theory, one could identify an almost infinite variety of conditions and resources that contribute to a population's niche. In practice, ecologists usually analyze a few critical resources for which populations might compete. Sunlight, soil moisture, and inorganic nutrients are important resources for plants. Food type, food size, and nesting sites are important for animals.

Ecologists distinguish the **fundamental niche** of a population, the range of conditions and resources that it can possibly tolerate and use, from its **realized niche,** the range of conditions and resources that it actually uses in nature. Realized niches are smaller than fundamental niches, partly because all tolerable conditions are not always present in a habitat, and partly because some resources are used by other species. We can visualize competition between two populations by plotting their fundamental and realized niches with respect to one or more resources **(Figure 53.9).** If the fundamental niches of two populations overlap, they *might* compete in nature.

EVALUATING COMPETITION IN NATURE The observation that several populations use the same resource does not demonstrate that competition is occurring. For example, all terrestrial animals consume oxygen, but they don't compete for oxygen because it is usually plentiful. Nevertheless, two general phenomena provide *indirect* evidence that interspecific competition in the past probably fostered the evolution of behaviors, structures, and ecological differences that enable species to avoid interspecific competition in the present. The first is the extremely common observation of **resource partitioning,** the use of different resources or the use of resources in different ways, by species living in the same place. For example, weedy plants might compete for water and dissolved nutrients in abandoned fields. But they avoid competition by partitioning these resources, collecting them from different depths in the soil **(Figure 53.10).**

A second phenomenon that suggests the importance of competition is observed in comparisons of species that are sometimes sympatric (that is, living in the same place) and sometimes allopatric (that is, living in different places). In several studies of animals, researchers have documented **character displacement:**

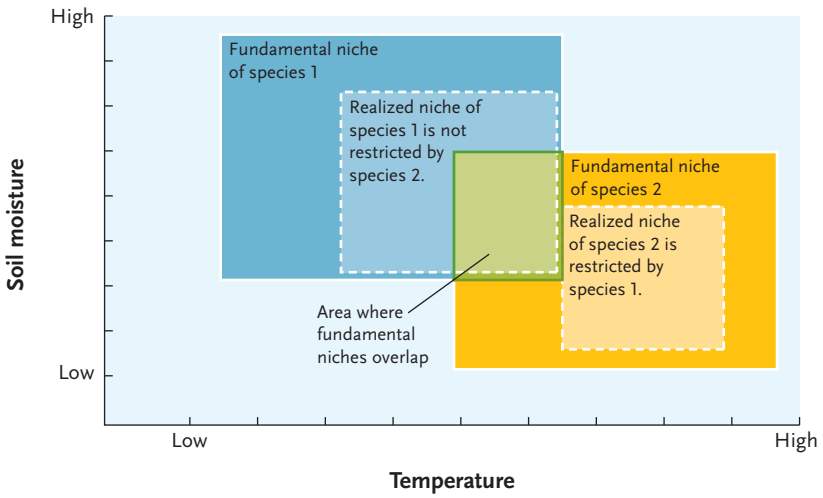

FIGURE 53.9 **Fundamental versus realized niches.** In this hypothetical example, both species 1 and species 2 can survive intermediate temperature and soil moisture conditions, as indicated by the green shading where their fundamental niches overlap. Because species 1 actually occupies virtually all of this overlap zone, its realized niche is not affected by the presence of species 2. By contrast, the realized niche of species 2 is restricted by the presence of species 1; species 2 occupies only the warmer and dryer parts of the habitat.

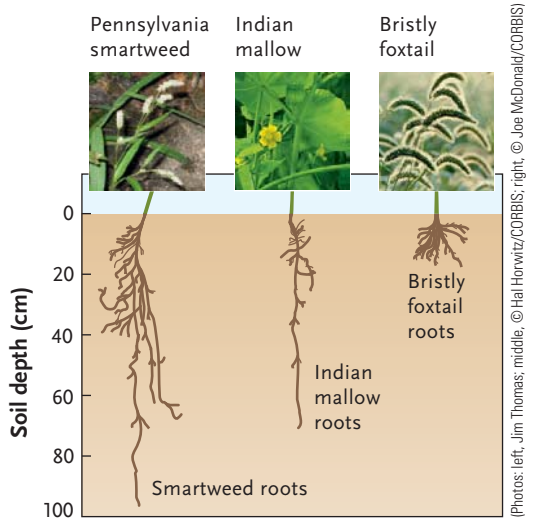

FIGURE 53.10 **Resource partitioning.** The root systems of three plant species that grow in abandoned fields partition water and nutrient resources in soil. Bristly foxtail grass *(Setaria faberi)* has a shallow root system; Indian mallow *(Abutilon theophrasti)* has a moderately deep taproot; and Pennsylvania smartweed *(Polygonum pensylvanicum)* has a deep taproot that branches at many depths.
© Cengage Learning 2014

allopatric populations are morphologically similar and use similar resources, but sympatric populations are morphologically different and use different resources. The differences between the sympatric populations allow them to coexist without competing. Differences in bill size among sympatric finch species on the Galápagos Islands (see Section 20.2) may be the product of character displacement **(Figure 53.11).**

Data on resource partitioning and character displacement merely suggest the possible importance of interspecific competition in nature. To demonstrate *conclusively* that interspecific competition limits natural populations, one must show that the presence of one population reduces the population size or distribution of its presumed competitor. In a classic field experiment, Joseph Connell of the University of California, Santa Barbara, determined that competition between two barnacle species caused the realized niche of one species to be smaller than its fundamental niche **(Figure 53.12).**

Connell first observed the distributions of barnacles in undisturbed habitats. *Chthamalus stellatus* is generally found in shallow water on rocky coasts, where it is periodically exposed to air. *Balanus balanoides* typically lives in deeper water, where it is usually submerged.

Connell determined the fundamental niche of each species by removing either *Chthamalus* or *Balanus* from rocks and monitoring the distribution of each species in the absence of the other. When Connell removed *Balanus* from rocks in deep water, larval *Chthamalus* colonized the area and produced a flourishing population of adults. Connell had observed that *Balanus* physically displaced *Chthamalus* from these rocks. Thus, interference competition from *Balanus* prevents *Chthamalus* from occupying areas where it would otherwise live. By contrast, the removal of *Chthamalus* from rocks in shallow water did not result in coloni-

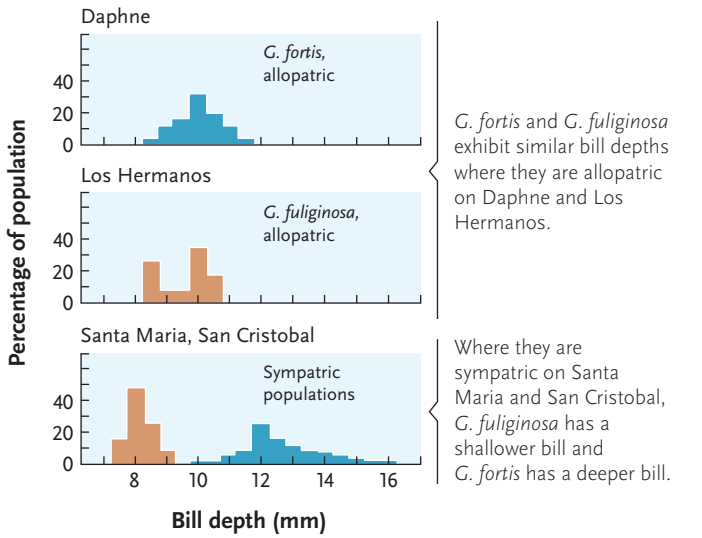

FIGURE 53.11 **Character displacement.** *Geospiza fortis* and *Geospiza fuliginosa* exhibit character displacement in the depth of their bills, a trait that is correlated with the sizes of seeds they eat.

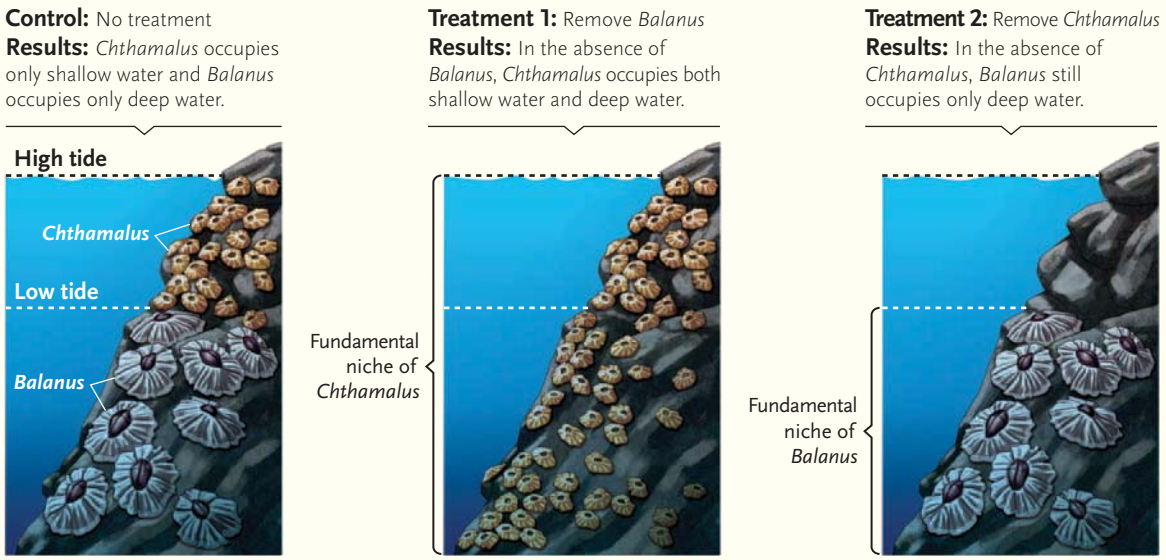

FIGURE 53.12 **Experimental Research**

Demonstration of Competition between Two Species of Barnacles

Question: Do two barnacle species limit one another's realized niches in habitats where they coexist?

Experiment: Connell observed a difference in the distributions of two barnacle species on a rocky coast: *Chthamalus stellatus* occupies shallow water, and *Balanus balanoides* lives in deeper water. He then determined the fundamental niche of each species by removing either *Chthamalus* or *Balanus* from rocks and monitoring the distribution of each species in the absence of the other.

Results: When Connell removed *Balanus* from rocks in deep water, larval *Chthamalus* colonized the area and produced a flourishing population of adults. By contrast, the removal of *Chthamalus* from rocks in shallow water did not result in colonization by *Balanus*.

Conclusion: In habitats where *Balanus* and *Chthamalus* coexist, the realized niche of *Chthamalus* is smaller than its fundamental niche because of competition from *Balanus*. The realized niche of *Balanus* is similar to its fundamental niche because it is not affected by the competitive interaction.

THINK LIKE A SCIENTIST Given the results of Connell's experiment, which species of barnacle would you describe as the stronger competitor?

Source: Joseph H. Connell. 1961. The influence of interspecific competition and other factors on the distribution of the barnacle *Chthamalus stellatus*. *Ecology* 42:710–723.

© Cengage Learning 2014

zation by *Balanus*. *Balanus* is apparently unable to live in habitats that are frequently exposed to air. Connell therefore concluded that competition from *Chthamalus* does not affect the distribution of *Balanus*. Thus, the competitive interaction between these two species is asymmetrical: *Balanus* has a substantial effect on *Chthamalus*, but *Chthamalus* has virtually no effect on *Balanus*.

In Symbiotic Associations, the Lives of Two or More Species Are Closely Intertwined

Some species have a physically close ecological association called **symbiosis** (*sym* = together, *bio* = life, *sis* = condition). Biologists define three types of symbiotic interactions—*commensalism*, *mutualism*, and *parasitism*—that differ in their effects.

Commensalism, in which one species benefits and the other is unaffected, is rare in nature, because few species are unaffected by their interactions with another. One possible example is the relationship between cattle egrets *(Bubulcus ibis)*, birds in the heron family, and the large grazing mammals with which they associate **(Figure 53.13).** Cattle egrets feed on insects and other small animals that their commensal partners flush from grass. Feeding rates of egrets are higher when they associate with large grazers than when they do not. The birds clearly

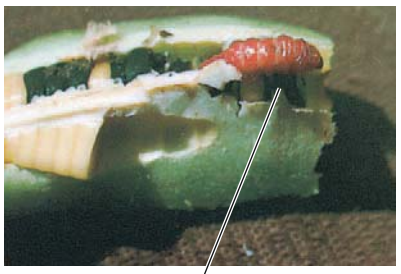
FIGURE 53.14 Mutualism between plants and animals. Several species of yucca plants (*Yucca* species) are each pollinated exclusively by one species of yucca moth (*Tegeticula* species). The adult stage of each moth appears at the time of year when its yucca plant flowers. These species are so mutually interdependent that the larvae of each moth species can feed on only one type of yucca, and the flowers of each yucca can be fertilized by only one species of moth. Most plant–pollinator mutualisms are much less specific.

A. Flowering yucca plant

Douglas Knight/Shutterstock.com



B. Female yucca moth

Harlo H. Hadow

A female yucca moth uses highly modified mouthparts to gather the sticky yucca pollen and roll it into a ball. She carries the pollen to another flower, and after piercing its ovary wall, she lays her eggs. She then places the pollen ball into the opening of the stigma.

C. Yucca moth larva

Harlo H. Hadow

When moth larvae hatch from the eggs, they eat some of the yucca seeds and gnaw their way out of the ovary to complete their life cycle. Enough seeds remain undamaged to produce a new generation of yuccas.

benefit from this interaction, but the presence of birds has no apparent positive or negative impact on the mammals.

Mutualism, in which both partners benefit, is extremely common. The coevolved relationships between flowering plants and animal pollinators are largely mutualistic (see Section 29.1). Animals that feed on a plant's nectar or pollen carry its gametes from one flower to another **(Figure 53.14).** Similarly, animals that eat the fruits of flowering plants disperse the seeds, "planting" them in a pile of nutrient-rich feces. These mutualistic relationships between plants and animals do not require active cooperation. Each species simply exploits the other for its own benefit.

Some associations between either bacteria or fungi and plants are also mutualistic. For example, mycorrhizae are fungi that grow alongside the roots of many plant species. These fungi facilitate the plants' uptake of nitrogen and phosphorus from the soil, and the plants provide the fungi with carbohydrates in return. Another important mutualism is the close relationship between the nitrogen-fixing bacterium *Rhizobium* and leguminous plants, such as peas, beans, and clover (see Section 35.3).

Mutualistic relationships between animal species are also common. For example, some small marine fishes feed on parasites that attach to the mouths and gills of large predatory fishes **(Figure 53.15).** Parasitized fishes hover motionless while the "cleaners" scour their tissues. The relationship is mutualistic because the cleaner fishes get a meal, and the larger fishes are relieved of parasites.

The relationship between the bullhorn acacia tree *(Acacia cornigera)* of Central America and a small ant species *(Pseudomyrmex ferruginea)* is one of the most highly coevolved mutualisms known **(Figure 53.16).** Each acacia is inhabited by an ant colony that lives in the tree's swollen thorns. The ants swarm out of the thorns to sting—and sometimes kill—herbivores that touch the tree. The ants also clip any vegetation that grows nearby. Thus, acacia trees that are colonized by ants grow in a space free of herbivores and competitors, and occupied trees grow faster and produce more seeds than unoccupied trees. In return, the plants produce sugar-rich nectar consumed by adult ants and protein-rich structures that the ants feed to their larvae. Ecologists describe the coevolved mutualism between these species as *obligatory,* at least for the ants; they cannot subsist on any other food sources.

Parasitism is a type of interaction in which one species, the **parasite,** uses another, the **host,** in a way that is harmful to the host. Parasite–host relationships are like predator–prey relationships: one population of organisms feeds on another. But parasites rarely kill their hosts quickly because a dead host is useless as a continuing source of nourishment.

James A Dawson/Shutterstock.com

FIGURE 53.15 Mutualism between animal species. A giant moray *(Gymnothorax javanicus)* remains nearly motionless in the water while bluestreak cleaner wrasses *(Labroides dimidiatus)* carefully remove and eat ectoparasites attached to its mouth. The moray is a predator, and the striped cleaner wrasse is a potential prey—but their mutualistic interaction supersedes a possible predator–prey interaction.

Tapeworms and other parasites that live *within* a host are **endoparasites.** Many endoparasites acquire their hosts passively, when a host accidentally ingests the parasite's eggs or larvae (see *Focus on Applied Research,* Chapter 31). Endoparasites generally complete their life cycle in one or two host individuals. By contrast, leeches (see Figure 31.31), aphids, mosquitoes, and other parasites that feed on the *exterior* of a host are **ectoparasites.** Most animal ectoparasites have elaborate sensory and behavioral mechanisms that allow them to locate specific hosts, and they feed on numerous host individuals during their lifetimes. Some plants, such as mistletoes (genus *Phoradendron*), live as ectoparasites on the trunks and branches of trees; their roots penetrate the host's xylem and extract water and nutrients.

Not all parasites feed directly on a host's tissues. The giant cowbirds described earlier are brood parasites, as are other species of cowbirds and cuckoos. Although oropendolas sometimes benefit from the presence of cowbirds, most brood parasites have negative effects on their hosts. For example, brood parasitism by the brown-headed cowbird *(Molothrus ater)* has played a large role in the near-extinction of Kirtland's warbler *(Dendroica kirtlandii).*

The feeding habits of some insects, called **parasitoids,** fall somewhere between true parasitism and predation. A female parasitoid lays eggs in the larva or pupa of another insect species, and her young consume the tissues of the living host. Because the hosts chosen by most parasitoids are highly specific, agricultural ecologists often release parasitoids to control populations of insect pests.

STUDY BREAK 53.1

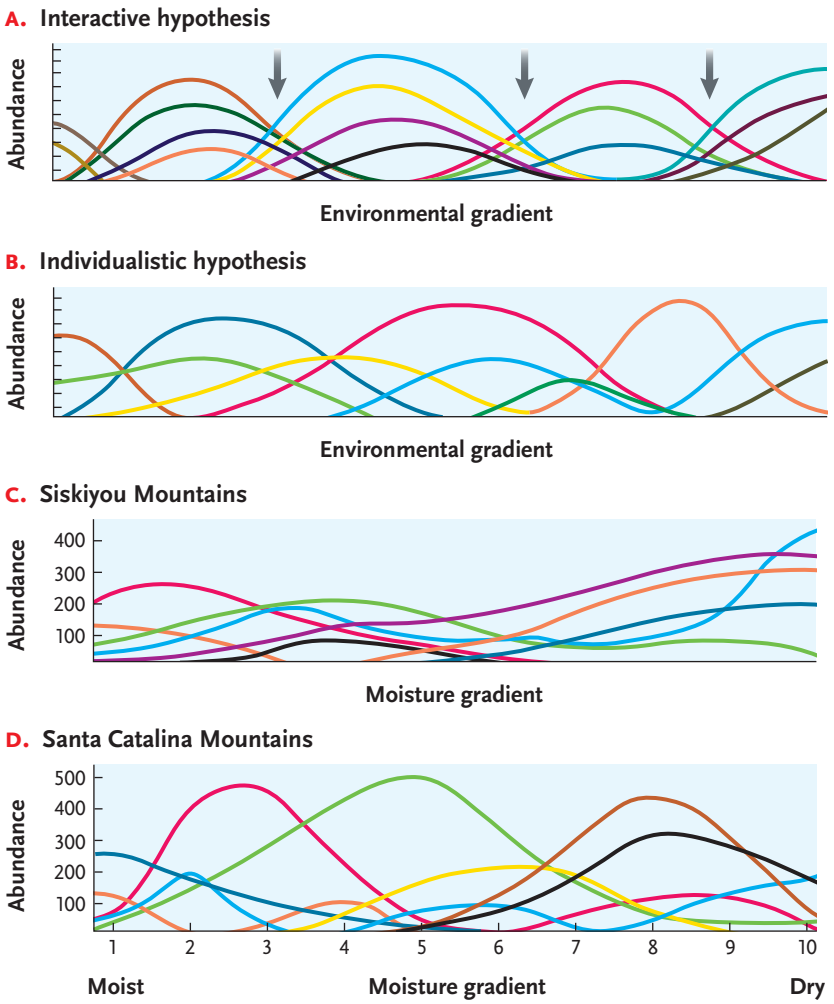
1. How might natural selection favor a carnivore that spends more time and energy capturing large prey than small prey?
2. What are the differences between cryptic coloration, aposematic coloration, and mimicry? Can a mimic ever have aposematic coloration?
3. How can field experiments demonstrate conclusively that two species compete for limiting resources?

THINK OUTSIDE THE BOOK

Using the terms and concepts introduced in this chapter, describe the interactions that humans have with ten other species. Try to pick at least eight species that we do not eat.

53.2 The Nature of Ecological Communities

Ecologists have often debated the nature of ecological communities, asking if they have emergent properties that transcend the interactions among the populations they contain.



Most Ecological Communities Blend into Neighboring Communities

How do complex population interactions affect the organization and functioning of ecological communities? In the 1920s, ecologists in the United States developed two extreme hypotheses about the nature of ecological communities. Frederic Clements of the University of Minnesota championed an *interactive* view of communities. He described communities as "superorganisms," assemblages of species bound together by complex population interactions. According to this view, each species in a community requires interactions with a set of ecologically different species, just as every cell in an organism requires services that other types of cells provide. Clements believed that once a mature community was established, its **species composition**—the particular combination of species that occupy the site—was at *equilibrium.* If a fire or some other environmental factor disturbed the community, it would return to its predisturbance state.

Henry A. Gleason of the University of Michigan proposed an alternative, *individualistic* view of ecological communities. He believed that population interactions do not always determine species composition. Instead, a community is just an assemblage of species that are individually adapted to similar environmental conditions. According to Gleason's hypothesis, communities do not achieve equilibrium; rather, they constantly change in response to disturbance and environmental variation.

In the 1960s, Robert Whittaker of Cornell University suggested that ecologists could determine which hypothesis was correct by analyzing communities along environmental gradients, such as temperature or moisture **(Figure 53.17).** According to Clements' interactive hypothesis, species that typically occupy the same communities should always occur together. Thus, their distributions along the gradient would be clustered in discrete groups with sharp boundaries between groups (see Figure 53.17A). According to Gleason's individualistic hypothesis, each species is distributed over the section of an environmental

The interactive hypothesis predicts that species within communities exhibit similar distributions along environmental gradients (indicated by the close alignment of several curves over each section of the gradient) and that boundaries between communities (indicated by arrows) are sharp.

The individualistic hypothesis predicts that species distributions along the gradient are independent (indicated by the lack of alignment of the curves) and that sharp boundaries do not separate communities.

Most gradient analyses support the individualistic hypothesis, as illustrated by distributions of tree species along moisture gradients in Oregon's Siskiyou Mountains and Arizona's Santa Catalina Mountains.

FIGURE 53.17 Two views of ecological communities. Each colored line represents the abundance of one plant species over the environmental gradient.

© Cengage Learning 2014

gradient to which it is adapted. Different species would have unique distributions, and species composition would change continuously along the gradient. In other words, communities would not be separated by sharp boundaries (see Figure 53.17B).

Most gradient analyses support Gleason's individualistic view of ecological communities. Environmental conditions vary continuously in space, and most plant distributions match these patterns (see Figure 53.17C, D). Species occur together in assemblages because they are adapted to similar conditions, and the species compositions of the assemblages change gradually across environmental gradients.

Nevertheless, the individualistic view does not fully explain all patterns observed in nature. Ecologists recognize certain assemblages of species as distinctive communities and name them accordingly—redwood forests and coral reefs are good examples. But the borders between adjacent communities are often wide transition zones, called **ecotones.** Ecotones are generally rich with species because they include plants and animals from both neighboring communities as well as some species that thrive only under transitional conditions. In some places, however, a discontinuity in a critical resource or some important abiotic factor produces a sharp community boundary. For example, chemical differences between soils derived from serpentine rock and sandstone establish sharp boundaries between communities of native California wildflowers and introduced European grasses **(Figure 53.18).**

Jasper Ridge Biological Preserve

FIGURE 53.18 Sharp community boundaries. Soils derived from serpentine rock have high magnesium and heavy metal content, which many plants cannot tolerate. Although native California wildflowers (bright yellow in this photograph) thrive on serpentine soil at the Jasper Ridge Preserve of Stanford University, introduced European grasses (green in this photograph) competitively exclude them from adjacent soils derived from sandstone.

2. **Why would you often find more species living in an ecotone than you would in the communities on either side of it?**

53.3 Community Characteristics

Although the species composition of any ecological community—whether terrestrial, freshwater, or marine—may vary somewhat over geographical gradients, every community has certain characteristics that define its overall appearance and structure.

The Growth Forms of Plants Establish a Terrestrial Community's Overall Appearance

The growth forms of plants—their sizes and shapes—vary markedly in different environments. Warm, moist environments support complex vegetation with multiple vertical layers. For example, tropical forests include a canopy, formed by the tallest trees; an understory of shorter trees and shrubs; an herb layer under openings in the canopy; vinelike lianas; and epiphytes, which grow on the trunks and branches of trees **(Figure 53.19).** By contrast, physically harsh environments are occupied by low vegetation with simple structure. For example, trees on mountaintops buffeted by cold winds are short, and the plants below them cling to rocks and soil. Other environments support growth forms between these extremes (see Chapter 51).

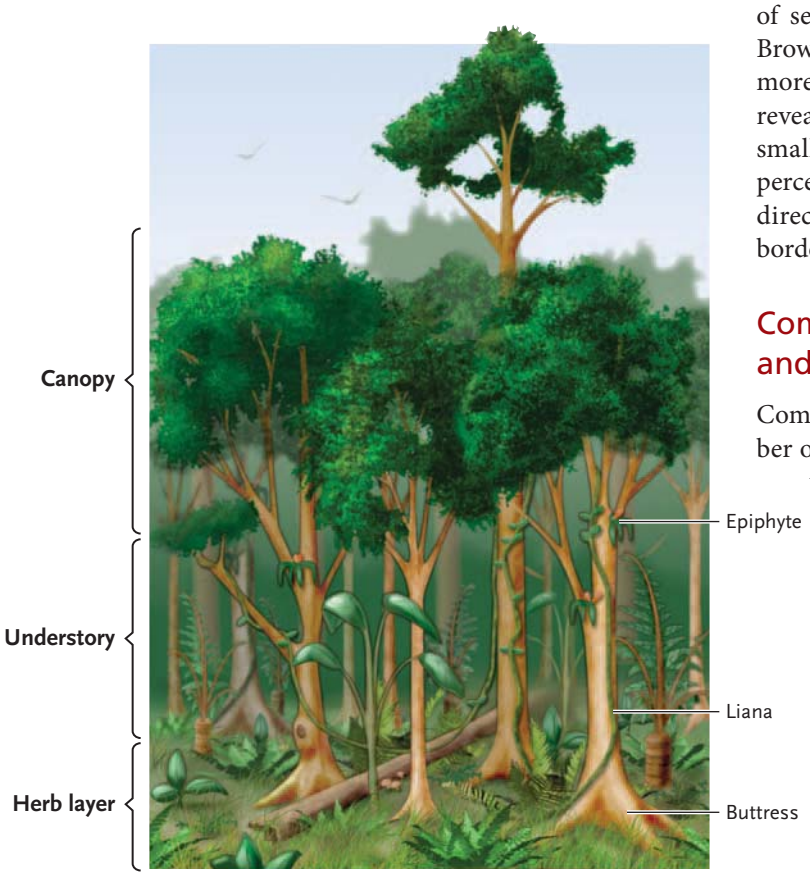

FIGURE 53.19 Layered forests. Tropical forests include a canopy of tall trees and an understory of short trees and shrubs. Huge vines (lianas) climb through the trees, eventually reaching sunlight in the canopy, and epiphytic plants grow on trunks and branches, increasing the structural complexity of the habitat.

© Cengage Learning 2014

Foundation Species Moderate the Abiotic Environment within a Community

In many ecological communities, one common species can function as a **foundation species,** defining the nature of a community by creating locally stable environmental conditions. For example, trees are the foundation species in forested ecosystems, because their form defines the physical structure of the community, and their leaves and branches moderate short-term fluctuations in abiotic environmental factors like temperature, runoff from rainfall, and wind speed.

Saltmarsh cordgrass *(Spartina alterniflora)* is a foundation species in the wetlands surrounding Narragansett Bay, Rhode Island, because patches of this meter-high grass slow the velocity of the incoming tide and stabilize the stony beach habitat along the shore. In the absence of *Spartina,* tidal surges move the stones on the beach, disrupting the germination and growth of several small, herbaceous plant species. John F. Bruno of Brown University surveyed the plants growing adjacent to more than 350 *Spartina* patches of varying size. His research revealed that large patches of *Spartina* are more effective than small patches in moderating tidal effects. Not surprisingly, the percentage of a stony beach occupied by herbaceous plants was directly proportional to the length of the *Spartina* patch that bordered the beach **(Figure 53.20).**

Communities Differ in Species Richness and the Relative Abundance of Species

Communities differ greatly in their **species richness,** the number of species that live within them. For example, the harsh environment on a low desert island may support just a few species of microorganisms, fungi, algae (photosynthetic protists), plants, and arthropods. By contrast, tropical forests, which grow under milder physical conditions, include many thousands of species. Ecologists have studied global patterns of species richness (described in Section 53.7) for decades. Today, as human disturbance of natural communities has already reached a tipping point, conservation biologists focus on such studies to determine which regions of Earth are most in need of preservation (see Chapter 55).

Within every community, populations differ in their commonness or the **relative abundance** of individuals. Some communities have just one or two **dominant species,** which represent a majority of the individuals present, as well as a number of rare species, each represented by just a few individuals. In other

The plants occupy very few beaches next to small sawgrass patches, but nearly all of the beaches next to large ones.
© Cengage Learning 2014

communities, species are represented by more equal numbers of individuals. For example, in a temperate deciduous forest in West Virginia, tulip poplar *(Liriodendron tulipifera)* and sassafras *(Sassafras albidum)* are dominant, accounting for nearly 85% of the trees. By contrast, a tropical forest in Costa Rica may include more than 200 tree species, each making up only a small percentage of the total.

Species richness and relative abundance together contribute to a community characteristic that ecologists call **species diversity.** To demonstrate the concept of species diversity, we will compare three hypothetical forest communities **(Figure 53.21).** Two of the communities include 50 trees distributed among 10 species. In Forest A, the dominant species is represented by 39 individuals, two species by two individuals each, and seven species by one individual each. In Forest B, each of the 10 species is represented by five individuals. Although both communities have the same species richness (10 species), Forest A is less diverse than Forest B, because more than three-quarters of its trees are of the same species. The third forest has only two tree species (Forest C in Figure 53.21); it is less diverse than either of the others.

Feeding Relationships within a Community Determine Its Trophic Structure

All ecological communities, regardless of their species richness, also have a trophic structure (*trophe* = nourishment) that comprises all of the plant–herbivore, predator–prey, host–parasite, and potential competitive interactions **(Figure 53.22).**

TROPHIC LEVELS We can visualize the trophic structure of a community as a hierarchy of **trophic levels,** defined by the feeding relationships among its species (see Figure 53.22A). Photosynthetic organisms are the **primary producers,** the first trophic level. Primary producers are often described as **autotrophs** (*auto* = self) because they capture sunlight and convert it into chemical energy, using simple *inorganic* molecules acquired from the environment to build larger *organic* molecules that other organisms can use. Plants are the dominant primary producers in terrestrial communities. Multicellular algae (macroalgae) and plants are the major primary producers in shallow freshwater and marine environments. Photosynthetic or chemosynthetic bacteria, cyanobacteria, and "protists" are the primary producers in deep, open water.

Animals, by contrast, are **consumers.** Herbivores, which feed directly on producers, form the second trophic level, the

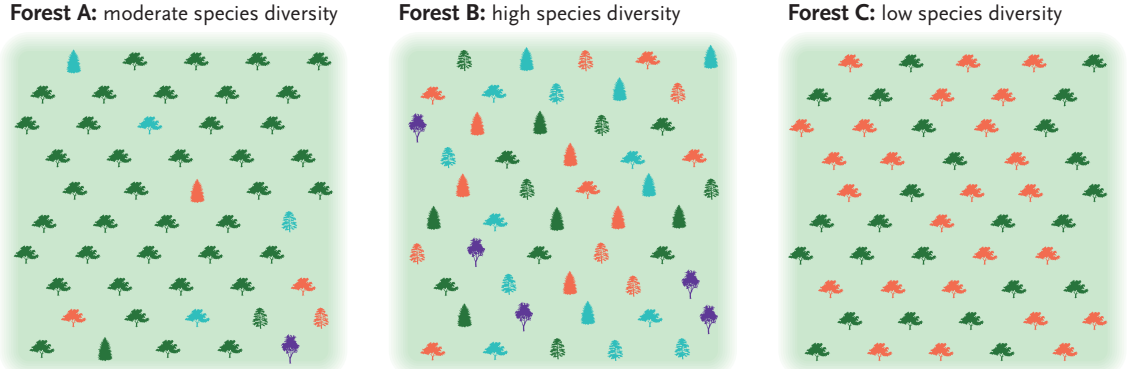

FIGURE 53.21 **Species diversity.** In this hypothetical example, each of three forests contains 50 trees. Forest A and forest B each include 10 tree species, but forest C includes only two tree species. Because forest A is dominated by one tree species, but forest B is not, ecologists would say that forest B is more diverse. Forest C, with only two tree species, is less diverse than the others.

© Cengage Learning 2014

primary consumers. Carnivores that feed on herbivores are the third trophic level, or **secondary consumers,** and carnivores that feed on other carnivores form the fourth trophic level, the **tertiary consumers.** For example, songbirds feeding on herbivorous insects are secondary consumers, and falcons feeding on songbirds are tertiary consumers. Some organisms, like humans and some bears, are **omnivores,** feeding at several trophic levels simultaneously.

A separate and distinct trophic level includes organisms that extract energy from the organic detritus ("refuse") produced at other trophic levels. Scavengers, or **detritivores,** are animals such as earthworms and vultures that ingest dead organisms, digestive wastes, and cast-off body parts such as leaves and exoskeletons. **Decomposers** are small organisms, such as bacteria and fungi, that feed on dead or dying organic material. As described in Chapter 54, detritivores and decomposers serve a critical ecological function because their activity reduces organic material to small inorganic molecules that producers can assimilate.

All of the consumers in a community—the animals, fungi, and diverse microorganisms—are described as **heterotrophs** (*hetero* = other) because they acquire energy and nutrients by eating other organisms or their remains.

FOOD CHAINS AND WEBS Ecologists depict the trophic structure of a community in a **food chain,** a portrait of who eats whom. Each link in a food chain is represented by an arrow pointing from food to consumer, thereby illustrating the direction in which energy flows through the food chain. Simple, straight-line food chains are rare in nature because most consumers feed on more than one type of food, and because most organisms are eaten by more than one type of consumer. These complex relationships are portrayed as a **food web,** a set of interconnected food chains with multiple links.

In the food web for the waters off the coast of Antarctica (see Figure 53.22B), most organisms at the bottom of the food web are tiny, and they occur in vast numbers. Huge pastures of phytoplankton (microscopic algae and diatoms) are responsible for most photosynthesis. They are consumed by herbivorous zooplankton (some "protists," copepods, and shrimplike krill), which are in turn eaten by larger species, such as carnivorous zooplankton, squids, fishes, and suspension-feeding baleen whales. Some of these secondary consumers are themselves eaten by birds and mammals at higher trophic levels. The top carnivore in this ecosystem, the orca *(Orcinus orca),* feeds on carnivorous birds and mammals. Ecological relationships within any food web are complex because many species feed at more than one trophic level. Moreover, wastes from all trophic levels are consumed and processed by a parallel food web of detritivores and decomposers (described further in Section 54.1).

FOOD-WEB ANALYSIS In the late 1950s, Robert MacArthur of Princeton University pioneered the analysis of food webs to determine how the many links between trophic levels may contribute to a community's **stability**—its ability to maintain its species composition and relative abundances when environmental disturbances eliminate some species from the community. MacArthur hypothesized that in species-rich communities, where animals feed on many food sources, the absence of one or two species would have only minor effects on the structure and stability of the community as a whole. He therefore proposed a connection between species diversity, food-web complexity, and community stability.

Recent research has confirmed MacArthur's reasoning. For example, the average number of links per species generally increases with increasing species richness. Comparative food-web analyses also reveal that the relative proportions of species at the highest, middle, and lowest trophic levels are reasonably constant across communities. When researchers compared the number of prey species to the number of predator species in food webs from 92 communities of freshwater invertebrates, they discovered that, regardless of species richness, a community includes between two and three prey species for every predator species.

Interactions among species in a food web are often complex, indirect, and hard to unravel. In desert communities of the American Southwest, for example, rodents and ants potentially compete for seeds, their main food source. And the plants that produce the seeds compete for water, nutrients, and space. Rodents generally prefer to eat large seeds, but ants prefer small seeds. Thus, feeding by rodents reduces the potential population sizes of plants that produce large seeds. As a result, the population sizes of plants that produce small seeds may increase, ultimately providing more food for ants.

Some analyses of food webs focus on interactions in which predators or prey have a significant influence on the growth rates and sizes of other populations in the community; these *strong interactions* can affect overall community structure. In the next section we provide examples of strong interactions when we describe how consumers influence the competitive interactions among populations of their prey.

53.4 Effects of Population Interactions on Community Characteristics

Numerous studies have shown that interspecific competition and predation can influence a community's species composition.

Interspecific Competition Can Reduce Species Richness within Communities

Interspecific competition can cause the local extinction of species or prevent new species from becoming established in a community, thus reducing its species richness. During the 1960s and early 1970s, ecologists emphasized competition as the primary factor structuring communities. Observations of resource partitioning and character displacement suggested that some process had fostered the evolution of differences in resource use among coexisting species, and competition provided the most straightforward explanation of these patterns.

Seeking to uncover direct evidence of competition, ecologists undertook many field experiments on competition in natural populations. The experiment on barnacles depicted in Figure 53.12 is typical of this approach, in which researchers determine whether adding or removing a species changes the distribution or population size of its presumed competitors. In

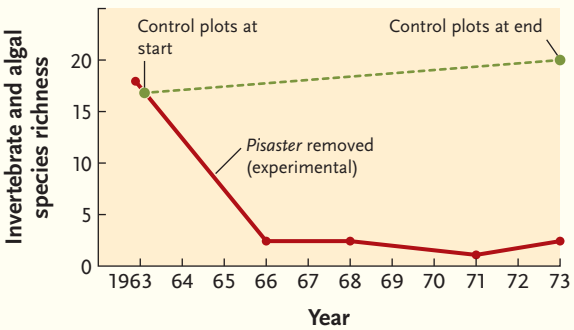
FIGURE 53.23 **Experimental Research**

Effect of a Predator on the Species Richness of Its Prey



Question: Does feeding by a predator influence the species richness and relative abundances of the species on which it feeds?

Experiment: The predatory sea star *Pisaster ochraceus* preferentially feeds on California mussels *(Mytilus californianus)*, which are the strongest competitors for space in rocky intertidal habitats in Washington State. Paine removed *Pisaster* from caged experimental study plots, but left control study plots undisturbed. He then monitored the species richness of *Pisaster's* invertebrate prey over many years.

Results: Paine documented an increase in California mussel populations in the experimental plots as well as complex changes in the feeding relationships among species in the intertidal food web. The overall effect of removing *Pisaster,* the top predator in this food web, was a rapid decrease in the species richness of invertebrates and algae. By contrast, control plots maintained their species richness over the course of the experiment.

© iStockphoto.com/Peter Herbig

Conclusion: Predation by the sea star *Pisaster ochraceus* maintains the species richness of its prey by preventing mussels from outcompeting other invertebrates and algae on rocky shores.

THINK LIKE A SCIENTIST Suggest one possible explanation for why the full effects of *Pisaster* removal were not evident until three years after the experiment was begun.

the early 1980s, two independent reviews of the literature on these field experiments, one by Joseph Connell and the other by Thomas W. Schoener of the University of California, Davis, suggested that competition is sometimes a potent force. Connell's survey, which included 527 published experiments on 215 species, identified competition in roughly 40% of the experiments and more than 50% of the species. Schoener's review, which used different criteria to evaluate 164 experiments on approximately 400 species, found that competition affected more than 75% of the species.

Although these reviews confirm the importance of competition, the ecological literature on which they were based probably contains several significant biases. First, ecologists who set out to study competition are more likely to study interactions in which they think competition occurs, and they are more likely to publish research that documents its importance. Accordingly, the literature includes more studies of competition in *K*-selected species than in *r*-selected species (review Section 52.5). Recall that populations of *r*-selected species, such as herbivorous insects, rarely reach carrying capacity, and competition may not limit their population sizes. Thus, the Connell and Schoener surveys may *overestimate* the importance of competition. Another bias, which Connell called "the ghost of competition past," *underestimates* the importance of competition. If, as many ecologists believe, the evolution of resource partitioning and character displacement is the result of past competition, we are unlikely to witness much competition today, even though it was once important in structuring those population interactions.

Ecologists have still not reached consensus about whether interspecific competition strongly influences the species composition and structure of most communities. Forest ecologists and vertebrate ecologists, who often study *K*-selected species, generally believe that competition has a profound effect on species distributions and resource use. Insect ecologists and marine ecologists, who often study *r*-selected species, argue that competition is not the major force governing community structure, pointing instead to predation or parasitism and physical disturbance.

Predators Can Boost Species Richness by Stabilizing Competitive Interactions among Their Prey

Predators can influence the species richness and structure of communities by reducing the population sizes of their prey. On the rocky coast of the American Northwest, for example, algae and sessile invertebrates compete for attachment sites on rocks, a requirement for life on a wave-swept shore. California mussels *(Mytilus californianus)* are the strongest competitors for space, eliminating other species from the community. But at some sites, predatory sea stars *(Pisaster ochraceus)* preferentially feed on mussels, reducing their numbers and creating space for other species to grow. Because the interaction between *Pisaster* and *Mytilus* affects other species as well, it qualifies as a strong interaction.

In the 1960s, Robert Paine of the University of Washington conducted removal experiments to evaluate the effects of *Pisaster* predation **(Figure 53.23).** In predator-free experimental plots, mussels outcompeted barnacles, chitons, limpets, and other invertebrate herbivores, reducing species richness from 18 species to two or three. In control plots that contained predators, however, all 18 species persisted. Ecologists describe predators like

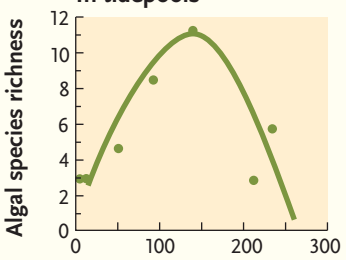
The Complex Effects of an Herbivorous Snail on Algal Species Richness

Question: How does feeding by periwinkle snails *(Littorina littorea)* influence the species richness of algae in intertidal communities?

Experiment: Lubchenco manipulated the densities of periwinkle snails in tidepools and on exposed rocks in a rocky intertidal habitat by creating enclosures that prevented snails from either entering or leaving her study plots. She then monitored the species composition of algae in the study plots and graphed them against periwinkle density.

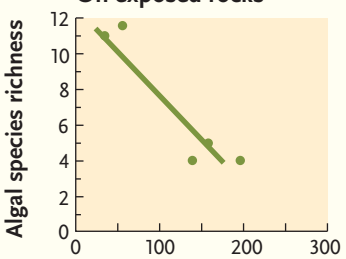


Results: The effects of periwinkle density on algal species richness varied dramatically between study plots in tidepools and on exposed rocks.

Periwinkle snails (*Littorina littorea*)

©Jane Burton/BruceColman, Ltd.

In tidepools



In tidepools, snails at low densities eat little algae, and *Enteromorpha* competitively excludes other algal species, reducing species richness. At high snail densities, heavy feeding on all species reduces algal species richness. At intermediate snail densities, grazing eliminates some *Enteromorpha,* allowing other species to grow.

***Enteromorpha* growing in tidepools**

©Jane Burton/BruceColman, Ltd.

On exposed rocks

On exposed rocks, periwinkles never eat much *Chondrus,* but they consume the tender, less successful competitors. Thus, feeding by periwinkles reinforces the competitive superiority of *Chondrus:* as periwinkle density increases, algal species richness declines.

***Chondrus* growing on exposed rocks**

Heather Angel/Natural Visions

Conclusion: Grazing by periwinkle snails has complex effects on the species richness of competing algae. In tidepools, where periwinkle snails preferentially feed on *Enteromorpha,* the competitively dominant alga, snails at an intermediate density remove some *Enteromorpha,* which allows weakly competitive algae to grow, increasing species richness. Feeding by snails at either low or high densities reduces algal species richness. On exposed rocks, where periwinkle snails rarely eat the competitively dominant alga *Chondrus,* feeding by snails reduces algal species richness.

THINK LIKE A SCIENTIST After reading all of this section of your text (Section 53.5), interpret Lubchenco's result for snails and algae in tidepools within the context of the intermediate disturbance hypothesis.

Pisaster as **keystone species,** those that have a greater effect on community structure than their numbers might suggest.

Herbivores May Counteract or Reinforce Competition among Their Food Plants

Herbivores also exert complex effects on communities. In the 1970s, Jane Lubchenco, then of Harvard University, studied herbivory in a periwinkle snail *(Littorina littorea),* a keystone species on rocky shores in Massachusetts **(Figure 53.24).** Periwinkles preferentially graze on the tender green alga *Enteromorpha.* In tidepools, which are usually submerged, *Enteromorpha* outcompetes other algae. Moderate feeding by periwinkles, however, eliminates some *Enteromorpha,* allowing less competitive algal species to grow. Moderate herbivory by periwinkles therefore increases algal species richness in tidepools. But on high rocks, which are exposed to air during low tide, the dehydration-resistant red alga *Chondrus* is competitively dominant. Periwinkles don't eat the

2. **What are keystone species, and how do they influence species richness in communities?**

53.5 Effects of Disturbance on Community Characteristics

Recent research tends to support the individualistic view that many communities are not in equilibrium and that their species composition changes frequently. Environmental disturbances—storms, landslides, fires, floods, and cold spells—often eliminate some species, providing opportunities for others to become established.

Frequent Disturbances Keep Some Communities in a Constant State of Flux

Physical disturbances are common in some environments. For example, lightning-induced fires commonly sweep through grasslands, powerful hurricanes routinely demolish patches of forest, and waves wash over communities that live at the edge of the sea.

Joseph Connell and his colleagues conducted an ambitious long-term study of the effects of disturbance on coral reefs, shallow tropical marine habitats that are among the most species-rich communities on Earth. In some parts of the world, reefs are routinely battered by violent storms, which wash corals off the substrate, creating bare patches in the reef. The scouring action of storms creates opportunities for coral larvae to settle on bare substrates and start new colonies; ecologists use the word *recruitment* to describe the process in which young individuals join a population.

From 1963 to 1992, Connell and his colleagues tracked the fate of the Heron Island Reef at the south end of Australia's Great Barrier Reef **(Figure 53.25).** The inner flat and protected crests of the reef are sheltered from severe wave action during storms, whereas some pools and crests are routinely exposed to physical disturbance. Because corals live in colonies of variable size, the researchers monitored coral abundance by measuring the percentage of the seafloor that colonies covered. They revisited marked study plots at intervals, photographing and identifying individual coral colonies.

Five major cyclones (marked by gray arrows in Figure 53.25) crossed the reef during the 30-year study period. Coral communities in the exposed areas of the reef were in a nearly continual state of flux. In exposed pools, four of the five cyclones reduced the percentage of cover, often drastically. On exposed crests, the cyclone of 1972 eliminated virtually all of the corals, and subsequent storms slowed the recovery of these

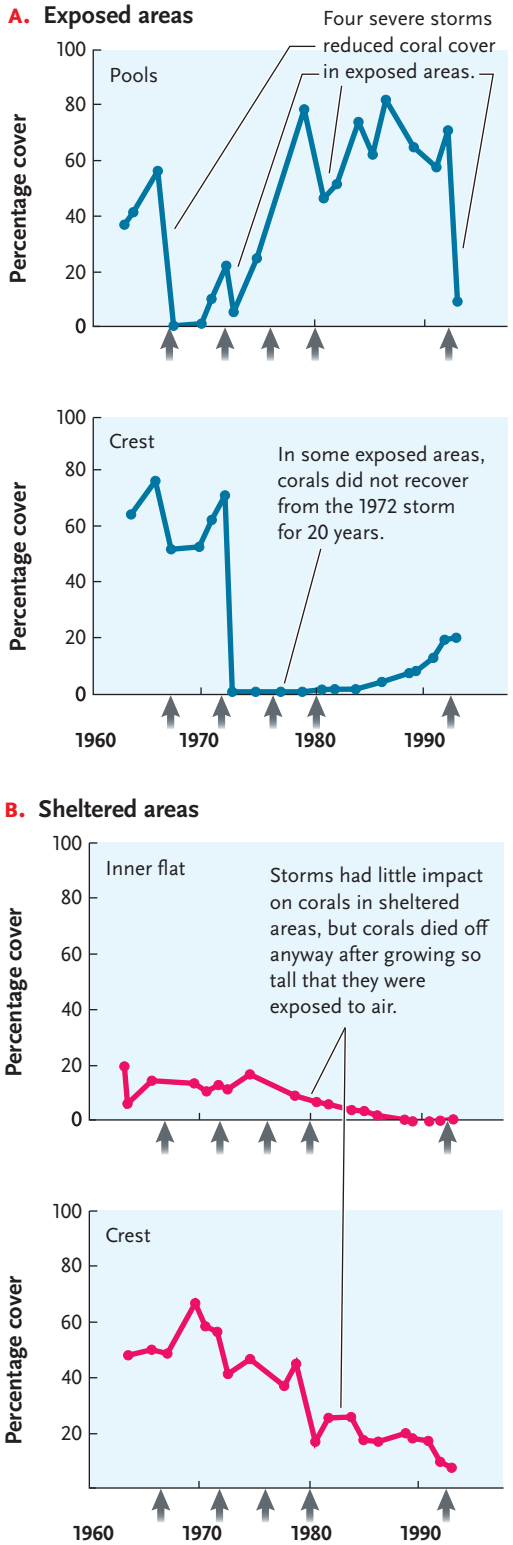

FIGURE 53.25 The effects of storms on corals. Five tropical cyclones (marked by gray arrows) damaged corals on the Heron Island Reef during a 30-year period. Storms reduced the percentage cover of corals in exposed parts of the reef **(A)** much more than in sheltered parts of the reef **(B).**

areas for 20 years. By contrast, corals in sheltered areas suffered much less storm damage. Nevertheless, their coverage also declined steadily during the study as a natural consequence of the corals' growth. As colonies grew taller and closer to the ocean's surface, their increased exposure to air resulted in substantial mortality.

Connell and his colleagues also documented recruitment, the growth of new colonies from settling larvae, in their study plots. They discovered that the rate at which new colonies developed was almost always higher in sheltered areas than in exposed areas. However, recruitment rates were extremely variable, depending in part on the amount of space that storms or coral growth had made available.

This long-term study of coral reefs illustrates that frequent disturbances prevent some communities from ever reaching any kind of equilibrium. Changes in the coral reef community at Heron Island result from the combined effects of external disturbances (storms) that remove coral colonies from the reef and internal processes (growth and recruitment) that either eliminate colonies or establish new ones. In this community, growth and recruitment are slow processes, and disturbances are frequent. Thus, the community never attains equilibrium.

Moderate Levels of Disturbance May Foster High Species Richness

According to the **intermediate disturbance hypothesis,** proposed by Connell in 1978, species richness is greatest in communities that experience fairly frequent disturbances of moderate intensity. Moderate disturbances create some openings for *r*-selected species to arrive and join the community, but they allow *K*-selected species to survive. Thus, communities that experience intermediate levels of disturbance contain a rich mixture of species. Where disturbances are severe and frequent, communities include only *r*-selected species that complete their life cycles between catastrophes. Where disturbances are mild and rare, communities are dominated by long-lived *K*-selected species that competitively exclude other species from the community.

Several studies in diverse habitats have confirmed the predictions of the intermediate disturbance hypothesis. For example, Colin R. Townsend and his colleagues at the University of Otago studied the effects of disturbance at 54 stream sites in the Taieri River system in New Zealand. Disturbance occurs in these communities when water flow from heavy rains moves the rocks, soil, and sand in the streambed, disrupting the habitats where animals live. Townsend and his colleagues measured how much of the substrate moved in different streambeds to index the intensity of the disturbance. Their results indicate that species richness is highest in areas that experience intermediate levels of disturbance **(Figure 53.26).**

Some ecologists have also suggested that species-rich communities recover from disturbances more readily than do less diverse communities. For example, David Tilman and his colleagues at the University of Minnesota conducted large-scale experiments in Midwestern grasslands on the relationship between species number and the ability of communities to recover from disturbance. Their results demonstrate that grassland plots with high species richness recover from drought faster than plots with fewer species.

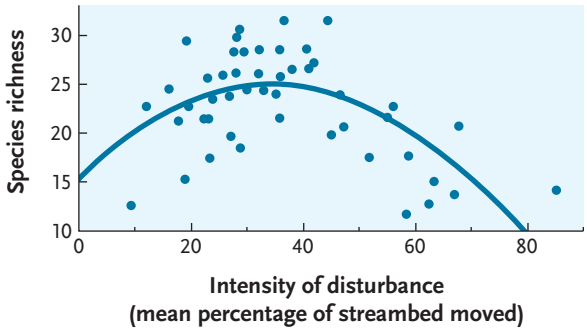

FIGURE 53.26 An observational study that supports the intermediate disturbance hypothesis. In the Taieri River system in New Zealand, species richness was highest in stream communities that experienced an intermediate level of disturbance.

2. **How do moderately severe and moderately frequent disturbances influence a community's species richness?**

53.6 Ecological Succession: Responses to Disturbance

In response to disturbance, communities undergo **ecological succession,** a somewhat predictable series of changes in species composition over time.

Succession Begins after Disturbance Alters a Landscape or Changes the Species Composition of an Existing Community

Primary succession begins when organisms first colonize terrestrial habitats without soil, such as those created by erupting volcanoes and retreating glaciers **(Figure 53.27).** Lichens (see Section 30.3), which derive nutrients from rain and bare rock, are usually the first visible colonizers of such inhospitable habitats. They secrete mild acids that erode rock surfaces, initiating the slow development of soil, which is enriched by the organic material lichens produce. After lichens modify a site, mosses (see Section 28.2) colonize patches of soil and grow quickly.

As soil accumulates, hardy *r*-selected plants—grasses, ferns, and broad-leaved herbs—colonize the site from sur-

rounding areas. Their roots break up rock, and as they die, their decaying remains enrich the soil. Detritivores and decomposers facilitate these processes. As the soil gets deeper and richer, increased moisture and nutrients support bushes and, eventually, trees. Late successional stages are often dominated by *K*-selected species with woody trunks and branches that position leaves in sunlight and large root systems that acquire water and nutrients from soil.

Roger K. Burnard

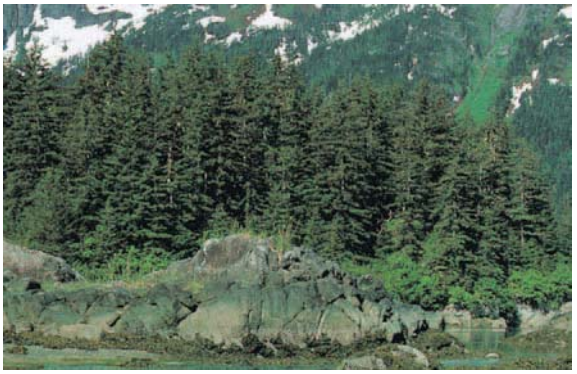
2 This site was covered with ice less than 10 years before this photo was taken. When a glacier retreats, a constant flow of meltwater leaches minerals, especially nitrogen, from the newly exposed substrate.

Roger K. Burnard

3 Once lichens and mosses have established themselves, mountain avens (genus *Dryas*) grows on the nutrient-poor soil. This pioneer species benefits from the activity of mutualistic nitrogen-fixing bacteria, spreading rapidly over glacial till.



Roger K. Burnard

4 Within 20 years, shrubby willows (genus *Salix*), cottonwoods (genus *Populus*), and alders (genus *Alnus*) take hold in drainage channels. These species are also symbiotic with nitrogen-fixing microorganisms.

Roger K. Burnard

5 In time, young conifers, mostly hemlocks (genus *Tsuga*) and spruce (genus *Picea*), join the community.

Roger K. Burnard

6 After 80 to 100 years, dense forests of Sitka spruce *(Picea sichensis)* and western hemlock *(Tsuga heterophylla)* have crowded out the other species.

FIGURE 53.27 Primary succession following glacial retreat. The retreat of glaciers at Glacier Bay, Alaska, has allowed ecologists to document primary succession on newly exposed rocks and soil.

In the classical view of ecological succession, long-lived species eventually dominate a community, and new species join it only rarely. This relatively stable, late successional stage is called a **climax community** because the dominant vegetation replaces itself and persists until an environmental disturbance eliminates it, allowing other species to invade. Local climate and soil conditions, the surrounding communities where colonizing species originate, and chance events determine the species composition of climax communities. However, recent research suggests that even "climax communities" change slowly in response to environmental fluctuations, as described below.

Secondary succession occurs after existing vegetation is destroyed or disrupted by an environmental disturbance, such as a fire, a storm, or human activity. The presence of soil makes the disturbed sites ripe for colonization. Moreover, the soil may contain numerous seeds that germinate after the disturbance. The early stages of secondary succession proceed rapidly, but later stages parallel those of primary succession.

Secondary succession in the north temperate zone is well studied in abandoned farms, called "old fields," where forests were cleared centuries ago. Because the transformation from old field back to forest takes at least a hundred years, ecologists use historical records to find the age of different stands of vegetation and reconstruct the successional sequence by comparing stands of different ages. In the Piedmont region of southeastern North America, an abandoned field is covered by crabgrass (genus *Digitaria*), an annual plant, during the first growing season. The following year, crabgrass is replaced by horseweed *(Conyza canadensis),* which cannot persist because it secretes substances that inhibit the germination of its own seeds. Ragweed *(Ambrosia artemisiifolia),* another annual, dominates during the third year, but it is gradually replaced by perennial asters (genus *Erigeron*) and broomsedges (genus *Andropogon*), which are, in turn, replaced by shrubs. Ten to fifteen years after the field was abandoned, pine (genus *Pinus*) seedlings germinate. Growing pines cast substantial shade and their fallen needles acidify the soil, making the site unsuitable for the plants from earlier successional stages. Because pines are intolerant of shade, pine seedlings don't flourish under mature pine trees. Thus, after 50 to 100 years, pines are replaced by a taller mixed hardwood forest of oaks (genus *Quercus*) and hickories (genus *Carya*), the seedlings of which are more shade tolerant than pines. The hardwood forest forms the climax community in the thick, moist soil after more than a century of successional change.

Similar climax communities sometimes arise from alternative successional sequences. For example, hardwood forests also develop in sites that were once ponds. During **aquatic succession,** debris from rivers and runoff accumulates in a body of water, causing it to fill in at its margins. The pond is transformed into a swamp, inhabited by plants adapted to a semisolid substrate. As larger plants get established, their high transpiration rates dry the soil, allowing other plant species to colonize. Given enough time, the site may become a meadow or forest, where an area of moist, low-lying ground is the only remnant of the original pond.

Community Characteristics Change during Succession

Several characteristics undergo directional change as succession proceeds. First, because *r*-selected species are short-lived and *K*-selected species long-lived, species composition changes rapidly in the early stages, but slowly in the late stages of succession. Second, species richness increases rapidly during the early stages because new species join the community faster than resident species become extinct; as succession proceeds, however, species richness stabilizes or may even decline. Third, in terrestrial communities that receive sufficient rainfall, the maximum height and total mass of the vegetation increase steadily as large species replace small ones, creating the complex structure of the climax.

Because plants influence the physical environment below them, the community itself increasingly moderates the microclimate. The shade cast by a forest canopy retains soil moisture and reduces temperature fluctuations. The trunks and canopy also reduce wind speed. By contrast, the short vegetation in an early successional stage does not effectively shelter the space below it.

Although ecologists usually describe succession in terms of vegetation, animals undergo succession, too. As the vegetation shifts, new resources become available, and animal species replace each other over time. Herbivorous insects, which often have strict food preferences, undergo succession along with their food plants. And as the herbivores change, so do their predators, parasites, and parasitoids. In old-field succession in eastern North America, different successional stages harbor a changing assortment of bird species **(Figure 53.28).**

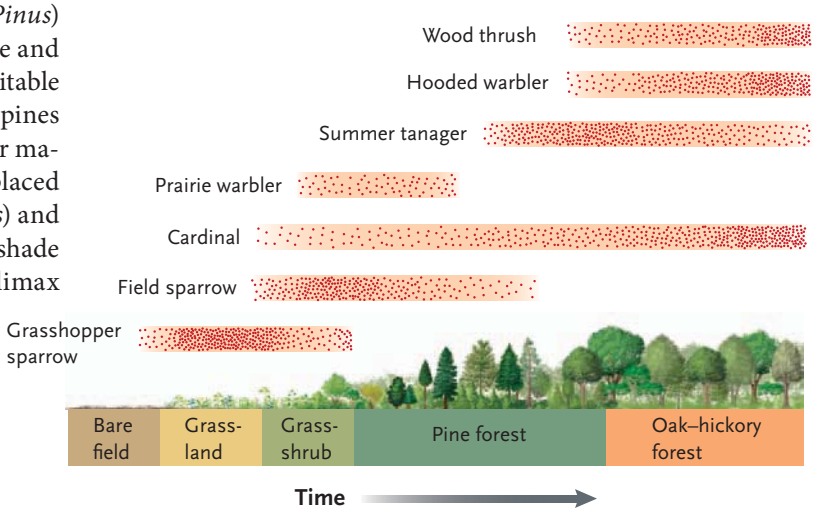

FIGURE 53.28 Succession in animals. Successional changes in bird species composition in an abandoned agricultural field in eastern North America parallel changes in plant species composition. Residence times of several representative species are illustrated. The density of stippling inside each bar illustrates the relative density of each species through time.

Several Hypotheses Help to Explain the Processes Underlying Succession

Differences in dispersal abilities, maturation rates, and life spans among species are at least partly responsible for ecological succession. Early successional stages harbor many *r*-selected species because they produce numerous small seeds that colonize open habitats and grow quickly. Mature successional stages are dominated by *K*-selected species because they are long-lived. Nevertheless, coexisting populations inevitably affect one another. Although the role of population interactions in succession is generally acknowledged, ecologists debate the relative importance of processes that either facilitate or inhibit the turnover of species in a community.

The **facilitation hypothesis** suggests that species modify the local environment in ways that make it less suitable for themselves but more suitable for colonization by species typical of the next successional stage. For example, when lichens first colonize bare rock, they produce a small quantity of soil, which is required by mosses and grasses that grow there later. According to this hypothesis, changes in species composition are both orderly and predictable because the presence of each stage facilitates the success of the next. Facilitation is very important in primary succession, but it may not be the best model of interactions that influence secondary succession.

The **inhibition hypothesis** suggests that new species are prevented from occupying a community by whatever species are already present. According to this hypothesis, succession is neither orderly nor predictable because each stage is dominated by whichever species happen to colonize the site first. Species replacements occur only when individuals of the dominant species die of old age or when an environmental disturbance reduces their numbers. Eventually, long-lived species replace short-lived species, but the precise species composition of a mature community is up for grabs.

Inhibition appears to play a role in some secondary successions that follow environmental disturbances. For example, rocky intertidal communities on sheltered shores in the Gulf of Maine include some habitat patches that are dominated by an alga *(Ascophyllum nodosum)* and other patches dominated by a mussel *(Mytilus edulis).* Do these patches represent different alternative states for the mature community in this habitat? In winter, small patches in this habitat are sometimes scoured clean by sea-borne ice, after which the patch undergoes succession. In 2009, Peter Petraitis of the University of Pennsylvania and colleagues from several other institutions reported on the fate of habitat patches in which they had experimentally simulated "ice scour." If mussels colonized the cleared site first, they grew faster than the algae and eventually dominated the community. But if the alga colonized first, it provided cover for sea stars and other predators, which consumed mussels that subsequently grew there. Thus, the species composition of the mature community depended on which species arrived at the site first.

The **tolerance hypothesis** asserts that succession proceeds because competitively superior species replace competitively inferior ones. According to this model, early-stage species neither facilitate nor inhibit the growth of later-stage species. Instead, as more species arrive at a site and resources become limiting, competition eliminates species that cannot harvest scarce resources successfully. In the Piedmont region of North America, for example, hardwood trees are more tolerant of shade than pine trees are, and hardwoods gradually replace pines during succession. Thus, the climax community includes only strong competitors. Tolerance may explain the species composition of many transitional and mature communities.

At most sites, succession probably results from a combination of facilitation, inhibition, and tolerance, coupled with interspecific differences in dispersal, growth, and maturation rates. Moreover, within a community, the patchiness of abiotic factors also strongly influences plant distributions and species composition. In the deciduous forests of eastern North America, maples (genus *Acer*) predominate on wet, low-lying ground, but oaks (genus *Quercus*) are more abundant at higher and drier sites. Thus, a mature deciduous forest is more often a mosaic of species than a uniform stand of trees.

Disturbance and density-independent factors also play important roles, in some cases speeding successional change. In northern forests, for example, moose prefer to feed on deciduous shrubs, accelerating the rate at which conifers replace them. In other cases, disturbance inhibits successional change, establishing a *disturbance climax* or **disclimax community.** In many grassland communities (see Section 51.4), grazing by large mammals and periodic fires kill the seedlings of trees that would otherwise become established. Thus, disturbance prevents the succession from grassland to forest, and grassland persists as a disclimax community.

On a local scale, disturbances often destroy small patches of vegetation, returning them to an earlier successional stage. A hurricane may knock over a few trees in a forest, creating small, sunny patches of open ground. Locally occurring *r*-selected species take advantage of the resources that are suddenly available and quickly colonize the openings. These local patches then undergo succession that is out of step with the immediately surrounding forest. Thus, moderate disturbance, accompanied by succession in local patches, can increase species richness in many communities.

STUDY BREAK 53.6

1. What is the difference between primary succession and secondary succession?
2. How does a climax community differ from early successional stages?
3. How do the three hypotheses about the causes of ecological succession view the role of population interactions in the successional process?

53.7 Variations in Species Richness among Communities

Species richness often varies among communities according to a recognizable pattern. Two large-scale patterns of species richness—latitudinal trends and island patterns—have captured the attention of ecologists for more than a century.

Many Types of Organisms Exhibit Latitudinal Gradients in Species Richness

Ever since Darwin and Wallace traveled the globe (see Section 20.2), ecologists have recognized broad latitudinal trends in species richness. For many, but not all, plant and animal groups, species richness follows a latitudinal gradient, with the most species in the tropics and a steady decline in numbers toward the poles **(Figure 53.29).** Several general hypotheses may explain these striking patterns.

Some hypotheses propose historical explanations for the *origin* of high species richness in the tropics. The benign climate in tropical regions allows some tropical organisms to have more generations per year than their temperate counterparts. And, given the small seasonal changes in temperature, tropical species may be less likely than temperate species to migrate from one habitat to another, thus reducing gene flow between geographically isolated populations (see Section 22.3). These factors may have fostered higher speciation rates in the tropics, accelerating the accumulation of species. Tropical communities may also have experienced severe disturbance less often than communities at higher latitudes, where periodic glaciations have caused repeated extinctions. Thus, new species may have accumulated in the tropics over longer periods of time.

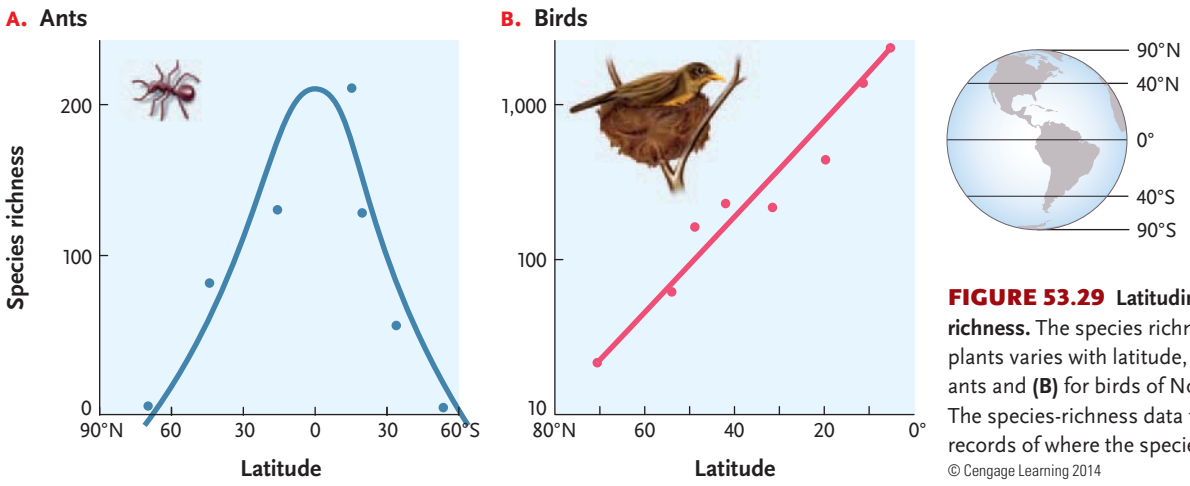
Other hypotheses focus on ecological explanations for the *maintenance* of high species richness in the tropics. Some resources are more abundant, predictable, and diverse in tropical communities. Tropical regions experience more intense sunlight, warmer temperatures in most months, and higher annual rainfall than temperate and polar regions (see Chapter 51). These factors provide a long and predictable growing season for the lush tropical vegetation, which supports a rich assemblage of herbivores, and through them many carnivores and parasites. Furthermore, the abundance, predictability, and year-round availability of resources allow some tropical animals to have specialized diets. For example, tropical forests support many species of fruit-eating bats and birds, which could not survive in temperate forests where fruits are not available year-round.

Species richness may therefore be a self-reinforcing phenomenon in tropical communities. Complex webs of population interactions and interdependency have coevolved in relatively stable and predictable tropical climates. Predator–prey, competitive, and symbiotic interactions may prevent individual species from dominating communities and reducing species richness.

The Theory of Island Biogeography Explains Variations in Species Richness

Although the species richness of communities may be stable over time, species composition is often in flux as new species join a community and others drop out. In the 1960s, Robert MacArthur of Princeton University and Edward O. Wilson of Harvard University addressed the question of why communities vary in species richness, using islands as model systems. Islands provide natural laboratories for studying ecological phenomena, just as they do for evolution (see *Focus on Basic Research* in Chapter 22). Island communities are often small, have well-defined boundaries, and are isolated from surrounding communities.

In developing the **equilibrium theory of island biogeography,** MacArthur and Wilson sought to explain variations in species richness on islands of different size and different levels of isolation from other landmasses **(Figure 53.30).** They hypothesized that the number of species on any island was governed by a give and take between two processes: the immigration of new species to the island and the extinction of species already there (Figure 53.30A).



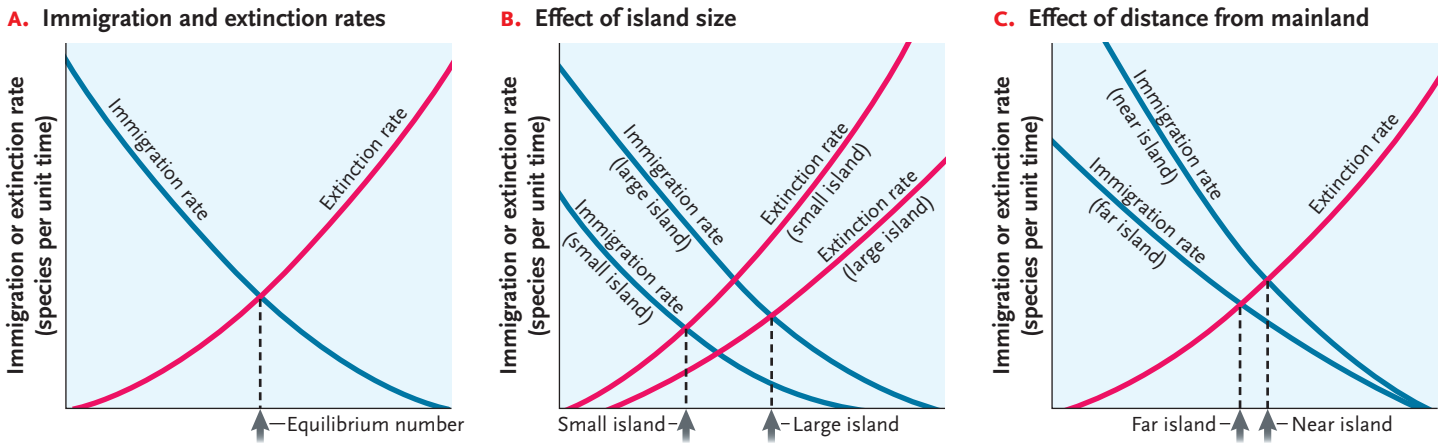


FIGURE 53.29 Latitudinal trends in species richness. The species richness of many animals and plants varies with latitude, as illustrated here **(A)** for ants and **(B)** for birds of North and Central America. The species-richness data for birds are based on records of where the species breed.

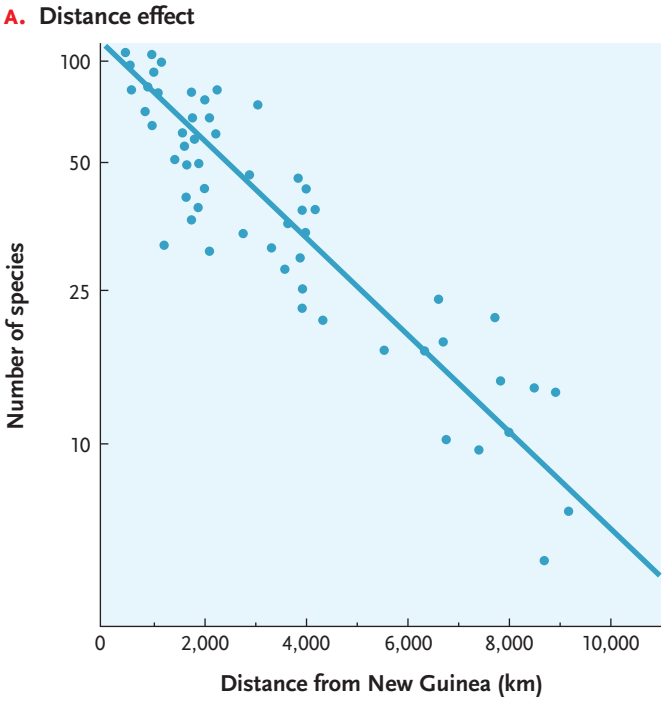
The number of species on an island at equilibrium (indicated by the arrow) is determined by the rate at which new species immigrate and the rate at which species already on the island become extinct.



Immigration rates are higher and extinction rates lower on large islands than on small islands. Thus, at equilibrium, large islands have more species than small ones.

Organisms leaving the mainland locate nearby islands more easily than distant islands, causing higher immigration rates on near islands. Thus, near islands support more species than far ones.

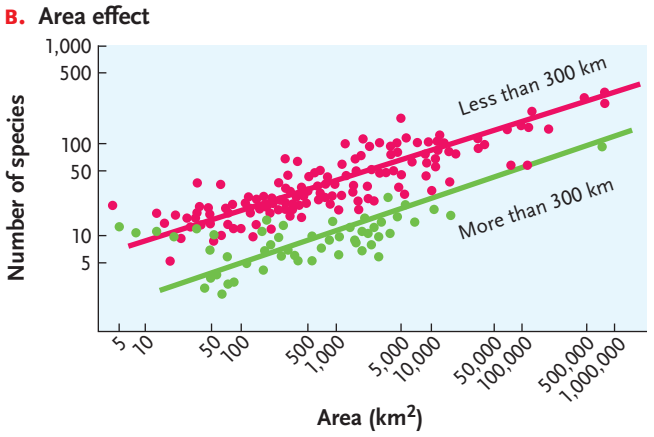


FIGURE 53.30 **Assumptions and predictions of the theory of island biogeography.**

© Cengage Learning 2014

According to the MacArthur–Wilson model, the mainland harbors a *species pool* from which species immigrate to offshore islands. Seeds and small arthropods are carried by wind or floating debris; some animals, such as birds, arrive under their own power. When few species are already on an island, the rate at which *new* species immigrate to the island is high. But as more species inhabit the island over time, the immigration rate declines because there are fewer species left

The number of lowland bird species on islands of the South Pacific declines with the islands' distance from the species source, the large island of New Guinea. Data in this graph were corrected for differences in the sizes of the islands. The number of bird species on each island is expressed as a percentage of the number of bird species on an island of equivalent size close to New Guinea.

The number of bird species on tropical and subtropical islands throughout the world increases dramatically with island area. The data for islands near to a mainland source and islands far from a mainland source are presented separately to minimize the effect of distance. Notice that the "distance effect" reduces the number of bird species on islands that are more than 300 km from a mainland source.

FIGURE 53.31 **Factors that influence bird species richness on islands.** **(A)** Fewer bird species occupy islands that are distant from the mainland source. **(B)** More bird species occupy large islands than small ones.

in the mainland pool that can still arrive on the island as *new* colonizers.

Once a species immigrates to an island, its population grows and persists for some time. But as the number of species on the island increases, the rate at which those species go extinct also rises. The extinction rate increases through time partly because there are more species that can go extinct there. In addition, as the number of species on the island increases, competition and predator–prey interactions can reduce the population sizes of some species and drive them to extinction.

According to MacArthur and Wilson's theory, an equilibrium between immigration and extinction determines the number of species that ultimately occupy an island. In other words, once equilibrium is reached, the number of species remains relatively constant because one species already on the island goes extinct in about the same time it takes a new species to immigrate to the island. The model does not specify which species immigrate to the island or which ones already on the island go extinct. It simply predicts that the number of species on the island is in equilibrium, although species composition is not. The ongoing processes of immigration and extinction establish a constant turnover in the roster of species that live on any island.

The MacArthur–Wilson model explains why some islands harbor more species than others. The model assumes that large islands have higher immigration rates than small islands do, partly because they present a larger target for dispersing organisms, and partly because once immigrants arrive on a large island, they will encounter sufficient resources to establish a population there. Moreover, it assumes that large islands have lower extinction rates because they can support larger populations and provide a greater range of habitats and resources. Thus, the model predicts that, at equilibrium, large islands have more species than small islands (Figure 53.30B). Similarly, it predicts that islands near the mainland have higher immigration rates than distant islands do, because dispersing organisms are more likely to land on islands that are close to their point of departure. Distance does not affect extinction rates. Thus, at equilibrium, islands that lie closer to a mainland source have more species than more distant islands (Figure 53.30C).

The equilibrium theory's predictions about the effects of area and distance are generally supported by observational data on plants and animals **(Figure 53.31).** Daniel Simberloff, one of Wilson's graduate students at Harvard University, was the first person to test the theory's predictions experimentally; he monitored the immigration of arthropods to, and extinction of arthropods on, individual red mangrove trees in the Florida Keys **(Figure 53.32).** The trees, with canopies that spread from 11 to 18 m in diameter, grow in shallow water and are isolated from their neighbors; thus, each tree is an island that harbors an arthropod community. The species pool on the Florida mainland includes about 1,000 arthropod species, but each mangrove island contains no more than 40 species at one time.

After cataloging the species on each island, Simberloff and Wilson hired an extermination company to eliminate all arthropods on them (Figure 53.32A). Simberloff then monitored both the immigration of arthropods to the islands and the extinction of species that became established on them. He surveyed six islands regularly for two years and at intervals thereafter.

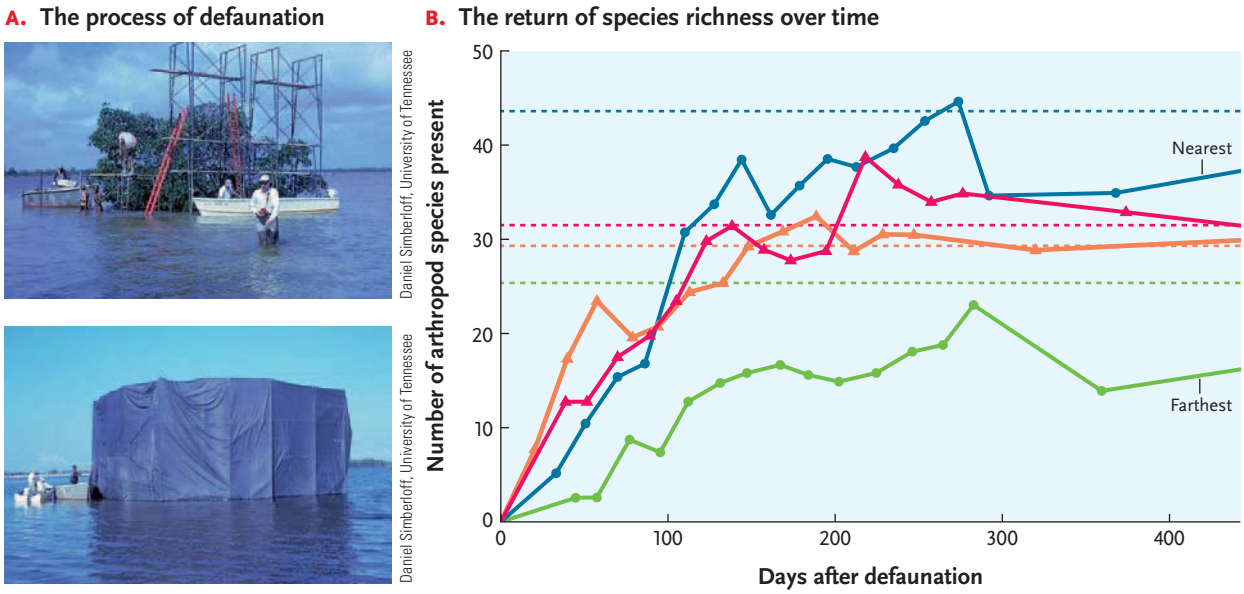

FIGURE 53.32 **An experimental test of the theory of island biogeography. (A)** After cataloguing the arthropods, Simberloff and Wilson hired an exterminating company to erect a tent over each mangrove island. Once the islands were fully covered, exterminators used methyl bromide—a pesticide that does not harm trees and leaves no residue—to eliminate all living arthropods. **(B)** On three of four islands, species richness gradually returned to the predefaunation level (indicated by color-coded dashed lines on the graph). The most distant island had not reached its predefaunation species richness after two years.

The Species-Area Effect: Does bacterial species richness vary with "island" size?

Ecologists have long recognized that the number of animal or plant species inhabiting an island is directly proportional to the island's size. In fact, the "species-area effect" also applies to contiguous habitats that are not isolated from each other: larger areas generally harbor more species than smaller areas, at least in part because larger areas include a greater variety of distinctive resources that facilitate resource partitioning by resident species.

A. Bacterial species richness as a function of treehole size

B. Slope of species–area function for organisms in contiguous habitats and on islands

Nevertheless, the species-area effect is less dramatic in contiguous habitats than it is among islands of different sizes. In other words, a graph of species richness versus area for contiguous habitats has a lower slope than a graph of species richness versus area among isolated islands (see Figure 53.31B for graph of island data), probably because colonization rates from one habitat patch to another are higher and extinction rates within habitat patches are lower in contiguous habitats than on islands. Previous research had shown an especially limited species-area effect (that is, a low slope of the graph) for bacteria sampled in contiguous habitats; this result probably reflects the ubiquity of bacteria and the ease with which they colonize areas adjacent to those where they already occur. But researchers had not previously investigated the species-area effect for bacteria living in truly isolated island-like habitats.

Research Question

Do bacteria living on small islands show the dramatic species-area effect observed in plants and animals?

Experiment

The buttresses of large European beech trees *(Fagus sylvatica)* often form bark-lined, watertight basins that hold small, but permanent, bodies of water. Each of these treehole basins houses a miniature community—an "island" isolated from other such basins—that subsists on nutrients derived from decaying leaf litter. Thomas Bell and his colleagues at the University of Oxford, England, sampled 29 treeholes, measuring their volume (an index of island size) and estimating the bacterial species richness in each.

Instead of using laborious traditional culture techniques to identify the bacteria in each community, the researchers used a molecular approach. They transferred 50 mL of water and sediment from each treehole into sterile vials, and then extracted total DNA from subsamples. They separated out gene fragments for the 16S ribosomal subunit (16S rRNA), which is specific to bacteria, and then amplified them using PCR. The resulting product was analyzed with gel electrophoresis.

Results

Each band appearing on the gel was scored as a distinct bacterial "species." The number of bands identified in the sample from each community served as an estimate of its species richness. Species richness in these 29 bacterial communities was directly proportional to "island" size, as measured by the volume of each basin **(Figure A).**

Conclusion

The results of this study indicate that bacteria living in treehole islands are subject to species-area effects like those observed for animals and plants on true islands. Moreover, the slope of the line in Figure A is very similar to the slope of the species-area relationship for animals and plants on islands—and much higher than the slope of species-area effects for any organisms sampled in contiguous habitats **(Figure B).**

THINK LIKE A SCIENTIST Plants in the clade Bromeliaceae, which includes pineapples, often grow as epiphytes in tropical forest canopies. The leaves of some bromeliad species form a cup that collects water and detritus, much the way British treeholes do. Bromeliads vary greatly in size, and the cups of large bromeliads hold more water than the cups of small ones. Would you expect the species richness of microorganisms and invertebrates living in bromeliad cup communities to exhibit a species-area functions more like those of contiguous habitats or like those of islands?

Source: T. Bell et al. 2005. Larger islands house more bacterial taxa. *Science* 308:1884.

© Cengage Learning 2014

The results of this experiment confirm several predictions of MacArthur and Wilson's theory (Figure 53.32B). Arthropods recolonized the islands rapidly, and within eight or nine months the number of species living on each island had reached an equilibrium that was near the original species number. In addition, the island nearest to the mainland had more species than the most distant island. However, immigration and extinction were incredibly rapid, and Simberloff and Wilson suspected that some species went extinct even before they had noted their presence. The researchers also discovered that three years after the experimental treatments, the species composition on the islands was still changing constantly and did not

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

remotely resemble the species composition in the islands before they were defaunated.

As described in *Insights from the Molecular Revolution,* the equilibrium view of species richness also applies to mainland communities, which exist as islands in a metaphorical sea of dissimilar habitat. Lakes are "islands" in a "sea" of dry land, and mountaintops are habitat "islands" in a "sea" of low terrain. Species richness in these communities is partly governed by the immigration of new species from distant sources and the extinction of species already present. As human activities disrupt environments across the globe, undisturbed sites function as island-like refuges for threatened and endangered species. Conservation biologists now apply the general lessons of MacArthur and Wilson's theory to the design of nature preserves (see Chapter 55).

In the next chapter we examine ecosystems, which include ecological communities interacting with their abiotic environments, focusing on the movements of energy and nutrients.

STUDY BREAK 53.7

1. **What factors may foster the maintenance of high species richness in tropical communities?**
2. **According to the equilibrium theory of island biogeography, what are the effects of an island's size and its distance from the mainland on the number of species that can occupy it?**

UNANSWERED QUESTIONS

Do species interactions change predictably across environments?

As we learned in this chapter, the population interactions that occur between species range from mutualistic to parasitic. Some biologists have suggested that we should expect more competitive interactions between species in some kinds of environments, but more positive interactions in others. Community ecology will become a more quantitative and predictive discipline if researchers focus on how abiotic and biotic environmental factors—such as the presence of particular community members, environmental gradients, or global climate change—influence the strength of the interactions between species. For example, as physical environments become more stressful, the abundance and distribution of species should be determined less by resource limitation and more by the stress itself. Accordingly, plants tend to compete far less with each other in stressful environments than they do under ideal growing conditions. Scientists are now engaged in the intellectual feedback of theory development and experimental testing aimed at generating a predictive framework for particular types of interactions and their consequences for community structure.

What is the relative importance of positive versus negative interactions for community structure?

It was once suggested that ecologists in capitalist societies, like the United States, tend to more often study competition and predation, but ecologists in socialist societies tend to study mutualism. Although the truth of this anecdote is unclear, it is remarkable that ecologists still do not agree on the relative importance of positive interactions (for example, mutualism or commensalism) versus negative interactions (such as predation or competition) in generating community structure. Advances in this area of study may result from "factorial" experiments, in which two or more types of interactions are manipulated. For example, one might examine the relative effects of excluding pollinators versus excluding herbivores on the success of a plant population. In factorial experiments, the researcher can conclude that one factor has a bigger effect than the other, because all other factors were controlled. These sorts of experiments may eventually lead to an emerging picture of the relative importance of positive versus negative population interactions.

How does the evolutionary history of a species influence its ecology today?

The great evolutionary biologist Theodosius Dobzhansky once noted that "Nothing in biology makes sense except in the light of evolution." Although we know a great deal about both ecology and evolutionary biology, researchers are only beginning to explore the impact of an organism's evolutionary history on its ecology. This very active area of research includes the use of phylogenetic information (see Chapter 24), selection experiments (see Chapter 21), and a knowledge of the genetic basis of particular traits (see Chapter 12). For example, are closely related species more likely to compete with each other than more distantly related species are? Do organisms that are well adapted to particular environments fare poorly in other environments? Why do some organisms specialize in their resource use? Are the population dynamics that species experience shaped by past evolutionary events? These questions are currently being addressed, and the answers uncovered by researchers may unravel many current mysteries about the ecology of populations and communities.

THINK LIKE A SCIENTIST

1. Is mutualism really just reciprocal parasitism? Are the benefits a partner gains in a mutualism just "taken" from the other partner (or are benefits garnered by other means)?
2. Would you expect close relatives to share the same parasites? Why, and what might the consequence of this be for community structure of hosts and parasites?

Anurag Agrawal

Anurag Agrawal is an associate professor in the Departments of Entomology and Ecology and Environmental Biology at Cornell University. He studies the evolutionary and community ecology of plant–insect interactions. To learn more about Dr. Agrawal's research, go to http://www.herbivory.com.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

53.1 Population Interactions

- Coevolution is the evolution of reciprocal adaptations in species that interact ecologically (Figure 53.1).
- Predators and herbivores use diverse adaptations to select, locate, capture, and ingest an appropriate diet (Figure 53.2). Plants have both structural and chemical defenses against herbivores. Animal prey may try to hide or escape from predators, defend themselves actively, or advertise their unpalatability (Figures 53.3–53.5). Some animal species mimic the appearance of poisonous species (Figure 53.6). Predators may evolve adaptations to counter prey defenses (Figure 53.7).
- Interspecific competition results if two or more populations use the same limiting resources; competition may lead to the extinction of one competitor (Figure 53.8). Ecologists use the ecological niche concept to visualize a population's resource use (Figure 53.9). Observations of resource partitioning (Figure 53.10) and character displacement (Figure 53.11) suggest that competition may be important, but only field experiments can demonstrate that competition occurs (Figure 53.12).
- Symbiosis is a close ecological association between species. In commensal interactions, one species benefits and the other is unaffected (Figure 53.13). In mutualistic interactions, both partners benefit (Figures 53.14–53.16). In parasitic interactions, one species benefits and the other is harmed.

Animation: Competitive exclusion

Animation: Hairston's experiment

53.2 The Nature of Ecological Communities

- An interactive view suggests that species in a community are bound together in a complex web of necessary biotic interactions; an individualistic view recognizes communities as loose assemblages of organisms that have similar physical requirements (Figure 53.17).
- Ecotones occur where adjacent communities grade into one another; sharp boundaries occur between communities where a critical resource or an important abiotic factor is discontinuous (Figure 53.18).

53.3 Community Characteristics

- In warm, moist environments, vegetation is tall and has a complex physical structure (Figure 53.19). In harsh, cold environments, vegetation is short and has a simple physical structure.
- Foundation species moderate the physical environment within communities (Figure 53.20).
- Communities differ in species richness and the relative abundances of species. Both characteristics contribute to a community's species diversity (Figure 53.21).
- Organisms are classified as producers, consumers, detritivores, or decomposers. Ecologists depict the trophic structure (feeding relationships) of communities in food webs (Figure 53.22). Food-web analyses seek to identify generalities about trophic structure and its relationship to community stability.

Animation: Rainforest food web

53.4 Effects of Population Interactions on Community Characteristics

- Interspecific competition often affects the species composition and structure of communities.
- Predators may increase species richness by reducing the population size of the competitively most successful prey, thus allowing other prey species to occupy the community (Figure 53.23).
- Herbivores sometimes increase species richness and sometimes decrease it (Figure 53.24).

53.5 Effects of Disturbance on Community Characteristics

- Environmental disturbances may eliminate populations from a community. Some communities, such as coral reefs, experience such frequent disturbance that their species composition is never at equilibrium (Figure 53.25).
- Disturbances of intermediate intensity and frequency allow both *r*-selected and *K*-selected species to occupy a site, increasing species richness (Figure 53.26).

53.6 Ecological Succession: Responses to Disturbance

- Ecological succession is a somewhat predictable change in species composition over time.
- Primary succession occurs on bare ground or rock (Figure 53.27). Secondary succession occurs where a community existed in the past (Figure 53.28).
- Species composition changes quickly and species richness rises rapidly during early successional stages. Early stages include short-lived *r*-selected species; later stages include long-lived *K*-selected species. Some communities eventually achieve a relatively stable climax state.
- Most communities include a mosaic of species that reflect patchiness in environmental conditions and the mixture of relatively undisturbed and recently disturbed sites.

Animation: Succession

53.7 Variations in Species Richness among Communities

- Communities near the equator have higher species richness than those near the poles (Figure 53.29). Explanations for this latitudinal gradient focus on either the origin or the maintenance of high species richness in the tropics.
- The equilibrium theory of island biogeography predicts that the number of species on an island represents a balance between the immigration of new species and the extinction of species already present (Figure 53.30). Studies show that large islands harbor more species than small islands, and islands near a mainland source have more species than distant islands (Figures 53.31 and 53.32).

UNDERSTAND & APPLY

Test Your Knowledge

1. According to optimal foraging theory, predators:
   a. always feed on the largest prey possible.
   b. always feed on the prey that are easiest to catch.
   c. choose prey based on the costs of capturing and consuming it compared to the energy it provides.
   d. feed on plants when animal prey are scarce.
   e. have coevolved mechanisms to overcome prey defenses.
2. The use of the same limiting resource by two species is called:
   a. brood parasitism.
   b. interference competition.
   c. exploitative competition.
   d. mutualism.
   e. optimal foraging.
3. The range of resources that a population can possibly use is called:
   a. its fundamental niche.
   b. its realized niche.
   c. character displacement.
   d. resource partitioning.
   e. its relative abundance.
4. Differences in the bill sizes of finch species living on the same island in the Galápagos may be caused by:
   a. predation.
   b. character displacement.
   c. mimicry.
   d. interference competition.
   e. cryptic coloration.
5. Bacteria that live in the human intestine assist digestion and feed on nutrients the human consumed. This relationship might best be described as:
   a. commensalism.
   b. mutualism.
   c. endoparasitism.
   d. ectoparasitism.
   e. predation.
6. The table below shows how many individuals were recorded for each of five species in five separate communities (a–e). Which community has the highest species diversity?

Community	Species 1	Species 2	Species 3	Species 4	Species 5
a	90	10	0	0	0
b	80	10	10	0	0
c	25	25	25	25	0
d	2	4	6	8	80
e	20	20	20	20	20

© Cengage Learning 2014

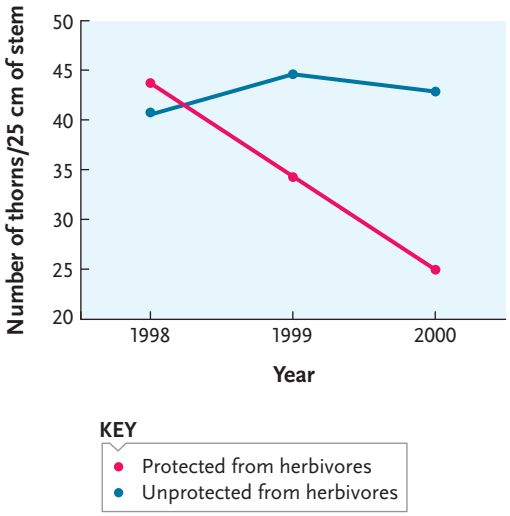
7. A keystone species:
   a. is usually a primary producer.
   b. has a critically important role in determining the species composition of its community.
   c. is always a predator.
   d. usually reduces the species diversity in a community.
   e. usually exhibits aposematic coloration.
8. Species richness is often highest in communities where disturbances are:
   a. very frequent and severe.
   b. very frequent and of moderate intensity.
   c. very rare and severe.
   d. of intermediate frequency and moderate intensity.
   e. very rare and mild.
9. The change in the species composition of a community from bare and lifeless rock to climax vegetation is called:
   a. disturbance.
   b. competition.
   c. secondary succession.
   d. primary succession.
   e. facilitation.
10. The equilibrium theory of island biogeography predicts that the number of species found on an island:
    a. increases steadily until it equals the number in the mainland species pool.
    b. is greater on large islands than on small ones.
    c. is smaller on islands near the mainland than on distant islands.
    d. can never reach an equilibrium number.
    e. is greater for islands near the equator than for islands near the poles.

Discuss the Concepts

1. After reading about the two potential biases in the scientific literature on competition, describe how future studies of competition might avoid such biases.
2. How do human activities disrupt the process of succession in terrestrial communities? Would you describe most of our activities as mild disturbances, moderate disturbances, or severe disturbances?
3. Humans are destroying natural communities at an ever-increasing pace. Using the predictions of the theory of island biogeography, develop hypotheses about what might happen as patches of natural habitats get smaller and smaller. How would you test these hypotheses?

Design an Experiment

Chaparral, a community of woody shrubs that is fairly common in California, often grows adjacent to grassland. The two communities are consistently separated by a "bare zone," usually less than 1 m wide, where no vegetation of either type grows. Ecologists have proposed two possible explanations for this strip of bare soil: (1) that the leaves of chaparral shrubs release harmful, water-soluble chemicals that keep the grass seeds from germinating in the adjacent soil; and (2) that small mammals living in the dense cover provided by chaparral consume the grass seeds before they germinate; the animals don't venture very far from the shrubs because they would be easy targets for predatory hawks. Design a set of field experiments to test the two hypotheses.



Apply Evolutionary Thinking

Five processes can foster microevolutionary change: gene flow, genetic drift, mutation, natural selection, and nonrandom mating (see Section 21.3). Which of those processes might contribute to the evolution of Batesian mimicry in two butterfly species? Would the same processes affect both the mimic and the model similarly? Which processes might have contributed to the evolution of the mutualistic relationship between ants and acacia trees, and how would their action on the two mutualists differ?

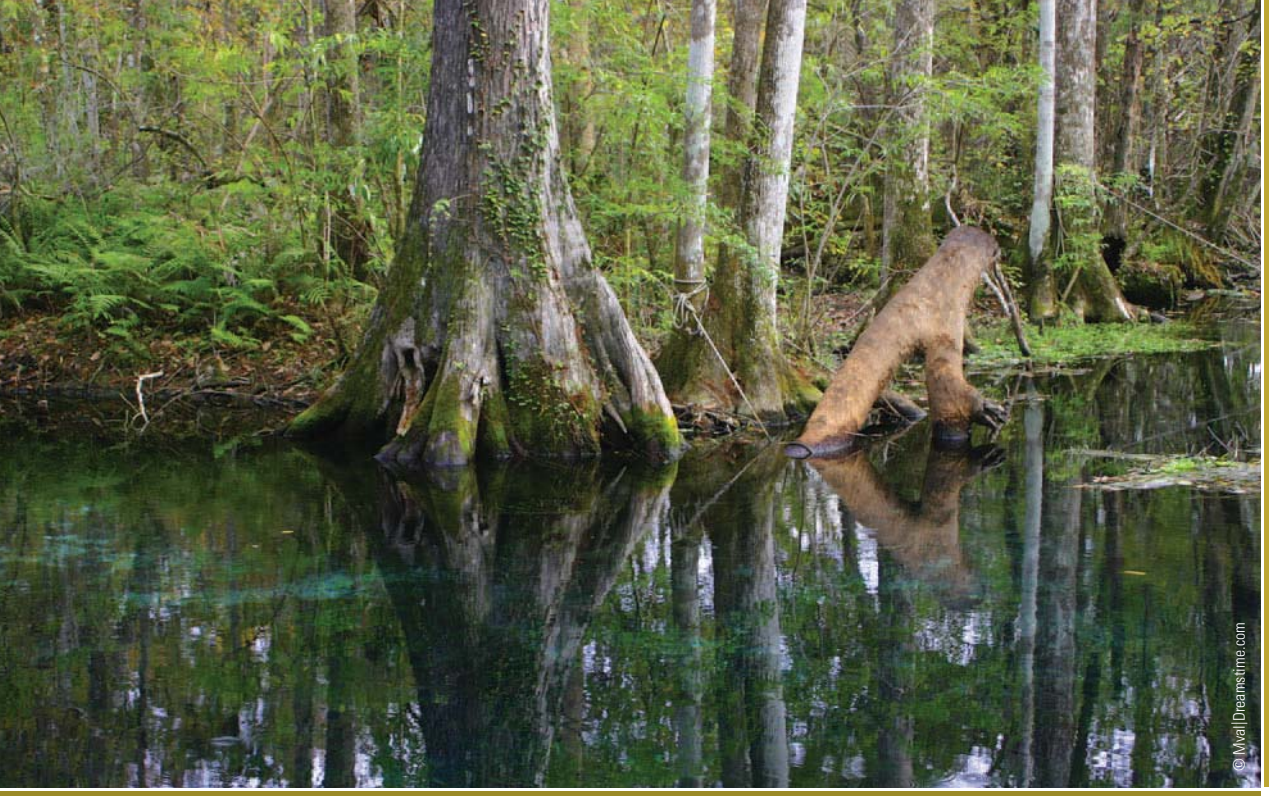
Interpret the Data



The Mediterranean shrub *Hormathophylla spinosa* loses as much as 80% of its flowers and fruits to herbivorous mammals each year, and biologists interpret the spines on its flowering stems as an antiherbivore adaptation. Jose M. Gomez and Regino Zamora of the University of Granada, Spain, conducted an exclosure experiment in which they used fences to protect some shrubs from feeding by herbivores and left other shrubs unprotected as controls. The accompanying graph illustrates the density of thorns on the experimental and control groups over a period of two years. How did the protected shrubs respond to the experimental reduction of feeding on the flowers and fruits? How did the unprotected shrubs respond to the control treatment? What benefits would unprotected shrubs derive from their response?

54.1 Modeling Ecosystem Processes

54.2 Energy Flow and Ecosystem Energetics

54.3 Nutrient Cycling in Ecosystems

54.4 Human Disruption of Ecosystem Processes

Ecosystems

Why it matters . . . Poor Lake Erie, the shallowest of the Great Lakes. Several major industrial cities, including Toledo, Cleveland, Erie, and Buffalo, sprawl along its shoreline. Most of its water comes from the river that flows past Detroit; other rivers that flow into it carry runoff from agricultural fields in Canada and the United States.

When Europeans first settled along its shores roughly 300 years ago, Lake Erie was a wetland paradise. Fishes and waterfowl reproduced in marshes and bays. Even after steel mills and oil refineries were built nearby in the 1860s and 1870s, the lake supported a busy fishing industry and was a famous recreation area.

By 1970, wetlands had been filled for building, bays had been dredged for shipping lanes, and the shoreline had been converted to beaches. Worst of all, household sewage, industrial effluent, and agricultural runoff had so polluted the lake that it no longer supported the activities that had made it famous **(Figure 54.1).** The water was murky with algae and cyanobacteria; dead fishes washed up on the shore; local health departments closed beaches; and the fishing industry collapsed.

How can a vibrant natural resource become a foul-smelling dump? The answer lies in the human activities that disrupt an **ecosystem,** a biological community and the physical environment with which it interacts. Between the 1930s and the 1970s, Lake Erie's concentration of phosphorus, which had been a limiting nutrient, tripled, largely from household detergents and agricultural fertilizers. High phosphorus concentrations encouraged the growth of photosynthetic algae, changing the phytoplankton community. The den-

sity of coliform bacteria, which originate in the human gut and serve as indicators of organic pollution, also skyrocketed as a result of the surge in sewage and nutrients entering the lake.

Increased phytoplankton and bacterial populations depleted oxygen in the lake's waters, contributing to changes elsewhere in the lake. Mayflies (*Hexagenia* species), whose larvae live in well-oxygenated bottom sediments, had once been so abundant that their aerial breeding swarms were a public nuisance. But they became nearly extinct in the polluted lake, replaced by oligochaete worms, snails, and other invertebrates. Along with overfishing, changes in the bottom fauna shifted the composition of the fish community; the catch of desirable food fishes declined to almost zero by the mid-1960s.

In 1972, Canada and the United States began efforts to restore the lake. They spent billions of dollars to reduce the influx of phosphates and limited fishing of the most vulnerable native species. Nonnative salmon (*Onchorhynchus* species) and other predatory fishes were introduced in the hope that they could bring the lake back to its original condition. Even the accidental introduction of zebra mussels *(Dreissina polymorpha),* an aquatic pest, inadvertently helped the effort because they feed on phytoplankton.

But, although somewhat improved, Lake Erie will never return to its former glory. Some native species are now extinct there, and the introduced species that replaced them function differently within the ecosystem. The lake still suffers periods of uncontrolled algal growth, fish kills, and high levels of harmful bacteria.

This story of an ecological disaster and partial recovery introduces ecosystem ecology, the branch of ecology that analyzes the flow of energy and the cycling of materials between an ecosystem's living and nonliving components. These processes make the resident organisms highly dependent on each other and on their physical surroundings. Ultimately, the Lake Erie ecosystem unraveled because human activities disrupted the flow of energy and the cycling of materials on which the organisms depended.

54.1 Modeling Ecosystem Processes

All organisms require steady supplies of energy and nutrients for their maintenance, growth, and reproduction. Studies of ecosystems often focus on the inputs and outputs (that is, the

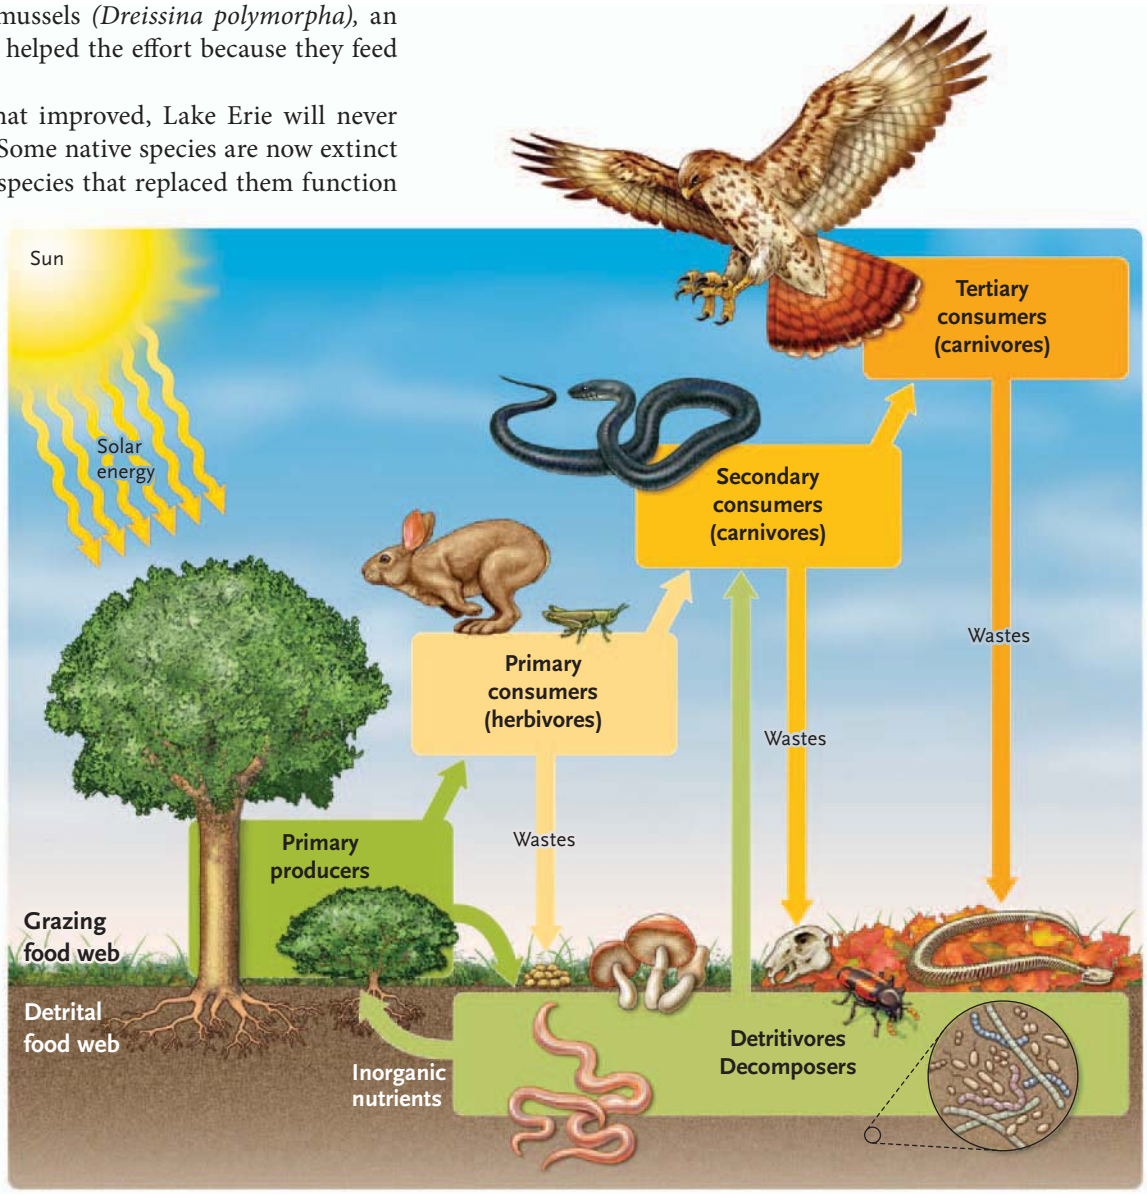

FIGURE 54.2 Grazing and detrital food webs. Energy and nutrients move through two parallel food webs in most ecosystems. The grazing food web includes producers, herbivores, and carnivores. The detrital food web includes detritivores and decomposers. Each box in this diagram represents many species.

gains and losses) of energy and nutrients to the ecosystem as a whole as well as the transfer of energy and nutrients within and between the ecosystem's biotic and abiotic components. Although the movements of energy and nutrients through an ecosystem are sometimes coupled, as when you eat a meal that contains both nutrients and calories, the inputs and outputs of energy and nutrients are fundamentally different (see Section 1.1). In virtually all ecosystems, sunlight constantly renews the supply of available energy, but, as dictated by the laws of thermodynamics (see Section 4.1), most of that energy is lost as heat in cellular respiration. By contrast, virtually all the nutrients that will ever be available for biological systems are already present on Earth, and they are constantly recycled between the abiotic and biotic components of ecosystems in what ecologists describe as **biogeochemical cycles.**

Researchers use several types of models to describe ecosystem processes. Food webs define the pathways through which energy and nutrients move within the biotic component of an ecosystem. Compartment models describe how nutrients move between living and nonliving nutrient reservoirs. Simulation models allow ecologists to predict how ecosystems will respond to perturbations of ecosystem processes.

Food Webs Illustrate the Transfer of Energy and Nutrients among Organisms

Food webs define the pathways by which energy and nutrients move through an ecosystem's biotic components (see Section 53.3). In most ecosystems, they move simultaneously through a *grazing food web* and a *detrital food web* **(Figure 54.2).** The grazing food web includes the producer, herbivore, and carnivore trophic levels. The detrital food web includes detritivores and decomposers. Because detritivores and decomposers subsist on the remains and waste products of organisms at every trophic level, the two food webs are closely interconnected. Detritivores also contribute to the grazing food web when carnivores eat them.

Compartment Models Track the Movement of Nutrients between Food Webs and Abiotic Reservoirs

Ecologists use a **compartment model** to describe nutrient cycling **(Figure 54.3).** Two criteria divide ecosystems into four compartments where nutrients accumulate. First, nutrient molecules and ions are described as either *available* or *unavailable,* depending on whether or not they can be assimilated by organisms. Second, nutrients are present either in *organic* material, the living or dead tissues of organisms, or in *inorganic* material, such as rocks and soil. For example, minerals in dead leaves on the forest floor are in the available organic compartment because they are in the remains of organisms that detritivores can eat. But calcium ions in limestone rocks are in the unavailable inorganic compartment because they exist in a nonbiological form that producers cannot assimilate.

Nutrients move rapidly within and between the available compartments. Living organisms are in the available organic compartment, and whenever heterotrophs consume food, they recycle nutrients within that reservoir (indicated by the oval arrow in the upper left of Figure 54.3). Producers acquire nutrients from the air, soil, and water of the available inorganic compartment. Consumers also acquire nutrients from the available inorganic compartment when they drink water or absorb mineral ions through the body surface. Several processes routinely transfer nutrients from organisms to the avail-

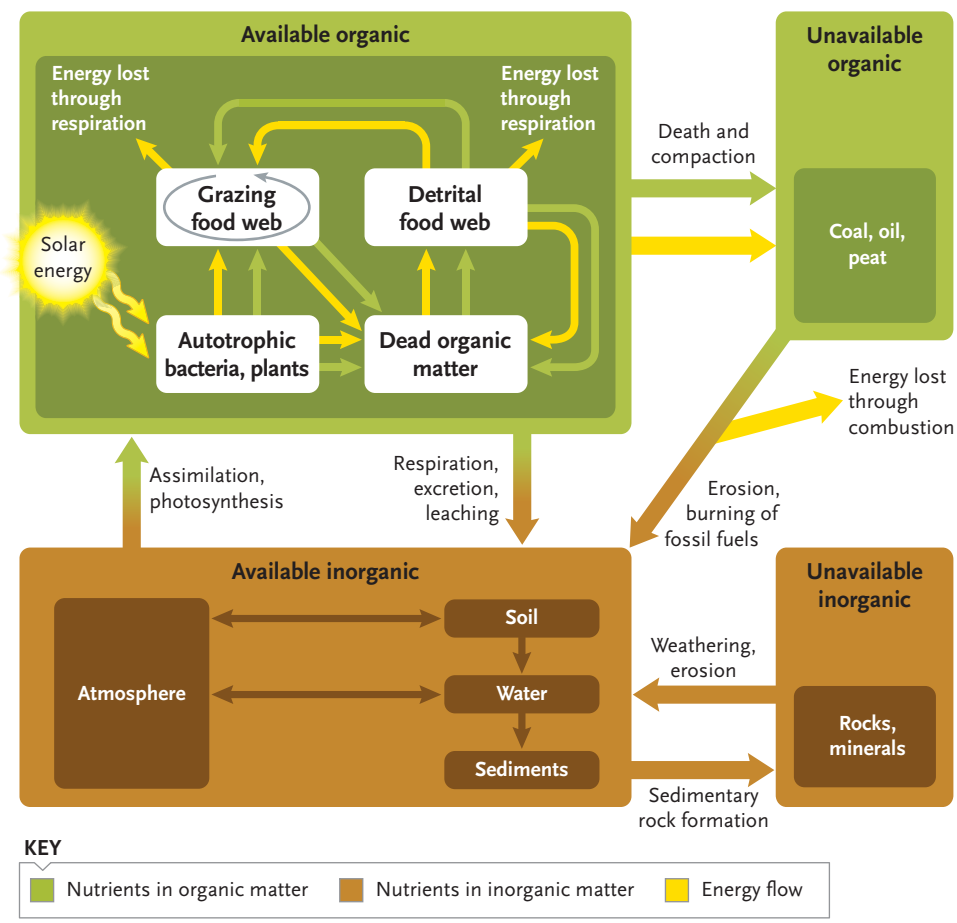

FIGURE 54.3 A compartment model of nutrient cycling. Nutrients are recycled through four major compartments within ecosystems. Processes that move nutrients from one compartment to another are indicated on the arrows. The upper left quadrant includes the living organisms in food webs and their organic remains; the oval arrow represents animal predation on other animals. The pathways of energy flow within and from the food webs are also illustrated. Unlike nutrients, energy is not conserved, but is instead lost from the ecosystem.

able inorganic compartment. As one example, respiration releases carbon dioxide, moving both carbon and oxygen from the available organic compartment to the available inorganic compartment.

By contrast, the movement of materials into and out of the unavailable compartments is generally slow. Sedimentation, a long-term geological process, converts ions and particles of the available inorganic compartment into rocks of the unavailable inorganic compartment. Materials are gradually returned to the available inorganic compartment when rocks are uplifted and eroded or weathered. Similarly, over millions of years, the remains of organisms in the available organic compartment were converted into coal, oil, and peat of the unavailable organic compartment.

Except for the input of solar energy, we have described energy flow and nutrient cycling as though ecosystems were closed systems. In fact, most ecosystems exchange energy and nutrients with neighboring ecosystems. For example, rainfall carries nutrients into a forest ecosystem, and runoff carries nutrients from a forest into a lake or river. Ecologists have mapped the biogeochemical cycles of important elements, often by using radioactively labeled molecules that they can follow in the environment. As you study the details of the four biogeochemical cycles described in Section 54.3, try to understand them in terms of the generalized compartment model of nutrient cycling.

Simulation Models Predict the Effects of Perturbations on Ecosystem Processes

The compartment model described above is a *conceptual model* of how ecosystems function. In other words, it ignores the nuts-and-bolts details of exactly how a specific ecosystem functions in favor of a generalized portrait of how all ecosystems function. Although it is a useful tool, a conceptual model doesn't really help us predict what would happen, say, if we harvested 10 million tons of introduced salmon from Lake Erie every year. We could simply harvest the fishes and see what happens. But ecologists prefer less intrusive approaches to study the potential effects of disturbances.

To understand how an ecosystem will respond to specific changes in physical factors, energy flow, or nutrient availability, ecologists turn to **simulation modeling.** Researchers gather detailed information about a specific ecosystem and then create a series of mathematical equations that define its most important relationships. For example, one set of equations might describe how nutrient availability limits photosynthesis by autotrophs. Another might relate population growth of zooplankton to the abundance of phytoplankton. Other equations would relate the population dynamics of primary carnivores to the availability of their food, and still others would describe how the densities of primary carnivores influence reproduction in populations at both lower and higher trophic levels. Thus, a complete simulation model is a set of interlocking equations that collectively predict how changes in one feature of an ecosystem might influence others.

Creating a simulation model is no easy task, because the relationships within every ecosystem are complex. First, you would identify the important species, estimate their population sizes, and measure the average energy and nutrient content of each. Next, you would describe the food webs in which they participate, measure the quantity of food each species consumes, and estimate the growth and reproduction of individuals in each population. For the sake of completeness, you would also determine the ecosystem's energy and nutrient gains and losses caused by erosion, weathering, precipitation, and runoff. You would repeat these measurements seasonally to identify annual variation in the factors. Finally, you might repeat the measurements over several years to determine the effects of year-to-year variation in climate and chance events.

After collecting these data, you would write equations that quantify the relationships in the ecosystem, including information about how temperature and other abiotic factors influence the ecology of each species. At last, you could begin to predict—possibly in great detail—the effects of harvesting 10 million or even 50 million tons of salmon annually from Lake Erie. Of course, you would have to refine the model whenever new data became available.

As we attempt to understand larger and more complex ecosystems—and as we create larger and more complex environmental problems—modeling becomes an increasingly important tool. If a model is based on well-defined ecological relationships and good empirical data, it can allow us to make accurate predictions about ecosystem changes without the need for costly and environmentally damaging experiments. But like all ideas in science, a model is only as good as its assumptions, and models must constantly be adjusted to incorporate new ideas and recently discovered facts.

STUDY BREAK 54.1

1. **In the generalized compartment model of biogeochemical cycling, how are the compartments where nutrients accumulate classified?**
2. **What are the advantages and disadvantages of relying on conceptual models that describe ecosystem function?**
3. **What data must ecologists collect before constructing a simulation model of an ecosystem?**

54.2 Energy Flow and Ecosystem Energetics

Ecosystems receive a steady input of energy from an external source, which in almost all cases is the sun. But as energy flows through an ecosystem, much of it is lost as heat without being used by organisms. In this section, we consider the details of energy flow and the efficiency of energy transfer from one trophic level to another.

Sunlight Provides the Energy Input for Practically All Ecosystems

Every minute of every day, Earth's atmosphere intercepts roughly 19 kcal of solar energy per square meter. (Recall from Chapter 2 that 1 kcal = 1,000 calories.) About half that energy is absorbed, scattered, or reflected by gases, dust, water vapor, and clouds without ever reaching the planet's surface (see Chapter 51). Most energy that reaches the surface falls on bodies of water or bare ground, where it is absorbed as heat or reflected back into the atmosphere; reflected energy warms the atmosphere, as we discuss later in this chapter. Only a small percentage contacts primary producers, and most of that energy evaporates water, driving transpiration in plants (see Section 34.3).

Ultimately, photosynthesis converts less than 1% of the solar energy that arrives at Earth's surface into chemical energy. But primary producers capture enough energy to create an average of several kilograms of dry plant material per square meter per year. On a global scale, they produce more than 150 billion metric tons of new biological material annually. Some of the solar energy that producers convert into chemical energy is transferred to consumers at higher trophic levels.

The rate at which producers convert solar energy into chemical energy is an ecosystem's **gross primary productivity.** But like all other organisms, producers use energy for their own maintenance. After deducting the energy devoted to these functions, which are collectively called cellular respiration (see Section 8.1), whatever chemical energy remains is the ecosystem's **net primary productivity.** In most ecosystems, net primary productivity is between 50% and 90% of gross primary productivity. In other words, producers use between 10% and 50% of the energy they capture for their own respiration.

Ecologists generally measure primary productivity in units of energy captured (kcal/m^2/yr) or in units of biomass created (g/m^2/yr). *Biomass* is the dry weight of biological material per unit area or volume of habitat. (We measure biomass as the *dry* weight of organisms because their water content, which fluctuates with water uptake or loss, has no energetic or nutritional value.) You should not confuse an ecosystem's productivity with its **standing crop biomass,** the total dry weight of plants present at a given time. Net primary productivity is the *rate* at which the standing crop produces *new* biomass.

The energy captured by plants is stored in biological molecules—mostly carbohydrates, lipids, and proteins. Ecologists can convert units of biomass into units of energy or vice versa as long as they know how much carbohydrate, protein, and lipid a sample of biological material contains (4.2 kcal/g of carbohydrate; nearly 4.1 kcal/g of protein; and 9.5 kcal/g of lipid). Thus, net primary productivity is a measure of the rate at which producers accumulate energy as well as the rate at which new biomass is added to an ecosystem. Because it is far easier to measure biomass than energy content, ecologists usually measure changes in biomass to estimate productivity. New biomass takes several forms: the growth of existing producers; the creation of new producers by reproduction; and the storage of energy as carbohydrates or lipids. Because herbivores eat all three forms of new biomass, net primary productivity also measures how much new energy is available for primary consumers.

Primary Productivity Varies Greatly on Global and Local Scales

The potential rate of photosynthesis in any ecosystem is proportional to the intensity and the duration of sunlight, which vary geographically and seasonally (see Chapter 51). Sunlight is most intense and day length least variable near the equator. By contrast, light intensity is weakest and day length most variable near the poles. Thus, producers at the equator can photosynthesize nearly 12 hours a day, every day of the year. Near the poles, photosynthesis is virtually impossible during the long, dark winter; in summer, however, plants can photosynthesize around the clock.

Sunlight is not the only factor that influences the rate of primary productivity, however; temperature as well as the availability of water and nutrients also have big effects. For example, many of the world's deserts receive plenty of sunshine but have low rates of productivity because water is in short supply and the soil is nutrient-poor. Thus, mean annual net primary productivity varies greatly on a global scale **(Figure 54.4),** reflecting variations in these environmental factors (see Chapter 51).

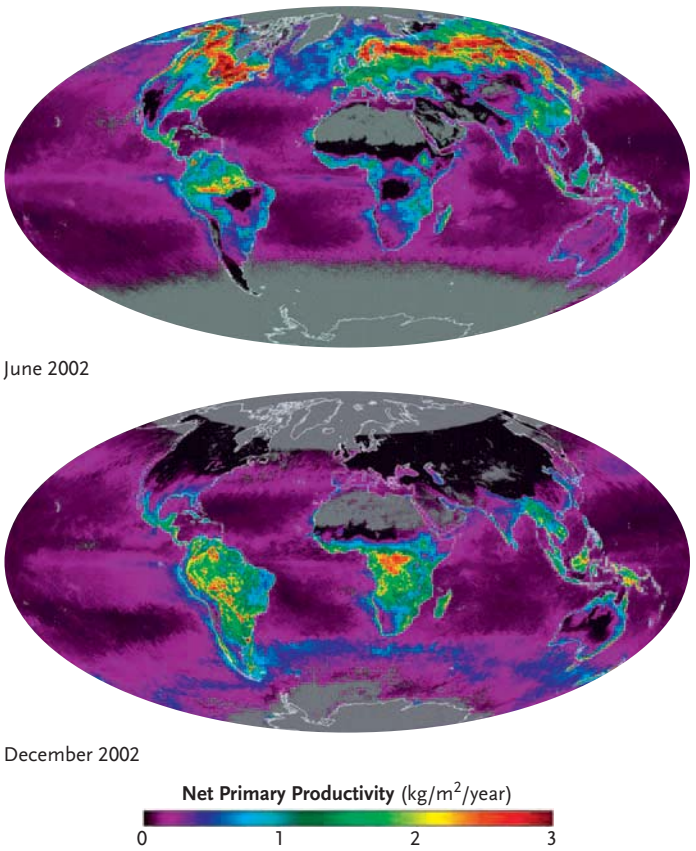

FIGURE 54.4 Seasonal and global variation in net primary productivity. Satellite data for 2002 provide a visual portrait of net primary productivity across Earth's surface in June and in December. The key indicates productivity measured as kilograms of carbon fixed by photosynthesis per square meter per year.

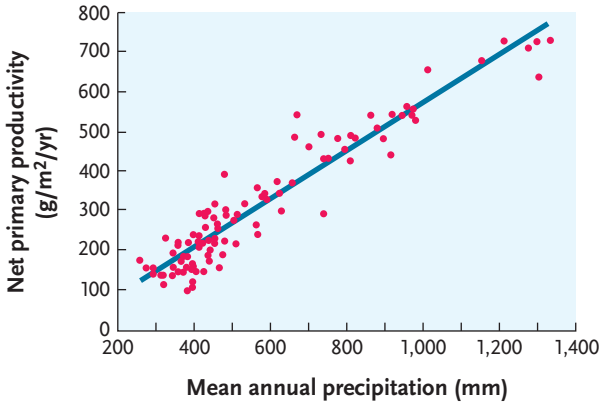

FIGURE 54.5 **Water and net primary productivity.** Mean annual net primary productivity increases with mean annual precipitation among 100 sites in the Great Plains of North America. These data include only aboveground productivity.

© Cengage Learning 2014

On a finer geographical scale, within a particular terrestrial ecosystem, mean annual net productivity often increases with the availability of water **(Figure 54.5).** In systems with sufficient water, a shortage of mineral nutrients may be limiting. All plants need specific ratios of macronutrients and micronutrients for maintenance and photosynthesis (see Section 35.1). But plants withdraw nutrients from soil, and if nutrient concentration drops below a critical level, photosynthesis may decrease or stop altogether. In every ecosystem, one nutrient inevitably runs out before the supplies of other nutrients are exhausted. The element in short supply is called a **limiting nutrient** because its absence limits productivity. Productivity in agricultural fields is subject to the same constraints as productivity in natural ecosystems. Farmers increase productivity by irrigating (adding water to) and fertilizing (adding nutrients to) their crops.

In freshwater and marine ecosystems, where water is always readily available, the depth of the water and the combined availability of sunlight *and* nutrients govern the rate of primary productivity. Productivity is high in near-shore ecosystems where sunlight penetrates shallow, nutrient-rich waters. Kelp beds and coral reefs, for example, which occur along temperate and tropical coastlines respectively, are among the most productive ecosystems on Earth **(Table 54.1).** By contrast, productivity is low in the open waters of a large lake or ocean: sunlight penetrates only the upper layers, and nutrients sink to the bottom. Thus, the two requirements for photosynthesis, sunlight and nutrients, are available in different places.

Although ecosystems vary in their net primary productivity, the differences are not always proportional to variations in their standing crop biomass (see Table 54.1). For example, biomass in temperate deciduous forests and temperate grasslands differs by a factor of 20, but the difference in their rates of net primary productivity is only twofold. Most biomass in trees is present in nonphotosynthetic tissues such as wood. As a result, their ratio of productivity to biomass is low (1,200 g/m^2 ÷ 30,000 g/m^2 = 0.040). By contrast, grasslands don't accumulate much biomass because annual mortality, herbivores, and fires remove plant material as it is produced; and their productivity to biomass ratio is much higher (600 g/m^2 ÷ 1,600 g/m^2 = 0.375).

TABLE 54.1 **Standing Crop Biomass and Net Primary Productivity of Different Ecosystems**

Ecosystem	Mean Standing Crop Biomass (g/m^2)	Mean Net Primary Productivity (g/m^2/yr)
Terrestrial Ecosystems		
Tropical rainforest	45,000	2,200
Tropical deciduous forest	35,000	1,600
Temperate rainforest	35,000	1,300
Temperate deciduous forest	30,000	1,200
Savanna	4,000	900
Boreal forest (taiga)	20,000	800
Woodland and shrubland	6,000	700
Cultivated land	1,000	650
Temperate grassland	1,600	600
Tundra and alpine tundra	600	140
Desert and thornwoods	700	90
Extreme desert, rock, sand, ice	20	3
Freshwater Ecosystems		
Swamp and marsh	15,000	2,000
Lake and stream	20	250
Marine Ecosystems		
Open ocean	3	125
Upwelling zones	20	500
Continental shelf	10	360
Kelp beds and reefs	2,000	2,500
Estuaries	1,500	1,500
World Average	**3,600**	**333**

From R. H. Whittaker. 1975. *Communities and Ecosystems.* 2nd ed. Macmillan.

Some ecosystems contribute more than others to overall net primary productivity **(Figure 54.6).** Ecosystems that cover large areas make substantial contributions, even if their productivity is low. Conversely, geographically restricted ecosystems make large contributions if their productivity is high. For example, the open ocean and tropical rainforests contribute about equally to total global productivity, but for different reasons. Open oceans have low productivity, but they cover nearly

two-thirds of Earth's surface. Tropical rainforests cover only a small area, but they are highly productive.

Some Energy Is Always Lost before It Is Transferred from One Trophic Level to the Next

Net primary productivity ultimately supports all the consumers in grazing and detrital food webs. Consumers in the grazing food web eat some of the biomass at every trophic level except the highest; uneaten biomass eventually dies and passes into detrital food webs. However, consumers assimilate only a portion of the material they ingest, and unassimilated material is passed as feces, which also supports detritivores and decomposers.

As energy is transferred from producers to consumers, some is stored in new consumer biomass, called **secondary productivity.** Nevertheless, two factors cause energy to be lost from the ecosystem every time it flows from one trophic level to another. First, animals use much of the energy they assimilate for maintenance or locomotion rather than the production of new biomass. Second, as dictated by the second law of thermodynamics, no biochemical reaction is 100% efficient; thus, some of the chemical energy liberated by cellular respiration is always converted to heat, which most organisms do not use.

Ecological efficiency is the ratio of net productivity at one trophic level to net productivity at the trophic level below it. For example, if the plants in an ecosystem have a net primary productivity of 100 g/m^2/yr of new tissue and the herbivores that eat those plants produce 10 g/m^2/yr, the ecological efficiency of the herbivores is 10%. The efficiencies of three processes—harvesting food, assimilating ingested energy, and producing new biomass—determine the ecological efficiencies of consumers.

Harvesting efficiency is the ratio of the energy content of food consumed to the energy content of food available. Predators harvest food efficiently when prey are abundant and easy to capture (see Section 53.1).

Assimilation efficiency is the ratio of the energy absorbed from consumed food to the food's total energy content. Because animal prey is relatively easy to digest, carnivores absorb between 60% and 90% of the energy in their food; assimilation efficiency is lower for prey with indigestible parts like bones or exoskeletons. Herbivores assimilate only 15% to 80% of the energy they consume because cellulose is not very digestible.

Production efficiency is the ratio of the energy content of new tissue produced to the energy assimilated from food. Production efficiency varies with maintenance costs. For example, endothermic animals often use less than 10% of their assimilated energy for growth and reproduction, because they use energy to generate body heat (see Section 48.8). Ectothermic animals, by contrast, channel more than 50% of their assimilated energy into new biomass.

The overall ecological efficiency of most organisms is between 5% and 20%. As a rule of thumb, only about 10% of the energy accumulated at one trophic level is converted into biomass at the next higher trophic level, as illustrated by energy transfers at Silver Springs, Florida **(Figure 54.7).** Producers in the Silver Springs ecosystem convert 1.2% of the solar energy they

What Is the Pattern of Energy Flow within the Silver Springs Ecosystem?

Hypothesis: Only a small percentage of the energy present in a trophic level is transferred to the next higher trophic level in the ecosystem.

Prediction: The energy content of the organisms present in each trophic level will decline steadily from the lowest to highest trophic levels.

Method: Howard T. Odum and his team analyzed energy flow in an aquatic ecosystem at Silver Springs, Florida. The producers in this small spring are mostly aquatic plants. The herbivores include snails, shrimp, insects, fishes, and turtles. The carnivores include a variety of invertebrates and fishes. The top carnivores are large fish. Sunlight is available as an energy source all year round. After defining the food web in this ecosystem, the researchers estimated the biomass and energy content (kcal/g) of each trophic level. They then constructed a diagram that illustrates how much energy is present at each trophic level and how much energy is lost as it works its way through the food web.

Results: The diagram illustrates annual energy flow for the spring ecosystem at Silver Springs, Florida. Numbers on the diagram indicate the quantity of energy (kcal/m^2/yr). Because the ecosystem is based on flowing water, small quantities of energy arrive from other ecosystems, and small quantities are exported in material carried away by stream flow.

Conclusion: The study supports the hypothesis that only a small proportion of the energy present at a trophic level is transferred to the next higher trophic level. Ultimately, all of the energy that passes through the grazing and detrital food webs is released as metabolically generated heat.

THINK LIKE A SCIENTIST The banks of many streams are covered with trees that cast shade over the water flowing through the stream. How would an increase in the number and density of trees growing alongside Silver Springs affect productivity in this ecosystem?

intercept into chemical energy (represented by 20,810 kcal of gross primary productivity). However, they use about two-thirds of this energy for respiration, leaving only one-third to be included in new plant biomass, the net primary productivity. All consumers in the grazing food web (on the right in Figure 54.7) ultimately depend on this energy source, which dwindles with each transfer between trophic levels. Energy is lost to respiration and export (that is, the transport of energy-containing materials out of the ecosystem by flowing water) at each trophic level. In addition, substantial energy flows into the detrital food web (on the left in Figure 54.7) as organic wastes and uneaten biomass. To determine the ecological efficiency of any trophic level, we divide its productivity by the productivity of the level below it. For example, the ecological efficiency of midlevel carnivores at Silver Springs is 111 kcal/yr ÷ 1,103 kcal/yr = 10.06%.

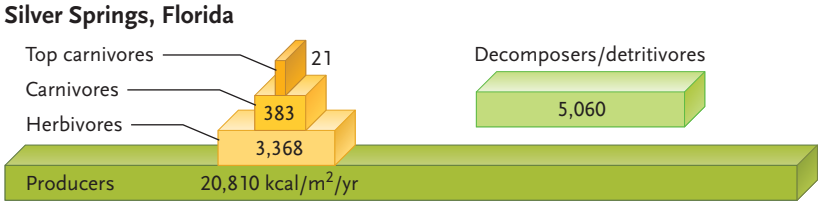

FIGURE 54.8 **Pyramids of energy.** The pyramid of energy for Silver Springs, Florida, shows that the amount of energy (in kcal/m²/yr) passing through each trophic level of the grazing food web decreases as it moves up the food web. The energy present in the parallel detrital food web is illustrated alongside the pyramid for the grazing food web.
© Cengage Learning 2014

The low ecological efficiencies that characterize most energy transfers illustrate one advantage of eating "lower on the food chain." Even though humans digest and assimilate meat more efficiently than vegetables, we might be able to feed more people if we all ate more vegetables directly instead of first passing these crops through another trophic level, such as cattle or chickens, to produce meat. The production of animal protein is costly because much of the energy fed to livestock is used for their own maintenance rather than the production of new biomass. But despite the economic—not to mention health-related—logic of a more vegetarian diet, a change in our eating habits alone won't eliminate food shortages or the frequency of malnutrition. Many regions of Africa, Australia, North America, and South America support vegetation that is suitable only for grazing by large herbivores. These areas could not produce significant quantities of edible grains and vegetables.

Ecological Pyramids Illustrate the Effects of Energy Losses

All organisms in a trophic level are the same number of energy transfers from the ecosystem's ultimate energy source. Plants are one energy transfer removed from sunlight; herbivores are two transfers away; carnivores feeding on herbivores are three transfers away; and carnivores feeding on other carnivores are four transfers away. As energy works its way up a food web, energy losses are multiplied in successive energy transfers, greatly reducing the energy available to support the highest trophic levels.

Consider a hypothetical example in which ecological efficiency is 10% for all consumers. Assume that the plants in a small field annually produce new tissues containing 100 kcal of energy. Because only 10% of that energy is transferred to new herbivore biomass, the 100 kcal in plants produces only 10 kcal of new herbivorous insects; only 1 kcal of new songbirds, which feed on insects; and only 0.1 kcal of new falcons, which feed on songbirds. Thus, after three energy transfers, only 0.1% of the energy from primary productivity remains at the highest trophic levels.

The inefficiency of energy transfer from one trophic level to the next has profound effects on ecosystem structure. Ecologists illustrate these effects in diagrams called **ecological pyramids.** Trophic levels in the grazing food web are drawn as stacked blocks, with the size of each block proportional to the energy, biomass, or numbers of organisms present; primary producers are illustrated at the bottom of the pyramid and higher-level consumers at the top. The energy or biomass in the organisms of the parallel detrital food web are often illustrated alongside the pyramid for the grazing food web.

Pyramids of energy typically have wide bases and narrow tops because each trophic level contains on average only about 10% as much energy as the trophic level below it, as illustrated by the pyramid of energy for Silver Springs, Florida **(Figure 54.8).**

The progressive reduction in productivity at higher trophic levels, as illustrated in Figure 54.7, usually establishes a **pyramid of biomass (Figure 54.9).** The biomass at each trophic level is pro-

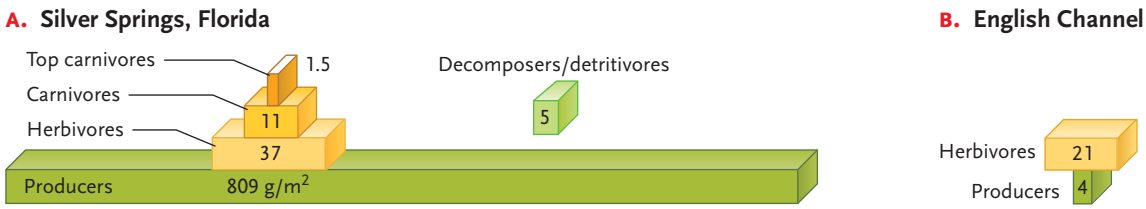

FIGURE 54.9 **Pyramids of biomass. (A)** The pyramid of standing crop biomass for the grazing food web at Silver Springs is bottom heavy, as it is for most ecosystems. The biomass present in the parallel detrital food web is illustrated alongside the pyramid for the grazing food web. **(B)** Some marine ecosystems, such as that in the English Channel, have an inverted pyramid of biomass because producers are quickly eaten by primary consumers. Only the producer and herbivore trophic levels are illustrated here. The data for both pyramids are given in grams of dry biomass per square meter.

portional to the chemical energy temporarily stored there. Thus, in terrestrial ecosystems, the total biomass of producers is generally greater than the total biomass of herbivores, which is, in turn, greater than the total biomass of predators (see Figure 54.9A). Populations of top predators—animals like mountain lions or alligators—contain too little biomass and energy to support another trophic level; thus, they have no nonhuman predators.

Freshwater and marine ecosystems sometimes exhibit inverted pyramids of biomass (see Figure 54.9B). In the open waters of a lake or ocean, primary consumers (zooplankton) eat the primary producers (phytoplankton) almost as soon as they appear. As a result, the standing crop of primary consumers at any moment in time is actually larger than the standing crop of primary producers. Food webs in these ecosystems are stable, however, because the producers have exceptionally high **turnover rates.** In other words, the phytoplankton divide and their populations grow so quickly that feeding by zooplankton doesn't endanger their populations or reduce their productivity. And on an annual basis, the *cumulative total* biomass of primary producers far outweighs that of primary consumers.

The reduction of energy and biomass also affects the population sizes of organisms at the top of a food web. Top predators are often relatively large animals, thus concentrating the limited biomass at the highest trophic levels in relatively few individuals **(Figure 54.10).** The extremely narrow top of this **pyramid of numbers** has grave implications for conservation biology. Because each top predator must patrol a large area to find sufficient food, the members of a population are often widely dispersed within their habitats. As a result, they are highly sensitive to hunting, habitat destruction, and random events, which can lead to local extinction (see Chapter 55). Top predators may also suffer from the accumulation of poisonous materials that move through food webs (see *Focus on Applied Research*). Even predators that feed below the top trophic level often suffer the ill effects of human activities.

Consumers Sometimes Regulate Ecosystem Processes in a Trophic Cascade

As you know from the preceding discussion, numerous abiotic factors—the intensity and duration of sunlight, rainfall, temperature, and the availability of nutrients—have significant effects on primary productivity. Primary productivity, in turn, has profound effects on populations of herbivores and the predators that feed on them. But what effect does feeding by these consumers have on primary productivity?

Recent research suggests that consumers may sometimes influence rates of primary productivity, especially in ecosystems with low species diversity and relatively few trophic levels. For example, food webs in North American salt marshes depend primarily on the productivity of salt marsh cordgrass *(Spartina alterniflora),* a foundation species that defines the nature of that coastal ecosystem (see Section 53.3). Cordgrass is consumed by herbivores, including the marsh periwinkle snail *(Littoraria irrorata).* In the southeastern United States, these herbivores are in turn consumed by blue crabs *(Callinectes sapidus),* mud crabs *(Eurytium limosum),* and terrapins *(Malaclemys terrapin).*

For many years, ecologists believed that the productivity of cordgrass was largely determined by the availability of nutrients in the salt marsh. However, research by Brian R. Silliman and Mark D. Bertness of Brown University showed that the productivity of cordgrass is actually regulated by what ecologists call a **trophic cascade**—predator–prey effects that reverberate through the population interactions at two or more trophic levels **(Figure 54.11).** Populations of the herbivorous periwinkle snails are controlled by the crabs and turtles that eat them. In the presence of these predators, snail populations are reduced in size, and the cordgrass grows luxuriantly. But when these predators are removed from the system, the snail populations grow rapidly, and feeding by the snails virtually eliminates the cordgrass, converting a highly productive ecosystem into a barren mudflat. Thus, cordgrass productivity is controlled *indirectly* by the abundance of predators that eat the snails that eat the cordgrass.

STUDY BREAK 54.2

1. What is the difference between gross primary productivity and net primary productivity?
2. What environmental factors influence rates of primary productivity in terrestrial and aquatic ecosystems?
3. Why is energy lost from an ecosystem at every transfer from one trophic level to the trophic level above it?
4. How can the presence of predators influence an ecosystem's productivity?

Biological Magnification and the Accumulation of Toxins at Higher Trophic Levels

The synthetic organic pesticide DDT (dichloro-diphenyl-trichloroethane) was first used widely during World War II. In the tropical Pacific, it killed mosquitoes that transmitted malarial parasites (*Plasmodium* species) to soldiers. In war-ravaged European cities, it controlled body lice that carried the bacteria causing typhus *(Rickettsia rickettsii)*. After the war, people started using DDT to kill agricultural pests, disease vectors, and insects in homes and gardens.

Although DDT is a stable hydrocarbon compound that is nearly insoluble in water, it is more mobile than its users expected. Winds carry it as a vapor, and water transports it as fine particles. DDT is also highly soluble in fats, accumulating in animal tissues—and it travels with animals wherever they go.

Unfortunately, consumers accumulate the DDT from all of the organisms they eat in their lifetimes. Primary consumers, like herbivorous insects, may ingest relatively small quantities. But a songbird that eats many insects will accumulate a moderate amount, and a predator that feeds on songbirds will accumulate even more. Thus, DDT and other nondegradable poisons become concentrated in organisms at higher trophic levels, a phenomenon called **biological magnification (Figure).** Although many organisms can partially metabolize DDT to other compounds, these products are also toxic or physiologically disruptive.

After the war, DDT moved rapidly through ecosystems, affecting organisms in ways that no one had predicted. In cities where DDT controlled Dutch elm disease, songbirds died after eating contaminated insects and seeds. In streams flowing through forests where DDT killed spruce budworms, salmon died because runoff carried the pesticide into their habitat. And in croplands around the world, new pests flourished because DDT indiscriminately killed the natural predators that had kept their populations in check.

Eventually, the effects of biological magnification began to show up in places far removed from the sites of DDT application. Top carnivores in some food webs were pushed to the brink of extinction. The reproduction of bald eagles, peregrine falcons, ospreys, and brown pelicans was disrupted because one DDT breakdown product interferes with the deposition of calcium in their eggshells. When birds tried to incubate their eggs, the shells cracked beneath the parents' weight. Even today, traces of DDT are found in the bodies of nearly all species, including in human fat and breast milk.

Since the 1970s, DDT has been banned in the United States, except for restricted applications to protect public health. Many hard-hit species have partially recovered, but some birds still lay thin-shelled eggs because they pick up DDT at their winter ranges in Latin America. As recently as 1990, the California State Department of Health recommended that a fishery off the coast of California be closed because DDT from industrial waste discharged 20 years earlier was still moving through that ecosystem. Moreover, DDT is still used in other countries, and some enters the United States on imported fruit and vegetables.

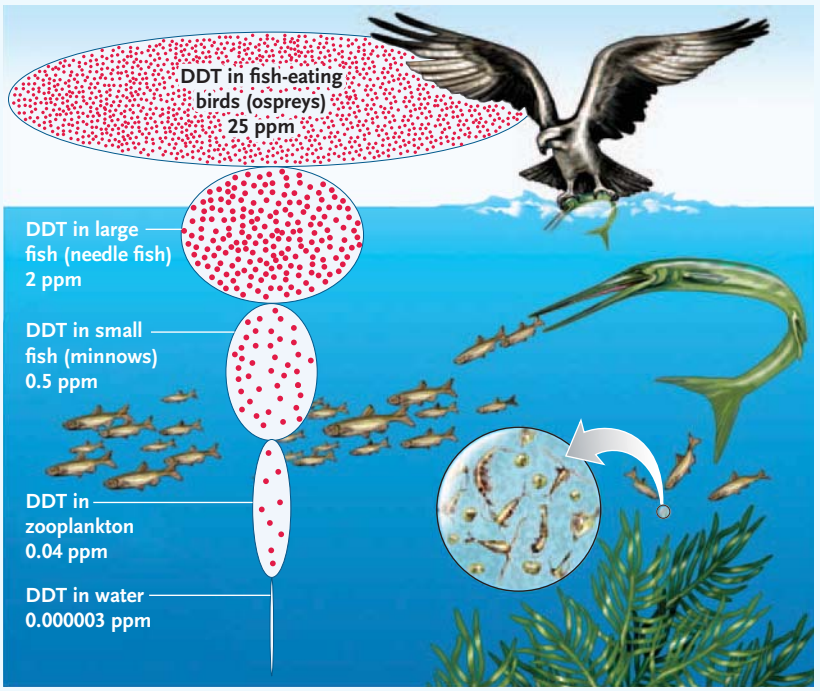

FIGURE **In this food web near Long Island Sound, New York, DDT concentration (measured in parts per million, ppm) was magnified nearly 10 million times between zooplankton and ospreys.**

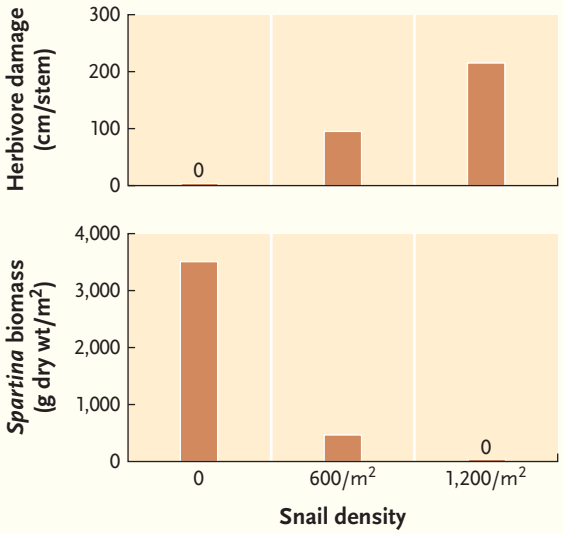

Biological magnification applies to many compounds that humans release into the environment. For example, polychlorinated biphenyls (PCBs), commonly used in the manufacture of plastics and electrical insulation, enter aquatic ecosystems in factory wastes. Their use has been banned in the United States since the 1970s. But these compounds break down very slowly, and vast deposits have accumulated in the bottom sediments of rivers and lakes. Once bottom-feeding organisms ingest them, the toxins work their way up food webs, accumulating at higher and higher concentrations in consumers. The effects on humans can be severe; pregnant women who regularly eat fish from the Great Lakes often give birth to children with below-average weight and neonatal behavioral problems. The pollution in some areas of New York State was so severe that the Department of Health advised people to avoid eating freshwater fish more than once a month. PCBs can be removed from aquatic ecosystems by dredging, but the dredging activity itself stirs up the polluted sediments, releasing the toxins into the water that flows above.

Question: How is the primary productivity of salt marsh grasses influenced by herbivores and their predators?

Experiment: Silliman and Bertness conducted a set of experiments to measure the effects of herbivores and their predators on the primary productivity of salt marsh cordgrass *(Spartina alterniflora)* along the coast of Sapelo Island, Georgia:

1. The researchers measured the effects on cordgrass of feeding by an herbivorous snail *(Littoraria irrorata)* by controlling snail densities within screened 1-m^2 enclosures (no snails, 600 snails, or 1,200 snails per enclosure) and measuring herbivore damage to cordgrass stems.
2. They created other enclosures that protected juvenile snails from their predators (crabs and terrapins) and compared the densities of juvenile snails that became established in protected versus unprotected areas.
3. They tethered snails to cordgrass stems at various locations in the marsh and monitored them to determine the rate at which they were consumed by predators.
4. All three experiments were replicated eight times in different parts of the marsh. The results reported here are from parts of the marsh where the cordgrass grew the tallest.

Results: The first experiment showed that herbivore damage increased with snail density, and cordgrass biomass decreased with snail density **(A).** The second experiment demonstrated that snail predators greatly reduce the density of juveniles that become established in the population: snail densities averaged 8.3 individuals/m^2 in unprotected enclosures versus 305/m^2 in protected enclosures. The third experiment revealed that 98% of the tethered snails were eaten by predators within 24 hours.

The researchers demonstrated that predators remove most herbivorous snails in this ecosystem, substantially reducing their impact on cordgrass. After predators are experimentally excluded from the system, snail densities increase dramatically, and high snail densities result in the near elimination of cordgrass **(B).**

Conclusion: The three experiments strongly suggest that cordgrass productivity is controlled by a top-down trophic cascade **(C).**

Blue crabs, a major predator on the snails, are a popular delicacy; the researchers note that so many blue crabs have been harvested from North American marshes that the crab populations are now imperiled. The elimination of this predator from marsh ecosystems is likely to result in a population explosion of snails, which in turn will virtually eliminate the cordgrass and thus the ecosystem itself.

THINK LIKE A SCIENTIST Both crabs and turtles are considered delicacies in many cultures. What effects would the harvesting of crabs and turtles have on the cordgrass salt marsh ecosystem?

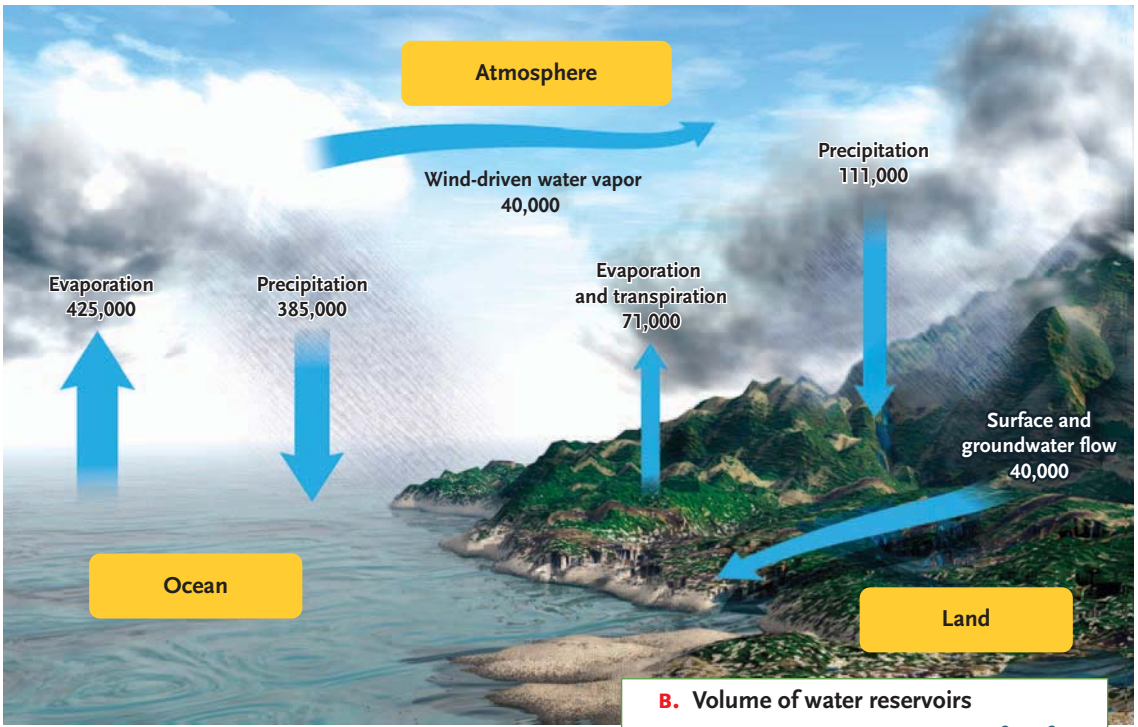
54.3 Nutrient Cycling in Ecosystems

The availability of nutrients is as important to ecosystem function as the input of energy. Photosynthesis—the conversion of solar energy into chemical energy—requires carbon, hydrogen, and oxygen, which producers acquire from water and air. Producers also need nitrogen, phosphorus, and other minerals (see Table 35.1). A deficiency in any of these minerals can reduce primary productivity.

Earth is essentially a closed system with respect to matter. Thus, unlike energy, for which there is a constant cosmic input, Earth already contains virtually all the nutrients that will ever be available for biological systems. Biogeochemical cycles constantly circulate nutrient ions or molecules between the abiotic environment and living organisms. Unlike energy, which flows through ecosystems and is gradually lost as heat, matter is conserved in biogeochemical cycles. Although there may be local shortages of specific nutrients, Earth's overall supplies of these chemical elements are never depleted.



Nutrients take various forms as they pass through biogeochemical cycles. Some materials, such as carbon, nitrogen, and oxygen, form gases, which move through global *atmospheric cycles.* Geological processes move other materials, such as phosphorus, through local *sedimentary cycles,* carrying them between dry land and the seafloor. Rocks, soil, water, and air are the reservoirs where mineral nutrients accumulate, sometimes for many years.

The Hydrologic Cycle Recirculates All the Water on Earth

Although it is not a mineral nutrient, water is the universal intracellular solvent for biochemical reactions. Nevertheless, only a fraction of 1% of Earth's total water is present in biological systems at any time.

The cycling of water, called the **hydrologic cycle,** is global, with water molecules moving from the ocean into the atmosphere, to the land, through freshwater ecosystems, and back to the ocean **(Figure 54.12).** Solar energy causes water to evaporate from oceans, lakes, rivers, soil, and living organisms, entering the atmosphere as a vapor and remaining aloft as a gas, as droplets in clouds, or as ice crystals. It falls as precipitation, mostly in the form of rain and snow. When precipitation falls on land, water flows across the surface or percolates to great depth in the soil, eventually reentering the ocean reservoir through the flow of streams and rivers.

A. The water cycle

B. Volume of water reservoirs

Water reservoirs	Volume (10^3 km^3)
Oceans	1,370,000
Polar ice, glaciers	29,000
Groundwater	4,000
Lakes, rivers	230
Soil moisture	67
Atmosphere (water vapor)	14

FIGURE 54.12 The hydrologic cycle. Water cycles through marine, atmospheric, and terrestrial reservoirs. **(A)** Labels on the arrows list the amount of water (in km^3/yr) moved among reservoirs by various processes. The amount of water entering the atmosphere through evaporation from the ocean plus evaporation and transpiration from land (425,000 + 71,000 = 496,000 km^3/yr) is equal to the amount falling as precipitation on the oceans and land (385,00 + 111,000 = 496,000 km^3/yr). Similarly, the quantity of water moving from ocean to land as wind-driven water vapor is balanced by the flow of runoff from the land to the ocean. **(B)** The oceans are by far the largest of the six major reservoirs of water on Earth.
