Studies of the Hubbard Brook Watershed

Because water always flows downhill, local topography affects the movement of dissolved nutrients in terrestrial ecosystems. A **watershed** is an area of land from which precipitation drains into a stream or river system. Thus, each watershed represents a part of an ecosystem from which nutrients exit through a single outlet, much the way a bathtub empties through a single drain. When several streams join to form a river, the watershed drained by the river encompasses all of the smaller watersheds drained by the streams. For example, the Mississippi River watershed covers roughly one-third of the United States, and it includes watersheds drained by the Illinois, Missouri, and Tennessee Rivers as well as many other watersheds drained by smaller streams and rivers.

Because watersheds are relatively self-contained units, they are ideal for large-scale field experiments about nutrient flow in ecosystems. Herbert Bormann of Yale University and Gene Likens of Cornell University have conducted a classic experiment on this topic since the 1960s. Bormann and Likens manipulated small watersheds of temperate deciduous forest in the Hubbard Brook Experimental Forest in the White Mountain National Forest of New Hampshire. They measured precipitation and nutrient input into the watersheds, the uptake of nutrients by vegetation, and the amount of nutrients leaving the watershed via streamflow. Nutrients exported in streamflow were monitored in water samples collected from V-shaped concrete weirs built into bedrock below the streams that drained the watersheds **(Figure A).** Impermeable bedrock underlies the soil, preventing water from leaving the system by deep seepage.

After collecting several years of baseline data on six undisturbed watersheds, the researchers cut all the trees in one small watershed in 1965 and 1966. They also applied herbicides to prevent regrowth. After establishing this experimental treatment, they monitored the output of nutrients in streams that drained experimental and control watersheds. They attributed differences in nutrient export between undisturbed watersheds (controls) and the clear-cut watershed (experimental treatment) to the effects of deforestation.

Gene E. Likens from Gene E. Likens et al., *Ecological Monographs*, 40(1):23–47, 1970.

FIGURE A **Weir used to measure the volume and nutrient content of water leaving a watershed by streamflow.**

The hydrologic cycle maintains its global balance because the total amount of water that enters the atmosphere is equal to the amount that falls as precipitation. Most water enters the atmosphere through evaporation from the ocean, which represents the largest reservoir on the planet. A much smaller fraction evaporates from terrestrial ecosystems, and most of that results from transpiration in green plants.

The constant recirculation provides fresh water to terrestrial organisms and maintains freshwater ecosystems such as lakes and rivers. Water also serves as a transport medium that moves nutrients within and between ecosystems, as demonstrated in a series of classic experiments in the Hubbard Brook Experimental Forest, described in *Focus on Basic Research*.

The Carbon Cycle Includes a Large Atmospheric Reservoir

Carbon atoms provide the backbone of most biological molecules, and carbon compounds store the energy captured by photosynthesis (see Section 9.1). Carbon enters food webs when producers convert atmospheric carbon dioxide (CO_2) into carbohydrates. Heterotrophs acquire carbon by eating other organisms or detritus. Although carbon moves somewhat independently in the sea and on land, a common atmospheric pool of CO_2 creates a global **carbon cycle (Figure 54.13).**

The largest reservoir of carbon is sedimentary rock, such as limestone or marble. Rocks are in the unavailable inorganic compartment, and they exchange carbon with living organisms at an exceedingly slow pace. Most *available* carbon is present as dissolved bicarbonate ions (HCO_3^-) in the ocean. Soil, the atmosphere, and plant biomass form other significant, but much smaller, reservoirs of available carbon. Atmospheric carbon is mostly in the form of molecular CO_2, a product of aerobic respiration. Volcanic eruptions also release CO_2 into the atmosphere.

Sometimes carbon atoms leave the organic compartments for long periods of time. Some organisms in marine food webs build shells and other hard parts by incorporating dissolved carbon into calcium carbonate ($CaCO_3$) and other insoluble salts. When shelled organisms die, they sink to the bottom and are buried in sediments. The insoluble carbon that accumulates as rock in deep sediments may remain buried for millions of years before tectonic uplifting brings it to the surface, where erosion and weathering dissolve sedimentary rocks and return carbon to an available form.

Over hundreds of millions of years, carbon atoms were also transferred to the unavailable organic compartment when soft-bodied organisms were buried in habitats where low oxygen concentration prevented decomposition. Under suitable geological conditions, these carbon-rich tissues were slowly converted to gas, petroleum, or coal, which humans now use as fossil fuels.

Bormann and Likens determined that vegetation absorbed substantial water and conserved nutrients in undisturbed watersheds. Plants used about 40% of the precipitation for transpiration. The rest contributed to runoff and groundwater. Control watersheds lost only about 8 to 10 kg of calcium per hectare each year, an amount that was replaced by the erosion of bedrock and input from rain. Moreover, control watersheds actually accumulated about 2 kg of nitrogen per hectare per year and slightly smaller amounts of potassium.

By contrast, the experimentally deforested watershed experienced a 40% annual increase in runoff. During a 4-month period in the summer, runoff increased 300%. Some mineral losses were similarly large. The net loss of calcium was 10 times higher than in the control watersheds **(Figure B)** and the loss of potassium 21 times higher.

Phosphorus losses did not increase; this mineral was apparently retained by the soil. However, the loss of nitrogen was an astronomical 120 kg per hectare per year. So much nitrogen entered the stream draining the experimental watershed that the stream became choked with algae and cyanobacteria. Thus, the results of the Hubbard Brook experiment suggest that deforestation increases flooding, decreases the fertility of ecosystems, and leads to nutrient enrichment of nearby aquatic ecosystems.

The Hubbard Brook Watershed project is an example of long-term ecological research (LTER), one of many in a network of such projects that provide remarkable insights into ecosystem processes. The network itself is funded by the National Science Foundation and described in detail at its web site: http://www.lternet.edu/.

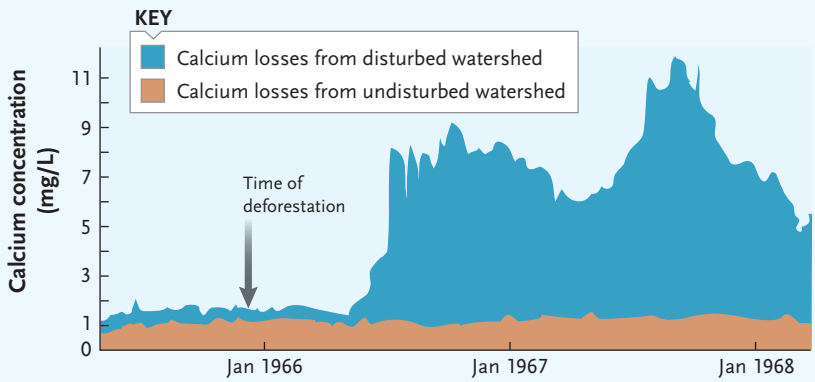

FIGURE B Calcium losses from a deforested watershed were much greater than those from controls. The arrow indicates the time of deforestation in early winter. Mineral losses did not increase until after the ground thawed the following spring; increased runoff also caused large water losses from the watershed.

The Nitrogen Cycle Depends on the Activity of Diverse Microorganisms

All organisms require nitrogen to construct nucleic acids, proteins, and other biological molecules. Earth's atmosphere had a high nitrogen concentration long before life originated. Today, a global **nitrogen cycle** moves this element between the huge atmospheric pool of gaseous molecular nitrogen (N_2) and several much smaller pools of nitrogen-containing compounds in soils, marine and freshwater ecosystems, and living organisms **(Figure 54.14).**

Molecular nitrogen is abundant in the atmosphere, but triple covalent bonds bind its two atoms so tightly that most organisms cannot use it. However, three biochemical processes—nitrogen fixation, ammonification, and nitrification **(Table 54.2)**—convert nitrogen into nitrogen compounds that primary producers can incorporate into biological molecules such as proteins and nucleic acids. Secondary consumers obtain their nitrogen by consuming primary producers, thereby initiating the movement of nitrogen through the food webs of an ecosystem.

In **nitrogen fixation** (see Section 35.3), molecular nitrogen (N_2) is converted into ammonia (NH_3) and ammonium ions (NH_4^+). Certain bacteria, including *Azotobacter* and *Rhizobium,* which collect molecular nitrogen from the air between soil particles, are the major nitrogen fixers in terrestrial ecosystems. The cyanobacteria partners in some lichens (see Section 30.3) also fix molecular nitrogen. Other cyanobacteria, such as *Anabaena* and *Nostoc,* are important nitrogen fixers in aquatic ecosystems; the water fern (genus *Azolla*) plays that role in rice paddies. Collectively, these organisms fix an astounding 200 million metric tons of nitrogen each year; nitrogen fixation can also result from lightning and volcanic action. Plants and other primary producers assimilate and use this nitrogen in the biosynthesis of amino acids, proteins, and nucleic acids, which then circulate through food webs.

Some plants, including legumes (such as beans and clover), alders (*Alnus* species), and some members of the rose family (Rosaceae), are mutualists with nitrogen-fixing bacteria. These plants acquire nitrogen from soils much more readily than plants that lack such mutualists. Although these plants have the competitive edge in nitrogen-poor soil, nonmutualistic species often displace them in nitrogen-rich soil.

In addition to nitrogen fixation, several other biochemical processes make large quantities of nitrogen available to producers. **Ammonification** of detritus by bacteria and fungi converts organic nitrogen into ammonia (NH_3), which dissolves into ammonium ions (NH_4^+) that plants can assimilate; some ammonia escapes into the atmosphere as a gas. **Nitrification** by certain bacteria produces nitrites (NO_2^-), which are converted by other bacteria to usable nitrates (NO_3^-). All of these compounds are water-soluble, and water rapidly leaches them from soil into streams, lakes, and oceans.

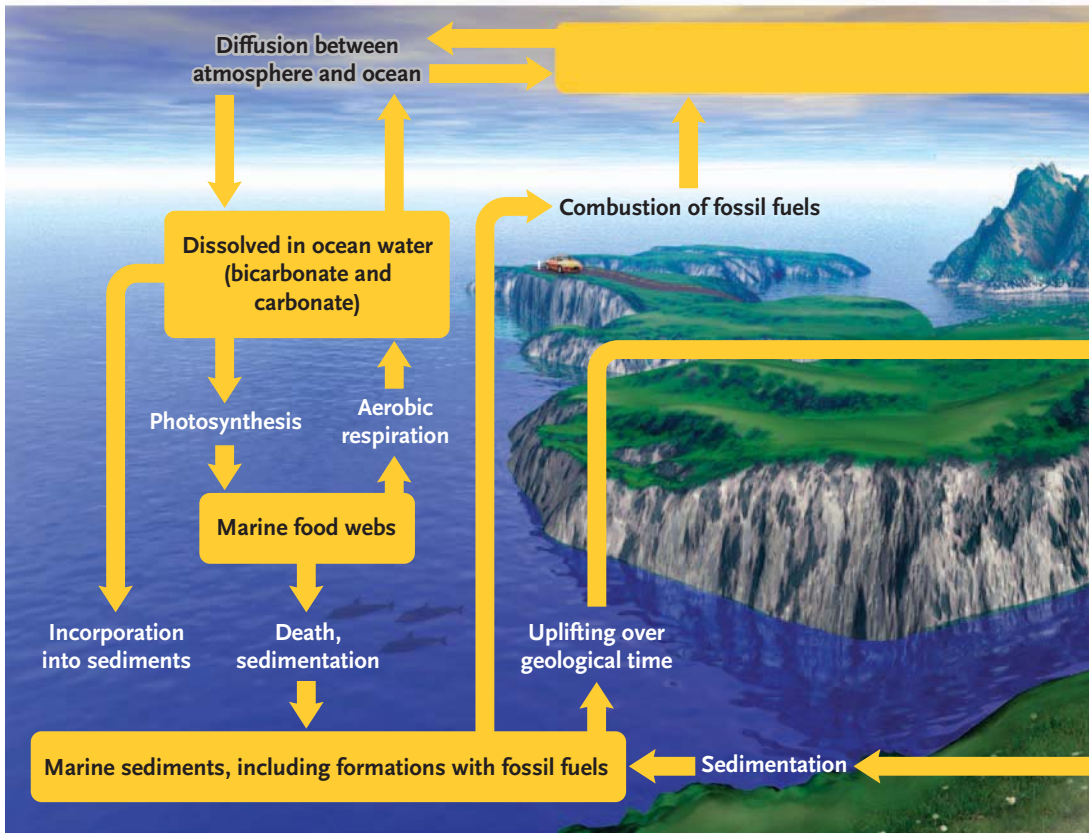
A. Amount of carbon in major reservoirs

Carbon reservoirs	Mass (10^{15} g)
Sediments and rocks	77,000,000
Ocean (dissolved forms)	39,700
Soil	1,500
Atmosphere	750
Biomass on land	715

B. Annual global carbon movement between reservoirs

Direction of movement	Mass (10^{15} g)
From atmosphere to plants (carbon fixation)	120
From atmosphere to ocean	107
To atmosphere from ocean	105
To atmosphere from plants	60
To atmosphere from soil	60
To atmosphere from burning fossil fuel	5
To atmosphere from burning plants	2
To ocean from runoff	0.4
Burial in ocean sediments	0.1

C. The global carbon cycle



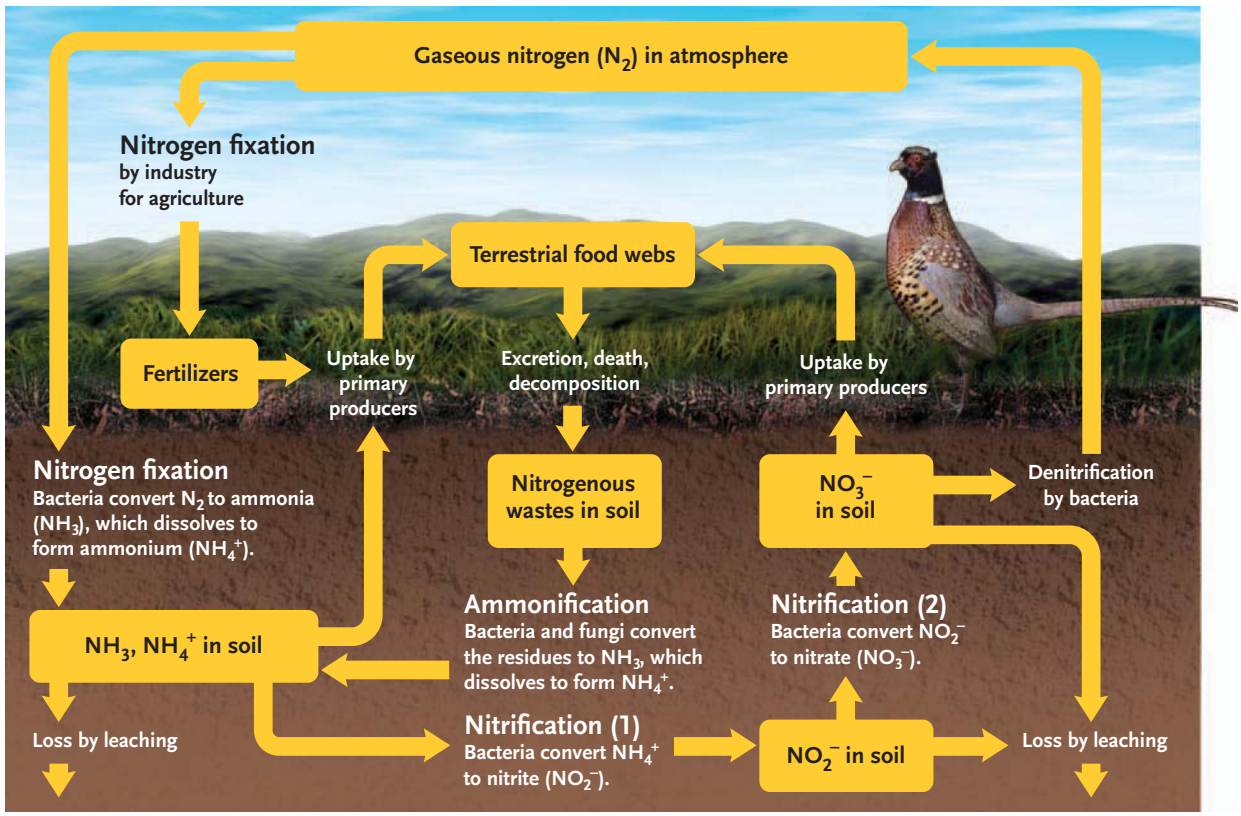


FIGURE 54.13 **The carbon cycle.** Marine and terrestrial components of the global carbon cycle are linked through an atmospheric reservoir of carbon dioxide. **(A)** By far, the largest amount of Earth's carbon is found in sediments and rocks. **(B)** Earth's atmosphere mediates most movements of carbon. **(C)** In this illustration of the carbon cycle, boxes identify major reservoirs, and labels on the arrows identify the processes that cause carbon to move between reservoirs.

FIGURE 54.14 **The nitrogen cycle in terrestrial ecosystems.** Nitrogen cycles through terrestrial ecosystems when unavailable molecular nitrogen is made available through the action of nitrogen-fixing bacteria. Other bacteria recycle nitrogen within the available organic compartment through ammonification and two types of nitrification, converting organic wastes into ammonium ions and nitrates. Denitrification converts nitrate to molecular nitrogen, which returns to the atmosphere. Runoff carries various nitrogen compounds from terrestrial ecosystems into oceans, where it is recycled in marine food webs.

Under conditions of low oxygen availability, **denitrification** by still other bacteria converts nitrites or nitrates into nitrous oxide (N_2O) and then into molecular nitrogen (N_2), which enters the atmosphere, completing the cycle. This action can deplete supplies of soil nitrogen in waterlogged or otherwise poorly aerated environments, such as bogs and swamps. In an interesting twist on the usual predator–prey relationships, several species of flowering plants that live in nitrogen-poor soils, such as the Venus' fly trap *(Dionaea muscipula),* capture and digest small insects as their primary nitrogen source.

The Phosphorus Cycle Includes a Large Sedimentary Reservoir

Phosphorus is a crucial element for the energy transfers within the cells of all organisms and for construction of nucleic acids (Sections 4.4 and 14.2). Because phosphorus compounds lack a gaseous phase, this element moves between terrestrial and marine ecosystems in a sedimentary cycle **(Figure 54.15).** Earth's crust is the main reservoir of phosphorus, as it is for other minerals, such as calcium and potassium, that undergo sedimentary cycles.

TABLE 54.2 Biochemical Processes That Influence Nitrogen Cycling in Ecosystems

Process	Organisms Responsible	Products	Outcome
Nitrogen fixation	Bacteria: *Rhizobium, Azotobacter, Frankia* Cyanobacteria: *Anabaena, Nostoc*	Ammonia (NH_3), ammonium ions (NH_4^+)	Assimilated by primary producers
Ammonification of organic detritus	Soil bacteria and fungi	Ammonia (NH_3), ammonium ions (NH_4^+)	Assimilated by primary producers
Nitrification (1) Oxidation of NH_3 (2) Oxidation of NO_2^-	 Bacteria: *Nitrosomonas, Nitrococcus* Bacteria: *Nitrobacter*	 Nitrite (NO_2^-) Nitrate (NO_3^-)	 Used by nitrifying bacteria Assimilated by primary producers
Denitrification of NO_3^-	Soil bacteria	Nitrous oxide (N_2O), molecular nitrogen (N_2)	Released to atmosphere

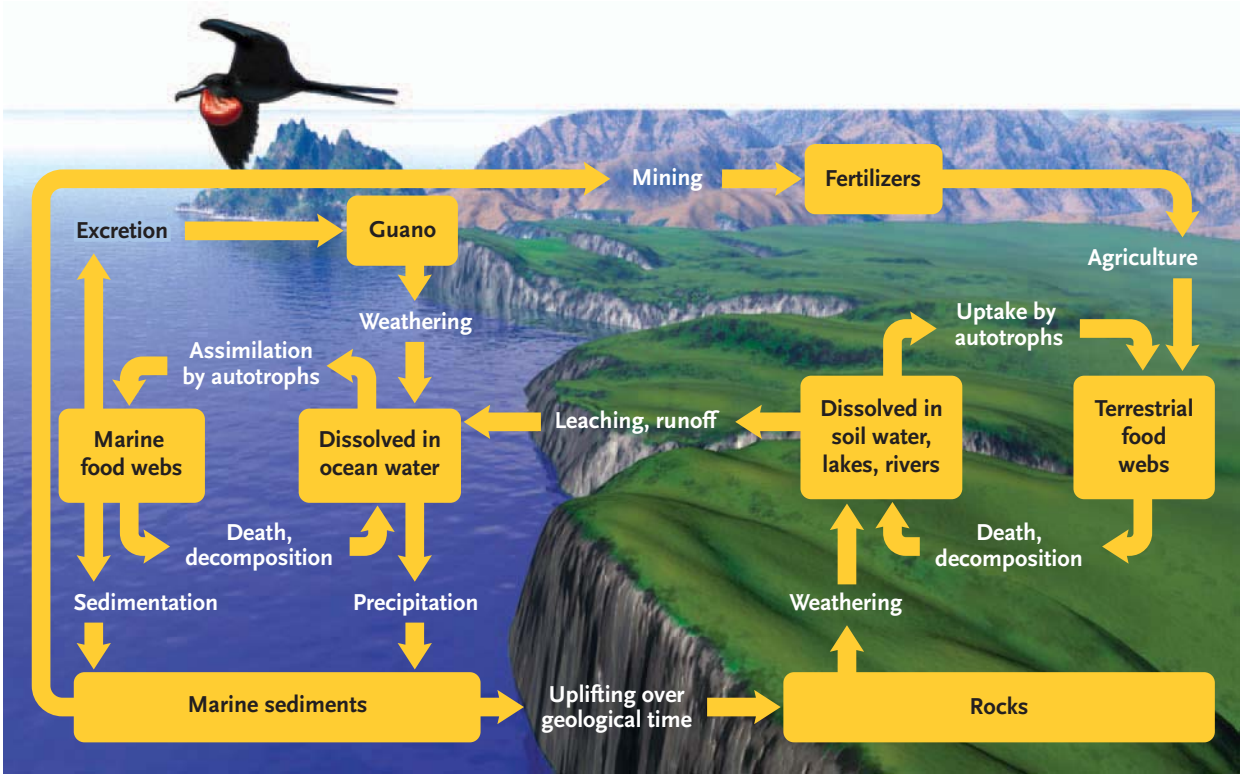

FIGURE 54.15 The phosphorus cycle. Phosphorus becomes available to biological systems when wind and rainfall dissolve phosphates in rocks and carry them into adjacent soil and freshwater ecosystems. Runoff carries dissolved phosphorus into marine ecosystems, where it precipitates out of solution and is incorporated into marine sediments.

© Cengage Learning 2014

Phosphorus is present in terrestrial rocks in the form of phosphates (PO_4^{3-}). In the **phosphorus cycle,** weathering and erosion carry phosphate ions from rocks to soil and into streams and rivers, which eventually transport them to the ocean. Once there, some phosphorus enters marine food webs, but most of it precipitates out of solution and accumulates for millions of years as insoluble deposits, mainly on continental shelves. When parts of the seafloor are uplifted and exposed, weathering releases the phosphates.

Plants absorb and assimilate dissolved phosphates directly, and phosphorus moves easily to higher trophic levels. All heterotrophs excrete some phosphorus as a waste product in urine and feces, which are decomposed, and producers readily absorb the phosphate ions that are released. Thus, phosphorus cycles rapidly *within* terrestrial communities.

Supplies of available phosphate are generally limited, however, and plants acquire it so efficiently that they reduce soil phosphate concentration to extremely low levels. Thus, like nitrogen, phosphorus is a common ingredient in agricultural fertilizers, and excess phosphates are pollutants of freshwater ecosystems. For many years, phosphate for fertilizers was obtained from *guano* (the droppings of seabirds that consume phosphorus-rich food), which was mined on small islands off the Pacific coast of South America. Most phosphate for fertilizer now comes from phosphate rock mined in Florida and other places with abundant marine deposits.

STUDY BREAK 54.3

1. How does the global hydrologic cycle maintain its balance?
2. What processes move large quantities of carbon from an organic compartment to an inorganic compartment?
3. What microorganisms drive the global nitrogen cycle, and how do they do it?
4. What is Earth's main reservoir for phosphorus, and why is it recycled at such a slow rate from that reservoir?

54.4 Human Disruption of Ecosystem Processes

Human activities—industrial processes, agricultural practices, and development—often disrupt biogeochemical cycles by moving materials from one nutrient compartment to another at unnaturally rapid rates. In this section we consider the consequences of human disruption of the carbon and nitrogen cycles.

Our Use of Combustible Energy Sources Has Disrupted the Carbon Cycle

The combustion of fossil fuels (oil, coal, and peat) and wood is transferring carbon from the reservoirs of organic nutrients to the atmospheric reservoir of inorganic nutrients at an unprecedented rate. Virtually all scientists agree that the resulting change

in the worldwide distribution of carbon is having severe consequences for Earth's climate, including a general warming that will cause a significant rise in sea level.

Concentrations of certain gases in the lower atmosphere have a profound effect on global temperature, which in turn has enormous impact on global climate. Molecules of carbon dioxide (CO_2), water, ozone, methane, nitrous oxide, and other compounds collectively act like a pane of glass in a greenhouse (hence they are described as *greenhouse gases*). They allow the short wavelengths of visible light to reach Earth's surface; but they impede the escape of longer, infrared wavelengths back into space, trapping much of that energy as heat. In short, greenhouse gases foster the accumulation of heat in the lower atmosphere, a warming action known as the **greenhouse effect,** which prevents Earth from being a cold and lifeless planet.

Since the late 1950s, scientists have measured atmospheric concentrations of CO_2 and other greenhouse gases at several remote sampling sites, which are free of local contamination and reflect the average concentrations of these gases in the atmosphere. Results indicate that concentrations of greenhouse gases have increased steadily for as long as they have been monitored **(Figure 54.16).** The graph of atmospheric CO_2 concentration through time has a regular zigzag pattern that follows the annual cycle of plant growth in the northern hemisphere. Photosynthesis withdraws so much CO_2 from the atmosphere during the northern hemisphere summer that its concentration falls. The concentration is higher during the northern hemisphere winter, when aerobic respiration continues, returning carbon to the atmosphere, and photosynthesis slows. The zigs and the zags in the data for CO_2 represent seasonal highs and lows, but the midpoint of the annual peaks and troughs has increased steadily. Many scientists interpret these data as evidence of a rapid buildup of atmospheric CO_2, which represents a shift in the distribution of carbon in the major reservoirs on Earth. Scientists estimate that the atmospheric CO_2 concentration has increased 35% in the last 150 years and 15% in the last 30 years.

What has caused the increase in the atmospheric concentration of CO_2? Burning of fossil fuels and wood is the largest contributor, because CO_2 is a combustion product of this process. Today, humans burn more wood and fossil fuels than ever before. In a paper published in *Nature Geoscience* in December 2009, Corinne Le Quéré at the University of East Anglia, UK, and colleagues from other institutions estimated that CO_2 emissions from the combustion of fossil fuels increased 29% between 2000 and 2008; more recent studies indicate that the trend has accelerated since 2008. Although slightly more than half the CO_2 emissions are absorbed by forests and marine phytoplankton, vast tracts of tropical forests are being cleared and burned (see Section 55.2), reducing the biosphere's capacity to maintain the carbon cycle as it existed before recent human activities disrupted it.

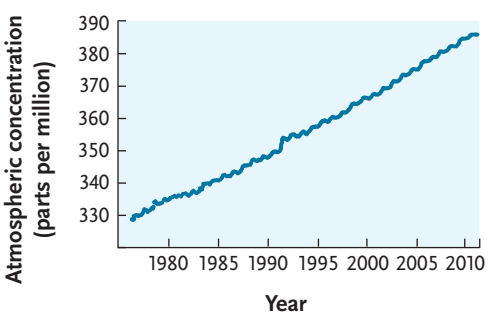

FIGURE 54.16 Increases in atmospheric concentration of carbon dioxide. Data have been collected at a remote monitoring station in Australia (Cape Grim, Tasmania) since 1976 and compiled by scientists at the Commonwealth Scientific and Industrial Research Organization, an agency of the Australian government.

© Cengage Learning 2014

Why is an increase in the atmospheric CO_2 concentration so alarming? As *Insights from the Molecular Revolution* describes, scientists are just beginning to discover many previously unforeseen effects of rising CO_2 levels in the atmosphere and in the oceans. Moreover, simulation models of the global climate suggest that increasing the concentration of any greenhouse gas is likely to intensify the greenhouse effect, contributing to a well-documented trend of global warming. According to the Intergovernmental Panel on Climate Change, an agency of the United Nations, the average global surface temperature increased more than 0.7°C during the twentieth century, with most of the increase occurring after 1980. Scientists have already documented significant changes in the geographical distributions of many organisms in response to that modest level of global warming (see Section 51.3).

Many different climate models now predict that the mean temperature of the lower atmosphere will rise 2.0° to 4.5°C during the twenty-first century, enough to increase ocean surface temperatures. Water expands when heated and the global sea level could rise as much as 0.4 m just from this expansion. In addition, because atmospheric temperature is rising fastest near the poles, global warming has already started melting Arctic glaciers and the Antarctic ice sheet, which might raise sea level even more, inundating low coastal regions. Waterfronts in Vancouver, Los Angeles, San Diego, Galveston, New Orleans, Miami, New York, and Boston could be submerged. So might agricultural lands in India, China, and Bangladesh, where much of the world's rice is grown. Global warming could also disturb regional patterns of precipitation and temperature. Areas that now produce much of the world's grains, including parts of Canada and the United States, would become arid scrub or deserts, and the now-forested areas to their north would become dry grasslands.

Most scientists believe that atmospheric levels of greenhouse gases will continue to increase at least until the middle of the twenty-first century and that global temperature will inevitably rise by several degrees. Although governments have repeatedly promised to stabilize and eventually reduce their CO_2 emissions, they have consistently failed to meet those objectives. Some countries fear that reforming our relationship to the carbon cycle will be too costly, but the economic and social costs of not doing so will be far higher. Stabilizing emissions at current levels will not reverse the damage already done, nor

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Ocean Acidification: Does it affect gene expression?

Because CO_2 is soluble in water, the oceans readily absorb it from the atmosphere—so much so that ecologists describe the oceans as a "sink" for atmospheric CO_2. Some environmental scientists have even suggested that the transfer of CO_2 from the atmosphere to the oceans may mitigate rising atmospheric CO_2 concentration. However, increasing the concentration of dissolved CO_2 decreases oceanic pH; in other words, the oceans are becoming more acidic as they absorb more of this gas. If the CO_2 concentration of the atmosphere continues to increase at its present rate, scientists predict a decrease in ocean surface pH of 0.2 to 0.4 by the end of the twenty-first century. Researchers worry about the possible adverse effects of ocean acidification on ocean ecosystems. In particular, will marine organisms be able to adapt to such changes?

Ocean acidification is a potential stress to marine organisms. In the lab, scientists are using genomics tools to understand the molecular mechanisms that underlie physiological responses to environmental stresses such as changes in temperature, osmolarity, and oxygen availability. In one approach, researchers use DNA microarrays (see Chapter 19) to analyze changes in the expression of many protein-coding genes simultaneously. The set of genes expressed in a cell at any time is called a *transcriptome;* the study of transcriptomes is *transcriptomics.* Understanding how ocean acidification affects the transcriptomes of marine organisms would help scientists understand the physiological mechanism that organisms might use to tolerate a more acidic ocean in the future.

Research Question

Does the pH of seawater affect the transcriptome?

Experiment

To answer the question, Anne Todgham and Gretchen Hofmann of the University of California, Santa Barbara, performed DNA microarray experiments on sea urchin *(Strongylocentrotus purpuratus)* larvae under different pH conditions. They studied this species because its larval skeleton is altered by low pH conditions, and because its genome has been sequenced. To vary pH, the researchers bubbled different concentrations of CO_2 through the seawater in tanks with developing larvae. In the control, the CO_2 concentration was equivalent to current atmospheric conditions; it produced a pH of 8.01. Two experimental conditions reflected predictions (made by the Intergovernmental Panel on Climate Change in 2007) of atmospheric CO_2 concentrations in the year 2100. The moderate treatment reflected an optimistic value that assumed some success in limiting future increases in atmospheric CO_2 concentration; it produced a pH of 7.96. The high treatment assumed no success in limiting future increases in atmospheric CO_2 concentration; it produced a pH of 7.88. Todgham and Hofmann's experiment is outlined in the **Figure** on the right.

Results

The researchers found subtle but statistically significant changes in the transcriptomes of the larvae growing in the moderate and high CO_2 conditions compared to the transcriptome of the larvae in the control condition:

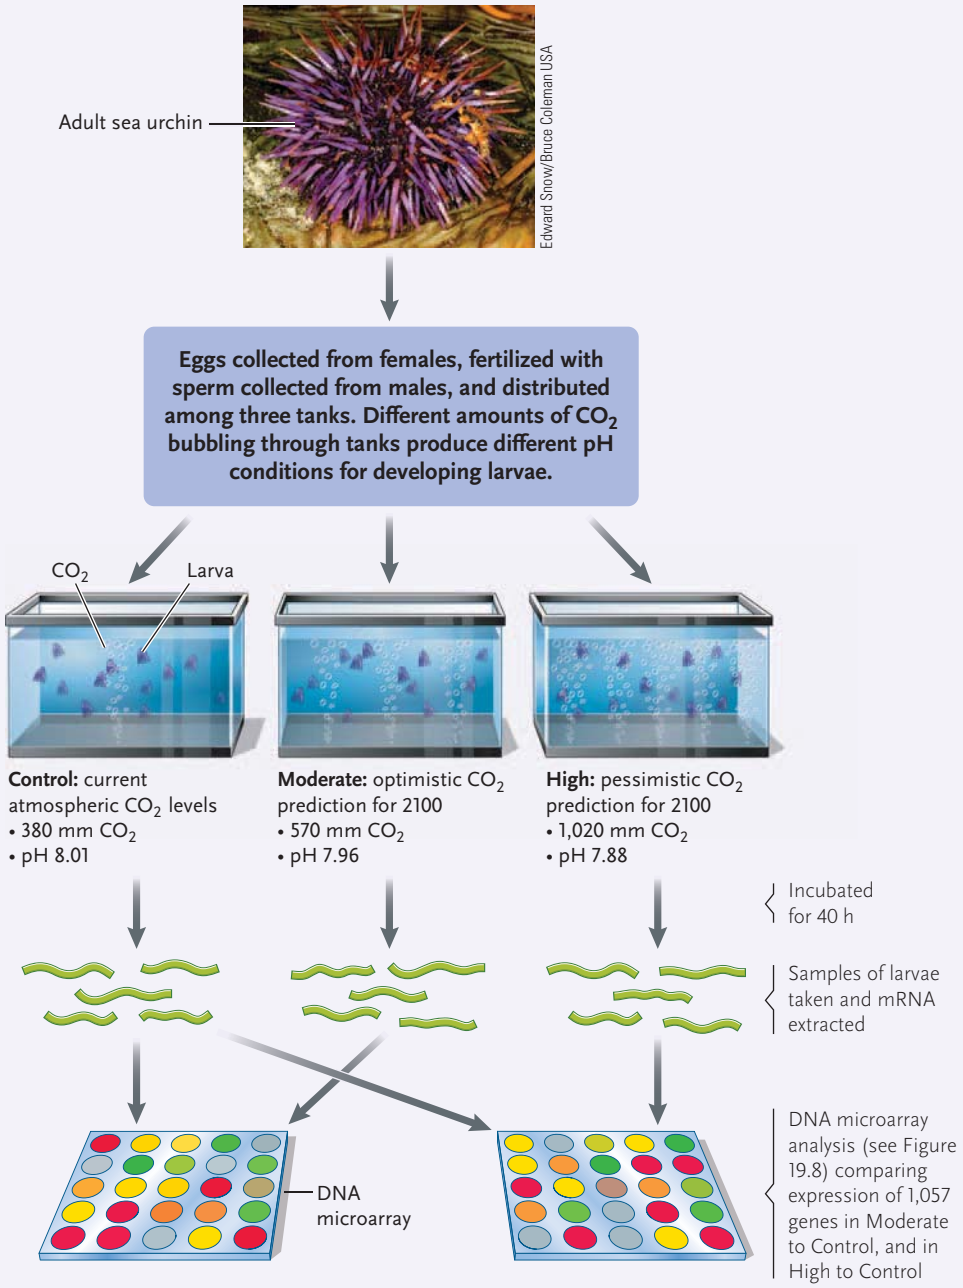
- Moderate CO_2—83 of the 1,057 genes analyzed showed statistically significant decreases in expression; no genes showed increases in expression. Approximately half the genes with decreased expression are involved in biomineralization (that is, the biological process of building a mineralized skeleton), the cellular stress response, and energy metabolism.
- High CO_2—178 genes showed statistically significant changes in expression, with 160 of them showing decreases and 18 showing increases. Approximately 70% of the genes showing decreased expression are involved in apoptosis (programmed cell death), the cellular stress response, and energy metabolism.
- The transcriptomic responses to moderate and high CO_2 conditions were largely distinct, with only 10 genes showing altered expression under both treatments.

Conclusion

This transcriptomics study demonstrated that acidification affects the expression of numerous genes, many of which are involved in four major cellular processes: biomineralization, cellular stress response, metabolism, and apoptosis. Although one might have expected that various genes would be turned on to cope with the environmental stress, ocean acidification mostly decreased gene expression. Importantly, the study showed that pathways other than calcification, a process previously shown to be affected at the physiological level by pH changes, are altered by acidification. This result suggests that scientists must consider a wide range of physiological processes when assessing the possible effects of future ocean acidification on marine organisms.

THINK LIKE A SCIENTIST Assuming that increasing concentrations of atmospheric carbon dioxide produce only a moderate decrease in the acidity of ocean waters, what effect will that change be likely to have on sea urchins?

Source: A. Todgham and G. E. Hofmann. 2009. Transcriptomic response of sea urchin larvae *Strongylocentrotus purpuratus* to CO2-driven seawater acidification. *The Journal of Experimental Biology* 212:2579–2594.



will it stop the trend toward global warming. Many scientists agree that in addition to reducing our emissions of greenhouse gases as soon as possible, we must increase reforestation efforts because large tracts of forest can withdraw significant amounts of CO_2 from the atmosphere. We might also step up agricultural research to develop heat-resistant and drought-resistant crop plants, which may provide crucial food reserves in regions that will be subject to the most drastic climate change.

Human Activities Have Altered the Nitrogen Cycle

Human activities are also disrupting the nitrogen cycle, primarily through the use of nitrogen-containing fertilizers, the farming and processing of livestock, and the combustion of fossil fuels.

Of all nutrients required for primary production, nitrogen is often the least abundant. By definition, agriculture de-

pletes soil nitrogen by removing nitrogen-containing plants from fields. Irrigation also fosters soil erosion and leaching, which remove even more. Traditionally, farmers rotated their crops, alternately cultivating nitrogen-fixing legumes and other types of plants in the same fields. In combination with other soil-conservation practices, crop rotation stabilized soils and kept them productive, sometimes for thousands of years.

In traditional agriculture, nearly all the nitrogen in living systems was made available by nitrogen-fixing microorganisms. Today, however, industrialized agriculture relies on the application of synthetic nitrogen-containing fertilizers. The production of synthetic fertilizers is expensive, and it uses fossil fuels both as a raw material and as an energy source; thus, fertilizer becomes increasingly costly as supplies of fossil fuels dwindle. Furthermore, rain and runoff leach excess fertilizer

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

from agricultural fields and carry it into aquatic ecosystems. Like the phosphorus in Lake Erie, nitrogen has become a major pollutant of freshwater ecosystems, artificially enriching the waters and allowing producers to expand their populations (see Section 51.5).

Human activities also add an enormous volume of nitrogen compounds to the atmosphere. For example, large-scale livestock production leaves behind mountains of organic wastes, which, through the action of the anaerobic microorganisms that decompose it, releases nitrous oxide (NO_2), a greenhouse gas. Moreover, whenever we burn fossil fuels at high temperatures in combustion engines, molecular nitrogen (N_2), which is abundant in the atmosphere, combines with molecular oxygen (O_2) to form nitric oxide (NO). This molecule readily converts to nitrogen dioxide gas (NO_2) or nitric acid vapors (HNO_3), which are major components of smog and acid rain.

According to the Millennium Ecosystem Assessment, a report published in March 2005 with the support of the United Nations, human activities more than doubled the amount of nitrogen released from land into other nitrogen reservoirs in the second half of the twentieth century. The report projects that the amount will double again over the next 50 years. These transfers of material contribute significantly to the pollution of aquatic ecosystems, acid rain, and global climate change.

STUDY BREAK 54.4

1. What is the greenhouse effect, and how does an increase in atmospheric CO_2 concentration affect it?
2. What human activities release the most CO_2 into the atmosphere?
3. What agricultural practices contribute to the disruption of the nitrogen cycle?

THINK OUTSIDE THE BOOK

Examine the ingredients listed on the labels of three cleaning products that you use in your household or residence hall. Search the Internet or sources in your library for information about how the disposal of these compounds on land or in sewage might contribute to the disruption of a biogeochemical cycle.

UNANSWERED QUESTIONS

How does the carbon cycle of a forest respond to climate change and urbanization?

As you've read in this chapter, human influences on the environment can have dramatic unforeseen consequences for ecosystems, altering energy flow and nutrient cycling. Given the complexity of ecosystems—the myriad scales of influence and multiple interactions among the organisms, the physical environment, and climate change variables—the precise response of an ecosystem is difficult to predict, even with advanced ecosystem models. We do know with certainty, however, that the carbon, nitrogen, and water cycles of forested ecosystems in the northeastern United States are changing, and they are likely to continue to do so.

Carbon cycle research in forested ecosystems often entails building an ecosystem model from quantitative data on the various pools and fluxes of carbon in the ecosystem and how these change with time. Scientists then correlate these changes with the environmental conditions and derive a mechanistic understanding that they can use to make predictions about how the ecosystem will respond to future changes. In theory, *gross primary productivity* (GPP) should be predictable from a basic understanding of photosynthesis and a general description of the ambient environmental conditions. In practice, however, the complexity of canopy architecture and leaf positioning, the timing of recurring natural phenomena, and the effects of herbivory and leaf losses from abiotic factors all make accurate predictions more difficult. Furthermore, the problem is dynamic because age-related changes in stand structure, disturbance, invasion, drought, seasonality, and pests or pathogens all add spatial and temporal complexities. Scientists should be able to predict *net primary productivity* (NPP), a key parameter used by ecologists to classify the world's ecosystems, from measurements of the cellular respiration and the relative abundances of representative organisms from the ecosystem.

Quantifying GPP and NPP on a large spatial scale can be challenging, and discovering the underlying mechanisms that control ecosystem responses to changes in environmental conditions is difficult. For example, studies at Black Rock Forest, a deciduous-oak-dominated forest in New York State, revealed that temporal heterogeneity (seasonal variation in leaf and stem respiration) and spatial heterogeneity (variations in canopy and hill-slope position) are important factors that must be included in models of canopy respiration. Nevertheless, some simplifications may be possible. For example, although the basal rate of respiration is quite variable and subject to acclimation, it may be predictable from basic plant properties such as their nitrogen concentrations. Furthermore, the temperature coefficient of respiration is relatively constant, greatly simplifying the construction of an ecosystem model. To consider the impact of tree respiration on ecosystem form and function fully, my research team experimented with models that explicitly consider physiological linkages between photosynthesis and respiration, as mediated by leaf carbohydrate pools. We found that when we included direct linkages to carbon gain in the analysis, the model correctly predicted a large (23%) decrease in the estimated nighttime canopy respiration during the growing season. This result emphasizes the need for a process-based modeling approach when estimating forest productivity.

Our research at Black Rock Forest has also demonstrated that human activities in New York City (60 miles to the south) may be influencing tree growth in both urban and rural areas, with significant changes in seedling size, biomass allocation, herbivory, stomatal densities, nutrient concentrations, efficiency of water use, and rates of key physiological processes such as photosynthesis and respiration. Urbanization has a clear effect on the land area developed, but current research is showing that human

activities in urban areas also influence forested ecosystems in the surrounding rural areas. Understanding how human activity, climate change, and forest ecosystems interact is crucial if we are to make prudent and sustainable development decisions, preserving the health of the ecosystems and the services they provide.

THINK LIKE A SCIENTIST Through what mechanisms might the presence of a large city influence primary productivity in a forest 60 miles away?

Kevin Griffin

Kevin Griffin is an associate professor at Columbia University's Lamont-Doherty Earth Observatory. His research centers on processes in plant and ecosystem ecology, the goal of which is to increase our understanding of both the role of vegetation in the global carbon cycle and the interactions between the carbon cycle and Earth's climate system. To learn more about Dr. Griffin's research, go to http://www.ldeo.columbia.edu/.

REVIEW KEY CONCEPTS

54.1 Modeling Ecosystem Processes

- Ecosystems include biological communities and the abiotic environmental factors with which they interact (Figure 54.1).
- Interconnected grazing and detrital food webs define the pathways along which energy and nutrients move through the biological components of an ecosystem (Figure 54.2).
- Compartment models describe energy flow and nutrient cycling in ecosystems (Figure 54.3).
- Simulation models are interlocking mathematical equations that define the relationships between populations and between populations and the physical environment. They allow researchers to predict the effects of changes in ecosystem structure and function.

Animation: The role of organisms in an ecosystem

54.2 Energy Flow and Ecosystem Energetics

- Photosynthesis converts only a small portion of the solar energy that reaches Earth into chemical energy.
- An ecosystem's gross primary productivity is the rate at which producers convert solar energy into chemical energy. Producers use some energy for respiration; some is converted to heat; and some remains in the ecosystem as net primary productivity.
- Primary productivity is measured in units of energy captured or biomass produced per unit area per unit time. Net primary productivity indexes the energy available to support heterotrophs. Ecosystems vary in productivity and in their contributions to Earth's total productivity (Figure 54.4, Table 54.1).
- On land, primary productivity is limited by the availability of sunlight, water, and nutrients; temperature; and the amount of photosynthetic tissue present. In marine and aquatic ecosystems, primary productivity is limited when sunlight and nutrients are not available in the same place (Figures 54.5 and 54.6).
- Only a fraction of the energy at any trophic level is converted into biomass at higher trophic levels. As energy passes through a food web, an average of 90% is lost at each transfer between trophic levels, limiting the number of trophic levels that a food web can support (Figure 54.7).
- Ecological pyramids portray the effects of energy losses. For terrestrial ecosystems, pyramids of energy, biomass, and numbers generally have broad bases and narrow tops (Figures 54.8–54.10).
- Feeding by predators can influence primary productivity through a trophic cascade (Figure 54.11).

Animation: Energy flow at Silver Springs

54.3 Nutrient Cycling in Ecosystems

- Earth is a closed system with respect to matter.
- Nutrients circulate in biogeochemical cycles between living organisms and nonliving reservoirs. Some biogeochemical cycles are atmospheric; others are sedimentary.
- Water circulates through the atmosphere, oceans, and terrestrial and freshwater ecosystems in a global hydrologic cycle. Water evaporates from the oceans and land and falls as precipitation. Runoff and streamflow return excess precipitation from the land to the oceans (Figure 54.12).
- The carbon cycles in terrestrial and aquatic ecosystems are linked through an atmospheric pool of CO_2, which primary producers assimilate. Respiration returns carbon to the atmosphere as CO_2. Earth's largest reservoir of carbon is unavailable in sedimentary rock. Other large reservoirs include coal, oil, and peat as well as dissolved bicarbonate and carbonate ions in seawater (Figure 54.13).
- Nitrogen is cycled between living organisms and an atmospheric pool of nitrogen gas. Bacteria and cyanobacteria make nitrogen available to the food web through the processes of nitrogen fixation, ammonification, and nitrification. Denitrification converts nitrogen compounds to molecular nitrogen, which enters the atmosphere (Figure 54.14, Table 54.2).
- Phosphorus undergoes a sedimentary cycle. Weathering and erosion of rock make phosphorus available; it is leached from soil and carried to the ocean. Dissolved phosphates precipitate out of seawater, forming insoluble deposits, which are eventually uplifted by tectonic processes (Figure 54.15).

54.4 Human Disruption of Ecosystem Processes

- Certain gases in the lower atmosphere create a greenhouse effect that traps heat near Earth's surface. Our reliance on the combustion of fossil fuels and wood has increased the atmospheric concentration of CO_2 substantially in recent decades (Figure 54.16), enhancing the greenhouse effect and raising the average surface temperature of the planet. Global warming has already had profound effects on the landscape and biological systems, and these effects are likely to increase for the foreseeable future.
- Human activities—particularly irrigation, the use of synthetic fertilizers, livestock farming, and the use of combustible fuels—have disrupted the nitrogen cycle. The consequences of shifting nitrogen among its natural reservoirs include the pollution of aquatic ecosystems, acid rain, and global climate change.

UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following events would move energy and material from a detrital food web into a grazing food web?
   a. A beetle eats the leaves of a living plant.
   b. An earthworm eats dead leaves on the forest floor.
   c. A robin catches and eats an earthworm.
   d. A falcon eats a robin.
   e. A bacterium decomposes the feces of an earthworm.
2. The total dry weight of plant material in a forest is a measure of the forest's:
   a. gross primary productivity.
   b. net primary productivity.
   c. cellular respiration.
   d. standing crop biomass.
   e. ecological efficiency.
3. Which of the following ecosystems has the highest rate of net primary productivity?
   a. open ocean
   b. temperate deciduous forest
   c. tropical rainforest
   d. desert and thornwoods
   e. cultivated land
4. Endothermic animals exhibit a lower ecological efficiency than ectothermic animals because:
   a. endotherms are less successful hunters than ectotherms.
   b. endotherms eat more plant material than ectotherms.
   c. endotherms are larger than ectotherms.
   d. endotherms produce fewer offspring than ectotherms.
   e. endotherms use more energy to maintain body temperature than ectotherms.
5. The amount of energy available at the highest trophic level in an ecosystem is determined by:
   a. only the gross primary productivity of the ecosystem.
   b. only the net primary productivity of the ecosystem.
   c. the gross primary productivity and the standing crop biomass.
   d. the net primary productivity and the ecological efficiencies of herbivores.
   e. the net primary productivity and the ecological efficiencies at all lower trophic levels.
6. Some freshwater and marine ecosystems exhibit an inverted pyramid of:
   a. biomass.
   b. energy.
   c. numbers.
   d. turnover.
   e. ecological efficiency.
7. Which process moves nutrients from the available organic compartment to the available inorganic compartment?
   a. respiration
   b. erosion
   c. assimilation
   d. sedimentation
   e. photosynthesis
8. Which of the following materials has a sedimentary cycle?
   a. water
   b. oxygen
   c. nitrogen
   d. phosphorus
   e. carbon
9. Which of the following statements is supported by the results of studies at the Hubbard Brook Experimental Forest?
   a. Most of the energy captured by primary producers is lost before it reaches the highest trophic level in an ecosystem.
   b. Deforested watersheds experience significantly less runoff than undisturbed watersheds.
   c. Deforested watersheds lose more calcium and nitrogen in runoff than undisturbed watersheds.
   d. Nutrients generally move through biogeochemical cycles very quickly.
   e. Deforested watersheds generally receive more rainfall than undisturbed watersheds.
10. Nitrogen fixation converts:
    a. atmospheric molecular nitrogen to ammonia.
    b. nitrates to nitrites.
    c. ammonia to molecular nitrogen.
    d. ammonia to nitrates.
    e. nitrites to nitrates.

Discuss the Concepts

1. A lake near your home became overgrown with algae and pondweeds a few months after a new housing development was built nearby. What data would you collect to determine whether the housing development might be responsible for the changes in the lake?
2. Some politicians question whether the recent increase in atmospheric temperature results from our release of greenhouse gases into the atmosphere. They argue that atmospheric temperature has fluctuated widely over Earth's history, and the changing temperature is just part of a historical trend. What information would allow you to refute or confirm their hypothesis? In addition, describe the pros and cons of reducing greenhouse gases as soon as possible versus taking a "wait and see" approach to this question.

3. If you could design the ideal farm animal—one that was grown as food for humans—from scratch, what characteristics would it have?
4. If you were growing a vegetable garden, identify the factors that might affect its primary productivity. How would you increase productivity? Identify some possible consequences of your gardening activities to nearby ecosystems.

Design an Experiment

Design an experiment to test the hypothesis that predators in an aquatic ecosystem regulate the ecosystem's primary productivity. Establish as many experimental ponds as you wish, and imagine stocking them with organisms at different trophic levels. If the hypothesis is correct, describe the results you would expect to record from each of your experimental treatments.

Interpret the Data

Amy Rosemond of Vanderbilt University and two colleagues at the Oak Ridge National Laboratory conducted a study of primary productivity in the algal community of Walker Branch, a stream in eastern Tennessee. In their experiment, they compared the productivity of algae that were eaten by snails (grazed) to the productivity of algae that were protected from herbivores (ungrazed) under three experimental treatments: (1) the addition of nitrogen to the stream; (2) the addition of phosphorus to the stream; and (3) the addition of both nitrogen and phosphorus to the stream. They compared the results of these treatments to control treatments of both grazed and ungrazed algae that received no nutrient enrichment. How would you interpret their results, presented in the accompanying graph? Was algal productivity controlled by the presence of herbivores, the addition of nutrients, or a combination of the two factors?

Apply Evolutionary Thinking

The dramatic loss of energy as it is transferred upward through a food web produces pyramids of energy, biomass, and numbers that are very narrow at the top. Which agent of evolution (Section 21.3) would you expect to influence allele frequencies in the relatively small populations that are typical of top predators? What are the long-term *evolutionary* effects of small population size?

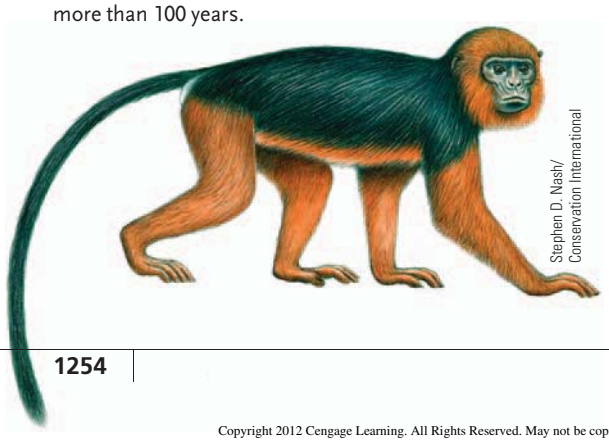
Biodiversity and Conservation Biology



Why it matters . . . Someone seems to have disappeared. Investigators thoroughly checked the missing subject's known haunts, but found no trace. They questioned others in the neighborhood, but came up with few leads. The subject was last seen alive in 1978. With so cold a trail to follow, investigators reluctantly marked the case file "Missing and Presumed Extinct."

The subject in this case was Miss Waldron's red colobus monkey, *Procolobus badius waldroni* **(Figure 55.1).** Named for a traveling companion of the taxonomist who first described it in 1933, this distinctively colored subspecies lived in large and noisy social groups in a remote forest on the border between Ivory Coast and Ghana in West Africa.

John Oates of the City University of New York led a research team that tried to locate Miss Waldron's red colobus. They used every imaginable method, including visual and auditory censuses, searching for scat ("dung") in natural habitats, interviewing local people, and looking in marketplaces where monkey meat is commonly traded. In 2000, more than 20 years after the last confirmed sighting, the researchers concluded that this monkey is probably extinct. A later search by a member of the team, William S. McGraw of Ohio State University, found the skin of one monkey that a hunter had shot six months before. But McGraw searched in vain for a living monkey, and he concluded that even if a few are still alive, the population is so small that continued hunting will surely eliminate it.

Procolobus badius waldroni may be the first primate subspecies to become extinct in more than 100 years—and only the second in the last 500 years. Monkeys and other primates are among the most closely monitored and protected species on Earth. Nonetheless, Oates and his colleagues concluded, these monkeys probably became extinct because they were hunted

FIGURE 55.1 Miss Waldron's red colobus. *Procolobus badius waldroni,* which weighed about 10 kg, may be the first primate subspecies to become extinct in more than 100 years.

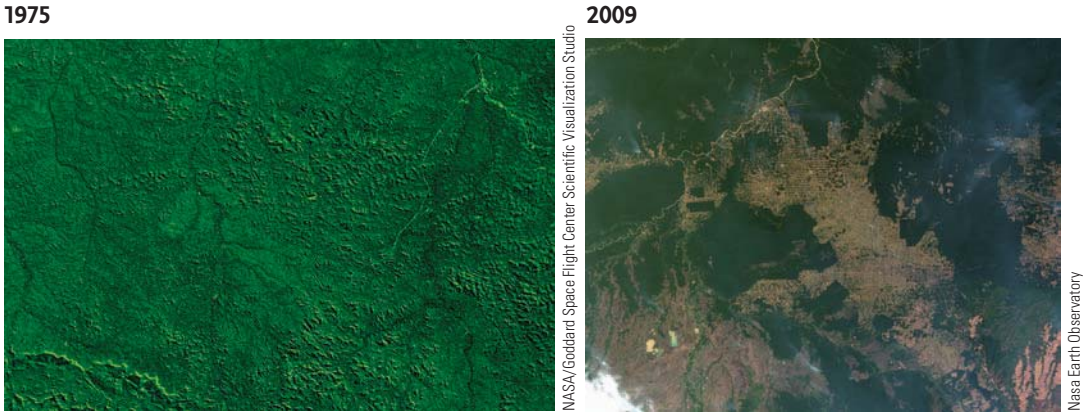

FIGURE 55.2 Deforestation in the Amazon Basin. Satellite photos of Rondonia, in the Brazilian Amazon, show how much of the forest was cut (light green) between 1975 and 2009. Each photo illustrates an area approximately 60 by 85 km.

locally for food by a growing human population and because humans have destroyed their natural habitats.

Miss Waldron's red colobus is just one of many species driven to extinction every year. Current threats to biodiversity—all of which ultimately result from our disruption of natural populations, communities, and ecosystems—are massive. The likely loss of this monkey should warn us that many taxa are at risk, even those that are most rigorously protected.

When ecologists speak of **biodiversity,** they are referring to the richness of living systems. At the most fundamental level of biological organization, biodiversity encompasses the *genetic variation* that is raw material for adaptation, speciation, and evolutionary diversification (see Chapters 21 and 22). At a higher level of organization, biodiversity includes *species richness* within communities (see Section 53.3). The number and variety of species within a community influence its overall characteristics, population interactions, and trophic structure. Finally, biodiversity exists at the *ecosystem level.* Complex networks of interactions bind species in an ecosystem together, and because different ecosystems interact within the biosphere, damage to one ecosystem can reverberate through others.

In this chapter we first describe how human activities threaten biodiversity and reflect on why we should protect it. We then consider theoretical and practical approaches to conservation biology, the scientific discipline that focuses on preserving Earth's biological resources.

55.1 The Biodiversity Crisis on Land, in the Sea, and in River Systems

Biodiversity is declining dramatically, perhaps faster than ever before in Earth's history. In this section, we describe the three broadest threats to biodiversity: the clearing of forests; the commercial overexploitation of marine fish populations; and hydrologic alterations of freshwater ecosystems. Bear in mind that these and other challenges are exacerbated by global climate change, which we have discussed in previous chapters.

Deforestation Disrupts the Carbon Cycle and May Lead to Desertification

Forests are among the habitats that humans most frequently clear and convert. According to the United Nations Forest Resources Assessment released in 2010, global deforestation occurs at a rate of 5.6 million hectares per year, or 15,000 hectares per day. In other words, an area of forest equivalent to 27,000 football fields is cleared of all trees every day.

Deforestation does not occur uniformly across the globe. Today, more than 90% of deforestation occurs in tropical regions, where many groups of organisms exhibit their highest diversity (described in Section 53.7). Forests are most often cut to clear land for grazing livestock; as a result, a few species of domesticated animals and the grasses they consume replace what had been a species-rich community. Brazil has experienced the most extensive recent damage, accounting for 25% of all deforestation during the late twentieth century **(Figure 55.2).** This assessment is particularly troubling because Brazil contains approximately 27% of the planet's total aboveground woody biomass.

Compounding the direct environmental damage, most tropical forests are burned as they are cleared, a process that adds CO_2 to the atmosphere, enhancing the greenhouse effect and increasing the rate of global warming (see Section 54.4). According to the Intergovernmental Panel on Climate Change, a Nobel Prize–winning agency of the United Nations, forest cutting contributes nearly 20% of all greenhouse gases released into the atmosphere. Ironically, intact forests remove substantial quantities of carbon dioxide from the atmosphere, a capacity that is diminished with every tree felled.

Once a forest is cut, heavy grazing or farming drains nutrients from the soil. To remain productive, even the best agricultural or grazing lands require either the application of fertilizers or long periods during which the land lies fallow, allowing plants to replenish the soil naturally. Unfortunately, the soil where tropical forests grow is often of marginal value (for reasons described in Chapter 51), and it is rapidly degraded; it becomes hard, even more nutrient-poor, unable to retain water, and likely to wash away.

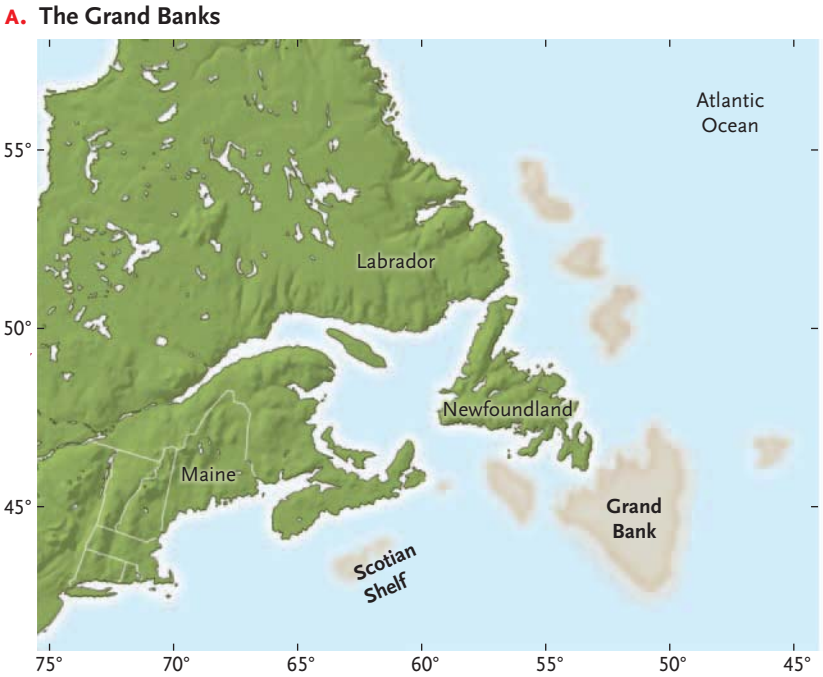
© Penny Tweedie/Alamy

When large tracts of subtropical forest are cleared and overused, the land often undergoes **desertification:** the groundwater table recedes to deeper levels; less surface water is available for plants; soil accumulates high concentrations of salts (a process called *salinization*); and topsoil is eroded by wind and water. In other words, the habitat is converted to desert.

Desertification speeds the loss of biodiversity locally, sometimes eliminating entire ecosystems. For example, desertification has decimated habitats in the Sahel region of Africa, just south of the Sahara **(Figure 55.3).** Excessive grazing of cattle and goats by an ever-expanding human population is the main reason for the Sahara's southward expansion at a rate of 5.5 to 8 km per year. Because the sand dunes of the expanding desert shift constantly, agriculture and grazing are nearly impossible, resulting in frequent famines among the inhabitants.

Desertification and salinization have also begun in the Everglades, a unique, shallow "river of grass" that covers much of southern Florida. The amount of fresh water flowing through South Florida to the Everglades has decreased approximately 70% since 1948, when an extensive network of canals and levees was built to reduce flooding. The rapidly growing human population in South Florida contributes directly to desertification, as groundwater is tapped for domestic use and to irrigate lawns, golf courses, and agricultural fields. Salt water from the Gulf of Mexico now intrudes into the water table, causing salinization of the soil. The Comprehensive Everglades Restoration Plan (CERP), approved by the U.S. Congress in 2000, seeks to restore the natural flow of the Everglades by 2030. This project may halt or reverse the desertification process.

Sadly, deforestation, desertification, and global warming reinforce each other in a positive feedback cycle. If scientists' projections are correct, desertification will lead to an increase in the average global temperature, speeding evaporation and the retreat of forests, which, in turn, will increase rates of desertification. If deforestation and desertification continue, we will soon lose a large proportion of Earth's forests and face a decrease in the area of habitable land.



Overexploitation Can Drive Species to Extinction

Many local extinctions result from **overexploitation,** the excessive harvesting of an animal or plant species. At a minimum, overexploitation leads to declining population sizes in the harvested species. In the most extreme cases, a species may be wiped out completely. Moreover, overexploitation can foster evolutionary changes in the exploited population, much the way guppies respond to natural predators in the streams of Trinidad (described in *Focus on Basic Research* in Chapter 52).

Humans have overexploited populations in every habitat we occupy. Today, overexploitation severely threatens marine ecosystems, the only environment from which we routinely harvest predators (such as tuna) as food. The fishery on the Grand Banks off the coast of Newfoundland, Canada, provides a sad example **(Figure 55.4).** For hundreds of years, fishermen used traditional line and small-net fishing to harvest a large but sustainable catch. During the twentieth century, however, new technology allowed them to locate and exploit schools of fishes more efficiently. As a result, roughly half the fish species harvested there are now overfished. Haddock *(Melanogrammus aeglefinus)* and yellowtail flounder *(Limanda ferruginea)* have been essentially eliminated from the Grand Banks; their populations will probably never recover. And because fishers preferentially harvest the oldest and largest individuals, which fetch a higher market price, Atlantic cod *(Gadus morhua)* now mature at a younger age (three years compared with five or six years) and smaller size.

As a consequence of overfishing, the average yield of the Grand Banks has declined to less than 10% of the highest historic levels. In the mid-1960s, Atlantic cod yielded a minimum of 350,000 tons per year. By the mid-1970s, the catch dropped to 50,000 tons per year. The Canadian government finally closed the fishery in 1993, after the cod catch fell below 20,000 tons for several consecutive years. But the damage had already been done: the most heavily exploited species are less marketable because of their smaller size, fish populations have decreased to dangerously low levels, and the fishing industry is

itself imperiled. This sequence of events has been replicated in fisheries around the world. Indeed, Ransom A. Myers and Boris Worm of Dalhousie University in Nova Scotia estimated that by 2003 modern fishing techniques had reduced the biomass of large predatory fishes by about 90% in marine ecosystems.

Hydrologic Alterations Endanger Freshwater and Wetland Ecosystems

Rivers have always played a key role in the development of human settlements because they provide a source of fresh water, a place to discard wastes, and a means to transport goods. Since ancient times, humans have also dammed rivers to capture reliable supplies of fresh water. When the human population—and the dams they built—were small, these **hydrologic alterations** (that is, changes to the pathways through which water moves in the hydrologic cycle) had primarily local effects. More recently, we have constructed massive dams that capture vast quantities of fresh water in reservoirs **(Figure 55.5).** We distribute water from these reservoirs for agricultural, industrial, and domestic uses. The dams also generate hydroelectric power and allow us to control water flow to mitigate flooding of low-lying land. Today, the large scale and ubiquity of these hydrologic alterations have made freshwater ecosystems among the most endangered on Earth.

The damming of rivers and the diversion of their flow wreaks havoc on many interconnected ecosystems. As you learned in Section 51.5, the physical characteristics of rivers change predictably from the head-waters of streams to the estuaries where they empty into the sea. River-dwelling organisms are adapted to specific physical conditions—such as temperature, depth, and flow rate—that are characteristic of each section of the river system. And downstream, the flow of water supports distinct communities of organisms, each adapted to the different environments in floodplains, wetlands, and estuaries.

In 2002, Stuart E. Bunn and Angela H. Arthington of Griffith University in Australia identified four ways in which hydrologic alterations threaten freshwater biodiversity. First, the flow rate and volume of rivers are key determinants of their

NASA NASA

FIGURE 55.5 Three Gorges Dam. In 2008, China completed the Three Gorges Dam, the world's largest hydroelectric dam, across the Yangtze River in Hubei Province. The dam is 2,300 m long and 185 m high. The reservoir behind it measures 660 km by 1.1 km and holds 39.3 km^3 of water. More than 1.25 million people had to be relocated from areas inundated by the reservoir.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

physical habitats, which have a major impact on the organisms that live there. For example, before it was dammed, the River Otra in Norway experienced low winter water flows, but raging summer floods. These conditions established a regular pattern of disturbance that eliminated many rooted plants from the riverbed. Now dammed, the river has a more regulated flow regime that allows a huge accumulation of plant biomass.

Second, the life histories of aquatic species, which evolved in response to natural flow patterns, are disrupted by changes in river flows. For example, reproduction by many aquatic invertebrates and fishes is triggered by temperature and day-length cues. Because the water released through dams is often drawn from the depths of the reservoirs behind them, it is colder than the natural flow, changing the cues available to organisms. Researchers working in China discovered that the cold water released by dams delayed spawning by as much as 30 days in some fish species.

Third, dams reduce a river system's "connectivity" (that is, the continuity of flow through a river and its streams and tributaries). Reduced connectivity prevents fishes and other animals from migrating freely through a river system. For example, salmon undertake a spawning migration from the sea, swimming upstream into the tributaries and streams where they reproduce. Dams hamper this already difficult upstream journey. In the Pacific Northwest, more than 400 hydroelectric dams on the Columbia River system prevent many salmon from reaching their spawning grounds; they have reduced the breeding habitat for Chinook salmon *(Onchorhynchus tshawytscha)* by 75%. Similar problems have eliminated migratory fish species from rivers throughout the world.

Finally, dams and reservoirs facilitate the introduction and success of nonnative species that thrive in disturbed habitats (discussed further below). For example, several species of large fishes collectively described as "Asian carp" have become established in the Mississippi River and its tributaries. These fishes feed voraciously on plankton. For years ecologists feared that they would spread into the Great Lakes, where they would outcompete native fish species that are the basis of a large fishing industry. In 2002 and 2004, the U.S. Army Corp of Engineers built two electric barriers in a canal that connected a tributary of the river to Lake Michigan, hoping to block the fishes' advance. But in late 2009 and early 2010, scientists detected genetic material from the carp on the far side of the fences. Some politicians have called for the closure of the canal as the only way to prevent the advance of these fishes into Lake Michigan; as of this writing, that proposal is the subject of several lawsuits.

Freshwater ecosystems are now under severe pressure. In the worst cases, human-induced hydrologic alterations have practically eliminated them: the Nile and the Colorado River now rarely discharge much water into the sea. Even in less dramatic cases, the effects of hydrologic alterations on biodiversity have been profound. Freshwater fish species have experienced marked declines in the last few decades. One 2006 estimate suggested that 56% of the freshwater fish species endemic to the Mediterranean region, more than 30% of the native species in North America, and 25% of those found in East Africa are now threatened with extinction. The status of freshwater invertebrates, though not as well documented, is probably comparable. Conservation biologists rank the restoration of natural flow patterns in river systems among their highest priorities.

STUDY BREAK 55.1

1. What factors have increased the likelihood of desertification in southern Florida?
2. What are the consequences of the overexploitation of fish populations?
3. How does the construction of a dam disrupt the lives of river-dwelling organisms?

THINK OUTSIDE THE BOOK

Search the Internet for updates about the spread of Asian carp in North America. What is the federal government doing to prevent their spread? Have they successfully invaded the Great Lakes? If so, what impact have they had on the native lake fishes?

55.2 Specific Threats to Biodiversity

Although the clearing of tropical forests, overexploitation of marine fisheries, and damming of rivers endanger entire ecosystems, many other human activities imperil natural populations. In this section, we briefly describe some of these threats.

Habitat Fragmentation Threatens Many Populations

When humans first colonize a pristine habitat, they build roads and then clear isolated areas for specific uses. Although this pattern of development initially affects only local populations, the negative effects spread rapidly to a regional scale. The remaining areas of *intact* habitat are inevitably reduced to small, isolated patches, a phenomenon that ecologists describe as **habitat fragmentation.**

Habitat fragmentation is a threat to biodiversity because small habitat patches can sustain only small populations of organisms. As you learned in Section 52.4, a habitat's *carrying capacity,* the maximum population size that it can support, varies with available resources. Populations that occupy small habitat patches inevitably experience low carrying capacities, a problem that is especially acute for species at the higher trophic levels (see Section 54.2). Furthermore, fragmented habitat patches are often separated by unsuitable habitat that organisms may be unable or unwilling to cross. As a result, individuals from one isolated population are unlikely to migrate into

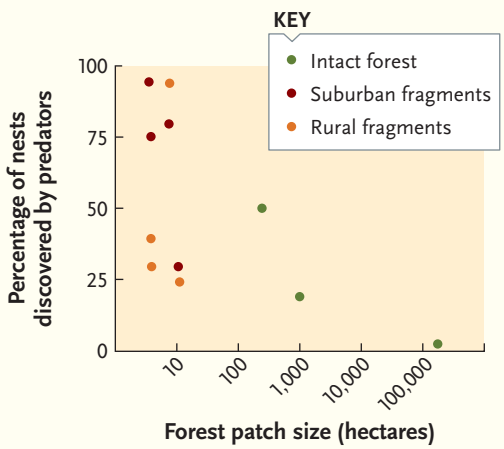

FIGURE 55.6 **Experimental Research**

Predation on Songbird Nests in Forests and Forest Fragments

Question: Are songbird nests in small forest fragments more likely to be found by predators than nests in large forest patches?

Experiment: Wilcove placed between 13 and 50 artificial bird nests, each containing three quail eggs, in three habitat types: large areas of intact forest, rural forest fragments, and suburban forest fragments. He placed about half the nests at each study site on the ground at the base of a tree or shrub and half the nests 1 to 2 m above the ground in a sapling or shrub. He checked the nests after seven days to determine what proportion of the nests had been subjected to predation.

Result: Predators generally found a larger proportion of the artificial bird nests in small forest fragments than they did in large forest patches.

Conclusion: Songbird nests are much more likely to suffer from predation in small forest fragments than they are in large patches of intact forest.

THINK LIKE A SCIENTIST Why do you think that Wilcove placed some nests at ground level and some 1 or 2 m above the ground? What might have happened to nests placed in the canopies of trees?

another, reducing gene flow between them. The combination of small population size and genetic isolation reduces genetic variability and fosters extinction (see Section 21.3).

In addition to reducing the amount of undisturbed habitat, habitat fragmentation jeopardizes the quality of the habitat that remains. Human activities create noise and pollution that spread into nearby areas. The removal of natural vegetation disrupts the local physical environment, exposing the borders of the remaining habitat to additional sunlight, wind, and rainfall. Increased runoff compacts the soil and makes it waterlogged. These phenomena are collectively described as **edge effects.**

The effects of habitat fragmentation are often profound. For example, populations of forest-dwelling, migratory songbirds have declined markedly in eastern North America since the late 1940s, largely because of habitat fragmentation in their North American breeding grounds and in their Caribbean and South American wintering grounds.

In 1994, Scott K. Robinson of the Illinois Natural History Survey and David S. Wilcove of the Environmental Defense Fund identified three factors that decrease populations of migratory songbirds in fragmented breeding habitats. First, small forest patches often lack specific habitat types—such as streams, cool ravines, or dense ground cover—that many songbird species require. Second, songbirds breeding in forest patches are more likely to suffer from brood parasitism (described in the opening of Chapter 53) by brown-headed cowbirds *(Molothrus ater)* than are those breeding in intact forests. Parasitized songbirds rear fewer than half as many young as they might otherwise raise, and their populations decline accordingly.

The third factor that reduces songbird numbers in forest fragments is increased nest predation by blue jays *(Cyanocitta cristata),* American crows *(Corvus brachyrhynchos),* common grackles *(Quiscalus quiscula),* squirrels (genus *Sciurus*), raccoons *(Procyon lotor),* and domestic dogs and cats. These predators, which feed on songbird eggs and young, are now superabundant in rural and suburban areas, and they enter adjacent forest fragments in search of an easy meal. Wilcove tested the predation hypothesis experimentally by placing artificial nests with quail eggs in intact forests and in forest fragments. Although he did not observe predation directly, he found that predators discovered only 2% of the nests in the largest intact forest, but they often found 50% or more of the nests placed in small, suburban forest fragments **(Figure 55.6).**

Many Forms of Pollution Overwhelm Species and Ecosystems

The release of **pollutants**—materials or energy in forms or quantities that organisms do not usually encounter—poses another major threat to biodiversity.

Although chemical pollutants, the by-products or waste products of agriculture and industry, are released locally, many spread in water or air, sometimes on a continental or global scale. Within North America, for example, winds carry airborne pollutants from coal-burning power plants to the Northeast **(Figure 55.7).** Sulfur dioxide (SO_2), which dissolves in water vapor and forms sulfuric acid, falls as **acid precipitation,** acidifying soil and bodies of water. Many lakes in northeastern North America have experienced a precipitous drop in pH from historical readings near 6 to values that are now well below 5—a 10-fold increase in acidity. Although the lakes once harbored lush aquatic vegetation and teemed with fishes, they are now crystal clear and nearly devoid of life.

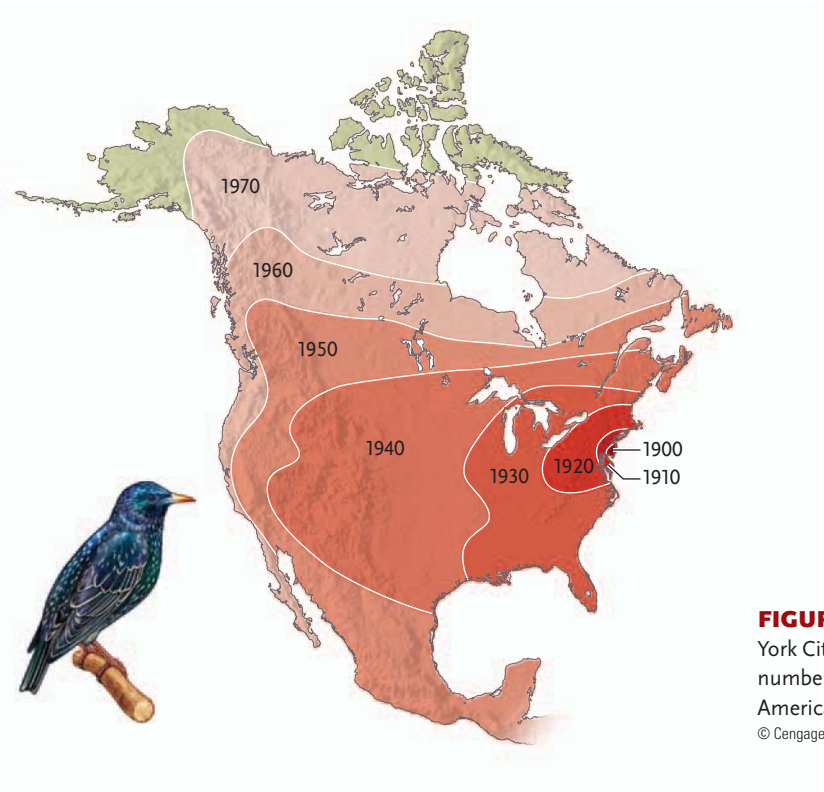
© Cengage Learning 2014

As residents of major cities and industrial areas know all too well, wastes produced by the combustion of fossil fuels in factories and automobile engines cause terrible local pollution, increasing rates of asthma and other respiratory ailments. Some airborne pollutants, notably CO_2, also join the general atmospheric circulation, where they contribute to the greenhouse effect and global warming.

Like air pollution, water pollution originates locally but has a much broader impact. Oil spills, for example, disrupt local ecosystems, killing most organisms near the spill. Because oil floats on water, it spreads rapidly to nearby areas. An explosion and fire on the Deepwater Horizon oil rig in April 2010 allowed more than 200 million gallons of oil to spill into the Gulf of Mexico. The uncapped well continued to spew oil for three months, until it was partially plugged in July 2010. The oil spill had a devastating short-term effect on organisms in the Gulf and adjacent wetlands; scientists are still unable to predict all of its long-term effects on this delicate ecosystem. As of early 2012, the Environmental Protection Agency was planning to implement the first eight projects of an early restoration plan at an estimated cost of nearly $60 million.

Pollution can also have serious effects on terrestrial ecosystems. As a recent disaster in India, Nepal, and Pakistan illustrates, the application of synthetic compounds to agricultural fields or livestock can have dire and far-reaching consequences. For thousands of years, enormous populations of vultures (several *Gyps* species)—estimated at more than 40 million birds—consumed the abandoned carcasses of farm animals across South Asia. In the early 1990s, however, farmers began to administer diclofenac, a new and inexpensive antiinflammatory drug, to injured livestock. Within a few years, vultures began to disappear; in 2006, scientists estimated that their populations had declined by more than 97%. Researchers determined that diclofenac, which causes fatal kidney failure in birds, was responsible for the deaths: vultures were ingesting substantial doses of the drug from the livestock carcasses they ate. All vulture species in South Asia are now on the verge of extinction, and although governments in the region have banned the sale of diclofenac, wildlife experts say that the vulture populations are unlikely to recover soon, if ever.

The decline in vulture populations has had a disastrous impact on urban and rural communities in South Asia. Livestock carcasses are now consumed by growing populations of feral dogs, many of which carry rabies. India has the world's highest human death toll from rabies—30,000 per year—and two-thirds of the cases are caused by dog bites. Populations of rats and flies also appear to be increasing. *Focus on Applied Research* in Chapter 54 describes another example of how pesticides and other chemicals accumulate at lethal concentrations in organisms living at higher trophic levels.



The Introduction of Exotic Species Often Eliminates Native Species

As humans travel from one habitat to another, we inevitably carry other species with us. Seeds cling to our legs, insects accompany us in our food and possessions, and some organisms hitch a ride on boats or cars. The introduction of nonnative organisms, called **exotic species,** into new habitats poses a serious threat to biodiversity.

Exotic species often prey upon, parasitize, or outcompete native species, leading to their extinction. Many have *r*-selected life histories; they mature quickly and reproduce prodigiously, and they thrive in the degraded habitats that humans so frequently create. In the absence of natural checks on population growth—such as competitors, predators, and parasites—exotics often experience exponential population growth (see Section 52.5).

The European starling *(Sturnus vulgaris)* provides an example of the explosive population growth and range expansion of an exotic species. These birds were released in North America in 1890 when a misguided individual, who wanted to introduce all of the bird species mentioned by Shakespeare into North America, imported them into Brooklyn, New York. Within 70 years, they had spread across the continent **(Figure 55.8);** their population size is now estimated at 200 million. Starlings pose a

FIGURE 55.8 Starling range expansion. After being introduced in New York City in 1890, European starlings *(Sturnus vulgaris)* increased their numbers and quickly extended their breeding range westward across North America. They reached the west coast by 1960 and Alaska by 1970.

© Cengage Learning 2014

serious threat to native birds, including several woodpecker species, because they successfully compete with them for nesting sites in natural cavities in trees.

Introduced plants often transform entire ecosystems. One of the best-known examples is kudzu *(Pueraria lobata),* a fast-growing species from Asia. In the early 1900s, it was widely planted in the southeastern United States as a source of animal feed. Later, a government agency planted it to stabilize soils and decrease erosion on deforested hillsides. But when kudzu has access to abundant nutrients and water, it can grow up to 30 cm *per day.* It spread quickly across the South, literally overgrowing almost all native plants **(Figure 55.9).**

© Angelina Lax/Photo Researchers, Inc.

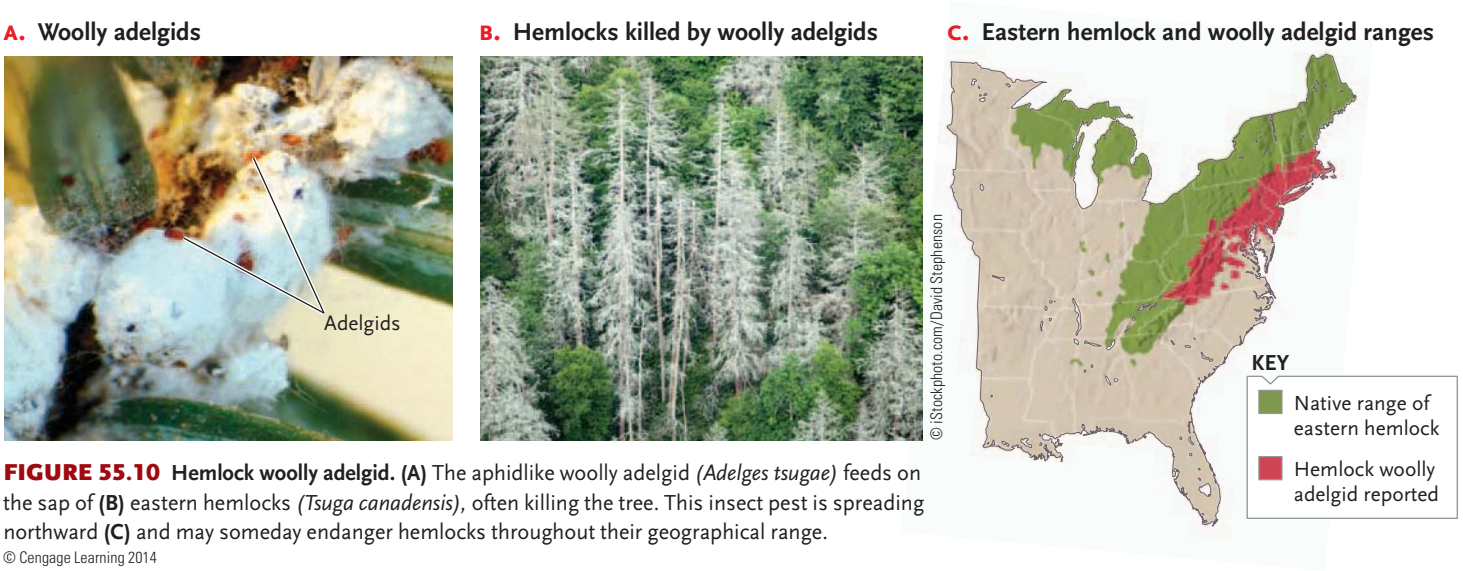

FIGURE 55.9 Kudzu, the vine that ate the South. Kudzu *(Pueraria lobata),* an introduced vine, grows so quickly that it often covers living trees or even abandoned buildings.

Exotic insects often become pests of agricultural crops and native plants. The hemlock woolly adelgid *(Adelges tsugae)* was accidentally introduced into North America from Asia. The adelgid kills eastern hemlocks *(Tsuga canadensis)* by feeding on their sap. It now threatens the trees from North Carolina to Massachusetts **(Figure 55.10).** But adelgids endanger far more than these evergreen trees. Hemlocks buffer the physical conditions below them: hemlock stands are cool in summer and warm in winter, sustaining a unique community of organisms that includes ruffed grouse *(Bonasa umbellus),* turkey *(Meleagris gallopavo),* white-tailed deer *(Odocoileus virginianus),* and snowshoe hare *(Lepus americanus).* Infested stands rarely survive more than a few years, and the communities established under pure stands of eastern hemlock will likely become extinct because of feeding by the adelgid.

The Spread of Disease-Causing Organisms Endangers Many Species

As exotic species become established in new habitats, they may carry disease-causing organisms with them. Because native species had no prior exposure to these pathogenic organisms, they never evolved resistance to them, leading to devastating outbreaks of disease. For example, amphibians have been in a worldwide decline since 1980. At least one-third of the roughly 6,300 described species are now threatened with extinction, and populations of nearly half of all amphibian species are declining in numbers. The sudden change in the status of these animals has sparked an enormous research effort aimed at identifying the primary causal factors. Although habitat destruction and

pollution have undoubtedly taken a great toll, scientists now attribute many recent amphibian declines and extinctions to infection by the chytrid fungus *Batrachochytrium dendrobatidis*. The fungus has been found in natural populations of more than 200 amphibian species, including frogs, salamanders and caecelians; more than 1,000 other species have been identified as susceptible to it **(Figure 55.11).**

This pathogenic fungus was first described in 1999 by researchers investigating skin infections in amphibians from North America, Central America, and Australia. Scientists have since learned that the fungus is very strange indeed: it is the only species in its group known to infect vertebrates; it infects only amphibians, feeding on keratin in their skin and in the mouthparts of their tadpoles; and even though it has an aquatic life cycle, it can infect fully terrestrial amphibians that never enter standing water. Researchers believe that the fungus interferes with amphibians' osmoregulation, an important physiological process that is partly mediated by their skin. We still do not know how the fungus spreads among individuals or populations. It may be carried from place to place by amphibians and other vertebrates.

JOEL SARTORE/National Geographic Stock

FIGURE 55.11 **Chytrid fungus infection.** These mountain yellow-legged frogs *(Rana muscosa)* from King's Canyon National Park in the southern Sierra Nevada of California succumbed to chytrid fungus infection.

Where did the pathogen originate? In 2004, researchers found the infection in specimens of African clawed frogs *(Xenopus laevis)* that had been collected in 1938 and preserved in South African museums. Other researchers have found evidence of the infection in a Canadian population of bullfrogs *(Rana clamitans)* collected in 1961. Thus, scientists hypothesize that the infection originated in southern Africa and was confined there for decades. How did it spread so rapidly to other continents? Beginning in the 1930s, African clawed frogs were exported from South Africa to many countries for use in biological research and for the pet trade. Sadly, the frog's popularity among scientists and hobbyists has resulted in the spread of an infection likely to cause the extinction of many other amphibian species.

Why did the fungus start to devastate amphibian populations only in the 1980s? Some researchers suggest that even small increases in temperature and related changes in cloud cover and humidity—all the result of global climate warming—have favored the growth of the pathogenic fungus in some habitats with high amphibian diversity. Other researchers argue that climate warming and pollution stress amphibian populations, making them more susceptible to infection by many pathogens.

Biologists are working feverishly to learn more about the fungus and its role in amphibian declines before a majority of amphibian species become extinct. In a broader—and even more frightening—context, ecologists who study the dynamics of disease in natural population are just beginning to grapple with the likely effects of climate change and other consequences of human activity on the spread and success of pathogenic organisms, including those that infect humans.

Human Activities Are Causing a Dramatic Increase in Extinction Rates

As you may remember from Section 23.4, extinction has been common in the history of life; roughly 10% of the species alive at any time in the past became extinct within 1 million years.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).

These *background extinction rates* eliminated perhaps seven or eight species per year. Paleobiologists have also documented at least five *mass extinctions,* during which extinction rates increased greatly above the background rate for short periods of geological time (see Figure 23.15).

At present, Earth appears to be experiencing the greatest mass extinction of all time. According to Edward O. Wilson of Harvard University, extinction rates today may be 1,000 times the historical background rate, meaning that thousands of species are being driven to extinction each year. The vast majority of extinctions are a direct result of the destructive human activities discussed previously.

If humans are causing the current mass extinction, why didn't it begin long ago? The answer lies in our increased rate of population growth (see Section 52.6). During the nineteenth and twentieth centuries, improvements in food production, sanitation, and health care increased human life expectancy. Our ever-increasing population consumes resources and produces wastes at an escalating rate. And until we change the way we live in relation to the environment that we share with all other species, our negative impact will grow along with our global population.

Search the Internet for updated information about the effects of the Deepwater Horizon oil spill in the Gulf of Mexico. Has the ecological impact of the spill become more evident over time?

55.3 The Value of Biodiversity

Given the many ways in which human activities are causing the dramatic decline in biodiversity, we should reflect on the present and future value of what we are destroying and contemplate why we might want to preserve it. Arguments for conserving biodiversity fall into three general groups: its direct benefit to humans, its indirect benefit to all living systems, and its intrinsic worth.

Biodiversity Benefits Humans Directly

Scientists constantly search for natural products that might provide humans with better food, clothing, or medicine. The development of a new medicine often begins when a scientist analyzes a traditional folk remedy or screens naturally occurring compounds for curative properties. Chemists then isolate and purify the active ingredient and devise a way to synthesize it in the laboratory. More than half of the 150 most commonly prescribed drugs were developed from natural products in this manner.

For example, *Taxol,* a drug treatment for breast and ovarian cancer, was isolated from the narrow strip of vascular cambium beneath the bark of the Pacific yew tree, *Taxus brevifolia* **(Figure 55.12).** Unfortunately, a fully grown, 100-year-old tree produces only a tiny amount of Taxol, and six trees must be destroyed to extract enough to treat one patient. Pacific yew trees are not abundant, and they grow slowly. Harvesting them for Taxol extraction could quickly lead to their extinction—and an end to the natural source of this life-saving compound. However, after much research, scientists now synthesize this widely used drug in the laboratory.

Wild plants and animals also serve as sources of genetic traits that may improve agricultural crops and domesticated livestock. For example, corn *(Zea mays)* is an annual plant. Its cultivation requires yearly planting, a laborious activity that leads to the erosion of topsoil. Farmers would rather grow a perennial strain of corn, one that would produce grain for years after a single planting. In 1978, botanists discovered teosinte *(Zea diploperennis)* a perennial plant closely related to corn, in the mountains of western Mexico. Researchers crossed the two species, producing a perennial corn. If they can increase the yield of this hybrid, it may prove to be an economically valuable crop.

Today, many agricultural researchers use genetic engineering, the transfer of selected genes from one species into another (see Section 18.2), to alter crop plants more precisely than they can using hybridization. The transferred genes may be chosen to increase resistance to pests or environmental stress, promote faster growth, or increase shelf life after harvesting. However, many scientists and environmentalists fear that genetically modified crops may create environmental hazards that will inadvertently endanger biodiversity. For example, a genetically modified plant or animal that escaped into a natural habitat might compete with naturally occurring species. Or a genetically modified plant might poison harmless animals as well as insect pests.

Ecosystem Services Benefit All Forms of Life

Humans and other species derive indirect benefits when ecosystems perform the ecological processes on which all life depends. These **ecosystem services,** as they are called, include the decomposition of wastes, nutrient recycling, oxygen production, maintenance of fertile topsoil, and air and water purification.

Some ecosystem services can even mitigate environmental damage caused by humans. As you may recall from Section 54.4, the combustion of fossil fuels produces CO_2 and other waste products that accumulate in the atmosphere, increasing the greenhouse effect and fostering global warming. Photosynthetic organisms use CO_2 for essential metabolic processes; thus, the forests that we clear and, even more importantly, communities of marine phytoplankton, withdraw CO_2 from the atmosphere and incorporate it into living organisms (see Figure 54.13), in a phenomenon called *carbon sequestration*. Recent research indicates that these organisms are essential for limiting the damage caused by the burning of fossil fuels. In the long run, biodiversity's indirect benefits, provided in the form of ecosystem services, may be even more valuable to humans than the direct benefits.

Biodiversity Has Intrinsic Worth beyond Its Utility to Humans

Some ethicists argue that we should preserve biodiversity because it has intrinsic worth, independent of its direct or indirect value to humans. They note that humans are just one species among millions in the remarkable network of life. Countering this position is the view that our immediate needs should always rank above those of other species and that we should use them to maximize our own welfare. The latter view inevitably leads to the disruption of natural environments and the loss of biodiversity. Framed in this way, the debate lies more within the realms of philosophy and public policy than biology. Nevertheless, many people feel an emotional or spiritual connection to natural landscapes and the plants and animals they harbor. Thus, biodiversity enhances human existence in intangible ways.

STUDY BREAK 55.3

1. How does biodiversity serve as a storehouse of genetic information that is potentially useful to humans?
2. What ecosystem services do naturally occurring organisms provide to humans?

55.4 Where Biodiversity Is Most Threatened

To slow the current rate of extinction and loss of biodiversity, conservation biologists must first identify where species are likely to become extinct.

Conservation Biologists Identified Biodiversity Hotspots

If we are to limit the effects of human activities and preserve biodiversity, we must know how biodiversity is distributed. Although species richness within communities generally increases from the poles to the tropics (see Section 53.7), broad latitudinal surveys do not provide enough detail to be useful in this effort.

In a survey published in 2000, Norman Myers of Oxford University and his colleagues in England and the United States pinpointed 25 **biodiversity hotspots,** areas where biodiversity is both concentrated and endangered by human encroachment. To qualify as a biodiversity hotspot under Myers' criteria, an area must harbor at least 1,500 endemic plant species (those that are found nowhere else), and it must have already lost at least 70% of its natural vegetation. As human activity in natural habitats has increased, the number of recognized terrestrial biodiversity hotspots has now grown to 34, although some workers identify more than 60.

Myers used the number of endemic species as a criterion for identifying hotspots because endemics tend to have highly specific habitat or dietary requirements, low dispersal ability, and restricted geographical distributions. Indeed, locally distributed species account for much of Earth's biodiversity; and if the local habitats where these species occur are at risk of development, the species are also at risk. Although the 25 original hotspots occupy only 1.4% of Earth's land surface, they include the only remaining habitat for approximately 45% of all terrestrial plant species and 35% of all terrestrial vertebrate species.

Researchers Now Pinpoint Sites Where Extinctions Are Imminent

The identification of biodiversity hotspots tells us where biodiversity is both concentrated and threatened, but most of these areas are large and heavily populated. Conservation biologists need more detailed information to identify specific localities where their efforts will have the greatest impact.

Building on Myers' pioneering study, a team of 30 collaborators in the United States, Australia, and the United Kingdom,

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

pinpointed sites where extinctions are imminent. In a paper published in 2005, they identified 595 locations in tropical forests, on islands, or in mountainous regions where 794 *trigger species*—highly endangered species of mammals, birds, reptiles, amphibians, and coniferous trees—are each confined to a single site **(Figure 55.13).** As defined by the Endangered Species Act, adopted by the U.S. Congress in 1973, an **endangered species** is one that is "in danger of extinction throughout all or a significant portion of its range."

The researchers used strict criteria for including a site in the list. First, it must harbor at least one species that has been officially designated as endangered by the World Conservation Union, an international organization. Second, it must contain at least 95% of the world population of that species. Third, it must have clearly definable boundaries within which habitats are distinct from those outside the boundary; examples of such bounded habitats include lakes, mountaintops, and forest fragments. The boundaries of the site thus define the area to be conserved. Although the 595 sites of imminent extinction are included within the biodiversity hotspots that Myers identified, the new approach has the practical advantage of pinpointing localized sites where conservation biologists can focus their efforts.

The research team also noted that 794 trigger species are in danger of imminent extinction, compared with 245 species from the same taxonomic groups that are known to have become extinct in the last 500 years. Thus, the rate of extinction in these groups of organisms is accelerating rapidly. Their analysis also reveals that the proportion of extinctions in mainland habitats (as opposed to islands) is also growing: only 20% of historical extinctions occurred in low-lying mainland areas, whereas more than 60% of trigger species live on the mainland today. Moreover, their study detected a taxonomic shift in extinction: 53% of historical extinctions were of bird species, but 51% of the trigger species are amphibians. Finally, the data reveal a geographic shift in extinctions: whereas only 21% of historical extinctions were in the New World tropics, 50% of the trigger species live in Central America, South America, and on Caribbean islands. These results indicate that species living in the New World tropics, especially in wet forests, are in the greatest danger.

The data from the new analysis allow conservation biologists to target their efforts, but the task is daunting. Although one-third of the 595 sites lie completely within protected areas, more than 40% lack any protection at all. Most of the sites are small (median size approximately 12,000 hectares), suggesting that they might be easy to protect, but small sites are also the most vulnerable to human encroachment. Adding to the difficulty, the human population density in areas surrounding the sites is nearly triple the average density worldwide. Nevertheless, conservation biologists are optimistic that this new approach to pinpointing the areas most in need of their attention will allow them to develop appropriate strategies for preventing the extinction of the trigger species and others that live within these areas.

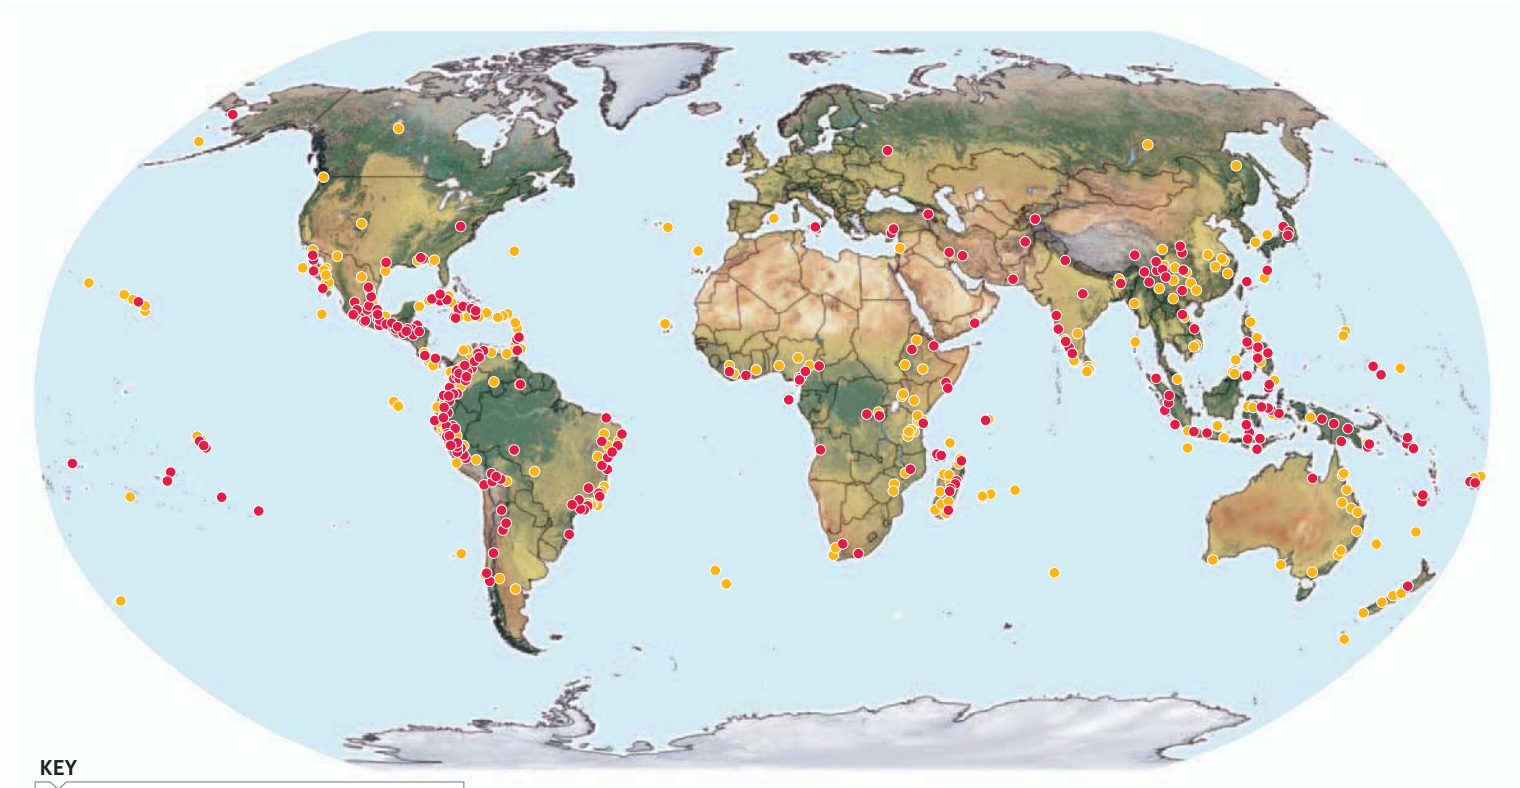

FIGURE 55.13 Pinpointing imminent extinctions. Taylor Ricketts and his colleagues identified 595 localities worldwide where at least one species of vertebrate or coniferous tree is in imminent danger of extinction. Sites marked in yellow are fully or partially protected. Those marked in red are unprotected or their protection status is unknown. The researchers mapped red localities over yellow ones to highlight areas in need of protection.

2. Why are conservation biologists especially concerned about the rapid rate of deforestation in the New World tropics?

55.5 Conservation Biology: Principles and Theory

Conservation biology is an interdisciplinary science that focuses on the maintenance and preservation of biodiversity. In this section we describe how conservation biologists use theoretical concepts from systematics, population genetics, behavior, and ecology to develop ways to protect habitats and the endangered species that live within them. We introduce practical applications of conservation theory in the next section.

Systematics Organizes Our Knowledge of the Biological World

To develop a conservation plan for any habitat, scientists must start with an inventory of its species. Their primary tool is systematics, the branch of biology that discovers, describes, and organizes our knowledge of biodiversity (see Chapter 24). Cataloguing the diversity of life may be the most daunting task that biologists face. After more than 200 years of work, systematists have described and named approximately 1.6 million species. However, they realize that this number represents only a fraction of existing species.

In 1982, Terry Erwin of the Smithsonian Institution studied beetle biodiversity at the Tambopata National Reserve in Southern Peru. He sprayed biodegradable insecticide into the canopy of one large tree and collected 15,869 individual beetles, which he sorted into 3,429 species. More than 90% of the individual beetles he collected belonged to species that had not yet been described. Erwin used this astounding result and a complex mathematical model to predict that approximately 30 million species currently exist.

Nigel Stork of the Natural History Museum in London later questioned Erwin's conclusions. Using additional data and a modified set of assumptions, he estimated that the actual number of living species was closer to 100 million. If his figure is correct, more than 98% of species—most of them arthropods, nematodes, bacteria, and archaeans—are still unknown to science. Regardless of whether biodiversity encompasses 30 million species or 100 million, systematists clearly have much work to do.

Recently, conservation biologists and systematists have begun to develop a new technology that will simplify the identification of species in the field, thereby facilitating the creation of a catalog of biodiversity. *Insights from the Molecular Revolution* describes the effort to develop a "DNA barcode scanner."

Population Genetics Informs Strategies for Species Preservation

When populations are reduced to small size, genetic drift inevitably reduces their genetic variability (see Section 21.3) and the evolutionary potential to adapt to changing environments. Thus, the loss of even a small fraction of a species' genetic diversity reduces its survival potential. To avoid this problem, conservationists strive not only to increase the population sizes of threatened or endangered species but also to maintain or increase their genetic variation, both within and between populations.

For example, the whooping crane *(Grus americana)* was once an abundant bird in wet grassland environments through much of central North America **(Figure 55.14).** By the early 1940s, excessive hunting and habitat destruction had caused their numbers to decline to just 21 individuals in two isolated populations. This population bottleneck and the resultant loss of genetic variability apparently contributed to developmental deformities of the spine and trachea that had not been seen previously.

During the 1970s, biologists began an aggressive conservation program. In addition to preserving habitats in the crane's summer and winter ranges, they initiated a carefully controlled captive breeding program designed to minimize the effects of inbreeding. Although more than 300 whooping cranes now survive in several wild and captive populations, recent research reveals that they still have a remarkably low level of genetic variability. As expected, the genetic effects of a severe population bottleneck may persist long after a population begins to increase in size.

Developing a DNA Barcode System

Everyone is familiar with the checkout scanners in stores: the cashier quickly passes an item's barcode over the scanner, and the register identifies it and records its price. The system works because the barcode on every item contains unique identifying information.

Research Question

In 2003, Paul Hebert, a population geneticist at the University of Guelph, Ontario, Canada, and his colleagues proposed an analogous method, called DNA barcoding, for identifying animal species quickly and accurately. The researchers envision using a handheld device to rapidly analyze DNA in the field; the resulting data would be sent to a database by cell phone, and minutes later an identification and a description of the species would appear on the instrument's screen.

Experiments

Hebert proposed using the first part of the *COI* (cytochrome oxidase 1) gene—a sequence of about 500 nucleotides—as the DNA barcode for animals because this mitochondrial gene varies greatly between animal species. Moreover, it appears to have no inserted or deleted DNA segments in most animals, making the alignment and comparison of sequences straightforward. Hebert's hope is that any *COI* gene sequence obtained in the field will provide a unique identifier for the species from which the DNA sample was obtained.

Results

Hebert's early tests of his barcode approach were promising and caught the attention of other researchers. For example, he and his collaborators first analyzed the *COI* gene sequence in the skipper butterflies of Costa Rica. Although adult skippers look pretty much alike, their caterpillars vary in appearance and in their food plant preferences, leading researchers to wonder if butterflies that had been assigned to one species *(Astraptes fulgerator)* might actually represent several. Analyses of the *COI* gene sequence sampled from 484 adults allowed Hebert and his colleagues to identify 10 distinctive DNA barcodes, suggesting that there are at least 10 species of skipper in Costa Rica rather than just one.

In early 2007, Hebert and his colleagues reported that they had used the DNA barcode to analyze 2,500 specimens of 643 North American bird species. The results were impressive: barcode differences between species were an order of magnitude greater than the differences within species, allowing the unambiguous identification of species from a short DNA sequence. Interestingly, the barcode analysis identified 15 probable new species that had not been previously identified and revealed that 8 supposed species of gull may be variants of just one species.

While the handheld analytical device is not yet ready for use in the field, Hebert's idea caught on quickly. In 2004 a consortium of major natural history museums and herbariums started the Barcode of Life Initiative, with the goal of creating a database of DNA barcodes linked to specimens already identified in their collections. The approach potentially could replace the traditional methods of systematic analysis using organismal and genetic characters to identify species.

Conclusion

Taken together, the results to date support using DNA barcodes, and using the *COI* gene sequence specifically for the barcode analysis, as a means of identifying animal species. Many researchers have joined the effort, and the Consortium for the Barcode of Life (http://barcodeoflife.org) now includes hundreds of member organizations around the world. They enter the results of their research into the Barcode of Life Data System (www.boldsystems.org), which, as of early 2012, included more than 1.5 million entries for more than 150,000 described species.

THINK LIKE A SCIENTIST How might DNA barcoding be useful in the effort to track the spread of Asian carp through North American rivers and lakes?

Studies of Population Ecology and Behavior Are Essential to Conservation Plans

Conservation programs for animals also require data about target species' ecology and behavior, including their feeding habits, movement patterns, and rates of reproduction.

Sea otters *(Enhydra lutris)* are predatory marine mammals that live along the coastline of the North Pacific Ocean. In the early 1700s, they numbered approximately 300,000 individuals **(Figure 55.15),** but commercial hunting reduced their numbers to about 3,000 individuals by the start of the twentieth century. Sea otters are keystone predators (see Section 53.4), and the destruction of sea otter populations had profound effects on the communities in which they lived. As the numbers of sea otters plummeted, populations of sea urchins, one of their favored prey, exploded; burgeoning sea urchin populations decimated local kelp beds, disrupting the communities of animals that live among these giant algae.

International treaties ended nearly all hunting of sea otters in 1911, and the populations subsequently recovered to about one-third of their original levels. Conservation biologists facilitated the recovery by reintroducing otters into southeastern Alaska, British Columbia, Washington, and California. Before deciding where otters should be reintroduced, scientists had to assess the resources available at different sites and determine how far individual otters would move, how rapidly they would reproduce, and how quickly their populations would spread. The reintroduction effort was successful at first. However, populations in California have experienced high mortality since the mid-1990s, and nearly half of those dying have been adults in their reproductive prime. Researchers have identified parasitic infections and heart disease as

leading causes of death, suggesting that some coastal environments are so badly degraded that they may no longer support populations of this species.

Using complex mathematical models, conservation biologists often conduct a **population viability analysis** (PVA) to determine how large a population must be to ensure its long-term survival. PVAs evaluate phenomena that may influence the longevity of the population or species: habitat suitability, the likelihood of catastrophic events, and other factors that may cause fluctuations in demographics, population size, or genetic variability. When conducting a PVA, researchers must decide what level of risk is acceptable for a given survival time. For example, should a conservation plan attempt to ensure a 95% probability that the species will survive for 100 years, or should it specify a 99% survival probability? An increase in either the survival probability or the survival time requires an increase in the size of the population that must be conserved. The **minimum viable population size** identifies the smallest population that fits the specifications of the conservation plan. *Focus on Applied Research* describes how biologists used PVA in the conservation of an Australian marsupial, the yellow-bellied glider *(Petaurus australis).*

Principles of Community Ecology and Landscape Ecology Guide Large-Scale Preservation Projects

Many conservation efforts focus on the preservation of entire communities or ecosystems. These projects often depend on the work of community and landscape ecologists.

SPECIES–AREA RELATIONSHIPS As you know from Chapter 53, community composition is dynamic: some species become extinct and others join the community through immigration. If we view patches of intact habitat as islands in a sea of unsuitable terrain, we can apply the predictions of the theory of island biogeography (see Section 53.7) to the design of protected areas. For example, we might expect that the number of species a patch will support depends on its size and proximity to larger patches.

Indeed, ecologists recognized long ago that large habitat patches sustain more species than small patches do **(Figure 55.16).** When plotted on a logarithmic scale, the species richness of a community increases steadily with the area sampled. In other words, for relatively small habitat patches, even minor increases in area allow a large increase in the number of resident species; nevertheless, as habitat patches get larger, the number of species present must eventually level off (once all species in the area are recorded as present). You encountered an example of the species–area relationship in our discussion of bird species richness on islands of different sizes (see Figure 53.31B).

As habitats become increasingly fragmented, edge effects exaggerate the species–area relationship in mainland habitat

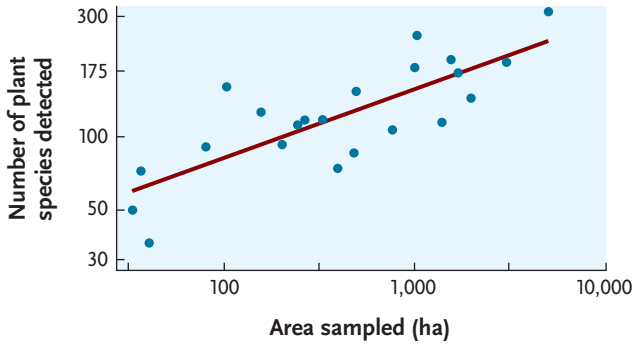

FIGURE 55.16 **The species–area relationship.** Data on plant distributions in nature preserves in Western Australia illustrate the relationship between the size of the area sampled and the number of species documented as present.

Preserving the Yellow-Bellied Glider

Predicting the future is never easy, especially the future of a threatened species. But population viability analysis (PVA) allows conservation biologists to predict how a species will fare under a range of possible scenarios. An effective PVA for an animal species requires detailed information about its diet, predators, mating habits, habitat preferences, space requirements, demography, geographical distribution, responses to climatic fluctuations and human disturbances, and a host of other aspects of its biology.

The Australian yellow-bellied glider *(Petaurus australis)* provides an example of how PVA is essential for a conservation effort. This marsupial, about the size of a squirrel, lives in small family groups in undisturbed *Eucalyptus* forests along Australia's eastern coast. Each glider family maintains a home range (the area it uses for feeding and other activities) of 25 to 85 hectares; the home ranges of neighboring families do not overlap. As a result, the population density of gliders has never been high. But glider populations have declined precipitously as forests have been cleared, and the species is now considered threatened.

Jean-Paul Ferrero/Auscape/ardea.com

Using data from nearly 20 published papers, two Australian conservation biologists, Russ Goldingay of the University of Wollongong and Hugh Possingham of The University of Adelaide, conducted a PVA for this species. They estimated age distributions in glider populations as well as survival probabilities, litter sizes, sex ratios, lifespan, and home range sizes. They analyzed these data using a mathematical model that predicts the viability for populations of various sizes. In most PVAs, a population is considered viable if it has a 95% probability of surviving for 100 years. Goldingay and Possingham introduced additional complexity to their analysis by assessing the effects of unpredictable environmental events, such as drought, on breeding success. They also conducted sensitivity analyses to examine how changing the values of specific parameters—such as litter size, mortality rates of the different age classes, or the frequency and severity of droughts—might influence the general predictions of the viability model.

After many thousands of these calculations, the researchers concluded that a viable population of gliders would require at least 150 family groups. They also suggested that a population of that size would need approximately 18,000 hectares (roughly 70 square miles). Currently, only one of the 15 existing conservation reserves is that large.

Goldingay and Possingham did not factor some common environmental disturbances—fire, disease, or predation by introduced species—into their analyses. Such disturbances could decimate a small glider population in short order. Thus, the outlook for gliders may be bleaker than the researchers suggest, because their estimates of minimum viable population size and minimum necessary habitat size are almost certainly too low. Given only this information, we might predict that the glider will inevitably become extinct.

However, there is some hope for the yellow-bellied glider. Goldingay and Possingham assumed that gliders don't move between populations, a behavior that promotes gene flow, because they had no data on gene flow in this species. The movement of individuals between populations could reduce the required minimum viable population size by decreasing the likelihood of genetic drift and the extinction of local populations. Biologists may even be able to transplant gliders from one population to another, effectively creating source and sink populations. This procedure might increase population size and genetic diversity in the most endangered populations. If successful, such an approach could stave off extinction.

As a result of this PVA, conservation biologists can determine which of the remaining forest tracts are large enough to sustain a yellow-bellied glider population. Thus, they now know where to concentrate their limited resources to secure the future survival of this species. Although predicting the future is difficult, PVAs allow conservation biologists to make accurate and reliable recommendations for selective transplants that will contribute to the conservation of threatened species.

patches **(Figure 55.17).** Consider two hypothetical patches of habitat: one is 100 m on a side, with a total area of 10,000 m^2; the other is 200 m on a side, with a total area of 40,000 m^2. Now, imagine that edge-effect disturbances penetrate 20 m into each patch from all directions. The small patch contains only 3,600 m^2 of intact habitat, but the large patch contains 25,600 m^2 of intact habitat. Although the large patch is only four times larger than the small patch, the large patch contains more than seven times as much *intact* habitat.

LANDSCAPE ECOLOGY Conservation biologists often use **landscape ecology** to design the size and geometry of nature reserves and other protected areas. Landscape ecology analyzes how large-scale ecological factors—such as the distribution of vegetation, topography, and human activity—influence local populations and communities.

When conservation biologists first applied concepts from landscape ecology to the design of protected areas, they debated whether nature preserves should comprise one large hab-

itat patch or several smaller patches. Based on the species–area relationship, large patches should harbor more species than small patches; large patches would also experience proportionately smaller edge effects; and large patches would better support populations of large animals that need substantial resources. Nevertheless, some conservation biologists argued that clusters of physically separate preserves are more effective in maintaining metapopulations of endangered species (see Section 52.5), especially if the patches are interconnected by corridors of intact habitat. Individuals could move between preserves, reviving any local populations that experience a decline.

Ellen I. Damschen of North Carolina State University and several colleagues conducted an ambitious long-term field experiment to test the effects of landscape corridors on plant species richness **(Figure 55.18).** Their results, published in 2006, suggest that habitat patches connected by corridors retain more native plant species than isolated patches do, and that corridors did not promote the entry of exotic species. Thus, corridors appear to be a useful feature in the design of nature preserves.

Landscape corridors are a key feature of efforts to prevent the extinction of the Florida panther (*Puma concolor coryi,* shown on page 1254). This subspecies is critically endangered: only 70 to 100 individuals remain from a population that once ranged throughout the southeastern United States. Other panther subspecies still inhabit the western states. Panthers are large predators, and each female requires nearly 20,000 hectares (more than 75 square miles) for hunting and breeding; males each require more than twice as much space.

Although the state and federal governments have set aside several panther conservation areas in Florida, 52% of the habitat panthers occupy is privately owned, and most of it is highly fragmented. Panthers frequently cross roads, and most panther deaths in Florida are caused by accidents with motor vehicles. Protected landscape corridors might enable panthers to move more safely between conservation areas. A preliminary study found that panthers already use such corridors, typically along wooded riverbanks, when they are available. The Florida Fish and Wildlife Service proposed the creation of an ambitious 6,100-hectare network of such corridors alongside the Caloosahatchee River to link several significant habitat fragments in neighboring counties.

BETA-DIVERSITY Conservation biologists now often focus their efforts preserving assemblages of organisms rather than individual species. As you know from Section 53.2, communities grade into one another as species composition changes across environmental gradients. That discussion focused on diversity *within* well-defined communities, a characteristic that ecologists identify as alpha diversity. But conservation biologists are increasingly interested in diversity *across* communities, which they call beta-diversity. Beta-diversity reflects the increasing numbers of species present in an area that includes a wide variety of habitats, vegetation types, and small-scale environments. The concept of beta-diversity is reflected in the slope of the species–area relationship: as the size of an area increases, so does the number of distinct environmental features it includes; and that environmental diversity supports a larger number of species.

By basing the design of nature preserves on the conservation of beta-diversity, conservation biologists can establish reserves that will protect more species. An ideal reserve system might include several large areas, each including a diversity of small-scale environments suitable for species that do not disperse readily, and many small reserves interconnected by landscape corridors. A reserve system distributed over an important environmental gradient would include species that replace each other across it. And as the global climate continues to warm over the coming decades, reserve systems that include protected areas at different altitudes or latitudes might allow some species to migrate into cooler environments over time.

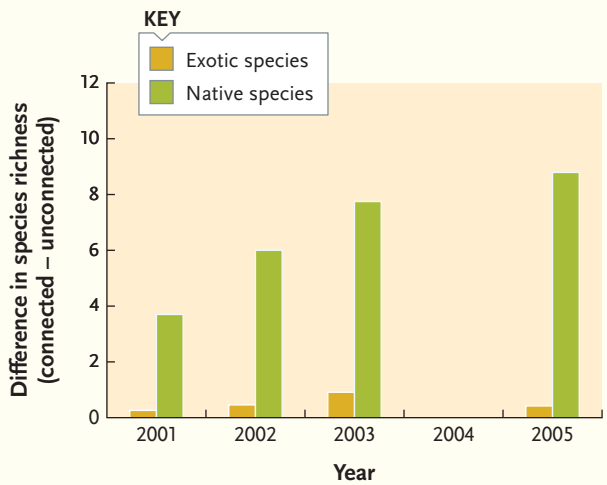

FIGURE 55.18 **Experimental Research**

Effect of Landscape Corridors on Plant Species Richness in Habitat Fragments

Question: Do landscape corridors connecting habitat patches influence the species richness of native and exotic plants within the habitat patches?

Experiment: Damschen and her colleagues studied changes in the community composition and species richness of the plants in open habitat patches within a longleaf pine *(Pinus palustris)* forest in South Carolina. Their experimental design included both isolated patches and patches that were connected to one another by a landscape corridor. All patches included the same land area, and their large size (1.375 ha each, including the landscape corridors) allowed the researchers to make a realistic assessment of the effects of landscape corridors. After creating the patches of open habitat within the forest in 2000, the researchers catalogued all plant species occurring in the patches through 2005, although they were unable to collect data in 2004.

Results: Over the course of the study, habitat patches that were connected by landscape corridors harbored increasingly more plant species than did isolated habitat patches. The researchers also noted that the difference in species richness between the two experimental treatments was caused by a difference in the number of native plant species present. The number of exotic species in connected and isolated habitat patches was similar.

Conclusion: Landscape corridors between patches of open habitat in longleaf pine forests increase the species richness of native species in open habitat patches, but they do not foster the entry of exotic species.

THINK LIKE A SCIENTIST Based on the results of this experiment, predict the effect that landscape corridors would have on the species richness of small animals (including insects) in patches of longleaf pine forests.

55.6 Conservation Biology: Practical Strategies and Economic Tools

Conservation biology seeks to protect native species, communities, and ecosystems from the effects of human activity. Meeting that goal and reversing some of the existing damage requires the integration of biological research with economic and social realities.

Conservation Efforts Aim to Preserve, Conserve, and Restore Habitats

Conservation groups often highlight efforts to preserve individual animal species, such as the giant panda *(Ailuropoda melanoleuca)* or California condor *(Gymnogyps californianus)*. The preservation of "charismatic megavertebrates," as these large animals are sometimes described, attracts substantial public support. Nonetheless, there is little point in trying to preserve natural populations of individual species if their habitats are in jeopardy. An alternative to species-based conservation focuses on the preservation of intact habitats; individual species are conserved as a consequence of preserving the habitats on which they depend. Conservation biologists approach this goal with a continuum of approaches, which fall into three general categories: *preservation, mixed-use conservation,* and *restoration.*

CONSERVATION THROUGH PRESERVATION

In many countries, habitats are preserved when an individual or organization purchases them and enforces strict standards of land use. In sensitive habitats, people may be excluded altogether; in other cases, access is restricted and the exploitation of resources is controlled. This approach works well in countries with efficient law enforcement and a tradition of private land ownership. In the United States, for example, the Nature Conservancy has purchased tracts of land to preserve native species in every state.

The preservation approach has been successful in preserving portions of the Pine Bush habitat near Albany, New York **(Figure 55.19).** This unique ecosystem arose approximately 11,000 years ago at the end of the last glacial period, when a massive deposit of sand was left near the western margin of Albany's current city limits. This sandy region formed an inland pine-barrens habitat in which pitch pine *(Pinus rigida),* scrub oak *(Quercus ilicifolia),* and dwarf chestnut oak *(Quercus prinoides)* are now the dominant vegetation. The Pine Bush is home to more than 50 plant and animal species that the state and federal government list as threatened or endangered. The habitat itself was once vulnerable because it lies within Albany's city limits; however, since 1988, the Pine Bush

has been jointly owned and protected by New York state, local municipalities, and the Nature Conservancy.

MIXED-USE CONSERVATION When outright preservation is impractical, conservation biologists advocate mixed-use conservation, which combines the protection of some land parcels with the controlled development of others.

The Ngorongoro Conservation Area (NCA) in Tanzania provides an example of mixed-use conservation. The NCA covers 829,000 hectares of grassland and borders the Serengeti National Park. Because it houses a high concentration of wildlife, the NCA is one of the most visited tourist destinations in eastern Africa. For the past several hundred years, the Maasai people have herded cattle, goats, and sheep in the Serengeti and Ngorongoro **(Figure 55.20).** The Maasai are nomadic pastoralists who frequently move their relatively small herds to new grazing areas in the region. As a result, their activities do not degrade the land or exclude native wildlife. In 1959 the Maasai agreed to vacate the Serengeti, which was converted into a national park, in return for retaining the rights to live and herd livestock within the NCA. The government of Tanzania helped create the necessary infrastructure within the NCA, including a constant water supply as well as social services. Under this agreement, 40,000 indigenous residents, most of them Maasai, live in this large and valuable conservation area.

© iStockphoto.com/bryttа

FIGURE 55.20 Mixed-use conservation. The Maasai use the Ngorongoro Conservation Area to graze cattle and goats.

CONSERVATION THROUGH RESTORATION Conservation biologists sometimes create restoration plans to reestablish the vitality of a previously disrupted community or ecosystem. This effort requires the removal of contaminants, impediments to the natural flow of water, and barriers to animal movement as well as the restoration of natural processes, such as periodic fires or floods. Most restoration projects also require replanting key plant communities and long-term management once restoration is complete.

Not all degraded habitats can be restored, and not all potential restoration projects are equally feasible. When making project decisions, restoration ecologists consider a number of factors: will the restored habitat be suitable for rare or endangered species, and will its creation increase endemic biodiversity? Would the restoration reunite previously fragmented land parcels? Will the restored habitat experience the periodic disturbances, such as fires or floods, that are essential for its continued existence? What are the costs of implementing the plan and maintaining the area? Finally, would the restored land be valued by local residents, and will they support and maintain it?

A successful restoration project is currently underway in the Brazilian Atlantic Forest, sponsored by the Instituto de Pesquisas Ecológicas (IPÊ), a Brazilian nongovernmental organization. In western São Paulo state, near the Morro do Diabo state park, IPÊ is trying to re-create the natural Brazilian Atlantic Forest ecosystem by planting native trees in habitat corridors between remaining forest fragments. These corridors of native tree species should facilitate the preservation of species in those forest patches and supply valuable botanical resources for endemic wildlife and local residents.

Successful Conservation Plans Must Incorporate Economic Factors

Biologists can almost always develop a plan to conserve a species, community, or ecosystem. But to be successful, a plan must be economically feasible, and it must provide direct benefits to local residents whose lives it will affect.

LOCAL INVOLVEMENT Early conservation efforts simply set aside protected areas in which most human activities were banned. Local people were denied access to resources within the preserve—resources that were sometimes essential for their survival. Not surprisingly, these plans generated antipathy towards conservationists and the organisms they were trying to preserve.

For example, the northern spotted owl *(Strix occidentalis caurina)* lives only in old growth coniferous forests of the Pacific Northwest, where many local residents worked in forestry or supporting industries. The suggestion that the owl be listed as an endangered species triggered a bitter political battle between conservationists and local residents because the conservation plan for the owls required closing large tracts of forest to logging. Washington State listed the owl as an endangered species in 1988, but local residents, who lost jobs when logging was reduced, remain hostile to these conservation efforts.

Conservation plans are more successful if they provide local residents with benefits that depend on the existence of a preserve. Chitwan National Park provides an excellent example. For more than 100 years, this area, located in south central Nepal near the northern border of India, was recognized as a hunting ground for local royalty. These activities decimated local populations of large mammals, especially the Bengal tiger *(Panthera tigris)* and one-horned rhinoceros *(Rhinoceros unicornis).* The area was opened for settlement during the late 1950s, and immigrants swarmed into the fragile grassland. As the human population exploded, the populations of tigers and rhinos dwindled by the mid-1960s.

The area was converted into Royal Chitwan National Park in 1973. Today, humans are excluded from the park for most of the year. But each January, after the monsoon rains end and the grasses have dried, local residents are welcomed into the park to harvest the grass, which they use to thatch roofs, make mats, and feed domestic animals **(Figure 55.21).** The area surrounding the Chitwan National Park has been designated as a buffer zone. Residents of the buffer zone receive 50% of the total revenue earned from park activities, including entrance fees. This income has changed the lifestyle of the people in the buffer zone, and they now value Chitwan and argue for its preservation. Today, more than 435 one-horned rhinos survive in Nepal, most of them in Chitwan National Park. And the Bengal tiger population of Chitwan has increased to 91 breeding adults.

ECOTOURISM In some preserves, governments enlist local residents in park development and operations, providing them with a viable livelihood. The most successful approach has been the development of **ecotourism,** in which visitors, often from wealthier countries, pay a fee to visit a nature preserve. Local people work as guides, cooks, and logistical and support staff.

© Joan Swinnerton/Alamy

FIGURE 55.21 Conservation and the local economy. Local residents support conservation efforts at the Royal Chitwan National Park, Nepal, because officials open the park for a grass harvest each year.

Not everyone agrees that ecotourism is helpful. Critics note that increased human traffic may degrade habitats, and unregulated ecotourism can eventually lead to overdevelopment. For example, several million people visit national parks in the western United States annually. Traffic jams, automobile accidents, and long lines routinely plague visitors at the most popular sites. Cranky ecotourists call for the construction of more roads and parking lots, which are inconsistent with the purpose of a national park because cars increase local air pollution and occasionally kill wildlife. In 2006, the government began charging a $20 fee for each automobile entering Yosemite National Park in California, hoping to limit the number of visitors arriving in private vehicles and to increase reliance on public transportation.

COUNTRYWIDE ECONOMIC APPROACHES In the mid-1990s, conservation biologists and economists developed the concept of **ecosystem valuation,** in which ecosystem services—such as carbon dioxide processing or water retention and purification, which are best provided by intact ecosystems—are assigned an economic value. These estimated values are used to negotiate contracts in which a private company or conservation organization pays a community, state, or country to maintain intact ecosystems. By one 1997 estimate, the gross global ecosystem valuation is roughly $18 trillion per year. If less obvious benefits provided by nature are tallied—soil formation, crop pollination, and nutrient cycling—the total value of ecosystem services rises to $33 trillion—almost twice the value of all goods produced by all humans on the planet.

The implementation of ecosystem valuation exchanges is determined on a case-by-case basis, depending on what ecosystem services the paying organization wants to preserve. Costa Rica is leading the way in this effort by creating valuation contracts with several corporations. For example, in 1998, the Monteverde Conservation League signed a contract with a local electrical company to ensure the continued flow of water

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

from the Bosque Eterno de los Niños, a forest preserve. The company had plans to build a hydroelectric dam on the Rio Esperanza, and feared that deforestation upstream would disrupt water flow through the dam. The contract specifies that the electrical company will pay the people who live upstream to preserve their forests rather than cutting them. Thus, both the forests and water flow are preserved, maintaining the forest ecosystem and generating badly needed electricity.

Biodiversity is a precious resource that is disappearing rapidly throughout the world. It can still be conserved through a monumental effort to catalog the diversity of living organisms and develop an understanding of their ecological relationships. Perhaps the major challenges for conservation biologists are to educate the human population about the value of biodiversity and to develop conservation plans that will enlist the support of people who live among the threatened species.

3. **How can the concept of ecosystem services be used to foster conservation of threatened habitats and species?**

UNANSWERED QUESTIONS

Conservation biology is a young science in a rapidly changing world. Our field is brimming with unanswered questions about scarcity, diversity, and extinction. Many of the questions proposed by conservation biologists are interesting, but only a subset may offer answers useful to policy makers, field practitioners, and nongovernmental organizations trying to find cost-effective ways to head off the global biodiversity crisis. I have selected two areas where basic conservation science can inform global policies and local efforts to prevent the current extinction crisis from dooming many species to oblivion.

How can we preserve species that are likely to become extinct?

Some estimates state that up to 50% of all species on Earth could disappear by the end of the century as a result of: (1) land conversion in the tropics, where more than 50% of all species occur, and (2) climate change. Professor E. O. Wilson of Harvard University has calculated that more than 100 species go extinct each day. So, ask the cynics, "What are they? Can you name them?"

To save species from imminent extinction, we need to know which species are highly endangered, where they live, what resources they require, and why they are threatened. Led by Taylor Ricketts, biologists from all major conservation organizations used published data to identify the "trigger species" of vertebrates and conifers most likely to go extinct in the next 20 years. We found 794 species in 585 locations for which the entire global population, ranked as endangered or critically endangered, is limited to a single site. Half of these sites contain rare, endemic amphibians, many of which are threatened by the deadly chytrid fungus. Can we find a way to stop the spread of this fungus, or reduce its virulence, to avoid a mass extinction of amphibians? Half of all threatened localities are on tropical mountains. Can we save these habitats as watersheds that provide vital ecosystem services to communities living downstream? What about the 350,000 to 400,000 species of vascular plants, perhaps 10% of which are known only from a single site? What about the millions of species of invertebrates, some so rare that their entire distribution may be limited to the crowns of a few tropical forest tree species? Can we protect all of these areas that are the last refuge for many species? Or is the task so overwhelming that we should try to save only what seems feasible?

Can we find the political will to protect global biodiversity?

Answers to this second question could provide a solution to those posed above. A new global treaty, REDD (Reduced Emissions from Deforestation and Degradation), is currently being negotiated. It offers the greatest conservation opportunity of our lifetimes. Can we seize it? If most of the world's endemic species live in the tropics and a high percentage occur in moist tropical forests, can we forge a new agreement that values these forests for the carbon they sequester, and in so doing, protect much of the world's biodiversity? Deforestation and degradation of moist tropical forests account for 20% of the greenhouse gas emissions recorded annually. These emissions could become much larger if peat swamp forests in Sumatra and other carbon-rich areas are burned, cleared, and converted to plantations. Can we harness the political will to create a carbon financing mechanism that rewards tropical countries that protect their carbon-rich and species-rich forests? Will REDD be a turning point in the race to secure a more stable climate and avoid biological catastrophe?

THINK LIKE A SCIENTIST Write down 20 unanswered questions for which scientists must quickly find answers to save life on Earth. A recently published paper (W. J. Sutherland et al. 2009. One hundred questions of importance to the conservation of global biological diversity. *Conservation Biology* 23:557–567) offers a longer list. Does your list overlap with the most pressing 100 questions identified by biologists, conservationists, and policy-makers?

Eric Dinerstein

Eric Dinerstein is the World Wildlife Fund chief scientist and Vice President for Science. He is a co-architect and co-author of the Global 200 ecoregions, an analysis to identify the most biologically important ecoregions on Earth in the terrestrial, freshwater, and marine realms. He and his staff developed a framework for targeting priority areas for conserving tiger populations across Asia that is now widely adopted. To learn more about Dr. Dinerstein's work, go to http://www.worldwildlife.org/who/experts/eric-dinerstein.html.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

55.1 The Biodiversity Crisis on Land, in the Sea, and in River Systems

- Deforestation is occurring at an alarming rate, especially in tropical regions (Figures 55.1 and 55.2). In addition to adding greenhouse gases to the atmosphere, deforestation may lead to desertification and the loss of entire ecosystems (Figure 55.3). Deforestation, desertification, and global warming reinforce each other in a positive feedback cycle.
- Overexploitation of natural populations reduces their sizes and may induce evolutionary responses in the exploited populations (Figure 55.4).
- Dams and other factors causing hydrologic alterations endanger freshwater ecosystems by changing the structure of riverine habitats, disrupting life histories of aquatic species, decreasing connectivity in river systems, and facilitating the establishment of exotic species (Figure 55.5).

Animation: Acid deposition

Animation: Effects of deforestation

Animation: Global crises by region and habitat

Animation: Humans affect biodiversity

55.2 Specific Threats to Biodiversity

- Habitat fragmentation reduces the size of intact habitat patches, and edge effects diminish the quality of remaining habitat (Figure 55.6). Only small populations, which are subject to genetic drift and an increased likelihood of extinction, can inhabit small habitat patches.
- Although pollution is released locally, it often spreads regionally and globally, especially in bodies of water and the atmosphere (Figure 55.7).
- Exotic species often contribute to the extinction of native species through competition, predation, or parasitism (Figures 55.8–55.10). Humans frequently introduce exotics into communities either intentionally or inadvertently.
- The decline of amphibian species is at least partly caused by the spread of a pathogenic chytrid fungus (Figure 55.11). New and introduced disease-causing organisms pose serious threats to biodiversity.
- Although extinction has been common in the history of life, human activities have recently initiated what may be the greatest mass extinction of all time. Some biologists estimate that extinction rates today may be 1,000 times the background extinction rate.

Animation: Habitat loss and fragmentation

Animation: Effect of air pollution in forests

55.3 The Value of Biodiversity

- Biodiversity provides direct benefits to humans because natural populations of organisms can be sources of useful natural products as well as genetic resources that can improve domesticated crops and animals (Figure 55.12).
- Biodiversity provides indirect benefits to humans by maintaining normal ecosystem processes, some of which help to counteract the harmful effects of human activities.
- Ethicists and environmentalists argue that biodiversity should be preserved simply because of its intrinsic worth.

55.4 Where Biodiversity Is Most Threatened

- Biodiversity hotspots harbor large numbers of endemic species and are threatened by human activities.
- Conservation biologists have pinpointed areas where several groups of vertebrates and coniferous plants are in imminent danger of extinction (Figure 55.13). An analysis of these data suggests that the extinction rate is accelerating and that species in the New World tropics are especially at risk.

Animation: Resource depletion and degradation

Animation: Biodiversity hotspots

55.5 Conservation Biology: Principles and Theory

- Conservation biology draws its theoretical foundation from systematics, population genetics, population ecology, behavior, community ecology, and landscape ecology.
- Systematists provide taxonomic inventories of biodiversity that are helpful for establishing conservation priorities.
- Conservation biologists design breeding programs to maintain or increase the genetic variability of species being preserved (Figure 55.14).
- Conservation biologists study the population ecology and behavior of targeted species (Figure 55.15), and they may use population viability analyses to determine the minimum viable population size necessary to conserve threatened species.
- Studies in community ecology have established the generality of the species–area effect: large habitat patches harbor more species than small habitat patches do (Figure 55.16).
- From the perspective of landscape ecology, biologists have debated the advantages and disadvantages of establishing one large reserve versus several smaller ones that are connected by habitat corridors (Figures 55.17 and 55.18).
- Conservation biologists now include analyses of diversity across communities in their designs for nature preserves in an effort to preserve whole assemblages of organisms.

55.6 Conservation Biology: Practical Strategies and Economic Tools

- Efforts to conserve communities or ecosystems follow one of three general strategies. *Preservation* requires the restriction or prohibition of human access to the area (Figure 55.19). *Mixed-use conservation,* an approach that balances the conflicting demands of habitat preservation and development, allows local residents to use the protected area in limited ways (Figure 55.20). *Restoration* attempts to recreate natural communities and ecosystems in places that have already been degraded by human activities.
- Conservation plans must also incorporate economic and social factors to win local support. Most conservation plans now include the involvement of local residents to generate revenue for their communities (Figure 55.21). Ecosystem valuation also encourages the preservation of ecosystems by assigning them a significant economic value.

UNDERSTAND & APPLY

Test Your Knowledge

1. The greatest extinction in the history of life on Earth:
   a. occurred at the end of the Permian period.
   b. occurred at the end of the Cretaceous period.
   c. occurred at the end of the Ordovician period.
   d. occurred at the end of the Cambrian era.
   e. may be occurring now.
2. Which of the following activities is the most fundamental cause of the worldwide crisis in river ecosystems?
   a. overexploitation of predatory fishes
   b. damming of rivers
   c. pollution from power plants
   d. invasion by exotic species
   e. deforestation
3. Habitat fragmentation has damaged populations of breeding birds in North America because:
   a. the remaining habitat patches rarely contain enough food for birds to rear their offspring.
   b. the nests of birds in small habitat patches are frequently attacked by predators.
   c. pairs of breeding birds cannot easily move from one habitat patch to another.
   d. female birds cannot locate potential mates in small habitat patches.
   e. small habitat patches do not have enough edges to provide adequate hiding places.
4. Deforestation:
   a. is a problem only in the tropics.
   b. may speed desertification.
   c. is slowed by grazing and farming.
   d. permanently enriches the soil.
   e. leads to the formation of lush grasslands.
5. Chemical pollutants:
   a. can spread rapidly from the places they are released.
   b. do not appear to influence global climate change.
   c. have contributed to global mass extinctions.
   d. rarely affect natural bodies of water.
   e. rarely influence animals feeding at higher trophic levels.
6. Which of the following is most likely to be a biodiversity hotspot?
   a. a patch of forest in the middle of North America that is 500 km from the nearest big city
   b. a series of uninhabitable sand dunes in the Sahara Desert
   c. a botanical garden that houses representatives of 25,000 plant species
   d. a tropical island with many endemic species and a growing human population
   e. a suburban neighborhood where fields have been converted to backyards and playgrounds
7. Population viability analyses allow conservation biologists to:
   a. identify the source population from which an individual dispersed to a sink population.
   b. determine how large an area must be preserved for the protection of a threatened species.
   c. identify whether individuals of a threatened species are reproductively mature.
   d. predict the minimum population size of a threatened species that is likely to survive.
   e. predict whether a threatened species will use habitat corridors.
8. Beta-diversity is a measure of:
   a. species diversity across community boundaries.
   b. the number of species within one community.
   c. the number of endemic species found in a particular place.
   d. the likelihood that a particular species will become extinct in the next 20 years.
   e. the minimum population size needed to conserve an endangered species.
9. For which of the following species has the use of habitat corridors been proposed as an important conservation tool?
   a. sea otters
   b. bay checkerspot butterflies
   c. Florida panthers
   d. whooping cranes
   e. Eastern hemlocks
10. The main goal of restoration ecology is the reestablishment of:
    a. natural patterns of water flow.
    b. the vitality of a degraded ecosystem.
    c. the historical corridors linking forest fragments.
    d. the natural barriers to animal movement.
    e. ecotourism.

Discuss the Concepts

1. National parks are often established in ecologically sensitive areas. In many places they have become so popular that visitors endanger the ecosystems the parks were originally designed to preserve. How can the goals of conservationists, who work to maintain intact ecosystems, be balanced with those of citizens who wish to visit intact ecosystems? In other words, how would you regulate domestic ecotourism?
2. How do concepts from population genetics, metapopulation dynamics, and beta-diversity apply to the design of nature preserves? Do they suggest different ideal designs for nature preserves?
3. Imagine that you are a conservation biologist who has been asked to develop a conservation plan for a species of lizard that lives in the deserts of the American Southwest. What sorts of data would you collect before developing a final plan?

Design an Experiment

Devise a field study to determine whether the species–area relationship applies to aquatic ecosystems, such as ponds and lakes, as it does to terrestrial habitats.

Interpret the Data

The accompanying **Table** compares statistics on imminent extinctions versus historical extinctions in five groups of organisms. The data are divided into three geographic categories. In which of the three habitat categories are extinctions accelerating the most? In which group of organisms are extinctions accelerating the most? What do these data suggest about where conservation biologists should focus their efforts if the goal is to preserve as many species as possible?

Apply Evolutionary Thinking

Overexploitation of marine fish stocks has depleted natural populations and caused a reduction in the age and size at which many fish species become reproductively mature. What sort of government regulations of fishing might reverse the current trend toward smaller adult size? Explain your answer in terms of the selection pressures that fishing places on targeted species.

Animal Behavior

Why it matters . . . Male white-crowned sparrows *(Zonotrichia leucophrys)* are handsome birds with a song that birdwatchers describe as a "plaintive whistle" followed by a "husky trilled whistle." This distinctive song is a critical part of a male white-crown's **behavioral repertoire,** the set of actions that it can perform in response to stimuli in its environment. A male sparrow's song is one of the ways he struts his stuff. The song not only announces his presence to rival males, but it also signals to females that he is available as a potential mate. Experienced birders easily recognize this song, which differs from that of song sparrows *(Melospiza melodia)* and swamp sparrows *(Melospiza georgiana),* as sound spectrograms illustrate **(Figure 56.1).** In fact, every songbird species produces vocal signals that are characteristic of its species and its species alone.

Every animal species' behavioral repertoire includes a variety of actions and responses. For example, in early spring, male white-crowned sparrows leave their wintering grounds in Mexico and fly thousands of kilometers to their northern breeding range; migrating birds expend immense quantities of energy on the trip, and many die before completing it. On arrival, they occupy habitat patches that contain the resources necessary for breeding—suitable cover, potential nesting sites, and abundant food. Then, they start to sing, repeating their song thousands of times a day. Males also perform elaborate courtship behaviors. And once the young hatch, the chicks communicate with their parents, eliciting the care they need before leaving the nest.

All of these behaviors have associated costs in both time and energy, and many also attract the attention of predators. Given the costs and dangers associated with these behaviors, what benefits do the birds gain from performing them? The ultimate evolutionary benefit is obvious: with luck, individuals that perform these complex and diverse behaviors may leave more sur-

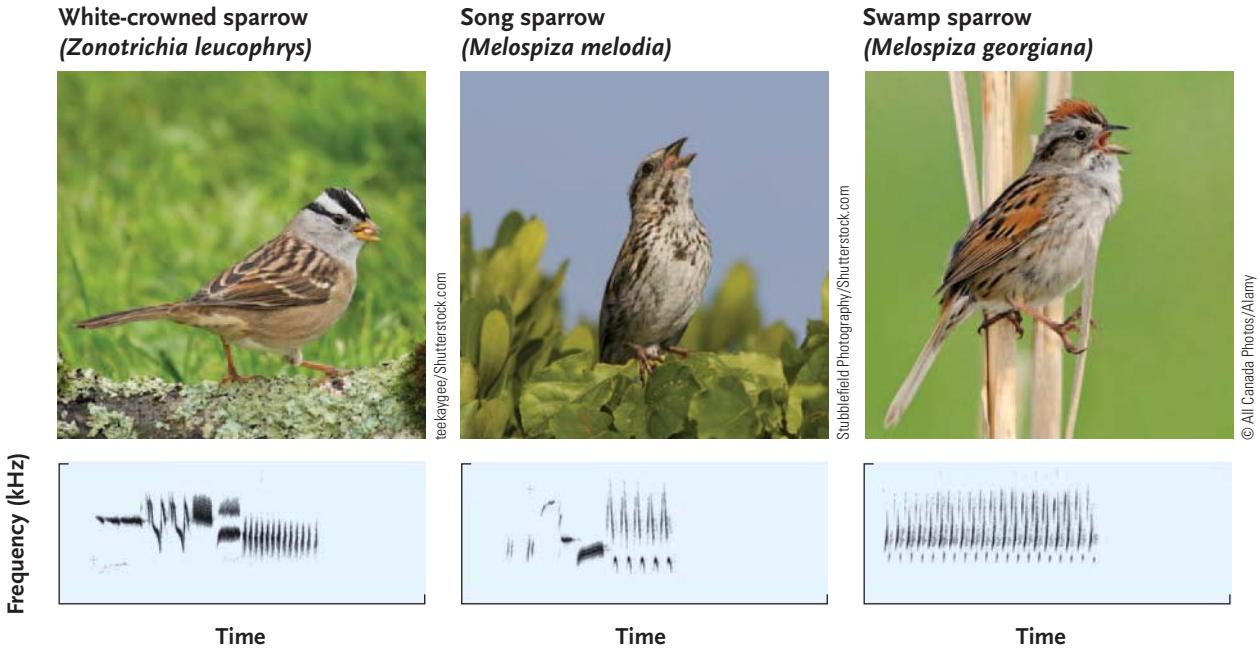

FIGURE 56.1 Songbirds and their songs. Sound spectrograms (visual representations of sound graphed as frequency versus time) illustrate differences in the songs of the white-crowned sparrow, the song sparrow, and the swamp sparrow.

viving offspring than those that do not. Thus, each species' behavioral repertoire is a set of evolved responses that ultimately contribute to the reproductive success and fitness of the individuals performing them.

The study of **animal behavior** involves discovering how animals respond to specific stimuli and why they respond in predictable and characteristic ways. A comprehensive approach to animal behavior studies first crystallized in the 1930s, when European researchers—notably Konrad Lorenz, Niko Tinbergen, and Karl von Frisch, who shared a Nobel Prize for their work in 1973—developed the discipline of **ethology,** which focuses on how evolutionary processes shape inherited behaviors and the ways that animals respond to specific stimuli. Tinbergen identified four basic questions that any broad study of animal behavior should address: (1) What mechanisms trigger a specific behavioral response? (2) How does the expression of a behavior develop as an animal matures? (3) What is the behavior's ecological function and how does it increase an animal's chances of surviving and reproducing? (4) How did the behavior evolve?

Advances in **neuroscience**—the integrated study of the structure, function, and development of the nervous system—now allow researchers to explore Tinbergen's first and second questions about the *proximate causes* of behavior—*how* genetic, cellular, physiological, and anatomical mechanisms underlie an animal's ability to detect and respond to stimuli in species-specific ways.

Comparable advances in genetic analysis and evolutionary theory enable scientists to address Tinbergen's third and fourth questions about the *ultimate causes* of behavior—*why* behaviors have adaptive value and *why* the genetic and physiological mechanisms that underlie specific behaviors are subject to microevolutionary change. The behavior of animals is closely tied to their ecological circumstances, and if particular alleles contribute to the development of a behavior that enhances an animal's fitness in the environment it occupies, natural selection will cause the frequency of those alleles to increase in the next generation (see Section 21.3).

In this chapter, after first considering the genetic and experiential bases of animal behavior, we examine the neurophysiological and endocrinological control of specific behaviors. We then turn our attention to the ecology and evolution of several broad categories of animal behavior: orientation, navigation, and migration; habitat selection and territoriality; communication; reproductive behavior and mating systems; and social behavior, including behaviors described as altruistic.

56.1 Instinctive and Learned Behaviors

For many years, animal behaviorists debated whether animals are born with the ability to perform most behaviors completely or whether experience is necessary to shape their actions. Extensive research in neuroscience has demonstrated that no behavior is determined entirely by genetics or entirely by environmental factors. Instead, behaviors develop through complex gene–environment interactions, which we illustrate with a description of how male white-crowned sparrows learn their adult song.

Why do adult male white-crowns sing a song that no other species sings? Perhaps young males possess an innate ("inborn") ability to sing the "right" song the first time they try. According to this hypothesis, their distinctive song would be an **instinctive**

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

behavior, a genetically "programmed" response that appears in complete and functional form the first time it is used. Or perhaps they produce the song only after hearing the songs of adult male white-crowns that live nearby. If that hypothesis is correct, their species-specific song would be a **learned behavior,** one that is dependent upon having a particular experience during development.

Genetics and Experience Contribute to an Animal's Behavior

How can we determine whether a particular behavior has instinctive and/or learned components? If the white-crowned sparrow's song is instinctive, isolated male nestlings that have never heard other males should be able to sing their species' song when they mature. But if the learning hypothesis is correct, young birds deprived of certain essential experiences should not sing "properly" as adults.

In a set of pioneering experiments conducted at Rockefeller University, Peter Marler tested these alternative hypotheses. He took newly hatched white-crowns from nests in the wild and reared them individually in soundproof cages. Some chicks listened to recordings of a male white-crowned sparrow's song when they were 10 to 50 days old; others did not. The juvenile males in both groups first started to vocalize when they were about 150 days old, initially producing whistles and twitters that only vaguely resembled the songs of adults. But gradually the young males that had listened to their species' song began to sing better and better approximations of that song. At about 200 days of age, they were right on target, producing a song that was nearly indistinguishable from the one they had heard months before. By contrast, males in the group that had not heard white-crown songs never came close to singing the way wild males do.

These results revealed that learning is essential for a young male white-crowned sparrow to acquire the full song of its species. Although birds isolated as nestlings did sing instinctively, the acoustical experience of listening to their species' song early in life enabled them to reproduce it months later. We can therefore reject the hypothesis that white-crowned sparrows hatch from their eggs with the ability to produce the "right" song. Their species-specific song—and presumably those of other songbirds—has both instinctive and learned components.

Although early researchers generally classified behaviors as *either* instinctive *or* learned, we now know that most behaviors include *both* instinctive and learned components. Nevertheless, some behaviors have a strong instinctive basis, whereas others are mostly learned **(Table 56.1).** Researchers use a variety of techniques to unravel the instinctive and learned components of specific behaviors. In some studies, observations and experiments based on simple environmental manipulation are sufficient. In others, researchers conduct more elaborate deprivation experiments (as described above), breeding studies, or experiments based on gene knockouts.

TABLE 56.1 Instinctive Behaviors and Learned Behaviors

	Behavior	Description
Instinctive behaviors (strong genetic basis)	Fixed action patterns	Stereotyped actions, often initiated by a sign stimulus
	Feeding behaviors	Innate food preferences and hunting tactics
	Defensive behaviors	Responses to predators
	Reproductive behaviors	Mating habits and parental care activities
Learned behaviors (strong experiential basis)	Imprinting	Affinity for caretaker species, developed during critical period
	Classical conditioning	Association between phenomena that are usually unrelated
	Operant conditioning	Trial-and-error learning
	Cognition	Insight learning in novel situations
	Habituation	Loss of responsiveness

© Cengage Learning 2014

Instinctive Behaviors Are Performed without Prior Experience

Instinctive behaviors—which are often grouped into functional categories, such as feeding behaviors, defensive responses, mating behaviors, and parental care activities—can be performed without the benefit of prior experience. We therefore assume that they have a strong genetic basis and that natural selection has preserved them as adaptive behaviors.

STEREOTYPED BEHAVIORS Many instinctive behaviors are highly stereotyped; in other words, when triggered by a specific cue, they are performed over and over in almost exactly the same way. Such behaviors are called **fixed action patterns,** and the simple cues that trigger them are called **sign stimuli.** For example, sign stimuli and fixed action patterns govern the transfer of food from herring gull *(Larus argentatus)* parents to their offspring: very young chicks secure food from their parents through a begging response (the fixed action pattern), which is triggered by a red spot on the lower bill of an adult (the sign stimulus). This cue "releases" the begging behavior of hungry baby gulls, which peck at the spot on the parent's bill. In turn, the tactile stimulus delivered by the pecking chick serves as a sign stimulus that induces the adult bird to regurgitate food stored in its crop. The baby gulls then feed on the chunks of seafood that lie before them. We know that the spot on the par-

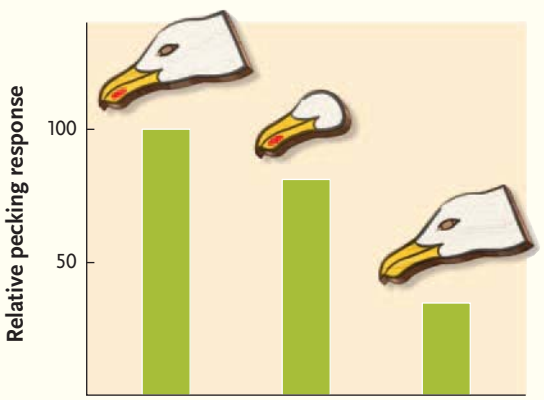
FIGURE 56.2 Experimental Research

The Role of Sign Stimuli in Parent–Offspring Interactions

Question: What feature of the parent's head triggers pecking behavior in young herring gulls?



Experiment: Niko Tinbergen and A. C. Perdeck tested the responses of young herring gull *(Larus argentatus)* chicks to cardboard cutouts of an adult herring gull's head and bill. They waved these models in front of the chicks and recorded how often a particular model elicited a pecking response from the chicks. One cutout included an entire gull's head with a red spot near the tip of the bill, another cutout included just the bill with the red spot, and the third cutout included the entire head but lacked the red spot.

Result: Young herring gulls pecked at the model of the bill with a red spot almost as often as they pecked at the model of an entire head with a red spot, but they pecked much less frequently at the model of an entire head that lacked a red spot.

Herring gulls *(Larus argentatus)*

© Johner Images/Alamy

Conclusion: Begging behavior by young herring gulls is triggered by a simple sign stimulus, the red spot on the parent's bill. Experimental tests revealed that herring gull chicks respond more to the presence of the contrasting spot than they do to the outline of an adult's head.

THINK LIKE A SCIENTIST Why might natural selection favor the evolution of a sign stimulus–fixed action pattern interaction as the mechanism through which herring gulls provide food to their offspring? What are the advantages of this interaction between offspring and parent relative to one in which parents simply regurgitate food for their offspring as soon as the parents return to the nest?

Source: N. Tinbergen and J. C. Perdeck. 1950. On the stimulus situation releasing the begging response in the newly hatched herring gull chick (*Larus argentatus argentatus* Pont.). *Behaviour* 3:1–39.

ent's bill releases the begging response of the young gull because the same response is triggered by an artificial bill that looks only vaguely like a herring gull's bill, as long as it has a dark contrasting spot near the tip **(Figure 56.2).** Thus, even very simple cues can activate fixed action patterns.

Natural selection has molded the behavior of some parasitic species to exploit the relationship between sign stimuli and fixed action patterns for their own benefit. For example, birds that are brood parasites lay their eggs in the nests of other species (see *Why It Matters* at the beginning of Chapter 53). When a brood parasite's egg hatches, the alien nestling produces exaggerated versions of sign stimuli that are ordinarily exhibited by its hosts' own chicks: opening its mouth, bobbing its head, and calling vigorously. These behaviors elicit vigorous feeding by the foster parents, and the young brood parasite often receives more food than the hosts' own young **(Figure 56.3).**

Although instinctive behaviors are often performed completely the first time an animal responds to a stimulus, they can be modified by an individual's experiences. For example, the fixed action patterns of a young herring gull change through time. Although the youngster initially begs by pecking at almost anything remotely similar to an adult gull's bill, it eventually learns to recognize the distinctive visual and vocal features associated with its parents. The chick uses this information to become increasingly selective about the stimuli that elicit its begging behavior. Thus, even largely instinctive behaviors can be modified in response to particular experiences during their early performances.

INDIVIDUAL DIFFERENCES IN INSTINCTIVE BEHAVIORS Because the performance of instinctive behaviors does not depend on prior experience, behavioral differences between individuals may reflect genetic differences between them. Stevan Arnold, then at the University of Chicago, tested that hypothesis by studying the innate responses of captive newborn garter snakes *(Thamnophis elegans)* to the olfactory stimuli provided by potential food items that they had never before encountered. Arnold measured the snakes' responses to cotton swabs that had been dipped in a smelly extract of banana slug *(Ariolimax columbianus),* a shell-less mollusk. A snake "smells" by tongue-flicking, which draws volatile chemicals into a special sensory organ in the roof of its mouth. If the young snake had been born to a mother captured in coastal California, where adult garter snakes regularly eat banana slugs, it almost always began tongue-flicking at the slug-scented cotton swab **(Figure 56.4).** By contrast, newborn snakes whose parents came from inland California, where banana slugs do not occur, rarely tongue-flicked at the swabs. Thus, although the coastal and inland snakes belong to the same species, their instinctive responses to the volatile chemicals associated with banana slugs were markedly different.

FIGURE 56.4 Genetic control of food preference. (A) Banana slugs *(Ariolimax columbianus)* are a preferred food of **(B)** an adult garter snake *(Thamnophis elegans)* from coastal California. **(C)** A newborn garter snake from a coastal population flicks its tongue at a cotton swab drenched with tissue fluids from a banana slug.

In another experiment, Arnold tested whether newborn snakes would feed on bite-sized chunks of slug. After a brief flick of the tongue, 85% of the newborn snakes from a coastal population routinely struck at the slug and swallowed it, despite having had no prior experience with this prey. By contrast, only 17% of newborn snakes from the inland population ate slugs consistently, even when no other food was available.

Arnold hypothesized that coastal and inland garter snakes possess different alleles at one or more gene loci controlling their odor-detection mechanisms, leading to differences in their behavior. To test this hypothesis, Arnold crossbred coastal and inland snakes. If genetic differences contribute to the different food preferences of the two snake populations, then hybrid offspring, which receive genetic information from each parent, should behave in an intermediate fashion. Results of the experiment confirmed his prediction: when presented with bite-sized chunks of slug, 29% of the newborn snakes of mixed parentage consumed them every time.

Many additional experiments have confirmed that genetic differences between individuals can translate into behavioral differences between them. *Insights from the Molecular Revolution* describes a striking example of a single gene that influences the grooming behavior of mice. Bear in mind that single genes do not control complex behavior patterns directly. Instead, the alleles present affect the kinds of enzymes that cells can produce, influencing the biochemical pathways involved in the development of an animal's nervous system. The resulting neurological differences can translate into a behavioral difference between individuals that have certain alleles and those that do not.

Learned Behaviors Depend on an Individual's Prior Experience

Unlike instinctive behaviors, learned behaviors are not performed completely the first time an animal responds to a specific stimulus. Instead, they change in response to the environmental stimuli that an individual experiences. Behavioral scientists generally define **learning** as a process in which experiences change an animal's behavioral responses. Different types of learning occur under different environmental circumstances. In this section we consider *imprinting, classical conditioning, operant conditioning, cognition,* and *habituation.*

Some animals learn the identity of a caretaker or the key features of a suitable mate during a *critical period,* a restricted stage of development early in life. This type of learning is called **imprinting.** For example, newly hatched geese imprint on their mother's appearance and identity, staying near her for months. And when they reach sexual maturity, they try to mate with other geese, which exhibit the visual and behavioral stimuli on

A Knockout by a Whisker: What is the function of disheveled genes in mice?

Almost all eukaryotic organisms share a series of developmental interactions called the *wingless/Wnt* pathway. The pathway was originally discovered in fruit flies, in which mutations in the pathway cause changes in the wings and other segmental structures.

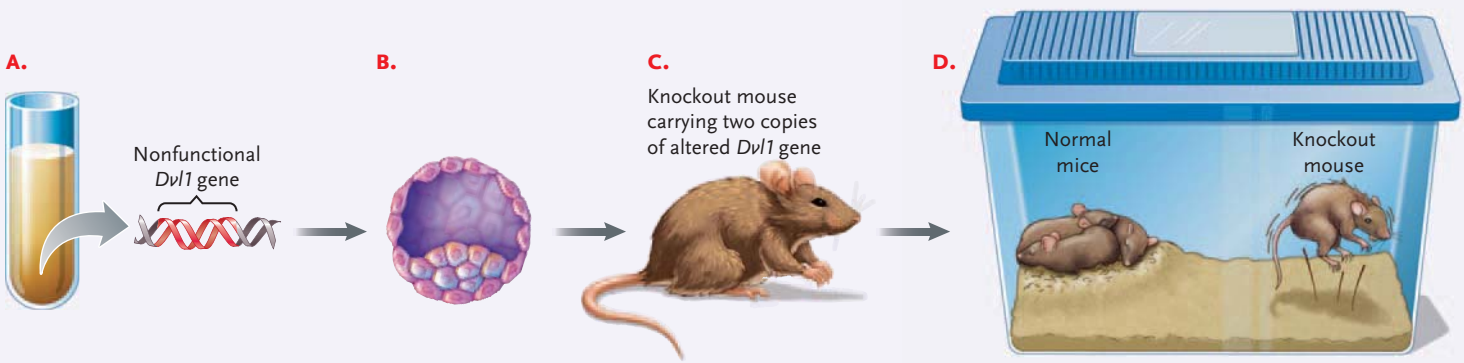
Research Question

The mouse genome includes three genes closely related to *disheveled (dsh),* one of the genes in the *Drosophila wingless/Wnt* pathway. No function has been identified for the proteins they encode, but they are highly active in both embryos and adults. Their function must be important, but what could it be?

Experiment

Nardos Lijam and his coworkers in several laboratories, including Case Western University, the Universities of Colorado and Maryland, and the National Institutes of Health in Bethesda, Maryland, answered this question by developing a line of mice that lacked *Dvl1,* one of the *disheveled* genes. First they constructed an artificial copy of *Dvl1* with the central section scrambled so that no functional proteins could be made from its encoded directions **(Figure A).** Next they introduced the artificial gene into embryonic mouse cells and injected the cells into very early mouse embryos **(Figure B).** Some mice grown from these embryos were heterozygotes, with one normal copy of the *Dvl1* gene and one nonfunctional copy. Matings between heterozygotes produced some individuals that carried two copies of the altered *Dvl1* gene and no normal copies. Individuals in which the normal gene is eliminated are called knockout mice for the missing gene **(Figure C).** (The procedure for making knockout mice is described in Section 18.2.)

Surprisingly, the knockout mice grew to maturity with no apparent morphological defects in any tissue examined, including the brain. Their motor skills, sensitivity to pain, cognition, and memory all appeared to be normal. However, their social behavior was a different story. When housed with normal mice, the knockouts failed to take part in common social activities: grooming, tail pulling, mounting, and sniffing. Rather than building nests and sleeping in huddled groups, as normal mice do, the knockouts tended to sleep alone in half-built nests. Heterozygotes for the *Dvl1* gene—that is, mice with one normal and one altered copy of the gene—behaved normally in all these social activities.



The knockout mice also jumped around wildly in response to abrupt, startling sounds while the response of normal mice was less extreme **(Figure D).** Because a specific neural circuit in the brain inhibits the startle response of normal mice, the reaction of the knockout mice suggested that this inhibitory circuit was probably altered. Humans with schizophrenia, obsessive-compulsive disorders, Huntington disease, and some other brain dysfunctions also show an intensified startle reflex similar to that of the *Dvl1* knockout mice.

Conclusion

The analysis revealed that the *Dvl1* gene modifies developmental pathways affecting complex social behavior in mice, and probably in other mammals. It was one of the first genes affecting mammalian behavior to be identified. The similarity in startle-reflex intensity between the knockout mice and humans with neurological or psychiatric disorders also suggests that mutations in the *Dvl* genes and the *wingless* developmental pathway may underlie some of these disorders. If so, further studies of the *Dvl* genes may give us clues to the molecular basis of these ailments as well as a possible means to their cure.

THINK LIKE A SCIENTIST If a recessive genetic mutation contributed to the development of a mental disorder in humans, could the genetic basis of the disorder be eliminated from the population?

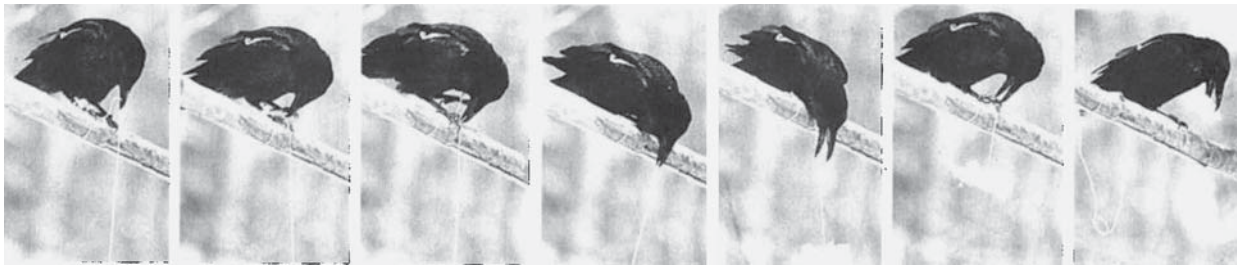
which they had imprinted as youngsters. When Konrad Lorenz, one of the founders of ethology, tended a group of newly hatched greylag geese *(Anser anser),* they imprinted on him instead of an adult of their own species **(Figure 56.5).** The male geese not only followed Lorenz about, but they also courted humans when they achieved sexual maturity.

Other forms of learning can occur throughout an animal's lifetime. Russian physiologist Ivan Pavlov's classic experiments with dogs explored **classical conditioning,** a type of learning in which animals develop a mental association between two phenomena that are usually unrelated. Dogs generally salivate when they eat. The food is called an *unconditioned stimulus* because the dogs respond to it instinctively; no learning is required for the stimulus (food) to elicit the response (salivation). In his experiment, Pavlov rang a bell just before offering food to dogs. After about 30 trials in which dogs received food immediately after the bell rang, the dogs associated the bell with feeding time, and they drooled profusely whenever it rang—even when no food was forthcoming. Thus, the bell became a *conditioned stimulus,* one that elicited a particular learned response. In classical conditioning, an animal learns to respond to a conditioned stimulus when it precedes an unconditioned stimulus that normally triggers the response.



In another form of associative learning, called trial-and-error learning or **operant conditioning,** animals learn to link a voluntary activity, called an *operant,* with its favorable consequences, called a *reinforcement.* For example, a laboratory rat will explore a new cage randomly. If the cage is equipped with a bar that releases food when it is pressed, the rat will eventually lean on the bar by accident (the operant) and immediately receive a morsel of food (the reinforcement). After just a few such experiences, a hungry rat will learn to press the bar in its cage more frequently—as long as bar-pressing behavior is followed by access to food. Laboratory rats also learn to press bars to turn off disturbing stimuli, such as bright lights.

Many researchers have wondered whether animals can solve a novel problem by using insight, "thinking up" a solution rather than making a series of trial-and-error attempts at resolving it. This process, called **cognition,** implies that an animal is aware of its circumstances, defines a specific goal, and then uses reasoning to achieve the goal. Bernd Heinrich of the University of Vermont demonstrated that common ravens *(Corvus corax)* used cognition to solve a problem that they (and presumably their ancestors) had never before encountered: how to capture a morsel of food that dangled below their perches on a string **(Figure 56.6).** After looking at the string and looking at the food, a raven pulled up a loop of string, secured it against the perch with its foot, and then reached down again to pull up another loop. After repeating these actions six or eight times, the raven gained access to the food.

Animals typically lose their responsiveness to frequent stimuli that are not quickly followed by the usual reinforcement. This learned loss of responsiveness, **habituation,** saves the animal the time and energy of responding to stimuli that are no longer important. For example, the sea hare *Aplysia,* a shell-less mollusk, typically responds to a touch on the side of its body by retracting its delicate gills, a response that helps protect it from approaching predators. But if an *Aplysia* is touched repeatedly over a short period of time with no harmful consequences, it stops retracting its gills.

THINK OUTSIDE THE BOOK

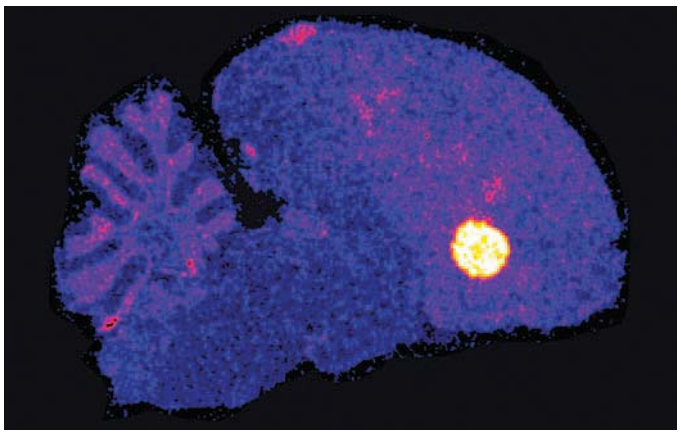
Observe a dog, a cat, or even a human baby and analyze its behavior over a few days. Try to identify examples of behaviors that result from classical conditioning, operant conditioning, and habituation. Explain why you think those types of learning produced the behaviors you observed.

56.2 Neurophysiological and Endocrine Control of Behavior

Research in neuroscience has shown that all behavioral responses, even those that are either mostly instinctive or mostly learned, depend on an elaborate foundation provided by the biochemistry and structure of neurons (nerve cells). The neurons that regulate an innate response as well as those that make it possible for an animal to learn something are products of complex developmental processes in which genetic information and environmental contributions are intertwined. Although the anatomical and physiological basis for some behaviors is present at birth, an individual's experiences alter cells of its nervous systems in ways that produce particular patterns of behavior.

Research on many animal species has also revealed that hormones are the chemical signals triggering the performance of specific behaviors. They often accomplish this function by regulating the development of neurons and neural networks or by stimulating the cells within endocrine glands to release chemical signals. In this section we use examples from research on several animal species to explore general principles about how neurophysiology and endocrine function influence behavior.

Discrete Neural Circuits in Specific Brain Regions Control Singing Behavior in Songbirds



Marler's experiments (see Section 56.1) help explain the physiological underpinnings of singing behavior in male white-crowned sparrows. If acoustical experience shapes this behavior, a sparrow chick's brain must be able to acquire and store information present in the songs of other males. Then, months later, when the young male starts to sing, its nervous system must have matched its vocal output to the stored memory of the song that it had heard earlier. Eventually, when it achieves a good match, the sparrow's brain must "lock" on the now complete song and continue to produce it when the bird is singing.

Additional experiments have provided detailed information about the nature of the sparrow's nervous system. Young birds that did not hear recorded song during their critical period, between 10 and 50 days old, never produced the full song of their species, even if they heard it later in life. In addition, young birds that heard recordings of *other* bird species' songs during the critical period never generated replicas of those songs as they matured. These and other findings suggested that certain neurons in the young male's brain are influenced only by the acoustical signals from individuals of its own species, and only during the critical period. Neuroscientists have identified the neuron clusters, called *nuclei* (singular, *nucleus*), that make song learning and song production possible.

Moreover, every behavioral trait appears to have its own neuroanatomical basis. For example, a male zebra finch, *Taeniopygia guttata,* another songbird, can discriminate between the songs of strangers and the songs of established neighbors on adjacent **territories.** (In many bird species, territories are plots of land, defended by individual males or breeding pairs, within which the territory holders have exclusive access to food and other necessary resources. Territories are discussed further in Section 56.4.) The ability to discriminate between the songs of neighbors and those of strangers also involves a nucleus in the forebrain. Cells in this nucleus fire frequently the first time that the song of a new zebra finch is played to a test subject. But as the song is played again and again, these cells cease to respond, indicating that the bird becomes habituated to a now familiar song, although it still reacts to the songs of strangers. The neurophysiological networks that make this selective learning possible enable male zebra finches to behave differently toward familiar neighbors, which they largely ignore, and unfamiliar singers, which they attack and drive away.

The Activation of Specific Genes Fosters the Development of Nuclei That Regulate a Bird's Song

Molecular and cellular techniques reveal that learning depends on the expression of specific genes in neurons. When a bird is exposed to relevant acoustical stimuli, such as the songs of potential rivals of its own species, certain genes are "turned on" within neurons in the song-controlling nuclei of the bird's brain. For example, when a zebra finch hears the elements of its species' song, a gene called *zenk* becomes active in certain regions of the brain, producing an enzyme that changes the structure and function of the neurons **(Figure 56.7).** In effect, the ZENK enzyme

programs the neurons of the bird's brain to "anticipate" key acoustical events of potential biological importance. When these events occur, they trigger additional changes in the bird's brain that affect its actions. As a result, a territory owner habituates to (that is, learns to ignore) a singing neighbor with which it has already adjusted territorial boundaries; but it retains the ability to detect and repel new intruders of its own species, which represent a real threat to its continued control of its territory.

Hormones Regulate the Development of Cells and Networks That Form the Neural Basis of Behavior

How did the neurons in an adult zebra finch acquire the remarkable capacity to change in response to specific stimuli? In zebra finches, only males sing courtship songs. Very early in a male songbird's life, certain cells in its brain produce the hormone estrogen, which affects target neurons in an area of the developing brain called the *higher vocal center.* The presence of this hormone leads to a complex series of biochemical changes that result in the production of more neurons in parts of the brain that regulate singing. By contrast, the brains of developing females do not produce estrogen, and in the absence of this hormone, the number of neurons in the higher vocal center of females *declines* over time **(Figure 56.8).** Experiments have shown that when young female zebra finches are given estrogen, they produce more neurons in the higher vocal center; but the treated females do not sing later in life unless they are also treated with androgens (male hormones).

Thus, genetically induced hormone production contributes to song learning and singing behavior in male zebra finches by regulating the numbers and types of neurons in the brain centers that produce those behaviors. The development of these neurons primes them for additional changes in response to specific acoustical experiences during the bird's development. For example, specific stimuli, such as the songs of either familiar or unfamiliar males, can trigger the expression of specific genes that influence the behavior of adult birds.

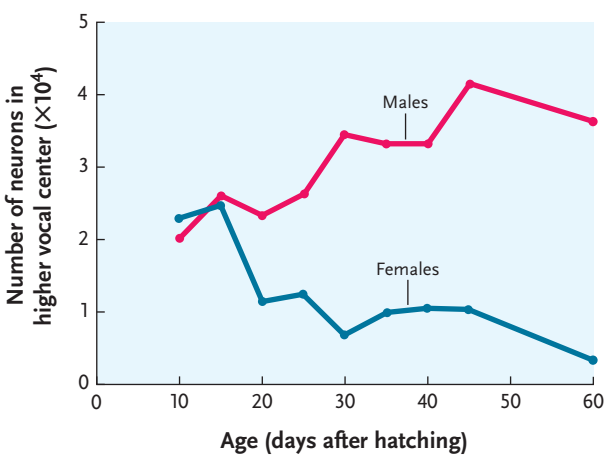

FIGURE 56.8 Hormonally induced changes in brain structure. The brains of young male zebra finches secrete estrogen, a hormone that stimulates the production of neurons in the higher vocal center; these changes contribute to song learning and singing behavior. Lacking this hormone, the brains of young female zebra finches lose neurons in the higher vocal center; females do not sing their species songs.

Changing Hormone Concentrations Alter the Behavior of Animals as They Mature

Just as estrogen influences the development of singing ability in zebra finches, other hormones mediate the development of the nervous system in other species. Indeed, a change in the concentration of a certain hormone is often the physiological trigger that induces important changes in an animal's behavior as it matures.

In honeybees *(Apis mellifera),* worker bees perform different tasks for the colony's welfare as they grow older: bees that are less than 15 days old tend to care for larvae and maintain the hive, whereas those that are more than 15 days old often make foraging excursions from the hive to collect the nectar and pollen that bees eat **(Figure 56.9).** These behavioral changes are induced by rising concentrations of juvenile hormone (see Section 42.5), which is released by a gland near the bee's brain. Despite its name, circulating levels of juvenile hormone actually increase as a honeybee gets older.

Juvenile hormone may exert its effect on the bee's behavior by stimulating genes in certain brain cells to produce proteins that affect nervous system function. One such chemical, *octopamine,* stimulates neural transmissions and reinforces memories. It is concentrated in the antennal lobes, a part of the bee's brain that contributes to the analysis of chemical scents in the bee's external environment. Octopamine is present at higher concentrations in the older, foraging bees that have higher levels of juvenile hormone. And when extra juvenile hormone is administered to bees experimentally, their production of octopamine increases. Thus, increased octopamine levels in the antennal lobes may help a foraging bee home in on the odors of flowers where it can collect nectar and pollen.

The honeybee example illustrates how genes and hormones interact in the development of behavior. Genes code for the production of hormones, which change the intracellular environment of assorted target cells. The hormones then directly or indirectly change the genetic activity and enzymatic biochemistry in their targets. If the cells in question are neurons, the changes in their biochemistry translate into changes in the animal's behavior.

Hormone Levels Affect Reproductive Activity in Many Animals

The African cichlid fish *(Haplochromis burtoni)* provides an example of how hormones regulate reproductive behavior. Some adult males maintain nesting territories on the bottom of Lake Tanganyika in East Africa. Territory holders are brightly colored, and they exhibit elaborate behavioral displays that attract egg-laden females to their territories. These males defend their

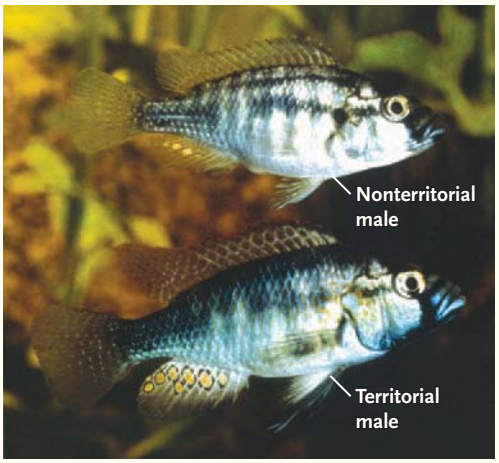
real estate aggressively against neighboring territory holders and against incursions by males that have no territories of their own. By contrast, nonterritorial males are much less colorful and aggressive; they do not control a patch of suitable nesting habitat, and they make no effort to court females.

The behavioral differences between the two types of males are caused by differences in their levels of circulating sex hormones. Recall from Section 49.3 that gonadotropin-releasing hormone (GnRH) stimulates the testes to produce testosterone and sperm. When the circulating testosterone is carried to the brain, it modulates the activity of neurons that regulate sexual and aggressive behavior. In territorial fish the GnRH-producing neurons in the hypothalamus are large and biochemically active, but in nonterritorial fish they are small and inactive. In the absence of GnRH, the testes do not produce testosterone; the testosterone-deficient fish do not court females with sexual displays, nor do they usually attack other males.

What causes the differences in the neuronal and hormonal physiology of the two types of male fish? Russell Fernald and his students at Stanford University conducted laboratory experiments in which they manipulated the territorial status of males **(Figure 56.10).** Four weeks later, they compared the coloration and behavior as well as the size of the GnRH-producing cells in the brains of the experimental fishes with those of the control males that had retained their original status. Males that had held territories in the past, but had then been defeated by another male, quickly lost their bright colors and stopped being combative. Moreover, their GnRH-producing cells were smaller than those of the successful territory-holding controls. Conversely, males that gained a territory in the experiment quickly developed bright colors and displayed aggressive behaviors toward other males. And the GnRH-producing cells in their brains were larger than those of fishes that had maintained their status as non-territory-holding controls.



The neuronal, hormonal, and behavioral differences between the two experimental groups of males are therefore correlated with a key environmental variable: success or failure in the acquisition and maintenance of a territory. The neurons that process this information transmit their input to the hypothalamus where it affects the size of the GnRH cells, which in turn dictates the hormonal state of the male. A decrease in GnRH production can turn a feisty territorial male into a subdued drifter, biding his time and building his energy reserves for a future attempt at defeating a weaker male and taking over his territory. If successful in regaining territorial status, the male's GnRH levels will increase again, and the once-peaceful male will revert to vigorous sexual and aggressive behavior.

Note the general similarity of these processes to those described for the white-crowned sparrow's song learning: the fish's brain possesses cells that can change their biochemistry, structure, and function in response to well-defined social stimuli. These physiological changes make it possible for the fish to modify its behavior, depending on its social circumstances. In the following sections, we consider the ecology and evolution of specific categories of behavior.

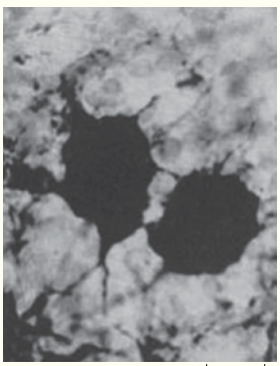
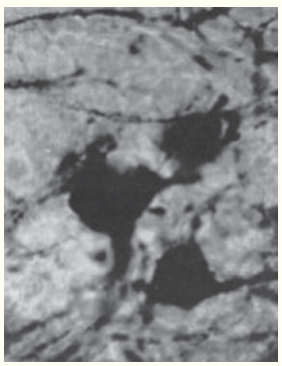
Effects of the Social Environment on Brain Anatomy and Chemistry

A. African cichlid fish *(Haplochromis burtoni)*



Russell Fernald, Stanford University

Question: How does the acquisition or loss of a territory affect the brain anatomy and chemistry of an African cichlid fish *(Haplochromis burtoni)*?



Experiment: Fernald and his students housed groups of male cichlids in aquariums in their laboratory. Males that established and maintained territories in the aquariums were brightly colored, whereas those that could not hold territories were pale and drab. The researchers then moved some small territorial males into tanks where larger males had already established territories. The newly introduced males could not establish and maintain territories under these experimental conditions, and therefore changed status from territorial to nonterritorial. The researchers also moved some large nonterritorial males into tanks with smaller territorial males. Under these experimental conditions, the newly introduced males quickly established and maintained territories, changing their status from nonterritorial to territorial. Other males, left in their original tanks so that their territorial status did not change, served as controls. Four weeks later, the researchers examined the brains of the experimental and control fish and measured the size of the neurons that produce GnRH, a hormone that stimulates bright coloration as well as aggressive behavior and mating behavior in males.

Result: The GnRH-producing cells in the brains of experimental males that had lost their territories were much smaller than those in the brains of control males that had maintained their territories. By contrast, the GnRH-producing cells in the brains of experimental males that had gained territories were much larger than those of control males that had never held territories.

56.3 Migration and Wayfinding

Most animals move through their environments at some stage of their life cycles. Although some species move only short distances to find suitable environmental conditions, many others undertake large-scale movements on a seasonal schedule.

Migrating Animals Make Long Round-Trips on a Seasonal Cycle

Many animal species undertake a seasonal **migration,** traveling from the area where they were born to a distant and initially

unfamiliar destination, and returning to their birth site later. The Arctic tern *(Sterna paradisaea),* a seabird, makes an annual round-trip migration of up to 70,000 km **(Figure 56.11).** Many other vertebrate species, including gray whales and salmon, also undertake long and predictable journeys. Even some arthropods migrate long distances. For example, spiny lobsters (*Panulirus* species) form long conga lines as they move between coral reefs and the open ocean floor on a seasonal cycle **(Figure 56.12).**

Mark Conlin/Getty Images

FIGURE 56.12 **Migrating arthropods.** Spiny lobsters *(Panulirus argus)* make seasonal migrations between coral reefs and the open ocean floor. As many as 50 individuals march in single file for several days.

Animals Use Wayfinding Mechanisms to Guide Their Movements

Moving animals use various wayfinding mechanisms to arrive at their destination. Biologists group these mechanisms into three general categories: *piloting, compass orientation,* and *navigation.* Many species probably use a combination of these mechanisms to guide their movements.

The simplest wayfinding mechanism is **piloting,** in which animals use familiar landmarks to guide their journey. For example, gray whales *(Eschrichtius robustus)* migrate from Alaska to Baja California and back using visual cues provided by the Pacific coastline of North America.

Some animals also use specific landmarks to identify their nest site or places where they have stashed food. In a famous experiment published in 1938, Niko Tinbergen showed that female digger wasps *(Philanthus triangulum),* which nest in soil, use visual landmarks to find their nests after flying off in search of food. Tinbergen arranged pinecones in a circle around one nest while the female was still inside. As she left, she flew around the area, apparently noting nearby landmarks. Tinbergen then moved the circle of pinecones a short distance away. Each time the female returned, she searched for her nest within the pinecone circle—but she never found it unless the pinecones were returned to their original position.

In a more sophisticated wayfinding mechanism, **compass orientation,** animals move in a particular direction, often over a specific distance or for a prescribed length of time. Some day-flying migratory birds, for example, orient themselves using the sun's position in the sky in conjunction with an internal biological clock. The internal clock allows the bird to use the sun as a compass, compensating for changes in its position through the day; the clock may also allow some birds to estimate how far they have traveled since beginning their journey. Other migratory animals use polarized light or Earth's magnetic field as a compass.

Some birds that migrate at night use the positions of stars to determine their direction. The indigo bunting *(Passerina cyanea),* for example, flies about 3,500 km from the northeastern United States to the Caribbean or Central America each fall, and makes the return journey each spring. Stephen Emlen of Cornell University demonstrated that these birds use celestial cues to direct their migration **(Figure 56.13).** Emlen confined individual buntings in cone-shaped test cages. He lined the sides of the cages with blotting paper, placed inkpads on the bottom, and kept the cages in an outdoor enclosure so that the birds had a full view of the sky. Whenever a bird made a directed movement, its inky footprints indicated the direction in which it was trying to fly. Emlen found that on clear nights in fall, the footprints pointed to the south; on clear nights in spring, they pointed north. On cloudy nights, when

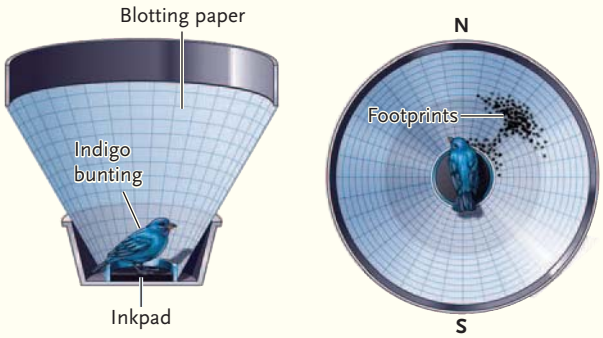
FIGURE 56.13 **Experimental Research**

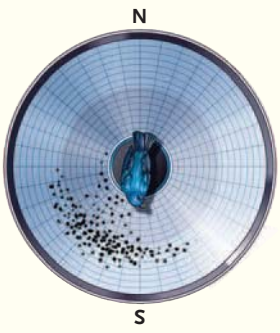
Experimental Analysis of the Indigo Bunting's Star Compass

Question: Do indigo buntings *(Passerina cyanea)* use the positions of stars in the night sky to orient their migrations?

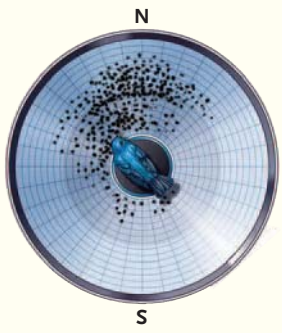


Experiment: Emlen placed individual buntings in cone-shaped test cages. He lined the sides of the cages with blotting paper, placed inkpads on the bottom, and kept the cages in an outdoor enclosure so that the birds had a full view of the sky. Whenever a bird made a directed movement, its inky footprints indicated the direction in which it was trying to fly. Emlen predicted that the footprints would show the buntings' inclination to migrate south in autumn and north in spring.

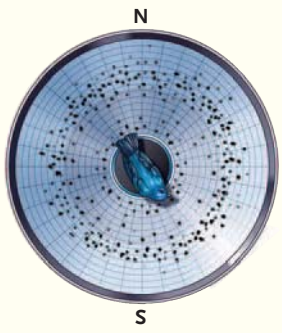
Results: On clear nights in autumn, the footprints pointed to the south; on clear nights in spring, they pointed north. On cloudy nights, when buntings could not see the stars, their footprints were evenly distributed in all directions.



Indigo bunting



John L. Absher/Shutterstock.com



Side (left) and overhead (right) views of the test cage with blotting paper on the sides and an inkpad on the bottom

In autumn, the bunting footprints indicated that they were trying to fly south.

In spring, the bunting footprints indicated that they were trying to fly north.

On cloudy nights, when buntings could not see the stars, their footprints indicated a random pattern of movement.

Conclusion: Indigo buntings use the positions of the stars to direct their seasonal migrations. When they could see the stars above their test cages, they moved in the predicted direction; but when clouds obscured their view of the stars, they moved in random directions.

THINK LIKE A SCIENTIST In this experiment, does the position of the stars stimulate buntings to make their migration, or does it simply give them cues about the direction in which they should fly?

Source: S. T. Emlen. 1967. Migratory orientation of the indigo bunting, *Passerina cyanea*. Part I: Evidence for use of celestial cues. *The Auk* 84:309–342.

the buntings could not see the stars, their footprints were evenly distributed in all directions, indicating that their compass required a view of the stars.

The most complex wayfinding mechanism is **navigation,** in which an animal moves toward a specific destination, using both a compass and a "mental map" of where it is in relation to the destination. Human hikers in unfamiliar surroundings routinely use navigation to find their way home: they use a map to determine their current position and the necessary direction of movement and a compass to orient themselves in that direction. Scientists have documented true navigation in only a few animal species. Perhaps the most notable is the homing pigeon *(Columba livia),* which can navigate to its home coop from any direction. Recent research suggests that homing pigeons probably use the sun's position as their compass and olfactory cues as their map.

Seasonal Variation in Food Supply May Explain the Evolution of Migratory Behavior

Migratory behavior entails obvious costs, such as the time and energy devoted to the journey and the risk of death from exhaustion or predator attack. Why then do some species migrate? What benefits accrue to an individual that undertakes a costly migration?

For migratory birds, the most widely accepted hypothesis focuses on seasonal changes in food supplies. The amount of insect food available in northern forests increases explosively during the warm spring and summer, providing abundant resources to produce eggs and rear offspring. Then, during the late fall and winter, insects all but disappear. A few bird species that forage on seeds and dormant insects do not head south. However, energy supplies are more predictably available in tropical overwintering grounds, and migratory birds may have a better chance of surviving there. The following spring they return north to exploit the food bonanza on their summer breeding grounds.

The two-way migratory journeys may provide other benefits as well. Avoiding the northern winter is probably adaptive

because endotherms must increase their metabolic rates just to stay warm in cold climates (see Section 48.8). But in summer the days are longer at high latitudes than they are in the tropics (see Section 51.2), giving adult birds more time to collect enough food to rear a brood.

Seasonal changes in food supply also underlie the migration of monarch butterflies *(Danaus plexippus),* the larvae of which eat only milkweed (*Asclepias* species) leaves. In eastern North America, milkweed plants grow only during spring and summer. Many adult monarchs head south in late summer, when milkweeds are beginning to die, migrating as much as 4,000 km from eastern and central North America to central Mexico, where they cluster in spectacular numbers **(Figure 56.14).** Unlike migrant birds, these insects do not feed on their overwintering grounds. Instead, their metabolic rate decreases in the cool mountain air, and the butterflies become inactive for months, thereby conserving precious energy reserves. When spring arrives, the butterflies become active again and begin the return migration to northern breeding habitats. The northward migration is slow, however, and many individuals stop along the way to feed and lay eggs. But their offspring, and their offspring's offspring, continue the northward migration through the summer; some descendants eventually reach southern Canada for a final round of breeding. The summer's last generation then returns south to the spot where their ancestors, two to five generations removed, spent the previous winter.

For other animals, the migration to breeding grounds may provide special conditions necessary for reproduction. For example, gray whales migrate south to breeding grounds in quiet, shallow lagoons where predators are rare and warm water temperatures will not stress their calves.

56.4 Habitat Selection and Territoriality

The geographical range of nearly every animal species includes a mosaic of habitat types. The breeding range of white-crowned sparrows, for example, encompasses forests, meadows, housing developments, and city dumps. An animal's choice of habitat is critically important because the habitat provides food, shelter, nesting sites, and the other organisms with which it interacts. If an animal chooses a habitat that does not provide appropriate resources, it will not survive and reproduce.

Animals Use Multiple Criteria for Selecting Habitats

On a large spatial scale, animals almost certainly use multiple criteria to select the habitats they occupy, but no research has yet established any general principles about how animals make these choices. When a migrating bird arrives at its breeding range, for example, it probably cues on large-scale geographical features, such as a pond or a patch of large trees. If it does not find the food or nesting resources it needs—or if other individuals have already depleted those resources—it may move to another habitat patch.

On a very fine spatial scale, basic responses to physical factors enable some animals to find suitable habitats. The simplest such mechanism is called a **kinesis** (*kinesis* = movement), a change in the rate of movement or the frequency of turning movements in response to environmental stimuli. For example, the terrestrial crustaceans known as wood lice (Isopoda) typically live under rocks and logs or in other damp places. Although these arthropods are not attracted to moisture *per se,* laboratory experiments have shown that when a wood louse encounters dry soil, it exhibits a kinesis, scrambling around and turning frequently; when it reaches a patch of moist soil, it moves much less. As a result, these animals accumulate in moist habitats. Biologists infer that this behavior is adaptive because wood lice exposed to dry soil quickly dehydrate and die. Other animals may exhibit a **taxis** (*taxis* = arrangement), a response that is directed either toward or away from a specific stimulus. For example, cockroaches (Blattodea) exhibit negative phototaxis: they actively avoid light and seek darkness, which are behaviors that make them harder for visually oriented predators to detect.

Genetics and Learning Influence Habitat Selection

Biologists generally assume that habitat selection is adaptive and has been shaped by natural selection in most animal species. For example, some animals instinctively select habitats where they are well camouflaged, a means of avoiding detection by predators (see Figure 53.3); predators would discover and eliminate any individual that fails to select a matching background—along with any alleles responsible for the mismatch. Many insects have a genetically determined preference for the plants that they eat during their larval stage. Adults often restrict their mating and egg-laying activities to these food plants, effectively selecting the habitats where their offspring will live and feed, as described in the discussion of sympatric speciation (see Section 22.3).

Vertebrates sometimes exhibit such innate preferences, as demonstrated by two closely related European bird species, blue tits *(Parus caeruleus)* and coal tits *(Parus ater).* Adult blue tits feed mostly in oak trees, whereas coal tits prefer to feed in pines. When Linda Partridge of Edinburgh University reared the young of both species in cages without any vegetation at all and then offered them a choice between oak branches and pine branches, coal tits immediately gravitated toward pines and blue tits toward oaks, strongly suggesting that the preference is innate **(Figure 56.15).** Further research demonstrated that each species feeds most successfully in the tree species it prefers. Thus, natural selection probably fostered these preferences.

Habitat preferences can be molded by experiences early in life, however. For example, the tadpoles of red-legged frogs *(Rana aurora)* usually live in aquatic habitats cluttered with sticks, strands of algae, and plant stems; when given a choice in the laboratory, they prefer striped backgrounds to plain ones. By contrast, tadpoles of the closely related cascade frog *(Rana cascadae)* live over gravel bottoms, and they prefer plain substrates over striped ones. However, when red-legged frogs are reared over plain substrates and cascade frogs over striped substrates, they no longer exhibit preferences for their usual substrates.

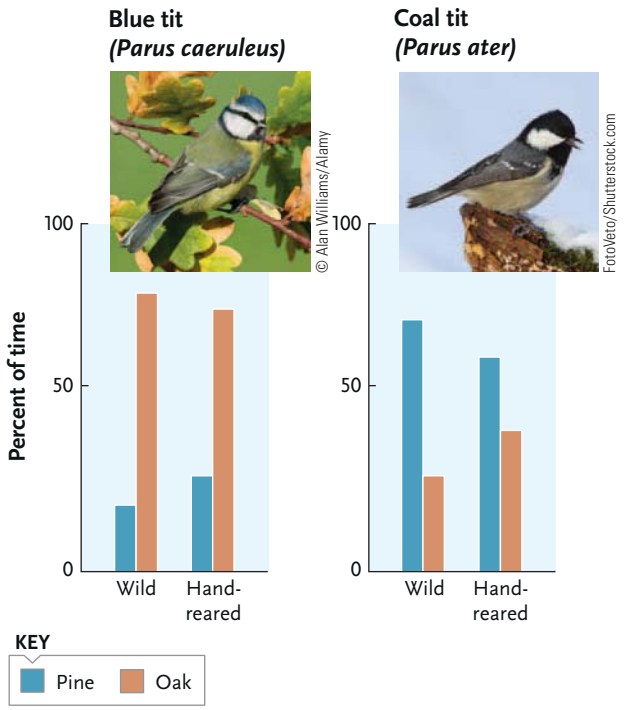

FIGURE 56.15 Habitat selection by birds. Wild blue tits show a strong preference for oak trees, and coal tits show a strong preference for pine trees. Birds that were hand-reared in a vegetation-free environment showed identical, though slightly weaker, preferences.

Animals Sometimes Defend Patches of Habitat for Their Exclusive Use

Under some circumstances, animals may defend a **territory** from other members of their species, retaining more or less exclusive use of the resources it contains. Territorial behavior occurs in all major groups of vertebrates, many insects, and some other invertebrates, but it is by no means universal. In many organisms, territorial behavior occurs only during the breeding season.

Animals establish and defend territories only if some critical resource is in short supply. Moreover, the resource must be fixed in space so that the area around it can be defended. For example, during the breeding season, most songbirds defend a territory within which they build a nest and collect food for their young. By contrast, most sea birds, such as terns and penguins, do not defend feeding territories. Although they defend a tiny area around the nest, which they build on shore, they never attempt to defend the patches of ocean where they collect food; fishes come and go at will and thus do not constitute a defendable resource.

Territorial defense is always a costly activity. Patrolling territory borders, performing displays hundreds of times per day, and chasing intruders take time and energy. Moreover, territorial displays increase an animal's likelihood of being injured or captured by a predator.

Experiments conducted by Catherine Marler and Michael Moore of Arizona State University illustrate the cost of territorial behavior in Jarrow's spiny lizard *(Sceloporus jarrovi).* Male lizards ordinarily exhibit strong territoriality only during the autumn mating season, when elevated blood levels of testosterone stimulate their aggressive behavior. The researchers implanted small doses of testosterone under the skin of experimental animals in June and July, during the *nonmating* season; controls received a placebo treatment. Testosterone-enhanced males were more active and displayed more often than control males. But even though experimental males spent less time feeding, they used about 30% more energy per day than control males. Over the course of about 7 weeks, a significantly higher percentage of experimental males died—a clear sign that engaging in territorial behavior is costly.

Maintaining a territory has definite benefits, however, such as having access to nesting sites, food supplies, and refuges from predators. For example, the surgeonfish *(Acanthurus lineatus),* which lives in the coral reefs around American Samoa, may engage in as many as 1,900 chases per day to defend a small territory from other algae-eating fish species. But territory holders consume up to five times more food than nonterritorial fish.

2. **What are the costs of maintaining a territory, and what are the benefits?**

56.5 The Evolution of Communication

When resident animals advertise their presence in their territories, they are communicating information to nearby animals. In the formal language of animal behavior studies, all communication systems involve an interaction between a *signaler,* the animal that transmits information, and a *signal receiver,* the animal that intercepts the information and makes a behavioral response. Natural selection has adjusted the ability of signalers to transmit information and the ability of receivers to get the message.

Animal Signals Can Activate Different Sensory Receptors in Receivers

Biologists categorize animal signals according to the sensory receptors, or "channels," through which the signal acts: *acoustical, visual, chemical, tactile,* or *electrical.* Each channel has specific advantages.

Bird songs are examples of **acoustical signals;** a signaler produces a sound that is heard by a signal receiver. Many animals use the acoustical channel, including a host of nocturnal and burrow-dwelling insects and amphibians. These signals reach distant receivers, even at night and in cluttered environments where visual signals are less effective.

Because humans frequently use facial expressions and body language to send messages, **visual signals** are a familiar form of communication. In many animals, visual signals are *ritualized;* in other words, they have become exaggerated and stereotyped over evolutionary time, forming an easily recognized visual display **(Figure 56.16).** Visual displays can even be useful at night or in the darkness of the deep sea; some animals, such as fireflies and certain fishes, send bioluminescent signals to distant receivers.

Many species release **chemical signals,** which carry messages to signal receivers through the olfactory channel. Scent

marking (spraying) by male dogs is an example. In particular, mammals and insects often communicate through **pheromones,** distinctive volatile chemicals released in minute amounts to influence the behavior of members of the same species. For example, a worker ant's body contains a battery of glands, each releasing a different pheromone **(Figure 56.17).** One set of pheromones recruits fellow workers to battle colony invaders; another set stimulates workers to collect food that has been discovered outside the colony. Other animals release pheromones to attract mates. Female silkworm moths *(Bombyx mori)* produce bombykol, a single molecule of which can generate a message in specialized receptors on the antennae of any male silkworm moth that is downwind (see Figure 41.19).

Kenneth W. Fink/Photo Researchers, Inc.

FIGURE 56.18 **Tactile signals.** Grooming by hyacinth macaws *(Anodorhynchus hyacinthinus)* removes parasites and dirt from feathers. The close physical contact also promotes friendly relations between groomer and groomee.

In many species, touch conveys important messages from a signaler to a receiver. **Tactile signals** operate only over very short distances, but for social animals living in close company, they play a significant role in the development of friendly bonds between individuals **(Figure 56.18).**

Some freshwater fish species, especially those that occupy murky tropical rivers where visual signals could not be seen, use weak **electrical signals** to communicate. These fishes have electric organs that can release charges of variable intensity, duration, and frequency, allowing substantial modulation of the message that a signaler sends. Among the New World knifefishes (Gymnotiformes), including the electric eel *(Electrophorus electricus),* electrical discharges can signal threats, submission, or a readiness to breed.

Honey Bees Use Several Communication Channels to Transmit Complex Messages

When animals need to convey a complex message, they may use several channels of communication simultaneously. For example, as Karl von Frisch demonstrated, the dance of the honey bee *(Apis mellifera)* involves tactile, acoustical, and chemical communication **(Figure 56.19).** When a foraging honey bee discovers pollen or nectar, it returns to its colony and performs a complex dance on the vertical surface of the honeycomb in the complete darkness of the hive. The dancer moves in a circle, attracting a crowd of work-

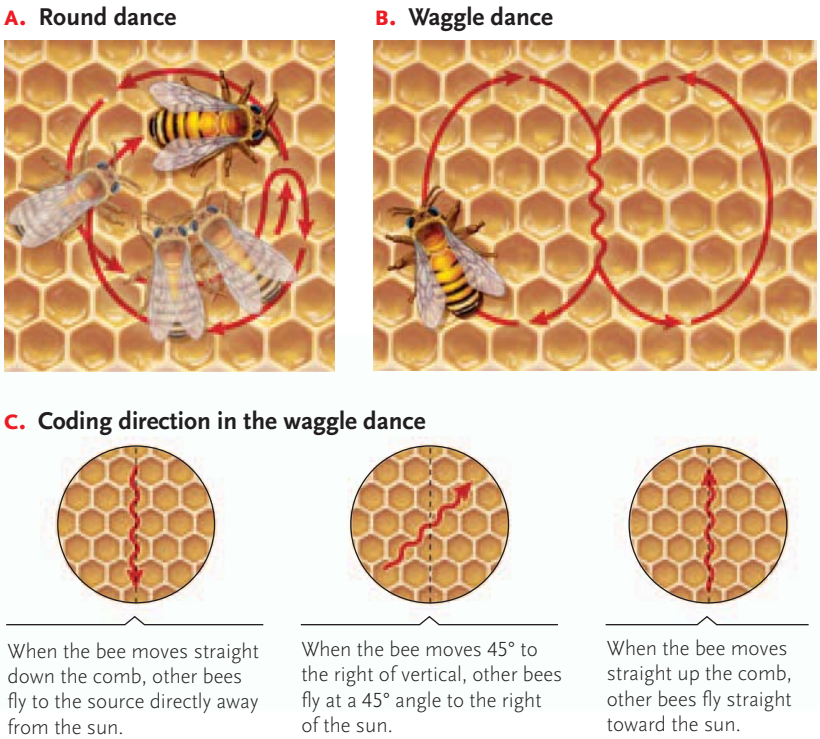

FIGURE 56.19 **Dance communication by honey bees.** Foraging honey bees *(Apis mellifera)* transmit information about the location of a food source by dancing on the vertical honeycomb. **(A)** If the food source is close to the hive, the forager performs a "round dance." **(B)** If the food source is more than about 75 m from the hive, the forager performs a "waggle dance" that indicates the distance to the food source. **(C)** The dancing bee indicates the direction to a distant food source by the angle of the waggle run.

ers, some of which follow and maintain physical contact with the dancer. From the dance, they acquire information about the distance and direction they will need to fly to locate the food source.

When the food source is less than about 75 m from the hive, the bee performs a "round dance" (see Figure 56.19A). It moves in tight circles, swinging its abdomen back and forth. Bees surrounding the dancer produce a brief acoustical signal, which stimulates the dancer to regurgitate a sample of the food it discovered. The regurgitated sample serves as a chemical cue to other workers, which then leave the hive to search for that type of food.

If the food source is more distant, the forager performs what von Frisch described as the "waggle dance." The bee dances a half circle in one direction and then dances in a straight line while waggling its abdomen before dancing a half circle in the other direction (see Figure 56.19B). With each waggle, the dancer produces a brief buzzing sound. Von Frisch determined that the angle of the straight run relative to vertical on the honeycomb indicates the direction of the food source relative to the position of the sun (see Figure 56.19C). The duration of the waggles and buzzes that the bee makes on the straight run carries information about the distance to the food; the longer the time spent waggling and buzzing, the further the food is from the hive.

Biologists Use Evolutionary Hypotheses to Analyze Communication Systems

Signal receivers often respond to communication from signalers in predictable ways. For example, a male white-crowned sparrow generally avoids entering a neighboring territory simply because it hears the song of the resident male. Similarly, young male baboons often retreat without a fight when they see an older male's visual threat display **(Figure 56.20),** even though they may lose the chance to mate with a female. Why do these receivers behave in ways that appear to be beneficial to their rivals, but not to themselves?

When biologists try to explain behavioral interactions, their hypotheses focus on how an animal's actions may allow it to contribute offspring to the next generation. In our first example, the retreating male sparrow avoids wasting time and energy on a battle he is likely to lose. Moreover, ousting the current resident might be more tiring and risky than finding a suitable unoccupied breeding site. This hypothesis predicts that resident males should almost always win physical contests. In cases when an intruder does win a territory from a resident, it may do so only after a prolonged series of exhausting clashes. Observations of territorial species—whether birds, lizards, frogs, fishes, or insects—generally support these predictions.

Applying a similar argument to competition among male baboons, we can predict that smaller or younger males will concede females to threatening older rivals without fighting. The signal receiver retreats after receiving the threat because he judges that he would be demolished in real combat—after all, a male baboon's canine teeth are not just for show. Evolutionary analyses therefore suggest that both the signaler and the signal receiver benefit from the transfer of information in their communication system.

An evolutionary analysis also helps to explain the strange yell of ravens *(Corvus corax),* which scavenge carcasses of deer, elk, or moose in northern forests during winter. When one of these large birds comes across a food bonanza, it may call loudly, attracting a crowd of hungry ravens. The calling behavior and sharing of resources puzzled Bernd Heinrich of The University of Vermont. Wouldn't a quiet raven eat more, survive longer, and produce more offspring than a noisy bird? If natural selection favored the raven's calling behavior, we might expect that the cost of calling (in terms of lost food) would be offset by a reproductive benefit for the individual caller. Heinrich noticed that paired, territory-owning adults did not yell loudly when they found goat carcasses that he had hauled into the Maine woods; instead, they fed quietly. Only young, wandering ravens that happened upon a carcass in another bird's territory advertised their discovery. The signals of these birds attracted other nonterritorial ravens, which collectively overwhelmed the resident pair's attempts to drive them away. Only then was a wanderer likely to have a chance to feed in an area that would otherwise be off-limits.

56.6 The Evolution of Reproductive Behavior and Mating Systems

In many animal species, communication coordinates the reproductive activities of males and females and governs the interactions between parents and offspring. In this section, we examine how several elements of behavior contribute to the reproductive success of individuals.

Males and Females Use Different Reproductive Strategies

In sexually reproducing species, males and females often differ in their overall **reproductive strategies,** the set of behaviors that lead to reproductive success. This difference arises in part from a fundamental difference in the amount of **parental investment,** the time and energy devoted to the production and rearing of offspring, provided by the two sexes. Because eggs are much larger than sperm, females almost always contribute more energy than males to the production of a gamete.

A male might increase the number of offspring that carry his alleles simply by mating with multiple females, especially if he does not spend time and energy providing parental care to his offspring. Thus, in many animal species, males compete intensely for access to females, and any trait that increases a male's access or attractiveness to females has a big reproductive payoff.

Entirely different selection pressures operate on females. Their reproductive output is generally limited by the number of eggs they can produce, and mating with multiple males will not increase that number. But the success of her offspring may depend on the attributes of their father or the territory he holds. Thus, females of many species choose their mates carefully. In some cases, females mate with males whose territories include abundant resources, ensuring an ample food supply for their young. In other cases, females choose robust males that will contribute "good genes" (that is, alleles that confer a high likelihood of surviving and reproducing) to her offspring, increasing their chances of long-term success.

Male Competition for Females and Female Mate Choice Foster Sexual Selection

Male competition for access to females coupled with the females' choice of mates establishes a form of natural selection called **sexual selection,** that is, selection for mating success (see Section 21.3). As a result of sexual selection, males are larger than females in many species, and males have ornaments and weapons, such as horns and antlers, that are useful for attracting females as well as for butting, stabbing, or intimidating rival males. Males typically show off these elaborate structures in complex **courtship displays** to attract the attention of females. For example, male peafowl *(Pavo cristatus)* strut in front of females while spreading a gigantic fan of tail feathers, which they shake, rattle, and roll **(Figure 56.21).**

Why should females choose males that display exaggerated structures conspicuously? Biologists have developed several hypotheses to explain the attraction. First, a male's large size, bright feathers, or large horns might indicate that he is particularly healthy, that he can harvest resources efficiently, or simply that he has managed to survive to an advanced age. These traits are, in effect, signals of male quality, and if they reflect a male's genetic makeup, he is likely to fertilize a female's eggs with sperm containing successful alleles. In some cases, big, showy males hold large, rich territories, and females that choose them gain access to the resources their territories contain.

© Bee2733|Dreamstime.com

FIGURE 56.21 Sexual selection for ornamentation. The attractiveness of a peacock *(Pavo cristatus)* to females depends in part on the number of eyespots on his extraordinary tail. The offspring of males with elaborate tails are more successful than the offspring of males with plainer tails.

The degree to which females *actively* choose genetically superior mates varies among species. In the northern elephant seal *(Mirounga angustirostris),* for example, female choice is passive. Large numbers of females gather on beaches to give birth to their pups before becoming sexually receptive again. Males locate these clusters of females and fight to keep other males away. The winners have exceptional reproductive success, but only after engaging in violent combat with rival males. In this kind of mating system, females are practically guaranteed to receive sperm from large and powerful males in superb physiological condition, attributes that may well be associated with alleles that will increase their offspring's chances of living long enough to reproduce.

In other species, females exercise more active mate choice, copulating only after inspecting a group of potential partners. Among birds, active female mate choice is most apparent at **leks,** display grounds where each male courts attentive females from a small territory. Male sage grouse *(Centrocercus urophasianus),* a lekking bird of western North America, gather in open areas among stands of sagebrush. Each male defends just a few square meters, where it struts in circles while emitting booming calls and showing off its elegant tail feathers and big neck pouches **(Figure 56.22).** Females wander among the displaying males, presumably analyzing the males' visual and acoustical displays. Eventually, each female selects a mate from among the dozens of males present. Females repeatedly favor males that come to the lek daily, defend their small area vigorously, and display more frequently than the average lek participant. In other words, favored males can sustain their territorial

FIGURE 56.22 Lekking behavior. Male sage grouse *(Centrocercus urophasianus)* use their ornamental feathers in visual courtship displays performed at a lek, where each male has his own small territory. The smaller brown females observe the prancing males before choosing a mate.

defense and high display rate over long periods, an ability that may correlate with useful genetic traits.

Experimental studies of peafowl suggest that the top peacocks at a lek may indeed supply advantageous alleles to their offspring. In nature, peahens prefer males whose tails have many ornamental eyespots (see Figure 56.21). In an experiment on captive birds, some females were mated to males with highly attractive tails, but others were paired with males whose tails were less impressive. The offspring of both groups were reared under uniform conditions for several months and then released into an English woodland. After three months on their own, the offspring of fathers with impressive tails survived better and weighed significantly more than did those whose fathers had less attractive tails. Apparently, a peahen's mate choice does provide her offspring with a survival advantage.

Another hypothesis argues that females select showy males even though their ornate structures and elaborate displays may impede their locomotion or attract the attention of a predator. According to this hypothesis, any male that survives *despite* carrying such a handicap must have a very strong constitution indeed, and he will pass those successful alleles—as well as the alleles responsible for the ornamental handicap—to the female's offspring.

Patterns of Parental Care and Territoriality Influence Mating Systems

In the examples of mate choice just described, successful males inseminate many females, increasing their reproductive success dramatically. But one male mating with many females is only one of several **mating systems,** the ways in which males and females pair up. Some species are **promiscuous:** individuals do not form close pair bonds, and both males and females mate with multiple partners. Other species are **monogamous:** one male and one female form a long-term association. Finally, some species are **polygamous:** *either* males *or* females may have multiple mating partners. If one male mates with many females, the relationship is called **polygyny;** if one female mates with multiple males, it is called **polyandry.**

Mating systems appear to have evolved to maximize reproductive success, partly in response to the amount of parental care that offspring require and partly in response to other aspects of a species' ecology. For example, the young of most songbird species, like the white-crowned sparrow, are helpless upon hatching; all they can do is open their mouths and peep, signaling to their parents that they are ready to be fed. These young require lots of parental care, and they are more likely to flourish if both parents bring food to the nest. As you might expect, nearly all songbirds are monogamous, and males and females team up to provide parental care to their offspring.

In some other bird species, such as red-winged blackbirds *(Agelaius phoeniceus),* males establish large, resource-filled territories, and females select mates largely by the quality of the real estate a male holds. Any male with an exceptionally fine territory will be desirable, even if another female has already established herself there. A second female may judge that more resources are available in his territory than in a neighboring one, despite competition with the other female. However, if many females have already settled in a male's territory, intense competition from them may make it less attractive. Given this pattern of habitat and mate choice by females, red-winged blackbirds have a polygynous mating system; males may fertilize the eggs of multiple females and provide little if any direct care to their offspring.

The Comparative Method Reveals How Nest-Building Behaviors Evolved in Swallows and Martins

Even before a pair of birds or other animals has mated, they often prepare a nest or den where they rear their young. The locations and structures of nests vary widely, sometimes even within a clade (that is, a monophyletic evolutionary lineage). For example, among the clade of birds that includes swallows and martins—two species of which are pictured at the opening of Chapter 22—some species excavate long nesting burrows in soil, others nest in preexisting cavities in rocks or trees, and still others build mud nests of varying complexity on vertical substrates. Given the extraordinary variety of nesting habits in these birds, biologists long wondered about the evolution of their nest-building behavior. Which type of nest is ancestral within the group? Do closely related species share the same nesting habits?

David W. Winkler of Cornell University and Frederick H. Sheldon of the Academy of Natural Sciences in Philadelphia used "the comparative method," combining phylogenetic analysis with observations on behavior, to investigate these questions. Using data from DNA hybridization studies, they constructed a phylogenetic tree for 17 swallow and martin species; a more distantly related bird species, the tufted titmouse *(Parus bicolor),* served as the outgroup **(Figure 56.23).** (You may wish to review the construction of phylogenetic trees in Section 24.2.) The phylogenetic

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

analysis revealed that both the outgroup and an African species in the clade, the black sawwing *(Psalidoprocne holomelas),* branched off the tree first; thus, their behaviors probably represent the ancestral condition. The remaining species fall into one of two subclades, the "core martins" and "*Hirundo* and its allies."

Winkler and Sheldon then superimposed data about nesting behaviors of the 18 species on the phylogenetic tree. Their results indicate that digging a nest burrow is the ancestral behavior because it is observed not only in the titmouse and African sawwings, but also in some "core martin" species that branched off the tree early in the group's evolution (on the left side of Figure 56.23). The analysis also shows that each of the other two nesting behaviors evolved once, presumably in the common ancestor of species that exhibit the behavior. Within the "core martins" clade, more recently derived species (all descended from one common ancestor) nest in preexisting cavities. Within the "*Hirundo* and its allies" clade, all species build mud nests on vertical substrates. The phylogenetic tree also illustrates how the three different patterns of mud nest construction (open mud cup, covered mud cup, and mud cup with entrance) evolved within the latter clade. Thus, superimposing nesting behaviors on the phylogenetic tree allowed the researchers to identify when each of the observed nest-building behaviors first evolved.

FIGURE 56.23 The comparative method, applied to nesting behavior in swallows and martins. Superimposing nest-building behaviors on a phylogenetic tree for 17 species of swallows and martins allowed researchers to determine the pattern in which these diverse behaviors evolved. The question marks indicate phylogenetic relationships that the analysis could not resolve precisely.

56.7 The Evolution of Social Behavior

Social behavior, the interactions that animals have with other members of their species, has profound effects on an individual's reproductive success. Some animals are solitary, getting together only briefly to mate (rhinoceroses and leopards); others spend most of their lives in small family groups (gorillas); still others live in groups with thousands of relatives (termites and honey bees). Some species, such as some African antelopes and humans, live in large social units composed primarily of nonrelatives.

Group Living Carries Both Benefits and Costs

Ecological factors have a large impact on the reproductive benefits and costs of social living. Groups of cooperating predators frequently capture prey more effectively than they would on their own. For example, white pelicans *(Pelecanus erythrorhynchos)* often encircle a school of fish before moving in for the kill. Conversely, prey that are subject to intense predation often gain safety in numbers. Those living in groups have more watchful eyes to detect an approaching predator. In addition, a predator may be confused when multiple prey scatter in many directions. Finally, few predators have the capacity to capture every individual in a prey cluster, so that some prey escape while the predator pursues others.

Some prey species, such as musk oxen *(Ovibos moschatus),* join forces to defend themselves actively (see the photo that opens this chapter). Even some insects, such as Australian sawfly caterpillars *(Perga dorsalis),* exhibit cooperative defensive behavior **(Figure 56.24).** When predators disturb the caterpillars, all members of the group rear up and writhe about, regurgitating sticky, pungent oils that they have collected from the eucalyptus leaves they eat. Although the caterpillars can store these oils safely, they are toxic and repellent to bird predators.

A group of sawflies regurgitates more repellent eucalyptus oils than a single individual, which may explain why these insects form their simple societies. If this hypothesis is correct, solitary individuals should be at greater risk of being eaten than those that live communally. Birgitta Sillén-Tullberg of the University of Stockholm, Sweden, tested this prediction by offering sawfly caterpillars to young great tits *(Parus major),* a songbird species. Birds that received caterpillars one at a time consumed an average of 5.6, but those that received them in groups of 20 ate an average of only 4.1 caterpillars. As Sillén-Tullberg had predicted, the caterpillars were somewhat safer in a group than on their own.

In some environments, the costs of social clumping can be significant. These costs may include increased competition for food. For example, when thousands of royal penguins *(Eudyptes schlegeli)* crowd together in huge colonies **(Figure 56.25),** the pressure on the local food supplies is great, increasing the risk of starvation. Communal living also facilitates the spread of contagious diseases and parasites. Nestlings in large colonies of cliff swallows *(Petrochelidon pyrrhonota)* are often stunted in growth because their nests are swarming with blood-feeding parasites, which move easily from nest to nest under crowded conditions. Such costs are probably why the vast majority of animals do not live in large, complex societies.

Fitness Varies among the Members of a Dominance Hierarchy

Recognizing the costs as well as the benefits of social living, biologists have examined features of social living that appear to reduce the fitness of some individuals. For example, some animal species form **dominance hierarchies,** social systems in which each individual's behavior is governed by its place in a highly structured social ranking. In a typical dominance hierarchy, the dominant or *alpha* individual rules the roost; subordinate individuals typically concede valuable resources to more dominant animals without so much as a peep of protest.

Although dominant individuals gain first access to resources, they also incur costs. Frequent challenges from lower ranking individuals may induce a stress response in dominant animals, which must constantly defend their status. For example, in some primates, wild dogs, and other mammals, dominant males have higher blood levels of cortisol and other stress-related hormones (see Section 42.4) than do subordinates. Elevated cortisol levels may induce high blood pressure, the disruption of sugar metabolism, and other pathological conditions.

Why does a subordinate remain in the group when dominant companions reduce its chances for reproductive success? A possible explanation is that survival rates and reproductive success may be even lower for animals that live by themselves: a solitary baboon surely quickens the pulse of a passing leopard **(Figure 56.26).** A subordinate member of a group gains the benefits, such as protection against predators, that come with being part of the group. Low-ranking males may even have the chance to mate with one of the group's females when dominant males are not watching, thus ensuring some representation of their alleles in the next generation. And if a low-ranking individual lives long enough, its social superiors may be toppled by predation, accidents, or old age, and a one-time subordinate may find itself high on the social register with food and mates galore.

FIGURE 56.26 The cost of living alone. A solitary olive baboon *(Papio anubis)* confronts a leopard *(Panthera pardus)* bravely, but without much chance of survival.

Kin Selection May Explain Altruistic Behavior in Some Animal Species

In some species, group members appear to sacrifice their own reproductive success to help individuals that are not their direct descendants; such behaviors are collectively called **altruism.** For example, subordinate members of a wolf pack do not reproduce, but they share captured prey with the dominant pair and that pair's offspring. Altruistic behavior, by its very definition, appears to contradict a basic premise of Darwinian evolutionary theory, namely that natural selection favors traits that increase an *individual's* relative fitness. Why don't subordinate wolves simply save the energy spent on helping, bide their time until they can become dominant, and then produce their own offspring?

Behavioral ecologist William D. Hamilton of University College, London, provided a solution to this puzzle. He recognized that alleles favoring altruism could be propagated indirectly if altruistic individuals sacrificed personal reproduction to help their relatives reproduce. Helping relatives in this way can propagate the helper's own genes because the family shares alleles inherited from their ancestors.

We can quantify the average percentage of alleles that relatives are likely to share by calculating their degree of relatedness **(Figure 56.27).** We start by considering half siblings who, by definition, share only one genetic parent. Half siblings share on average 25% of their alleles by inheritance from their shared parent, making their degree of relatedness 0.25. By contrast, full siblings, who share the same genetic mother *and* father, share 25% of their alleles through the mother *and* 25% of their alleles through the father, for a total, on average, of 25% + 25% = 50% of their alleles. In other words, the degree of relatedness for full siblings is 0.50. The degree of relatedness between a nephew or niece and an aunt or uncle is 0.25, and the degree of relatedness between first cousins is 0.125. Thus, individuals should be more likely to help close relatives because, by increasing a close relative's fitness, the individual is helping to propagate some of its own alleles.

If altruistic behavior reduces the reproductive success of an individual exhibiting that behavior, how could an allele that promotes altruistic behavior persist or even increase in frequency in a population? The answer depends on the overall number of offspring that carry the allele in the next generation. Altruistic behavior may increase the survival of the altruist's relatives—and they may share the allele in question. If the altruistic behavior allows the assisted relatives to produce proportionately more offspring than the altruist might have produced without helping them, the allele for altruism can increase in frequency in the population. This form of natural selection is aptly called **kin selection.**

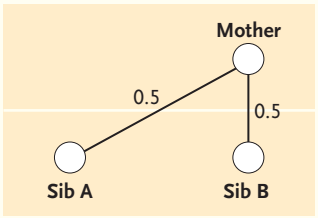
FIGURE 56.27 **Research Method**

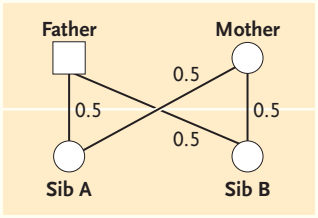
Calculating Degrees of Relatedness



Purpose: The kin-selection hypothesis suggests that the extent of altruistic behavior exhibited by one individual to another is directly proportional to the percentage of alleles they share. The hypothesis therefore predicts that individuals are more likely to help close relatives because, by increasing a close relative's fitness, the individual is helping to propagate some of its own alleles. Researchers calculate the degree of relatedness between individuals to test this prediction.

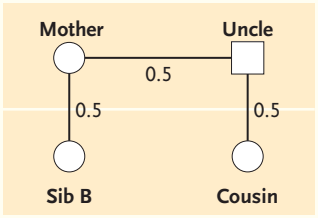
Protocol: To calculate the degree of relatedness between any two individuals, we first draw a family tree that shows all of the genetic links between them. The alleles of a parent are shuffled by recombination and independent assortment in the gametes they produce, so we can calculate only the average percentage of a parent's alleles that offspring are likely to share.

We start by considering *half* siblings, those who share only one genetic parent. Each sibling receives half of its alleles from its mother. Because a parent has only two alleles at each gene locus, the probability of sibling A getting a particular allele from its mother is 0.5 (decimal notation for 50%). Similarly, the probability of sibling B getting the same allele from its mother is also 0.5. Statistically, the probability that two independent events—in this case, the transfer of an allele to sibling A *and* the transfer of *the same* allele to sibling B—will both occur is the product of their separate probabilities. For half-siblings, we multiply the probabilities of the two links in the chain that connect them to calculate the likelihood that both siblings receive the same allele from their mother: $0.5 \times 0.5 = 0.25$; thus, the degree of relatedness for half siblings is 0.25.



Now consider two *full* siblings, who share the same genetic mother *and* father. They are connected to each other by two chains of relatedness; by multiplying the probabilities associated with the links in each chain, they share 25% of their alleles through the mother *and* 25% of their alleles through the father. After multiplying the probabilities for the links in each chains, we *add* the probabilities for the two chains. Thus, the degree of relatedness for full siblings is $0.25 + 0.25 = 0.50$.

Half siblings



Relatedness = (0.5) (0.5) = 0.25

Full siblings

Relatedness
Through mother = (0.5) (0.5) = 0.25
Through father = (0.5) (0.5) = 0.25
Total relatedness = 0.25 + 0.25 = 0.5

First cousins

Relatedness = (0.5) (0.5) (0.5) = 0.125

Interpreting the Results: Each link drawn between a parent and an offspring or between full siblings indicates that those two individuals share, on average, 50% of their alleles. We can calculate the total relatedness between any two individuals by multiplying out the probabilities across all of the links between them. Thus, the degree of relatedness between a niece and an uncle is 0.25, and the degree of relatedness between first cousins is 0.125.

© Cengage Learning 2014

For example, suppose a male wolf helps his parents rear four pups to adulthood, pups that would have died without the extra assistance provided by the altruist. Because the pups are his siblings, they share 50% of his genes; thus, on average the helper wolf has created "by proxy" two ($0.50 \times 4 = 2$) copies of any allele that contributed to his altruistic behavior. The costs of his altruism must be measured against this indirect reproductive success. If he had abstained from altruism, the helper wolf might have raised, say, two surviving offspring of his own. Each of his offspring would carry half of his alleles, preserving just one ($0.50 \times 2 = 1$) copy of a given allele. Under these hypothetical circumstances, reproducing on his own would have resulted in lower fitness (that is, fewer copies of his alleles in the next generation) than helping to raise his siblings. Evolutionary biologists use the term **inclusive fitness** to describe the sum of an individual's classical fitness (that is, the number of successful offspring it produces) plus the fitness gained through the offspring produced by its relatives.

Although our example of the altruistic wolf is hypothetical, biologists have observed sibling helpers in many bird and mammal species. The phenomenon is especially common among animals in which inexperienced young adults are unable to control sufficient resources to reproduce successfully on their own. Their altruistic behavior not only assists reproduction by their close relatives, but it may also provide useful practice for rearing their own future offspring.

Hamilton's kin-selection hypothesis explains altruistic behavior between closely related individuals, but behavioral biologists have also observed examples of altruism between

nonrelatives. For example, the common vampire bat *(Desmodus rotundus),* which feeds on the blood of sleeping mammals, must consume a meal every two days to avoid starving to death. Bats that have consumed a large meal often share their bounty with unrelated members of their group. Why would one bat share its resources with a nonrelative? Robert Trivers, then of Harvard University, proposed that individuals will help nonrelatives if they are likely to return the favor in the future. Trivers called this form of altruistic behavior **reciprocal altruism,** because each member of the partnership can potentially benefit from the relationship. Trivers hypothesized that reciprocal altruism would be favored by natural selection as long as individuals that do *not* reciprocate—called "cheaters" by behavioral biologists—are denied future aid. Observations of vampire bats and some other animals have confirmed Trivers' hypothesis: when a vampire bat accepts a "blood donation" from another bat, but then refuses to share food that it has collected, the other bats refuse to share their food with it in the future.

An Unusual Genetic System May Explain Altruism in Eusocial Insects

Hamilton's insights lead to a critical prediction about self-sacrificing behavior: altruism should usually be directed to close relatives. The evidence from many animal species overwhelmingly supports this prediction, but some species of ants, bees, wasps, and termites, those known as eusocial insects, provide a truly remarkable example. In **eusocial** insects, thousands of related individuals—a large percentage of them sterile female workers—live and work together in a colony for the reproductive benefit of a single queen and her mate(s). The workers may even die in defense of their colonies. How did this self-sacrificing social behavior evolve, and why does it persist over time? The failure of altruistic workers to reproduce should doom any alleles that promote altruism to early extinction.

For example, in a honey bee *(Apis mellifera)* colony, which may contain 30,000 to 50,000 related individuals, the only fertile female is the queen bee; all of the workers are her daughters **(Figure 56.28).** The queen's role in the colony is to reproduce. The workers perform all other tasks in maintaining the hive, from feeding the queen and her larvae to constructing new honeycomb and foraging for nectar and pollen. They also transfer food to one another and sometimes guard the entrance to the hive. Some pay the ultimate sacrifice when they sting intruders: this act of defense tears open the bee's abdomen, leaving the stinger and the poison sac behind in the intruder's skin, but killing the bee.

Why do bees and other eusocial insects devote their entire lives to helping their mother produce hundreds of thousands of eggs? One answer may lie in a genetic phenomenon called **haplodiploidy,** an unusual pattern of sex determination in these insects **(Figure 56.29).** Like many other organisms, female bees are diploid, receiving one set of chromosomes from each parent. But male bees are haploid: they hatch from unfertilized eggs. When a queen bee mates with one drone (a male), all of the sperm he delivers are genetically identical because males have only one set of chromosomes. Thus, all workers inherit exactly the same set of alleles from their male parent, producing a 50% degree of relatedness among them. Like other diploid organisms, the workers are also related to each other by an average of 25% through their female parent. Adding these two components of relatedness, we see that *on average* workers are related to each other by 75%, a higher degree of relatedness than they would have to any offspring they produced if they were fertile.

This extremely high degree of relatedness among the workers in some eusocial insect colonies may explain their exceptional level of cooperation. When Hamilton first worked out this explanation of social behavior in these insects, he suggested that the workers devote their lives to caring for their siblings—the queen's other offspring—because a few of those siblings, which carry 75% of the workers' alleles, may become future queens and produce enormous numbers of offspring themselves.

CLOSER LOOK

FIGURE 56.29 Haplodiploidy in social insects.

SUMMARY The genetic system of eusocial insects produces full siblings that have an exceptionally high degree of relatedness. Although this simplified model ignores recombination between the queen's two sets of chromosomes, it demonstrates how half the workers are related to each other by 50% and half are related to each other by 100%. Thus, the average degree of relatedness among workers is 75%. Including recombination would complicate the illustration, but the conclusion would be the same.

THINK LIKE A SCIENTIST How would the average degree of relatedness among workers in a bee colony change if the queen mated with two drones instead of just one?

UNANSWERED QUESTIONS

Who else is watching and listening?

Studies of communication have typically concentrated on the signaler and the intended receiver. But others are lurking in the background—eavesdroppers who are also attending to these signals. These third parties often use the signal to the signaler's detriment. Some flies, for example, listen for calling male crickets and deposit their larvae on the caller; the larvae eventually kill the cricket as they use him as a food source. Sometimes the signal that makes a male more attractive to females has the same effect on eavesdroppers. Male túngara frogs, for example, can add a "chuck" to the "whine" component of their call. These more complex calls make them more attractive to female frogs but also increase their risk of being captured by frog-eating bats or found by blood-sucking flies. Other animals circumvent this cruel bind by evolving signals in "private channels" to which intended receivers, but not predators, are privy. Ultraviolet signals in swordtail fishes and electrical signals in weakly electric fish are two examples. Increasingly, communication systems are being analyzed from the perspective of a complex communication network rather than the more simple two-way interactions.

Why do females prefer attractive mates?

One reason that females prefer attractive mates is that females can use the ornaments of males to judge their quality in terms of performance and survivorship. A superior male might provide better resources for the female and her offspring, or even pass on better genes to their young. Alternatively, male courtship traits must stand out against a sometimes chaotic background of environmental noise and signals from competing males. To stand out more than others, males might evolve signals that are better at stimulating the female's sensory, neural, and cognitive systems. If a species has evolved visual pigments that allow individuals to locate orange fruit, for example, males should evolve orange colors, because they

will better stimulate the female's visual system. Such a scenario has been suggested for guppies. Researchers who study *sensory drive* try to understand how selection on sensory systems in one context, such as feeding, can influence functions in other contexts, such as mate choice.

To what degree is human behavior influenced by natural selection?

Cooperative and altruistic behavior sometimes evolve in animal societies. Since all societies face similar basic challenges, it is not surprising that cooperation can also be important in human societies. Strong evidence suggests that cooperation has evolved under selection in animal societies, but does logic demand that it has evolved under selection in humans as well? If not, what data would provide strong evidence for the evolution of human social behavior?

The field of evolutionary psychology, which poses these questions, is constrained because the invasive experimental approaches that have been so successful in animal biology cannot be applied to humans. Here the cross-cultural, comparative approach has made some important advances. These questions are being pursued by researchers in biology and psychology as well as anthropology and sociology. This mix of researchers with different approaches guarantees excitement and controversy about these very basic questions that ask why we are who we are.

THINK LIKE A SCIENTIST Tamarins, a group of small-bodied New World monkeys, usually give birth to fraternal (nonidentical) twins. Cells are sometimes exchanged between the two fetuses during development, resulting in chimeras. One male, for example, might have sperm cells which, according to their genetic constitution, are his brother's sperm and not his. This phenomenon explains the results of a laboratory study in which the genetic father of some offspring was really their uncle, who lived in a distant cage, and not the presumed "father," who was caged with the mother. Given what we know about how degrees of relatedness influence altruistic behavior, how might this phenomenon influence the social behavior of tamarins in the wild?

Michael J. Ryan

Michael J. Ryan is the Clark Hubbs Regents Professor in Zoology at The University of Texas at Austin, where he studies the evolution and function of animal behavior. Most of his work has addressed sexual selection and communication in frogs and fish. To learn more about Dr. Ryan's research, go to http://www.sbs.utexas.edu/ryan/.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

56.1 Instinctive and Learned Behaviors

- Although most behaviors have both instinctive and learned components, many are either largely instinctive or largely learned (Table 56.1). Some behaviors are produced only if the animal's nervous system acquires inputs from specific experiences during a critical stage of its development (Figure 56.1).
- Instinctive behaviors are those that an animal performs completely the first time it is presented with a stimulus.
- Fixed action patterns are highly stereotyped behaviors that animals exhibit in response to simple cues called sign stimuli (Figures 56.2 and 56.3). Fixed action patterns often change through time in response to an animal's experiences.
- Behavioral differences between individuals often reflect underlying genetic differences. Research on garter snakes suggests that certain food preferences are genetically based (Figure 56.4).
- Learned behaviors develop only after an animal has had certain experiences in its environment. The different forms of learning include imprinting (Figure 56.5), classical conditioning, operant conditioning, and cognition (Figure 56.6). Habituation is a learned loss of responsiveness to specific stimuli.

56.2 Neurophysiological and Endocrine Control of Behavior

- Animal behavior requires an anatomical, physiological, and biochemical foundation based in the nervous system. An individual's experience alters cells of the nervous system in ways that produce particular patterns of behavior.
- The physiological basis of bird singing behavior resides in specific neuron clusters, called nuclei, that communicate with each other in the bird's brain.
- Bird song and some other behaviors develop only after specific genes are activated within the neurons that produce the behavior (Figure 56.7).
- Hormones can mediate the expression of specific behaviors by activating genes that change the biochemistry, morphology, and number of neurons in specific nuclei. Estrogen stimulates the production of neurons in the higher vocal center of male zebra finches (Figure 56.8).
- Age-related changes in hormone levels can alter the behavior of animals over the course of their lives. Changes in juvenile hormone concentration are correlated with changes in task specialization in honeybees (Figure 56.9).
- Behavioral interactions with other individuals can alter an animal's hormone levels, inducing changes in its behavior. Research on male cichlid fishes suggests that variations in coloration and aggressive behavior associated with territorial status and social interactions are mediated by the production of certain hormones (Figure 56.10).

Animation: Hormonal control of behavior

56.3 Migration and Wayfinding

- Some animals migrate seasonally, traveling from their birthplace to a distant locality and back again (Figures 56.11 and 56.12).
- Migrating animals use various behaviors to find their way. In piloting, animals use familiar landmarks to guide their journey. In compass orientation, animals use the position of the sun or stars, polarized light, or the Earth's magnetic field as a guide (Figure 56.13). In navigation, animals use mental maps of their position to find their destination.
- Biologists often interpret migratory behavior as an adaptive response to changing food supplies (Figure 56.14). Some animals breed in northern habitats when food is plentiful during the spring and summer. They generally head south to seasonally more productive habitats before the onset of winter.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

56.4 Habitat Selection and Territoriality

- Animals use multiple criteria to select their habitats.
- Kineses and taxes help animals orient to appropriate portions of the habitats they occupy.
- Habitat selection often has a largely genetic basis, but learning and prior experience influence habitat selection in some species (Figure 56.15).
- Animals may maintain territories to gain exclusive use of defendable resources that are in short supply. The costs of territoriality include the time and energy devoted to territory defense, the risk of injury from fights, and exposure to predators.

56.5 The Evolution of Communication

- Animal communication occurs between a signaler, which sends a message, and a signal receiver, which receives and interprets the message.
- Animals communicate using acoustical, visual, chemical, tactile, or electrical signals (Figures 56.16–56.18). Each sensory channel provides specific advantages. Animals may use more than one channel simultaneously.
- Honey bees use a combination of tactile, acoustical, and chemical channels to share information about the location of food sources (Figure 56.19).

Animation: Honeybee dances

56.6 The Evolution of Reproductive Behavior and Mating Systems

- Males and females exhibit different reproductive strategies. Males can increase their reproductive success by inseminating the eggs of many females. Females generally seek mates that provide successful alleles to offspring, have access to abundant resources, or help care for young.
- Males often compete for access to females (Figure 56.20). Sexual selection has produced elaborate structures that males use for displays and for aggressive interactions with other males (Figures 56.21 and 56.22). Females may prefer males that have showy structures and great stamina, which are signs that they possess successful alleles.
- The type of mating system a species uses is tied to its pattern of territoriality and the amount of parental care the male parent provides.
- The comparative method allows biologists to trace the evolution of specific behaviors, such as nest building, by superimposing the behaviors on a phylogenetic tree for the lineage (Figure 56.23).

56.7 The Evolution of Social Behavior

- Social interactions between individuals have both benefits and costs. Group living may provide better protection from predators, more efficient feeding, and communal care of young (Figures 56.24 and 56.26). The costs of living in a group include increased competition for scarce resources and an increase in the spread of contagious diseases (Figure 56.25).
- Dominance hierarchies are highly structured societies in which some individuals have high status and first access to resources.
- Altruistic behavior appears to contradict Darwinian evolutionary theory, because altruistic individuals sacrifice their own fitness for the benefit of others. However, kin selection may ensure that individuals display altruistic behavior to close relatives that share some of their alleles (Figures 56.27).
- An unusual mechanism of sex determination, haplodiploidy, makes the workers in some eusocial insect colonies more closely related to each other than siblings in most species are (Figures 56.28 and 56.29). Haplodiploidy may have fostered the evolution of highly altruistic behavior.

UNDERSTAND & APPLY

Test Your Knowledge

1. Marler concluded that white-crowned sparrows can learn their species' song only:
   a. after receiving hormone treatments.
   b. during a critical period of their development.
   c. under natural conditions.
   d. from their genetic father.
   e. if they are reared in isolation cages.
2. A stimulus that always causes an animal to behave in a highly stereotyped way is called:
   a. fixed action pattern.
   b. an instinct.
   c. habituation.
   d. a sign stimulus.
   e. a reinforcement.
3. Arnold's experiments on the feeding preferences of garter snakes demonstrated that food choice is largely governed by a snake's:
   a. early experiences.
   b. genetics.
   c. size and color.
   d. diet while it was developing inside its mother.
   e. trial-and-error learning.
4. The development of the song system in male songbirds depends on:
   a. direct connections between sensory neurons and motor neurons.
   b. a decrease in the number of neurons in the song system.
   c. the behaviors of females, which stimulate hormone production.
   d. the successful defense of a territory.
   e. the production of estrogen early in life.
5. In cichlid fishes, high levels of the hormone GnRH:
   a. make females more receptive to male attention.
   b. cause males to be sexually aggressive but not territorial.
   c. stimulate a male to defend its territory.
   d. cause males to abandon their territories.
   e. cause males to lose their bright colors.
6. Which of the following statements about animal migration is true?
   a. Piloting animals use the position of the sun to acquire information about their direction of travel.
   b. Animals migrating by compass orientation use mental maps of their position in space.
   c. Navigating animals use familiar landmarks to guide their journey.
   d. Navigating animals use a compass and a mental map of their position to reach a destination.
   e. Most migrating birds use olfactory cues to return to the place where they hatched from eggs.

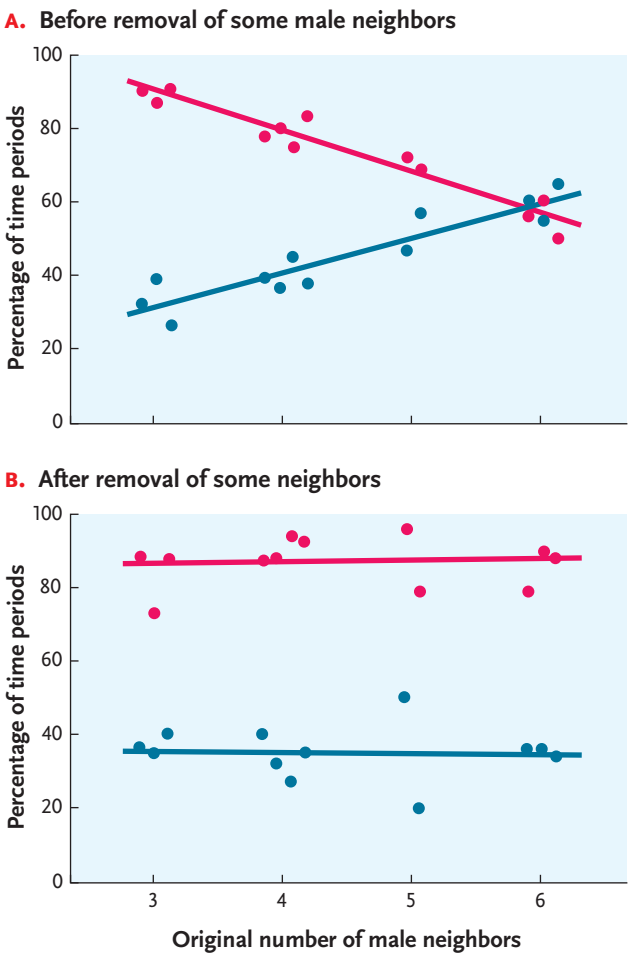
7. Which signal type would provide the fastest communication between bats flying in a dark forest?
   a. chemical signals
   b. acoustical signals
   c. visual signals
   d. tactile signals
   e. electrical signals
8. In comparison to males, the females of many animal species:
   a. compete for mates.
   b. choose mates that are well camouflaged in their habitats.
   c. choose to mate with many partners.
   d. are always monogamous.
   e. choose their mates carefully.
9. Social behavior:
   a. is exhibited *only* by animals that live in groups with close relatives.
   b. cannot evolve in animals that maintain territories.
   c. evolved because group living provides benefits to individuals in the group.
   d. is never observed in insects and other invertebrate animals.
   e. can be explained only by the hypothesis of kin selection.
10. The degree of relatedness between a parent and its biological offspring:
   a. is the same as that between full siblings.
   b. is less than that between brother and sister.
   c. depends on how many siblings the parent has.
   d. promotes an individual's reproductive success.
   e. is the same as between first cousins.

Discuss the Concepts

1. Using an example from your own experience, explain why habituation to a frequent stimulus might be beneficial. Also describe an example in which habituation might be harmful or even dangerous.
2. Is learning always superior to instinctive behavior? If you think so, why do so many animals react instinctively to certain stimuli? Are there some environmental circumstances in which being able to respond "correctly" the first time would have a big payoff?
3. In Chapter 55, you learned about some of the environmental changes associated with global warming. What effects might global warming have on animal species that undertake seasonal migrations?
4. Although females provide parental care far more often than males in the animal kingdom as a whole, exceptions exist, especially among birds and fishes. Develop three evolutionary hypotheses to explain why male birds are so likely to involve themselves in caring for their offspring.

Design an Experiment



You find that some fruit flies in your lab are quick to come to a dish containing citrus oils, but others are not as responsive. How could you test whether these behavioral differences are caused by genetic differences among the flies or environmental differences in their prior experience?

Apply Evolutionary Thinking

Some birds that are frequently kept as pets, such as parrots and myna birds, have the ability to imitate human speech faithfully. Develop a hypothesis that explains why the ability to be a good mimic might have evolved in these species. What features of the birds' brains might be involved in this behavior?

Interpret the Data

A female Seychelles warbler *(Acrocephalus sechellensis)* typically produces just one egg per nesting event. A male of this species will guard his mate from the attentions of neighboring males until she lays that egg, thereby increasing the likelihood that he fathered the offspring inside it. Jan Komdeur of the University of Groningen, The Netherlands, studied the behavior of male Seychelles warblers—before females had laid eggs—in relation to the number of other males that lived nearby. First, Komdeur watched focal males (that is, the ones being studied) for 30 s time periods and recorded the percentage of time periods in which they fed or guarded mates. Then, for focal males with more than three male neighbors, Komdeur experimentally reduced the number of neighbors to three and surveyed the behavior of the focal males again to see if it changed. His results are illustrated in the graphs reproduced below. (Because males sometimes performed both behaviors during the same observation period, some observation periods counted toward both behaviors; thus, the percentages of time periods spent foraging or mate guarding sum to more than 100%.) If a male warbler has many male neighbors, what cost is associated with ensuring his paternity of his mate's egg?

J. Komdeur. 2001. Mate guarding the Seychelles warbler is energetically costly and adjusted to paternity risk. *Proceedings of the Royal Society of London B* 268:2103–2111. By permission of the Royal Society.

Appendix A: Answers*

Chapter 1

Study Break

STUDY BREAK 1.1

1. The major levels in the hierarchy of life and some of their emergent properties are: cells—life; organisms—learning; populations—birth and death rates; communities, ecosystems, biosphere—diversity and stability.
2. Organisms use energy collected from the external environment for growth (including the production of new molecules and cells), maintenance and repair of body parts, and reproduction.
3. A life cycle is the series of structurally and functionally distinct developmental stages through which organisms pass.

STUDY BREAK 1.2

1. In artificial selection, humans selectively breed individuals with desirable heritable characteristics to enhance those traits in the next generation. In natural selection, genetically-based characteristics that increase survival and reproduction become more common in the next generation.
2. Random changes in DNA—mutations—may change the structure of proteins that contribute to the physical appearance and internal functions of an organism.
3. Being camouflaged may make an animal less likely to be noticed by a predator.

STUDY BREAK 1.3

1. In the cells of prokaryotic organisms, DNA is not separated from other parts of the cell. In the cells of eukaryotic organisms, DNA is enclosed within a nucleus.
2. Humans are classified in Domain Eukarya and Kingdom Animalia.

STUDY BREAK 1.4

1. A scientific hypothesis must be falsifiable. In other words, we must be able to imagine what sort of data would demonstrate that the hypothesis is incorrect.
2. The copper lizard models told the researchers how frequently lizards would perch in the sun just by chance and what the temperatures of nonthermoregulating lizards would be.
3. Model organisms are usually easy to maintain and study, and they have been so well studied that researchers already know a lot about their biology.
4. When scientists describe a set of ideas as a "theory," they recognize that the ideas have already withstood many scientific tests.

Think Like a Scientist

FIGURE 1.11

Animals are more closely related to fungi than they are to plants. According to the phylogenetic tree, animals and fungi shared a common ancestor more recently than did animals and plants.

FIGURE 1.15

To test the effects of two experimental variables simultaneously, you would need to design an experiment that had experimental and control groups for both variables (that is, fertilizer and water). One group might receive both fertilizer and water; a second group would receive fertilizer but no water; a third group would receive water but no fertilizer; and a fourth group would receive neither fertilizer nor water. You could then compare the results of the four treatments to see the effects of both experimental variables, alone and in combination, on your plants.

FIGURE 1.16

The temperature is not very variable among the shaded sites in this environment. Most of the models were in shaded sites, and the temperatures of the shaded sites are clustered around 19° to 20°C.

Interpret the Data

Anolis gundlachi does not regulate its body temperature. The graphs show that lizards perch in patches of sun at about the same rate as randomly positioned models and that lizards and models exhibit similar distributions of body temperatures. These data suggest that this lizard species perches at random with respect to environmental factors that might influence its body temperature.

Chapter 2

Study Break

STUDY BREAK 2.1

An element is a pure substance that consists of one type of atom. An atom is the smallest unit of an element that retains its chemical and physical properties. A molecule is a collection of atoms chemically combined in fixed numbers and ratios. Molecules can consist of the same atoms, as is seen for the two oxygen atoms in the molecule oxygen, or of different atoms, as in the combination of two hydrogen atoms and one oxygen atom in a molecule of water. Molecules with component atoms that are different, such as water, are compounds.

STUDY BREAK 2.2

1. Protons and neutrons are found in the nucleus of an atom. Electrons are found in orbitals located in energy levels (shells) that surround the nucleus.
2. Carbon-11 has six protons and five neutrons. Oxygen-15 has eight protons and seven neutrons.
3. The number of valence electrons—the electrons in the outermost shell of an atom—determines its chemical reactivity. If the outermost shell is not completely filled with electrons, the atom tends to be chemically reactive, whereas if that shell is completely filled, the atom is nonreactive.

STUDY BREAK 2.3

1. An ionic bond forms between atoms when those atoms gain or lose electrons completely. An example is the ionic bond in NaCl.
2. A covalent bond forms when atoms share a pair of valence electrons rather than gaining or losing them completely.
3. Electronegativity is a measure of an atom's attraction for the electrons it shares in a chemical bond with another atom. When electrons are shared equally, the atoms remain uncharged and the result is a nonpolar covalent bond. When electrons are shared unequally, one atom carries a partial negative charge and the other atom carries a partial positive charge. The molecule then has polarity, and the bond is a polar covalent bond.
4. In a chemical reaction, atoms or molecules interact to form new chemical bonds or break old ones. Atoms are added to or removed from molecules, or linkages of atoms in molecules are rearranged as a result of bond formation.

STUDY BREAK 2.4

1. Hydrogen bonds between neighboring water molecules produce a water lattice. The constant breakage and reformation of hydrogen bonds in the lattice allows water to flow easily. The polarity of water molecules also contributes to the properties of water; that is, in liquid water, the lattice resists invasion by other molecules unless the invading molecules also contain polar regions that can form competing attractions with water molecules. In that case, the water lattice opens, forming a cavity in which the polar or charged molecule can move. However, nonpolar molecules are unable to affect the water lattice. Hydrogen bonds also give water its unusual ability to resist changes in temperature by absorbing or releasing heat energy, its unusually high boiling point, and its unusually high internal cohesion and surface tension.
2. A solute is a dissolved substance. A solvent is a substance capable of dissolving another substance. A solution is a solute dissolved in a solvent. For example, salt (NaCl) is a solute that can dissolve in the solvent water.

STUDY BREAK 2.5

1. Acids are hydrogen ion (proton, H^+) donors; bases are proton acceptors. An acid dissociates in water to produce a hydrogen ion and an anion. Most bases dissociate in water to give hydroxide ions, which then accept protons to produce water.
2. Buffers act to control the pH of a solution. In living organisms, buffers keep the pH of body and cell fluids within a narrow range, enabling normal cell and body functions to occur. Outside of the normal pH range, the functions of proteins can be affected, thereby adversely affecting the functions of the organism.

Think Like a Scientist

UQ

Properties of natural soils can determine the flow pattern and how much carbon source can be delivered to bacteria, therefore controlling their capability of remediating uranium. In addition, the abundance and spatial distribution of certain minerals can affect the magnitude of energy sources for the bacteria and therefore the efficiency of uranium bioremediation.

3. Using a pH of 2.5 for peak reflux and pH of 4.0 for clinical reflux, the H^+ concentration is 0.003 *M* greater, and OH^- concentration is 0.0000000000968377 (9.68377×10^{-11}) *M* less than a pH of 4.0.

Chapter 3

Study Break

STUDY BREAK 3.1

1. Organic molecules are molecules based on carbon. Hydrocarbons are a type of organic molecule that consists of carbon linked only to hydrogen atoms.
2. The maximum number of bonds that a carbon atom can form is four.
3. Carboxyl groups donate a hydrogen ion in water and therefore act as acids. Amino groups accept a hydrogen ion in water and therefore act as bases. Phosphate groups donate hydrogen ions in water and therefore act as acids.
4. In a dehydration synthesis reaction, components of water (—H and —OH) are removed. In hydrolysis, the components of a water molecule are added to functional groups as molecules are broken down into smaller subunits.

STUDY BREAK 3.2

A monosaccharide is the structural unit of carbohydrate molecules. Monosaccharides are simple sugars such as trioses, pentoses, and hexoses. Glucose, galactose, and fructose are hexoses. A disaccharide is a molecule assembled from two monosaccharides linked by a dehydration synthesis reaction. Lactose, sucrose, and maltose are disaccharides. A polysac-

charide is a polymer of monosaccharide subunits. The subunits are identical or different, depending on the particular polysaccharide. Glycogen, starch, cellulose, and chitin are polysaccharides.

STUDY BREAK 3.3

The three most common lipids found in living organisms are neutral lipids, phospholipids, and steroids. Most neutral lipids consist of a three-carbon backbone chain formed from glycerol, with each carbon linked to a fatty acid side chain. In the most common phospholipids, glycerol is the backbone, with two of its binding sites linked to fatty acids. The third binding site is linked to a polar phosphate group. Steroids have structures based on a framework of four carbon rings. Differences in side groups attached to the rings distinguish the different types of steroids.

STUDY BREAK 3.4

1. Differences in the side groups (R in the figures) give the amino acids their individual properties.
2. A peptide bond is the bond between the C of the carboxyl group of one amino acid and the N of the amino group of the adjacent amino acid (see Figure 3.19). The bond is formed in a dehydration synthesis reaction between an amino group of one amino acid and a carboxyl group of another amino acid.
3. Domains are distinct structural subdivisions in the final folded forms of proteins. They are the result of the amino acid sequence of the protein (the primary structure of the protein) and the secondary, tertiary, and quaternary (if more than one polypeptide is involved) structures of the protein.

STUDY BREAK 3.5

1. Nucleic acids are formed from nucleotide monomers. A nucleotide consists of a nitrogenous base, a five-carbon sugar, and a phosphate.
2. In DNA, the five-carbon sugar is deoxyribose; in RNA it is ribose. DNA has the pyrimidine nitrogenous base T (thymine), and RNA has U (uracil).

Think Like a Scientist

FIGURE 3.24

In the presence of a high concentration of urea, the formation of the four disulfide bridges of the native enzyme apparently only rarely occurs. As a result, only a low level of enzyme activity is measured in the solution. The other enzymes appear to have formed three-dimensional structures, but likely they contain nonnative disulfide linkages and therefore result in inactive enzymes. Overall, the result strengthens Anfinsen's conclusions because it means that particular disulfide linkages are responsible for the stable, and therefore active, form of the enzyme. If the enzyme instead forms with incorrect pairs of disulfide linkages, the structure is sufficiently different that enzyme activity is lost.

IMR

1. The enzyme that assembles DNA molecules in the bacterium *Escherichia coli* (see Figure 3.26B). The enzyme has two domains, one to assemble the DNA molecules (the polymerase domain) and the other to correct mistakes during DNA assembly (the exonuclease domain).
2. The method of analysis described in *Insights from the Molecular Revolution* was the comparison of domain structure and organization. Fundamentally, the domains consist of particular sequences of amino acids. The function of a domain depends on the sequence of amino acids plus the higher-order structures it forms within the protein. As a domain diverges through evolutionary time, core functional elements must stay the same or highly similar in order that the function of the domain be retained. At the same time, other parts of the domain can experience changes in amino acid sequence. Therefore, through bioinformatics-based computer analysis of proteins sharing a particular function, researchers can determine how the domain has changed over time and, thereby, construct a phylogenetic tree based on the changes.

UQ

In type 2 diabetes, SREBPs in the liver are activated, and this leads to overproduction of fatty acids and triglycerides. Inhibitors of SREBP processing might reduce plasma triglycerides and prevent their toxic effects on blood vessels.

Interpret the Data

1. LDL was highest in the saturated fats diet group, and HDL was lowest in the *trans* fatty acids diet group.
2. The *trans* fatty acid group had the highest LDL-to-HDL ratio.
3. From best to worst diet: *cis* fatty acids, saturated fats, *trans* fatty acids.

Chapter 4

Study Break

STUDY BREAK 4.1

1. Kinetic energy is the energy of motion, whereas potential energy is stored energy.
2. An isolated system exchanges neither matter nor energy with its environment. A closed system can exchange energy, but not matter, with its environment. An open system can exchange both energy and matter with its environment.

STUDY BREAK 4.2

1. The change in energy content of a system, and its change in entropy. Reactions tend to be spontaneous when the products have less potential energy than the reactants, and when the products are less ordered than the reactants.
2. The greater the negative value of ΔG, the further a reaction will proceed toward completion and therefore the greater the concentration of product molecules versus reactant molecules.
3. An exergonic reaction releases free energy—ΔG is negative because the products contain less free energy than the reactants. An endergonic reaction requires free energy from the surroundings to run—ΔG is positive because the products contain more free energy than the reactants.

   In a catabolic reaction, energy is released during the breakdown of a complex reactant molecule to a simpler product molecule, whereas in an anabolic reaction, energy is used to create a product molecule that is more complex than the reactant molecule.

   Individual reactions may be exergonic or endergonic. When a series of reactions (each of which may have a positive or a negative ΔG value) forms a metabolic pathway, the pathway is catabolic if the overall sum of individual reaction ΔG values is negative, and it is anabolic if the overall sum of individual reaction ΔG values is positive.

STUDY BREAK 4.3

1. ATP contains the five-carbon sugar ribose, with the nitrogenous base adenine linked to one of the carbons and a chain of three phosphate bonds to another carbon. The phosphate groups are closely associated with each other and their negative charges strongly repel each other, making the bonding arrangements unstable and storing potential energy. Hydrolysis of ATP to remove one or two of the three phosphates is a spontaneous reaction that relieves the repulsion and releases large amounts of free energy.
2. Many individual reactions found in living cells are not spontaneous because they have a positive ΔG. By joining such a reaction to another reaction with a large negative ΔG, the reaction can be completed. The combined reaction is called a coupled reaction. ATP participates in coupled reactions in the enzyme-driven process of energy coupling; that is, ATP comes into close contact with a reactant molecule in an endergonic reaction. When ATP is hydrolyzed, the terminal phosphate group is transferred to the reactant molecule, which makes that molecule less stable so that the reaction continues spontaneously.

STUDY BREAK 4.4

1. Enzymes accelerate reactions by reducing the activation energy of a reaction, the initial input of energy required to start a reaction. Enzymes lower activation energy by rearranging the atoms and bonds of the reacting molecules into the transition state, an activated state that is highly unstable. With relatively little change in energy, the transition state can move forward toward products or backward toward reactants.
2. No.

STUDY BREAK 4.5

1. There is a maximum rate at which an enzyme can combine with substrates and release products. Beyond that point, increasing substrate concentration does not increase the reaction rate any further.
2. In competitive inhibition, the inhibitor competes with the normal substrate molecule for binding to the active site of the enzyme, whereas in noncompetitive inhibition, the inhibitor does not compete directly with the substrate for binding to the active site.
3. As the temperature increases, the increasing kinetic motions of the enzyme's amino acid chains eventually disrupt the enzyme's three-dimensional structure, causing it to unfold and denature. At that point, there is no enzyme activity.

STUDY BREAK 4.6

A ribozyme is an RNA molecule that accelerates the rate of a biological reaction. A ribozyme qualifies as an enzyme because it remains unchanged after the reaction is complete; that is, it is a true catalyst.

Think Like a Scientist

IMR

Both the 5′ and 3′ constant regions are necessary for the active ribozyme structure to form.

UQ

The problem is that each nucleotide in the ribozyme would need to serve as template for polymerization. This means that the ribozyme would have to open up its own structure and inactivate its own catalytic site. Therefore, the existence of such a molecule seems very unlikely. However, it may be possible to design such a molecule if it has two catalytic centers, or if the crucial parts of the ribozyme do not need to template because they exist twice in the molecule.

Test Your Knowledge

1. c 2. d 3. b 4. c 5. e 6. a 7. a 8. b 9. d 10. e

Interpret the Data

1. ΔG is minus 5.5 minus 3.5 = −9 kcal/mol for the mutated polypeptide and minus 2.0 minus 4.0 = −6.0 kcal/mol for the parent polypeptide.
2. Binding of both of the polypeptides is exergonic and spontaneous, and the parent polypeptide would yield more free energy on binding.
3. No, because the ΔG is less negative, it would not be as energetically favorable.

Chapter 5

Study Break

STUDY BREAK 5.1

The plasma membrane is a bilayer of lipid and suspended protein molecules that bounds the cytoplasm of a cell. The lipid bilayer is hydrophobic; therefore, it is a barrier to the passage of water-soluble substances. The membrane has protein channels through which selected water-soluble substances are able to pass.

STUDY BREAK 5.2

The DNA of a prokaryotic cell is located in the nucleoid region, a central area of the cell that has no membrane around it to separate it from the cytoplasm. In most prokaryotes, the DNA is a folded mass. In its unfolded state, it is a circular DNA molecule.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

STUDY BREAK 5.3

1. Most of the DNA of a eukaryotic cell is found within a nucleus located roughly in the center of the cell. The nucleus is bounded by the nuclear envelope, a membrane that separates its contents from the cytoplasm. The DNA is complexed with proteins and organized into several linear chromosomes.
2. The nucleolus is an area within the nucleus. It forms around the genes for rRNA in the chromosomes and is the location in which the information in those genes is copied into rRNA. The rRNA combines with proteins in the nucleolus to form the large and small ribosomal subunits. A large and a small ribosomal subunit function together in the cytoplasm to synthesize proteins.
3. The endomembrane system is a collection of organelles, membranous channels, and vesicles that form a major traffic network for the synthesis, distribution, and storage of proteins and other molecules. Its structure includes the endoplasmic reticulum (ER) and the Golgi complex. The rough ER has ribosomes on its outer surface. Proteins synthesized by those ribosomes enter the ER lumen, where they fold into their final shape and may be modified chemically. Then they are delivered to other regions of the cell within vesicles that pinch off from the rough ER. Most of the proteins made on rough ER go to the Golgi complex.

   The smooth ER consists of membranes that lack ribosomes. Functions of the smooth ER include synthesis of lipids that become parts of cell membranes.

   The Golgi complex is a stack of flattened, membranous sacs. The *cis* face of this organelle receives vesicles containing proteins released from the rough ER and continues their chemical modifications. The proteins are then sorted into vesicles that pinch off from the *trans* face of the Golgi complex, the side that faces the plasma membrane. Some of the released vesicles remain in the cytoplasm as storage vesicles of various types, whereas others, called secretory vesicles, release their contents to the outside of the cell.
4. A mitochondrion is an organelle enclosed by two membranes. The outer mitochondrial membrane is smooth and covers the outside of the organelle. The inner mitochondrial membrane is highly folded into cristae. Within the inner membrane is the mitochondrial matrix, which contains DNA and ribosomes. Most of the energy required for eukaryotic cellular activities is generated by reactions in the cristae and the matrix. Those reactions break down sugars, fats, and other fuel molecules into water and carbon dioxide, releasing energy mostly in the form of ATP.
5. The cytoskeleton is an internal cytoplasmic network of filaments and tubules composed mainly of actin and tubulin proteins. The function of the cytoskeleton is to maintain the shape of the cell, reinforce the plasma membrane, and organize internal structures. Changes in the cytoskeleton are responsible for movements of cell organelles, movements of parts of the cell, or movements of the whole cell.

STUDY BREAK 5.4

1. A chloroplast has two membranes: an outer boundary membrane and an inner boundary membrane. The latter, similar to the cristae of the mitochondrion, is highly folded. The two membranes enclose an inner compartment known as the stroma. Within the stroma is a membrane system composed of flattened, closed sacs called thylakoids. Chloroplasts are the sites of photosynthesis in plant cells. The thylakoid membranes contain chlorophyll and other molecules that absorb light energy and convert it into chemical energy. Enzymes in the stroma use the chemical energy to make carbohydrates and other complex organic molecules from water, carbon dioxide, and other simple inorganic precursors.
2. The tonoplast, the membrane surrounding the central vacuole, contains transport proteins that move substances into and out of the vacuole. Central vacuoles also store organic and inorganic salts, organic acids, sugars, storage proteins, pigments, and, in some cells, waste products. Chemical defense molecules are found in the central vacuoles of some plants.

STUDY BREAK 5.5

1. Anchoring junctions are spots or belts that run entirely around cells, effectively sticking adjacent cells together. Microfilaments (in adherens junctions) or intermediate filaments (in desmosomes) anchor the junction in the underlying cytoplasm. Tight junctions involve fusion of a network of junction proteins in the outer halves of the plasma membranes of adjacent cells, forming a tight seal that can keep even ions from moving between the cells. Gap junctions open direct channels between adjacent cells through which ions and small molecules can pass directly. The gap junctions are formed by aligned hollow protein cylinders in the plasma membranes of two cells.
2. The extracellular matrix (ECM) is a complex of proteins and polysaccharides secreted by the cells that it surrounds. Depending on the nature of the network of proteoglycans (carbohydrate-rich glycoproteins) in the ECM, the consistency ranges from soft and jellylike to hard and elastic.

Think Like a Scientist

FIGURE 5.11

Presumably a nuclear envelope-associated component recognizes the nuclear localization signal of proteins destined to enter the nucleus. A logical location for such a component is in association with the nuclear pore complex. Clearly, a very restricted region of a protein can be sufficient to direct nuclear localization. In the same vein, the transport system must be able to be highly selective in recognizing proteins with such a small nuclear localization signal.

FIGURE 5.17

The chemical is inhibiting a step in the pathway for protein secretion from the cell. Possible steps affected are the transport of the protein in vesicles from the ER to the Golgi complex, the production of secretory vesicles by budding from the Golgi membranes, or the release of the protein at the cell surface by exocytosis.

IMR

All the *Methanococcus* genes related to genes in other organisms would have had sequences similar just to those in bacteria rather than some similar to bacterial genes and others similar to eukaryotic genes.

UQ

Perturbing the activity of individual genes and proteins allows cell biologists to determine whether each plays a necessary role in a given cellular process, but does not indicate what mechanistic role the protein performs or how it cooperates with other proteins to perform its functions. On the other hand, reconstituting a process in a test tube allows cell biologists to build a functioning system from individual components and understand how each contributes to the system, but does not address the functional importance of each component in the context of the cell. Both approaches can be technically challenging, but reconstitution is often more challenging because it requires both identification of all of the important players and the isolation of the players in a functional form.

Test Your Knowledge

1. b 2. e 3. c 4. a 5. b 6. c 7. b 8. b 9. b 10. d

Interpret the Data

Most of the cathepsin activity occurs in the fraction containing the lysosomal marker enzymes (fraction 5), thus localizing the worm cathepsin activity to the lysosome.

Chapter 6

Study Break

STUDY BREAK 6.1

1. The fluid mosaic model proposes that the membrane consists of a fluid phospholipid bilayer in which proteins are embedded and float freely.
2. Integral proteins include transport proteins, receptor proteins, recognition proteins, and cell adhesion proteins. Peripheral proteins include microtubules, microfilaments, intermediate filaments, and proteins that link the cytoskeleton together.

STUDY BREAK 6.2

1. In passive transport, molecules and ions move across the membrane from the side with the higher concentration to the side with the lower concentration; that is, the difference in concentration provides the energy for passive transport. In active transport, molecules and ions move across the membrane from the side with the lower concentration to the side with the higher concentration—that is, against the concentration gradient. The energy for active transport comes from the hydrolysis of ATP.
2. The transport of substances through membranes based solely on molecular size and lipid solubility is simple diffusion. The diffusion of polar and charged molecules across membranes with the help of transport proteins is facilitated diffusion.

STUDY BREAK 6.3

1. Osmosis is the passive transport of water across a membrane. This movement follows concentration gradients. For osmosis to occur, there must be a selectively permeable membrane—that is, a membrane that will allow water molecules, but not molecules of the solute, to pass. As long as the solute is at different concentrations on the two sides of the membrane, water movement will occur; that is, it is not necessary for pure water to be present on one side of the membrane.
2. If animal cells are in a hypertonic solution, water molecules will move by osmosis from within the cells to the surrounding solution. If the outward movement of water exceeds the capacity of the cells to replace the lost water, the cells will shrink.

STUDY BREAK 6.4

1. Active transport is the movement of substances across membranes against their concentration gradients by pumps; the energy for active transport comes from ATP hydrolysis. In primary active transport, ATP hydrolysis directly drives the process; that is, the same protein that transports a substance also hydrolyzes ATP. In secondary active transport, ATP hydrolysis indirectly drives the process; that is, the transport proteins themselves do not hydrolyze ATP. Rather, the transporters use a favorable concentration gradient of ions, generated by primary active transport (when ATP hydrolysis is used), as their energy source for active transport of a different ion or molecule.
2. A membrane potential is a voltage difference across a membrane. Ion transport by membrane pumps contributes to this voltage difference. The sodium–potassium pump in the plasma membrane pushes three sodium ions out of the cell and two potassium ions into the cell with each turn of the pump. This leads to an accumulation of positive charges outside the membrane, causing the inside of the cell to become negatively charged with respect to the outside of the cell. In addition, an unequal distribution of ions across the membrane is created by passive transport. The electrical potential difference (voltage) across the plasma membrane is the membrane potential.

STUDY BREAK 6.5

1. In exocytosis, secretory vesicles in the cytoplasm contact and fuse with the plasma membrane, releasing their contents to the outside of the cell.
2. Endocytosis is a mechanism by which substances are brought into the cell from the exterior. The substances become trapped in pitlike depressions that bulge inward from the plasma membrane. The depression pinches off as an endocytic vesicle. In bulk-phase endocytosis, no binding by surface receptors is involved. Extracellular water is taken in together with any other molecules that are in solution in the water. This is the simplest form of endocytosis. In receptor-mediated endocytosis, molecules to be taken in become bound to the outer cell surface by receptor proteins. The receptor proteins are specific in that they recognize and bind only certain molecules from the solution that surrounds the cell. The molecules recognized are mostly proteins or other molecules carried by proteins. Once the receptors have bound their target molecules, the receptors collect into a coated pit, a depression in the plasma membrane. The pits, with the contained

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

target molecules, pinch off from the plasma membrane to form endocytic vesicles.

Think Like a Scientist

FIGURE 6.6

The protein synthesis inhibitors did not affect the pattern of the membrane proteins. Therefore, new protein synthesis is not necessary for generating the intermixed pattern of membrane proteins. The temperature experiment shows that intermixing depends on the temperature. This makes sense if the intermixing is a property of the membrane because, as you learned earlier in the chapter, the phospholipid bilayer can freeze into a semisolid, gel-like state at low temperatures. Logically, membrane proteins would not be able to move or they would only be able to move a little under those conditions. Together, these experiments support the fluid bilayer model and reject the new protein synthesis model.

FIGURE 6.11

The hydrolysis of ATP to ADP plus phosphate is key to the ability of the channel protein to transport ions. If the rate of hydrolysis of ATP was reduced drastically, the primary active transport pump would only be able to move the ion it transports at a much lower rate.

IMR

The result showed that unlabeled LDL competed with labeled LDL for binding to the cells. The interpretation was that there are specific binding sites for LDL on the cell surface and that their number is limited. The result supported the researchers' overall conclusion because it indicated that specific binding was occurring in the experiments rather than nonspecific binding; that is, there is a specific receptor for LDL.

UQ

Restricting the passage of protons aids in conservation of the membrane's electrochemical potential.

Test Your Knowledge

Interpret the Data

1. Cell set B is displaying resistance because these cells fail to accumulate paclitaxel. They are using active transport to move the anticancer drug back out across the cell membrane.
2. The drug treatment imatinib has a slight but significant effect on increasing the accumulation of the labeled paclitaxel in set A; however, a much more dramatic effect is seen using either of these drugs on cell set B. This suggests that in cell set B, the active transport mechanism is inhibited by the presence of these additional drugs.

Chapter 7

Study Break

STUDY BREAK 7.1

Specificity of a cellular response depends on the signal–receptor interaction. Specificity starts with the signal molecule; that is, the specific signal molecule is the messenger that elicits a specific cellular response. For example, the hormone epinephrine causes glucose to be released into the bloodstream. Specificity also depends on the target cells; that is, only target cells respond to the signal molecule because they exclusively have receptors for the signal molecule.

STUDY BREAK 7.2

1. Protein kinases are enzymes that add phosphate groups to other proteins. The result of phosphorylation is that the protein will be either stimulated or inhibited in its activity. The cellular responses of signal transduction pathways are produced through the actions of protein kinases.
2. Amplification is the phenomenon of an increase in the magnitude of each step of a signal transduction pathway. Amplification typically occurs because the proteins conducting each step of the pathway are enzymes; that is, each enzyme, when it is becomes activated, activates large numbers of molecules entering the next step of the pathway.

STUDY BREAK 7.3

1. For a receptor tyrosine kinase to become activated, the signal molecule first binds to the receptor, which then assembles into a dimer. The receptor adds phosphate groups to tyrosines on the cytoplasmic side of itself, which activates the receptor.
2. A fully activated receptor tyrosine kinase has phosphorylated tyrosines on each of its two monomers. A signaling protein that recognizes a phosphorylated tyrosine as well as surrounding parts of the polypeptide binds to the receptor. Depending on the signaling protein, the binding itself may activate the signaling protein, or it is activated by tyrosine phosphorylation catalyzed by the receptor. In its activated form, the signaling protein initiates a transduction pathway leading to a cellular response. A given receptor can initiate different responses because different combinations of signaling proteins can bind to the receptor.

STUDY BREAK 7.4

1. The first messenger in a G-protein–coupled receptor–controlled pathway is the extracellular signal molecule. When it binds to the G-protein–coupled receptor, it activates a site on the cytoplasmic side of the receptor; the activated receptor, in turn, activates the G protein next to it.
2. The effector is activated by the G protein. The effector is a plasma-associated enzyme that generates a nonprotein signal molecule called the second messenger. The second messenger leads to the activation of protein kinases leading to the cellular responses triggered by the signal molecule.
3. A main way the pathway is turned off is by the conversion of cAMP to 5′-AMP by phosphodiesterase. As long as the receptor is bound by the signal molecule, cAMP is being generated by the activated effector. The continued synthesis of cAMP balances the degradation of cAMP by phosphodiesterase, ensuring that the pathway continues to run. However, if the signal molecule no longer is bound to the receptor, the effector again becomes inactive, cAMP therefore is not generated, and existing cAMP is rapidly degraded by phosphodiesterase. As a result, the protein kinase cascade is shut down and no cellular responses occur.

STUDY BREAK 7.5

1. The steroid receptor is within the cell, whereas the receptor tyrosine kinase and G-protein–coupled receptors are in the membrane or associated with the membrane. Also, the activated steroid receptor directly activates genes, whereas the other two receptors, when active, are just the first steps in pathways that may or may not activate genes.
2. A steroid hormone brings about a specific cellular response because whether a cell responds to a steroid hormone depends on whether it has the internal receptor for the hormone. Then within the cells with the receptor, the specific genes that are controlled are those with regulatory sequences that are recognized by the activated receptor.

STUDY BREAK 7.6

Signal transduction pathways, cellular response systems triggered by cell adhesion molecules, and communication pathways that involve gap junctions between adjacent cells might be integrated in a cross-talk network.

Think Like a Scientist

FIGURE 7.2

The experiment showed that the second messenger was not a protein, or any other large molecule that would be denatured by boiling.

FIGURE 7.7

The transduction pathways controlled by the receptor tyrosine kinase would be active all the time, producing cellular responses in an uncontrolled manner—that is, in the absence of the signal molecule. Mutations such as this are known to be associated with some cancers.

FIGURE 7.9

There are two main possibilities. One is that the receptor would no longer recognize the first messenger signal molecule. In this case, the cellular response(s) controlled by the signal molecule would not occur. The other is that the receptor would be active even in the absence of the first messenger signal molecule. In this case, cellular response(s) would occur in an uncontrolled way. As you learned in the text, there are a very large number of G-protein–coupled receptors and they control a great many cellular processes. Thus, malfunctions of these receptors can have serious consequences. In fact, mutations in genes for G-protein–coupled receptors have been shown to be responsible for more than 30 human diseases.

IMR

You would test U0126 first in an animal model and, if the results were promising, then in humans in clinical trials. In fact, U0126 has been shown to reduce influenza virus propagation in lungs of infected mice.

UQ

1. Perhaps the male's behavior induces the release of dopamine or another relevant neurotransmitter onto specific neurons in the brain of the female, which contain progestin receptors and are involved in regulation of sexual behavior. The dopamine, in turn, may activate those receptors leading to neuronal changes resulting in the expression of sexual behavior.
2. To answer this question, you have to think of other situations in which the environment might cause the release of a neurotransmitter that then, via cross talk, activates a steroid receptor resulting in changes in behavior. Perhaps stimulation from pups activates neuronal steroid hormone receptors, resulting in changes in maternal behavior in a lactating mother. There are many other examples in which stimulation from the environment or another animal might, via neurotransmitter release, influence the function of a particular steroid hormone receptor (by activating it).

Interpret the Data

1. In normal cells the least amount of CFTR was found in vesicles, whereas the greatest amount was found in endoplasmic reticulum. In cells with the CF mutation the least amount of CFTR was found in Golgi bodies, whereas the greatest amount was found in endoplasmic reticulum.
2. The CFTR protein is found in almost the same amount in the endoplasmic reticulum of normal and CF cells.
3. The CFTR protein is held up in the endoplasmic reticulum.

Chapter 8

Study Break

STUDY BREAK 8.1

1. Oxidation is the removal of electrons from a substance; reduction is the addition of electrons to a substance.
2. Cellular respiration refers to the reactions in which oxygen is used as final electron acceptor; it includes the reactions that transfer electrons from organic molecules to oxygen and the reactions that make ATP. Oxidative phosphorylation is the process by which ATP is synthesized using the energy released by electrons as they are transferred to oxygen.

STUDY BREAK 8.2

1. The initial steps of glycolysis, which require 2 ATP, convert glucose to a phosphorylated derivative. The later steps, which release 4 ATP, remove electrons from the glucose derivatives and generate two molecules of pyruvate.
2. The redox reaction in glycolysis is the glyceraldehyde-3-phosphate (G3P) to 1,3-bisphosphoglycerate reaction (see Figure 8.7, step 6).
3. ATP is synthesized in glycolysis by substrate-level phosphorylation occurring in the 1,3-bisphosphoglycerate to 3-phosphoglycerate reaction (see Figure 8.7, step 7), and in the phosphoenolpyruvate (PEP) to pyruvate reaction (see Figure 8.7, step 10).
4. If excess ATP is present in the cytosol, it binds to and inhibits the activity of phosphofructokinase. As a result, the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

concentration of fructose-1,6-bisphosphate, the product of the phosphofructokinase reaction, decreases, and the subsequent reactions of glycolysis are slowed or stopped. This is reversed when the ATP level in the cytosol decreases. In the end, this control mechanism helps prevent the needless oxidation of fuel molecules when the cell has an adequate supply of ATP.

STUDY BREAK 8.3

The three-carbon pyruvate molecules are transported from the cytosol into the mitochondria, where they are converted into two-carbon acetyl units through pyruvate oxidation. The citric acid cycle oxidizes the acetyl units completely to carbon dioxide with the transfer of electrons to NAD^+ or FAD.

STUDY BREAK 8.4

1. Each complex contains a unique combination of nonprotein carriers that pick up and release electrons.
2. The proton pumps push protons (H^+) from the mitochondrial matrix to the intermembrane compartment, increasing the proton concentration there. The resulting proton gradient produces an electrical gradient across the inner mitochondrial membrane with the matrix negatively charged with respect to the intermembrane compartment. The charge and proton concentration differences together provide energy for ATP synthesis in what is called protonmotive force.

STUDY BREAK 8.5

Fermentation occurs when oxygen is absent or limited. The electrons carried by the NADH produced in glycolysis are transferred to an organic molecule instead of the electron transfer system. In lactate fermentation, the end product of glycolysis, pyruvate, is converted to lactate. The lactate stores electrons temporarily, transferring them to the mitochondrial electron transfer system when the oxygen content of cells returns to normal. In alcoholic fermentation, pyruvate is converted into ethyl alcohol.

Think Like a Scientist

FIGURE 8.13

The H^+ concentration will increase in the intermembrane compartment. The increase will lead to an increase in ATP production.

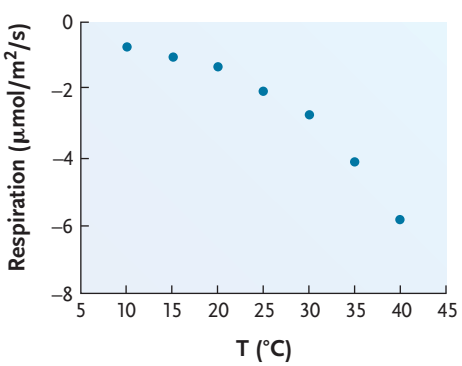
FIGURE 8.15

In the light, ATP synthesis would occur and then, in the dark, ATP synthesis would stop. This was in fact observed by Racker and Stoeckenius.

IMR

The observation indicates that the two UCPs are members of the same family of proteins and that presumably they have evolved by diversification from a common ancestral gene.

UQ



One possible hypothesis: there is a direct cause and effect relationship between altered regulation of mitochondrial expression and AD. If a significant number of mice whose genes were not genetically altered were to develop AD, this hypothesis would have to be rejected.

Test Your Knowledge

Interpret the Data

1.

2. Two.
3. A curve represents the data best. A Q10 of 2 indicates a curve because the respiration rate is doubling for every 10°C increase in temperature. This type of relationship is an exponential increase.
4. Temperatures are predicted to increase, which would increase respiration according to these data. The data are insufficient to predict the actual increase in respiration since the plants would likely change their enzyme amounts or types (acclimate) in response to the rising temperature. Further, temperature is not the only factor that will likely change with rising CO_2. Other factors include precipitation, cloud cover, nutrient availability, etc.

Chapter 9

Study Break

STUDY BREAK 9.1

1. The two stages of photosynthesis are: (1) the light-dependent reactions, in which the energy of sunlight is absorbed and converted into chemical energy in the form of ATP and NADPH; and (2) the light-independent (dark) reactions, in which electrons carried by NADPH are used as a source of energy to convert carbon dioxide from inorganic to organic form.
2. In plants, photosynthesis takes place in the chloroplast. The light-dependent reactions are carried out on the thylakoid membranes and stromal lamellae. The light-independent reactions are carried out in the stroma.

STUDY BREAK 9.2

1. The chlorophyll *a* molecules in the antenna complexes are normal molecules of the pigment, consisting of a carbon ring structure with a magnesium atom bound at the center and an attached hydrophobic side chain. These chlorophyll *a* pigments absorb light. The chlorophyll *a* molecules in the reaction centers have modified light absorption properties that result from interactions with particular proteins of the photosystems. The two special chlorophyll *a* molecules of photosystem II are P680; those of photosystem I are P700. These pigment molecules capture light energy from the antenna complex pigments in the form of an excited electron that is passed to a primary acceptor molecule. That electron is passed to the electron transfer system.
2. The making of NADPH begins when electrons derived from water splitting are pushed to higher energies by light absorption in photosystem II. The high-energy electrons pass to a primary acceptor in photosystem II and then down an electron transfer system to P700 in photosystem I, losing energy along the way. Light energy absorbed by photosystem I again excites the electrons, which pass to different electron carriers, ending with ferredoxin. The ferredoxin transfers high-energy electrons to $NADP^+$, which is reduced to NADPH by $NADP^+$ reductase.
3. In the linear electron flow pathway, electrons run through the entire set of photosystems and electron carriers, producing both NADPH and ATP. In the cyclic electron flow pathway, electrons flow cyclically around photosystem I; photosystem II is not involved. The cycle of electrons is through the cytochrome complex and plastocyanin to photosystem I, to ferredoxin, but then back to the cytochrome complex rather than on to $NADP^+$ reductase. Only ATP is produced by this pathway.

STUDY BREAK 9.3

1. Rubisco catalyzes a reaction combining carbon dioxide with RuBP to form two molecules of 3-phosphoglycerate (3PGA). Rubisco, an enzyme unique to photosynthetic organisms, is the key enzyme for producing the world's food because it is responsible for carbon dioxide fixation, a process that ultimately provides organic molecules for most of the world's organisms. Rubisco is the key regulatory site of the Calvin cycle for the following reason: During the daytime, sunlight powers the light-dependent reactions, and the NADPH and ATP produced by those reactions stimulate rubisco, which, in turn, keeps the Calvin cycle running. In darkness, however, NADPH and ATP levels are low, and as a result, rubisco's activity is inhibited and the Calvin cycle slows down or stops.
2. For each carbon atom that is released from the Calvin cycle in a carbohydrate molecule, one carbon dioxide molecule must enter the cycle. Therefore, to produce a molecule containing 12 carbon atoms, 12 molecules of carbon dioxide must enter the cycle.

STUDY BREAK 9.4

1. Photorespiration uses oxygen and releases CO_2. It occurs when oxygen concentrations are high relative to CO_2 concentrations. In that condition, rubisco acts as a Rubisco rather than a carboxylase, catalyzing the combination of RuBP with O_2 rather than CO_2. The toxic products formed by this reaction cannot be used in photosynthesis and are eliminated from the plant as CO_2. Photorespiration uses energy to salvage the carbons from phosphoglycolate, which greatly reduces the efficiency of energy use in photosynthesis. This can be seen in the reduced growth of plants grown under photorespiration conditions.
2. In the C_4 pathway, carbon fixation involves the reaction of CO_2 with phosphoenolpyruvate (PEP) to produce a four-carbon molecule, oxaloacetate. The oxaloacetate is reduced to malate by electrons transferred from NADPH, and malate then is oxidized to pyruvate in a reaction releasing CO_2, which is used in the rubisco-catalyzed first step of the Calvin cycle. In C_4 plants, carbon fixation and the Calvin cycle occur in different cell types: carbon fixation in mesophyll cells, and the Calvin cycle in bundle sheath cells. This alternative method of carbon fixation minimizes photorespiration.
3. In C_4 plants, carbon fixation and the Calvin cycle occur in different cell types, mesophyll cells and bundle sheath cells, respectively. In CAM plants, carbon fixation and the Calvin cycle occur at different times, at night and during the day, respectively.

STUDY BREAK 9.5

The reactions of photosynthesis and cellular respiration are essentially the reverse of one another, with CO_2 and H_2O the reactants of photosynthesis and the products of cellular respiration. Phosphorylation reactions involving electron transfer systems are part of each process, namely photophosphorylation in photosynthesis and oxidative phosphorylation in cellular respiration. G3P is an intermediate in both pathways: in photosynthesis it is a product of the Calvin cycle, and in cellular respiration it is generated in glycolysis in the conversion of glucose to pyruvate. In photosynthesis, G3P is used for the synthesis of sugars and other fuel molecules, and in cellular respiration, it is part of the catabolism of sugars to simpler organic molecules.

Think Like a Scientist

FIGURE 9.10

Two.

IMR

There are two types of subunit, so there are two genes that encode the complete enzyme. The enzyme consists of eight copies each of the small subunit, encoded by one of the genes, and of the large subunit, encoded by the other gene.

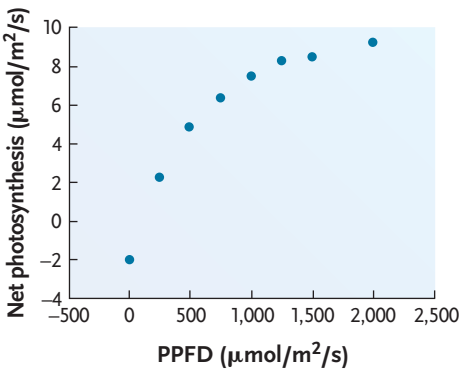
UQ

Imagine two types of desert plants. Some, like the wild watermelon plants of the Kalahari, grow very rapidly, with very robust photosynthesis, as soon as rain falls. They produce as many seeds as they can, quickly before severe drought sets in. This strategy requires rapid photosynthesis, even at the risk of photodamage. Others, such as desert scrub plants like sage, persist throughout the drought. They may grow slowly, with highly protected photosynthesis, even during times of rain. If they grew too fast, their large leaf surface areas would result in high water loss during drought. In some invasive plant species, aggressive photosynthesis and high growth rates have a selective advantage, allowing them to outcompete their rivals for resources like sunlight or growth space. In these cases, high rates of photosynthesis may be an advantage even as they risk photodamage. Other plants may invest for the longer term, building long-lived resilient structures (leaves, wood, etc.). The large investment may render risky photosynthetic

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

strategies less viable, instead preferring more "conservative" down-regulatory strategies. Still other plants may have to contend with lack of key nutrients, in which high photosynthetic rates or the need for rapid repair of the photosynthetic apparatus would be too "expensive" in terms of resources. Finally, humans have selected for traits in crop plants that are not related to photosynthetic yield—for example, tasty fruits, disease resistance, or short growing season. These traits often take precedence over photosynthetic efficiency.

Test Your Knowledge



1. d 2. b 3. a 4. c 5. e 6. a 7. b 8. d 9. d 10. b

Interpret the Data

1. When PPFD is zero, no photosynthesis is occurring, but respiration continues to occur. Based on the definition of net photosynthesis here and respiration from Chapter 8 *Interpret the Data,* respiration alone would have a negative value of CO_2 flux.

   The temperature for a respiration rate of 0.2 μmol/m^2/s is 25°C.

2.

3. A curve represents the data best. Net photosynthesis is saturating with increasing PPFD, indicating that some other factor (such as the amount of photosynthetic enzymes) is limiting photosynthesis.
4. Temperatures are predicted to increase, which would increase respiration according to the data and thus lower net photosynthesis. These data are insufficient to predict the actual impact of CO_2 concentrations on net photosynthesis because the plants would likely change their enzyme amounts or types (acclimate) in response to the rising temperature. Further, temperature is not the only factor that will likely change with rising CO_2. Other factors include precipitation, cloud cover, nutrient availability, etc.

Chapter 10

Study Break

STUDY BREAK 10.1

1. (1) An elaborate master program of molecular checks and balances ensures an orderly and timely progression through the cell cycle. (2) The process of DNA synthesis replicates each DNA chromosome into two copies with almost perfect fidelity. (3) A structural and mechanical web of interwoven "cables" and "motors" of the mitotic cytoskeleton separates the DNA copies precisely into the daughter cells.
2. A linear DNA molecule complexed with proteins
3. In mitosis, DNA replication is followed by the equal separation of the replicated DNA molecules and their delivery to daughter cells. The process ensures that the two cell products of a division have the same DNA content and the same genetic information as the parent cell entering division has.

STUDY BREAK 10.2

1. In order, the stages of mitosis are prophase, prometaphase, metaphase, anaphase, and telophase.
2. Each eukaryotic chromosome has a specialized region known as a centromere. The centromere is where a complex of several proteins, called a kinetochore, forms. During mitosis, some spindle microtubules attach to each kinetochore. These connections determine the outcome of mitosis because they attach the sister chromatids of each chromosome to microtubules leading to the opposite spindle poles; during anaphase, the spindle separates sister chromatids and pulls them to opposite spindle poles. In brief, the centromeres are key to chromosome segregation during mitosis. Although not mentioned in the chapter, this is also apparent when problems occur in which a chromosome fragment without a centromere breaks off from a chromosome. The fragment without a centromere cannot connect to the spindle and, hence, is not segregated properly.
3. Joined sister chromatid pairs attach to kinetochore microtubules during prometaphase and begin their migration to the metaphase plate. The spindle microtubules are also necessary for segregating the sister chromatids to opposite poles of the cell during anaphase. If colchicine is present, no spindle will form and no kinetochore microtubules are present to attach to the sister chromatids. Therefore, the cell will be stuck in mitosis with the condensed pairs of sister chromatids in an unorganized array.

STUDY BREAK 10.3

1. In animal cells, all of which have centrosomes, the spindle forms through division of the cell center. As the dividing centrosome separates into two parts, the microtubules of the spindle form between them. Plant cells lack centrosomes. In plant cells, the spindle microtubules simply assemble around the nucleus. In either case, the microtubules assemble in a parallel array that creates two poles in the dividing cell.
2. Chromosomes (sister chromatids) move apart during anaphase. During the anaphase movements, the kinetochores move along the kinetochore microtubules, which become shorter as anaphase progresses. The nonkinetochore microtubules slide over each other, decreasing the degree of overlap and pushing the poles farther apart. The total distance traveled by the chromosomes is the sum of the two movements.

STUDY BREAK 10.4

1. A Cdk can become active only once it has complexed with a cyclin protein. Each cyclin is present only during a particular segment of the cell cycle, controlled by when it is synthesized and degraded. Thus, the period in the cell cycle when a particular Cdk is active depends on when its activating cyclin is present.
2. When the kinase of the Cdk is activated upon binding to a cyclin, it phosphorylates target proteins in the cell, regulating their activities. Those proteins play roles in initiating or regulating key events of the cell cycle, namely DNA replication, mitosis, and cytokinesis. The progression through the cell cycle is regulated, then, by a succession of cyclin–Cdk complexes, each of which has specific regulatory effects.
3. An oncogene is an altered gene in an organism that contributes to the development of cancer—that is, uncontrolled cell division. Some of the genes that become oncogenes encode components of the cyclin–Cdk system that regulates cell division, whereas others encode proteins that regulate gene activity, form cell-surface receptors, or make up elements of the systems controlled by the receptors.
4. Metastasis is when cells break loose from a tumor, spread through the body, and grow into new tumors in other body regions.

STUDY BREAK 10.5

1. Prokaryotic cell division begins with replication of the bacterial chromosome, starting with duplication of the origin of replication. Once the origin of replication is duplicated, the two origins actively migrate to the two ends of the cells, a process that separates the two replicating chromosomes in the cell. Division of the cytoplasm then occurs by means of a partition of cell wall material that grows inward until the cell is separated into two parts. The cytoplasmic division divides the replicated DNA molecules and cytoplasmic structures between the daughter cells.
2. Present in eukaryotic cell division, but absent from prokaryotic cell division, are the following: the process of mitosis; any form of microtubules for chromosome segregation; a spindle apparatus; cyclin/CDK control proteins.

Think Like a Scientist

FIGURE 10.4

The colchicine would block spindle formation. As a result the cells would not be able to complete mitosis. In fact, colchicine is used to get cells to arrest in metaphase when the chromosomes are at their most condensed. At that stage, the chromosomes are the easiest to visualize by microscopy (see Figure 10.7).

FIGURE 10.12

The result supporting the kinetochore microtubule movement hypothesis would have been the movement of the bleached region toward the pole.

FIGURE 10.14

The result indicates that there are factors in the G_2 nucleus that accelerate the progress of the S nucleus towards mitosis.

IMR

The result indicates that expression of K cyclin (which occurred when the inducer was added) is sufficient to induce S phase entry in quiescent (G_0) cells.

UQ

Although *E. coli* is easy to culture, there is no known prokaryotic equivalent of mitosis; mammalian cells are hard to culture and cannot be kept in long-term culture (see *Focus on Basic Research*). *Focus on Model Organisms* provides abundant rationale for *Saccharomyces* as a model organism for this type of research. Ubiquitin is given this name because it is indeed ubiquitous—present in almost the same form in essentially all eukaryotes (see Chapter 16).

Test Your Knowledge

1. c 2. a 3. e 4. b 5. d 6. d 7. a 8. b 9. b 10. c

Interpret the Data

1. Radium exposure does not have an immediate effect on mitosis; that is, for about two hours after initiating radium exposure, there is not a significant drop in the number of cells in the population undergoing mitosis. (The researchers interpreted this to mean that not only were cells completing mitosis, but other cells commenced mitosis.) However, after about two hours of radium exposure, mitosis in the cell population exhibits a sudden drop to zero. In other words, radium blocks mitosis after a long enough exposure. The corollary is that there was no evidence for radium stimulating mitosis.
2. The effect of radium exposure was not permanent. Mitosis resumed about two hours after radium was removed. (Importantly, this result also shows that the decrease in mitosis as a result of radium exposure was not because of death of the cells.)

Chapter 11

Study Break

STUDY BREAK 11.1

1. Mitosis produces daughter cells that are genetically identical to the parent cell. Either a haploid or a diploid cell can undergo mitosis. Meiosis starts with a diploid cell. There is one round of DNA replication but two rounds of cell division, with the result that four haploid cells are produced from the parent diploid cell.
2. Recombination is the physical exchange of segments between the chromatids of homologous chromosomes. Recombination occurs in prophase I, when homologous chromosomes have each duplicated to produce sister chromatids and are aligned fully in an organization called a tetrad.
3. Meiosis II is the meiotic division that is similar to a mitotic division.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

STUDY BREAK 11.2

1. There are three ways in which sexual reproduction generates genetic variability. First, recombination, which involves the physical exchange of segments between homologous chromatids in prophase I of meiosis, generates new combinations of alleles. Second, the random separation of homologous chromosomes during meiosis generates genetic variability; that is, in metaphase I, for each homologous pair of chromosomes, one chromosome makes spindle connections leading to one pole and the other chromosome connects to the opposite pole. This process operates independently for each homologous pair of chromosomes; thus, for each meiosis random combinations of maternal and paternal chromosomes move to the poles during anaphase I. Third, the random joining of male and female gametes produces additional genetic variability.
2. The proportion of gametes that will have chromosomes that originate from the animal's female parent is: $(1/2)^6 = 1/64$.

STUDY BREAK 11.3

In animals, the diploid phase dominates the life cycle; mitotic divisions occur only in this phase. Meiosis in the diploid phase gives rise to products that develop directly into egg and sperm cells without undergoing mitosis.

In most plants, the life cycle alternates between haploid and diploid generations, both of which grow by mitotic divisions. Fertilization produces the diploid sporophyte generation; after growth by mitotic divisions, cells of the sporophyte undergo meiosis and produce haploid spores. The spores germinate and grow by mitotic divisions into the gametophyte generation. After growth of the gametophyte, cells develop directly into egg or sperm nuclei, which fuse in fertilization to produce the diploid sporophyte generation again.

Think Like a Scientist

IMR

The result suggests that CYP26B1 plays an essential role in germ cell development perhaps among all vertebrates, not just mammals.

UQ

The outcome depends on a variety of factors such as the extent of the rearrangement, its location in the genome and the particular organism or species being analyzed. However, very frequently, a phenomenon referred to as "synaptic adjustment" is observed. This allows the duplications and/or inversions to be accommodated (in many cases these just "loop out" from the fully paired homologs) and the homologs still succeed in synapsing. Occasionally, these rearrangements can also lead to nonhomologous synapsis and asynapsis.

Test Your Knowledge

1. b 2. a 3. d 4. c 5. b 6. b 7. b 8. d 9. a 10. b

Interpret the Data

1. At 20°C, one mother produced 21 male offspring; assuming 100 offspring, this would be 21%. This was the highest. The lowest was zero males produced by at least one mother at 20°C and 16-hour photoperiod. 15°C to 20°C seems to result in more male production than either higher or lower temperatures. No mothers produced male offspring at 25°C; some mothers produced no male offspring at 11°C. Less than 10% males were produced at 25°C or 11°C or at 20°C and 16-hour photoperiod.
2. At the moderate temperatures, slightly more males are produced with 12-hour days rather than 16-hour days. However, there is a wide range. If time has an effect, the effect is much less than the effect temperature has on the production of males.

NOTE: The authors concluded that the difference seen for photoperiod was not statistically significant, meaning that the difference seen could be merely because of chance.

Chapter 12

Study Break

STUDY BREAK 12.1

1. The numerical results approximate a 9:3:3:1 ratio. Therefore, both parents must be heterozygous for both genes. If we designate the alleles for one of the pairs of traits as *A* and *a,* and the alleles for the other pair of traits as *B* and *b,* each parent has the genotype *Aa Bb.*
2. A ratio of 1:1:1:1 is the typical outcome of a testcross involving a parent who is heterozygous for the alleles of two genes. Using the same allele symbols as in (1), the genotypes of the parents are *Aa Bb* and *aa bb;* this is a testcross.

STUDY BREAK 12.2

1. The color pattern involved is an incompletely dominant trait.
2. The fur colors here involve multiple alleles of a single gene. The allele symbols are *C* for wild type, c^{ch} for chinchilla, c^h for Himalayan, and *c* for albino, with dominance in the order $C \rightarrow c^{ch} \rightarrow c^h \rightarrow c$: that is, the *C* allele is completely dominant to the c^{ch} allele, the c^{ch} allele is completely dominant to the c^h allele, and so on. Therefore, we have these genotypes and phenotypes:
   C with c^{ch}, c^h, or c = agouti (*CC, Cc*^{ch}, *Cc*^{h}, *Cc*)
   c^{ch} with c^{ch}, c^h, or c = chinchilla ($c^{ch}c^{ch}$, $c^{ch}c^h$, $c^{ch}c$)
   c^h with c^h or c = Himalayan (c^hc^h, c^hc)
   c with *c* = albino *(cc)*

Think Like a Scientist

FIGURE 12.5

Purple-flowered F_2 plants are either *PP* or *Pp* in genotype. Only if *Pp* is selfed will you get purple-flowered and white-flowered progeny (it would be same as the $F_1 \times F_1$ self shown in the figure). There is a ratio of 1 *PP*:2 *Pp* plants as the Punnett square in the figure shows. Therefore, there is a 2 in 3 (two-thirds) chance that you will see both purple-flowered and white-flowered plants in the progeny.

FIGURE 12.8

This problem relates to the testcross shown in the figure. The ratio of the two types of progeny is approximately 1:1, a result that matches the Experiment 1 results in the figure. Therefore, the white-fat parent must have been heterozygous. The yellow-fat parent has to be homozygous recessive because of the information given about the fat-color phenotype. In short, the parents were *Ww* (white fat) × *ww* (yellow fat), which gives an expected 1:1 ratio of *Ww* (white fat):*ww* (yellow fat).

FIGURE 12.9

The cross would be *Rr Yy* × *Rr yy.* The progeny are determined by constructing a Punnett square and filling in the squares. For the *Rr Yy* parent, there are four types of gametes just as in the figure; that is, 1/4 *R Y,* 1/4 *R y,* 1/4 *r Y,* and 1/4 *r y.* For the *Rr yy* parent, there are two types of gametes; that is, 1/2 *R y* and 1/2 *r y.* This gives you 8 squares in this particular Punnett square with these progeny: 1/8 *RR Yy,* 1/8 *RR yy,* 1/8 *Rr Yy,* 1/8 *Rr yy,* 1/8 *Rr Yy,* 1/8 *Rr yy,* 1/8 *rr Yy,* and 1/8 *rr yy.* Collecting the genotypes with the same phenotypes together we get 3/8 round, yellow (1/8 *RR Yy* + 1/8 *Rr Yy* + 1/8 *Rr Yy*), 3/8 round, green (1/8 *RR yy* + 1/8 *Rr yy* + 1/8 *Rr yy*), 1/8 wrinkled, yellow (1/8 *rr Yy*), and 1/8 wrinkled, green (1/8 *rr yy*).

IMR

In Chapter 4, you learned that the substrate(s) for an enzyme interact with a small region of an enzyme called the *active site.* It is at the active site where enzyme catalysis occurs. The active site of an enzyme is formed by a particular array of amino acids in the polypeptide chain. Those amino acids have evolved to be optimal for enzyme activity. A mutation that alters an amino acid in or near the active site can affect the structure of the active site and, therefore, adversely affect the enzyme's catalytic activity. The extent of the deleterious effect depends on the particular amino acid substitution and the chemical changes brought about in the protein by the substitution.

UQ

If you sequence lots of species you will identify lots of regions of strong evolutionary constraint. If you look at many individuals within a species, you can look at the rate of fast-evolving alleles that might have responded to population-specific pressures or drift and start asking questions pertaining to the genome of the human. Ultimately, your choice will depend on the question you are trying to answer. If you are trying to understand developmental processes, cross-species comparisons are extremely useful, but if you are looking at immunity, maybe the within-species comparison is better.

Test Your Knowledge

1. (a) The *CC* parent produces all *C* gametes, and the *Cc* parent produces 1/2 *C* and 1/2 *c* gametes. All offspring would have colored seeds—half homozygous *CC* and half heterozygous *Cc.* (b) Both parents produce 1/2 *C* and 1/2 *c* gametes. Of the offspring, three-fourths would have colored seeds (1/4 *CC* + 1/2 *Cc*) and one-fourth would have colorless seeds (1/4 *cc*). (c) The *Cc* parent produces 1/2 *C* gametes and 1/2 *c* gametes, and the *cc* parent produces all *c* gametes. Half of the offspring are colored (1/2 *Cc*) and half are colorless (1/2 *cc*).
2. The genotypes of the parents are *Lele* and *lele.*
3. The taster parents could have a nontaster child, but nontaster parents are not expected to have a child who can taste PTC. The chance that they might have a taster child is 3/4. The chance of a nontaster child being born to the taster couple would be 1/4. Because each combination of gametes is an independent event, the chance of the couple having a second child, or any child, who cannot taste PTC is expected to be 1/4.
4. (a) All *A B.* (b) 1/2 *A b* + 1/2 *a b.* (c) 1/2 *A B* + 1/2 *a B.* (d) 1/4 *A B* + 1/4 *A b* + 1/4 *a B* + 1/4 *a b.*
5. (a) All *Aa BB.* (b) 1/4 *AA BB* + 1/4 *AA Bb* + 1/4 *Aa BB* + 1/4 *Aa Bb.* (c) 1/4 *Aa Bb* + 1/4 *Aa bb* + 1/4 *aa Bb* + 1/4 *aa bb.* (d) 1/4 *Aa Bb* + 1/8 *AA Bb* + 1/8 *Aa BB* + 1/8 *Aa bb* + 1/8 *aa Bb* + 1/16 *AA BB* + 1/16 *AA bb* + 1/16 *aa BB* + 1/16 *aa bb.*
6. (a) All *A B C.* (b) 1/2 *A B c* + 1/2 *a B c.* (c) 1/4 *A B C* + 1/4 *A B c* + 1/4 *a B C* + 1/4 *a B c.* (d) 1/8 *A B C* + 1/8 *A B c* + 1/8 *A b C* + 1/8 *A b c* + 1/8 *a B C* + 1/8 *a B c* + 1/8 *a b C* + 1/8 *a b c.*
7. Because the man can produce only 1 type of allele for each of the 10 genes, he can produce only 1 type of sperm cell with respect to these genes. The woman can produce 2 types of alleles for each of her 2 heterozygous genes, so she can produce 2 × 2 = 4 different types of eggs with respect to the 10 genes. In general, as the number of heterozygous genes increases, the number of possible types of gametes increases as 2^n, where n = the number of heterozygous genes.
8. Use a standard testcross; that is, cross the guinea pig with rough, black fur with a double recessive individual, *rr bb* (smooth, white fur). If your animal is homozygous *RR BB,* you would expect all the offspring to have rough, black fur.
9. One gene probably controls pod color. One allele, for green pods, is dominant; the other allele, for yellow pods, is recessive.
10. The cross *RR* × *Rr* will produce 1/2 *RR* and 1/2 *Rr* offspring. The cross *Rr* × *Rr* will produce 1/4 *RR,* 1/2 *Rr,* and 1/4 *rr* as combinations of alleles. However, the 1/4 *rr* combination is lethal, so it does not appear among the offspring. Therefore, the offspring will be born with only two types, *RR* and *Rr,* with twice as many *Rr* as *RR* in a 1:2 ratio (or 1/3 *RR* + 2/3 *Rr*).
11. The parental cross is *GG LeLe RR* × *gg lele rr.* All offspring of this cross are expected to be tall plants with green pods and round seeds, or *Gg Lele Rr.* When crossed, this heterozygous F_1 generation is expected to produce eight different phenotypes among the offspring: green–tall–round, green–dwarf–round, yellow–tall–round, green–tall–wrinkled, yellow–dwarf–round, green–dwarf–wrinkled, yellow–tall–wrinkled, yellow–dwarf–wrinkled, in a 27:9:9:9:3:3:3:1 ratio.

12. The genotypes are: bird 1, *Ff Pp;* bird 2, *FF PP;* bird 3, *Ff PP;* bird 4, *Ff Pp.*
13. Yes, it can be determined that the child is not hers, because the father must be AB to have both an A and B child with a type O wife; none of the woman's children could have type O blood with an AB father.
14. The cross is expected to produce white, tabby, and black kittens in a 12 : 3 : 1 ratio.
15. The mother is homozygous recessive for both genes, and the father must be heterozygous for both genes. The child is homozygous recessive for both genes. The chance of having a child with normal hands is 1/2, and that of having a child with woolly hair is 1/2. Using the product rule of probability, the probability of having a child with normal hands and woolly hair is $1/2 \times 1/2 = 1/4$.

Interpret the Data

Yes, the data support the hypothesis that the tolerance trait is dominant. Let us assign *T* as the symbol for the dominant allele for being tolerant, and *t* as the symbol for the recessive allele for being intolerant.

Cross 1: The crosses of true-breeding tolerant plants with true-breeding intolerant plants are $TT \times tt$. The F_1 offspring are *Tt*. If the tolerance trait is dominant, the $F_1 \times F_1$ crosses are genotypically $Tt \times Tt$, which produces an F_2 generation with a genotypic ratio of 1 *TT*:2 *Tt*:1 *tt,* which gives a phenotypic ratio of 3 alive (tolerant):1 dead (intolerant), which approximately matches the results.

Cross 2: As described for Cross 1, the F_1 plants have the *Tt* genotype. An $F_1 \times$ intolerant parent cross is $Tt \times tt$. The offspring from this cross are expected to have a genotypic ratio of 1 *Tt* :1 *tt,* which gives a phenotypic ratio of 1 alive:1 dead, which approximately matches the results.

Cross 3: An $F_1 \times$ tolerant parent cross is $Tt \times TT$. The offspring from this cross are expected to have a genotypic ratio of 1 *TT*:1 *Tt;* so all of the progeny are expected to be alive, which matches the results.

Chapter 13

Study Break

STUDY BREAK 13.1

The cross to use is the testcross. Here, the testcross would be *Aa Bb* × *aa bb.* A testcross is used so that you can follow the meiotic events in the dihybrid parent (including the consequences of crossing over between linked genes) because all of the gametes from the testcross parent carry recessive alleles for the genes in the cross. A testcross shows linkage when the ratio of 1 : 1 : 1 : 1 for the four possible phenotypes is not seen; that is, the 1 : 1 : 1 : 1 ratio result occurs when two genes assort independently. However, if two genes are linked, there will be excess of the two parental classes of progeny compared with the two recombinant classes.

STUDY BREAK 13.2

The differences between sex-linked inheritance and autosomal inheritance are seen clearly when reciprocal crosses are made and followed through to the F_2 generation. If sex-linked inheritance is involved, a cross of miniature-winged female × normal-winged male flies will give an F_1 generation of all normal-winged female and all miniature-winged male flies. (This result would not be found with autosomal inheritance. Instead, all F_1 flies—both males and females—would have normal wings.) Selfing the F_1 flies will give an F_2 generation with 1 : 1 normal-winged : miniature-winged flies in both sexes. (For autosomal inheritance, you would see a 3 : 1 ratio of normal-winged : miniature-winged flies in both sexes.)

In the reciprocal cross of true-breeding normal-winged female × miniature-winged male, the F_1 flies will all have normal wings if sex-linked inheritance is involved. (This result is the same as for autosomal inheritance.) Selfing the F_1 flies will give an F_2 generation in which all females will have normal wings and the males will be 1/2 normal-winged and 1/2 miniature-winged. (For autosomal inheritance, you would see a 3 : 1 ratio of normal-winged : miniature-winged flies in both sexes.)

In summary, reciprocal crosses show different segregation patterns of phenotypes for sex-linked inheritance and autosomal inheritance. The two modes of inheritance are easiest to distinguish in a cross of a mutant female × wild-type male because then, in the F_1 generation, all males show the mutant phenotype when sex-linked inheritance is involved.

STUDY BREAK 13.3

(a) Duplication of a chromosome segment occurs when a segment breaks from one chromosome and is inserted into its homolog.

(b) A Down syndrome individual results when nondisjunction of chromosome 21 during meiosis occurs (usually in females), producing gametes with two copies of chromosome 21 and one copy of every other chromosome. When such a gamete fuses with a normal gamete, the result is a zygote with three copies of chromosome 21 and two copies of the other chromosomes. This individual will have Down syndrome. Aneuploidy is the term for the condition of extra or missing chromosomes.

(c) A translocation occurs when a broken segment of a chromosome becomes attached to a different, nonhomologous chromosome.

(d) Polyploidy means that there are more sets of chromosomes than the typical diploid set. Polyploidy may result if the spindle fails to function properly in mitosis of cell lines leading to gametes. Cells affected in this way will have twice the normal number of sets of chromosomes. When meiosis subsequently occurs, the gametes produced will have two sets of chromosomes. Fusion of these gametes with, for instance, a gamete with one set of chromosomes will produce a zygote with three sets of chromosomes—a triploid cell.

STUDY BREAK 13.4

1. Autosomal recessive inheritance: For a child to exhibit an autosomal recessive trait, he or she must inherit one recessive allele from each parent. For autosomal recessive inheritance to explain Simpson syndrome in the family, the father must be homozygous for the Simpson syndrome allele, *ss,* and the mother must be heterozygous, *Ss.* The expectation would be that 1/2 of the children would be *Ss* and 1/2 would be *ss,* regardless of sex, and that is what is found. Therefore, on the assumption that the mother is heterozygous, the syndrome could be an autosomal recessive trait. Sex-linked recessive inheritance: One characteristic of sex-linked recessive inheritance is that affected females pass on the trait to all their sons. Here, we start with an affected male, and he would have to be X^sY if it is a sex-linked recessive trait. To explain the children, we would have to assume that the mother is heterozygous, X^SX^s. The cross of $X^SX^s \times X^sY$ is expected to give 1/2 females with the syndrome and 1/2 males with the syndrome, which is what is described. Therefore, the syndrome could be a sex-linked recessive trait.
2. Autosomal recessive inheritance: In pedigrees of autosomal recessive traits, the appearance of progeny with a trait when both parents do not have the trait is one common feature. If we assume that both parents are heterozygous, *Ww,* then the children can be explained; that is, you can get both wiggly-eared children (*ww,* expected frequency 1/4) and nonwiggly-eared children (*WW* or *Ww,* combined expected frequency 3/4), regardless of sex. Therefore, wiggly ears could be an autosomal recessive trait based on this family. Sex-linked recessive inheritance: Because a male individual has only one X chromosome, it is not possible for two nonwiggler parents to produce a wiggler daughter. To get a wiggler daughter, the male would have to be X^wY (wiggler) and the female would have to be X^WX^w (nonwiggler), which is not the case here. Therefore, we cannot conclude that ear wiggling is a sex-linked recessive trait based on this family.

STUDY BREAK 13.5

A mutant trait that shows cytoplasmic inheritance is caused by an alteration in the DNA of an organelle, either the mitochondrion or the chloroplast. A key property of cytoplasmic inheritance is that a trait is transmitted by a parent to all offspring, regardless of sex. The most common form of this is maternal inheritance, in which the progeny inherit the trait from their mother, paralleling the inheritance of mitochondria and mitochondrial DNA from the female parent and not from the male parent. This pattern of inheritance would not be seen for genes on chromosomes in the nucleus (as explained in Chapter 11).

Think Like a Scientist

FIGURE 13.2

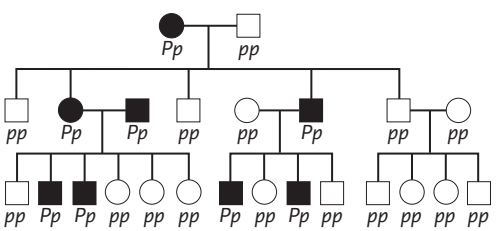
The two largest classes in the progeny of the testcross would be red, vestigial and purple, normal—that is, the parental phenotypes. In this case the parental phenotypes are not a wild-type flies and flies with both mutations, but flies each with just one of the mutant phenotypes and the other phenotype wild-type.

The two smallest classes in the progeny of the testcross would be wild-type flies and flies that are both purple and vestigial.

FIGURE 13.8

The woman with normal vision must have at least one c^+ allele. One of her X chromosomes is inherited from her father, who is color blind and therefore *c*Y in genotype. Therefore, the woman is heterozygous c^+c. The man has normal vision. He has one X and one Y chromosome so the only possibility for his genotype is c^+Y; the fact that his father was color blind is not a factor in this case. For the cross $c^+c \times c^+Y$, the expected progeny are 1/4 c^+c^+ (normal vision female) : 1/4 c^+c (normal vision female) : 1/4 c^+Y (normal vision male) : 1/4 *c*Y (color blind male). In sum, all female offspring will have normal vision and 1/2 of the males will have normal vision and 1/2 will be color blind.

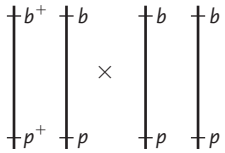
IMR



You learned about amino acids and protein structure in Section 3.4. Figure 3.17 shows the 20 amino acids. Glycine is a nonpolar amino acid, whereas arginine is positively charged polar amino acid. Since the varied properties and functions of proteins depend on the types and locations of the different amino acid side groups in their structures, it would be expected that a change from a nonpolar amino acid to a charged polar amino acid in a functionally important part of a protein would adversely affect the protein's function. Both glycine and alanine are nonpolar amino acids; the two amino acids are therefore similar, chemically speaking. You would speculate that substituting alanine for glycine would have a minimal effect on protein function.

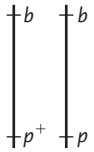
UQ

No, the genes in the del(5q) region still have some activity. In these patients, only one copy of the gene is lacking due to a chromosomal deletion. The other copy, or allele, is present and appears to have its normal function. Since these patients now only have one copy of the genes in this deleted region, there is a lowered gene dosage, referred to as "haploinsufficiency." A lowered gene dosage (and resultant production of lower protein levels) can have profound effects on cell growth. Scientists currently believe that the lowered gene expression of *multiple* genes in the del(5q) region work together to play a role in disease development.

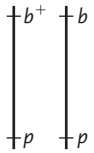


Test Your Knowledge

1. All sons will be color blind, but none of the daughters will be. However, all daughters will be heterozygous carriers of the trait.
2. The chance that her son will be color blind is 1/2, regardless of whether she marries a normal or color-blind male.
3. All these questions can be answered from the pedigree. Polydactyly is caused by a dominant allele, and the trait is not sex-linked. The genotypes of each person are:



Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.



4. The sequence of the genes is ADBC.
5. Let the allele for wild-type gray body color = b^+, and the allele for black body = b. Let the allele for wild-type red eye color = p^+, and the allele for purple eyes = p. Then the parents are:

The F_1 flies with black bodies and red eyes are:

and the flies with gray bodies and purple eyes are:

6. The genes are linked by their presence on the same chromosome (an autosome), but they are not sex-linked. Because the F_1 females must have produced 600 gametes to give these 600 progeny, and because 42 + 30 of these were recombinant, the percentage of recombinant gametes is 72/600, or 12%, which implies that 12 map units separate the two genes.
7. The initial cross is X^wX^w white female 3 $X^{w^+}Y$ red male. The F_1 females produced are $X^{w^+}X^w$, with red eyes, and the F1 males are X^wY, with white eyes.

   The cross of an F_1 female with a parental male, therefore, is $X^{w^+}X^w$ (red) 3 $X^{w^+}Y$ (red). The offspring are $X^{w^+}X^{w^+}$ and $X^{w^+}X^w$ females, both of which have red eyes, and $X^{w^+}Y$ (red) and X^wY (white) males in equal proportions. Thus the phenotypic ratio for females is 2 red : 0 white, and that for males is 1 red : 1 white.

   The cross of an F_1 male with a parental female is X^wY (white) × X^wX^w (white). All progeny of both sexes will be white-eyed.
8. You might suspect that a recessive allele is sex-linked and is carried on one of the two X chromosomes of the female parent in the cross. When present on the single X of the male (or if present on both X chromosomes of a female), the gene is lethal.

Interpret the Data

1. Data are expressed as µg of DNA to control for the amount of sample analyzed from each individual.
2. Smoking promotes the formation of DNA adducts. The more the individual smoked, the more adducts were observed.
3. Stopping smoking lowered the level of adduct formation.
4. The highest point in the data from the nonsmoker most probably reflects an exposure to high levels of passive or second-hand smoke in the nearby environment.

Chapter 14

Study Break

STUDY BREAK 14.1

^{35}S-labeled phages in this scenario will have labeled protein coats and labeled DNA. When these phages infect bacteria, radioactivity enters the cell and is found in the progeny phages. In addition, radioactivity is found in the phage material removed by the blender. ^{32}P-labeled phages in this scenario are like the phages in Hershey and Chase's experiment; they have labeled DNA but unlabeled protein. When these phages infect bacteria, radioactivity enters the cell and is found in the progeny phages. No radioactivity is found in the phage material removed by the blender.

STUDY BREAK 14.2

1. Adenine and guanine are purines. Thymine and cytosine are pyrimidines.
2. Complementary base pairs are held together by hydrogen bonds. Each base is attached to the deoxyribose sugar by a covalent bond.
3. Watson and Crick described the right-handed double helix that consists of two sugar–phosphate backbones on the outside and complementary base pairs between the two backbones. A complementary base pair is a purine paired with a pyrimidine, more specifically, an A with a T, and a G with a C. The two strands of DNA are antiparallel. The key dimensions of the molecule are: diameter = 2 nm; 1 base pair = 0.34 nm; 1 turn of the helix = 10 base pairs = 3.4 nm.
4. The question focuses on the complementary base-pairing rules: A = T and G = C. If A = 20%, then T = 20%, giving 40% of the DNA as A–T base pairs. Therefore, 60% of the base pairs in this DNA molecule are G–C, and the percentage of C is 30%.

STUDY BREAK 14.3

1. Complementary base pairing ensures that the new DNA double helix is a faithful copy of the parental DNA double helix. For whatever base is exposed on the template strand, the DNA polymerase inserts the nucleotide with the complementary base.
2. DNA polymerases cannot initiate a DNA strand; they can add DNA nucleotides only to the 3′ end of an existing strand. The primer serves to provide a short stretch of nucleic acid that can be extended by DNA polymerase. The primer consists of RNA, rather than DNA, and is made by primase.
3. DNA polymerase III is the main DNA polymerase for replication in *E. coli*. This enzyme extends each primer that is synthesized on the lagging strand template, and synthesizes the leading strand. DNA polymerase I is used in lagging strand DNA synthesis. This enzyme replaces DNA polymerase when a new DNA fragment reaches the 5′ end of the Okazaki fragment that was made previously. With its 5′→3′ exonuclease activity, DNA polymerase I removes the RNA primer of that Okazaki fragment, and with its 5′→3′ polymerizing activity it replaces that primer with DNA nucleotides. In this way the Okazaki fragment is converted from an RNA–DNA hybrid into a DNA fragment.
4. Telomeres are buffers against the progressive loss of the ends of chromosomes by repeated rounds of replication. Only when the hundreds to thousands of copies of the telomere repeats have been lost are genes exposed. When those genes are lost by continued chromosome shortening and/or when chromosomes break down in the absence of telomeres, the cell is severely damaged.

STUDY BREAK 14.4

Proofreading prevents errors from being introduced into the DNA sequence. The DNA sequence in an organism's genome specifies everything about that organism—most notably, its function and reproduction. If significant errors occur during replication, gene sequences could be changed and the function of the organism could be adversely affected. Particularly if there is a high rate of errors, as there would be in the absence of proofreading, these errors would have potentially lethal consequences.

As part of the proofreading process, DNA polymerase reverses and removes the mispaired nucleotide. The enzyme then continues to move forward, inserting the correct nucleotide.

DNA repair mechanisms then look for and correct any errors that were not detected by proofreading. For example, repair enzymes remove a section of the newly synthesized DNA with the mismatch, and DNA polymerase synthesizes a replacement section with the correct base pairing.

STUDY BREAK 14.5

1. The nucleosome consists of two molecules each of histones H2A, H2B, H3, and H4 assembled into a nucleosome core particle wrapped with almost two turns of DNA. The diameter of the nucleosome is 10 nm.
2. Histone H1 is responsible for the next level of chromosome packing above the nucleosome. H1 binds to the exit/entry point of DNA on the nucleosome and to the linker DNA and brings about a coiling of the chromatin into the 30-nm chromatin fiber. The coiled structure is called the solenoid.

Think Like a Scientist

FIGURE 14.2

Yes, theoretically this could have been done; that is, the transforming principle is the genetic material. Given that *R* and *S* cells are genetically different, the transforming principle released from heat-killed *R* cells could convert living *S* cells to *R* cells. However, only if all *S* cells in a mouse were converted to *R* cells would the mouse live. This is unlikely so, practically speaking, this proposed experimental design is not a good one.

FIGURE 14.3

Carbon is found in both protein and DNA. Therefore, the radioisotope would be found in phage coats on phage-infected cells, within phage-infected cells, and in progeny phages. The success of the Hershey and Chase experiment relied on using radioisotopes that were specific for DNA and protein which is why the isotopes of phosphorus and sulfur were used. The carbon radioisotope would have not been useful in the experiment to answer the question asked.

FIGURE 14.9

First consider the data in the Figure. After one generation in ^{14}N, all the DNA is ^{15}N–^{14}N. After two generations, 1/2 the DNA is ^{15}N–^{14}N and 1/2 is ^{14}N–^{14}N. Therefore, by understanding how the semiconservative replication mechanism works, after four replications you would expect 1/8 of the DNA to be ^{15}N–^{14}N, and 7/8 to be ^{14}N–^{14}N. After five replications you would expect 1/16 of the DNA to be ^{15}N–^{14}N and 15/16 to be ^{14}N–^{14}N.

FIGURE 14.15

Without normal DNA ligase activity, Okazaki fragments could not be joined and synthesis of a continuous lagging strand could not be completed. In actuality, a mutant DNA ligase of this kind would be lethal to the cell. Some temperature-sensitive mutants have been isolated for bacteria, though, in which DNA ligase activity is normal at normal growth temperatures but nonfunctional or only partially functional at high temperatures. At the high temperatures, such mutants accumulate Okazaki fragments because they cannot be joined into longer chains.

IMR

Males have one X chromosome whereas females have two. For a female to express an X-linked recessive trait, both of her X chromosomes must carry the mutant gene. However, for a male to express such a trait, he just needs one copy of the mutant chromosome. On probability grounds, therefore, it is more likely for a male to have an X-linked recessive trait because he only has to inherit one mutant chromosome in contrast to the situation for a female who must inherit two mutant copies.

UQ

Telomerase alone is not the sole determinant of telomere length. The complex of proteins at the telomere regulates access of telomerase to the telomere. Thus, even if the amount of telomerase in the cell is unchanged, certain conditions could alter the function of one or more proteins at the telomere to increase the ability of telomerase to elongate the chromosome ends.

Interpret the Data

1. Schedule B, CDDP (8h) followed by 5-FU, was the most effective treatment because it resulted in the lowest percentage of cell proliferation.
2. B was the only schedule in which cells were first treated with CDDP alone.

Chapter 15

Study Break

STUDY BREAK 15.1

1. Although most enzymes are proteins, not all proteins are enzymes. And, some proteins consist of more than one polypeptide subunit. Each different polypeptide is encoded by a different gene, hence the one gene–one polypeptide hypothesis.
2. There are four different letters in the code (A, U, G, C), so a five-letter code would have 4^5 possible combinations = 1,024 codons.

STUDY BREAK 15.2

1. 5′-GUUUAACCGAAUAAUGGCCUAC-3′
2. The promoter determines where transcription of a gene will begin. In prokaryotes, RNA polymerase binds to the nucleotide sequence of the promoter and orients in the correct way to transcribe the associated gene. In eukaryotes, transcription factors bind to the promoter and then recruit RNA polymerase, which then orients properly for transcription from the transcription start point.

STUDY BREAK 15.3

1. Both pre-mRNAs and mRNAs have a 5′ cap, exons, and a 3′ poly(A) tail. Only pre-mRNAs have introns, which are removed from pre-mRNAs to produce mRNAs.
2. Particular snRNPs bind to the ends of an intron using their contained RNAs to recognize the boundary sequences of the intron. Other snRNPs then bind, causing the intron to loop out, and completing the active spliceosome. Cleavage at each intron-exon junction, looping back of the intron on itself, and joining the two exons together completes the splicing event; the intron and snRNPs are then released.

STUDY BREAK 15.4

1. In eukaryotes, a complex of the small ribosomal subunit, initiator tRNA, initiation factors, and GTP binds to the 5′ cap of the mRNA and scans along the mRNA until it reaches the first AUG codon, which is the start codon. The anticodon of the initiator tRNA binds to the start codon, the large ribosomal subunit binds, and the initiation factors are released when GTP is hydrolyzed.

   In prokaryotes, a complex of the small ribosomal subunit, initiator tRNA, initiator factors, and GTP binds to the region of the mRNA where the AUG start codon is located, directed by a specific RNA sequence upstream of the start codon. The other steps are the same as those in eukaryotes.
2. The P site is where the tRNA with the growing polypeptide is located. Downstream of the P site is the A site. An incoming aminoacyl–tRNA enters the A site and its anticodon base pairs with the codon of the mRNA in that site. When the polypeptide is transferred to the amino acid on the tRNA in the A site, the ribosome translocates one codon along the mRNA. As translocation takes place, the empty tRNA that was in the P site is moved to the E site. It remains there, blocking a new aminoacyl–tRNA entering the A site until translocation is finished. Then the empty tRNA is released from the ribosome.
3. Proteins found in the cytosol are made on free ribosomes.

   Proteins are sorted to the endomembrane system by cotranslational import. The proteins begin their synthesis on free ribosomes. These proteins have signal sequences at their N-terminal ends that direct them and the ribosome to dock with a receptor on the rough ER membrane. Continued translation inserts the growing polypeptide into the lumen of the ER, and the signal sequence is removed by signal peptidase. The proteins are then tagged to target them for sorting to their final destinations. Some proteins remain in the ER, whereas others are transported via the Golgi to vesicles for sorting to lysosomes, secreting them from the cell, or depositing them in the plasma membrane.

   Proteins are sorted to mitochondria, chloroplasts, microbodies, and the nucleus by posttranslational import. Proteins destined for the mitochondria, chloroplasts, and microbodies have short N-terminal transit sequences that target them to the organelle. A transit sequence interacts with a specific transport complexes on the organelle, and the polypeptide is then taken into the organelle. The transit sequence is then removed. Proteins destined for the nucleus have a nuclear localization signal which is bound by a cytosolic protein. The complex then interacts with the nuclear pore complex and the polypeptide then is transported into the nucleus through the pore.

STUDY BREAK 15.5

1. A missense mutation involves a change from a sense codon to another sense codon that specifies a different amino acid. A silent mutation involves a change from one sense codon to another sense codon, but where both codons specify the same amino acid.
2. Genetic recombination occurs by crossing over between two homologous sequences. TE transposition occurs by integration into a new location with which the TE has no sequence homology.
3. Both: (1) have inverted repeats at their ends; (2) contain a transposase gene; and (3) integrate into target sites and cause a duplication of the target site.
4. A transposon is a mobile genetic element that moves from one location to another in the genome as a DNA molecule.

   A retrotransposon is a mobile genetic element that moves from one location to another in the genome using an RNA intermediate; that is, the integrated DNA element is transcribed to produce an RNA copy. The RNA copy is reverse-transcribed into DNA, which then integrates at a new location in that genome.

Think Like a Scientist

FIGURE 15.2

Skin color depends on the synthesis of a pigment. It is reasonable to assume that synthesis of a pigment involves a biosynthesis pathway. A hypothesis to explain the results is that mutations in genes that encode enzymes that control different steps in that pathway can result in albinism. Therefore, the first couple consists of two individuals each of whom are homozygous for the albinism mutation in one of those genes. That pairing can produce offspring who have the same genotypes as the parents with respect to the albinism genes, and, thus, they have albinism.

The individuals of the second couple, however, must be homozygous mutant for different genes involved in albinism. However, their other albinism gene is homozygous normal. Therefore, each offspring of this couple inherits a normal allele and a mutant allele of one albinism gene and a normal allele and a mutant allele of the other albinism gene. Because albinism is a recessive trait, the presence of the two normal genes of the genes results in the children having normal skin color.

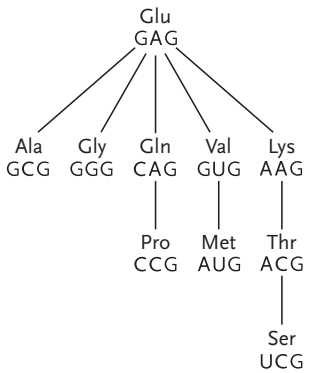
FIGURE 15.6

No. Although transcription occurs in highly similar ways in eukaryotes and prokaryotes, the initiation processes in particular are specific; that is, different promoter sequences are used, and eukaryotic RNA polymerases typically recognize only eukaryotic promoter sequences, and prokaryotic RNA polymerases typically recognize only prokaryotic promoter sequences. Therefore, *E. coli* RNA polymerase is unlikely to be able to recognize the promoter of the eukaryotic protein-coding gene in the figure.

IMR

The result provides support for the hypothesis that the conserved bases likely play an important functional role in peptide bond formation and, therefore, supports the conclusions of the study.

UQ



1. The first ribosomes were made only of RNA.
2. Not to make proteins, but to make simple protein fragments (peptides) that bind to RNA to help RNA carry out its biological functions before the evolution of proteins.

The codons specifying the amino acids are shown in the following figure:

Chapter 16

Study Break

STUDY BREAK 16.1

1. The Lac repressor is active when it is made. In normal cells, in the absence of lactose, the Lac repressor binds to the operator, blocking transcription. In the mutant, the Lac repressor is not made, so transcription can never be blocked because no repressor is available to bind to the operator. As a consequence, the lactose metabolizing enzymes will be made both in the presence and absence of lactose in the medium. The mutation involved is an example of a regulatory mutant. Mutations such as this were valuable to Jacob and Monod in developing the operon model for gene regulation.
2. The Trp repressor is inactive when it is made. In normal cells, in the presence of tryptophan, the Trp repressor is activated, binding to the operator and blocking transcription. In the mutant, the Trp repressor is not made, so the operon cannot be turned off when tryptophan is present. This means that the tryptophan biosynthesis enzymes will be produced both in the presence and absence of tryptophan.

STUDY BREAK 16.2

1. General transcription factors bind to the promoter and recruit RNA polymerase II, orienting the enzyme so that it will begin transcription at the beginning of the gene. Activators bind to regulatory sequences associated with genes and increase the rate of transcription. Activators that bind to regulatory sequences in the proximal promoter region interact directly with the general transcription factors at the promoter to exert their action. Activators that bind to regulatory sequences in the enhancer stimulate transcription indirectly. These latter activators bind to a coactivator that also binds to the complex of proteins at the promoter, and transcription then occurs at the maximal possible rate.
2. Histones are general negative regulators of gene expression. When DNA is complexed with histones in normal chromatin, gene promoters typically are not very accessible to the transcription machinery. By acetylating histones, the chromatin is remodeled, making the promoter now accessible to the transcription machinery. Acetylation of histones occurs in response to the binding of an activator to a regulatory sequence associated with the gene.

STUDY BREAK 16.3

1. A microRNA (miRNA), in a complex with particular proteins, binds to an mRNA by complementary base pairing. Either the proteins cut the mRNA in the region of pairing, thereby destroying that molecule, or the double-stranded RNA region blocks translation.
2. Removal of the poly(A) tail would result in the mRNA not being translated.

STUDY BREAK 16.4

1. Determination is the process by which the developmental fate of a cell is set. Differentiation is the establishment of a cell-specific developmental program in cells. Determination and differentiation are under molecular control. Regulatory genes encode regulatory proteins that bind to promoters of the genes they control, switching the genes on or off depending on the interaction.
2. The segmentation genes subdivide the embryo progressively into regions, thereby determining the segments of the embryo and the adult. In essence, they organize the embryo into segments. The homeotic genes specify the identity of each segment with respect to the body part it will become.

STUDY BREAK 16.5

1. A tumor suppressor gene encodes a product that has an inhibitory role in the cell division cycle. If a tumor suppressor gene is mutated so that its product is nonfunctional or its function is significantly diminished, then the gene's inhibitory control of cell division is lost or reduced. As a result, the cell may progress toward division.
2. A proto-oncogene encodes a product that has a stimulatory role in cell division. Mutations that lead to increased levels of that product have converted a proto-oncogene to an oncogene. The increased amount of product is stimulatory to cell division.
3. Some miRNAs have been shown to regulate the expression of mRNA transcripts of particular tumor suppressor genes. Overexpression of those miRNAs can abnormally inhibit the activity of those tumor suppressor genes, thereby removing or decreasing inhibitory signals for cell proliferation. Other miRNAs have been shown to regulate the expression of mRNA transcripts of particular proto-oncogenes. Inactivation of those miRNAs means that the proto-oncogenes are expressed at higher than normal levels, which can stimulate cell proliferation.

Think Like a Scientist

FIGURE 16.3

If the Lac repressor cannot bind to the operator, then the *lac* operon structural genes will be transcribed even in the absence of lactose because there is no block to the binding of RNA polymerase to the promoter. By contrast, in a normal cell, the Lac repressor binds to the operator and blocks RNA polymerase from transcribing the *lac* structural genes as long as lactose is absent from the medium.

FIGURE 16.5

If the Trp repressor cannot bind tryptophan, then the repressor could not be activated when tryptophan is present in the medium. Without an active repressor in this condition, RNA polymerase cannot be blocked from binding to the promoter. Therefore, the Trp structural genes will be transcribed. By contrast, in a normal cell, the presence of tryptophan in the medium activates the Trp repressor which then binds to the operator and blocks transcription of the *trp* structural genes by RNA polymerase.

IMR

First, the CREB monomer must have a binding site for itself so that it can form a dimer. Second, the dimer must have a binding site for CRE (cAMP response element) sequences in the enhancers for regulatory genes that it controls. Third, CREB must have a binding site for the Tax protein.

UQ

Dr. Kay's lab uses mice to test RNAi therapies against hepatitis C virus. You could test various RNAi agents via an intravenous infusion to find a dose where the viral load (or level) is reduced substantially without causing any dangerous toxicities that have been determined by standard laboratory testing of blood samples. Kay's lab aims to reduce viral load by at least 100-fold.

1. The woman would have an 8.6% chance of dying of cancer.
2. Her risk of dying of cancer is 18.0% if she carries a mutated *BRCA1* gene.
3. This study suggests a *BRCA1* mutation is more dangerous than a *BRCA2* mutation (in effect, *BRCA1* mutations are associated with a higher percentage of deaths). Sixteen out of 89 women with the *BRCA1* mutation died whereas only 1 out of 35 women with the *BRCA2* mutation died.
4. You would need to know the number of deaths of women who had a preventive mastectomy and the number of deaths of women who had a preventive oophorectomy.

Chapter 17

Study Break

STUDY BREAK 17.1

1. An F^+ cell contains the F factor plasmid in addition to the chromosomal DNA. The F factor enables an F^+ cell to conjugate with an F^- cell, which lacks the F factor. By a special replication mechanism, a copy of the F factor is transferred to the recipient F^- cell in an $F^+ \times F^-$ conjugation, so the recipient is converted to an F^+ cell.

   An Hfr cell has the F factor integrated into the chromosomal DNA. When an Hfr cell conjugates with an F^- cell, the F factor begins its replicative transfer into the recipient as in an $F^+ \times F^-$ conjugation and, by that transfer mechanism brings in chromosomal genes from the Hfr donor. Those chromosomal genes can recombine with the genes in the recipient. Because replication of the F factor begins in the middle of the plasmid, the entire F factor cannot be transferred to the recipient unless the entire chromosome is transferred to the recipient, which occurs only rarely. Hence, the recipient remains F^- in this conjugation experiment.
2. In gene segregation in sexually reproducing organisms, genetic material moves from one generation to the next, basically by descent. In horizontal gene transfer, the movement of genetic material between organisms is other than by descent. For instance, in transformation, a DNA molecule in the environment is taken up by a recipient cell—the DNA has moved horizontally from a donor cell (from which the DNA was released) to the recipient cell. Genetic recombination in the recipient can alter the phenotype of that cell.

STUDY BREAK 17.2

1. A virulent phage always enters the lytic cycle when it infects a bacterial cell. The end result is the assembly of many progeny phages and their release into the surroundings when the cell breaks open.

   A temperate phage enters either the lytic cycle or the lysogenic cycle when it infects a cell. The lytic cycle is the same as that for a virulent phage. The lysogenic cycle involves integration of the phage's chromosome into the bacterial chromosome. In the integrated state the phage—now called the prophage—is inactive and replicates only when the bacterial chromosome replicates. In response to an adverse environmental signal to the cell, the phage chromosome can excise itself from the bacterial chromosome and enter the lytic cycle.
2. Animal cells: Viruses without an envelope bind by their recognition proteins to receptor proteins in the host cell's plasma membrane and are then taken into the cell by receptor-mediated endocytosis. For some enveloped viruses, the genome-containing capsid enters the cell when the envelope fuses with the host cell's plasma membrane. For other enveloped viruses, the complete virus, with the envelope, enters the cell by endocytosis.

   Plant cells: All plant viruses lack envelopes. They enter cells either through mechanical injuries to leaves and stems or by the action of biting and feeding insects.
3. Non-retrovirus RNA viruses have RNA genomes that are replicated in an RNA-to-RNA manner. Retroviruses have RNA genomes that are replicated via a DNA intermediate: that is, the RNA genome is copied to double-stranded DNA by reverse transcriptase and the DNA molecule integrates into the host cell's nuclear chromosomes, from which location new RNA viral genomes are transcribed.

STUDY BREAK 17.3

Although all are infectious agents, viruses have protein coats, whereas viroids and prions do not. A virus consists of a nucleic acid genome surrounded by a protein coat and, in some cases an envelope. Viroids are naked, single-stranded RNA circular molecules. Prions are proteins.

Think Like a Scientist

FIGURE 17.1

The control plates were used to check that the mutant alleles in the two strains did not mutate back to normal alleles; that is, mutation back to the nonmutant state would allow the cells to grow on the minimal medium plates. By having more than one mutant allele in each strain (two in strain 1 and three in strain 2), Lederberg and Tatum were making it extremely unlikely to see colonies on the minimal plate; that is, for strain 1, two mutant alleles would have to mutate to normal alleles, and for strain 2, three mutant alleles would have to mutate to normal alleles. If we made the simple assumption that the rate of mutation from mutant to normal is the same for all genes, then the probability of having two genes mutate from mutant to normal is the square of the probability for one to mutate. Moreover, the probability of having three genes mutate from mutant to normal is the cube of the probability for one to mutate. Therefore, having just one mutant allele in each strain would mean that the probability of generating a nonmutant cell by mutation would be much higher than for the two- or three-mutant allele strains.

FIGURE 17.4

The transfer of chromosomal genes by conjugation is dependent on the F factor. Genes on the F factor direct the one-way transfer of a copy of the F factor to a recipient in $F^+ \times F^-$ conjugations. When the F factor is integrated into the chromosome to produce an Hfr, again the F factor genes direct a one-way transfer of DNA from donor to recipient, in this case involving the F factor attached to the bacterial chromosome. There is no mechanism, therefore, for transfer of chromosome genes in the opposite direction—that is, from recipient to donor.

FIGURE 17.8

As you learned in the text, the prophage state is maintained by a phage-encoded repressor molecule that prevents expression of phage genes for the lytic cycle. When the prophage is transferred into a recipient cell, that cell will not contain repressor proteins and, because it takes time for new repressor proteins to be synthesized, the result will be that the λ lytic cycle genes will be expressed and the recipient will be killed by phage release. If the recipient already contained a λ prophage, then repressor proteins would already be present and the transferred prophage would remain repressed with respect to the lytic cycle genes.

IMR

That the DNase converted the radioactive macromolecules from acid-insoluble to acid-soluble, whereas RNase did not, affirms that the macromolecules synthesized must be DNA and not RNA.

UQ

Researchers can further study the interactions between normal prion protein and prion aggregates and the effect of these interactions on neurons. One possible function for the normal prion protein is to act as a signaling molecule to regulate apoptosis. Interactions with prion particles may induce aberrant signaling through the normal prion protein. Since the normal prion protein also binds to many other molecules (for example, extracellular matrix components), one could also

The answer is shown in the figure. The segments of donor chromosomes transferred by each Hfr strain are shown, with the arrowheads showing the beginning.

Chapter 18

Study Break

STUDY BREAK 18.1

1. Each restriction enzyme recognizes a specific sequence in DNA, typically in the range of 4 to 6 bp, and cuts both strands of the DNA within the sequence. Restriction enzymes differ with respect to the DNA sequences—the restriction sites—they recognize and cut. The enzymes most useful for cloning produce sticky ends.
2. Replication origin so that the plasmid will replicate in *E. coli,* an antibiotic resistance gene to allow selection of bacteria containing the plasmid, a cluster of restriction sites (a multiple cloning site) to provide choices for inserting fragments of DNA, and the *lacZ*$^+$ gene to use in blue–white screening, in which colonies containing recombinant plasmids (white) are distinguished from colonies with vectors lacking inserted DNA (blue).
3. A cDNA library is a collection of clones in which DNAs that are complementary to the mRNAs in the cell have been inserted into a cloning vector. The array of particular clones in a cDNA library is directly related to the genes expressed in the cells from which the mRNAs are isolated. Therefore, not all genes are represented in any given cDNA library. By contrast, a genomic library is a collection of clones containing all the sequences of an organism inserted into a cloning vector. A genomic library contains all of the genes of an organism, as well as noncoding sequences found between and within genes.
4. PCR is a method to amplify a specific segment of DNA. The amplification process depends on DNA replication and, therefore, requires primers. A limitation of PCR, then, is that DNA sequence information must be available for the segment of DNA to be amplified. Otherwise, the primers cannot be synthesized. The ingredients of a PCR are the template DNA containing the sequence to be amplified, the two primers, a buffer, and a DNA polymerase that is tolerant to the high temperature used to denature the DNA repeatedly during the cycles of the reaction.

STUDY BREAK 18.2

1. Each human (or other organism) has unique combinations and variations of DNA sequences. DNA fingerprinting exploits these combinations and variations to distinguish between different individuals (with the exception of identical twins). Using DNA technologies to analyze the particular regions of the genome showing sequence variation, it is possible to compare two DNA samples to see if they are from the same person or not. DNA fingerprinting is used in several ways, including forensics, paternity testing, and basic research.
2. A transgenic organism is one into which a gene or genes from an external source have been introduced as a means to modify the organism genetically.
3. Germ-line cells develop into reproductive cells, so modifying this cell type genetically will lead to the genetic modification being passed to offspring. In somatic cell gene therapy, germ-line cells and their products are not involved, so the inserted genes remain with the individual and are not passed to offspring.

Think Like a Scientist

FIGURE 18.14

To demonstrate that the experiment was a success, it was necessary to show that a clone matched that of the donor genetically and, importantly, did not match that of the surrogate mother. Only by starting with genetically distinguishable kinds of sheep could that be demonstrated.

IMR

As discussed in Chapter 7, plasma membrane receptors, when activated by a signal molecule, transduce the signal into the cell and through a signal transduction pathway to bring about a cellular response. By knowing that signal transduction pathway is involved, researchers could set out to elucidate the pathway thereby providing information that could be useful for the design of disease control strategies.

UQ

Tissue-specific stem cell niches serve to both protect stem cells against environmental insults and control stem cell responses. Cellular and neuronal signals that control stem cell dormancy and proliferation are often uniquely adapted to these microenvironments. This ensures that tissue-specific stem cells receive signals in a tightly controlled manner.

Test Your Knowledge

1. e 2. d 3. a 4. a 5. d 6. b 7. e 8. b 9. a 10. d

Interpret the Data

An offspring must have one allele of each gene inherited from the male parent, and the other allele of each gene inherited from the female parent. The same goes for STR locus alleles.

Juvenile 1: Not the offspring of the two adults. The juvenile has one allele in common with the male parent (8 repeats = 72 bp), but its other allele came from neither adult (9 repeats = 81 bp). In other words, it is heterozygous for 8- and 9-repeat alleles.

Juvenile 2: Could be the offspring of the two adults. There was only one DNA fragment size amplified by PCR. The interpretation is that this juvenile is homozygous for a 6-repeat (54-bp) allele, which is why there is more DNA amplified (a thicker band). Each adult has a 6-repeat allele that could have passed to the juvenile.

Juvenile 3: Not the offspring of the two adults. This juvenile is heterozygous for 5-repeat (45-bp) and 11-repeat (99-bp) alleles. The 11-repeat allele could have been inherited from the female adult, but neither adult has the 5-repeat allele.

Juvenile 4: Could be the offspring. This juvenile is heterozygous for 6-repeat (54-bp) and 8-repeat (72-bp) alleles. It could have inherited the 6-repeat allele from either parent, but could have inherited the 8-repeat allele only from the male parent. Therefore, the 6-repeat allele would have had to come from the female parent.

Chapter 19

Study Break

STUDY BREAK 19.1

Having the complete sequence of a genome enables a researcher to ask questions about the organization of genes and of other sequences of importance in the genome. The most important question is how the functions of all of the genes in a genome direct that organism's life. It also allows researchers to compare gene content and gene order between organisms, which provides insight into how genomes evolve.

STUDY BREAK 19.2

1. In whole-genome shotgun genome sequencing, the entire genome is broken into thousands to millions of random, overlapping fragments, each fragment is cloned and sequenced, and then the genome sequence is assembled by computer on the basis of sequence overlaps between fragments.
2. Protein-coding genes, noncoding RNA genes, regulatory sequences associated with genes, origins of replication, transposable elements and related sequences, pseudogenes, and short repetitive sequences.
3. To find protein-coding genes in a bacterium, computer algorithms search a genome sequence for open reading frames (ORFs), which are defined as the DNA equivalent of a start codon (ATG) in frame (a multiple of three away) from a stop codon (TAG, TAA, or TGA). Such a segment of DNA could potentially produce an mRNA that could be translated into a protein. Other analyses would be required to show if any given ORF identified in this way is an actual protein-coding gene.

   To find protein-coding genes in a mammal, one also needs to find ORFs. However, the presence of introns in eukaryotic protein-coding genes complicates matters. Therefore, more sophisticated computer algorithms are needed—in this case ones that attempt to locate exon-intron boundaries while they search for ORFs.
4. Prokaryotic genomes vary widely in size. Nonetheless, their genes are densely packed in their genomes (a fairly consistent density of 900 genes per Mb), with little noncoding space between them. Genomes of eukaryotes also show a great range of sizes; overall, their genomes are much larger than those of prokaryotes. Gene density also varies considerably in eukaryotes, ranging from 500 per Mb for the single-celled yeast to fewer than 10 per Mb in mammals. There is no uniformity to the packing of genes, however.

   Prokaryotic genes are arranged either singly or in operons, depending on the genes. All eukaryotic genes are arranged singly; no operons are found in eukaryotes. The number of regulatory sequences typically is much higher for eukaryotic protein-coding genes than for prokaryotic protein-coding genes. There are no introns in prokaryotic protein-coding genes, whereas most eukaryotic protein-coding genes contain introns. Introns can make up significant proportions of eukaryotic genomes—for example, about 20% in humans. In contrast to prokaryotes, eukaryotes contain many pseudogenes, many transposable element sequences, and a variety of short repeated sequences. A prokaryotic chromosome has one origin of replication, whereas a eukaryotic chromosome may have hundreds to thousands of origins of replication.

STUDY BREAK 19.3

1. The function of a gene identified in a genome sequence may be assigned by a sequence similarity search of sequence databases to find a match with a gene of known function, by comparing the structure of the protein encoded by the gene with the structures of proteins with known function, and by experiments that alter the expression of the gene to see how the phenotype of a cell or organism is affected.
2. A genome-wide analysis of gene expression here could involve DNA microarray assays. The mRNAs could be isolated from untreated tissue culture cells and from cells treated with a steroid hormone. Convert each mRNA preparation to cDNAs using reverse transcriptase, using nucleotide precursors with different fluorescent labels for the two batches; for example, green for the untreated (reference) sample and red for the treated (experimental) sample. Mix the two cDNAs and pump them through a DNA chip prepared to have spots with DNA representing every gene in the genome. Allow hybridization to occur, and analyze the hybridization by laser detection. The colors of the spots indicate which genes are affected by the steroid hormone. Purely red spots represent genes that are active only in hormone-treated cells. Purely green spots represent genes that are

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

active only in untreated cells. Spots that are a mixture of green and red represent genes that are active in both types of cells. Based on controls, it would be possible to see if any of the genes have higher or lower expression levels in the treated cells.

3. The proteome is complete set of proteins that can be expressed by an organism's genome. Proteomics has the three major goals of determining the number and structures and functions of proteins of the proteome, determining the location of each protein within or outside the cell, and determining the physical interactions between proteins.

STUDY BREAK 19.4

1. Tandem duplication happens when homologous pairs of chromosomes do not line up properly in meiosis. As a result of unequal crossing over, one gamete inherits a chromosome with two copies of the stretch of DNA between the two points of crossing over, and therefore duplicate copies of any genes on that stretch of DNA. Dispersed duplication happens when transposable elements copy the DNA for a gene and insert the new copy somewhere else in the genome.
2. Gene duplication produces two identical copies of a gene that only evolve distinct functions as different mutations occur in each copy. Exon shuffling, by contrast, combines parts of two or more genes in an evolutionarily novel way. The protein coded for by the new gene contains a combination of domains that may never before have existed in one protein. Because a protein's domains usually each perform a different molecular function, the newly evolved protein may have a combination of functionalities unlike any previously existing protein.

Think Like a Scientist

UQ

Knowledge that an individual is genetically predisposed to developing a disease or is at greater risk for the aftereffects of disease based on genotype may cause emotional distress, and fear of discrimination by employers or insurance companies. Similar concerns may exist if genetic information suggests that disease treatment options for an individual are limited. The Genetic Information Nondiscrimination Act (GINA) was recently enacted to help address these concerns.

Test Your Knowledge

1. b 2. a 3. a 4. a 5. d 6. d 7. d 8. a 9. d 10. d

Interpret the Data

To find an open reading frame, you first find a start codon (see Figure 15.5), and then count three nucleotides at a time until you find a stop codon in the same reading frame (see Figure 19.4). This sequence contains 6 start codons and therefore 6 open reading frames. The first open reading frame begins with the start codon at the very beginning of the second line and has 145 codons between the start and stop codon, which makes it large enough to code for a functional protein. The other open reading frames have only 5, 15, 8, 28, and 11 codons between the start and stop codon, so they are very unlikely to code for functional proteins.

Chapter 20

Study Break

STUDY BREAK 20.1

1. Buffon did not understand how "anatomically perfect" animals could have useless structures.
2. Lamarck proposed: all species change through time, the changes are inherited by the next generation, the changes arise in response to environmental conditions, and specific mechanisms caused the changes.
3. The concepts of gradualism and uniformitarianism suggest that Earth's major geological features were produced by the very slow action of geological processes observed today. Thus, it must have taken more than 6,000 years for these features to assume their present forms.

STUDY BREAK 20.2

1. Darwin observed that living organisms often resemble fossils found in the same area; that organisms found on South America resembled one another, even if they occupied different environments; and that many species found on the Galápagos Islands resembled species from the South American mainland.
2. Darwin realized that the effects of competition for resources in nature were similar to the action of a plant or animal breeder who used only certain individuals as parents to produce the next generation.
3. Darwin's theory relied on physical explanations for the origin of biodiversity: he recognized that evolutionary change takes place within a population rather than in individuals; he recognized that natural selection is a multistage process; and he emphasized the importance of environmental conditions to the process of natural selection.

STUDY BREAK 20.3

1. Two problems that slowed the acceptance of Darwin's theory are that Mendel's genetic studies focused on simple traits and that these traits often changed in just a few generations.
2. Microevolution refers to small, genetically based changes within populations. Macroevolution refers to larger-scale evolutionary changes observed in species and more inclusive groups. Current research suggests that microevolutionary change and macroevolutionary change result from the same evolutionary processes.
3. Evidence for evolution comes from studies of adaptation, the fossil record, historical biogeography, comparative morphology, and comparative molecular biology.

Think Like a Scientist

FIGURE 20.12

The continued use of DDT to control mosquito populations would probably result in nearly 100% resistance to DDT in the populations of mosquitoes exposed to that insecticide.

FIGURE 20.14

Most vertebrate biologists agree that the loss of legs in snakes was probably favored by natural selection as a mechanism to facilitate locomotion through environments with dense vegetation or to facilitate burrowing underground.

IMR

The conclusion that the extinct woolly mammoth is similar genetically to living Asian elephants parallels Darwin's conclusion that extinct glyptodonts and living armadillos are closely related. In both cases, living organisms occupy the landmass where fossils of their extinct relatives are found.

UQ

If climate change rapidly disrupts physical environments everywhere on Earth, Arctic species are unlikely to adapt to those changes. Given the frequency of extinction in the fossil record, one might assume that most of the species living today will become extinct eventually, and rapid climate change is likely to speed that process.

Test Your Knowledge

Interpret the Data

The graph suggests that selective breeding of race horses did improve the speed of horses that won the Kentucky Derby between 1896 and 1960. However, the speed of winners has been stable since that time, suggesting that additional selection would not lead to future improvements in speed.

Chapter 21

Study Break

STUDY BREAK 21.1

1. The variation in skunks is qualitative.
2. The researchers used artificial selection to change the activity levels of the mice.
3. Genetic variation, differing environmental effects on individuals, and interactions between genes and the environment affect phenotypic variation in a population.

STUDY BREAK 21.2

1. Genotype frequencies specify how alleles are combined in individuals, and allele frequencies specify how common the alleles are.
2. The Hardy–Weinberg principle is a null model because it identifies the conditions under which evolution will *not* occur.
3. If genotype frequencies are not already in equilibrium, they will stop changing after one generation of random mating.

STUDY BREAK 21.3

1. Mutation and gene flow tend to increase genetic variation within populations, and natural selection and genetic drift tend to decrease it.
2. Stabilizing selection increases the representation of the average phenotype in a population.
3. Sexual selection, like directional selection, favors extreme phenotypes.

STUDY BREAK 21.4

1. Diploidy protects harmful recessive alleles because dominant alleles mask their effects in heterozygotes.
2. A balanced polymorphism is one in which two or more phenotypes are maintained in fairly stable proportions over many generations.
3. The sickle-cell allele is rare in Northern Europe because, in the absence of the malarial parasite, it confers no advantage on individuals that carry it.

STUDY BREAK 21.5

1. The adaptive value of a trait can be evaluated by comparing closely related species that live in different environments.
2. Natural selection preserves traits that were useful when the organisms subject to selection were alive and reproducing.

Think Like a Scientist

FIGURE 21.6

After nine or 10 generations of artificial selection, the distance run and average speed appear to have leveled off for three of the four experimental lines of mice. The data suggest that continued artificial selection might not have a very strong ongoing effect on these traits.

FIGURE 21.9

Dachshunds are the product of directional selection on two traits: body length was increased and leg length was decreased.

FIGURE 21.10

Natural selection may select against a genetic predisposition for multiple births in humans because newborn triplets or quadruplets are each much smaller than the offspring of a single-child pregnancy and would therefore have a higher mortality rate.

FIGURE 21.11

A decline in bird populations might decrease natural selection against gall-making flies that produced large galls. As a result, the average size of goldenrod galls would likely increase.

FIGURE 21.13

Lengthening the male widowbirds' tails had a much larger effect on the number of mates they attracted than shortening their tails did.

FIGURE 21.15

No, the association between shell color and pattern and the habitat occupied is not absolute. The data in the graph indicate that virtually all populations of snails include individuals with different shell colors and striping patters. The data show that the majority of snails in populations in wooded habitats have brown, unstriped shells and that the majority of snails in populations in hedges and fields have yellow, striped shells.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

FIGURE 21.16
Yes, the data indicate the fish's preference for the dark brown form of the water boatmen over the medium brown and pale brown forms: fish ate a higher percentage of dark brown water boatmen at every percentage availability. Nevertheless, this preference did not override the frequency-dependence of their food choice.

IMR
If the ban on whaling had taken effect 34 years later than it actually did, the amount of genetic variability in humpback whale populations today would undoubtedly be lower than the level revealed in the 1993 study. Of course, with a worldwide population of only 5,000 individuals in 1966, the species may well have become extinct if the ban had not taken effect at that time.

UQ
If recombination induces mutations, then regions of high recombination should have many differences between species. This suggests a test for whether recombination rate and genetic variation are connected mechanistically vs. connected by the action of natural selection. Both mechanistic and selective explanations predict that regions of high recombination have lots of genetic variation *within* species—more than regions of low recombination—but only mechanistic explanations predict that genetic differences *between* species should be greater in regions of high recombination than in regions of low recombination.

Test Your Knowledge
1. c 2. b 3. c 4. d 5. b 6. e 7. a 8. b 9. c 10. d

Interpret the Data
The graphs illustrate the action of directional selection favoring birds with deeper bills because the distribution of bill depths in the survivors (lower graph) is shifted slightly to the right of the distribution of bill depths in the population before the drought (upper graph).

Chapter 22

Study Break

STUDY BREAK 22.1
1. The morphological species concept defines species based on morphological differences among them. The biological species concept defines species as populations that can successfully interbreed under natural conditions. The phylogenetic species concept defines a species as a cluster of populations with a recent shared evolutionary history.
2. Clinal variation is a pattern of smooth variation along a geographical gradient.

STUDY BREAK 22.2
1. Prezygotic isolating mechanisms either prevent individuals of different species from mating or prevent sperm of one species from fertilizing the eggs of another. Postzygotic isolating mechanisms limit the survivorship or reproductive capability of hybrid individuals.
2. The scenario illustrates a behavioral isolating mechanism.

STUDY BREAK 22.3
1. In the first stage of allopatric speciation, populations become geographically separated. In the second stage, they become reproductively isolated.
2. Some populations of bent grass survive better on unpolluted soil, whereas others survive better on polluted soil.
3. Insects from different host races spend most of their time on different host plant species. Thus, they rarely encounter each other and would be unlikely to mate under natural conditions.

STUDY BREAK 22.4
1. Natural selection cannot promote reproduction isolation in allopatric populations directly, but it can lead to genetic divergence which results in reproductive isolation.
2. Polyploidy changes the number of chromosome sets in the cells of an organism. Polyploid individuals are often reproductively isolated from their parent species because their gametes contain different numbers of chromosomes. When a gamete from a polyploid individual fuses with a gamete from a nonpolyploid individual, the resulting offspring is usually sterile because the odd number of chromosomes cannot segregate properly during meiosis.

Think Like a Scientist

FIGURE 22.13
Yes, the pollination agent should have little impact on temporal reproductive isolation. Copper-tolerant plants, which flower earlier than pasture plants, would simply attract insect pollinators before pasture plants did.

FIGURE 22.16
After a spontaneous doubling of the chromosomes in the hybrid offspring, the allopolyploid would have $2n = 20$.

FIGURE 22.18
The difference in chromosome structure between humans and their closest relatives among the apes represents a postzygotic reproductive isolating mechanism, because, at a minimum, these structural differences would prevent human and ape chromosomes from pairing up during meiosis.

IMR
The eight floral traits that differ between the two monkey-flower species attract different animal pollinators. Genetic differences in anthocyanin and carotenoid pigment concentrations influences petal color; bees are attracted to purple flowers with yellow nectar guides, and hummingbirds are attracted to red flowers. Differences in petal width and flower width allow bees to land on *M. lewisii* flowers, but not on *M. cardinalis* flowers. The small volume of concentrated nectar in *M. lewisii* flowers is suitable for bees, and the large volume of dilute nectar in *M. cardinalis* flowers is suitable for hummingbirds. Differences in the positions of male and female reproductive parts allow bees to collect pollen from *M. lewisii* on their legs and body and hummingbirds to collect pollen from *M. cardinalis* on their foreheads.

UQ
Most of the asexual organisms for which the biological species definition is not a good match are bacteria. Because these organisms do not exhibit as much morphological distinctness as many animals do, biologists rely on comparisons of their DNA or RNA sequences to analyze their evolutionary relationships. These data allow researchers to construct phylogenetic trees for the organisms they study, indicating that any new species definition that applies to them would probably resemble the phylogenetic species definition more than the morphological species definition.

Test Your Knowledge
1. a 2. e 3. c 4. d 5. b 6. e 7. b 8. c 9. a 10. b

Interpret the Data
The graphs suggest that sympatric populations of the three frog species experience temporal prezygotic reproductive isolation. Populations that are allopatric exhibit substantial overlap in breeding times, especially in March, April, and May. By contrast, sympatric populations exhibit almost no overlap in breeding times.

Chapter 23

Study Break

STUDY BREAK 23.1
1. Hard parts, such as the shells or bones of animals, are the materials most likely to fossilize.
2. The fossil record provides an incomplete portrait of life in the past because not all organisms are equally likely to form fossils; fossils do not form in all types of habitats; and fossils are often destroyed by geological processes and erosion.
3. The fossil record provides information about the morphology of ancient organisms; how structures changed over time; and the proliferation and extinction of evolutionary lineages. It also offers indirect evidence about the behavior, ecology, and physiology of organisms that lived in the past.

STUDY BREAK 23.2
1. Continental drift caused large-scale geographical separation of populations and lineages that subsequently evolved in isolation.
2. Sea levels fell whenever a large proportion of Earth's water was incorporated into glaciers.

STUDY BREAK 23.3
1. Continuous distribution requires no special explanations. Biologists infer that lineages with a continuous distribution simply occupy all or one part of their historical range.
2. Distantly related species that live in widely separated parts of the world may resemble each other because convergent evolution fosters similar adaptations to the environments they occupy.

STUDY BREAK 23.4
1. A population of organisms may occupy a new adaptive zone after the evolution of a key morphological innovation that allows it to use the environment in a unique way or after a once-successful group of organisms declines.
2. Huge volcanic eruptions triggered a chain of events that led to the mass extinction at the end of the Permian period. These eruptions warmed the atmosphere and oceans enough to melt frozen undersea methane reserves. The methane entering the atmosphere warmed the climate even further, creating a "runaway greenhouse" effect.
3. The first major adaptive radiation of animals took place in the Cambrian era.

STUDY BREAK 23.5
1. The horse lineage was highly branched, and it included some species that were larger and some that were smaller than their ancestors.
2. Phyletic gradualism predicts that morphological change is slow and steady, producing fossils with morphologies that are intermediate between the structures found in lower and higher strata. The punctuated equilibrium hypothesis predicts that morphological changes occur rapidly as new species form and that most species experience little morphological change for long periods of time.

STUDY BREAK 23.6
1. Allometry refers to the differential growth of body parts. Heterochrony refers to changes in the timing of developmental events.
2. Similar developmental control genes are present in a wide variety of animals, plants, fungi, and prokaryotes. Their widespread distribution suggests that they were present in the ancestor of all these organisms and have been conserved through countless generations.
3. The *Pitx1* gene is expressed in fin buds that later produce spines, and it is not expressed in those that fail to produce spines.

Think Like a Scientist

FIGURE 23.18
No, artificial selection has not reversed the many evolutionary trends observed in the fossil record for horses. A reduction in body size appeared multiple times in horse evolution.

FIGURE 23.19
The changes in rib number over time in *Bergamia* and *Ogyginus* appear to be the products of directional selection that alternated between favoring increased rib number and decreased rib number. However, the observed changes in rib number may have been induced by genetic drift.

FIGURE 23.20
Once they became distinct as different species, *M. colligatum*, new species #7, and new species #9 sometimes exhibited more gradual change in overall morphological difference than did most of the other species.

FIGURE 23.23
The structural difference in the flowers of *D. decorum* and *D. nudicaule* might help maintain reproductive isolation between the two species by restricting bee and hummingbird pollinators to one species or the other.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

IMR
The prolonged expression of *Hoxd* genes in the developing limbs of tetrapods is an example of heterochrony, a change in the timing of developmental events.

UQ
For genes that are very pleiotropic—that is, have many diverse functions—regulatory evolution may be more likely. Shifts in gene expression domains can produce rapid morphological change while leaving other functions intact. However, we can never rule out coding changes, especially if gene duplication has reduced pleiotropy.

Test Your Knowledge
1. a 2. e 3. b 4. d 5. c 6. c 7. a 8. d 9. e 10. b

Interpret the Data
The data illustrate allometric growth in this evolutionary lineage. Brain size increased more than 200% over three million years, but body size increased only about 50%.

Chapter 24

Study Break

STUDY BREAK 24.1
1. The system of binomial nomenclature avoids ambiguity in the naming of species because it assigns a unique two-part name to each species.
2. The taxonomic hierarchy helps biologists organize information about different species because it categorizes them into increasingly inclusive groups. Species that are included in a lower taxonomic category share many characteristics, whereas those included only in the same higher taxonomic category share fewer characteristics.

STUDY BREAK 24.2
1. A phylogenetic tree is a formal hypothesis about the evolutionary relationships among species. A classification is an arrangement of organisms into hierarchical groups that reflect their relatedness.
2. A monophyletic taxon contains an ancestor and all of its descendants. A polyphyletic taxon includes species from different clades. A paraphyletic taxon includes an ancestor and some, but not all, of its descendants.

STUDY BREAK 24.3
1. Systematists use homologous characters in their analyses because similarities in homologous characters indicate genetic relatedness and shared ancestry.
2. Morphological traits are often useful for tracing the evolutionary relationships within a group of organisms because they can be observed and measured in fossils as well as in living organisms.
3. Molecular characters provide several advantages in systematic analyses: (1) they provide abundant data; (2) molecular sequences can be compared between distantly related organisms that share no organismal characteristics or between closely related species with only minor morphological differences; and (3) proteins and nucleic acids are not directly affected by developmental or environmental factors that cause nongenetic morphological variation.

STUDY BREAK 24.4
Traditional systematics emphasizes the divergence of groups as well as branching evolution. Groups that have evolved very different morphology are sometimes placed in a taxon that is different from the one to which the rest of their clade is assigned.

STUDY BREAK 24.5
1. Outgroup comparison is a technique that compares the group under study—the ingroup—to more distantly related organisms—the outgroup—to identify the ancestral and derived versions of characters. Character states observed in the outgroup are considered ancestral.
2. In a cladistic analysis, organisms with synapomorphies (shared derived characters) are grouped together within a clade.
3. The principle of parsimony suggests that the cladogram or phylogenetic tree with the fewest number of hypothesized evolutionary changes is the best current hypothesis about the phylogenetic history of a group.

STUDY BREAK 24.6
1. An assumption that underlies the use of genetic sequence differences as molecular clocks is that mutations arise at a relatively constant rate.
2. Birds are more closely related to non-avian dinosaurs than they are to crocodilians.

STUDY BREAK 24.7
1. Different strains of HIV were acquired from chimpanzees and from sooty mangabey monkeys.
2. Phylogenetic analyses of prokaryotes based on morphological data were not very successful because prokaryotes do not have many morphological features. Analyses based on molecular sequence data have been more successful because researchers can identify many molecular differences among the lineages of prokaryotes.

Think Like a Scientist

FIGURE 24.12
No, the data in the table do not contain any information that would allow the development of an hypothesis about the evolutionary relationship of cycads and ginkgophytes. For the five characters listed, these groups exhibit identical character states. The phylogenetic trees illustrated in the figure are actually based on data about many additional characters in all of the plant groups listed. The analysis in the figure is simplified to illustrate the parsimony method for evaluating phylogenetic trees.

FIGURE 24.14
The *Yp1* sequence in *Drosophila* appears to have accumulated mutations slightly faster than the cytochrome *b* sequence in honeycreepers, as revealed by the average numbers of units of genetic distance that evolved per million years.

IMR
The ancestors of whales must have undergone many morphological changes as they made the transition from land to the sea. Three obvious changes include modifications of their limbs into flippers; modification of their overall shape to facilitate more efficient swimming; and modifications of their sensory systems to function under water instead of in the open air.

UQ
The Linnaean system of classification cannot easily incorporate the phenomenon of horizontal gene transfer because it pigeonholes species into a nested hierarchy of rigidly defined taxonomic categories. Although a phylogenetic view of biodiversity also depends on the vertical transmission of derived traits from one generation to the next, horizontal gene transfer can at least be illustrated on phylogenetic trees.

Test Your Knowledge
1. c 2. b 3. a 4. b 5. e 6. a 7. a 8. e 9. d 10. c

Interpret the Data
The European wildcat is the domestic cat's closest relative. The clade that includes jaguars, lions, and leopards is the sister clade to tigers. Bobcats are more closely related to cougars than to ocelots because they share a more recent common ancestor with cougars.

Chapter 25

Study Break

STUDY BREAK 25.1
1. Only in a reducing atmosphere can amino acids be produced from simpler chemicals and energy. Without amino acids there can be no life. Thus, any theory for the origin of life must consider the necessity of reducing conditions.
2. Current thinking is that early Earth's atmosphere *per se* was not reducing; scientists have looked for localized regions where conditions were of a reducing nature, such as ocean floor hydrothermal vents. Another hypothesis is that some amino acids had an extraterrestrial origin.

STUDY BREAK 25.2
Lipid bilayers in the form of membranes are present in all present-day cellular organisms. Therefore, it is more intuitive to conceive of a path from a simple lipid bilayer system to a membrane-bound cell than it is to conceive of a transition of a clay-based system to a cellular system.

STUDY BREAK 25.3
The basic tenet of the theory of endosymbiont origins for mitochondria and chloroplasts is that organelles such as mitochondria and chloroplasts originated from symbiotic relationships between two prokaryotic organisms. An anaerobic prokaryotic is proposed to have ingested an aerobic prokaryote, which persisted in the cytoplasm, continuing to respire aerobically. A gradual process of mutual adaptation transformed the cytoplasmic aerobes into mitochondria.

The same basic mechanism is believed to have led to the appearance of membrane-bound plastids (including chloroplasts) at a later time. In this case, nonphotosynthetic aerobic cells with mitochondria are proposed to have ingested photosynthetic prokaryotes that were perhaps similar to present-day cyanobacteria. Again, through mutual adaptation, the photosynthetic prokaryotes changed into plastids.

Think Like a Scientist

FIGURE 25.2
The experiment used boiling water to create water vapor. Bacteria would have been killed by the boiling water.

IMR
The RNA world model states that the first genes and enzymes were RNA molecules—that is, ribozymes. Ribozymes, which are RNA molecules capable of catalyzing biochemical reactions, may have functioned both as informational molecules and catalysts in protocells, without requiring protein enzymes. Thus, the observation that a ribozyme could become activated within the protocell-like vesicles supports the RNA world model and the possibility that living cells may have developed from protocells.

UQ
Two possible related explanations might be summarized as "division of labor" and "efficiency." In an "RNA world," RNA would have a dual function, both as the transcriptional unit (RNA copy of DNA) and the molecule that carries out the activity of catalyzing biochemical reactions. With a division of labor between proteins, the work unit, and RNA, the informational unit, RNA becomes more specialized and efficient and, hence, the whole process becomes more efficient. Proteins then evolve specialization to catalyze biochemical reactions.

1. d 2. e 3. d 4. a 5. b 6. c 7. e 8. e 9. d 10. e

Interpret the Data
1. Asteroid impacts declined before levels of atmospheric oxygen began to rise.
2. Oxygen was much less abundant while carbon dioxide was much more abundant in the atmosphere when the first cells arose compared to levels today.
3. Oxygen (21%) is now more abundant in the atmosphere than carbon dioxide (currently 0.038%).

Chapter 26

Study Break

STUDY BREAK 26.1
1. Prokaryotes have no major cytoplasmic organelles that are equivalent to the endoplasmic reticulum, the Golgi complex, mitochondria, or chloroplasts of eukaryotes, nor does it have lysosomes.

   The genetic material of a prokaryote generally is a single, circular DNA molecule localized in a nonmembrane-bound central region of the cell called a nucleoid. By contrast, the genetic material of a eukaryote is distributed among a number of linear chromosomes, which

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

consist of DNA complexed with basic proteins known as histones.

Most prokaryotes are surrounded by a cell wall located outside the plasma membrane. Animal cells do not have a cell wall, but plants, fungi, and some other eukaryotes do. The compositions of the eukaryotic cell walls are chemically different from bacterial cell walls.

2. A chemoheterotroph oxidizes organic molecules as its energy source and obtains carbon in organic form. A photoautotroph uses light as its energy source and carbon dioxide as its carbon source.
3. Obligate anaerobes are poisoned by oxygen. They survive either by fermentation, or by a form of respiration in which inorganic molecules are used as final electron acceptors. Facultative anaerobes use oxygen when it is present but live by fermentation when conditions are anaerobic.
4. Nitrogen fixation is the reduction of atmospheric nitrogen (N_2) to ammonia (NH_3). Nitrification is the conversion of ammonium (NH_4^+) to nitrate (NO_3^-).

   Nitrogen fixation, an exclusively prokaryotic process, is the only means of replenishing the nitrogen sources used by most microorganisms, and by all animals and plants.
5. A biofilm is a complex aggregation of microorganisms (either one or multiple microorganisms, many or all of them prokaryotes) attached, in most cases, to a surface. Biofilms are used in a variety of beneficial applications, including bioremediation of toxic organic chemicals contaminating groundwater. On the other hand, biofilms can have adverse effects on human health. For instance, biofilms can result in antibiotic-resistant infections if they adhere to surgical materials, such as catheters and implants.

STUDY BREAK 26.2

1. An exotoxin is a toxic protein that is secreted from the bacterium that makes it, or is released when that bacterium lyses. An endotoxin is a normal lipopolysaccharide component of the outer membrane of Gram-negative bacteria; it is released when the bacteria die and lyse. An exoenzyme is an enzymatic protein that is released from cells.

   An exotoxin interferes with biochemical processes of body cells. An endotoxin overstimulates the immune system, often causing inflammation. Depending on the bacterium, the endotoxin release has different effects, which may include organ failure and death. An exoenzyme digests plasma membranes, causing cells of the infected host to rupture and die. Exoenzymes may also digest extracellular materials and red and white blood cells.
2. Many pathogenic bacteria develop resistance to antibiotics as a result of mutations. The mutations allow the bacteria to break down the antibiotics or otherwise counteract their effects. Pathogenic bacteria may also develop resistance to antibiotics as a result of horizontal gene transfer when antibiotic resistance genes on plasmids are transferred between bacteria by conjugation, or when DNA containing an antibiotic resistance gene is introduced into the pathogen in other ways, such as by transformation or transduction.

STUDY BREAK 26.3

1. See Table 25.1 for a comparison of the properties of organisms in each of the three domains. The classification of Archaea as a distinct domain was based on comparisons of DNA and rRNA sequences.
2. A methanogen lives in reducing environments, generating energy by converting substrates such as carbon dioxide, hydrogen gas, methanol or acetate into methane gas. All known methanogen belong to the Euryarchaeota.
3. Extreme halophilic archaeans live in high-salt environments, requiring at least 1.5 M NaCl in order to live. Most of these organisms are aerobic chemoheterotrophs, obtaining energy from sugars, alcohols, and amino acids using pathways similar to those of bacteria. All known extreme halophilic archaeans belong to the Euryarchaeota.
4. Extreme thermophiles live in extremely hot environments such as thermal hot springs and hydrothermal ocean floor vents. Psychrophiles grow optimally at temperatures in the range −10°C to −20°C, such as in the Antarctic and Arctic oceans.

Think Like a Scientist

FIGURE 26.13

A likely scenario is that the individuals harbored populations of the bacterium, which, at some point, changed from being harmless to being infectious, resulting in ulcers. Indeed, there is evidence that young children may acquire *Helicobacter* causing a chronic infection which confers on them a lifelong susceptibility to developing ulcers.

IMR

Regulation of gene expression in bacteria was discussed in Section 16.1. In some way the bacteria must "sense" their density and then trigger the transition from planktonic to biofilm growth. Changes in gene expression must involve molecular signals, probably involving operons (see Section 16.1). Thus, down-regulation of a gene or of genes in an operon would require repression of those genes or the removal of a gene activator, whereas up-regulation would require removal of repression or the production of a gene activator.

UQ

One possibility is that the last universal common ancestor (LUCA) of all life on the planet had a genome composed not of DNA but of RNA. If the switch to DNA-based genomes occurred after LUCA, once in the lineage that led to Bacteria and once entirely independently in the lineage that led to Archaea and Eukarya, then the two machineries for replicating DNA need not be related to one another. A second possibility is that LUCA had a DNA-based genome but that the cellular replication machinery was displaced by that of a virus in either the bacterial or archaeal/eukaryal lineages.

Test Your Knowledge

Interpret the Data

1. Freezing occurs at 0°C, and *Pseudomonas* will not grow at or near freezing temperatures.
2. Yes, the growth rate at 20°C (293 K) is 0.44 and at 4°C (277 K) it is 0.012. The growth rate is more than 36 times slower at refrigeration than room temperature, indicating that refrigeration is sufficient.

Chapter 27

Study Break

STUDY BREAK 27.1

A protist is distinguished from a prokaryote by having typical eukaryotic cell features like a nuclear envelope surrounding its genetic material, and cell organelles such as mitochondria (in most protists), chloroplasts (in some protists), endoplasmic reticulum, Golgi complex, and so on.

Distinguishing protists from fungi, animals, and plants is more blurry. Fungi are nonmotile at all stages of their life cycles, whereas most protists are motile or have motile stages in their life cycles. Cell wall structure is also different from fungi, and from plants. Protists differ from both animals and plants by lacking highly differentiated structures and by not having complex developmental stages. Collagen, the extracellular support protein of animals, is absent in protists.

STUDY BREAK 27.2

1. Excavates' nuclear genomes contain genes that are of mitochondrial origin, arguing that they once had mitochondria.
2. The chloroplast will have two membranes: one derived from the plasma membrane of the engulfing eukaryote and the other from the plasma membrane of the cyanobacterium.

Think Like a Scientist

FIGURE 27.11

Sequence more diatom genomes so as to obtain more data about similarities and differences.

IMR

Binding of a signal molecule—in this case cAMP—to its G-protein–coupled receptor activates the receptor. The activated receptor activates the G protein that was associated with the cytoplasmic end of the receptor. The activated G protein then activates the effector molecule for the pathway, which, in this case, is adenylyl cyclase. The cAMP activates protein kinases in the signal transduction pathway specific for the response, including the kinase discussed in the box.

UQ

1. Evolution is a dynamic field of study utilizing many tools, from fossils to gene sequence data to complicated mathematical models. New ideas about the first eukaryotes and the significance of endosymbioses will continue to emerge by using the scientific method.
2. Anything is possible, but no current evidence suggests prokaryotes evolved from a single-celled eukaryote. Fossil evidence and evidence for the endosymbiotic theory support a prokaryote-first world. Unlike *Giardia* that has mitochondrial genes, for example, prokaryotes do not have "eukaryotic" genes that appear to have no (or lost) function.

Test Your Knowledge

1. e 2. d 3. d 4. b 5. b 6. c 7. b 8. a 9. b 10. c

Interpret the Data

1. The 50 $\mu mol/m^2/s$ irradiance treatment has a maximum at ~450 $\mu mol/m^2/s$. The 1,200 $\mu mol/m^2/s$ irradiance treatment has a maximum above 1,200 $\mu mol/m^2/s$. No, the maximum was different for the low irradiance treatment, because 50 $\mu mol/m^2/s$ was too low a level of light to maximize photosynthesis, so the diatoms increased their rates of photosynthesis in increased light levels. The 1,200 $\mu mol/m^2/s$ irradiance treatment reached its photosynthesis maximum at the treatment light level, indicating that this was an optimal light level.
2. The low irradiance treatment has a higher photosynthesis efficiency with light.

Chapter 28

Study Break

STUDY BREAK 28.1

1. Evolution of a root system gave land plants access to minerals and water in soil and provided physical support for aerial parts. The evolving shoot system of land plants, including lignified tissues in stems, allowed vascular plants to grow taller and stay erect, thereby gaining better access to sunlight for photosynthesis. Reproductive structures borne on aerial stems (such as flowers) might serve as platforms for more efficient dispersal of spores from the parent plant. Vascular tissues were innovations for distributing water (xylem) and sugars (phloem) through the plant body.
2. Homosporous plants produce a single type of sexual spore and are in effect bisexual, with each gametophyte capable of producing both sperm and eggs. Heterosporous species, including angiosperms and gymnosperms, produce two types of spores, which develop into sexually different gametophytes that produce either sperm or eggs. Plant scientists associate the evolution of heterospory with several key reproductive innovations in land plant evolution, including the protection of male gametes inside pollen grains and the protection of plant embryos inside seeds.

STUDY BREAK 28.2

1. Like aquatic plants, bryophytes produce flagellated sperm that must swim through water to reach eggs, and they lack a complex vascular system (although some have a primitive type of conducting tissue). Bryophytes do have parts that are rootlike, stemlike, and leaflike, although the

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

"roots" are rhizoids, and bryophyte "stems" and "leaves" did not evolve from the same structures that vascular plant stems and leaves did. Sporophytes of some species have a water-conserving cuticle and stomata. Like most plants, bryophytes also have both sexual and asexual reproductive modes.

2. In general, mosses are the bryophytes that most closely resemble vascular plants. Some species produce structurally complex gametophytes that have a central strand of primitive water-conducting tissue that resembles the xylem of vascular plants, and in a few species the water-conducting cells are surrounded by sugar-conducting tissue resembling the phloem of vascular plants.

STUDY BREAK 28.3

1. In bryophytes, the gametophyte is much larger than the sporophyte and obtains its nutrition independently. The comparatively tiny sporophyte remains attached to the gametophyte and depends on the gametophyte for much of its nutrition. In modern lycophytes (club mosses and their close relatives), the gametophyte is free-living—though it is nourished by mycorrhizae instead of carrying out photosynthesis—and it is smaller than the sporophyte, which is a photosynthetic autotroph.
2. Fern leaves often take the form of feathery fronds, and roots extend from underground stems called rhizomes. Whisk ferns lack true leaves and roots; instead, small leaflike scales dot an upright, green, branching stem, which arises from a horizontal rhizome system anchored by rhizoids. Horsetail sporophytes typically have underground rhizomes and roots that anchor the rhizome to the soil. The scalelike leaves are arranged in whorls about a photosynthetic stem.
3. In horsetails, the sporangia that produce spores are borne in strobili, and spores are carried away from the plant by air currents. In ferns, sporangia are produced on the lower surface or margin of leaves, and spores are forcefully dispersed from the parent plant when contraction of a beltlike annulus rips open the sporangium and ejects the spores.

Think Like a Scientist

IMR

Perhaps, because extant lycophytes and known lycophyte fossils all have relatively rudimentary xylem, the water-transporting vascular tissue. Among other impacts, the discovery of an ancient lycophyte species having well-developed xylem would open up numerous questions about genetic variations and evolutionary shifts within the lycophyte group, including the possibility that vascular tissues began to arise earlier than previously thought.

UQ

If the number and density of genes remain largely unchanged, increases in chromosome number should generally increase independent assortment because genes will be distributed on more independent linkage groups. The result is a higher effective recombination rate. Such changes in chromosome number may happen because of fission of existing chromosomes into more than one chromosome. In most eukaryotes, one obstacle that chromosomes produced by fission must overcome is the development of a centromere in which spindle fibers link sister chromatids. Chromosomes produced by duplication do not generally need a new centromere, but must also overcome being the odd chromosome in the population. The likelihood that a chromosome will be duplicated is at least partly based on the dosage sensitivity of the genes located on it. For example, the human genetic disorder Down syndrome is caused by the presence of an extra copy of chromosome 21 (trisomy 21). Thus, the consequences of gene duplication to phenotype and fitness play a significant role in shaping which regions of the genome may duplicate or not—in plants, animals, and all other eukaryotes.

Test Your Knowledge

Interpret the Data

1. The data summarized in Figure A support the hypothesis that a single endosymbiosis event correlated with the evolution of all photosynthesizing organisms. This event corresponds with the node at which the clade including green plants, red algae, and glaucophytes diverged from the clade including alveolates and heterokonts (diatoms and their relatives).
2. Yes. The cladogram shows less evolutionary distance between green plants and glaucophytes than between green plants and red algae.

Chapter 29

Study Break

STUDY BREAK 29.1

1. The four major reproductive adaptations that evolved in gymnosperms include pollen and the ovule, both of which shelter spores; pollination rather than dispersal of swimming sperm; and the seed as a "package" that protects and often nourishes the embryo.
2. The three basic parts of a seed are the embryo sporophyte, endosperm, and outer seed coat. The endosperm nourishes the embryo sporophyte, and the seed coat protects it.
3. Features that make conifer sporophytes structurally more complex than other gymnosperms include anatomically complex needlelike or scalelike leaves that are adapted to aridity and the production of resins as metabolic by-products.

STUDY BREAK 29.2

1. The lack of fossil early angiosperms, including obvious transitional forms, has made it difficult to trace a clear evolutionary path for flowering plants. As a result plant scientists have proposed several, often conflicting, classification schemes for angiosperms.
2. Seeds leaves (cotyledons) and pollen morphology are two major features used to distinguish monocots and eudicots. Monocots have a single seed leaf and pollen grain with a single groove. Eudicots have two seed leaves and pollen grains with three grooves. Monocots (such as grasses, lilies, and palms) also generally have fibrous root systems, leaves with parallel veins, flower parts in multiples of three, and scattered vascular bundles in stems. Eudicots (most flowering trees and shrubs, roses, sunflowers, beans) usually have netlike leaf venation, a primary taproot, flower parts in fours or fives, and vascular tissues arranged in a ring.
3. Adaptations that have contributed to the evolutionary success of angiosperms include vascular tissue modifications that make transport of water and nutrients more efficient; double fertilization, which results in enhanced nutrition (endosperm) for embryos; physical protection of embryos within ovaries and seeds; and coevolution with animal pollinators, which increases the likelihood that pollination will occur.

STUDY BREAK 29.3

1. All land plants carry the *LFY* gene, which encodes the regulatory protein LEAFY. Researchers studying the protein's effects in groups as different as mosses and angiosperms have found that while the phenotypic effects—and resulting adaptations—vary markedly in different plant groups, only a few changes in the base sequence of the *LFY* gene have been associated with the shifts.
2. Among other benefits, having the entire sequences of a variety of plant genomes allows researchers to use the resulting to elucidate the relationship between large-scale shifts in genomes and the evolution of fundamental characteristics of major lineages.

Think Like a Scientist

FIGURE 29.14

In fact, several studies have compared angiosperm photoreceptor genes with those of mosses and ferns. Among other outcomes, such comparative studies can help shed light on whether and how phytochromes came to have new or refined functions during the course of plant evolution.

IMR

The study authors proposed that other factors worthy of study include the roles of regulatory elements acting in a genome, of microRNAs, posttranslational modification of gene products, and epigenetic factors (changes in gene expression unrelated to a change in the DNA sequence of a gene or genome).

UQ

One explanation hinges on the theory that all apical meristems (except root meristems), whether vegetative or reproductive, produce lateral organs as an innate function. Vegetative meristems produce leaves that arise laterally on the stem, and flower meristems produce sepals that arise laterally on the floral axis. According to this theory, once a flower meristem is formed, it will automatically produce sepals with no new gene functions needed. Then, if B-gene function is added to the baseline gene activity in the meristem (which includes E function), petals will be produced—so instead of requiring A+B function to produce petals, only B function is required. Stamen and carpel formation is exactly the same as in the ABC model: B+C= stamens, and C = carpels. Thus, only two gene functions, B and C, in addition to E, are required for the formation of all four floral organs types.

Interpret the Data

1. Wild AN (annual) genotypes, which grow in inland habitats that experience summer drought, are adapted to flower earlier, when moisture is still available. The later flowering times of PE (perennial) plants reflect such plants' adaptation to coastal habitats having year-round moisture.
2. Populations of *M. guttatus* plants that differ with respect to a chromosomal inversion show divergent life history adaptations to contrasting environments. Populations adapted to survive in inland habitats affected by summer drought show a pattern of annual (AN) reproduction, whereas populations adapted to moister coastal habitats show a pattern of perennial (PE) reproduction. Interpreting the results graphed in Figure C, both AN and PE plants grown in an AN setting flourished in the moist early spring, but PE plants died back several months sooner than would be expected if they had been in their wild, coastal habitat.

Chapter 30

Study Break

STUDY BREAK 30.1

1. Some fungi are multicellular while others, the yeasts, are single cells. (Some species alternate between these two forms at different life cycle stages.) The cells of all fungi are surrounded by a hardened wall; in most cases the hardener is the polysaccharide chitin. The body of a multicellular fungus consists of a dense mesh of filaments called hyphae, which in some groups are separated into cell-like compartments by cross walls (septa). Aggregations of hyphae are the structural foundation for all other parts that develop as part of a multicellular fungus. For example, in some species modified hyphae form rhizoids that anchor the fungus to its substrate.
2. Fungal spores are microscopic, usually nonmotile reproductive cells in which haploid nuclei are surrounded by a tough outer wall. They are produced sexually or asexually. Sexual spores are produced by genetically different parent fungi and may unite in a sexual process that gives rise to a diploid life stage. Asexual spores are genetically identical to the parent fungus and may give rise to a new, haploid individual.
3. Many fungal species have a life cycle stage called a dikaryon, which contains two haploid nuclei (a condition expressed as $n + n$). A dikaryon forms as the result of

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

plasmogamy, a sexual stage in which the cytoplasms of two genetically different partners fuse. This fusion ensures genetic diversity in new individuals. At some point after a dikaryon forms, the nuclei fuse (karyogamy) to form a short-lived zygote. Meiosis in the zygote produces haploid nuclei that become packaged into sexual spores.

STUDY BREAK 30.2

1. The main phyla of fungi are the Chytridiomycota, Zygomycota, Glomeromycota, Ascomycota, and Basidiomycota. Chytrids are the only fungi that produce motile, flagellated spores. Zygomycetes often reproduce asexually, but sometimes reproduce sexually by way of hyphae that occur in + and − mating strains; haploid nuclei in the hyphae function as gametes. Following plasmogamy, further development produces zygospores in which karyogamy gives rise to diploid zygotes (2*n* nuclei), which then undergo meiosis as sexual spores form. Glomeromycetes reproduce asexually, by way of spores that form at the tips of hyphae. In ascomycetes, chains of asexual spores called conidia, each containing a haploid nucleus, develop during asexual reproduction. Ascomycetes produce haploid sexual spores in pouchlike cells called asci. Most basidiomycetes reproduce only sexually: club-shaped basidia develop on a basidiocarp (for example, a "mushroom") and bear sexual spores on their outer surface. When dispersed, the spores may germinate and give rise to a haploid mycelium. Cytoplasmic fusion may occur between hyphae of two compatible mating strains, producing a dikaryotic mycelium from which basidiocarps may grow. Microsporidia, single-celled parasites that may be related to zygomycetes, resemble spores but lack mitochondria. Fungi for which no sexual life stage has been identified are placed in a convenience grouping called "conidial fungi."
2. Anatomically, the simplest fungi are chytrids, which are microscopic, and zygomycetes, which have aseptate hyphae. Ascomycetes, basidiomycetes, and glomeromycetes all form septate (walled) hyphae.
3. Most chytrids are aquatic, but some are parasites of insects, plants, and some animals. Others are symbiotic partners in the gut of cattle and some other herbivores.

   Many zygomycetes are saprobes in soil, feeding on plant detritus. Their metabolic activities release mineral nutrients that plant roots can take up. Some zygomycetes are parasites of insects or spoil stored grains, bread, fruits, and vegetables such as sweet potatoes. Others are used in manufacturing products such as industrial pigments and pharmaceuticals. Many more are highly destructive plant pathogens and several can be human pathogens, causing athlete's foot, ringworm infections, and more serious illnesses. The pink bread mold *Neurospora crassa* has been crucial in genetic research.

   Some basidiomycetes participate in vital mutualistic associations (mycorrhizae) with the roots of forest trees. Others produce prized edible mushrooms.

   Rusts and smuts are parasites that cause serious diseases in wheat, rice, and other plants.

   Glomeromycetes are all specialized to form mycorrhizae with plant roots.

STUDY BREAK 30.3

1. A lichen is a communal life form representing a symbiosis between a photosynthetic green alga or species of cyanobacteria (the photobiont) and a nonphotosynthetic fungus (the mycobiont). The algal cells supply the lichen's carbohydrates, most of which are absorbed by the fungus. In some cases, the alga is protected from desiccation or some other environmental threat.
2. A mycorrhiza is a symbiotic association between a fungus and plant roots. The fungal hyphae make mineral ions and sometimes water available to the plant's roots, and in exchange the fungus absorbs carbohydrates, amino acids, and possibly other growth-enhancing substances provided by the plant. Mycorrhizae greatly enhance the plant's ability to extract various nutrients, especially phosphorus and nitrogen, from soil, and they are crucial to the survival of many plant species.
3. In endomycorrhizae the hyphae of a fungus (typically a glomeromycete) enter plant roots, where their tips branch into clusters called arbuscules where exchanges of nutrients take place. In ectomycorrhizae the fungal partners are basidiomycetes. Their hyphae surround plant roots but do not penetrate them.

Think Like a Scientist

IMR

As the text describes, chytrids may have arisen very early in fungal evolution. Accordingly, a comparison of 18S rRNA sequences among different living chytrids might shed valuable light on the early origins of fungi—and perhaps on the assumed divergence of fungi and animal lineages from a common protist ancestor.

UQ

1. Ecological theory predicts that species with complete overlap in the way they use resources and interact with other species would not coexist in a community. Therefore, it is likely that ectomycorrhizal fungi that coexist on a single tree differ in factors such as how they gain nutrients from the tree, how they gain nutrients from the surrounding soil, how they interact with the tree (for example, what parts of the root system they colonize, what types and amounts of nutrients they provide, or what additional benefits they confer to the tree), where they occur in space (for example, at what soil depth they occur), or how they respond to different environmental conditions (such as rainfall and temperature).
2. Because mycorrhizal symbiosis may be controlled by the plant symbiont, the fungal symbiont, or both, the dominance of fungal symbionts within a community may result from interactions between different fungal symbionts (for example, direct competition between mycelia or indirect competition for nutrients) or from differences in the way they interact with the tree (such as the "selection" by the tree of one symbiont over another).
3. Understanding the nature of interactions between plants, fungi, and the environment can be beneficial for protecting rare fungal or plant species, maintaining forest diversity, predicting the effects of climate or land use change, and improving the outcome of restoration efforts.

Test Your Knowledge

1. a, c 2. b, e 3. a 4. d 5. c, d 6. e 7. c 8. a 9. b, e 10. d

Interpret the Data

1. In the dark, no. The number of fusion events in wild-type pairs showed the same pattern as matings between wild-type and mutant hyphae.
2. In white and blue light, the most fusion events occurred in crosses in which one or both hyphae were mutants, regardless of mating type. The fewest fusion events under these light conditions occurred in crosses in which one or both hyphae were the **a** mating type. In green and red light, the pattern shifted. The most fusion events occurred when the cross included one mutant and one wild-type hypha. The researchers hypothesized that, in general, light inhibits fusion of wild-type (+) strains of *C. neoformans*. These results support that hypothesis. Red light wavelengths predominate in shade, so it is not surprising that overall the most fusion events occurred in darkness and in red light conditions.

Chapter 31

Study Break

STUDY BREAK 31.1

1. Several characteristics distinguish animals from plants: plant cells have cell walls, but animal cells do not; almost all plants are autotrophic, whereas all animals are heterotrophic; and plants are usually sessile, but animals are motile at some stage of their life cycle. Animals differ from fungi in that the cells of fungi have cell walls, and most fungi are sessile.
2. The ability of animals to move through the environment allows them to search for and pursue the food items that supply them with nutrients and energy.

STUDY BREAK 31.2

1. A tissue is a group of cells that share a common structure and function. The three primary tissue layers that contribute to the bodies of most animals are endoderm, mesoderm, and ectoderm.
2. Humans are bilaterally symmetrical.
3. The coelom is a space within which internal organs can move independently of the body wall muscles. The fluid within it provides protection for internal organs. In some animals the coelom functions as a hydrostatic skeleton.
4. Having a segmented body may allow an animal to survive damage to some parts of its body segments and may allow improved control over body movements.

STUDY BREAK 31.3

1. Molecular sequence studies have confirmed the distinctions between the Parazoa and the Eumetazoa, between the Radiata and the Bilateria, and between the Protostomia and the Deuterostomia.
2. A schizocoelom appears to be the ancestral body cavity among the protostomes.

STUDY BREAK 31.4

1. Sponges do not exhibit any kind of body symmetry.
2. A sponge gathers food from its environment by drawing water into its body through numerous small pores and harvesting particulate matter from the water with its choanocytes, or collar cells.

STUDY BREAK 31.5

1. Cnidarians capture animal prey by stinging it with their nematocysts and using their tentacles to pull it into their mouths.
2. The anthozoans, including sea anemones and corals, have only a polyp stage in their life cycle.
3. Ctenophores capture microscopic plankton in sticky filaments on their two tentacles, which are then drawn across the mouth.

STUDY BREAK 31.6

1. Free-living flatworms have digestive, excretory, nervous, and reproductive systems. Tapeworms lack a digestive system.
2. Ectoprocts, brachiopods, and phoronid worms all have a circular or U-shaped feeding structure called a lophophore, a characteristic that reveals their close evolutionary relationship.
3. The anatomical and physiological systems that allow squids and other cephalopods to be more active than other types of mollusks include a closed circulatory system with accessory hearts and a complex nervous system with giant nerve fibers. Many cephalopods use their excurrent siphon to expel jets of water, allowing them to move rapidly through the environment.
4. The organ systems that exhibit segmentation in most annelid worms include: respiratory surfaces; parts of the nervous, circulatory, and excretory systems; and the body wall and coelom.

STUDY BREAK 31.7

1. The cuticle protects a nematode from the digestive enzymes of its host.
2. Although the rigid exoskeletons of arthropods do not expand, these animals grow a new, soft exoskeleton inside the existing one. After shedding the old exoskeleton, they grow to a larger size by expanding the new exoskeleton with either water or air before it hardens.
3. The body regions of the four living subphyla of arthropods differ in how they have become fused. Chelicerates have a fused cephalothorax and an abdomen. Crustaceans show variable patterns, but many have a fused cephalothorax and an abdomen. Myriapods have a head and a trunk. Hexapods have a separate head, thorax, and abdomen.
4. Insects with incomplete metamorphosis hatch from their eggs as wingless nymphs, which vary in how closely they resemble adults; nymphs then undergo metamorphosis

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

into the adult form. Insects with complete metamorphosis hatch from eggs as larvae, which are always very different from adults. After becoming a pupa, their cells and tissues are reorganized into the adult form.

Think Like a Scientist

IMR

The location of the two genes encoding leucine-carrying tRNAs in trilobites is expected to match that found in chelicerates. That location, which is shared with both mollusks and annelids, appears to be the ancestral state for this character. Because the trilobite clade originated before the other arthropod clades, we would expect it to exhibit the ancestral state for this character.

UQ

1. Recent genetic comparisons of invertebrate taxa confirm the distinction between Parazoa and Eumetazoa and the distinction between Radiata and Bilateria.
2. The nucleotide sequences most likely to shed light on the diversity of living invertebrates are those in small subunit ribosomal RNA, mitochondrial DNA, and *Hox* genes of species within the protostome and deuterostome lineages.

Test Your Knowledge

Interpret the Data

Leech therapy worked better than drug therapy to relieve the pain of arthritis in the thumbs of the patients tested. The effect of leech therapy persisted for at least two months after just one treatment.

Chapter 32

Study Break

STUDY BREAK 32.1

1. Echinoderms have a water vascular system, which operates the tube feet that are used for locomotion and/or feeding.
2. Water enters the pharynx of a hemichordate through its mouth, and it exits the pharynx through the branchial slits. The animal extracts oxygen and particulate food from the water as it passes through the pharynx.

STUDY BREAK 32.2

1. The animal is not a chordate, because chordates have a dorsal nerve cord.
2. Vertebrates have an internal bony skeleton, including a cranium and vertebral column in most groups, as well as structures derived from neural crest cells.

STUDY BREAK 32.3

1. Vertebrates have multiple *Hox* gene complexes, which provide them with several copies of each *Hox* gene. Cephalochordates have just one *Hox* gene complex.
2. Of the three groups listed, Gnathostomata has the most species, and Amniota has the fewest.

STUDY BREAK 32.4

1. Hagfishes lack bone, paired fins, and scales in their skin. Hagfishes have neither a cranium nor a vertebral column, and lampreys have only rudimentary traces of vertebrae. These observations suggest that their lineages arose before these structures appeared in vertebrates.
2. The derived traits possessed by conodonts and ostracoderms include structures made of bone or a bonelike material and, in some ostracoderms, a brain divided into three regions.

STUDY BREAK 32.5

1. Sharks are more efficient predators than acanthodians or placoderms were because they have well-developed sensory systems to detect prey; their lightweight skeletons and absence of heavy body armor allow them to pursue prey rapidly; and they have numerous teeth that are replaced when damaged or worn, as well as a loosely attached upper jaw that permits them to suck in large chunks of food.
2. The air bladders of ray-finned bony fishes increase their locomotor abilities by allowing them to rise or sink easily in the water. Their fin rays allow them to engage in precise movements during locomotion.
3. The lungs of lungfish allow them to survive in environments with low oxygen content because they can acquire oxygen from the air.

STUDY BREAK 32.6

1. For the first tetrapods, the advantages of moving onto land included abundant food resources, the rarity of predators, and readily available oxygen. The disadvantages included the need for more skeletal support against gravity, mechanisms to prevent dehydration in air, and modifications of sensory systems so that they would function in air.
2. The parts of the amphibian life cycle that are most dependent on water are the egg and larval stages.

STUDY BREAK 32.7

1. The amniote egg freed amniotes from a dependence on standing water because it can survive on land. The shells of amniote eggs mediate gas exchange and water exchange with the environment.
2. Among the three amniote lineages, the Synapsida includes the mammals, the Anapsida includes turtles, and the Diapsida includes lizards, snakes, crocodilians, and birds.
3. Because lizards are lepidosaurs and both birds and crocodilians are archosaurs, crocodilians are more closely related to birds than they are to lizards.

STUDY BREAK 32.8

The overall structure of turtles differs from other amniotes in that their bodies are enclosed within a bony, keratin-covered shell.

STUDY BREAK 32.9

1. Besides their loss of legs, snakes differ from their lizard ancestors in having smaller skull bones, and the connections between them are more elastic.
2. Various species of lizards feed on vegetation, insects, or larger animals. Virtually all snakes are carnivores, and they swallow their prey whole.

STUDY BREAK 32.10

1. Several characteristics reveal the close evolutionary relationship of crocodilians and birds, including a four-chambered heart and maternal care of offspring.
2. The specific adaptations that allow birds to fly either reduce their weight or increase their muscle power. Weight-reducing adaptations include a lightweight skeleton, the absence of teeth and a urinary bladder, and the habit of laying an egg as soon as it has a shell. Power-promoting adaptations include large wing muscles, efficient digestive, respiratory, and circulatory systems, and a high metabolic rate.
3. The structure of a bird's bill reflects its diet. For example, hummingbirds that drink nectar have long thin bills, and parrots that eat hard nuts have stout sharp bills. Wings and feet are adapted to birds' flying habits and habitats. For example, ducks have webbed feet that allow them to paddle in water, and albatrosses have long thin wings that work efficiently for long distance flight.

STUDY BREAK 32.11

1. Most mammals were probably active at night during the Mesozoic era to avoid competition with and predation by dinosaurs, most of which were active during the day.
2. The key adaptations that allow mammals to be active under many types of environmental conditions include insulating fur and fat and a high metabolic rate that generates lots of body heat.
3. The three major groups of living mammals are distinguished on the basis of their reproductive habits. Monotremes lay eggs. Marsupials give birth to relatively undeveloped young after a short period of gestation. Placentals give birth to more developed young after a long period of gestation.

STUDY BREAK 32.12

1. The characteristics that allow many species of primates to spend a lot of time in trees include flexible shoulder and hip joints, grasping hands, and excellent depth perception.
2. The lowest taxonomic group that includes monkeys, apes, and humans is the Anthropoidea. The lowest taxonomic group that includes only apes and humans is the Hominoidea.
3. Gorillas, chimpanzees, and bonobos are the apes that spend the most time on the ground.

STUDY BREAK 32.13

1. Researchers usually use the criterion of bipedal locomotion to distinguish between humans and apes. Humans (that is, hominins) are bipedal, and apes are not.
2. The strongest evidence suggesting that Neanderthals and modern humans belong to different species comes from mtDNA sequence data: the differences between gene sequences of Neanderthals and humans are much greater than the differences between any two modern humans.
3. Independent genetic studies of mitochondrial DNA and the Y chromosome indicate that all human populations are descended from a common ancestor that originated in Africa and then migrated to various regions on Earth.

Think Like a Scientist

FIGURE 32.8

Based on information in the figure, a change from radial to bilateral symmetry accompanied the evolution of an increased number of *Hox* genes in the *Hox* gene complex.

IMR

If early primates were leaping or climbing through trees, increased visual acuity and better depth perception would allow them to estimate the distances between branches, decreasing their likelihood of falling. Increased olfactory function would not contribute to better arboreal locomotion.

UQ

Viviparity could provide several benefits. By carrying her developing young, the mother can protect them from some detrimental environmental factors; she can regulate the temperature at which they develop by regulating her own body temperature; she can provide them with nutrients and energy throughout their development; and she can select a favorable environment into which she releases them when they are born.

Interpret the Data

According to this analysis, turtles fall within the diapsid lineage, and they are more closely related to archosaurs (alligator and chicken) than to lepidosaurs (tuatara and iguana). The results of this analysis, therefore, contradict the traditional view.

Chapter 33

Study Break

STUDY BREAK 33.1

1. A land plant's shoot system consists of its photosynthetic tissues and organs—stems, leaves, and buds. Stems are frameworks for upright growth and favorably position leaves for light exposure and flowers for pollination. Leaves increase a plant's surface area and thus its exposure to sunlight. Buds eventually extend the shoot or give rise to a new, branching shoot. The shoot system of a flowering plant also includes flowers and fruits. Parts of the shoot system store carbohydrates manufactured during photosynthesis.

   The root system usually grows below ground. It anchors the plant, and sometimes structurally supports its upright parts. It also absorbs water and dissolved minerals from soil and stores carbohydrates.
2. Meristem tissue is self-perpetuating embryonic tissue. Apical meristems, at the tips of shoots and roots, gives rise to a young plant's stems, buds, roots, and other primary

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tissues. In plants that show secondary growth, cylinders of lateral meristem tissue give rise to (often woody) secondary tissues that increase the diameter of older stems and roots.

STUDY BREAK 33.2

1. The ground tissue system makes up most of the plant body. It includes three types of structurally simple tissues—parenchyma, collenchyma, and sclerenchyma—each of which is composed mainly of one type of cell. Parenchyma makes up most of a plant's primary tissue and typically has air spaces between its cells, which are alive at maturity and can continue to divide. Subgroups of parenchyma cells are specialized for photosynthesis, secretion, and storage (of starch). Collenchyma is flexible ground tissue that contains cellulose. Its cells remain alive and metabolically active at maturity. They provide mechanical support for parenchyma and often collectively form strands or a sheathlike cylinder under the dermal tissue of growing shoot regions and leaf stalks. Cells of sclerenchyma are dead at maturity, but they develop thick secondary walls while alive that typically are lignified and provide additional support and protection in mature plant parts.
2. Xylem and phloem are the tissues of the vascular tissue system. The two types of xylem cells, called tracheids and vessel members, both develop thick, lignified secondary cell walls and die at maturity. The empty cell walls of abutting cells serve as pipelines for water and minerals. The conducting cells of phloem, called sieve tube members, form sieve tubes that conduct solutes, mainly sugars made during photosynthesis, throughout a plant.
3. The dermal tissue system serves as a skinlike protective covering for the plant body. Cells of the epidermis are tightly packed and cover the primary plant body. They secrete a cuticle that coats all plant parts except the very tips of the shoot and most absorptive parts of roots. Some epidermal cells become modified for specialized functions. Examples include guard cells, which form stomata; root hairs, which absorb water and minerals; and hairlike trichomes, which function in defense against herbivory or secrete sugars that attract pollinators.

STUDY BREAK 33.3

1. Stems have four main functions: (1) they provide mechanical support for body parts involved in growth, photosynthesis, and reproduction; (2) they house the vascular tissues (xylem and phloem), which transport products of photosynthesis, water and dissolved minerals, hormones, and other substances throughout the plant; (3) they often are modified to store water and food; and (4) they have specific stem regions that contain meristematic tissue, which gives rise to new cells of the shoot.

   A plant stem is divided into modules, each consisting of a node, where leaves are attached, and an internode, the space between nodes. New primary growth occurs in buds—a terminal bud at the apex of the main shoot, and lateral buds, which produce branches (lateral shoots), in the leaf axils. Meristem tissue in buds gives rise to leaves, flowers, or both.

   In eudicots, most primary growth in a stem's length occurs directly below the shoot apical meristem. When a meristematic cell divides, one of its daughter cells becomes an initial, a cell that remains as part of the meristem. The other daughter cell becomes a derivative, which typically divides once or twice and then enters on the path to differentiation. As derivatives differentiate, they give rise to three primary meristems: protoderm, procambium, and ground meristem. These primary meristems produce cells that differentiate into specialized cells and tissues. In eudicots, the primary meristems are also responsible for elongation of the plant body. Each primary meristem occupies a different position in the shoot tip. Outermost is protoderm, which gives rise to the stem's epidermis. Inward from the protoderm the ground meristem gives rise to ground tissue (mostly parenchyma). Procambium, which produces the primary vascular tissues, is sandwiched between ground meristem layers. In most plants, inner procambial cells give rise to xylem and outer procambial cells to phloem. The developing vascular tissues become organized into vascular bundles that are wrapped in sclerenchyma and thread lengthwise through the parenchyma. In the stems and roots of most eudicots and some conifers, the vascular bundles form a stele (vascular cylinder) that vertically divides the column of ground tissue into an outer cortex and an inner pith.
2. Leaves are organs specialized for photosynthesis. In both eudicots and monocots, the leaf blade provides a large surface area for absorbing sunlight and carbon dioxide. Many eudicot leaves have a broad, flat blade attached to the stem by a petiole. Unless a petiole is very short, it holds a leaf away from the stem and helps prevent individual leaves from shading one another. In most monocot leaves, such as those of rye grass or corn, the blade is longer and narrower and its base simply forms a sheath around the stem.
3. Leaves develop on the sides of the shoot apical meristem. Initially, meristem cells near the apex divide and their derivatives elongate. The resulting bulge enlarges into a thin, rudimentary leaf, or leaf primordium. As the plant grows and internodes elongate, the leaves become spaced at intervals along the length of the stem or its branches. Leaf tissues typically form several layers. Uppermost is epidermis, with cuticle covering its outer surface. Just beneath the epidermis is mesophyll, which is composed of loosely packed parenchyma cells that contain chloroplasts. Leaves of many plants, especially eudicots, contain two layers of mesophyll. Palisade mesophyll cells contain more chloroplasts and are arranged in compact columns with smaller air spaces between them, typically toward the upper leaf surface. Spongy mesophyll, which tends to be located toward the underside of a leaf, consists of irregularly arranged cells with a network of air spaces that enhance the uptake of carbon dioxide and release of oxygen during photosynthesis and account for 15% to 50% of a leaf's volume. Below the mesophyll is another cuticle-covered epidermal layer. Except in grasses and a few other plants, this layer contains most of the stomata through which water vapor exits the leaf and gas exchange occurs. Vascular bundles form a network of veins throughout the leaf.
4. Plants that live for many years may spend part of their lives in a juvenile phase, and then shift to a mature, or adult phase. The differences between juveniles and adults often are reflected in leaf size and shape, in the arrangement of leaves on the stem, or in a change from vegetative growth to a reproductive stage. Most woody plants must attain a certain size before their meristem tissue can respond to the hormonal signals that govern flower development.

STUDY BREAK 33.4

1. Most eudicots have a taproot system—a single main root, or taproot, that is adapted for storage and smaller branching lateral roots. As the main root grows downward, its diameter increases, and the lateral roots emerge along the length of its older, differentiated regions. Grasses and many other monocots develop a fibrous root system in which several main roots branch to form a dense mass of smaller roots. Fibrous root systems are adapted to absorb water and nutrients from the upper layers of soil, and tend to spread out laterally from the base of the stem.
2. The root apical meristem and the actively dividing cells behind it form the zone of cell division. Cells in the center of the root tip become the procambium; those just outside the procambium become ground meristem; and those on the periphery of the apical meristem become protoderm. The zone of cell division merges into the zone of elongation, where most of the increase in a root's length occurs. Above the zone of elongation, cells may differentiate further and take on specialized roles in the zone of maturation.
3. Primary root growth produces a system of vascular pipelines extending from root tip to shoot tip. The root procambium produces cells that mature into the root's xylem and phloem. Ground meristem gives rise to the root's cortex, its ground tissue of starch-storing parenchyma cells that surround the stele. In many flowering plants, the outer root cortex cells give rise to an exodermis, a thin band of cells that may limit water losses from roots and help regulate the absorption of ions. The innermost layer of the root cortex is the thin endodermis, which helps control the movement of water and dissolved minerals into the stele. Between the stele and the endodermis is the pericycle, which gives rise to lateral roots. In some cells in the developing root epidermis, the outer surface extends into root hairs.

STUDY BREAK 33.5

1. Secondary growth processes add girth to roots and stems over two or more growing seasons. In plant species that have secondary growth, older stems and roots become more massive and woody through the activity of two types of lateral meristems. One of these meristems, the vascular cambium, produces secondary xylem and phloem. The other, the cork cambium, produces cork, a secondary epidermis that is one element of bark.
2. Vascular cambium consists of two types of cells—fusiform initials and ray initials. Fusiform initials are derived from cambium inside the vascular bundles and give rise to secondary xylem and phloem cells. Secondary xylem forms on the inner face of the vascular cambium, and secondary phloem forms on the outer face. Ray initials are derived from the parenchyma cells between vascular bundles. Their descendants form spokelike rays of parenchyma cells—horizontal channels that carry water sideways through the stem. As the mass of secondary xylem inside the ring of vascular cambium increases, it forms hard tissue known as wood. Bark encompasses all the living and nonliving tissues between the vascular cambium and the stem surface. It includes the secondary phloem and the periderm, the outermost portion of bark that consists of cork, cork cambium, and secondary cortex.
3. Roots of some plant species undergo secondary growth, but the ring of vascular cambium develops differently than it does in stems. When their primary growth is complete, these roots have a layer of residual procambium between the xylem and phloem of the stele. The vascular cambium arises in part from this residual cambium, and in part from the pericycle. Eventually, the cambial tissues arising from the procambium and those arising from the pericycle merge into a complete cylinder of vascular cambium. As in stems, the vascular cambium gives rise to secondary xylem to the inside and secondary phloem to the outside. As secondary xylem accumulates, older roots can become thick and woody.

Think Like a Scientist

FIGURE 33.3

If part of an apical meristem were to be removed, hormonal signals would prompt the remaining meristematic cells to give rise to replacement cells.

IMR

Obvious subjects for subsequent research include identifying specific genes *MIXTA* regulates, and characterizing the protein products that directly influence the shape of epidermal cells in *A. majus* petals.

UQ

Despite producing progeny cells that adopt different fates, both shoot and root stem cells are pluripotent cells that share the properties of continuous division and self-renewal, and thus their molecular signatures are likely to be more similar than different.

Test Your Knowledge

Interpret the Data

1. The data show wider than usual annual growth rings for the twentieth century. In their research report, Dr. Jacoby and his coworkers concluded that "recent warming is unusual relative to temperatures of the past 450 years."

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

2. It was important for the study authors to begin by acknowledging that the width of rings formed by individual trees shows natural variations related to each tree's growth. Including a graph of the ring-width measurements from a single 500-year-old tree allows for a clear comparison of that pattern with the graph that charts aggregated data from many trees—which you will notice follows a quite similar pattern.
3. The lower line represents sample size in the study. It shows that relatively few very old trees (with rings formed before 1550) were available to be sampled, with a steady rise in the number of available trees that began forming rings in subsequent centuries. The line also reveals consistency in the number of core samples dating from about 1850, when the Industrial Revolution and more intensive burning of fossil fuels began. This consistency lends credence to the reliability of the study's findings.
4. Airborne smoke and ash reduce the amount of solar energy that reaches Earth's surface. Less available sunlight is likely to translate into reduced photosynthesis and plant growth, which in turn will be reflected in the width of tree rings that form during that period.

Chapter 34

Study Break

STUDY BREAK 34.1

1. After an H^+ gradient is established (by proton pumping out of the cell), the resulting inward flow of H^+ down its concentration gradient provides the energy to actively transport other substances into the cell.
2. Water potential is potential energy stored in water. It is the driving force for osmosis, which in turn is responsible for the movement of water into and out of plant cells, including root cells.

STUDY BREAK 34.2

1. In the apoplastic pathway, water and dissolved substances do not pass through living root cells but instead move through the continuous network of adjoining cell walls and air spaces. When apoplastic water and solutes reach the endodermis, however, they must detour around the impermeable Casparian strip and pass through cells to move into the stele. The symplastic pathway passes through living cells. Water that diffuses into root cells moves in this pathway from cell to cell through plasmodesmata.
2. Epidermal cells of root hairs actively transport most mineral ions into root epidermal cells. These ions travel inward via the transmembrane pathway. Other ions may be dissolved in apoplastic water. They ultimately travel to the xylem in the symplast after crossing into and through endodermal cells of the Casparian strip. Once an ion reaches the stele it enters the xylem.

STUDY BREAK 34.3

1. In the cohesion–tension mechanism, water transport begins as water evaporates from the walls of mesophyll cells inside leaves and into the intercellular spaces. This water vapor escapes by transpiration through open stomata. As water molecules exit the leaf, they are replaced by others from the mesophyll cell cytoplasm. The water loss gradually reduces the water potential in a transpiring cell below the water potential in the leaf xylem. Water from the xylem in the leaf veins then follows the gradient into cells, replacing the water lost in transpiration.
2. Stomata open and close in response to changing environmental cues, such as light levels (detected via blue-light receptors), CO_2 concentration in the air spaces inside leaves, and the amount of water available to the plant. Stomata open when hydrogen ions are pumped out of guard cells, setting up the symport of H^+ and K^+ into the guard cells through ion channels. Water then follows by osmosis. Stomata close when H^+ pumping in guard cells ceases and K^+ moves out of guard cells, with water again following by osmosis. Through their ability to open and close, stomata help regulate water loss by plants and the uptake of carbon dioxide for photosynthesis.

STUDY BREAK 34.4

1. Translocation is the long-distance transport of substances in plants. The term generally applies to the transport of organic compounds, mainly sucrose, in phloem. Transpiration is the evaporation of water from a plant's aerial parts, mainly leaves. This water moves from roots upward to aerial parts in the xylem.
2. The mechanism of pressure flow moves sucrose from a source (such as a leaf or stem) into sieve tubes. Pressure builds up at the source end of a sieve tube system as sucrose enters sieve tubes at sources and water follows by osmosis. Under high pressure, sucrose moves by bulk flow toward a sink (plant parts that take up sucrose as metabolic fuel), where the sugar is unloaded.

Think Like a Scientist

FIGURE 34.7

In general, analysis shows that efforts to directly measure xylem pressure—most notably, by inserting a needlelike pressure probe into xylem conduits of living plants—produce unreliable findings because puncturing the conduit with the probe skews the measurements.

FIGURE 34.12

Recent research has shown that, at least in the case of aphids, the insect's saliva contains substances that inhibit normal mechanisms that might otherwise quickly seal small punctures in plant tissues.

FIGURE 34.13

The main known sucrose channels are sucrose/H^+ antiporters and symporters. Other phloem nutrients enter sink cells by other means, including nonselective cation channels, aquaporins, H^+/ATPases, and amino acid/H^+ symporters.

IMR

Experiments show that environmental factors such as drought and high salinity, both of which affect water balance, help determine which specific PIP genes are expressed in leaf cells.

UQ

The results support a hypothesis that active transport may sometimes move substances through plasmodesmata. Active transport is unidirectional—a transported solute moves either into or out of a cell—and the tracer moved unidirectionally in the experiments. The halt in tracer movement when cell metabolism was inhibited by sodium azide also is consistent with an active transport mechanism, because active transport requires ATP produced by the cell's metabolism.

Test Your Knowledge

1. b 2. d 3. e 4. a 5. a 6. b 7. e 8. c 9. c 10. c

Interpret the Data

1. In both graphs, the darker blue blocks represent the movement of deionized water through girdled branch segments over time. The lighter blue blocks represent the movement of a potassium chloride solution through girdled branch segments over time.
2. The results support the hypothesis because the values for the flow of pure water are consistently lower than the flow values of the KCl solution.
3. Results were substantially the same for both species, in that in both there was a marked increase in flow rates when the researchers switched from deionized water to the KCl solution. There was, however, a species-specific difference in the magnitude of the increased flow.

Chapter 35

Study Break

STUDY BREAK 35.1

1. Plants require relatively large amounts of macronutrients, such as nitrogen, sulfur, potassium, and calcium, and trace amounts of micronutrients, such as iron, chlorine, zinc, nickel, and copper.
2. Plants vary in their nutritional requirements. For example, leafy plants require more nitrogen and magnesium than other plant types do, and alfalfa, a grass, requires significantly more potassium than lawn grasses do. An adequate amount of an essential element for one plant also may be toxic for another. For these reasons, the nutrient content of soils is an important factor determining which plants grow well in a given location.

STUDY BREAK 35.2

1. Humus is important in soil because it generally contains nutrient-rich organic material and because it absorbs water, which contributes to the water-holding capacity of soil.
2. The amount of water that is available in soil to be taken up by plant roots depends primarily on the relative proportions of different soil components. Water moves quickly through sandy soils, whereas soils rich in clay and humus tend to hold the most water.
3. A plant's ability to absorb soil minerals depends partly on cation exchange, in which one cation, usually H^+, replaces a soil cation. As H^+ enters the soil solution, it displaces adsorbed mineral cations attached to clay and humus, freeing them to move into roots. Anions in the soil solution, such as nitrate (NO_3^-), sulfate (SO_4^{2-}), and phosphate (PO_4^-), generally move more readily into root hairs. Soil pH also affects the availability of some mineral ions because chemical reactions in very acid (pH : soils can trigger chemical reactions that bind various mineral cations in compounds that are insoluble in soil water.

STUDY BREAK 35.3

1. As described in this chapter and in Section 28.3, a mycorrhiza is a symbiotic association between a fungus and plant roots. Most plants form mycorrhizal associations, which facilitate the plant's ability to extract soil nutrients such as nitrogen and phosphorus. As with plant roots, mineral ions enter fungal hyphae by way of transport proteins. Some of the plant's sugars and nitrogenous compounds nourish the fungus, and as the root grows, it takes up a portion of the minerals that the fungus has secured. In some types of mycorrhizae the fungus actually lives inside cells of the root cortex.
2. Nitrogen fixation refers to the incorporation of atmospheric nitrogen into compounds, especially nitrate (NO_3^-), which plants can readily take up. Ammonification is a process in which soil bacteria known as ammonifying bacteria break down decaying organic matter and convert it to ammonium (NH_4^+). In nitrification, nitrifying bacteria oxidize NH_4^+ to NO_3^-. Inside root cells, absorbed NO_3^- is converted by a multistep process back to NH_4^+. In this form, it is rapidly used to synthesize organic molecules, mainly amino acids.
3. Associations with bacteria supply nitrogen to certain types of plants, such as legumes. The host plant provides organic molecules that the bacteria use for cellular respiration, and the bacteria supply NH_4^+ that the plant uses to produce nitrogenous molecules. In legumes the nitrogen-fixing bacteria reside in root nodules. Usually, a single species of nitrogen-fixing bacteria colonizes a single legume species, drawn to the plant's roots by chemical attractants (mainly flavonoids) that the roots secrete. By way of exchanged molecular signals, bacteria then are able to penetrate a root hair and form a colony inside the root cortex. Each cell in a root nodule may contain several thousand bacteria (now called bacteroids). The plant takes up some of the nitrogen fixed by the bacteroids, and the bacteroids use some compounds produced by the plant.

Think Like a Scientist

FIGURE 35.9

Apparently not. Recent studies have identified a few species of nodule-forming bacteria (though not in the genera *Rhizobium* and *Bradyrhizobium*) that lack *nod* genes. The bacteria may enter root cortex cells by infiltrating cracks in the epidermis where lateral roots arise.

IMR

These lines of research may lead to methods for reducing the amount of phosphate fertilizers added to crop plants by identifying mycorrhizal fungi providing the most efficient phosphate uptake—or by engineering crop plants with an improved capacity to take in this essential nutrient.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

UQ

Even after microorganisms satisfy their N requirements, they continue to consume nitrogen-containing organic compounds because they need the carbon in these compounds to fuel metabolism and growth.

Test Your Knowledge

1. e 2. c 3. d 4. c 5. b 6. c 7. a 8. d 9. a 10. e

Interpret the Data

1. Overall, aspen leaf litter contained about twice as much nitrogen but the same amount of carbon as leaf litter of pines and spruces, so with aspens the ratio of nitrogen to carbon in leaf litter was about half the value as in the other species. Lodgepole pine litter (the pine needles) was significantly higher in both cellulose and lignin than were trembling aspen or Engelmann spruce litter. The study data showed no statistically different values among the species in either fine or coarse root biomass.
2. Although we see clear species-specific differences in the values, overall the species with the lowest litter nitrogen—the pines and spruces—have significantly higher ratios of lignin to nitrogen.
3. There was no significant difference in root biomass among the three tree species in the study plots.

Chapter 36

Study Break

STUDY BREAK 36.1

1. The two alternating generations of plants are the sporophyte (spore-producing) and gametophyte (gamete-producing) generations.
2. Sporophytes produce spores that give rise to gametophytes. Gametophytes then may produce gametes; male gametophytes produce sperm, and female gametophytes produce eggs. In all seed plants the sporophyte is much larger and longer-lived than the gametophyte, and the gametophyte is protected within sporophyte tissues for all or part of its life. Gametophytes also are dependent upon the sporophyte for their nutrition.

STUDY BREAK 36.2

1. Flowers are specialized for reproduction. Before an angiosperm can produce a flower, biochemical signals (triggered in part by environmental cues such as day length and temperature) travel to the apical meristem of a shoot. In response, cells there change their activity: instead of continuing vegetative growth, the shoot is modified into a floral shoot that will give rise to floral organs.
2. Pollen grains are the mature male gametophytes. They arise by the following steps:
   a. Spores that give rise to male gametophytes are produced in a flower bud's anthers.
   b. Diploid microsporocytes inside an anther's pollen sacs undergo meiosis; eventually each one produces four small haploid microspores.
   c. Microspores then divide by mitosis.
   d. One of the two resulting nuclei divides again by mitosis, yielding a three-celled immature gametophyte: two haploid sperm cells and a third cell that will control the development of a pollen tube after pollen lands on a receptive stigma.
   e. A mature male gametophyte consists of the pollen tube and sperm cells.
3. Female gametophytes develop inside ovules in a flower's carpels. They arise by the following steps:
   a. In an ovule, a diploid megasporocyte divides by meiosis, forming four haploid megaspores.
   b. Three (usually) of these megaspores disintegrate.
   c. The remaining megaspore undergoes three rounds of mitosis without cytokinesis. The result is a single large cell with eight nuclei arranged in two groups of four.
   d. One nucleus in each group migrates to the center of the cell.
   e. After the cell undergoes cytokinesis a cell wall forms around these two polar nuclei, forming a large "central cell."
   f. A wall also forms around each of the remaining nuclei, and three of them, including an egg cell, cluster near the micropyle.
   g. The result is an embryo sac containing seven cells and eight nuclei. This sac is the mature female gametophyte.

STUDY BREAK 36.3

1. A pollen grain that lands on a compatible stigma absorbs moisture and germinates a pollen tube, which burrows through the stigma and style toward an ovule. Chemical cues from the two synergid cells help guide the pollen tube toward the egg. Before or during these events, the pollen grain's haploid sperm-producing cell divides by mitosis, forming two haploid sperm. When the pollen tube reaches the ovule, it enters through the micropyle and an opening forms in its tip. The two sperm are released into the cytoplasm of a disintegrating synergid. Next double fertilization occurs: typically, one sperm nucleus fuses with the egg to form a diploid ($2n$) zygote. The other sperm nucleus fuses with the central cell, forming a cell with a triploid ($3n$) nucleus. Tissues derived from the $3n$ cell are called endosperm.
2. As a seed matures, the embryo inside it develops a root–shoot axis with a root apical meristem at one end and a shoot apical meristem at the other end. Depending on the plant group, one or two cotyledons also develop. In monocots a single large cotyledon develops and stores endosperm; protective tissues arise around the root and shoot apical meristems. In eudicots, two endosperm-storing cotyledons form. Near the micropyle the radicle (embryonic root) attaches to the cotyledon at a region called the hypocotyl. Beyond the hypocotyl is the epicotyl, which has the shoot apical meristem at its tip and which often bears a cluster of tiny foliage leaves, the plumule. At germination, when the root and shoot first elongate and emerge from the seed, the cotyledons are positioned at the first stem node with the epicotyl above them and the hypocotyl below them.
3. Imbibition causes the seed coat to split, and water and oxygen move more easily into the seed. Metabolism switches into high gear as cells divide and elongate to produce the seedling. Enzymes that were synthesized before dormancy become active; other enzymes are produced as the genes encoding them begin to be expressed. The increased gene activity and enzyme production mobilize the seed's food reserves in cotyledons or endosperm. Nutrients released by the enzymes sustain the developing seedling sporophyte until its root and shoot systems are established.

STUDY BREAK 36.4

1. Flowering plants may reproduce asexually (vegetatively) by fragmentation, in which cells in a piece of the parent plant dedifferentiate and then regenerate a whole plant; by apomixis, in which a diploid embryo develops from an unfertilized egg or from diploid cells in ovule tissue; or by the production of structures such as rhizomes or suckers from a nonreproductive plant part, typically meristem tissues in a bud on a root or stem.
2. Totipotency is the capacity of fully differentiated cells to dedifferentiate, return to an unspecialized embryonic state, and then develop into a fully functional mature plant. Plant tissue culture procedures trigger the development of a mass of dedifferentiated cells (a callus), some of which regain totipotency and develop into plantlets.

STUDY BREAK 36.5

1. A homeotic gene is a regulatory gene in the genome of an organism that encodes a transcription factor. In *A. thaliana,* homeotic genes govern the development of the root and shoot tissue systems, as well as of floral organs.
2. The two basic mechanisms of plant morphogenesis are oriented cell division and cell expansion. Oriented cell division establishes the general shape of a plant organ, and cell expansion enlarges the cells in a developing organ in particular directions. They increase in circumference (girth) when new cell walls form parallel to the nearest plant surface (such as the surface of a stem or tree trunk) or when cell walls form at right angles both to the nearest surface and to the transverse plane.
3. Leaves arise through a developmental program that begins with gene-regulated activity in meristematic tissue. Hormones or other signals may arrive at target cells via the stem's vascular tissue, activating genes that regulate development. Small phloem vessels penetrate a young leaf primordium almost immediately after it begins to bulge out from the underlying meristematic tissue, followed by xylem. A growing primordium becomes cone-shaped (wider at its base than at its tip). Rapid mitosis in a particular plane in cells along the flanks of the cone (perpendicular to the surface in eudicots and parallel to the surface in monocots) produce the leaf blade that is characteristic of the particular species. Leaf tip cells typically are the first to stop dividing. By the time a leaf has expanded to its mature size, mitosis has ended and the leaf is a fully functional photosynthetic organ.

Think Like a Scientist

FIGURE 36.9

Researchers may use several strategies for identifying the signaling events that guide pollination. One approach is to identify mutants that show particular defects in the guidance steps, and then analyze the defects to shed light on what kind of signal(s) operate in normal plants. Some investigators also employ microscopy-based real-time assays to directly observe pollen-tube behavior in various mutants.

FIGURE 36.24

It seems they do. Versions of the ABCE system have been discovered in eudicots including petunia *(Petunia)* and snapdragon *(Antirrhinum),* among others. A modified ABC-like system appears to operate in monocots that have been studied, including members of the lily family, corn, and rice, although much less is known about the particular gene classes that may be involved.

IMR

Because trichomes are accessible and transparent, different mutants can (and do) serve as cellular "laboratories" for studying a range of subcellular processes, including interactions among organelles and the behavior of the actin and microtubule cytoskeletons under varying conditions.

UQ

1. Pollen tube guidance signals are likely to be species specific. Since they are involved in mating, it is likely that these signals ensure that successful pollination, and consequently fertilization, occur only within compatible species. It is also likely that the later the guidance event, the more specific is the guidance signal. For example, the guidance signal from an ovule is likely more selective and specific than those that mediate early interactions between a pollen tube and stigma.
2. If pollen tube growth and guidance are defective, seeds are not produced. Around 80% of the world's staple food is derived from seeds of crop plants, so studying this process is very important agriculturally. By understanding pollen tube guidance signals, we are equipping ourselves with knowledge using which we could: (a) improve seed yield; (b) regulate interspecies hybridizations and, thereby, generate novel plant hybrids; and (c) contain pollen spreading from genetically modified crops—a possibility that will reassure concerned public and regulatory agencies.

tion, supplemental ABA made no significant difference in the seed germination rate.

Chapter 37

Study Break

STUDY BREAK 37.1

1. Auxins, gibberellins, cytokinins, and brassinosteroids all promote the growth of plant parts, and ethylene stimulates cell division in seedlings. Abscisic acid is the major growth-inhibiting plant hormone.
2. Ethylene is a good example of a hormone that can stimulate or inhibit growth at various stages of the plant life cycle. In seedlings, it simultaneously slows elongation of the stem and stimulates cell divisions that increase stem girth. In mature plants of deciduous species, it governs senescence (including fruit ripening) and the abscission of flowers, fruits, and leaves. Studies of brassinosteroids have revealed that this family of steroid hormones has different effects in different tissues—for example, promoting the elongation of vascular tissue and pollen tubes, but inhibiting elongation in roots.
3. Two general types of signal response pathways convert chemical signals into altered plant cell activity. Some plant hormones and growth factors bind to receptors at the target cell's plasma membrane. Others cross the plasma membrane and bind to receptors inside the cell. Second messengers enhance the cellular response.

STUDY BREAK 37.2

1. General plant responses to attack include mobilization of jasmonates and salicylic acid, systemin (in tomato), the hypersensitive response, PR proteins, and secondary metabolites (phytoalexins). Gene-for-gene recognition is a pathogen-specific response.
2. Salicylic acid (SA) is considered to be a general systemic response to damage because experiments show that when a plant is wounded, soon thereafter SA can be detected in a variety of its tissues.
3. While the hypersensitive response is underway, SA also is synthesized and operates in other defensive chemical pathways in a plant. This effect includes the synthesis of PR (pathogenesis-related) proteins that attack pathogenic cells.

STUDY BREAK 37.3

1. Directional light of blue wavelengths is the direct stimulus for phototropism. The most widely accepted scientific explanation for gravitropism is the sinking of amyloplasts in cells surrounding vascular bundles in response to gravity. Sinking amyloplasts may provide a mechanical stimulus that triggers a gene-guided redistribution of IAA. The changing auxin gradient in turn adjusts a plant's growth pattern.
2. Unlike tropisms, nastic movements occur in response to nondirectional stimuli, such as mechanical pressure resulting from an insect brushing against hairlike sensory structures in the leaves of a Venus flytrap plant.

STUDY BREAK 37.4

1. Plant responses to changes in photoperiod rely on different chemical forms of the blue-green pigment phytochrome. Daylight converts the inactive phytochrome (P_r) to an active form, (P_{fr}). When light levels fall, P_{fr} reverts to P_r. This switching mechanism helps regulate light-related processes such as photosynthesis.
2. Photoperiod length is a factor in the seasonal flowering of many angiosperms. Spinach and irises are examples of long-day plants, which flower in spring when the period of daylight extends at least 9 to 16 hours. Chrysanthemums and potatoes are examples of short-day plants, which flower as day-length becomes shorter than some critical period, a condition that occurs naturally in the fall.
3. Dormancy is an adaptive response because it attunes a plant's growth to the most favorable environmental conditions for survival.

STUDY BREAK 37.5

1. Some response pathways may directly stimulate gene transcription whereas others might inhibit gene expression. Some pathways have an intermediary step, in which the original signal triggers the synthesis of regulatory proteins that in turn promote or inhibit the expression of still other genes.
2. Second messengers boost cellular responses to a hormonal signal by setting in motion a cascade of activated protein kinases, which in turn activate cell proteins that carry out the cell's response.
3. Although Chapter 7 focuses on signal transduction pathways in animals, in fact the basics of some transduction pathways are similar in animals and plants. In both groups we see examples of one-step signal transduction (in which a signal exerts its effect by binding a cell receptor) and of signaling cascades such as second messenger systems.

Think Like a Scientist

FIGURE 37.3

Quite possibly. When eudicot seedlings are used in phototropism research, it is the lower stem rather than the seedling shoot tip that appears to bend, so the Darwins might have concluded that the "factor" that caused bending was present in the lower stem. Only recently did researchers show convincingly that in eudicots the auxin signal for phototropism also is transmitted downward from the shoot tip. The research, reported in 2011 by a team at Purdue University, relied on sophisticated genetic techniques to establish that, in *A. thaliana* seedlings, auxin accumulates in the shoot tip and then is redistributed laterally and downward. Intervening steps have yet to be resolved and are sure to be the subject of future experiments.

IMR

As described in Section 37.1, the second messenger inositol triphosphate (IP_3), which is involved in ABA responses that close stomata, was first discovered in animals (and fungi). So was the plant second messenger cGMP (cyclic guanosine monophosphate), which serves as a second messenger in animals, fungi, and even some bacteria.

UQ

1. The genome reorganization occurs in a specific subset of the genome and reproducibly occurs under the same stress conditions. Therefore, it is not random, but the mechanism by which these regions of the genome are recognized is currently unknown. Most mutation systems are assumed to be random within the genome although there is evidence that transposons do have preferential sites.
2. The data indicate that the environment can direct higher rates of mutations to particular regions of the genome and, therefore, mutating and selecting plants simultaneously might provide a better frequency of adaptive mutations. Because plants are sessile, do they need mechanisms that enable the generation of diversity in the face of chronic stress growth conditions for evolution? If so, partitioning of the plant genome into regions that are protected from change (because they are essential) and variable regions (in which changes have phenotypic effects but are not lethal) is important to identify. Using the information might permit the more rapid breeding of stress tolerant crops.

Test Your Knowledge

1. e 2. a 3. c 4. b 5. b 6. b, c 7. a 8. e 9. c 10. e

Interpret the Data

1. Overall, many more *Yucca* genes are up-regulated (expression enhanced) in response to BR and auxin than are down-regulated (expression suppressed).
2. The brassinosteroid (BR) down-regulated many more *Yucca* genes than did auxin. Also, a small number of genes that are up-regulated by auxin are down-regulated by BR. In an even smaller number of genes the reverse was true—that is, the genes were up-regulated by BR but down-regulated by auxin.
3. There is no overlap between the "up" and "down" bubbles of each hormone because a given hormone does not have contrasting effects on the same gene. Thus, with respect to each hormone there are two distinct groups of *Yucca* genes—those the hormone up-regulates and those it down-regulates.

Chapter 38

Study Break

STUDY BREAK 38.1

1. Multicellularity made it possible for animals to create an internal fluid environment for fulfilling the nutrient supply, waste removal, and osmotic balance needs of individual cells. As a result, multicellular organisms could evolve to occupy a variety of habitats, including dry terrestrial environments, in which single cells cannot survive. Multicellularity also allowed major life functions to be distributed among specialized groups of cells, with each group having a single activity. The specialized groups of cells are typically organized into tissues, the tissues into organs, and the organs into organ systems.
2. A tissue is a group of cells with the same structure and function. Cells in the tissue work together to perform one or more activities. An organ integrates two or more different tissues into a structure that carries out a specific function. An organ system coordinates the activities of two or more organs to carry out a major body function.

STUDY BREAK 38.2

1. Exocrine and endocrine glands are formed by epithelia. An exocrine gland remains connected to the epithelium by a duct, whereas an endocrine gland is suspended in connective tissue underlying the epithelium, with no ducts leading to the epithelial surface.
2. Loose connective tissue, fibrous connective tissue, cartilage, bone, adipose tissue, and blood.
3. Skeletal, cardiac, and smooth.

STUDY BREAK 38.3

See Figure 36.10.

STUDY BREAK 38.4

A stimulus—a change in the external or internal environment—starts the homeostatic control system. The stimulus is detected by a *sensor,* an *integrator* compares the environmental change with a set point, and the *effector* or effectors become activated by the integrator and function to return the environmental parameter to the set point.

Think Like a Scientist

IMR

When the cells are growing singly, the cells are separate and they remain undifferentiated. When they cover the culture dish and begin piling up on one another, the cells are in contact with one another. In some way, this contact triggers a change in the genetic programs of the cells so that they make a transition from being undifferentiated to becoming differentiated.

UQ

Some organisms needed to anticipate light in order to harvest its energy, whereas other organisms needed to avoid its damaging ultraviolet radiation. Thus, anticipation, via circadian rhythm, was and is crucial for survival.

Test Your Knowledge

1. b 2. a 3. e 4. c 5. b 6. a 7. c 8. e 9. e 10. d

Interpret the Data

Yes, these data are consistent with the hypothesis. Taurine is known to inhibit vasopressin. The figure shows a method by which taurine could act as part of a negative feedback loop. Taurine release is directly stimulated by vasopressin; therefore, its levels are directly increased by vasopressin, which could lead to negative feedback of vasopressin release.

Chapter 39

Study Break

STUDY BREAK 39.1

1. A dendrite receives signals and conducts them toward the cell body. An axon conducts signals away from the cell body toward another neuron or effector.
2. An afferent neuron conducts information from its sensory receptors to interneurons. Efferent neurons conduct signals from interneuron networks to effectors, the muscles and glands that carry out the response. The afferent and efferent neurons constitute the peripheral nervous system (PNS). Interneurons process information from afferent neurons and send a response to the efferent neurons. Interneurons form the brain and spinal cord, the central nervous system (CNS).
3. In an electrical synapse, the plasma membrane of the axon terminal of the presynaptic cell is in direct contact with the postsynaptic cell, allowing ions to pass directly between the cells when an electrical impulse arrives. In a chemical synapse, the presynaptic and postsynaptic cells are separated by a small gap. Neurotransmitters released from the presynaptic cell diffuse across the gap and bind to receptors in the plasma membrane of the postsynaptic cell. If enough neurotransmitter molecules bind to those receptors, the postsynaptic cell generates a new electrical impulse, which travels along its axon to the next neuron or effector in the circuit.

STUDY BREAK 39.2

1. At the peak of an action potential, the plasma membrane of the neuron enters a short refractory period, in which the threshold for generation of an action potential is much higher than normal. Only the region in front of the action potential can fire, meaning that the impulse can only move in one direction—that is, toward the axon tip. The refractory period remains in effect until the membrane again reaches the resting potential. By that time, the action potential has moved too far away to cause a second action potential in the same region.
2. Neurons insulated with myelin sheaths have gaps in the sheaths called nodes of Ranvier, where the axon membrane is exposed to extracellular fluids. The inward movement of sodium ions at a node produces depolarization and an action potential, but the adjacent myelin sheath prevents the excess positive ions from exiting through the membrane. Instead, they diffuse rapidly to the next node where they cause depolarization, inducing an action potential there. Continuation of this process allows the action potential to jump rapidly along the axon from node to node, at a faster rate than a nonmyelinated neuron of the same diameter.

STUDY BREAK 39.3

1. A neurotransmitter is synthesized in a neuron, is released into the synaptic cleft from a presynaptic axon terminal, and binds to receptors in the plasma membrane of the postsynaptic cell. Depending on the type of receptor, a neurotransmitter either stimulates or inhibits the generation of action potentials.
2. A neurotransmitter that binds to an ionotropic neurotransmitter receptor, like all neurotransmitters, is stored in synaptic vesicles in the cytoplasm at an axon terminal. When an action potential arrives at the terminal, the change in membrane potential opens voltage-gated Ca^{2+} channels in the axon terminal, allowing Ca^{2+} to flow back into the cytoplasm. The rise in Ca^{2+} concentration triggers the release of the neurotransmitters into the synaptic cleft by exocytosis. Neurotransmitters that bind to an ionotropic neurotransmitter receptor diffuse across the synaptic cleft and open or close ligand-gated ion channels in the postsynaptic neuron's membrane. Most of the channels regulate Na^+ or K^+ movement through the membrane, although some regulate Cl^-. Depending on the ion flow, action potentials are either stimulated or inhibited in the postsynaptic neuron.

STUDY BREAK 39.4

One way a postsynaptic neuron integrates signals is through summation of EPSPs and IPSPs that alter the neuron's membrane potential. EPSPs move the membrane potential toward the threshold for an action potential, whereas IPSPs move the membrane potential away from the threshold for an action potential. The final change in membrane potential depends on the particular array of EPSPs and IPSPs received. The patterns of synaptic connections made by a neuron also contribute to integration.

Think Like a Scientist

FIGURE 39.7

You could use an experimental setup similar to that of Loewi but with just one heart. Add acetylcholine to the solution surrounding that heart and monitor the strength and rate of its beating. The results should mimic that of Loewi's experiments; that is, the heart should respond to the acetylcholine by exhibiting a rapid decrease in the strength and rate of its beating.

FIGURE 39.11

The activity of the K^+ channel is responsible for causing the membrane potential to fall. Inhibiting the K^+ channel would decrease significantly the outflow of K^+ and, therefore, slow the fall in membrane potential. In other words, it would take much longer than normal for the membrane potential to reach its resting value.

IMR

The chimeric proteins must fold in an appropriate way in order to function. The hydrophilic domain must have a three-dimensional structure that can recognize the neurotransmitter, and the membrane-embedded hydrophobic domain must have a three-dimensional structure that can carry out the ion conduction function. The simplest interpretation of the results is that only two of the five artificial receptors had hydrophobic domains that were folded properly for conducting ions.

UQ

If we understood the biological nature of conscious thought, then perhaps we could design a more rational judicial system, for example.

Test Your Knowledge

1. d 2. b 3. a 4. c 5. e 6. a 7. c 8. b 9. e 10. a

Interpret the Data

1. Cyanide inhibits the transport of Na^+ out of the squid axon, as evidenced by the decrease in the rate of ^{22}Na lost from the axon.
2. The addition of broken-down ATP has no effect on the cyanide-caused inhibition of Na^+ transport out of the axon.
3. The addition of ATP increases the rate of ^{22}Na transport out of the axon, somewhat reversing the effects of the cyanide. These results mean that cyanide likely is poisoning the Na^+/K^+ active transport pump, which depends upon ATP hydrolysis for its action. An injection of ATP overcomes the cyanide inhibition until that ATP is used up, and then the curve shows a decrease again in ^{22}Na transport out of the axon (at around the three hour point).

Chapter 40

Study Break

STUDY BREAK 40.1

1. A nerve net is a loose meshwork of neurons organized in a radial pattern that reflects the radial symmetry of the animal in which it is found. Nerves are bundles of axons surrounded by connective tissue. Nerve cords are bundles of nerves.
2. Cephalization is the formation of a distinct head region containing ganglia, which form a major central control center or brain, and major sensory structures. Cephalization is found in more complex invertebrates and in all vertebrates.

STUDY BREAK 40.2

(a) Sympathetic nervous system; this is the classic "fight or flight" scenario for this autonomic nervous system division. (b) Parasympathetic nervous system.

STUDY BREAK 40.3

1. The blood–brain barrier is a distinct separation between the blood and the brain resulting from tight junctions between the epithelial cells forming the walls of the capillaries in the brain. The blood–brain barrier regulates exchanges between blood and brain, in particular preventing most dissolved substances from entering the cerebrospinal fluid, thereby protecting the brain and spinal cord from viruses, bacteria, and toxic substances that may be in the blood.
2. Gray matter consists of nerve cell bodies and dendrites; white matter consists of axons, many of them surrounded by myelin sheaths.
3. The brain stem regulates a number of the body's vital housekeeping functions without conscious involvement or control by the cerebrum, including heart and respiration rates, blood pressure, constriction and dilation of blood vessels, coughing, and reflex activities of the digestive system.
4. The cerebellum is an outgrowth of the pons, but it is structurally and functionally separate from the brain stem. The cerebellum has extensive connections with other parts of the brain, through which it receives sensory inputs from receptors in muscles and joints, from balance receptors in the inner ear, and from the receptors of touch, vision, and hearing. The cerebellum integrates the various sensory signals and compares them with signals from the cerebrum that control voluntary body movements. Information flow from the cerebellum to the cerebrum, brain stem, and spinal cord modifies and fine-tunes movements of the body. In humans, the cerebellum also is involved in the learning and memory of motor skills.

   The cerebral cortex is a thin, folded layer of gray matter that forms the surface of the cerebrum. The cerebral cortex contains sensory areas that receive and integrate sensory information of many kinds, including touch, pain, temperature, pressure, hearing, vision, smell, and taste. It also contains motor areas that are involved in controlling body movements and position, and association areas, which integrate information from the sensory areas and send responses to the motor area. Most higher functions of the human brain, including critical thinking, abstract thought, musical ability, and aspects of personality, involve activities of many regions of the cerebral cortex.

STUDY BREAK 40.4

Short-term memory involves transient changes in neurons. Short-term memory loss resulting from aging may be caused by a loss of control of the mechanisms involved, or, more likely, by a loss or degeneration of the neurons that constitute the short-term memory system.

Learning first involves storing memories. If the short-term memory system is faulty, perhaps due to loss or degeneration of neurons, then the transfer of short-term memories to the long-term memory system will be impaired. Another possibility is a loss or degeneration of the neurons responsible for long-term memory.

Think Like a Scientist

FIGURE 40.7

A slow response to the knee-jerk reflex test might indicate a defect in nerve conduction.

FIGURE 40.13

Yes. Information from the right visual field crosses over to the left side of the brain, and vice versa, via the optic chiasm. So, when a split-brain patient is shown a flower vase in the right visual field, this information crosses over to the left side of the brain (the optic chiasm is still intact even though the corpus callosum is severed). It is important to realize that each hemisphere of the brain specializes in different things. The right side of the brain is concerned with things such as artistic abili-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ties and intuitive thinking, while the left side of the brain is concerned with language, reasoning, and mathematics. Because the two hemispheres can no longer communicate with each other, information about the flower vase is constrained to the left hemisphere once it crosses over through the optic chiasm. Since this hemisphere is involved in language, the patient will be able to describe the object without the help of the other hemisphere.

IMR

The key aspect of the experimental design was that the knockout mice lacked NMDA receptor function just in the hippocampus.

UQ

A good guess is that the generalist will show better learning. The reason is that it normally must find food across a wide variety of environmental conditions that might vary in unpredictability. Therefore, learning ability would be highly adaptive. The specialist could adapt quite well by "hard wiring" an attraction to all the specific chemical cues that are normally associated with its single food source. Of course, only an experimental test would verify this hypothesis.

Test Your Knowledge

Interpret the Data

1. In the first 5-minute interval, the control rats were more active than the rats exposed prenatally to MDMA.
2. 76 photobeam breaks
3. The rats exposed to MDMA moved most during the last 5-minute interval.
4. Yes, because the two groups of rats had different patterns of movement. The control rats began to move around the cage almost immediately. The MDMA rats were less active to begin with but continued moving long after the control rats had settled down.

Chapter 41

Study Break

STUDY BREAK 41.1

1. Sensory transduction is the conversion of a stimulus into a change in membrane potential.
2. The signals from particular sensory receptors are routed by afferent neurons to specific regions of the CNS. Processing of the incoming signals by those regions gives the "sense" of the stimulus—a smell, pain, and so forth.

STUDY BREAK 41.2

1. Proprioceptors detect stimuli that are processed to provide the animal with information about movements and position of the body.
2. All proprioceptors are mechanoreceptors because they are stimulated by a mechanical force.

STUDY BREAK 41.3

1. Octopuses have mechanoreceptors on their head and tentacles, similar to the lateral line of fishes. These mechanoreceptors detect vibrations in the water. Many insects have sensory receptors in the form of hairs or bristles that vibrate in response to sound waves, whereas some insects (for example, moths, grasshoppers, and crickets) have auditory organs on either side of the abdomen or on the first pair of walking legs.
2. In humans, vibrations representing sound frequencies are transmitted into the fluid-filled inner ear. They travel through the inner ear and cause the basilar membrane to vibrate in response, bending the sensory hair cells and stimulating them to release a neurotransmitter that triggers action potentials in afferent neurons leading from the inner ear. The vibrations from a particular sound frequency cause the basilar membrane to vibrate maximally at one particular location, stimulating the hair cells in that region to initiate action potentials. That information is sent to the brain, which integrates it into a perception of the sound stimulus.

STUDY BREAK 41.4

(a) A photopigment is an association of retinal with one of several different opsin proteins. (b) A photoreceptor is a receptor specialized for detection of colors (different wavelengths of light). (c) A ganglion cell's receptive field is the specific set of photoreceptors that sends signals to that cell. Receptive fields are usually circular and vary in size; the smaller the receptive field, the more precise the information sent to the brain and the sharper the image.

STUDY BREAK 41.5

1. Most odor perceptions arise from a combination of different olfactory receptors, which are located in the nasal cavities in humans. We have about 1,000 different olfactory receptor types, each of which responds to a different class of chemicals. The stimulated olfactory receptors send signals via the olfactory bulbs to the olfactory centers of the cerebral cortex, where the signals are interpreted as particular smells.
2. Chemicals bind to taste receptors and generate signals. Signals from taste receptors are relayed to the thalamus. From there, some signals go to gustatory centers in the cerebral cortex where they are integrated to produce taste perception. Other signals go to the brain stem and limbic system, which links tastes to involuntary visceral and emotional responses, such as sensations of pleasure or revulsion.

STUDY BREAK 41.6

The other sensory receptors involve specialized receptor structures. Afferent neurons synapse with the receptors. When a receptor is stimulated, the change in membrane potential (sensory transduction) is transmitted to the afferent neuron, which transmits the signal to the interneuron networks of the CNS. By contrast, both thermoreceptors and nociceptors consist of free nerve endings formed by the dendrites of afferent neurons, with no specialized receptor structures involved.

STUDY BREAK 41.7

Electroreceptors are used in aquatic vertebrates for electrolocation (locating other animals such as prey), electrocommunication (communicating with other members of the same species), and killing prey (involving high-voltage discharge).

Think Like a Scientist

IMR

The researchers showed clearly that a particular cDNA expressed in nonneuronal cells resulted in a receptor that responded specifically to capsaicin. Since a cDNA is derived from an mRNA, which encodes a protein, the receptor must be proteinaceous. The researchers also demonstrated that, in the transformed nonneuronal cells, capsaicin stimulation produced an influx of Ca^{2+}, thereby supporting the conclusion that the protein encoded by the cDNA is an ion channel.

UQ

1. Photoreceptors (they will clearly "detect" that the color of the eggs is odd); chemoreceptors (although the taste of the eggs is not altered, the person eating the green eggs may make a facial expression that leads you to believe that he or she has detected an altered taste). Combining an MRI and a PET scan might be a good method for testing synesthesia.
2. Detection and response to light are logically a key sensory system for any living organism—from prokaryotes to plants to animals—but sensing light with photoreceptors does not to have to involve "vision." Yet, the genes for photoreceptor proteins would logically be of early evolutionary origin.

Test Your Knowledge

Interpret the Data

1. Most of the bird pairs support the hypothesis, with k, l, and m providing the strongest data.
2. Pairs d and h show little difference between species, but pair g does not fit the hypothesis.
3. Overall the data appear to support the hypothesis.

Chapter 42

Study Break

STUDY BREAK 42.1

1. A *hormone* is a signaling molecule secreted by one group of cells and transported through the circulatory system to other, target cells, whose activities they change. Specific target cells react to the hormone because they carry receptors for the hormone. The best-known hormones are secreted by cells of the endocrine system and elicit a response in target cells that have receptors for the hormone. An *exocrine secretion* is a molecule released from an exocrine gland. Such molecules are secreted into ducts that lead outside the body or into the cavities of the digestive tract.
2. In *endocrine signaling,* a hormone secreted by an endocrine gland into the ECF is transported in the blood and causes a response in a target cell that has a receptor for the hormone. In *autocrine signaling,* a local regulatory molecule is released from a cell and binds to cell surface receptors on the same cells that produce the molecule, triggering a response.

STUDY BREAK 42.2

1. Glucagon, a peptide hormone, triggers a response by binding to a surface receptor. Glucagon binding activates the receptor, which triggers a signal transduction pathway inside the cell, leading to phosphorylation of target proteins. The altered activities of the phosphorylated proteins produce responses in the target cells, in this case the breakdown of glycogen in liver cells to glucose.

   Aldosterone, a steroid hormone, passes though the plasma membrane and binds to an internal receptor in the cytoplasm or nucleus, activating it. The hormone-activated receptor complex binds to control sequences in the DNA that the receptor recognizes and either activates or inhibits transcription of the associated target genes. Through binding to a receptor, the hormone affects transcription of specific genes in target cells.
2. A target cell could respond to different hormones if it carries receptors for those different hormones. Turning this around, a target cell will respond only to one hormone if it just has the receptor for that hormone. The same hormone could produce different effects in different cells if there are different receptors for that hormone, each triggering a distinct response pathway.

STUDY BREAK 42.3

1. The hypothalamus and anterior pituitary gland are connected by nerve and vascular tissues. The hypothalamus releases peptide neurosecretory hormones into the linking blood vessels. These hormones regulate the secretion of peptide hormones by the anterior pituitary gland. The pituitary hormones regulate several key body systems.
2. Secretion of hormones from the anterior pituitary is controlled by releasing hormones (RHs) and inhibiting hormones (IHs), which are released by the hypothalamus. For the posterior pituitary, neurosecretory neurons directly secrete the hormones into the circulatory system.

STUDY BREAK 42.4

1. Parathyroid hormone stimulates the dissolution of calcium and phosphate ions from bone and their release into the bloodstream.
2. The adrenal medulla secretes epinephrine and norepinephrine. Epinephrine prepares the body for handling stress or physical activity by, among other actions: (1) increasing heart rate; (2) breaking down glycogen and fats, thereby releasing glucose and fatty acids into the blood for fuel; (3) dilating blood vessels in the heart, skeletal muscles, and lungs to increase blood flow; (4) constricting blood vessels elsewhere, thereby raising blood pressure, reducing blood flow to the intestine and kidneys, and inhibiting smooth muscle contraction, which reduces water loss and slows down the digestive system; and (5) dilating airways in the lungs, thereby increasing air flow.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Norepinephrine has similar effects to epinephrine on heart rate, blood pressure, and blood flow to the heart muscle. In contrast to epinephrine, norepinephrine causes blood vessels in skeletal muscles to contract.

3. Glucocorticoids and mineralocorticoids are the two major classes of steroid hormones secreted by the adrenal cortex. Glucocorticoids help maintain the concentration of glucose and other fuel molecules in the blood, and mineralocorticoids regulate the levels of Na^+ and K^+ in blood and the ECF.
4. Estradiol is an estrogen and progesterone is a progestogen; both are steroid hormones. Estradiol produced by the ovaries stimulates maturation of sex organs at puberty and development of secondary sexual characteristics. Progesterone, also produced by the ovaries, prepares and maintains the uterus for implantation of a fertilized egg and the growth and development of an embryo.

STUDY BREAK 42.5

In general, invertebrates have fewer hormones regulating fewer body processes and responses than vertebrates do. Peptide and steroid hormones are produced in both invertebrates and vertebrates. However, most of those hormones are different in structure and molecular function in the two groups, even though the reaction pathways stimulated by the hormones are the same.

Think Like a Scientist

FIGURE 42.5

Mutant forms of the receptor could be produced *in vitro,* placed in liposomes, and tested for their ability to respond to epinephrine by measuring an increase in cAMP levels within fused cells. For example, specific mutations affecting the ability to bind epinephrine or activate the associated G protein could be found. For the latter, some specific mutations might not be able to activate the G protein, whereas others might activate the G protein constitutively.

IMR

It is possible that tamoxifen caused the breast cancer cells to make more of the receptor, which then resulted in a higher luciferase level.

UQ

Although no animal model perfectly mimics human breast cancer, animals are useful in understanding the effect of specific exposures on breast cancer risk and the risk of recurrence, without having to worry that some unintended factors explain the findings. Further, it is far easier to study the effects of timing of exposure to estrogenic compounds, and multigenerational effects, on breast cancer in animal models than it is in humans. The benefits of cell culture studies include the ability to perform highly mechanistic studies to understand causal effects of estrogens and their biological targets in affecting breast cancer growth. Main weakness of cell culture studies is that breast cancer cells are studied in isolation from other cells in the breast which are known to interact with the cancer cells to impact their growth.

Test Your Knowledge

1. b 2. d 3. a 4. c 5. c 6. e 7. a 8. b 9. d 10. b

Interpret the Data

1. The level of growth hormone was not constant over the 24-hour period. The level of this hormone increased markedly immediately after the onset of sleep and then declined in the middle of the sleep period. Another increase in growth hormone level occurred upon waking and then the level dropped to a level similar to that of presleep.
2. The level of prolactin also is not constant over the 24-hour period. The fluctuations in prolactin levels in the period before sleep are similar to those seen in that period for growth hormone. The level of prolactin increased in the sleep period, showing a rise immediately after sleep onset and continuing to a maximum level at the time of waking. The level of prolactin then decreased to a level similar to that of presleep.
3. Mostly there is no consistent relationship between the levels of the two hormones over the 24-hour period. The only exception is the initial rise in prolactin and in growth hormone that occurred with sleep onset.
4. Yes. The correlation between high level of prolactin with sleep and low level of prolactin with wakefulness supports the hypothesis. However, it cannot be determined from the data if the sleep-related rise in prolactin is directly dependent on sleep, or whether other factors triggered by sleep are involved.

Chapter 43

Study Break

STUDY BREAK 43.1

1. An axon terminal of an efferent neuron makes a synapse called a neuromuscular junction with a muscle fiber. When an action potential arrives at that junction, the axon terminal releases acetylcholine, which triggers an action potential in the muscle fiber that moves in all directions over its surface and penetrates to the interior of the fiber through T tubules. When the action potential reaches the end of the T tubules, ion channels are opened in the sarcoplasmic reticulum that allow Ca^{2+} ions to flow from the sarcoplasmic reticulum into the cytosol. Troponin then binds the ion and undergoes a conformational change that allows tropomyosin to enter the grooves in the actin helix of the thin filaments. As a result, the myosin-binding sites are uncovered, and the crossbridge cycle is turned on, leading to muscle contraction.
2. In the sliding filament mechanism of muscle contraction, the thin filaments on each side of a sarcomere slide over the thick filaments toward the center of the A band, thereby bringing the Z lines closer together. A crossbridge cycle is responsible for the contraction. At the beginning of the cycle, the myosin crossbridge has an ATP bound to it and is not in contact with the actin of the thin filament. The ATP is hydrolyzed, causing the myosin crossbridge to bend away from the tail and bind to a myosin-binding site on the thin filament that was uncovered in response to the release of Ca^{2+} ions into the cytosol from the sarcoplasmic reticulum. When the myosin crossbridge binds to the actin, the crossbridge snaps back toward the myosin tail to produce the power stroke that pulls the thin filament over the thick filament. ADP and phosphate are released from the crossbridge in this step. A new molecule of ATP now binds to the crossbridge, causing the myosin to detach from the actin. The cycle then repeats.
3. Contraction intensity: low in slow aerobic fibers, intermediate in fast aerobic fibers, and high in fast anaerobic fibers.

   Fatigue resistance: high in slow aerobic fibers, intermediate in fast aerobic fibers, and low in fast anaerobic fibers.

   Oxidative phosphorylation capacity: high in slow aerobic fibers, high in fast aerobic fibers, and low in fast anaerobic fibers.

   Number of mitochondria: many in slow aerobic fibers, many in fast aerobic fibers, and few in fast anaerobic fibers.

   Myoglobin content: high in slow aerobic, high in fast aerobic, and low in fast anaerobic.

STUDY BREAK 43.2

1. A hydrostatic skeleton provides support to the body or body part through muscles acting on compartments filled with fluid under pressure. In vertebrates, the penis is a hydrostatic skeletal structure.

   An exoskeleton is a rigid external body covering. The force of muscle contraction against the covering provides support to the body or part of the body. In vertebrates, the shell of a turtle or tortoise and the bony plates in the skin, the abdominal ribs, the collarbones, and most of the bony skull of the American alligator are exoskeletal structures.

   An endoskeleton consists of internal body structures such as bones. The force of muscle contraction against the internal body structures provides support. In vertebrates, the endoskeleton is the primary skeletal system.
2. The bones of the vertebrate endoskeleton provide support for the body and body parts, protect key internal organs, store calcium and phosphate ions, and are the sites where new blood cells form.

STUDY BREAK 43.3

1. Synovial joints consist of the ends of two bones that are enclosed by a fluid-filled capsule of connective tissue. Fluid within the capsule and a smooth layer of cartilage over the ends of the bones enable the bones to slide easily as the joint moves. In these joints, ligaments extend across the joints across the capsule. The ligaments confine the motion of the joint and protect it to an extent from deleterious effects of heavy loads.

   Cartilaginous joints have no fluid-filled capsule surrounding them, and the bones involved are covered with cartilage. The bones of the joint are covered by and connected with fibrous connective tissue. Cartilaginous joints are less movable than synovial joints.
2. Antagonistic muscle pairs are muscles arranged so that bones can be extended, flexed, or rotated in opposite directions around a joint. For example, in humans, the biceps and triceps muscles are an antagonistic muscle pair.

FIGURE 43.4

ATPase hydrolyzes ATP to ADP and inorganic phosphate. The existence of ATPase activity on myosin suggests that the sliding of thick (myosin) and thin (actin) filaments over each other requires, at least in part, energy released from ATP hydrolysis.

FIGURE 43.5

ATPase hydrolyzes ATP to ADP and inorganic phosphate. The existence of ATPase activity on myosin suggests that the sliding of thick (myosin) and thin (actin) filaments over each other requires, at least in part, energy released from ATP hydrolysis.

IMR

You would want to repeat the same kind of study with other mammals to see which genes change expression in response to training in the same way as was found in the racehorse study. One could use humans and dogs in such a study, and perhaps some other mammals that can be trained in the way needed.

UQ

Skeletal muscle consumes metabolites, including fatty acids and carbohydrates, both for movement and for building new muscle. Thus, maintaining and using new muscle could increase fat metabolism and its breakdown and oxidation for energy, while also diverting carbohydrates, which are often converted to fat, away from fat cells and to muscle cells.

Interpret the Data

1. Seven out of the nine treated children showed an increase in vertebral area during the study.
2. None of the six untreated control children showed an increase in vertebral area.
3. The treated children experienced a mean of 2.6 fractures per year, less than half of the mean of 6.3 fractures per year in the untreated children.
4. Yes.

Chapter 44

Study Break

STUDY BREAK 44.1

1. The three basic features of animal circulatory systems are: (1) a specialized fluid medium for transporting molecules, exemplified by the blood of vertebrates; (2) a muscular heart for pumping the fluid; and (3) tubular vessels for distributing the fluid pumped by the heart.
2. In an open circulatory system, there is no distinction between blood and interstitial fluid. Vessels from the heart release hemolymph directly into body spaces and the fluid

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

is subsequently collected and reenters the heart. In a closed circulatory system, blood is channeled in blood vessels leading to and from the heart and is distinct from the interstitial fluid.

In an open circulatory system, most of the fluid pressure generated by the heart dissipates when the blood is released into the body spaces. Consequently, blood flows relatively slowly. Humans could not function as we do with such a system, because we would not be able to distribute oxygen efficiently throughout the body, nor would we be able to eliminate the wastes we produce.

3. Atria are chambers of the heart that receive blood returning to the heart. Ventricles are chambers of the heart that pump blood from the heart. Arteries are vessels of circulatory systems that conduct blood away from the heart at relatively high pressure. Veins are vessels of circulatory systems that carry blood back to the heart.
4. The systemic circuit of the circulatory system is the circuit from the heart to most of the tissues and cells of the body and back to the heart. The pulmocutaneous circuit goes from the heart to the skin and lungs or gills in amphibians and back to the heart. The pulmonary circuit goes from the heart to the lungs and back to the heart.

STUDY BREAK 44.2

1. Erythrocytes originate as pluripotent stem cells in the red bone marrow. In humans and other mammals, they lose their nucleus, cytoplasmic organelles, and ribosomes as they mature, becoming essentially a membrane-bound hemoglobin reservoir that is not capable of protein synthesis. At the end of their life span—about 4 months—erythrocytes are engulfed by macrophages, a type of leukocyte, in the spleen, liver, and bone marrow.
2. Low oxygen content triggers a negative feedback mechanism to increase erythrocytes in the blood. The kidneys are stimulated to synthesize the hormone erythropoietin (EPO), which stimulates stem cells in the bone marrow to increase erythrocyte production. EPO synthesis is stopped when the oxygen content of the blood rises above normal levels.
3. Leukocytes act as the first line of defense against invading organisms, eliminate dead and dying cells from the body, and remove cellular debris. Platelets assist in blood clotting. When blood vessels are damaged, platelets stick to the collagen fibers exposed to leaking blood and recruit other platelets to the site. Eventually a plug forms at the site, sealing off the damaged area.

STUDY BREAK 44.3

1. The right atrium receives blood in the systemic circuit returning to the heart in vessels coming from the entire body, with the exception of the lungs. The right atrium pumps blood into the right ventricle.

   The right ventricle receives blood from the right atrium, and pumps it into the pulmonary arteries going to the lungs, beginning the pulmonary circuit.

   The left atrium receives blood returning from the lungs in the pulmonary veins, completing the pulmonary circuit. The left atrium pumps this blood into the left ventricle.

   The left ventricle pumps the blood received from the left atrium into the aorta where the blood begins its path in the systemic circuit.
2. Systole is the period of contraction and emptying of the heart. Diastole is the period of relaxation and filling of the heart between contractions.
3. Neurogenic hearts beat under the control of signals from the nervous system. If the signals cease, this type of heart stops beating. Myogenic hearts maintain a contraction rhythm without signals from the nervous system. In the event of a serious trauma to the nervous system, this type of heart keeps beating.
4. Pacemaker cells of the SA node undergo regularly timed depolarizations, which initiate waves of contraction that travel over the heart. The waves stop before they reach the bottom part of the heart as they encounter an insulating layer of connective tissue. The contraction signals at this point excite cells of the AV node, and then pass to the bottom of the heart along Purkinje fibers. There they induce waves of contraction that begin at the bottom of the heart and move upwards, expelling blood from the ventricles into the aorta and pulmonary arteries.

STUDY BREAK 44.4

1. Blood flow through capillary networks is controlled by contraction of smooth muscles in arterioles and by contraction of precapillary sphincters at the junctions of capillaries and arterioles.
2. In most body tissues, there are small spaces between capillary endothelial cells, but in the brain the capillary endothelial cells are tightly sealed together, forming a blood–brain barrier.
3. The two major mechanisms are diffusion along concentration gradients and bulk flow. Diffusion along concentration gradients occurs both through the spaces between the capillary endothelial cells and through the plasma membranes. The direction of movement of the molecule or ion depends on the concentration gradient. Thus, oxygen and glucose, which are at higher concentrations in the capillaries, diffuse into the interstitial fluid and then into the cells of the tissues. Carbon dioxide, which is at a higher concentration in the interstitial fluid, diffuses into the capillaries.

   Bulk flow carries water, ions, and molecules out of the capillaries. Driven by the pressure of the blood, which is higher than the pressure of the interstitial fluid, bulk flow occurs through the spaces between capillary endothelial cells.

STUDY BREAK 44.5

1. Arterial blood pressure must be regulated within limits to provide sufficient blood flow for the brain and other tissues and to prevent damage to blood vessels, tissues, and organs that would occur at high blood pressures.
2. The three main mechanisms for regulating blood pressure are: (1) controlling cardiac output (the pressure and amount of blood pumped by the ventricles); (2) controlling the degree of constriction of the blood vessels (mostly the arterioles); and (3) controlling the total blood volume.
3. The hormone epinephrine raises blood pressure by increasing the strength and rate of the heart rate, and by stimulating vasoconstriction of arterioles in certain parts of the body.

STUDY BREAK 44.6

Lymph is interstitial fluid, an aqueous solution containing molecules, ions, infecting bacteria, damaged cells, cellular debris, and lymphocytes. Because the lymph capillaries consist of a single layer of endothelial cells, the lymphatic fluid can enter them at sites where the endothelial cells overlap when the pressure of the interstitial fluid forces the flaps open. The openings produced are large enough for cells to enter.

Think Like a Scientist

FIGURE 44.12

An SA node dysfunction would involve nonnormal electrical signals. Because the SA node is the pacemaker for cardiac contraction, SA node dysfunction would result in an abnormal heart rhythm. The abnormality could be a rate of heart contraction that is too fast or too slow, depending on the dysfunction.

FIGURE 44.18

You would use the same norepinephrine-treated rabbit aorta preparation without endothelium as in the experiment described. The effect of NO in solution can then be determined. In an experiment like this, Furchgott and his colleagues demonstrated that the NO caused a relaxation of the muscle. Similar experiments by other researchers confirmed the result.

IMR

The key element of the experimental design was that the specific knockout of both α_{1D}-adrenergic receptor genes in the mice enabled the researchers to study just one variable—the loss of the receptor. Studies with drugs could not lead to conclusions specifically about this receptor because no drug selectively affects just one subtype of adrenergic receptors.

UQ

1. Probably not. The most common form of hemophilia is a result of a mutation in clotting factor VIII (see Section 42.2), and lampreys lack that clotting factor.
2. When a blood vessel is injured during surgery or extended bed rest, the body uses platelets and fibrin to form a blood clot. The coagulation process is similar in lampreys and mammals, so the molecular basis of drugs used to prevent DVT could be elucidated by using DVT preventive drugs on lampreys.

Test Your Knowledge

1. d 2. e 3. b 4. b 5. c 6. a 7. e 8. e 9. d 10. a

Interpret the Data

1. No. Nifedipine reduces blood pressure and heart rate prior to noticeable increases in plasma nifedipine (below 10 ng/mL).
2. Both capsules reduce blood pressure, but the GITS capsule seems to also reduce heart rate. Since reducing blood pressure or heart rate will decrease the workload on the heart, both will achieve this goal; however, GITS might be more effective.
3. Contracten XL causes greater elevation of nifedipine, which doesn't appear to be necessary for the beneficial effects. Based on these data alone, GITS capsules would be better at reducing workload with fewer side-effects.

Chapter 45

Study Break

STUDY BREAK 45.1

1. Mucous layers are physical barriers to pathogens. Mucous layers may contain toxins and other chemicals that kill pathogens. The aqueous environment in contact with an epithelial surface may inhibit or kill pathogens by being acidic, or by containing enzymes or bile juices.
2. Innate immunity provides a nonspecific, immediate response to a pathogen. It is the first response system that comes into play when a pathogen is encountered, but it retains no memory of the encounter. The innate immune responses include inflammation and specialized cells that attack pathogens.

   Adaptive immunity, by contrast, provides a specific response to a pathogen, and it retains a memory of exposure to the pathogen so that it can respond more quickly to future attacks. The adaptive immune response takes several days to become protective, in contrast to minutes for an innate immune response.

STUDY BREAK 45.2

1. The inflammatory response is characterized by heat, pain, redness, and swelling at the infection site.
2. Inflammation-mediating molecules released at the infection site cause the dilation of local blood vessels and increase their permeability. As a result, blood flow increases and fluid leaks from the blood vessels. Heat, redness, and swelling are direct consequences of these effects. Pain is caused by the migration of macrophages and neutrophils to the infection site, and their activities at the site.
3. The complement system is a nonspecific defense mechanism in which more than 30 interacting plasma proteins are activated by molecules on the surface of pathogens. Activated complement system proteins produce membrane attack complexes that insert into the plasma membrane of many types of bacterial cells and coat other types of cells with fragments of the complement proteins. Membrane-attack complexes create pores that lead to loss of osmotic balance, which causes the pathogens to lyse. Pathogens coated with complement protein fragments are recognized by phagocytes that then engulf and destroy the pathogens.
4. Viral pathogens do not have surface molecules that are distinct from those of the host. The main strategies used by the host in innate immunity are interferon and natural killer cells.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

STUDY BREAK 45.3

1. The antibody-mediated immune response uses antibodies secreted by plasma cells (differentiated from activated B cells) to target antigens in various body fluids. The cell-mediated immune response uses cytotoxic T cells to target and kill cells infected with a pathogen.
2. An antibody is a member of the immunoglobulin (Ig) family of proteins. It consists of four polypeptides, two of which are identical heavy chains and two of which are identical light chains. Structurally, an antibody looks like a Y. Each of the two arms of the Y involves pairing of a light chain with part of the heavy chain. The tail of the Y consists of the remaining parts of the heavy chains paired together. Each heavy chain and each light chain has a variable region and a constant region. The variable regions, which occur at the top half of the arms of the Y, form two identical binding sites for the antigen with which the antibody can react.
3. DNA rearrangements of genes during differentiation are responsible for generating diverse light-chain genes and heavy-chain genes for the B-cell receptor and for the T-cell receptor. In brief, there are many different V DNA segments, one C DNA segment, and a few different J (joining) DNA segments. During differentiation, a light-chain gene is assembled from one V segment, one J segment, and the C segment, creating a gene that can be transcribed. Transcription of the gene produces a pre-mRNA that is spliced to remove introns and generate the translatable mRNA. The various combinations of segments plus imprecision in the joining at the DNA level of the V and J segments produces many types of light-chain genes. A similar DNA rearrangement process occurs for heavy-chain genes. Together, this results in tremendous variability in the antibody molecules that can be made.
4. Clonal selection is the process by which an antigen stimulates the production of a clone of B-cell-derived plasma cells that secrete antibodies against that antigen. Clonal selection accounts for the rapid response, specific action, and diversity of antibodies seen for the adaptive immune system. It also accounts for immunological memory through the production of memory B cells and memory T cells.
5. Immunological memory is the aspect of adaptive immunity that allows for a rapid, intense immune reaction to develop if the body encounters an antigen it has seen before.

STUDY BREAK 45.4

1. Immunological tolerance, a feature of the adaptive immune system, protects the body's own molecules from attack by its immune system. B cells and T cells are involved in the development of immunological tolerance, but the exact process is not understood.
2. Basically, an allergy results from an overreaction of the immune system to a particular antigen. The substances responsible for allergic reactions are a class of antigens known as allergens. Allergens stimulate B cells to secrete IgE antibodies in high amounts. IgE binds to mast cells, which are then induced to oversecrete histamine. Histamine contributes to inflammation, and at high amounts, the histamine-induced inflammation can be severe and even life threatening.

STUDY BREAK 45.5

Invertebrates lack the adaptive immune system seen in mammals; they have no B or T cells, for instance. Invertebrate immune defenses, like the innate immune system of mammals, are nonspecific. For example, all invertebrates have phagocytic cells that engulf pathogens, and many invertebrates produce antimicrobial proteins such as lysozyme. Also, many invertebrates produce proteins of the immunoglobulin family. Although these are not antibody molecules, in some invertebrates they provide a protective function against some pathogens.

Think Like a Scientist

FIGURE 45.5

The key cellular event is the interaction of an antigen-presenting B cell with a helper T cell that differentiated as a result of encountering and recognizing the same antigen as did the B cell.

FIGURE 45.10

Memory cytotoxic T cells in the cell-mediated response are cells that have been programmed to recognize a particular antigen of a pathogen. Similar to the memory cells for the antibody-mediated immune response, memory cytotoxic T cells are long-lived and serve to mount a rapid response should the same antigen be detected on the surface of an infected host cell.

IMR

A logical target would be the expression of FasL in the melanoma cells. A reduction in or absence of FasL receptors on the melanoma cell surface would reduce or abolish the induction of apoptosis of cytotoxic T cells.

UQ

MHC-I genes are highly polymorphic. The large number of MHC-I variants expands the number of antigens that can potentially be targeted by the immune system. A new MHC-I molecule like HLA-C with unique characteristics might be selected for in a population if it allowed the host immune system to better control a pathogen that would otherwise evade the immune system. In fact, some investigators have hypothesized that pathogens put pressure on the evolution of MHC-I sequences.

1. At 110 months, about 1% of the women who were not infected with any HPV type and about 17% of women who were infected with HPV16 had cervical cancer.
2. Women infected with both HPV16 and HPV18 must be in the HPV16 group.
3. Yes, by adding the percentages of individual groups.
4. Yes.

Chapter 46

Study Break

STUDY BREAK 46.1

1. The respiratory medium is the environmental source of oxygen and the repository for released CO_2. For aquatic animals, water is the respiratory medium; for terrestrial animals, it is air. The respiratory surface is the layer of epithelial cells between the body and the respiratory medium. Gas exchange occurs across the respiratory surface—O_2 in and CO_2 out of the body. In certain small animals, the body surface itself is the respiratory surface. Among larger animals, aquatic animals use gills, insects use tracheal systems, and terrestrial animals use lungs as the respiratory surface.
2. The advantage of water over air as a respiratory medium is that it readily enables the respiratory surface to remain wet at all times. Two key advantages of air over water as a respiratory medium are: (1) there is much more oxygen in air than in water; and (2) air is much less dense and less viscous than water, so significantly less energy is needed to move air over the respiratory surface than to move water.

STUDY BREAK 46.2

1. The advantages of gills to water-breathing animals over skin breathing are greater efficiency of gas exchange, the ability to live in more diverse habitats, and the potential to achieve a greater body mass.
2. In countercurrent exchange, the respiratory medium flows in the opposite direction of the blood flow under the respiratory surface. Examples are the flow of water over the gills in sharks, fishes, and some crabs and the one-way flow of air through the lungs of birds; all these are opposite to the flow of blood. The advantage of this mechanism is that it maximizes the amounts of O_2 and CO_2 exchanged with the respiratory medium.
3. In the tracheal system, fine branches called tracheoles end in tips that are in contact with body cells. The tracheole tips are filled with fluid, and gas exchange occurs through the fluid and the plasma membrane of the body cells in contact with the tips. Air enters the tracheal system through spiracles on the body surface. Movement of air through the tracheal system occurs by muscle-driven contractions and expansions of air sacs within the system.
4. In positive pressure, breathing, gulping, swallowing, or pumping action forces air into the lungs. In negative pressure, breathing, muscular activity expands the lungs, lowering the pressure of air in the lungs and thereby causing air to be pulled inward.

STUDY BREAK 46.3

1. Contraction of the diaphragm and the external intercostal muscles pulls the ribs upward and outward, expanding the chest and lungs. By this negative pressure mechanism, the air pressure within the lungs is lower than outside of the body. The higher outside pressure drives air into the lungs, expanding and filling them. Relaxation of the diaphragm and the intercostal muscles reverses the pressure condition, and the elastic recoil of lungs expels the air.
2. For conscious exhalation, you contract the internal intercostal muscles between the ribs to pull the diaphragm down while simultaneously contracting abdominal muscles to compress the abdominal organs and force them upward against the diaphragm to expel air from the lungs.
3. The most important feedback stimulus for breathing is the level of CO_2 in the blood.
4. The chemoreceptors in the medulla respond to the CO_2 level in the blood. If it rises, the medulla triggers an increase in the rate and depth of breathing. If it falls, the medulla triggers a decrease in the rate and depth of breathing.

STUDY BREAK 46.4

1. Hemoglobin is present in red blood cells. O_2 diffuses from alveoli into the plasma solution in the capillaries and then into the red blood cells. In the red blood cells, the O_2 binds to hemoglobin, thereby lowering the partial pressure of O_2 in the plasma. This leads to more O_2 molecules diffusing down the oxygen concentration gradient from alveolar air to blood.

   The binding of O_2 to hemoglobin is reversible. Further, the affinity of hemoglobin for O_2 increases as the partial pressure of O_2 increases and vice versa. This property is important for determining the release of O_2 from hemoglobin keyed to tissue requirements.
2. CO has much greater affinity for hemoglobin than does O_2, and so it displaces O_2 from hemoglobin, reducing the amount of O_2 carried in the blood. Because the brain does not monitor O_2 levels, and other receptors do not respond until blood O_2 levels are critically low, victims can easily lapse into unconsciousness and death.

STUDY BREAK 46.5

- More blood per unit body weight than land animals
- Additional red blood cells, many stored in the spleen and released during a dive
- More myoglobin in muscles than land animals
- Slowing of the heart by as much as 90%
- Reduction of blood circulation to internal organs and muscles by up to 95%
- Retention of lactic acid in the muscles with no release into the blood until the animal returns to the surface

Think Like a Scientist

FIGURE 46.14

The specific mutations presumably involved in the evolutionary adaptation of deer mice to high altitude had to have occurred in a relatively short period of time, given that the mice could have only inhabited the alpine areas no earlier than 10,000 years ago.

IMR

Expression vectors were described in Chapter 18. They contain a selectable marker for selecting *E. coli* transformants that contain them, an origin of replication sequence for replication of the plasmid independently of the bacterial chromosome, and restriction sites for cloning genes of interest into the vector. Most important here is the expression of myoglobin in *E. coli.* The source of the myoglobin gene is the sperm whale, which is a eukaryote. Eukaryotes use different molecular signals for the transcription of protein-coding genes and for the translation of the resulting mRNAs. Therefore, to express a myoglobin gene in *E. coli,* it must be inserted into an expression vector that has, for transcription, a transcription terminator sequence in addition to the bacterial promoter and, for translation, a ribosome binding site so that protein synthesis will be initiated at the correct start codon. Using an expression vector to synthesize a eukaryotic protein in *E. coli* is diagrammed in Figure 18.11.

UQ

1. Carbon dioxide level.
2. Contraction of smooth muscle in the heart is under the control of the autonomic nervous system. Nicotine stimulates the postganglionic neurons of both the sympathetic (increases heart rate) and parasympathetic (decreases heart rate) divisions and disrupts heart rate rhythm. Therefore, research is focused on both divisions, as nicotine affects the opposing actions of these divisions.

Test Your Knowledge

Interpret the Data

1. Tobacco smoke significantly increased the lung tissue damage in these mice.
2. The tobacco-exposed mice given tomato juice showed significantly less tissue damage than tobacco-exposed mice without tomato juice. This suggests that something in the tomato juice is protecting again lung tissue damage, which supports the hypothesis that lycopene has a protective effect.

Chapter 47

Study Break

STUDY BREAK 47.1

1. Carnivores primarily eat other animals as their source of organic materials. Herbivores primarily eat plants as their source of organic materials. Omnivores obtain their organic materials from any digestible organic source.
2. Essential nutrients are the amino acids, fatty acids, vitamins, and minerals that the animal cannot make itself and must obtain from its diet. The list of essential nutrients varies among animal types.
3. Deposit feeders pick up or scrape particles of organic matter from solid material they live in or on. Suspension feeders ingest small organisms that are suspended in water. Depending on the animal, the ingested organisms may be bacteria, protozoa, algae, or small crustaceans, or fragments of those organisms.

STUDY BREAK 47.2

1. Intracellular digestion takes place within body cells, whereas extracellular digestion takes place outside the cells, either in a pouch or a tube enclosed by the body.
2. (1) Mechanical processing, to break up the food; (2) secretion of enzymes and other substances that aid digestion; (3) enzymatic hydrolysis of food molecules into simpler molecular subunits; (4) absorption of the molecular subunits into body fluids and cells; and (5) elimination of undigested materials.

STUDY BREAK 47.3

1. The two classes of vitamins are the water-soluble vitamins and the fat-soluble vitamins. Fat-soluble vitamins ingested in the diet in excess of bodily needs can be stored in adipose tissues. In contrast, excess water-soluble vitamins in the diet are excreted in the urine. Hence, it is critical that humans meet their daily requirements for the water-soluble vitamins.
2. The four layers of the gut are the mucosa, the submucosa, the muscularis, and the serosa. The muscularis layer, which is formed from two smooth muscle layers, is responsible for peristalsis.
3. Pepsin is secreted from chief cells into the stomach lumen as an inactive precursor molecule, pepsinogen. The pepsinogen is converted to pepsin by the highly acid conditions of the stomach. Pepsin is a digestive enzyme that begins the digestion of proteins by making breaks in polypeptide chains.
4. In the small intestine, the digestion of macromolecules into their molecular subunits occurs, and those subunits are absorbed. In the large intestine, water and mineral ions are absorbed from the remaining digestive contents, leaving the undigested remnants, the feces, which are expelled from the body.

STUDY BREAK 47.4

1. Gastrin stimulates the secretion of pepsinogen and HCl in the stomach. Pepsin generated by cleavage of pepsinogen digests protein in the swallowed food. Gastrin also stimulates contraction of the stomach and the intestines. Cholecystokinin (CCK), released in the duodenum in response largely to fat content in chyme, inhibits gastric activity; that is, CCK has the opposite effect of gastrin.
2. The hypothalamus has two interneuron centers that play a central role in regulating the digestive processes. One center stimulates appetite and reduces oxidative metabolism. The other center works in opposition to the first center by stimulating the release of a peptide hormone that inhibits appetite.

STUDY BREAK 47.5

1. Incisors nip or cut food. Canines bite and pierce food. Premolars and molars crush, grind, and shear food.
2. Symbiotic microorganisms aid digestion in many herbivores by assisting in the breakdown of plant material. The microorganisms synthesize cellulase, an enzyme vertebrates cannot make, which hydrolyzes the cellulose of plant cell walls into glucose subunits.

Think Like a Scientist

FIGURE 47.21

One could colonize the intestines of the germ-free normal mice with bacteria harvested from the intestines of obese (*ob/ob*) and (as a control) wild-type (ob^+/ob^+) mice and determine the effect on body fat. If the intestinal bacteria directly contribute to production of body fat, the prediction is that the percentage of body fat in obese mice would increase significantly whereas it would not in wild-type mice. Gordon's research group did this experiment and observed the result of the prediction.

IMR

Although rats are a highly used model mammal for experiments, rats are different enough from humans that results from experiments with rats cannot necessarily be assumed to parallel results from similar experiments in humans. To test whether a drug found effective in rats is effective in humans would require clinical trials in which administration of the drug to human subjects is done in a carefully designed experiment.

UQ

1. Tortoises are ectotherms and allocate energy to activity associated with maintaining body temperature; hares are endotherms and allocate energy to physiological processes to maintain body temperature.
2. They are used widely as stored energy. In fact, fats are an excellent source of energy in the diet.

Test Your Knowledge

Interpret the Data

1. About 30% (0.30) of the Hazda had fewer than five copies of the *AMY-1* gene.
2. Yes, about 10% of the European-Americans had more than 10 copies of the *AMY-1* gene.
3. Yes, the data support the hypothesis that a starchy diet favors duplications of the *AMY-1* gene. Cultural groups with a high-starch diet have, proportionally, more copies of the *AMY-1* gene than cultural groups with low-starch diets.

Chapter 48

Study Break

STUDY BREAK 48.1

Osmosis is a process in which water molecules move across a selectively permeable membrane from a region where they are more highly concentrated to one where they are less highly concentrated.

Osmolarity is the total solute concentration of a solution. Osmolarity is measured in osmoles per liter of solution, where an osmole is the number of solute molecules and ions (in moles).

A solution that is hypoosmotic has lower osmolarity than the solution on the other side of a selectively permeable membrane. The solution with the higher osmolarity is said to be hyperosmotic.

An osmoregulator is an animal that uses an active control mechanism to keep the osmolarity of cellular and extracellular fluids the same. This osmolarity value may differ from the osmolarity of the surroundings.

Tubules that carry out osmoregulation and excretion are formed from transport epithelium, a layer of cells with specialized transport proteins in their plasma membranes that move specific molecules and ions into and out of the tubule.

STUDY BREAK 48.2

Protonephridia are found in flatworms and larval mollusks. They are the simplest invertebrate excretory tubules. Body fluids enter the end of protonephridia and are moved through the tubule by movement of cilia on the flame cells. As the fluids move through the protonephridia, some molecules and ions are reabsorbed, and others, including nitrogenous wastes, are secreted into the tubules. Excess fluid is released through pores connecting the network of protonephridia to the body surface.

Metanephridia are found in annelids and most adult mollusks. Body fluids enter the funnel-like proximal end, driven by cilia surrounding that end. Some molecules and ions are reabsorbed as the fluids move through the tubule, and other ions and nitrogenous wastes are secreted into the tubule and excreted from the body surface.

Malpighian tubules are found in insects and other arthropods. Body fluids enter the tubules through spaces between the tubule cells. The distal ends of the tubules empty into the gut. Pressure is not used in the filtration step in Malpighian tubules. The secretion of K^+ from the hemolymph into the lumen draws in Cl^-. The accumulation of KCl causes water to enter the tubule from the hemolymph by osmosis. Organic wastes now are secreted into the tubule. When the fluids reach the hindgut and rectum, K^+ and Cl^- are reabsorbed, followed by water. As water leaves, uric acid precipitates as crystals that are excreted from the rectum in the feces.

STUDY BREAK 48.3

1. At the proximal end, a human nephron forms a cuplike region called Bowman's capsule. Bowman's capsule surrounds the glomerulus, a complex of blood capillaries. The capsule and the glomerulus are located in the renal cortex. The proximal convoluted tubule descends in a U-shaped bend called the loop of Henle into the renal medulla, and ascends again to form the distal convoluted tubule. Up to eight distal convoluted tubules drain into one collecting duct.
2. The collecting ducts are permeable to water but not to salt ions. The ducts, which begin in the cortex and descend into the medulla of the kidney, become surrounded by an ever-increasing solute concentration. As the urine passes

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

down the collecting ducts, water moves osmotically out of the ducts, causing the concentration of the urine to increase. At the bottom of the collecting ducts, the urine is about four times more concentrated than body fluids.

STUDY BREAK 48.4

The RAAS compensates for excessive loss of salt and body fluids. The ADH system compensates for excessive water intake or loss. Combined, the two systems play an important role in regulating the interactions between the kidneys and the rest of the body.

The RAAS is activated when the Na^+ concentration of body fluids falls, causing the volume of extracellular fluids and blood pressure also to drop. Cells in the juxtaglomerular apparatus secrete renin, which activates angiotensinogen to produce angiotensin I. Angiotensin-converting enzyme converts angiotensin I to angiotensin II, which has three effects: (1) It constricts arterioles around the body, thereby quickly increasing blood pressure; (2) It stimulates the secretion of aldosterone from the adrenal cortex, which increases Na^+ reabsorption in the kidneys and raises the osmolarity of body fluids; as a result, water moves from the tubules into the interstitial fluid, conserving water; and (3) It stimulates thirst so that more water is brought into the body. The RAAS is suppressed if NaCl concentration in body fluids is higher than normal.

In the ADH system, ADH is released from the posterior pituitary when osmoreceptors in the hypothalamus detect an increase in the osmolarity of body fluids. ADH increases water reabsorption from the distal convoluted tubules and collecting ducts of the kidney; as a result, urinary output is reduced and water is conserved. In the case of a decrease in osmolarity, ADH release from the pituitary is inhibited, thereby decreasing water reabsorption in the kidney.

STUDY BREAK 48.5

1. Marine teleosts live in seawater, which is hyperosmotic to their body fluids. They drink seawater continuously to replace water lost to the environment by osmosis. Na^+, K^+, and Cl^- ions from the seawater they drink are excreted by the gills. Nitrogenous wastes are released from the gills, primarily as ammonia, by simple diffusion.

   Freshwater fishes live in fresh water, which is hypoosmotic to their body fluids. They take in water by osmosis and excrete excess water. Salts needed for bodily functions are obtained from food and by active transport through the gills from the water. Nitrogenous wastes are excreted from the gills as ammonia.
2. The excretion of urea in mammals involves expelling the urea in solution—urine. Thus, there is loss of water with excretion of nitrogenous waste as urea. Excretion of nitrogenous waste in the form of uric acid conserves water because uric acid crystals are almost water-free.

STUDY BREAK 48.6

Ectothermy applies to animals that obtain heat energy primarily from the environment; endothermy applies to animals that obtain heat energy primarily from internal reactions. Generally speaking, ectotherms are highly successful in warm environments, but their bodily functions slow down as the temperature drops. Endotherms remain active over a broader range of environmental temperatures than ectotherms do, but they require an almost constant supply of energy to maintain their body temperature.

STUDY BREAK 48.7

1. The thermoregulatory responses shown by ectotherms can be physiological, such as regulating blood flow to internal organs or to the skin, or behavioral, such as physically moving to a location in the environment suitable for their heat energy needs at the time.
2. Thermal acclimatization refers to the physiological changes that many ectotherms make to compensate for seasonal shifts in environmental temperature.

STUDY BREAK 48.8

Temperature regulation in endothermic animals involves mechanisms that balance internal heat production against heat loss from the body. Internal heat production is controlled by negative feedback pathways triggered by thermoreceptors in the skin, the hypothalamus, and the spinal cord. When a deviation from the set point occurs, this system operates to return the core temperature to that set point through changes in metabolic processes, behavioral activities, and control of heat loss at the skin surface.

FIGURE 48.12

Heritable central diabetes insipidus must be caused by some defect in the amount of ADH. That could result from mutations affecting the hypothalamus or pituitary, which are involved in the synthesis and release of ADH. Heritable nephrogenic diabetes insipidus must be caused by some defect in the action of ADH. Mutations in this case could be in genes encoding the ADH receptor or the aquaporins involved in the response.

IMR

The ORE is at a significant distance from the site where transcription begins, indicating that is likely is in the enhancer for the gene. It is located too far from the transcription site to be a regulatory sequence in the promoter proximal region. (Refer to Section 16.2 for information about regulatory sequences in eukaryotic protein-coding genes.)

UQ

Recurrence of kidney disease in a transplanted kidney suggests that the disease is not intrinsic to the kidney, but reflects factors made elsewhere that act on the kidney in some way. Recurrent disease is in general much less common in inherited forms of kidney disease which, for the most part, are defects in kidney-expressed proteins. One interesting clinical observation occurs in patients with Alport syndrome, a disease of the basement membrane protein type 4 collagen. Alport syndrome patients develop kidney disease, and can also have deafness and eye problems. Patients with kidney failure from Alport syndrome who receive kidney transplants sometimes develop new antibodies directed against normal type 4 collagen (which was absent previously). This can lead to a different form of kidney disease characterized by antibody-mediated inflammation of the glomeruli.

Chapter 49

Study Break

STUDY BREAK 49.1

Recall that asexual reproduction produces offspring with genes from only one parent. In most animals that undergo asexual reproduction, the offspring are produced by mitosis and, therefore, are genetically identical to one another and to the parent. Such genetic homogeneity can be advantageous in stable and uniform environments. Another advantage is that individuals do not need to use energy to produce gametes or to find and select a mate. Further, for individuals in sparse populations, or for sessile animals, asexual reproduction can be an advantage. A disadvantage is that a genetically homogeneous population may not adapt readily to new environments.

By contrast, sexual reproduction always generates genetic diversity among offspring. This provides a population the opportunity to adapt to changing environments, and perhaps to move to and colonize new environments. Disadvantages of sexual reproduction include the expenditure of energy and raw materials to produce gametes and to find and select mates. Another disadvantage of sexual reproduction is that it produces fewer offspring per parent than does asexual reproduction; that is, asexual reproduction of a female produces all-female progeny, each of which can produce offspring for the next generation. However, in sexual reproduction, only one half of the progeny of a mating are females and only they can produce the offspring of the next generation.

STUDY BREAK 49.2

1. Egg coats are surface coats around the egg. They are added during oocyte development or fertilization. Egg coats provide protection against mechanical injury, infection by microorganisms, and, in some species, loss of water.

   Mammalian eggs have an egg coat called the zona pellucida immediately surrounding the egg. This gel-like coating is called the vitelline coat in other organisms. In birds, a thick solution of proteins—the egg white—surrounds a vitelline coat. Bounding the egg white is a hard shell.
2. The slow block to polyspermy occurs in many organisms, including mammals. The fusion of egg and sperm triggers an increase in calcium ions in the cytosol. The calcium ions activate proteins that initiate a high level of metabolic activity in the egg. The released calcium ions also cause the cortical granules to fuse with the plasma membrane of the egg and release their contents to the outside. Enzymes released from those granules alter the egg coats in a matter of minutes after fertilization, and this blocks further sperm from attaching and penetrating the egg.

STUDY BREAK 49.3

- FSH stimulates a number of oocytes to begin meiosis. A follicle forms around each oocyte.
- FSH and LH interact to stimulate follicle cells to secrete estrogens.
- Later in the cycle, an increased level of estrogen leads to a new burst of release of FSH and LH. This new LH stimulates follicle cells to release enzymes that digest away the follicle wall, leading to egg release.
- The new LH also causes the remaining follicle cells to grow into the corpus luteum.
- FSH and LH levels decrease. This removes the stimulatory signal for follicular growth, and no new follicles grow in the ovary.

STUDY BREAK 49.4

The oral contraceptive pill inhibits the secretion of FSH and LH by the pituitary. FSH and LH stimulate oocytes in the ovaries to begin meiosis. They also stimulate follicle cells that surround the oocytes to secrete estrogens. Later, LH causes ovulation—the release of an egg. Therefore, without FSH and LH, ovulation cannot occur.

Think Like a Scientist

FIGURE 49.12

The menstrual cycle would not proceed normally; that is, menstruation would not occur.

FIGURE 49.13

Look for a correlation between vocalization and stage of the menstrual cycle in nonhuman mammals as measured by hormonal levels. One study with giant pandas, for example, showed that the acoustic structure of female chirps differs depending on the stage of the menstrual cycle. Potentially, a male giant panda could use such vocal cues, although that has yet to be determined. (Reference: B. D. Charlton et al. 2010. Female giant panda *(Ailuropoda melanoleuca)* chirps advertise the caller's fertile phase. *Proceedings of the Royal Society B* 277:1101–1106.)

IMR

The study showed clearly a human male superiority in olfactory sensitivity for bourgeonal. (The authors stated that it was the first study to show a male superiority in olfactory sensitivity.) Potentially, this might be due to differences in its behavioral relevance for males and females, although that remains to be shown. (Reference: P. Olsson and M. Laska. 2010. Human male superiority in olfactory sensitivity to the sperm attractant odorant bourgeonal. *Chemical Senses* 35:427–432.)

UQ

It could be used in cases of a low sperm count (few sperm produced), poorly motile or immotile sperm, incomplete sperm maturation, or inability to produce sperm by ejacula-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tion (sperm could be collected surgically from the epididymis).

Test Your Knowledge

1. b 2. a 3. d 4. a 5. e 6. c 7. b 8. e 9. c 10. d

Interpret the Data

1. The lowest sperm count, 58.7 million/mL, was in Columbia, Missouri. The highest, 102.9 million/mL, was in New York, New York.
2. The lowest percent motile sperm was 48.2% in Columbia, Missouri, and the highest was 56.4% in New York, New York.
3. Based on these data, the adverse effects of age and STDs were unlikely explanations for the high sperm count in New York, New York, relative to the other locations, since New York had the highest average age and highest percentage of men with a history of STDs. The data do not show a clear correlation between smoking and sperm count, but it could have been a factor explaining the results.
4. The data support the hypothesis that living near farmland may adversely affect male reproductive function, but further study would be needed to eliminate other variables that could have contributed to the differences.

Chapter 50

Study Break

STUDY BREAK 50.1

1. In cleavage divisions, cycles of DNA replication and division occur without the production of new cytoplasm. Therefore, the cytoplasm of the egg partitions into many cells without increasing in overall size or mass. In cell division in an adult organism, the mitotic cell cycle involves cycles of DNA replication and division interspersed with cell growth; that is, the cell grows, then divides, then the two progeny cells grow, then divide, and so on. New cytoplasm is produced during these cell cycles so that, overall, there is an increase in mass of the cells.
2. The three primary cell layers of the embryo are produced by gastrulation. They are ectoderm, mesoderm, and endoderm.

STUDY BREAK 50.2

1. The gray crescent establishes the dorsal–ventral axis, with the gray crescent marking the future dorsal side.
2. If cells of the dorsal lip of the blastopore are transplanted to another location in the egg, they cause a second blastopore, and subsequently a second embryo, to form in that region.
3. The extraembryonic membranes in birds and their functions are as follows:
    - Yolk sac: Surrounds the yolk, which provides nutrients to the embryo.
    - Chorion: Exchanges oxygen and carbon dioxide with the environment through the egg shell.
    - Amnion: Encloses the embryo and secretes amniotic fluid into the space that provides an aquatic environment in which the embryo can develop.
    - Allantois: Stores nitrogenous wastes, primarily in the form of uric acid, that are derived from the embryo. Part of the allantoic membrane forms a bed of capillaries that is connected to the embryo and that delivers carbon dioxide from the embryo to the chorion and picks up oxygen absorbed through the shell.

STUDY BREAK 50.3

1. The three primary tissues, ectoderm, mesoderm, and endoderm, give rise to the tissues and organs of the embryo.
2. The central nervous system, notably the brain and spinal cord, develops from the neural tube. Neural crest cells give rise to parts of the nervous system (including cranial nerves, ganglia of the autonomic nervous system, peripheral nerves from the spinal cord to body structures, and nerves of the developing gut) and contribute to a variety of other body structures (for example, bones of the inner ear and skull, cartilage of facial structures, teeth, pigment cells in the skin, and the adrenal medulla).

STUDY BREAK 50.4

1. Cells of the trophoblast are responsible for implantation of the blastocyst in the endometrium (uterine lining). When the blastocyst is ready for implantation, trophoblast cells secrete proteases that digest pathways between endometrial cells. Dividing trophoblast cells fill the spaces and, through continued digestion and division, the blastocyst burrows into the endometrium and eventually becomes covered by a layer of endometrial cells. From then on, cells originating in the trophoblast support the development of the embryo/fetus in the uterus through the production of the chorion.

    The inner cell mass becomes the embryo/fetus itself. During implantation, the inner cell mass separates into the epiblast and the hypoblast. The epiblast produces the ectoderm, mesoderm, and endoderm of the developing embryo. The hypoblast gives rise to part of the extraembryonic membranes.
2. Oxytocin. This hormone is responsible for stimulating contractions of the uterus.

STUDY BREAK 50.5

1. Cell division, cell movement, and cell adhesion.
2. Induction is the process whereby a region of the embryo acts on other cells to alter the course of development. Induction is brought about by proteins; hence, induction is under genetic control.

Think Like a Scientist

FIGURE 50.13

The embryo/fetus and mother are different genetically. Therefore, the cells of the embryo/fetus will have surface antigens recognized as foreign by the mother. This will induce an immune response by the mother (see Chapter 45) in which antibodies will be produced that will attack the cells of the embryo/fetus and likely kill it.

FIGURE 50.18

You could put that cloned cDNA into an expression vector and transform it into separated cells that do not demonstrate selective cell adhesion. If the cadherin produced in the transformed cells is responsible for selective cell adhesion, then that property should not be detectable in those cells. To test that, you would test the transformed cells with cells known to adhere to cells that naturally have that cadherin on their surfaces.

FIGURE 50.20

In induction, the presence of one tissue triggers a change in the developmental fate of another tissue. If donor tissue (duck cells) induce the formation of dorsal structures in recipient tissue, the donor tissues will cause the recipient tissue to form dorsal structures and will not themselves form those structures. Therefore, both sets of dorsal structures in the recipient are formed from chick cells.

IMR

The normal (or close-to-normal) HMG box amino acid sequence is necessary for the SRY protein to bind to regulatory regions of genes that it controls. The missense mutations in the experiments described altered the structure of the HMG box region sufficiently to prevent or significantly inhibit binding. (a) A nonsense mutation in the *SRY* gene upstream of the HMG box-encoding gene would result in a truncated protein that does not include the HMG box. This protein could not activate the composite *AMH*–luciferase gene—no luciferase would be produced. (b) A nonsense mutation downstream of the HMG box-encoding region would result in a truncated SRY protein that still includes the HMG box. In this case a luciferase signal would be seen but only if the shortened SRY protein still folds to produce an HMG box that can bind to the *AMH* gene regulatory sequence. (c) A frameshift mutation changes the reading frame of the resulting mRNA by +1 or −1. This means that the encoded amino acid sequence downstream of the mutation is completely different from that encoded by the normal gene. Therefore, in this case no HMG box will be present in the protein and luciferase will not be produced.

UQ

No (and, in fact, there are not any). This can be inferred from the description of sex determination in mammals and from the list of gynandromorph animals. The significance of the research is unchanged.

Much can be learned about sex determination in mammals by studying sex determination in other organisms, and one could argue that understanding why it is different in other animals only provides greater insight into sex determination in mammals.

Test Your Knowledge

1. d 2. e 3. b 4. a 5. e 6. c 7. d 8. d 9. b 10. c

Interpret the Data

1. Heart defects were the most common birth defect in the single-birth group.
2. Heart defects were more common in the multiple-birth group than in the single-birth group.
3. Multiples had more than twice the risk of central nervous system defects than did single-birth infants.
4. No, the 0.93 relative risk of chromosomal defects indicates that multiple pregnancy decreases the relative risk of chromosomal defects in offspring.

Chapter 51

Study Break

STUDY BREAK 51.1

1. Studies of ecosystems are more "inclusive" than studies of populations because ecosystems include the populations of many different species.
2. Mathematical models are useful in ecological research because they help scientists formalize hypotheses about the relationships between variables and because they allow researchers to simulate the effects of changing variables before investing time and resources in experiments or observational studies.

STUDY BREAK 51.2

1. Because of Earth's spherical shape, sunlight striking the planet's surface is more concentrated near the equator than at the poles. As a result, temperatures are higher at low latitudes. The concentrated sunlight near the equator heats the atmosphere, causing air masses near the equator to rise, establishing three circulation cells in the Northern Hemisphere and three in the Southern Hemisphere.
2. Earth's fixed tilt on its axis causes seasonal variation in the amount of sunlight striking the temperate zone as the planet orbits the sun.
3. Dry conditions prevail at 30° N and S latitudes because sinking air masses warm as they descend, causing them to absorb water from the land.
4. Mountains affect local precipitation because rising air masses on the windward side of a mountain cool adiabatically and release moisture. When the air masses descend on the leeward side of a mountain, they warm and absorb moisture, causing a rain shadow.

STUDY BREAK 51.3

1. *Anolis* lizards in the Dominican Republic bask more frequently at high elevation than they do at low elevation.
2. Global warming will likely cause the geographical distributions of species to shift or expand to higher latitudes and to higher elevations.

STUDY BREAK 51.4

1. Tropical rainforest and temperate rainforest are the terrestrial biomes that receive the most rainfall.
2. Savannas, chaparral, and temperate grasslands are renewed by periodic fires.
3. Tropical rainforests and temperate rainforests have the tallest vegetation. Arctic and alpine tundra have the shortest vegetation.
4. Trees are usually evergreen in tropical rainforest, temperate rainforest, and taiga.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

STUDY BREAK 51.5

1. Dissolved oxygen concentration is usually high in the headwaters of a stream, gradually diminishing as water flows into a river.
2. The factors that cause seasonal overturns in lakes include seasonal changes in environmental temperature, variations in wind velocity, and the fact that water is densest at 4°C.
3. Oligotrophic lakes are better than eutrophic lakes for recreational purposes because the water in oligotrophic lakes is clear, whereas the water in eutrophic lakes is often clogged with strands of algae and cyanobacteria.

STUDY BREAK 51.6

1. The benthic province of the ocean includes all of the bottom sediments. The pelagic province includes all of the water.
2. Estuaries experience the largest fluctuations in salinity over time.
3. Estuaries, the intertidal zone, and the upper layer of the oceanic pelagic zone receive substantial energy inputs from sunlight.
4. The benthos of the oceanic zone receives nutrients and energy from the detritus sinking from the upper layers of water.
5. Chemoautotrophic bacteria are the primary producers of hydrothermal vent communities and cold seep communities. Unlike photosynthetic organisms of the photic zone, they use hydrogen sulfide and other molecules, instead of sunlight, as an energy source for their chemosynthetic activity.

Think Like a Scientist

FIGURE 51.9

If global climate change increased the air temperatures in the habitats occupied by these lizards, they would be likely to bask in patches of sun less frequently.

FIGURE 51.11

Climate warming will not change the distribution of biomes on the climograph, because the biomes will still occur at particular combinations of temperature and precipitation. However, global warming will probably change the distribution of biomes on the Earth's surface, as reflected in the map in Figure 51.12. Biomes may shift toward the north and south as the climate warms at higher latitudes.

FIGURE 51.25

Housing developments on hilly ground pose a danger to nearby lakes because household wastes, such as human sewage and waste water, flow downhill into lake basins. The chemicals in these wastes promote eutrophication of the lakes.

IMR

We would not expect to find antifreeze proteins in fishes that live in the tropics because those fishes probably never experience freezing conditions in their habitats. Biologists interpret the antifreeze as evolutionary adaptations to the freezing conditions that polar-dwelling fishes routinely encounter.

UQ

We should expect to see the loss of species in mountaintop habitats because the species have no cooler habitats into which they can migrate. We would also expect to see the loss of polar species, especially those that depend on sea ice, the extent of which is shrinking rapidly.

Test Your Knowledge

Interpret the Data

1. SSTs have predicted 19 El Niño events and 22 La Niña events from 1950 through 2008.
2. These events differ greatly in magnitude and duration.
3. There is no absolute pattern in the occurrence of the two types of events, although it appears that very pronounced events of one type are followed by an event of the other type.

Chapter 52

Study Break

STUDY BREAK 52.1

1. A population's size is simply the number of individuals it contains. Its density is the number of individuals per area or volume of habitat occupied.
2. A clumped pattern of dispersion implies that individuals in the population help each other or that some vital resource in the environment also has a clumped distribution. A uniform pattern of dispersion implies that individuals in the population repel each other. A random pattern of dispersion does not imply either positive or negative interactions among individuals in the population.

STUDY BREAK 52.2

1. A life table usually summarizes statistics about the age-specific survival rates, age-specific mortality rates, and age-specific fecundity of a population.
2. Humans in the industrialized countries exhibit Type I survivorship curves because they provide lots of care to their offspring, thus reducing infant and childhood mortality to low levels.

STUDY BREAK 52.3

1. Children spend most of their energy on growth and maintenance; they devote energy to reproduction later in life.
2. Fecundity and the amount of parental care devoted to each offspring exhibit an inverse relationship because organisms that produce few offspring can devote substantial time and energy to each, whereas those that produce many offspring can devote only minimal time and energy to each.

STUDY BREAK 52.4

1. The model of exponential population growth predicts unlimited population growth through time, generating a J-shaped curve of population size versus time. The logistic model predicts that population growth slows down as the population approaches its carrying capacity, generating an S-shaped curve of population size versus time.
2. Carrying capacity is the maximum number of individuals in a population that an environment can support. The carrying capacity is thus a property of the environment with reference to a particular population.
3. A time lag is a delay in a population's response to a changing environment. It may cause a population's size to oscillate around its carrying capacity.

STUDY BREAK 52.5

1. The effects of density-dependent factors get stronger (that is, they affect a larger percentage of the individuals in the population) as the population's density increases. The effects of density-independent factors do not change (that is, they affect the same percentage of the individuals in a population) as the population's density changes.
2. The effects of infectious diseases are usually density-dependent because disease-causing pathogens spread more quickly through dense populations of the organisms they infect.

STUDY BREAK 52.6

1. Humans have sidestepped the controls that regulate the populations of other organisms by expanding their geographical range to include a wide variety of habitats, by increasing the carrying capacity through agricultural production, and by decreasing their death rate through the introduction of medical care and improved sanitation.
2. The age structure of a population influences its future population growth by determining how many individuals will reach reproductive age in the future. Populations with a bottom-heavy age structure (that is, with many young children) will experience a growth spurt when children alive today reach sexual maturity. Populations with a more even age structure will not experience a dramatic future increase in population size.

Think Like a Scientist

FIGURE 52.17

The increases and decreases in spider numbers in the two treatments appear to be unrelated to the presence or absence of lizards. Changes in weather or the availability of prey may be responsible for these overarching changes in spider numbers.

FIGURE 52.19

If unregulated development destroyed suitable habitat patches that are home to source populations or close to source populations, the development would prevent butterflies in source populations from colonizing sink populations. As a result, more sink populations would become extinct.

FIGURE 52.20

The lynx and hare appear to be on a 10-year population cycle. From the data presented in the graph, the lynx population increase followed the hare population increase almost instantaneously in 1865, 1885, and 1905. The lynx population increased more slowly after increases in the hare population in 1855, 1875, 1895, 1915, and 1925.

IMR

The assumption that the adult armadillos living closest to a juvenile were its likely parents may have caused the researchers to underestimate how far individual armadillos move in their lifetimes. If the researchers had identified parents that lived a greater distance from the juvenile, their estimate of how far a young armadillo moved after weaning would have been higher.

UQ

1. The "ideal" conditions under which the equations predict growth simply never exist, as is clear, for example, from the growth of populations illustrated in the chapter (see growth of *Thrips imaginis*). Therefore, unlike a law such as the law of gravity, population growth cannot simply be predicted by applying the logistic or exponential equation for population growth. The mathematical growth models are constructed after basic observations define the variables of the models.
2. The time scales for most population studies are too short to consider selection, genetic drift, or mutation. Molecular studies allow population biologists to measure changes in gene frequencies at the time scales of single generations and before those changes are manifested in noticeable changes in fecundity or survival (or morphology and behavior).

Test Your Knowledge

Interpret the Data

The data in the *Albertosaurus* life table suggest that it had a survivorship pattern falling between Types I and II, though perhaps leaning more toward Type I. This species was most vulnerable to mortality between hatching and age two.

Chapter 53

Study Break

STUDY BREAK 53.1

1. Some carnivores spend more time and energy capturing large prey than small prey because large prey provides a larger return on their investment of time and energy in the hunt.
2. Cryptic coloration makes an organism inconspicuous, allowing it to blend in with its surroundings. Aposematic coloration makes an organism highly conspicuous, advertising its unpalatability. Mimicry allows one organism, the mimic, to resemble another species, the model; models are usually unpalatable or poisonous. A mimic will have aposematic coloration if it resembles an aposematic model.
3. Field experiments can demonstrate that two species are competing for limiting resources if the removal of one

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

species increases population size or density in the other or if the addition of a potential competitor decreases the population size or density of the other.

STUDY BREAK 53.2

1. Gleason's individualistic view of communities suggests that they are just chance assemblages of species that happen to be adapted to similar abiotic environmental conditions.
2. Ecologists find more species living in an ecotone than in the communities on either side of it because ecotones contain species from both neighboring communities as well as species that are adapted to transitional environmental conditions.

STUDY BREAK 53.3

1. The plant growth forms found in tropical forests include a canopy of tall trees, an understory of shorter trees and shrubs, an herb layer, vinelike lianas, and epiphytes.
2. The species richness of a community is the number of species it contains. Relative abundance refers to the commonness or rarity of species in the community.
3. Pigeons, which eat grain and other vegetable matter, are included in the second trophic level, primary consumers. Peregrine falcons, which feed on pigeons and other birds, are in the third trophic level, secondary consumers.

STUDY BREAK 53.4

1. On the one hand, the ecological literature may overestimate the importance of competition because ecologists are more likely to study and publish papers on interactions in which competition is important than on interactions in which it is not. On the other hand, the literature may underestimate the importance of competition because, if strong competition between species cannot persist for long periods of time, we are unlikely to find populations competing strongly in nature.
2. Keystone species are those that have a substantial effect on community structure even if their populations are not very dense. Keystone species may either increase or decrease species richness in the communities they occupy.

STUDY BREAK 53.5

1. Strong storms allow coral communities to be rejuvenated through the recruitment of new individuals because they scour the seafloor, removing existing coral colonies from the community. These openings provide spaces where coral larvae may settle and initiate the growth of new colonies.
2. Moderately severe and moderately frequent disturbances increase a community's species richness by creating opportunities for *r*-selected species to colonize the habitat while allowing populations of *K*-selected species to persist.

STUDY BREAK 53.6

1. Primary succession occurs in places without soil; secondary succession occurs after a disturbance has destroyed vegetation.
2. A climax community differs from earlier successional stages in having taller, longer-lived vegetation, generally higher species richness, and a buffered physical environment under the vegetation.
3. Three hypotheses about the underlying causes of succession differ in how they view the role of population interactions. The facilitation hypothesis specifies no particular role for population interactions. The inhibition hypothesis suggests that the species already present prevent other species from joining a community. The tolerance hypothesis suggests that as environmental conditions within the community change during succession, only species that can compete strongly under the changing conditions will persist.

STUDY BREAK 53.7

1. Some explanations of the high species richness in the tropics suggest that the benign climate and historically low levels of severe disturbance have fostered more rapid rates of speciation. Other explanations suggest that the year-round availability of food resources and complex food webs allow more species to coexist in tropical regions.
2. According to the equilibrium theory of island biogeography, large islands will harbor more species than small islands, and islands that are close to the mainland will harbor more species than those that are farther away.

Think Like a Scientist

FIGURE 53.8

Yes, the presence of *P. caudatum* does appear to have an effect on *P. aurelia* in the mixed cultures. In the presence of *P. caudatum,* the population size of *P. aurelia* is lower than it is when the latter species is grown alone.

FIGURE 53.12

Given the results of Connell's experiment, *Balanus* appears to be a stronger competitor than *Chthamalus,* at least in deep water. The former species is able to displace the latter species from that habitat. *Balanus* does not compete with *Chthamalus* at all in shallow water, because the former species is unable to occupy shallow water, presumably because it is not physiologically adapted to do so.

FIGURE 53.23

The removal of *Pisaster* eventually resulted in a drastic reduction in species richness and an increase in the density of *Mytilus* in experimental plots. The full effects of the experiment would not be evident until other species of organisms had been eliminated by old age, predation, or other factors and a new cohort of *Mytilus* became established in the plot. This sequence of changes may have begun began shortly after the experiment was established, but its full effects were apparently not evident until three years had elapsed.

FIGURE 53.24

Lubchenco's result for snails and algae in tidepools is consistent with the predictions of the intermediate disturbance hypothesis. An intermediate density of snails, which establishes an intermediate-level disturbance, results in the highest algal species richness in tidepools.

IMR

The communities of organisms living in bromeliad cups are analogous to those living in British treeholes. Thus, we would expect the species richness of microorganisms and invertebrates living in bromeliad cup communities to exhibit species-area functions similar to those observed in communities living on islands.

UQ

1. Many, but certainly not all, mutualisms involve partners "taking" resources from each other. In pollination, for example, bees take pollen, and plants take the bees' time and direct their movements.
2. Yes, because of shared traits among close relatives. This is one reason cannibalism may be rare.

Test Your Knowledge

1. c 2. c 3. a 4. b 5. b 6. e 7. b 8. d 9. d 10. b

Interpret the Data

The protected shrubs responded to the exclusion of herbivores by steadily reducing the density of thorns on their flowering stems over two years. The unprotected shrubs continued to produce a high density of thorns on their flowering stems. The unprotected shrubs' production of thorns probably protected their flowers and fruits feeding by herbivores, allowing them to produce seeds.

Chapter 54

Study Break

STUDY BREAK 54.1

1. In the generalized compartment model of biogeochemical cycling, nutrient pools are classified as available or unavailable and as organic or inorganic.
2. The advantage of using conceptual models of ecosystem function is that they are a simplification of the processes that determine ecosystem function in nature. The disadvantage of these models is that they do not include processes that carry nutrients and energy out of one ecosystem and into another; neither do they include the details of exactly how specific ecosystems function. Thus, conceptual models do not provide precise predictions about potential changes in ecosystem function.
3. Before constructing a simulation model of an ecosystem, ecologists must collect data about the population sizes of important species, the average energy and nutrient content of each, the food webs in which they participate, the quantity of food each species consumes, and the productivity of each population; the ecosystem's energy and nutrient gains and losses caused by erosion, weathering, precipitation, and runoff; and seasonal and annual variations in these factors.

STUDY BREAK 54.2

1. Gross primary productivity is a measure of the total amount of solar energy converted into chemical energy by the producers in an ecosystem. Net primary productivity is the amount of chemical energy that remains after deducting the producers' maintenance costs from the gross primary productivity.
2. In terrestrial ecosystems, primary productivity may be influenced by the availability of light, water, and nutrients and by the environmental temperature. In aquatic ecosystems, primary productivity is often limited by the joint availability of light and nutrients in the same place.
3. Energy is lost from an ecosystem at every transfer between trophic levels because some of the energy is not assimilated, because organisms use some of the energy they assimilate for maintenance costs, and because biological processes are never 100% efficient.
4. The presence of predators can influence an ecosystem's productivity by consuming herbivores and thereby changing the population dynamics of the herbivores and the plants they eat. These effects can reverberate through an ecosystem in a trophic cascade.

STUDY BREAK 54.3

1. The global hydrologic cycle maintains its balance because the amount of water returned to the atmosphere by evaporation and transpiration is equal to the amount that falls as precipitation. Runoff from the land maintains the balance between terrestrial and marine components of the cycle.
2. Respiration, excretion, leaching, and the burning of fossil fuels move large quantities of carbon from an organic compartment to an inorganic compartment of an ecosystem.
3. Bacteria, cyanobacteria, and fungi drive the global nitrogen cycle through their activities in nitrogen fixation, ammonification, nitrification, and denitrification.
4. Marine sediments are Earth's main reservoir for phosphorus, which is recycled slowly after geological uplifting and erosion make it available to producers.

STUDY BREAK 54.4

1. The greenhouse effect refers to the tendency of certain gases, called greenhouse gases, to foster the accumulation of heat in the lower atmosphere by hindering the escape of infrared heat into space. CO_2 enhances the greenhouse effect because it is one of the greenhouse gases.
2. The combustion of fossil fuels and wood is the human activity that releases the most CO_2 into the atmosphere.
3. Irrigation, the use of synthetic nitrogen-containing fertilizers, the harvesting of crops, and the rearing of livestock contribute to the disruption of the nitrogen cycle.

Think Like a Scientist

FIGURE 54.7

An increased number of trees growing along the banks of Silver Springs would limit the amount of sunlight reaching the primary producers in the water. As a result, productivity and the numbers of organisms at all trophic levels would probably decrease.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

FIGURE 54.11
The removal of crabs and turtles would allow snail populations to increase in size. The increasing snail populations would consume the cordgrass, thereby destroying the ecosystem.

IMR
Moderate acidification of ocean water appears to affect the transcription of genes that influence biomineralization. Thus, the production of tests (that is, shells) by sea urchins might be adversely affected.

UQ
Large cities release substantial quantities of airborne pollutants that can be carried by prevailing winds even to distant forests. These materials can have a profound influence on the health and biological activity of primary producers in the forest.

Test Your Knowledge

1. c 2. d 3. c 4. e 5. e 6. c 7. a 8. d 9. c 10. a

Interpret the Data

The productivity of the algal community in Walker Branch is controlled by both nutrients and herbivores. The graph illustrates that for grazed algae, the addition of nitrogen, phosphorus, or both nitrogen and phosphorus increased productivity over the level seen in the control treatment. Similarly, for ungrazed algae, the addition of nitrogen or the combination of nitrogen and phosphorus increased productivity over the level measured in the controls. The graph also illustrates the significant impact of grazing by herbivorous snails: in the control treatment and two of the three experimental treatments, ungrazed algae had much higher productivity than grazed algae.

Chapter 55

Study Break

STUDY BREAK 55.1

1. The growing human population in south Florida has increased the likelihood of desertification there by withdrawing groundwater for agricultural, recreational, and residential uses faster than it is replenished.
2. Overexploitation of fish populations typically causes fishes to reach reproductive maturity at a smaller size and younger age, decreases population sizes, and sometimes leads to the extinction of populations.
3. The construction of dams changes the water flow in rivers, leading to changes in the physical structure of the river and the species that inhabit it; disrupting the environmental cues that trigger successful reproduction of organisms; inhibiting the free movement of migrating animals through all parts of the river system; and opening the habitat to invasion by species that originated elsewhere.

STUDY BREAK 55.2

1. Habitat fragmentation in eastern North America has affected breeding songbirds by reducing the variety of habitats available to them, increasing the frequency of brood parasitism of their nests, and increasing the rate of predation on their eggs and young.
2. The use of the anti-inflammatory drug diclofenac on livestock has decimated vulture populations in South Asia. Diclofenac is highly toxic to birds, and the vultures ingest it when they feed on the carcasses of livestock.
3. By one estimate, extinction rates today may be 1,000 times greater than the background extinction rate evident in the fossil record.

STUDY BREAK 55.3

1. Living systems are a storehouse of potentially useful genetic information because naturally occurring compounds may prove to be useful in the treatment of disease, in the manufacture of new products, or in agriculture.
2. Naturally occurring organisms provide many ecosystem services, such as the sequestration of carbon dioxide, fixation of nitrogen into forms that plants can absorb, recycling of nutrients with ecosystems, and the retention of water in ecosystems.

STUDY BREAK 55.4

1. Conservation biologists identify a site as one where extinction is imminent if it houses 95% or more of the individuals in an endangered species and it has definable boundaries that encompass distinctive habitats.
2. Conservation biologists are especially alarmed about deforestation in the New World tropics because these forests harbor many species in imminent danger of becoming extinct.

STUDY BREAK 55.5

1. Population bottlenecks—large, temporary reductions in a population's size—inevitably foster genetic drift, thereby reducing a population's genetic variability, which increases its likelihood of becoming extinct.
2. A population viability analysis allows a conservation biologist to identify the minimum population size that is likely to survive both predictable and unpredictable environmental change. It therefore specifies how many individuals must be conserved for the continued survival of the population and species.
3. Several small preserves would collectively experience more edge effects than one large preserve of the same total size.

STUDY BREAK 55.6

1. The Pine Bush habitat in the state of New York is an example of conservation through preservation.
2. The Royal Chitwan National Park has been judged a success because local residents benefit from the park's existence and therefore support it, and because populations of many animals, including tigers and rhinoceroses, have increased within its borders.
3. Economists can determine the economic values of specific ecosystem services and convince local governments that it is economically beneficial to preserve ecosystems and the services they provide.

Think Like a Scientist

FIGURE 55.6
Wilcove placed nests in different positions because predators look for prey in different parts of the habitat. If most of the predators sought food on or close to the ground, any nests placed high in trees might have experienced lower rates of predation.

FIGURE 55.18
The results of this study suggest that the species richness of small animals might also be higher in tracts of forest connected by landscape corridors than in unconnected patches of similar size. Small animals should be able to use the corridors to move from one patch to another. It is difficult to predict the effects of corridors on exotic small animal species.

IMR
DNA barcoding might be useful in the effort to track the spread of Asian carp through North American rivers and lakes because biological samples can be subjected to DNA barcoding analysis to detect the presence of these species in habitats in which they had not previously been found.

UQ
Student answers may vary. Because students are asked to come up with a list of unanswered questions on their own, we can't really provide an answer to this question.

Test Your Knowledge

1. e 2. b 3. b 4. b 5. a 6. d 7. d 8. a 9. c 10. b

Interpret the Data

Extinctions in mountain habitats are accelerating the most, exhibiting a potential for more than a 20-fold (366/17) increase. Among groups, extinctions are accelerating the most among amphibians, which exhibit a potential 12-fold (408/34) increase. Conservation biologists should therefore focus their efforts on amphibians that live in mountainous regions.

Chapter 56

Study Break

STUDY BREAK 56.1

1. An instinctive behavior is a genetically or developmentally programmed response that appears in complete and functional form the first time it is used. A learned behavior is one that is dependent on having a particular kind of experience during development.
2. Arnold demonstrated that the receptiveness of garter snakes to a meal of banana slugs had a genetic basis by breeding snakes that almost always eat banana slugs with snakes that rarely eat them. The behavior of the hybrid offspring was intermediate between the behaviors of the two parent populations.
3. Tail wagging by a dog when it sees its owner pick up a leash is an example of classical conditioning.
4. Sleeping through an alarm clock is an example of habituation.

STUDY BREAK 56.2

1. The conclusion that certain neurons in a young male bird's brain are influenced only by acoustical signals from its own species and only during a critical period is supported by two observations: (1) young birds that did not hear taped songs during the critical period never produced the full song of their species; and (2) young birds that heard recordings of *other* bird species' songs during the critical period never generated replicas of those songs as they matured.
2. The role of the ZENK enzyme in song learning is to program the nerve cells of the bird's brain to anticipate key acoustical events of potential biological importance.
3. A high estrogen concentration in the brains of young male zebra finches stimulates the production of more neurons in the higher vocal center.
4. The loss of a territory by a male African cichlid fish causes its brain to produce less GnRH.

STUDY BREAK 56.3

1. When piloting, animals use familiar landmarks to guide their journey. In compass orientation, animals use external environmental cues such as the position of the sun or stars as a compass to move in a particular direction, often over a specific distance or for a prescribed length of time. When navigating, animals use a compass as well as a mental map of their position in relation to their destination.
2. Seasonal changes in temperature and food availability are the most likely selection pressures responsible for the evolution of migratory behavior in birds.

STUDY BREAK 56.4

1. Wood lice accumulate in moist habitats because they move much less in moist habitats than they do in dry habitats.
2. The costs of maintaining a territory include the time and energy needed to defend territory borders, the possibility of being injured or killed during a territorial encounter, and the increased likelihood of being noticed and captured by a predator. The benefits of holding a territory include access to all of the resources within the territory.

STUDY BREAK 56.5

1. Humans consciously use acoustical, visual, and tactile channels to communicate with each other.
2. A honey bee uses the waggle dance to communicate the location of a distant food source to its hive mates.
3. A young wandering raven that discovers a food source in the territory of other ravens will call vigorously to attract other ravens from outside the territory. Collectively, the nonterritory holders can overwhelm the defenses of the resident birds and then consume the food.

STUDY BREAK 56.6

1. For monogamous species, the males that are most attractive to females are those that can demonstrate their good genes with large showy morphological characteristics and

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

elaborate behavioral displays and those that hold territories rich in resources.
2. Male sage grouse perform displays at a lek, trying to attract the attention of females. Female sage grouse go to a lek to evaluate the qualities of the males that are displaying there.
3. A female red-winged blackbird might settle in the territory of a male even in the presence of other resident females if the male's territory is very rich in resources.

STUDY BREAK 56.7

1. The social behavior of musk oxen and sawfly larvae includes cooperative defense of the group against predators.
2. Among the animals in a dominance hierarchy, the most dominant individuals are the most likely to reproduce.
3. The genetic system in eusocial insects promotes altruistic behavior because the workers in a colony are more closely related to each other than are siblings in most other animal species.

Think Like a Scientist

FIGURE 56.2

The sign stimulus/fixed action pattern interaction between parent herring gulls and their offspring ensures that the parent regurgitates food to a chick that is hungry. Herring gulls may have multiple chicks in the nest, and the hungriest chick is likely to be the one that taps most vigorously on the parent's bill.

FIGURE 56.10

The GnRH production and behavior of cichlid fishes each influence the other in a feedback loop. When a male loses status, his GnRH production decreases, leading to a reduction in his aggressive behavior. However, if his aggressive behavior increases because of changing social circumstances, his GnRH production will increase, reinforcing his aggressive behavior.

FIGURE 56.13

The results of Emlen's experiment indicate that the position of the stars only provides cues about the direction in which they should migrate. Birds attempted to take off from the cages to begin a migration even under cloudy conditions when they could not see any stars.

FIGURE 56.29

If the queen in a bee colony mated with two drones instead of just one, the average degree of relatedness among the workers would decrease. Although their relatedness through their shared mother would not change, some workers would be unrelated to each other through their different fathers.

IMR

As described in Section 21.3, a recessive mutation is not easily eliminated from a population because recessive mutations have no impact on heterozygotes. Some form of genetic screening would be necessary to identify people who carry the mutation and counsel them about the possible consequences of having children together. Unidentified heterozygotes could produce offspring who are homozygous for the mutation and would therefore exhibit the condition that it causes.

UQ

If the partner of a female is able to discriminate between offspring that are his own and those that are not, he should bias any paternal care in favor of his true son in preference to his nephew. The production of chimeras could also give rise to conflicts between a male and a female because the offspring would be more closely related to the female parent than to the female's partner (i.e., the offspring's uncle).

Test Your Knowledge

1. b 2. d 3. b 4. e 5. c 6. d 7. b 8. e 9. c 10. a

Interpret the Data

The results suggest that the more male neighbors a Seychelles warbler has, the more time he spends guarding his mate; and the more time he spends guarding his mate, the less time he can devote to collecting food. When the number of neighboring males was experimentally reduced, the focal males spent more time feeding and less time guarding their mates.

Appendix B: Classification System

The classification system presented here is based on a combination of organismal and molecular characters and is a composite of several systems developed by microbiologists, botanists, and zoologists. This classification reflects current trends toward a phylogenetic approach to taxonomy, one that incorporates the ever more detailed information about the relationships of monophyletic lineages provided by new molecular sequence data. In keeping with these trends, we have omitted reference to the traditional taxonomic categories, such as "class" and "order." Instead, we present the major monophyletic lineages in each of the three domains, and we indicate their relationships within a nested hierarchy that parallels that of traditional Linnaean classification.

Although researchers generally agree on the identity of the major monophyletic lineages, the biologists who study different groups have not established universal criteria for identifying the somewhat arbitrary taxonomic categories included in the traditional Linnaean hierarchy. As a result, a "class" or an "order" of flowering plants may not be the equivalent of a "class" or an "order" of animals. In fact, as described in *Unanswered Questions* at the end of Chapter 24, systematic biologists are shifting toward a more phylogenetic approach to taxonomy and classification, such as the one represented here.

Bear in mind that we include this appendix to introduce the diversity of life and illustrate many of the evolutionary relationships that link monophyletic groups. Like all phylogenetic hypotheses, this classification is open to revision as new information becomes available. Moreover, the classification is incomplete because it includes only those lineages that are described in Unit Four.

Prokaryotes and Eukaryotes

Organisms fall into two groups, prokaryotes and eukaryotes, based on the organization of their cells. Prokaryotes consist of the Domains Bacteria and Archaea and are characterized by a central region, the nucleoid, which has no boundary membrane separating it from the cytoplasm, and by membranes typically limited to the plasma membrane. Most prokaryotes are single-celled, although some are found in simple associations. All other organisms are eukaryotes, which make up the Domain Eukarya. Eukaryotes are characterized by cells with a central, membrane-bound nucleus, and an extensive membrane system. Some eukaryotes are single-celled, while others are multicellular.

Domain Bacteria

The largest and most diverse group of prokaryotes. Includes photoautotrophs, chemoautotrophs, and heterotrophs.

Proteobacteria Gram-negative bacteria that include chemoautotraphs, chemoheterotrophs, and photoautotrophs. Some are aerobic and some are anaerobic. Five subgroups of proteobacteria are recognized.

Spirochetes Helically spiraled bacteria that move by twisting in a corkscrew pattern

Chlamydias Gram-negative intracellular parasites of animals, with cell walls that lack peptidoglycans

Gram-Positive Bacteria Chemoheterotrophic bacteria with thick cell walls

Cyanobacteria Photoautotrophic Gram-negative bacteria that carry out photosynthesis using the same chlorophyll as in plants and release oxygen as a by-product

Domain Archaea

Prokaryotes that are evolutionarily between eukaryotic cells and the bacteria. Most are chemoautotrophs. None is photosynthetic. Originally discovered in extreme habitats, they are now known to be widely dispersed. Compared with bacteria, the Archaea have a distinctive cell wall structure and unique membrane lipids, ribosomes, and RNA sequences. Some are symbiotic with animals, but none is known to be pathogenic.

Euryarchaeota Includes methanogens, extreme halophiles, and some extreme thermophiles

Nanoarchaeota Extreme thermophile (only one member known). Lives as a symbiont of a thermophilic member of the Crenarchaeota.

Crenarchaeota Includes most of the archaean extreme thermophiles, as well as psychrophiles; mesophilic species comprise a large part of plankton in cool, marine waters

Thaumoarchaeota All living species (four) are mesophilic chemoautotrophs. Other members are represented by DNA sequences in environmental samples.

Korarchaeota Only living member is a thermophile. Other members are represented by DNA sequences in environmental samples.

Domain Eukarya

Protists A collection of single-celled and multicelled lineages, which are almost certainly not a monophyletic group.

Excavata (excavates) Single-celled animal parasites that have greatly reduced mitochondria, or organelles derived from mitochondria, and move by means of flagella; most have a scooped out (excavated) feeding apparatus on the ventral surface of the cell

Metamonada (metamonads)—consist of the Diplomonadida and the Parabasala

Diplomonadida (diplomonads)—cells have two nuclei; move by multiple freely beating flagella

Parabasala (parasabala)—move by freely beating flagella and an undulating membrane formed by a flagellum buried in a fold of cytoplasm

Euglenozoa (euglenozoans)—mostly single-celled, highly motile cells that swim using flagella and have disc-shaped inner mitochondrial membranes

Euglenids—free-living with anterior flagella; most are photosynthetic autotrophs

Kinetoplastids—nonphotosynthetic heterotrophs that live as animal parasites. Their single mitochondrion contains a large DNA–protein deposit called a kinetoplast.

Chromalveolata (chromalveolates) Heterogeneous group with a range of forms and life styles

Alveolata (alveolates)—characterized by small membrane-bound vesicles called alveoli in a layer under the plasma membrane

Ciliophora (ciliates)—motile, primarily single-celled highly complex heterotrophs; swim by means of cilia

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Dinoflagellata (dinoflagellates)—nonmotile single-celled marine heterotrophs or autotrophs; shell formed from cellulose plates

Apicomplexa (apicomplexans)—nonmotile parasites of animals with apical complex for attachment and invasion of host cells

Stramenopila (stramenopiles)—characterized by two different flagella, one with hollow tripartite projections, and the other plain

Oomycota (oomycetes)—water molds, white rusts, and mildews; all are funguslike heterotrophs lacking chloroplasts

Bacillariophyta (diatoms)—single-celled autotrophs that carry out photosynthesis by pathways similar to those of plants; covered by a glassy silica shell; most are free-living, whereas some are symbionts

Chrysophyta (golden algae)—colonial; each cell of the colony has a pair of flagella and is covered by a glassy shell consisting of plates or scales; most are autotrophs that carry out photosynthesis by pathways similar to those of plants

Phaeophyta (brown algae)—photosynthetic autotrophs

Rhizaria (rhizarians) Amoebas with stiff, filamentous pseudopodia; some with outer shells

Radiolaria (radiolarians)—marine heterotrophs; glassy internal skeleton with projecting axopods—raylike strands of cytoplasm supported internally by long bundles of microtubules

Foraminifera (forams)—marine heterotrophs; shells, most of which are chambered, spiral structures, consist of organic matter reinforced by calcium carbonate

Chlorarachniophyta (chlorarachniophytes)—green, photosynthetic amoebas

Archaeplastida (archaeplastids) Red algae, green algae, and land plants *(viridaeplantae),* photosynthesizers with a common evolutionary origin

Rhodophyta (red algae)—marine seaweeds, typically multicellular with plantlike bodies; most are reddish in color

Chlorophyta (green algae)—green single-celled, colonial, and multicellular autotrophs that carry out photosynthesis using the same pigments as plants; likely ancestor of land plants

Amoebozoa (amoebozoans) Includes most of the amoebas as well as the slime molds. All use pseudopods for locomotion and for feeding.

Amoebas—single-celled; use lobose (non-stiffened) pseudopods for locomotion and feeding

Cellular slime molds—heterotrophs; primarily individual cells; move by amoeboid motion, or as a multicellular mass

Plasmodial slime molds—heterotrophs; live as plasmodium, a large composite mass with nuclei in a common cytoplasm, that moves and feeds like a giant amoeba

Opisthokonta (opisthokonts) A single posterior flagellum at some stage in the life cycle; consist of the fungi, animals, and two protist groups, the choanoflagellates and the nucleariids.

Choanoflagellata (choanoflagellates)—motile protists with a single flagellum surrounded by collar of closely packed microvilli; likely ancestor of animals and fungi

Nucleariidae (nucleariids)—heterotrophic, mainly spherical amoebae with radiating, fine pseudopods that are not supported by microtubules; more closely related to fungi than to animals

Plantae Multicellular autotrophs, mostly terrestrial, and most of which gain energy via photosynthesis; life cycle characterized by alternation of a gametophyte (gamete-producing) generation and sporophyte (spore-producing) generation

Bryophytes (seedless plants)—nonvascular plants and seedless vascular plants

Hepatophyta (liverworts)—leafy or simple flattened thallus with rhizoids; no true leaves, stems, roots, or stomata (porelike openings for gas exchange); spores in capsules[1]

Anthocerophyta (hornworts)—simple flattened thallus, hornlike sporangia[1]

Bryophyta (mosses)—feathery or cushiony thallus; some with hydroids; spores in capsules[1]

Lycophyta (club mosses)—simple leaves, cuticle, stomata, true roots; most species have sporangia on sporophylls; fertilization by swimming sperm[2]

Pterophyta (ferns, whisk ferns, horsetails)—*Ferns:* Finely divided leaves; sporangia in sori. *Whisk ferns:* Branching stem from rhizomes; sporangia on stem scales. *Horsetails:* hollow stem, scalelike leaves, sporangia in strobili.[2]

Spermatophyta (seed plants)—vascular plants in which embryos develop within seeds

Gymnosperms—seeds born on stems, on leaves, or under scales

Cycadophyta (cycads)—shrubby or treelike with palmlike leaves; male and female strobili on separate plants

Ginkgophyta (ginkgoes)—lineage with a single living species *(Ginkgo biloba);* tree with deciduous, fan-shaped leaves; male, female reproductive structures on separate plants

Gnetophyta (gnetophytes)—shrubs or woody vinelike plants; male and female strobili on separate plants

Coniferophyta (conifers)—predominant extant gymnosperm group; mostly evergreen trees and shrubs with needlelike or scalelike leaves; male and female cones usually on the same plant

Anthophyta (angiosperms/flowering plants)—reproductive structures in flowers

Monocotyledones (monocots)—grasses, palms, lilies, orchids and their relatives; a single cotyledon (seed leaf); pollen grains have one groove

Eudicotyledones (eudicots)—roses, melons, beans, potatoes, most fruit trees, others; two cotyledons; pollen grains have three grooves

Other major angiosperm lineages: magnoliids (magnolias and relatives); star anise (Family Illicium); water lilies (Family Nymphaeaceae); *Amborella* (Family Amborellaceae)

Fungi Heterotrophic, mostly multicellular organisms with cell wall containing chitin and cell nuclei occurring in threadlike hyphae; life cycle typically includes both asexual and sexual phases, with sexual structures used as the basis for phylum-level classification. Single-celled species are known as yeasts.

Chytridiomycota (chytrids)—mostly aquatic; asexual reproduction by way of motile zoospores; sexual reproduction via gametes produced in gametangia; hyphae mostly aseptate

Zygomycota (zygomycetes)—terrestrial; asexual reproduction via nonmotile haploid spores formed in sporangia; sexual spores (zygospores) form in zygosporangia; aseptate hyphae

Glomeromycota (glomeromycetes)—terrestrial; asexual reproduction via spores at the tips of hyphae; form mycorrhizal associations with plant roots

Ascomycota (ascomycetes/sac fungi)—terrestrial and aquatic; sexual spores form in asci; asexual reproduction occurs via conidia (nonmotile spores); septate hyphae

Basidiomycota (basidiomycetes)—terrestrial; reproduction usually via sexual basidiospores produced by basidia; septate hyphae

Basidiomycetes: mushroom-forming fungi and relatives

Teliomycetes: rusts

Ustomycetes: smuts

Conidial fungi—not a true phylum but a convenience grouping of species for which no sexual phase is known

Microsporidia—single-celled sporelike parasites of animals, other groups; phylogeny uncertain

[1]Nonvascular plants (bryophytes)—A polyphyletic group of plants with no specialized structures for transporting water and nutrients; swimming sperm require liquid water for sexual reproduction

[2]Seedless vascular plants—A polyphyletic group of plants in which embryos are not housed inside seeds

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Animalia Multicellular heterotrophs; nearly all with tissues, organs, and organ systems; motile during at least part of the life cycle; sexual reproduction in most; embryos develop through a series of stages; many with larval and adult stages in life cycle

Parazoa Animals lacking tissues and body symmetry

Porifera (sponges)—multicellular; extract oxygen and particulate food from water drawn into a central cavity

Eumetazoa Animals with tissues and either radial or bilateral symmetry

Radiata—acoelomate animals with radial symmetry and two tissue layers

Cnidaria (cnidarians)—two tissue layers; single opening into gastrovascular cavity; nerve net; nematocysts for defense and predation; some sessile, some motile; most are predatory, some with photosynthetic endosymbionts; freshwater and marine

Hydrozoa: hydrozoans

Scyphozoa: jellyfishes

Cubozoa: box jellyfishes

Anthozoa: sea anemones, corals

Ctenophora (comb jellies)—two (possibly three) tissue layers; feeding tentacles capture particulate food; beating cilia provide weak locomotion; marine

Bilateria—animals with bilateral symmetry and three tissue layers

Protostomia—acoelomate, pseudocoelomate, or schizocoelomate; many with spiral, indeterminate cleavage; blastopore forms mouth; nervous system on ventral side

Lophotrochozoa—many with either a lophophore for feeding and gas exchange or a trochophore larva

Ectoprocta (bryozoans)—coelomate; colonial; secrete hard covering over soft tissues; lophophore; sessile; particulate feeders; marine

Brachiopoda (lamp shells)—coelomate; dorsal and ventral shells; lophophore; sessile; particulate feeders; marine

Phoronida (phoronid worms)—coelomate; secrete tubes around soft tissues; lophophore; sessile; particulate feeders; marine

Platyhelminthes (flatworms)—acoelomate; dorsoventrally flattened; complex reproductive, excretory, and nervous systems; gastrovascular cavity in many; free-living or parasitic, often with multiple hosts; terrestrial, freshwater, and marine

Turbellaria: free-living flatworms

Trematoda: flukes

Monogenoidea: flukes

Cestoda: tapeworms

Rotifera (wheel animals)—pseudocoelomate; microscopic; complete digestive system; well-developed reproductive, excretory, and nervous systems; particulate feeders; major components of marine and freshwater plankton

Nemertea (ribbon worms)—schizocoelomate; proboscis housed within rhynchocoel; complete digestive tract; circulatory system; predatory; mostly marine

Mollusca (mollusks)—schizocoelomate; many with trochophore larva; many with shell secreted by mantle; body divided into head–foot, visceral mass, and mantle; well-developed organ systems; variable locomotion; herbivorous or predatory; terrestrial, freshwater, and marine

Polyplacophora: chitons

Gastropoda: snails, sea slugs, land slugs

Bivalvia: clams, mussels, scallops, oysters

Cephalopoda: squids, octopuses, cuttlefish, nautiluses

Annelida (segmented worms)—schizocoelomate; many with trochophore larva; segmented body and organ systems; well-developed organ systems; many use hydrostatic skeleton for locomotion; some predatory, some particulate feeders, some detritivores; terrestrial, freshwater, and marine

Polychaeta: marine worms

Oligochaeta: freshwater and terrestrial worms

Hirudinea: leeches

Ecdysozoa—cuticle or exoskeleton is shed periodically

Nematoda (roundworms)—pseudocoelomate; body covered with tough cuticle that is shed periodically; well-developed organ systems; thrashing locomotion; many are parasitic on plants or animals; mostly terrestrial

Onychophora (velvet worms)—schizocoelomate; segmented body covered with cuticle; locomotion by many unjointed legs; complex organ systems; predatory; terrestrial

Arthropoda (arthropods)—schizocoelomate; jointed exoskeleton made of chitin; segmented body, some with fusion of segments in head, thorax, or abdomen; complex organ systems; variable modes of locomotion, including flight; specialization of numerous appendages; herbivorous, predatory, or parasitic; terrestrial, freshwater, and marine

Trilobita: trilobites (extinct)

Chelicerata: horseshoe crabs, spiders, scorpions, ticks, mites

Crustacea: shrimps, crayfishes, lobsters, crabs, barnacles, copepods, isopods

Myriapoda: centipedes, millipedes

Hexapoda: springtails and insects

Deuterostomia—enterocoelomate; many with radial, determinate cleavage; blastopore forms anus; nervous system on dorsal side in many

Echinodermata (echinoderms)—secondary radial symmetry, often organized around five radii; hard internal skeleton; unique water vascular system with tube feet; complete digestive system; simple nervous system; no circulatory or respiratory system; generally slow locomotion using tube feet; predatory, herbivorous, particulate feeders, detritivores; exclusively marine

Asteroidea: sea stars

Ophiuroidea: brittle stars

Echinoidea: sea urchins, sand dollars

Holothuroidea: sea cucumbers

Crinoidea: feather stars, sea lilies

Concentricycloidea: sea daisies

Hemichordata (acorn worms)—pharynx perforated with branchial slits; proboscis; complex organ systems; tube-dwelling in soft sediments; particulate or deposit feeders; exclusively marine

Chordata (chordates)—notochord; segmental body wall and tail muscles; dorsal hollow nerve chord; perforated pharynx; complex organ systems; variable modes of locomotion; extremely varied diets; terrestrial, freshwater, and marine

Cephalochordata: lancelets

Urochordata: tunicates, sea squirts

Vertebrata: vertebrates

Myxinoidea: hagfishes

Petromyzontoidea: lampreys

Placodermi: placoderms (extinct)

Chondrichthyes: sharks, skates, and rays

Acanthodii: acanthodians

Actinopterygii: ray-finned fishes

Sarcopterygii: fleshy-finned fishes

Amphibia: salamanders, frogs, caecelians

Synapsida: mammals

Anapsida: turtles

Diapsida: sphenodontids, lizards, snakes, crocodilians, birds

Glossary

3′ end The end of a polynucleotide chain at which a hydroxyl group is bonded to the 3′ carbon of a deoxyribose sugar.

3′ untranslated region (3′ UTR) The part of an mRNA between the stop codon and the 3′ end of the molecule; this region does not code for amino acids.

5′ cap In eukaryotes, a guanine-containing nucleotide attached in a reverse orientation to the 5′ end of pre-mRNA and retained in the mRNA produced from it. The 5′ cap on an mRNA is the site where ribosomes attach to initiate translation.

5′ end The end of a polynucleotide chain at which a phosphate group is bound to the 5′ carbon of a deoxyribose sugar.

5′ untranslated region (5′ UTR) The part of an mRNA between the 5′ end of the molecule and the start codon; this region does not code for amino acids.

10-nm chromatin fiber The most fundamental level of chromatin packing of a eukaryotic chromosome in which DNA winds for almost two turns around an eight-protein nucleosome core particle to form a nucleosome and linker DNA extends between adjacent nucleosomes. The result is a beads-on-a-string type of structure with a 10-nm diameter.

30-nm chromatin fiber Level of chromatin packing of a eukaryotic chromosome in which histone H1 binds to the 10-nm chromatin fiber causing it to package into a coiled structure about 30 nm in diameter and with about six nucleosomes per turn. Also referred to as a *solenoid*.

A site The site where the incoming aminoacyl–tRNA carrying the next amino acid to be added to the polypeptide chain binds to the mRNA.

abdomen The region of the body that contains much of the digestive tract and sometimes part of the reproductive system; in insects, the region behind the thorax.

abiotic Nonbiological, often in reference to physical factors in the environment.

abscisic acid (ABA) A plant hormone involved in the abscission of leaves, flowers, and fruits, dormancy of buds and seeds, and closing of stomata.

abscission In plants, the dropping of flowers, fruits, and leaves in response to environmental signals.

absorption Within the digestive tube, the process in which molecular subunits are absorbed from the digestive contents into body fluids and cells.

absorption spectrum Curve representing the amount of light absorbed at each wavelength.

abyssal zone The bottom sediments that lie permanently below deep ocean water.

acclimitization A process by which an animal adjusts to live and function at higher altitudes to permit adequate oxygen delivery to the tissues.

accommodation A process by which the lens changes to enable the eye to focus on objects at different distances.

acid Proton donor that releases H^+ (and anions) when dissolved in water.

acid precipitation Rainfall with low pH, primarily created when gaseous sulfur dioxide (SO_2) dissolves in water vapor in the atmosphere, forming sulfuric acid.

acid-growth hypothesis A hypothesis to explain how the hormone auxin promotes growth of plant cells; it suggests that auxin stimulates H^+ pumps in the plasma membrane to move H^+ from the cell interior into the cell wall, which increases wall acidity, making the wall expandable.

acidity The concentration of H^+ in a water solution, as compared with the concentration of OH^-.

acoelomate A body plan of bilaterally symmetrical animals that lack a body cavity between the gut and the body wall.

acoustical signaling A means of animal communication in which a signaler produces a sound that is heard by a signal receiver.

acquired immunity *See* **adaptive (acquired) immunity.**

acquired immunodeficiency syndrome (AIDS) A constellation of disorders that follows infection by the human immunodeficiency virus (HIV).

acrosome A specialized secretory vesicle on the head of an animal sperm, which helps the sperm penetrate the egg.

acrosome reaction The process in which enzymes contained in the acrosome are released from an animal sperm and digest a path through the egg coats.

actin A protein that, in an interaction with the protein myosin, causes muscle contraction.

action potential The abrupt and transient change in membrane potential that occurs when a neuron conducts an electrical impulse.

action spectrum Graph produced by plotting the effectiveness of light at each wavelength in driving photosynthesis.

activation energy The initial input of energy required to start a reaction.

activator A regulatory protein that controls the expression of one or more genes.

active immunity The production of antibodies in the body in response to exposure to a foreign antigen.

active parental care Parents' investment of time and energy in caring for offspring after they are born or hatched.

active site The region of an enzyme to which substrate(s) bind and where catalysis occurs.

active transport The mechanism by which ions and molecules move against the concentration gradient across a membrane, from the side with the lower concentration to the side with the higher concentration.

adaptation Characteristic that helps an organism survive longer or reproduce more under a particular set of environmental conditions.

adaptation, evolutionary The accumulation of adaptive traits over time.

adaptation, sensory *See* **sensory adaptation.**

adaptive (acquired) immunity The response by the body to eliminate cellular pathogens that involves mechanisms of the adaptive immune system.

adaptive immune system The inherited mechanisms leading to the synthesis of molecules that target pathogens in a specific way. The adaptive immune system is one of two components of the immune system in vertebrates. It is not found in invertebrates.

adaptive radiation A cluster of closely related species that are each adaptively specialized to a specific habitat or food source.

adaptive trait A genetically based characteristic, preserved by natural selection, that increases an organism's likelihood of survival or its reproductive output.

adaptive zone An environment or part of an environment that may be occupied by a group of species exploiting resources in a similar manner.

adductor muscle A muscle that pulls inward toward the median line of the body; in bivalve mollusks, it pulls the shell closed.

adenine A purine that base-pairs with either thymine in DNA or uracil in RNA.

adherens junction Animal cell junction in which intermediate filaments are the anchoring cytoskeletal component.

adhesion The adherence of molecules to the walls of conducting tubes, as in plants.

adiabatic cooling A decrease in temperature without the actual loss of heat energy, occurring in air masses that expand as they rise in the atmosphere.

adipocytes Densely clustered cells within adipose tissue that are specialized for fat storage.

adipose tissue Connective tissue containing large, densely clustered cells called *adipocytes* that are specialized for fat storage.

adrenal cortex The outer region of the adrenal glands, which contains endocrine cells that secrete two major types of steroid hormones, the glucocorticoids and the mineralocorticoids.

adrenal medulla The central region of the adrenal glands, which contains neurosecretory neurons that secrete the catecholamine hormones epinephrine and norepinephrine.

adrenergic receptors G-protein–coupled receptors to which hormones originating in the adrenal gland can bind.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

adrenocorticotropic hormone (ACTH) A hormone that triggers hormone secretion by cells in the adrenal cortex.

adventitious root A root that develops from the stem or leaves of a plant.

aerobe An organism that requires oxygen for cellular respiration.

aerobic respiration The form of cellular respiration found in eukaryotes and many prokaryotes in which oxygen is a reactant in the ATP-producing process.

afferent arteriole The vessel that delivers blood to the glomerulus of the kidney.

afferent neuron A neuron that transmits stimuli collected by a sensory receptor to an interneuron.

agar A gelatinous product extracted from certain red algae or seaweed used as a culture medium in the laboratory and as a gelling or stabilizing agent in foods.

agarose gel electrophoresis Technique by which DNA, RNA, or protein molecules are separated in an agarose gel subjected to an electric field.

age structure A statistical description or graph of the relative numbers of individuals in each age class in a population.

age-specific fecundity The average number of offspring produced by surviving females of a particular age.

age-specific mortality The proportion of individuals alive at the start of an age interval that died during that age interval.

age-specific survivorship The proportion of individuals alive at the start of an age interval that survived until the start of the next age interval.

agglutination One of two important mechanisms to clear foreign antigens from the body, the immobilization of pathogens by antibodies.

aggregate fruit A fruit that develops from multiple separate carpels of a single flower, such as a raspberry or strawberry.

agonist A muscle that causes movement in a joint when it contracts.

albumin The most abundant protein in blood plasma, important for osmotic balance and pH buffering; also, the portion of an egg that serves as the main source of nutrients and water for the embryo.

alcohol A molecule of the form R—OH in which R is a chain of one or more carbon atoms, each of which is linked to hydrogen atoms.

alcoholic fermentation Reaction in which pyruvate is converted into ethyl alcohol and CO_2 in a two-step series that also converts NADH into NAD^+.

aldehyde Molecule in which the carbonyl group is linked to a carbon atom at the end of a carbon chain, along with a hydrogen atom.

aldosterone A mineralocorticoid hormone released from the adrenal cortex that increases the amount of Na^+ reabsorbed from the urine in the kidneys and absorbed from foods in the intestine, reduces the amount of Na^+ secreted by salivary and sweat glands, and increases the rate of K^+ excretion by the kidneys, keeping Na^+ and K^+ balanced at the levels required for normal cellular function.

aleurone The thin layer of cells that separates the endosperm of a seed from the pericarp.

algin Alginic acid, found in the cell walls of brown algae.

allantois In an amniote egg, an extraembryonic membrane sac that fills much of the space between the chorion and the yolk sac and store's the embryo's nitrogenous wastes.

allele One of two or more versions of a gene.

allele frequency The abundance of one allele relative to others at the same gene locus in individuals of a population.

allergen A type of antigen responsible for allergic reactions, which induces B cells to secrete an overabundance of IgE antibodies.

allometric growth A pattern of postembryonic development in which parts of the same organism grow at different rates.

allopatric speciation The evolution of reproductive isolating mechanisms between two populations that are geographically separated.

allopolyploidy The genetic condition of having two or more complete sets of chromosomes from different parent species.

all-or-nothing principle The principle that an action potential is produced only if the stimulus is strong enough to cause depolarization to reach the threshold.

allosteric activator Molecule that converts an enzyme with an allosteric site, a regulatory site outside the active site, from the inactive form to the active form.

allosteric inhibitor Molecule that converts an enzyme with an allosteric site, a regulatory site outside the active site, from the active form to the inactive form.

allosteric regulation Specialized control mechanism for enzymes with an allosteric site, a regulatory site outside the active site, that may either slow or accelerate activity depending on the enzyme.

allosteric site A regulatory site outside the active site.

alpha (α) helix A type of secondary structure of a polypeptide in which the amino acid chain is twisted into a regular, right-hand spiral.

α-melanocyte-stimulating hormone (alpha-MSH) A peptide hormone released from the hypothalamus that inhibits appetite.

alpine tundra A biome that occurs on high mountaintops throughout the world, in which dominant plants form cushions and mats.

alternation of generations The regular alternation of mode of reproduction in the life cycle of an organism, such as the alternation between diploid (sporophyte) and haploid (gametophyte) phases in plants.

alternative hypothesis An explanation of an observed phenomenon that is different from the explanation being tested.

alternative splicing Mechanism by which a pre-mRNA in a eukaryotic cell is processed by reactions that join exons in different combinations to produce different mRNAs from a single gene.

altruism A behavioral phenomenon in which individuals appear to sacrifice their own reproductive success to help other individuals.

Alveolata (alveolates) A subgroup of the Chromalveolata protist evolutionary group; characterized by small, flattened, membrane-bound vesicles called alveoli in a layer just under the plasma membrane.

alveolus (plural, *alveoli*) One of the millions of tiny air pockets in mammalian lungs, each surrounded by dense capillary networks.

amacrine cell A type of neuron that forms lateral connections in the retina of the eye, connecting bipolar cells and ganglion cells.

amino acid A molecule that contains both an amino and a carboxyl group.

amino group Group that acts as an organic base, consisting of a nitrogen atom bonded on one side to two hydrogen atoms and on the other side to a carbon chain.

aminoacylation The process of adding an amino acid to a tRNA. Also referred to as *charging*.

aminoacyl–tRNA A tRNA linked to its "correct" amino acid, which is the finished product of aminoacylation.

aminoacyl–tRNA synthetase An enzyme that catalyzes aminoacylation.

aminopeptidase An enzyme that hydrolyzes small peptides to produce individual amino acids.

ammonification A metabolic process in which bacteria convert organic nitrogen compounds into ammonia and ammonium ions; part of the nitrogen cycle.

amniocentesis Technique of prenatal diagnosis in which cells are obtained from the amniotic fluid for DNA testing, for biochemical analysis, or to test for the presence of chromosomal mutations.

amnion In an amniote egg, an extraembryonic membrane that encloses the embryo, forming the amniotic cavity and secreting amniotic fluid, which provides an aquatic environment in which the embryo develops.

Amniota The monophyletic group of vertebrates that have an amnion during embryonic development.

amniote egg A shelled egg that can survive and develop on land.

amoeba A descriptive term for a single-celled protist that moves by means of temporary cellular projections called *pseudopods*.

Amoebozoa (amoebozoans) A protist evolutionary group that includes most of the amoebas as well as the cellular and plasmodial slime molds; characterized by the use of pseudopods for locomotion and feeding for all or part of their life cycles.

amplification An increase in the magnitude of each step as a signal transduction pathway proceeds.

amygdala A gray-matter center of the brain that works as a switchboard, routing information about experiences that have an emotional component through the limbic system.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

amyloplast Colorless plastid that stores starch in plants.

anabolic-androgenic steroid (AAS) A synthetic derivative of androgens that mimics their effects. Also called an *anabolic steroid.*

anabolic pathway A metabolic pathway in which energy is used to build complicated molecules from simpler ones; also called a *biosynthetic pathway.* An individual reaction in an anabolic pathway is an anabolic reaction, also called a *biosynthetic reaction.*

anabolic reaction Metabolic reaction that requires energy to assemble simple substances into more complex molecules.

anabolic steroid *See* **anabolic-androgenic steroid (AAS).**

anaerobe An organism that does not require oxygen to live.

anaerobic respiration The form of cellular respiration found in some prokaryotes in which a molecule other than oxygen is used in the ATP-producing process.

anagenesis The slow accumulation of evolutionary changes in a lineage over time.

anal sphincter A muscular ring that controls the opening and closing of the anus.

anaphase The phase of mitosis during which the spindle separates sister chromatids and pulls them to opposite spindle poles.

anaphase-promoting complex (APC) An enzyme complex activated by M phase–promoting factor that controls the separation of sister chromatids and the onset of daughter chromosome separation in anaphase of mitosis.

anaphylactic shock A severe inflammation stimulated by an allergen, involving extreme swelling of air passages in the lungs that interferes with breathing, and massive leakage of fluid from capillaries that causes blood pressure to drop precipitously.

anapsida A lineage of amniotes that lack a bony temporal arch in the skull.

anatomy The study of the structures of organisms.

ancestral character state A trait that was present in a distant common ancestor.

anchoring junction Cell junction that forms belts that run entirely around cells, "welding" adjacent cells together.

androgen One of a family of hormones that promote the development and maintenance of sex characteristics.

aneuploid An individual with extra or missing chromosomes.

angiosperm A flowering plant. Its egg-containing ovules mature into seeds within protected chambers called *ovaries.*

angiotensin A peptide hormone that raises blood pressure quickly by constricting arterioles in most parts of the body; it also stimulates release of the steroid hormone aldosterone.

angiotensin I In the renin-angiotensin-aldosterone system (RAAS), the molecule produced by cleavage of the plasma protein angiotensinogen.

angiotensin II In the renin-angiotensin-aldosterone system (RAAS), the molecule converted from angiotensin I by angiotensin-converting enzyme (ACE); angiotensin II is a hormone that constricts arterioles to raise blood pressure, stimulates synthesis of aldosterone and its secretion from the adrenal cortex, and stimulates thirst.

angiotensin-converting enzyme (ACE) In the renin-angiotensin-aldosterone system (RAAS), the enzyme that converts angiotensin I to angiotensin II.

animal behavior The responses of animals to specific internal and external stimuli.

animal pole The end of the egg where the egg nucleus is located, which typically gives rise to surface structures and the anterior end of the embryo.

Animalia The taxonomic kingdom that includes all living and extinct animals.

anion A negatively charged ion.

annual An herbaceous plant that completes its life cycle in one growing season and then dies.

annulus In ferns, a ring of thick-walled cells that nearly encircles the sporangium and functions in spore release.

antagonistic pair Two skeletal muscles, one of which flexes as the other extends to move joints.

antenna A chemosensory appendage attached to the head of some adult arthropods.

antenna complex (light-harvesting complex) In photosystems, the sites at which light is absorbed and converted into chemical energy during photosynthesis, an aggregate of many chlorophyll pigments and a number of carotenoid pigments that serves as the primary site of absorbing light energy in the form of photons.

anterior Indicating the head end of an animal.

anterior pituitary The glandular part of the pituitary, composed of endocrine cells that synthesize and secrete several tropic and nontropic hormones.

anther The pollen-bearing part of a stamen.

antheridium (plural, *antheridia*) In plants, a structure in which sperm are produced.

Anthocerophyta The phylum comprising hornworts.

Anthophyta The phylum comprising flowering plants.

Anthropoidea The monophyletic lineage of primates comprising monkeys, apes, and humans.

antibody A highly specific soluble protein molecule that circulates in the blood and lymph, recognizing and binding to antigens and clearing them from the body.

antibody class The molecular type of an antibody determined by the constant regions of the heavy chains of the molecule.

antibody-mediated immunity Adaptive immune response in which plasma cells secrete antibodies. Also called *humoral immunity.*

anticodon The three-nucleotide segment in a tRNA that pairs with a codon in an mRNA.

antidiuretic hormone (ADH) A hormone secreted by the posterior pituitary that increases water absorption in the kidneys, thereby increasing the volume of the blood.

antigen A foreign molecule that triggers an adaptive immunity response.

antigen-presenting cell (APC) A cell that presents an antigen to T cells in antibody-mediated immunity and cell-mediated immunity.

antihistamines Substances that block histamine receptors thereby reducing symptoms of an allergic reaction.

antiparallel Strands of double-stranded DNA that run in opposite directions with the 3′ end of one strand opposite the 5′ end of the other strand.

antiport A secondary active transport mechanism in which a molecule moves through a membrane channel into a cell and powers the active transport of a second molecule out of the cell. Also referred to as *exchange diffusion.*

aorta A large artery from the heart that branches into arteries leading to all body regions except the lungs.

aortic body One of several small clusters of chemoreceptors, baroreceptors, and supporting cells located along the aortic arch that measures changes in blood pressure and the composition of arterial blood flowing past it.

aphotic zone Deeper water of a lake or ocean where sunlight does not penetrate.

apical dominance Inhibition of the growth of lateral buds in plants due to auxin diffusing down a shoot tip from the terminal bud.

apical meristem A region of unspecialized dividing cells at shoot tips and root tips of a plant.

apical surface The outer surface of epithelial cells.

Apicomplexa (apicomplexans) A lineage within the Alveolata subgroup of the Chromalveolata protist evolutionary group; nonmotile parasites of animals characterized by the apical complex, a special grouping of fibrils, microtubules, and organelles at one end of the cell that functions in attachment and invasion of host cells.

apomixis In plants, the production of offspring without meiosis or formation of gametes.

apomorphy A derived character state.

apoplastic pathway The route followed by water moving through plant cell walls and intercellular spaces (the apoplast). *Compare* **symplastic pathway.**

apoptosis A type of programmed cell death.

aposematic coloration Bright, contrasting patterns that advertise the unpalatability of poisonous or repellant species.

appendicular skeleton The bones comprising the pectoral (shoulder) and pelvic (hip) girdles and limbs of a vertebrate.

appendix A fingerlike sac that extends from the cecum of the large intestine.

applied research Research conducted with the goal of solving specific practical problems.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

aquaporin A specialized protein channel that facilitates diffusion of water through cell membranes.

aquatic succession A process in which debris from rivers and runoff accumulates in a body of fresh water, causing it to fill in at the margins.

aqueous humor A clear fluid that fills the space between the cornea and lens of the eye.

Archaea One of two domains of prokaryotes; archaeans have some unique molecular and biochemical traits, but they also share some traits with Bacteria and other traits with Eukarya.

archaeal chromosome DNA molecule in archaeans in which hereditary information is encoded.

Archaeplastida (archaeplastids) An evolutionary group consisting of the Rhodophyta and Chlorophyta protists, and the land plants; all are photosynthesizers.

archegonium The flask-shaped structure in which bryophyte eggs form.

archenteron The central endoderm-lined cavity of an embryo at the gastrula stage, which forms the primitive gut.

Archosauromorpha A diverse group of diapsids that comprises crocodilians, pterosaurs, and dinosaurs (including birds).

arctic tundra A treeless biome that stretches from the boreal forests to the polar ice cap in Europe, Asia, and North America.

arteriole A branch from a small artery at the point where it reaches the organ it supplies.

artery A vessel that conducts blood away from the heart at relatively high pressure.

artificial selection Selective breeding of organisms to ensure that certain desirable traits appear at higher frequency in successive generations.

ascending reticular formation Part of the reticular formation containing neurons that convey stimulatory signals via the thalamus to arouse and activate the cerebral cortex. It is responsible for the sleep–wake cycle. Also called the *reticular activating system*.

ascocarp In ascomycete (sac) fungi, a reproductive body that bears or contains asci.

ascus (plural, *asci*) A saclike cell in ascomycetes (sac fungi) in which meiosis gives rise to haploid sexual spores (meiospores).

asexual reproduction Any mode of reproduction in which a single individual gives rise to offspring without fusion of gametes; that is, without genetic input from another individual. *See also* **vegetative reproduction.**

association area One of several areas surrounding the sensory and motor areas of the cerebral cortex that integrate information from the sensory areas, formulate responses, and pass them on to the primary motor area.

aster Radiating array produced as microtubules extending from the centrosomes of cells grow in length and extent.

asthma In an allergic reaction, a severe response to allergens that involves constriction of airways in the lungs.

astrocyte A star-shaped glial cell that provides support to neurons in the vertebrate central nervous system.

asymmetrical Characterized by a lack of proportion in the spatial arrangement or placement of parts.

atmosphere The component of the biosphere that includes the gases and airborne particles enveloping the planet.

atom The smallest unit that retains the chemical and physical properties of an element.

atomic nucleus The nucleus of an atom, containing protons and neutrons.

atomic number The number of protons in the nucleus of an atom.

atomic weight The weight of an element in grams, equal to the mass number.

ATP (adenosine triphosphate) The primary agent that couples exergonic and endergonic reactions.

ATP/ADP cycle The continual hydrolysis and resynthesis of ATP in living cells.

ATP synthase A membrane-spanning protein complex that couples the energetically favorable transport of protons across a membrane to the synthesis of ATP.

atrial natriuretic factor (ANF) A peptide hormone that inhibits renin release and increases the filtration rate by dilating the arterioles that deliver blood to glomeruli and by inhibiting aldosterone release.

atrial siphon A tube through which invertebrate chordates expel digestive and metabolic wastes.

atriopore The hole in the body wall of a cephalochordate through which water is expelled from the body.

atrioventricular node (AV node) A region of the heart wall that receives signals from the sinoatrial node and conducts them to the ventricle.

atrium (plural, *atria*) A body cavity or chamber surrounding the perforated pharynx of invertebrate chordates; also, one of the chambers that receive blood returning to the heart.

autoimmune disease A malfunction of the immune system in which the body reacts against its own proteins or cells.

autoimmune reaction The production of antibodies against molecules of the body.

autonomic nervous system A subdivision of the peripheral nervous system that controls largely involuntary processes including digestion, secretion by sweat glands, circulation of the blood, many functions of the reproductive and excretory systems, and contraction of smooth muscles in all parts of the body.

autopolyploidy The genetic condition of having more than two sets of chromosomes from the same parent species.

autosomal dominant inheritance Pattern in which the allele that causes a trait is dominant, and only homozygous recessives are unaffected.

autosomal recessive inheritance Pattern in which individuals with a trait are homozygous for a recessive allele.

autosome Chromosome other than a sex chromosome.

autotroph An organism that produces its own food using CO_2 and other simple inorganic compounds from its environment and energy from the sun or from oxidation of inorganic substances.

autumn overturn A process in which winds mix the water in a lake vertically, equalizing the concentrations of dissolved gases and nutrients at all depths.

auxin Any of a family of plant hormones that stimulate growth by promoting cell elongation in stems and coleoptiles, inhibit abscission, govern responses to light and gravity, and have other developmental effects.

auxotroph A mutant strain that requires for its growth a nutrient supplement that is not needed by the wild-type strain.

Avogadro's number The number 6.022×10^{23}, derived by dividing the atomic weight of any element by the weight of an atom of that element.

***Avr* gene** A gene in certain plant pathogens that encodes a product triggering a defensive response in the plant.

axial skeleton The bones comprising the head and trunk of a vertebrate: the cranium, vertebral column, ribs, and sternum (breastbone).

axil The upper angle between the stem and an attached leaf.

axon The single elongated extension of a neuron that conducts signals away from the cell body to another neuron or an effector.

axon hillock A junction with the cell body of a neuron from which the axon arises.

axon terminal A branch at the tip of an axon that ends as a small, buttonlike swelling.

B cell A lymphocyte that recognizes antigens in the body.

Bacillariophyta (diatoms) A lineage of the Stramenopila subgroup of the Chromalveolata protist evolutionary group; single-celled organisms covered by an intricate, glassy silica shell.

bacillus (plural, *bacilli*) A cylindrical or rod-shaped prokaryote.

background extinction rate The average rate of extinction of taxa through time.

Bacteria One of the two domains of prokaryotes; collectively, bacteria are the most metabolically diverse organisms.

bacterial chromosome DNA molecule in bacteria in which hereditary information is encoded.

bacterial flagellum *See* **flagellum.**

bacteriophage A virus that infects bacteria. Also referred to as a *phage*.

bacteroid A rod-shaped or branched bacterium in the root nodules of nitrogen-fixing plants.

balanced polymorphism The maintenance of two or more phenotypes in fairly stable proportions over many generations.

bark The tough outer covering of woody stems and roots, composed of all the living and nonliving

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tissues between the vascular cambium and the stem surface.

Barr body The inactive, condensed X chromosome seen in the nucleus of female placental mammals.

basal angiosperm Any of the earliest branches of the flowering plant lineage; includes the star anise group and water lilies.

basal body Structure that anchors cilia and flagella to the surface of a cell.

basal lamina The membrane that fixes the epithelium to underlying tissues (also called the *basement membrane*).

basal nucleus One of several gray-matter centers that surround the thalamus on both sides of the brain and moderate voluntary movements directed by motor centers in the cerebrum.

basal surface The inner surface of epithelial cells.

base Proton acceptor that reduces the H^+ concentration of a solution.

base-pair mismatch An error in the assembly of a new nucleotide chain in which bases other than the correct ones pair together.

basic research Research conducted to search for explanations about natural phenomena in order to satisfy curiosity and to advance collective knowledge of living systems.

basidiocarp A fruiting body of a basidiomycete; mushrooms are examples.

basidiospore A haploid sexual spore produced by basidiomycete fungi.

basidium (plural, *basidia*) A small, club-shaped structure in which sexual spores of basidiomycetes arise.

basilar membrane A part of the floor of the cochlear duct, which anchors sensory hair cells in the organ of Conti and which vibrates in response to vibrations moving through the inner ear.

basophil A type of leukocyte that is induced to secrete histamine by allergens.

Batesian mimicry The form of defense in which a palatable or harmless species resembles an unpalatable or poisonous one.

Bayesian methods A statistical technique that evaluates a given phylogenetic tree by determining the probability that it is correct given the distribution of character states included in the analysis.

B-cell receptor (BCR) The receptor on B cells that is specific for a particular antigen.

behavioral isolation A prezygotic reproductive isolating mechanism in which two species do not mate because of differences in courtship behavior; also known as ethological isolation.

behavioral repertoire The set of actions that an animal can perform in response to stimuli in its environment.

benthic province The bottom sediments in the ocean.

benthos Species living in and on the bottom sediments of the ocean.

beta (β) sheet A type of primary structure in a polypeptide in which the amino acid chain zigzags in a flat plane to form a beta strand, and beta strands then align side by side in the same or opposite direction.

biennial A plant that completes its life cycle in two growing seasons and then dies; limited secondary growth occurs in some biennials.

Bikonta (bikonts) Eukaryotes with two flagella.

bilateral symmetry The body plan of animals in which the body can be divided into mirror image right and left halves by a plane passing through the midline of the body.

bilayer A membrane with two molecular layers.

bile A mixture of substances including bile salts, cholesterol, and bilirubin that is made in the liver, stored in the gallbladder, and used in the digestion of fats.

bile salts A component of bile, consisting of derivatives of cholesterol and amino acids, that aids fat digestion.

bilirubin A component of bile consisting of a waste product derived from worn-out red blood cells.

binomial Relating to or consisting of two names or terms.

binomial nomenclature The naming of species with a two-part scientific name, the first indicating the genus and the second indicating the species.

biodiversity The richness of living systems as reflected in genetic variability within and among species, the number of species living on Earth, and the variety of communities and ecosystems.

biodiversity hot spot An area where biodiversity is both highly concentrated and endangered.

biofilm A prokaryotic multicellular association consisting of a complex aggregation of microorganisms (either one or multiple species) attached, in most cases, to a surface.

biogeochemical cycle Any of several global processes in which a nutrient circulates between the abiotic environment and living organisms.

biogeographical realm A major region of Earth that is occupied by distinct evolutionary lineages of plants and animals.

biogeography The study of the geographical distributions of plants and animals.

bioinformatics The application of mathematics and computer science to extract information from biological data, including those related to genome structure and function.

biological clock An internal time-measuring mechanism that adapts an organism to recurring environmental changes.

biological evolution The process by which some individuals in a population experience changes in their DNA and pass those modified instructions to their offspring.

biological lineage An evolutionary sequence of ancestral organisms and their descendants.

biological magnification The increasing concentration of nondegradable poisons in the tissues of animals at higher trophic levels.

biological research The collective effort of individuals who have worked to understand how living systems function.

biological species concept The definition of species based on the ability of populations to interbreed and produce fertile offspring.

bioluminescent An organism that glows or releases a flash of light, particularly when disturbed.

biomass The dry weight of biological material per unit area or volume of habitat.

biome A large scale vegetation type and its associated microorganisms, fungi, and animals.

bioremediation Applications of chemical and biological knowledge to decontaminate polluted environments.

biosignature Particular organic molecules in sedimentary rocks that could only have been formed by cellular activity.

biosphere All regions of Earth's crust, waters, and atmosphere that sustain life.

biosynthetic reaction An individual reaction in an anabolic pathway (biosynthetic pathway).

biota The total collection of organisms in a geographical region.

biotechnology The manipulation of living organisms to produce useful products.

biotic Biological, often in reference to living components of the environment.

bipedalism The habit in animals of walking upright on two legs.

bipolar cell A type of neuron in the retina of the eye that connects the rods and cones with the ganglion cells.

blade The expanded part of a leaf that provides a large surface area for absorbing sunlight and carbon dioxide.

blastocoel A fluid-filled cavity in the blastula embryo.

blastocyst An embryonic stage in mammals; a single-cell-layered hollow ball of about 120 cells with a fluid-filled blastocoel in which a dense mass of cells is localized to one side.

blastodisc A disclike layer of cells at the surface of the yolk produced by early cleavage divisions.

blastomere A small cell formed during cleavage of the embryo.

blastopore The opening at one end of the archenteron in the gastrula that gives rise to the mouth in protostomes and the anus in deuterostomes.

blastula The hollow ball of cells that is the result of cleavage divisions in an early embryo.

blending theory of inheritance Theory suggesting that hereditary traits blend evenly in offspring through mixing of the blood of the two parents.

blood A fluid connective tissue composed of blood cells suspended in a fluid extracellular matrix called **plasma.**

blood–brain barrier A specialized arrangement of capillaries in the brain that prevents most substances dissolved in the blood from entering the cerebrospinal fluid and thus protects the brain and spinal cord from viruses, bacteria, and toxic substances that may circulate in the blood.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

blood pressure The measurement of the hydrostatic pressure on the walls of the arteries as the heart pumps blood through the body.

body system *See* **organ system.**

Bohr effect The reduction in affinity of hemoglobin for O_2 that results from a conformational change caused by lowered pH.

bolting Rapid formation of a floral shoot in plant species that form rosettes, such as lettuce.

bolus The food mass after chewing.

bone The densest form of connective tissue, in which living cells secrete the mineralized matrix of collagen and calcium salts that surrounds them; forms the skeleton.

bony temporal arches Bones that border the temporal fenestrae in the skulls of some amniotes.

book lungs Pocketlike respiratory organs found in some arachnids consisting of several parallel membrane folds arranged like the pages of a book.

boreal forest A biome that is a circumpolar expanse of evergreen coniferous trees in Europe, Asia, and North America.

Bowman's capsule An infolded region at the proximal end of a nephron that cups around the glomerulus and collects the water and solutes filtered out of the blood.

brachiation A pattern of locomotion among primates in which an individual swings below branches from one handhold to another.

brain A single, organized collection of nervous tissue in an organism's head that forms the control center of the nervous system and major sensory structures.

brain stem A stalklike structure formed by the pons and medulla, along with the midbrain, which connects the forebrain with the spinal cord.

branchial slits Openings in the walls of the pharynx that allow water to exit the pharynx.

brassinosteroid Any of a family of plant hormones that stimulate cell division and elongation and differentiation of vascular tissue.

breathing The exchange of gases with the respiratory medium by animals.

bronchiole One of the small, branching airways in the lungs that lead into the alveoli.

bronchus (plural, *bronchi*) An airway that leads from the trachea to the lungs.

brown adipose tissue A specialized tissue in which the most intense heat generation by nonshivering thermogenesis takes place.

brown algae *See* **Phaeophyta.**

brown fat *See* **brown adipose tissue.**

brush border The fingerlike projections of the plasma membrane of the epithelial cells covering the intestinal villi.

Bryophyta The phylum of nonvascular plants to which mosses are assigned.

bryophyte A general term for plants (such as mosses) that lack internal transport vessels.

budding A mode of asexual reproduction in which a new individual grows and develops while attached to the parent.

buffer Substance that compensates for pH changes by absorbing or releasing H^+.

bulbourethral gland One of two pea-sized glands on either side of the prostate gland, which secrete a mucous fluid that is added to semen.

bulk feeder An animal that consumes sizeable food items whole or in large chunks.

bulk flow The group movement of molecules in response to a difference in pressure between two locations.

bulk-phase endocytosis Mechanism by which extracellular water is taken into a cell together with any molecules that happen to be in solution in the water. Also referred to as *pinocytosis*.

C_3 pathway *See* **light-independent reaction;** also referred to as the *Calvin cycle*.

C_4 pathway In C_4 plants the pathway to fix CO_2 into oxaloacetate in mesophyll cells and then produce CO_2 for the Calvin cycle in bundle sheath cells.

Ca^{2+} pump (calcium pump) Pump that pushes Ca^{2+} from the cytoplasm to the cell exterior, and also from the cytosol into the vesicles of the endoplasmic reticulum.

cadherin A cell surface protein responsible for selective cell adhesions that require calcium ions to set up adhesions.

calcitonin A nontropic peptide hormone that lowers the level of Ca^{2+} in the blood by inhibiting the ongoing dissolution of calcium from bone.

callus An undifferentiated tissue that develops on or around a cut plant surface or in tissue culture.

calorie (cal) The amount of heat required to raise 1 g of water by 1°C, known as a "small" calorie; when capitalized, a unit equal to 1,000 small calories.

Calvin cycle *See* **light-independent reaction.**

calyx The outermost whorl of a flower, made up of sepals; early in the development of a flower, it encloses all the other parts, as in an unopened bud.

CAM pathway In CAM plants the pathway to fix CO_2 into oxaloacetate and then produce CO_2 for the Calvin cycle, both occurring in mesophyll cells, but separated by time of day. CAM stands for "crassulacean acid metabolism."

cancer When a tumor becomes malignant and its cells invade and disrupt surrounding tissues.

canines Pointed, conical teeth of a mammal, located between the incisors and the first premolars, that are specialized for biting and piercing.

CAP (catabolite activator protein) Key regulatory molecule involved in positive gene regulation of the *lac* operon.

CAP site Region in the promoter of the *lac* operon and in the promoters of a large number of other operons that control the catabolism of many sugars to which activated catabolite activator protein (CAP) binds, thereby enabling RNA polymerase to bind and transcribe the operon's structural genes.

capillary The smallest diameter blood vessel, with a wall that is one cell thick, which forms highly branched networks well adapted for diffusion of substances.

capsid The protective layer of protein that surrounds the nucleic acid core of a virus in free form; also known as a *coat*.

capsule An external layer of sticky or slimy polysaccharides coating the cell wall in many prokaryotes.

carapace A protective outer covering that extends backward behind the head on the dorsal side of an animal, such as the shell of a turtle or lobster.

carbon cycle The global circulation of carbon atoms, especially via the processes of photosynthesis and respiration.

carbonyl group The reactive part of aldehydes and ketones, consisting of an oxygen atom linked to a carbon atom by a double bond.

carboxyl group The characteristic functional group of organic acids, formed by the combination of carbonyl and hydroxyl groups.

carboxypeptidase An enzyme that digests peptides to produce amino acids.

cardiac cycle The systole-diastole sequence of the heart.

cardiac muscle The contractile tissue of the heart.

carnivore An animal that primarily eats other animals.

carotenoid Molecule of yellow-orange pigment by which light is absorbed in photosynthesis.

carotid body A small cluster of chemoreceptors and supporting cells located near the bifurcation of the carotid artery that measures changes in the composition of arterial blood flowing through it.

carpel The reproductive organ of a flower that houses an ovule and its associated structures.

carrageenan A chemical extracted from the red alga *Eucheuma* that is used to thicken and stabilize paints, dairy products such as pudding and ice cream, and many other creams and emulsions.

carrier A heterozygote—an individual who carries a recessive mutant allele and could pass it on to offspring, but does not display its symptoms.

carrier protein Transport protein that binds a specific single solute and transports it across the lipid bilayer.

carrying capacity The maximum size of a population that an environment can support indefinitely.

Cartagena Protocol on Biosafety An international agreement that promotes biosafety as it relates to the handling and use of genetically modified organisms.

cartilage A tissue composed of sparsely distributed chondrocytes surrounded by networks of collagen fibers embedded in a tough but elastic matrix of the glycoprotein.

cartilaginous joint A joint between bones that is not very movable and in which the ends of the bones are covered with layers of cartilage but with no fluid-filled capsule surrounding them.

Casparian strip A thin, waxy impermeable band that seals abutting cell walls in roots; the strip helps control the type and amount of solutes that enter the stele by blocking the apoplastic pathway at the endodermis and forcing substances to pass through cells (the symplast).

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

catabolic pathway A metabolic pathway in which energy is released by the breakdown of complex molecules to simpler compounds. An individual reaction in a catabolic pathway is a catabolic reaction.

catabolic reaction Cellular reaction that breaks down complex molecules such as sugar to make their energy available for cellular work.

catalysis The process of accelerating a chemical reaction with a catalyst.

catalyst Substance with the ability to accelerate a spontaneous reaction without being changed by the reaction.

catastrophism The theory that Earth has been affected by sudden, violent events that were sometimes worldwide in scope.

catecholamine Any of a class of compounds derived from the amino acid tyrosine that circulates in the bloodstream, including epinephrine and norepinephrine.

cation A positively charged ion.

cation exchange Replacement of one cation with another, as on a soil particle.

$CD4^+$ T cell A type of T cell in the lymphatic system that has CD4 receptors on its surface. This type of T cell binds to an antigen-presenting cell in antibody-mediated immunity.

$CD8^+$ T cell A type of T cell in the lymphatic system that has CD8 receptors on its surface. This type of T cell binds to an antigen-presenting cell in cell-mediated immunity.

cDNA library The entire collection of cloned cDNAs made from the mRNAs isolated from a cell.

cecum A blind pouch formed at the junction of the large and small intestine.

cell Smallest unit with the capacity to live and reproduce.

cell adhesion molecule A cell surface protein responsible for selectively binding cells together.

cell adhesion protein Protein that binds cells together by recognizing and binding receptors or chemical groups on other cells or on the extracellular matrix.

cell body The portion of the neuron containing genetic material and cellular organelles.

cell center *See* **centrosome.**

cell culture Living cells growing in a growth medium in a laboratory vessel.

cell cycle The sequence of events during which a cell experiences a period of growth followed by nuclear division and cytokinesis.

cell differentiation A process in which changes in gene expression establish cells with specialized structure and function.

cell expansion A mechanism that enlarges the cells in specific directions in a developing organ.

cell fractionation Technique that divides cells into fractions containing a single cell component.

cell junction Junction that seals the spaces between cells and provides direct communication between cells.

cell lineage Cell derivation from the undifferentiated tissues of the embryo.

cell plate In cytokinesis in plants, a new cell wall that forms between the daughter nuclei and grows laterally until it divides the cytoplasm.

cell signaling The system of communication between cells through signaling pathways.

cell theory Three generalizations yielded by microscopic observations: all organisms are composed of one or more cells; the cell is the smallest unit that has the properties of life; and cells arise only from the growth and division of preexisting cells.

cell wall A rigid external layer of material surrounding the plasma membrane of cells in plants, fungi, bacteria, and some protists, providing cell protection and support.

cell-mediated immunity An adaptive immune response in which a subclass of T cells—cytotoxic T cells—becomes activated and, with other cells of the immune system, attacks host cells infected by pathogens, particularly those infected by a virus.

cellular respiration The process by which energy-rich molecules are broken down to produce energy in the form of ATP.

cellular slime mold Any of a variety of primitive organisms of the phylum Acrasiomycota, especially of the genus *Dictyostelium;* the life cycle is characterized by a slimelike amoeboid stage and a multicellular reproductive stage.

cellulose One of the primary constituents of plant cell walls, formed by chains of carbohydrate subunits.

centimorgan *See* **map unit.**

central canal The central portion of the vertebral column in which the spinal cord is found.

central dogma The name given by Francis Crick to the flow of information from DNA to RNA to protein.

central nervous system (CNS) One of the two major divisions of the nervous system containing the brain and spinal cord.

central vacuole A large, water-filled organelle in plant cells that maintains the turgor of the cell and controls movement of molecules between the cytosol and sap.

centriole A cylindrical structure consisting of nine triplets of microtubules in the centrosomes of most animal cells.

centromere A specialized chromosomal region that connects sister chromatids and attaches them to the mitotic spindle.

centrosome (cell center) The main microtubule organizing center of a cell, which organizes the microtubule cytoskeleton during interphase and positions many of the cytoplasmic organelles.

cephalothorax The anterior section of an arachnid, consisting of a fused head and thorax.

cerebellum The portion of the brain that receives sensory input from receptors in muscles and joints, from balance receptors in the inner ear, and from the receptors of touch, vision, and hearing.

cerebral cortex A thin outer shell of gray matter covering a thick core of white matter within each hemisphere of the brain; the part of the forebrain responsible for information processing and learning.

cerebrospinal fluid Fluid that circulates through the central canal of the spinal cord and the ventricles of the brain, cushioning the brain and spinal cord from jarring movements and impacts, as well as nourishing the CNS and protecting it from toxic substances.

cervix The lower end of the uterus.

channel protein Transport protein that forms a hydrophilic channel in a cell membrane through which water, ions, or other molecules can pass, depending on the protein.

chaparral A biome comprising a scrubby mix of short trees and shrubs that dominates coastal land between 30° and 40° latitude, where winters are cool and wet and summers hot and dry.

chaperone protein (chaperonin) "Guide" protein that binds temporarily with newly synthesized proteins, directing their conformation toward the correct tertiary structure and inhibiting incorrect arrangements as the new proteins fold.

character A specific heritable attribute or property of an organism.

character differences Alternative forms of characters. Also called a *trait.*

character displacement The phenomenon in which allopatric populations are morphologically similar and use similar resources, but sympatric populations are morphologically different and use different resources; may also apply to characters influencing mate choice.

character states One or more forms of a character used in a phylogenetic analysis.

charging *See* **aminoacylation.**

charophyte A member of the group of green algae most similar to the algal ancestors of land plants.

checkpoint Internal control of the cell cycle that prevents a critical phase from beginning until the previous phase is complete.

chelicerae The first pair of fanglike appendages near the mouth of an arachnid, used for biting prey and often modified for grasping and piercing.

chemical bond Link formed when atoms of reactive elements combine into molecules.

chemical equation A chemical reaction written in balanced form.

chemical reaction A reaction that occurs when atoms or molecules interact to form new chemical bonds or break old ones.

chemical signal Any secretion from one cell type that can alter the behavior of a different cell that bears a receptor for it; a means of cell communication.

chemical synapse In the nervous system where the plasma membranes of the presynaptic and postsynaptic cells are separated by a narrow gap. Communication across such a synapse occurs by means of a neurotransmitter; that is, an electrical impulse

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

arriving at an axon terminal of the presynaptic cell triggers release of a neurotransmitter that crosses the gap and binds to a receptor on the postsynaptic cell, triggering an electrical impulse in that cell.

chemiosmotic hypothesis Model proposing that mitochondrial electron transfer produces an H^+ gradient and that the gradient powers ATP synthesis by ATP synthase.

chemoautotroph An organism that obtains energy by oxidizing inorganic substances such as hydrogen, iron, sulfur, ammonia, nitrites, and nitrates and uses carbon dioxide as a carbon source.

chemoheterotroph An organism that oxidizes organic molecules as an energy source and obtains carbon in organic form.

chemokine A protein secreted by activated macrophages that attracts other cells, such as neutrophils.

chemoreceptor A sensory receptor that detects specific molecules, or chemical conditions such as acidity.

chemotroph An organism that obtains energy by oxidizing inorganic or organic substances.

chiasmata *See* **crossover.**

chief cells Cells in the gastric glands of the stomach lining that secrete pepsinogen.

chitin A polysaccharide that contains nitrogen and is present in the cell walls of fungi and the exoskeletons of arthropods.

Chlorarachniophyta (chlorarachniophytes) A lineage within the Rhizaria protist evolutionary group; green, photosynthetic amoebas that also engulf food.

chlorophyll Molecule of green pigment that absorbs photons of light in photosynthesis.

Chlorophyta (green algae) A lineage within the Archaeplastida protist evolutionary group; autotrophs that carry out photosynthesis using the same pigments as plants.

chloroplast The site of photosynthesis in plant cells.

chlorosis An abnormal yellowing of plant tissues due to lack of chlorophyll; a sign of nutrient deficiency or infection by a pathogen.

choanocyte One of the inner layer of flagellated cells lining the body cavity of a sponge.

Choanoflagellata (choanoflagellates) A group of minute, single-celled protists found in water; the flask-shaped body has a collar of closely packed microvilli that surrounds the single flagellum by which it moves and takes in food. Choanoflagellates are a subgroup of the opisthokonts.

cholecystokinin (CCK) Hormone released in response to fat, and to a lesser extent protein, in the chyme that enters the duodenum and inhibits gastric activity.

cholesterol The predominant sterol of animal cell membranes.

chondrocyte A cartilage-producing cell.

chorion In an amniote egg, an extraembryonic membrane that surrounds the embryo and yolk sac completely and exchanges oxygen and carbon dioxide with the environment; becomes part of the placenta in mammals.

chorionic villus (plural, *villi*) One of many treelike extensions from the chorion, which greatly increase the surface area of the chorion.

chorionic villus sampling Technique of prenatal diagnosis in which cells are obtained from portions of the placenta that develop from tissues of the embryo for DNA testing, for biochemical analysis, or to test for the presence of chromosomal mutations.

Chromalveolata (chromalveolates) A protist evolutionary group consisting of the Alveolata and the Stramenopila.

chromatin Any assemblage of eukaryotic nuclear DNA molecules and their associated proteins.

chromoplast Plastid containing red and yellow pigments.

chromosomal mutation A variation from the normal condition in chromosome structure or chromosome number.

chromosomal protein A histone and nonhistone protein associated with DNA in a eukaryotic nuclear chromosome.

chromosome In eukaryotic cells, a linear structure composed of a single DNA molecule complexed with protein. Each eukaryotic species has a characteristic number of chromosomes in the nucleus. Most prokaryotes have a single, usually circular chromosome with few or no associated proteins.

chromosome segregation The equal distribution of daughter chromosomes to each of the two cells that result from cell division.

chromosome theory of inheritance The principle that genes and their alleles are carried on the chromosomes.

Chrysophyta (golden algae) A lineage of the Stramenopila subgroup of the Chromalveolata protist evolutionary group; mostly colonial protists in which each cell of a colony has a pair of flagella and is surrounded by a glassy shell.

chylomicron A small triglyceride droplet coated with a layer of lipoprotein from the endoplasmic reticulum.

chyme Digested content of the stomach released for further digestion in the small intestine.

chymotrypsin An enzyme that digests peptides to produce small peptides.

ciliary body A fine ligament in the eye that anchors the lens to a surrounding layer of connective tissue and muscle.

Ciliophora (ciliates) A lineage of the Alveolata subgroup of the Chromalveolata protist evolutionary group.

cilium Motile structure, extending from a cell surface, that moves a cell through fluid or fluid over a cell.

circadian rhythm Any biological activity that is repeated in cycles, each about 24 hours long, independently of any shifts in environmental conditions.

circulatory system An organ system consisting of a fluid, a heart, and vessels for moving important molecules, and often cells, from one tissue to another.

circulatory vessel An element of the circulatory system through which fluid flows and carries nutrients and oxygen to tissues and remove wastes.

circumcision Removal of the prepuce for religious, cultural, or hygienic reasons.

cisternae Membranous channels and vesicles that make up the endoplasmic reticulum.

citric acid cycle Series of reactions in which acetyl groups are oxidized completely to carbon dioxide and some ATP molecules are synthesized. Also referred to as *Krebs cycle* and *tricarboxylic acid cycle.*

clade A monophyletic group of organisms that share homologous features derived from a common ancestor.

cladistics An approach to systematics that uses shared derived characters to infer the phylogenetic relationships and evolutionary history of groups of organisms.

cladogenesis The evolution of two or more descendant species from a common ancestor.

cladogram A branching diagram in which the endpoints of the branches represent different species of organisms, used to illustrate phylogenetic relationships.

claspers A pair of organs on the pelvic fins of male crustaceans and sharks, which help transfer sperm into the reproductive tract of the female.

class A Linnaean taxonomic category that ranks below a phylum and above an order.

class II major histocompatibility complex (MHC) A collection of proteins that present antigens on the cell surface of an antigen-presenting cell in an antibody-mediated immune response.

classical conditioning A type of learning in which an animal develops a mental association between two phenomena that are usually unrelated.

classification An arrangement of organisms into hierarchical groups that reflect their relatedness.

clathrin The network of proteins that coat and reinforce the cytoplasmic surface of cell membranes.

cleavage Mitotic cell divisions of the zygote that produce a blastula from a fertilized ovum.

climate The weather conditions prevailing over an extended period of time.

climax community A relatively stable, late successional stage in which the dominant vegetation replaces itself and persists until an environmental disturbance eliminates it, allowing other species to invade.

climograph A graph that portrays the particular combination of temperature and rainfall conditions where each terrestrial biome occurs.

cline A pattern of smooth variation in a characteristic along a geographical gradient.

clitoris The structure at the junction of the labia minora in front of the vulva, homologous to the penis in the male.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

cloaca The cavity in reptiles, birds, amphibians, and many fishes into which both the intestinal and genital tracts empty.

clonal analysis A method of culturing meristematic tissue that contains a mutated embryonic cell having a readily observable trait, such as the absence of normal pigment.

clonal expansion In antibody-mediated immunity, the proliferation of an activated $CD4^+$ T cell by cell division to produce a clone of cells.

clonal reproduction The type of asexual reproduction in which the parent and offspring are genetically identical to one another.

clonal selection The process by which a lymphocyte is specifically selected for cloning when it encounters a foreign antigen from among a randomly generated, enormous diversity of lymphocytes with receptors that specifically recognize the antigen.

clone An individual genetically identical to an original cell from which it descended.

cloning vector DNA molecule into which a DNA fragment can be inserted to form a recombinant DNA molecule for the purpose of cloning.

closed circulatory system A circulatory system in which the fluid, blood, is confined in blood vessels and is distinct from the interstitial fluid.

clumped dispersion A pattern of distribution in which individuals in a population are grouped together.

cnidocyte A prey-capturing and defensive cell in the epidermis of cnidarians.

CO_2 fixation Process in which electrons are used as a source of energy to convert inorganic CO_2 to an organic form.

coactivator (mediator) In eukaryotes, a large multiprotein complex that bridges between activators at an enhancer and proteins at the promoter and promoter proximal region to stimulate transcription.

coat *See* **capsid.**

coated pit A depression in the plasma membrane that contains receptors for macromolecules to be taken up by endocytosis.

coccus (plural, *cocci*) A spherical prokaryote.

cochlea A snail-shaped structure in the inner ear containing the organ of hearing.

codominance Condition in which alleles have approximately equal effects in individuals, making the alleles equally detectable in heterozygotes.

codon Each three-letter word (triplet) of the genetic code.

coelom A fluid-filled body cavity in bilaterally symmetrical animals that is completely lined with derivatives of mesoderm.

coelomate A body plan of bilaterally symmetrical animals that have a coelom.

coenocytic Condition in which a single cell has many nuclei.

coenzymes Organic cofactors that include complex chemical groups of various kinds.

coevolution The evolution of genetically based, reciprocal adaptations in two or more species that interact closely in the same ecological setting.

cofactor An inorganic or organic nonprotein group that is necessary for catalysis to take place.

cognition A form of learning in which animals use insight to solve a novel problem; sometimes called trial-and-error learning.

cohesion The high resistance of water molecules to separation.

cohesion–tension mechanism of water transport A model of how water is transported from roots to leaves in vascular plants; the evaporation of water from leaves pulls water up in xylem by creating a continuous negative pressure (tension) that extends to roots.

cohort A group of individuals of similar age.

coleoptile A protective sheath that covers the shoot apical meristem and plumule of the embryo in monocots, such as grasses, as it pushes up through soil.

coleorhiza A sheath that encloses the radicle of an embryo until it breaks out of the seed coat and enters the soil as the primary root.

collagen Fibrous glycoprotein—very rich in carbohydrates—embedded in a network of proteoglycans.

collecting duct A location where urine leaving individual nephrons is processed further.

collenchyma A ground tissue that flexibly supports rapidly growing plant parts. Its elongated cells are alive at maturity and collectively often form strands or a sheathlike cylinder under the dermal tissue of growing shoot regions and leaf stalks.

colon The main part of the large intestine.

colony Multiple individual organisms of the same species living in a group.

combinatorial gene regulation The combining of a few regulatory proteins in particular ways so that the transcription of a wide array of genes can be controlled and a large number of cell types can be specified.

commaless The sequential nature of the words of the nucleic acid code, with no indicators such as commas or spaces to mark the end of one codon and the beginning of the next.

commensalism A symbiotic interaction in which one species benefits and the other is unaffected.

community Populations of all species that occupy the same area.

community ecology The ecological discipline that examines groups of populations occurring together in one area.

companion cell A specialized parenchyma cell that is connected to a mature sieve tube member by plasmodesmata and assists sieve tube members both with the uptake of sugars and with the unloading of sugars in tissues.

comparative genomics Comparison of the sequences of entire genomes (or extensive portions of them) to understand evolutionary relationships and the basic biological similarities and differences among species.

comparative morphology Analysis of the structure of living and extinct organisms.

compartment model A graphical depiction of the pathways through which nutrients and energy move between the living and nonliving components of an ecosystem.

compass orientation A wayfinding mechanism that allows animals to move in a particular direction, often over a specific distance or for a prescribed length of time.

competitive exclusion principle The ecological principle stating that populations of two or more species cannot coexist indefinitely if they rely on the same limiting resources and exploit them in the same way.

competitive inhibition Inhibition of an enzyme reaction by an inhibitor molecule that resembles the normal substrate closely enough so that it fits into the active site of the enzyme.

complement system A nonspecific defense mechanism activated by invading pathogens, made up of more than 30 interacting soluble plasma proteins circulating in the blood and interstitial fluid.

complementary base pairing Feature of DNA in which the specific purine–pyrimidine base pairs A–T (adenine–thymine) and G–C (guanine–cytosine) occur to bridge the two sugar–phosphate backbones.

complementary DNA (cDNA) A DNA molecule that is complementary to an mRNA molecule, synthesized by reverse transcriptase.

complete digestive system A digestive system having a mouth at one end, through which food enters, and an anus at the other end, through which undigested waste is voided.

complete flower A flower in which all four whorls (sepals, petals, stamens, carpels) are present.

complete medium A growth medium containing a full complement of nutrient substances that a wild-type microorganism can make for itself.

complete metamorphosis The form of metamorphosis in which an insect passes through four separate stages of growth: egg, larva, pupa, and adult.

complex virus A bacteriophage with a DNA genome that has a tail attached at one side of a polyhedral head.

compound A molecule whose component atoms are different.

compound eye The eye of most insects and some crustaceans, composed of many faceted, light-sensitive units called ommatidia fitted closely together, each having its own refractive system and each forming a portion of an image.

concentration The number of molecules or ions of a substance in a unit volume of space.

concentration gradient A difference in concentration of molecules or ions between two areas.

condensation reaction Reaction during which the components of a water molecule are removed, usually as part of the assembly of a larger molecule from smaller subunits. Also referred to as *dehydration synthesis reaction.*

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

conduction The flow of heat between atoms or molecules in direct contact.

cone In the vertebrate eye, a photoreceptor in the retina that is specialized for detection of different wavelengths (colors). In cone-bearing plants, a cluster of sporophylls.

conformation The overall three-dimensional shape of a protein.

conformational change Alteration in the three-dimensional shape of a protein.

conformers Animals having internal environments that change as the external environment changes.

conidiophore In ascomycete fungi, a modified hyphal branch that gives rise to conidia.

conidium (plural, *conidia*) An asexual spore produced by many species of ascomycetes.

Coniferophyta The major phylum of cone-bearing gymnosperms, most of which are substantial trees; includes pines, firs, and other conifers.

conjugation In bacteria, the process by which DNA of the donor cell moves through the cytoplasmic bridge into the recipient cell. With some types of donor cells, this can lead to genetic recombination in the recipient cell. In ciliate protists, a process of sexual reproduction in which individuals of the same species temporarily couple and exchange genetic material.

connective tissue Tissue having cells scattered through an extracellular matrix; forms layers in and around body structures that support other body tissues, transmit mechanical and other forces, and in some cases act as filters.

conodont An abundant, bonelike fossil dating from the early Paleozoic era through the early Mesozoic era, now described as a feeding structure of some of the earliest vertebrates.

consciousness Awareness of oneself, identity, and surroundings, with understanding of the significance and likely consequences of events.

conservation biology An interdisciplinary science that focuses on the maintenance and preservation of biodiversity.

constant (C) region For the light and heavy polypeptides of a particular type of antibody molecule, the regions that have the same amino acid sequences for all molecules.

consumer An organism that consumes other organisms in a community or ecosystem.

contact inhibition The inhibition of movement or proliferation of normal cells that results from cell–cell contact.

continental climate Climate not moderated by the distant ocean.

continental drift The long-term movement of continents as a result of plate tectonics.

continuous distribution A geographical distribution in which a species lives in suitable habitats throughout a geographical area.

contraception The prevention of pregnancy.

contractile vacuole A specialized cytoplasmic organelle that pumps fluid in a cyclical manner from within the cell to the outside by alternately filling and then contracting to release its contents at various points on the surface of the cell.

control Treatment that tells what would be seen in the absence of the experimental manipulation.

convection The transfer of heat from a body to a fluid, such as air or water, that passes over its surface.

convergent evolution The evolution of similar adaptations in distantly related organisms that occupy similar environments.

copulation The physical act involving the introduction of the accessory sex organ of a male into the accessory sex organ of a female to accomplish internal fertilization.

coral reef A structure made from the hard skeletons of coral animals or polyps; found largely in tropical and subtropical marine environments.

corepressor In the regulation of gene expression in bacteria, a regulatory molecule that combines with a repressor to activate it and shut off an operon.

cork A nonliving, impermeable secondary tissue that is one element of bark.

cork cambium A lateral meristem in plants that forms periderm, which in turn produces cork.

cornea The transparent layer that forms the front wall of the eye, covering the iris.

corolla The structure formed collectively by the petals of a flower.

coronary arteries The arteries from the aorta that branch extensively over the heart, supplying blood to the cardiac muscle cells.

corpus callosum A structure formed of thick axon bundles that connect the two cerebral hemispheres and coordinate their functions.

corpus luteum Cells remaining at the surface of the ovary during the luteal phase; the structure acts as an endocrine gland, secreting several hormones: estrogens, large quantities of progesterone, and inhibin.

cortex Generally, an outer, rindlike layer. In mammals, the outer layer of the brain, the kidneys, or the adrenal glands. In plants, the outer region of tissue in a root or stem lying between the epidermis and the vascular tissue, composed mainly of parenchyma.

cortical granule A secretory vesicle just under the plasma membrane of an egg cell.

cortical reaction The reaction in which cortical granules fuse with the plasma membrane of the egg and release their contents to the outside.

cortisol The major glucocorticoid steroid hormone secreted by the adrenal cortex, which increases blood glucose by promoting breakdown of proteins and fats.

cotranslational import A mechanism by which a polypeptide being sorted via the endomembrane system in a eukaryotic cell begins its import into the endoplasmic reticulum simultaneously with translation of the mRNA encoding the polypeptide.

cotransport *See* **symport.**

countercurrent exchange A mechanism in which the water flowing over the gills moves in a direction opposite to the flow of blood under the respiratory surface.

coupled reaction Reaction that occurs when an exergonic reaction is joined to an endergonic reaction, producing an overall reaction that is exergonic.

courtship display A behavior performed by males to attract potential mates or to reinforce the bond between a male and a female.

covalent bond Bond formed by electron sharing between atoms.

cranial nerve A nerve that connects the brain directly to the head, neck, and body trunk.

cranium The part of the skull that encloses the brain.

crassulacean acid metabolism (CAM) A biochemical variation of photosynthesis that was discovered in a member of the plant family Crassulaceae. Carbon dioxide is taken up and stored during the night to allow the stomata to remain closed during the daytime, decreasing water loss.

Crenarchaeota A major group of the domain Archaea that contains most of the extreme thermophiles. The group also includes psychrophiles and mesophiles. Members include obligate anaerobes, facultative anaerobes, and aerobes.

criss-cross inheritance The transmission pattern characteristic of an X-linked allele from a parent of one sex to a "child" of the opposite sex to a "grandchild" of the first sex.

crista Fold that expands the surface area of the inner mitochondrial membrane.

critical period A restricted stage of development early in life during which an animal has the capacity to respond to specific environmental stimuli.

crop Of birds, an enlargement of the digestive tube where the digestive contents are stored and mixed with lubricating mucus.

cross-fertilization Fertilization of one plant by a different plant.

crossing-over The recombination process in meiosis, in which chromatids exchange segments.

crossover Site of recombination during meiosis. Also referred to as a *chiasmata*.

cross-pollination *See* **cross-fertilization.**

cross-talk Interaction by which cell signaling pathways communicate with one another to integrate their responses to cellular signals.

cryptic coloration Coloration that allows an organism to match its background and hence become less vulnerable to predation or recognition by prey.

cryptochrome A light-absorbing protein that is sensitive to blue light and that may also be an important early step in various light-based growth responses.

C-terminal end The end of an amino acid chain with a $—COO^-$ group.

cupula In certain mechanoceptors, a gelatinous structure with stereocilia extending into it that moves with pressure changes in the surrounding

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

water; movement of the cupula bends the stereocilia, which triggers release of neurotransmitters.

cuticle The outer layer of plants and some animals, which helps prevent desiccation by slowing water loss.

Cycadophyta A phylum of palmlike gymnosperms known as cycads; the pollen-bearing and seed-bearing cones (strobili) occur on separate plants.

cyclic AMP (cAMP) In particular signal transduction pathways, a second messenger that activates protein kinases, which elicit the cellular response by adding phosphate groups to specific target proteins. cAMP functions in one of two major G-protein–coupled receptor–response pathways.

cyclic electron flow An electron transport pathway associated with photosystem I in photosynthesis that produces ATP without the synthesis of NADPH.

cyclin In eukaryotes, protein that regulates the activity of CDK (cyclin-dependent kinase) and controls progression through the cell cycle.

cyclin-dependent kinase (CDK) A protein kinase that controls the cell cycle in eukaryotes.

cytochrome Protein with a heme prosthetic group that contains an iron atom.

cytokine A molecule secreted by one cell type that binds to receptors on other cells and, through signal transduction pathways, triggers a response. In innate immunity, cytokines are secreted by activated macrophages.

cytokinesis Division of the cytoplasm into two daughter cells following nuclear division in mitosis or meiosis.

cytokinin A hormone that promotes and controls growth responses of plants.

cytoplasm All the parts of the cell that surround the central nucleus (eukaryotes) or nucleoid region (prokaryotes).

cytoplasmic determinants The mRNA and proteins stored in the egg cytoplasm that direct the early stages of animal development in the period before genes of the zygote become active.

cytoplasmic inheritance Pattern in which inheritance follows that of genes in the cytoplasmic organelles, mitochondria, or chloroplasts.

cytoplasmic streaming Intracellular movement of cytoplasm.

cytosine A pyrimidine that base-pairs with guanine in nucleic acids.

cytoskeleton The interconnected system of protein fibers and tubes that extends throughout the cytoplasm of a eukaryotic cell.

cytosol Aqueous solution in the cytoplasm containing ions and various organic molecules.

cytotoxic T cell A T lymphocyte that functions in cell-mediated immunity to kill body cells infected by viruses or transformed by cancer.

daily torpor A period of inactivity and lowered metabolic rate that allows an endotherm to conserve energy when environmental temperatures are low.

dalton A standard unit of mass, about 1.66×10^{-24} grams.

day-neutral plant A plant that flowers without regard to photoperiod.

decomposer A small organism, such as a bacterium or fungus, that feeds on the remains of dead organisms, breaking down complex biological molecules or structures into simpler raw materials.

dedifferentiation A process in which cells lose their normal regulatory controls and revert partially or completely to an embryonic developmental state.

deep vein thrombosis A medical condition that results when sitting for a long period of time causes blood to pool in the veins of the body below the heart and then clot, particularly in the legs.

defecation reflex The opening of the anal sphincter and expulsion of feces in response to feces entering the rectum and stretching the rectal wall.

degeneracy (redundancy) The feature of the genetic code in which, with two exceptions, more than one codon represents each amino acid.

dehydration synthesis reaction *See* **condensation reaction.**

deletion Chromosomal alteration that occurs if a broken segment is lost from a chromosome.

demographic transition model A graphical depiction of the historical relationship between a country's economic development and its birth and death rates.

demography The statistical study of the processes that change a population's size and density through time.

denaturation A loss of both the structure and function of a protein due to extreme conditions that unfold it from its normal conformation.

dendrite The branched extension of the nerve cell body that receives signals from other nerve cells.

dendritic cell A type of phagocyte, so called because it has many surface projections that resemble dendrites of neurons, which engulfs a bacterium in infected tissue by phagocytosis.

denitrification A metabolic process in which certain bacteria convert nitrites or nitrates into nitrous oxide and then into molecular nitrogen, which enters the atmosphere.

density-dependent Description of environmental factors for which the strength of their effect on a population varies with the population's density.

density-independent Description of environmental factors for which the strength of their effect on a population does not vary with the population's density.

deoxyribonucleic acid (DNA) The large, double-stranded, helical molecule that contains the genetic material of all living organisms.

deoxyribonucleotide Nucleotide containing deoxyribose as the sugar; deoxyribonucleotides are components of DNA.

deoxyribose A 5-carbon sugar to which a nitrogenous base and a phosphate group link covalently in a nucleotide of DNA.

depolarized State of the membrane (which was polarized at rest) as the membrane potential becomes less negative.

deposit feeder An animal that consumes particles of organic matter from the solid substrate on which it lives.

derivative One of the daughter cells produced when a plant cell divides; it typically divides once or twice and then enters on the path to differentiation.

derived character A new version of a trait found in the most recent common ancestor of a group.

dermal tissue system The plant tissue system that comprises the outer tissues of the plant body, including the epidermis and periderm; it serves as a protective covering for the plant body.

dermis The skin layer below the epidermis; it is packed with connective tissue fibers such as collagen, which resist compression, tearing, or puncture of the skin.

descending reticular formation Part of the reticular formation that receives information from the hypothalamus and connects with interneurons in the spinal cord that control skeletal muscle contraction, thereby controlling muscle movement and posture.

descent with modification Biological evolution.

desert A sparsely vegetated biome that forms where rainfall averages less than 25 cm per year.

desertification A process in which large tracts of subtropical forest are cleared and overused, the groundwater table recedes to deeper levels, less surface water is available for plants, soil accumulates high concentrations of salts, and topsoil is eroded by wind and water.

desmosome Anchoring junction for which microfilaments anchor the junction in the underlying cytoplasm.

determinate cleavage A type of cleavage in protostomes in which each cell's developmental path is determined as the cell is produced.

determinate growth The pattern of growth in most animals in which individuals grow to a certain size and then their growth slows dramatically or stops.

determination Mechanism in which the developmental fate of a cell is set.

detritivore An organism that extracts energy from the organic detritus (refuse) produced at other trophic levels.

development A series of programmed changes encoded in DNA, through which a fertilized egg divides into many cells that ultimately are transformed into an adult, which is itself capable of reproduction.

diabetes mellitus A disease that results from problems with insulin production or action.

diacylglycerol (DAG) In particular signal transduction pathways, a second messenger that activates protein kinases, which elicit the cellular response by adding phosphate groups to specific target proteins. DAG is involved in one of two major G-protein–coupled receptor–response pathways.

diapsid A member of a group within the amniote vertebrates having a skull with two temporal arches.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Their living descendants include lizards and snakes, crocodilians, and birds.

diastole The period of relaxation and filling of the heart between contractions.

diastolic blood pressure The low point of the arterial blood pressure in the cardiac cycle that occurs between ventricular contractions.

diatoms *See* **Bacillariophyta.**

differentiation Process by which cells that have been committed to a particular developmental fate by the determination process now develop into specialized cell types with distinct structures and functions.

diffusion The net movement of ions or molecules from a region of higher concentration to a region of lower concentration.

digestion The splitting of carbohydrates, proteins, lipids, and nucleic acids in foods into chemical subunits small enough to be absorbed into the body fluids and cells of an animal.

digestive tract Part of an extracellular digestive system; it is tubelike with two openings that form a separate mouth and anus. Digestive contents move in one direction through specialized regions of the tube, from the mouth to the anus.

dihybrid A zygote produced from a cross that involves two characters.

dihybrid cross A cross between two individuals that are heterozygous for two pairs of alleles.

dikaryon The life stage in certain fungi in which a cell contains two genetically distinct haploid nuclei.

Dinoflagellata (dinoflagellates) A lineage of the Alveolata subgroup of the Chromalveolata protist evolutionary group; mostly single-celled marine phytoplankton that live as heterotrophs or autotrophs or sometimes using both modes of nutrition.

dioecious Having male flowers and female flowers on different plants of the same species.

dipeptidase An enzyme that splits dipeptides (two amino acids joined together) into individual amino acids.

diploblastic An animal body plan in which adult structures arise from only two cell layers, the ectoderm and the endoderm.

diploid An organism or cell with two copies of each type of chromosome in its nucleus.

directional selection A type of selection in which individuals near one end of the phenotypic spectrum have the highest relative fitness.

disaccharidase An enzyme that splits disaccharides (two sugar molecules joined together) into individual monosaccharides (single sugar molecules).

disclimax community An ecological community in which regular disturbance inhibits successional change.

discontinuous replication Replication in which a DNA strand is formed in short lengths that are synthesized in the direction opposite of DNA unwinding.

disjunct distribution A geographical distribution in which populations of the same species or closely related species live in widely separated locations.

dispersal The movement of organisms away from their place of origin.

dispersed duplication Gene copies that are found in different places in the genome, often on two different chromosomes.

dispersion The spatial distribution of individuals within a population's geographical range.

disruptive selection A type of natural selection in which extreme phenotypes have higher relative fitness than intermediate phenotypes.

dissociation The separation of water to produce hydrogen ions and hydroxide ions.

distal convoluted tubule The tubule in the human nephron that drains urine into a collecting duct that leads to the renal pelvis.

disulfide linkage Linkage that occurs when two sulfhydryl groups interact during a linking reaction.

DNA *See* **deoxyribonucleic acid.**

DNA chip *See* **DNA microarray.**

DNA fingerprinting Technique in which DNA samples are used to distinguish between individuals of the same species.

DNA helicase An enzyme that catalyzes the unwinding of DNA template strands.

DNA hybridization Technique in which a gene or sequence of interest is identified in a set of clones when it base pairs with a single-stranded DNA or RNA molecule called a nucleic acid probe.

DNA ligase In DNA replication, an enzyme that seals the nicks left after RNA primers are replaced with DNA.

DNA methylation Process in which a methyl group is added enzymatically to cytosine bases in the DNA.

DNA microarray A solid surface divided into a microscopic grid of thousands of spaces each containing thousands of copies of a DNA probe. DNA chips are used commonly for analysis of gene activity and for detecting differences between cell types. Also referred to as a *DNA chip.*

DNA polymerase I In *E. coli,* the replication enzyme that replaces the RNA primer at the start of a new DNA segment with DNA.

DNA polymerase III The principal replication polymerase in *E. coli* that synthesizes the majority of the new DNA.

DNA repair mechanism Mechanism to correct base-pair mismatches that escape proofreading.

DNA technologies Techniques to isolate, purify, analyze, and manipulate DNA sequences.

domain In protein structure, a distinct, large structural subdivision produced in many proteins by the folding of the amino acid chain. In systematics, the highest taxonomic category; a group of cellular organisms with characteristics that set it apart as a major branch of the evolutionary tree.

dominance The masking effect of one allele over another.

dominance hierarchy A social system in which the behavior of each individual is constrained by that individual's status in a highly structured social ranking.

dominant The allele expressed when paired with a recessive allele.

dominant species The species that is represented by a large proportion of the individuals present in an ecological community.

dormancy A period in the life cycle in which biological activity is suspended.

dorsal Indicating the back side of an animal.

dorsal lip of the blastopore A crescent-shaped depression rotated clockwise 90° on the embryo surface that marks the region derived from the gray crescent, to which cells from the animal pole move as gastrulation begins.

dosage compensation mechanism Mechanism in placental mammals by which the effects of most genes carried on the X chromosome in females are equalized in females (who have two X chromosomes) and males (who have one X chromosome).

double fertilization A characteristic feature of sexual reproduction in flowering plants. In the embryo sac, one sperm nucleus unites with the egg to form a diploid zygote from which the embryo develops, and another unites with two polar nuclei to form the primary endosperm nucleus.

double helix Two nucleotide chains wrapped around each other in a spiral.

double-helix model Model of DNA consisting of two polynucleotide strands twisted around each other.

downy mildews One of the subgroups of the Oomycota; parasites of plants.

duodenum A short region of the small intestine where secretions from the pancreas and liver enter a common duct.

duplication Chromosomal alteration that occurs if a segment is broken from one chromosome and inserted into its homolog.

E site The site where an exiting tRNA binds before its release from the ribosome in translation.

ecdysis Shedding of the cuticle, exoskeleton, or skin; molting.

ecdysone A steroid hormone secreted by the prothoracic glands of insects.

echolocation A technique for locating prey by making squeaking or clicking noises, and then listening for the echoes that bounce back from objects in their environment.

ecological community An assemblage of species living in the same place.

ecological efficiency The ratio of net productivity at one trophic level to net productivity at the trophic level below it.

ecological isolation A prezygotic reproductive isolating mechanism in which species that live in the same geographical region occupy different habitats.

ecological niche The resources a population uses and the environmental conditions it requires over its lifetime.

ecological pyramid A diagram illustrating the effects of energy transfer from one trophic level to the next.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ecological succession A somewhat predictable series of changes in the species composition of a community over time.

ecology The study of the interactions between organisms and their environments.

ecosystem Group of biological communities interacting with their shared physical environment.

ecosystem ecology An ecological discipline that explores the cycling of nutrients and the flow of energy between the biotic components of an ecological community and the abiotic environment.

ecosystem services The ecological processes on which all life depends, which include decomposition of wastes, nutrient recycling, oxygen production, maintenance of fertile topsoil, and air and water purification.

ecosystem valuation A process in which ecosystem services are assigned an economic value.

ecotone A wide transition zone between adjacent communities.

ecotourism An activity in which visitors, often from wealthy countries, pay a fee to visit a nature preserve.

ectoderm The outermost of the three primary germ layers of an embryo, which develops into epidermis and nervous tissue.

ectomycorrhiza A mycorrhiza that grows between and around the young roots of trees and shrubs but does not enter root cells.

ectoparasite A parasite that lives on the exterior of its host organism.

ectotherm An animal that obtains its body heat primarily from the external environment.

edge effect A phenomenon in which the removal of natural vegetation disrupts the local physical environment, exposing the borders of the remaining habitat to additional sunlight, wind, and rainfall.

effector In signal transduction, a plasma membrane–associated enzyme, activated by a G protein, that generates one or more second messengers. In homeostatic feedback, the system that returns the condition to the set point if it has strayed away.

effector T cell A cell involved in effecting—bringing about—the specific immune response to an antigen.

efferent arteriole The arteriole that receives blood from the glomerulus.

efferent neuron A neuron that carries the signals indicating a response away from the interneuron networks to the effectors.

egg cell The female reproductive cell.

elastin A rubbery protein in some connective tissues that adds elasticity to the extracellular matrix—it is able to return to its original shape after being stretched, bent, or compressed.

electrical signaling A means of animal communication in which a signaler emits an electric discharge that can be received by another individual.

electrical synapse In the nervous system, where plasma membranes of the presynaptic and postsynaptic cells are in direct contact and communication across such a synapse occurs by the direct flow of an electrical signal.

electrocardiogram (ECG) Graphic representation of the electrical activity within the heart, detected by electrodes placed on the body.

electrochemical gradient A difference in chemical concentration and electric potential across a membrane.

electromagnetic spectrum The range of wavelengths or frequencies of electromagnetic radiation extending from gamma rays to the longest radio waves and including visible light.

electron Negatively charged particle outside the nucleus of an atom.

electron microscope Microscope that uses electrons to illuminate the specimen.

electron transfer system Stage of cellular respiration in which high-energy electrons produced from glycolysis, pyruvate oxidation, and the citric acid cycle are delivered to oxygen by a sequence of electron carriers.

electronegativity The measure of an atom's attraction for the electrons it shares in a chemical bond with another atom.

electroreceptor A specialized sensory receptor that detects electrical fields.

element A pure substance that cannot be broken down into simpler substances by ordinary chemical or physical techniques.

elimination Referring to the digestive tube, the process in which undigested materials are expelled through the anus.

elongation In transcription, the step in which RNA polymerase (RNA polymerase II in eukaryotes) moves along the gene extending the RNA chain, with the DNA continuing to unwind ahead of the enzyme. In translation, the step in which the assembled translation complex reads the string of codons in the mRNA one at a time while joining the specified amino acids into the polypeptide.

elongation factor (EF) A protein that aids in an elongation step of translation.

embryo An organism in its early stage of reproductive development, beginning in the first moments after fertilization.

embryo sac The female gametophyte of angiosperms, within which the embryo develops; it usually consists of seven cells: an egg cell, an endosperm mother cell, and five other cells with fleeting reproductive roles.

embryogenesis Stages of development from a fertilized egg to an embryo.

embryophyte Any plant in which the embryo is retained within maternal tissue.

emergent property Characteristic that depends on the level of organization of matter, but does not exist at lower levels of organization.

emigration The movement of individuals out of a population.

enantiomers Isomers that are mirror images of each other. Also referred to as *optical isomers.*

endangered species A species in danger of extinction throughout all or a significant portion of its range.

endemic species A species that occurs in only one place on Earth.

endergonic reaction Reaction that can proceed only if free energy is supplied.

endocrine gland Any of several ductless secretory organs that secrete hormones into the blood or extracellular fluid.

endocrine system The system of glands that release their secretions (hormones) directly into the circulatory system.

endocytic vesicle Vesicle that carries proteins and other molecules from the plasma membrane to destinations within the cell.

endocytosis In eukaryotes, the process by which molecules are brought into the cell from the exterior involving a bulging in of the plasma membrane that pinches off to form an endocytic vesicle.

endoderm The innermost of the three primary germ layers of an embryo, which develops into the gastrointestinal tract and, in some animals, the respiratory organs.

endodermis The innermost layer of the root cortex; a selectively permeable barrier that helps control the movement of water and dissolved minerals into the stele.

endomembrane system In eukaryotes, a collection of interrelated internal membranous sacs that divide a cell into functional and structural compartments.

endomycorrhiza A mycorrhiza in which the fungal hyphae penetrate into cells of the root.

endoparasite A parasite that lives in the internal organs of its host organism.

endoplasmic reticulum (ER) In eukaryotes, an extensive interconnected network of cisternae that is responsible for the synthesis, transport, and initial modification of proteins and lipids.

endorphin One of a group of small proteins occurring naturally in the brain and around nerve endings that bind to opiate receptors and thus can raise the pain threshold.

endoskeleton An internal body structure, such as bones, that provides support.

endosperm Nutritive tissue inside the seeds of flowering plants.

endospore A small, metabolically inactive, asexual spore that develops within some bacterial cells when environmental conditions become unfavorable.

endosymbiont Organism that lives symbiotically within a host cell.

endosymbiont theory The proposal that the membranous organelles of eukaryotic cells (mitochondria and chloroplasts) may have originated from symbiotic relationships between two prokaryotic cells.

endotherm An animal that obtains most of its body heat from internal physiological sources.

endothermic Referring to a reaction that absorbs energy, that is, a reaction in which the products have more potential energy than the reactants.

endotoxin A lipopolysaccharide released from the outer membrane of the cell wall when a bacterium dies and lyses.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

end-product inhibition *See* **feedback inhibition.**

energy The capacity to do work.

energy budget The total amount of energy that an organism can accumulate and use to fuel its activities.

energy coupling The process in living cells by which the hydrolysis of ATP is coupled to an endergonic reaction so that energy is not wasted as heat.

energy levels Regions of space within an atom where electrons are found. Also referred to as *shells*.

enhancer In eukaryotes, a region at a significant distance from the beginning of some protein-coding genes that contain regulatory sequences to which regulatory proteins bind to stimulate or inhibit the rate of transcription initiation over and above that seen for regulatory events at the promoter proximal elements.

enterocoelom In deuterostomes, the body cavity pinched off by outpocketings of the archenteron.

enthalpy The potential energy in a system.

entropy Disorder, in thermodynamics.

enveloped virus A virus that has a surface membrane derived from its host cell.

enzymatic hydrolysis A process in which chemical bonds are broken by the addition of H^+ and OH^-, the components of a molecule of water.

enzyme Protein that accelerates the rate of a cellular reaction.

enzyme specificity The ability of an enzyme to catalyze the reaction of only a single type of molecule or group of closely related molecules.

eosinophil A type of leukocyte that targets extracellular parasites too large for phagocytosis in the inflammatory response.

epiblast The top layer of the blastodisc.

epicotyl The upper part of the axis of an early plant embryo, located between the cotyledons and the first true leaves.

epidermis A complex tissue that covers an organism's body in a single, continuous layer or sometimes in multiple layers of tightly packed cells.

epididymis A coiled storage tubule attached to the surface of each testis.

epigenetics A phenomenon in which a change in gene expression does not involve a change in the DNA sequence of the gene or of the genome.

epiglottis A flaplike valve at the top of the trachea.

epilimnion The top layer of the limnetic zone in a lake.

epinephrine A nontropic amine hormone secreted by the adrenal medulla.

epiphyte A plant that grows independently on other plants and obtains nutrients and water from the air.

epistasis Interaction of genes, with one or more alleles of a gene at one locus inhibiting or masking the effects of one or more alleles of a gene at a different locus.

epithelial tissue Tissue formed of sheetlike layers of cells that are usually joined tightly together, with little extracellular matrix material between them. They protect body surfaces from invasion by bacteria and viruses, and secrete or absorb substances.

epitope The small region of an antigen molecule to which BCRs or TCRs bind.

equilibrium potential The electrical potential necessary to balance the diffusional potential of an ion at the plasma membrane of an axon.

equilibrium theory of island biogeography A hypothesis suggesting that the number of species on an island is governed by a give and take between the immigration of new species to the island and the extinction of species already there.

ER (endoplasmic reticulum) lumen The enclosed space surrounded by a cisterna.

erythrocyte A red blood cell, which contains hemoglobin, a protein that transports O_2 in blood.

erythropoietin (EPO) A hormone that stimulates stem cells in bone marrow to increase erythrocyte production.

esophagus A connecting passage of the digestive tube.

essential amino acid Any amino acid that is not made by the human body but must be taken in as part of the diet.

essential element Any of a number of elements required by living organisms to ensure normal reproduction, growth, development, and maintenance.

essential fatty acid Any fatty acid that the body cannot synthesize but needs for normal metabolism.

essential mineral Any inorganic element such as calcium, iron, or magnesium that is required in the diet of an animal.

essential nutrient Any of the essential amino acids, fatty acids, vitamins, and minerals required in the diet of an animal.

estivation Seasonal torpor in an animal that occurs in summer.

estradiol A form of estrogen.

estrogen Any of the group of female sex hormones.

estuary A coastal habitat where tidal seawater mixes with fresh water from rivers, streams, and runoff.

ethology A discipline that focuses on how animals behave in their natural environments.

ethylene A plant hormone that helps regulate seedling growth, stem elongation, the ripening of fruit, and the abscission of fruits, leaves, and flowers.

eudicot A plant belonging to the Eudicotyledones, one of the two major classes of angiosperms; their embryos generally have two seed leaves (cotyledons), and their pollen grains have three grooves.

Euglenids A lineage of the Euglenozoa subgroup of the Excavata protist evolutionary group; free-living with anterior flagella.

Euglenozoa (euglenozoans) A subgroup of the Excavata protist evolutionary group; single-celled, highly motile cells that swim by means of flagella and that contain mitochondria characterized by disc-shaped cristae.

Eukarya The domain that includes all eukaryotes, organisms that contain a membrane-bound nucleus within each of their cells; all protists, plants, fungi, and animals.

eukaryote Organism in which the DNA is enclosed in a nucleus.

eukaryotic chromosome A DNA molecule, with its associated proteins, in the nucleus of a eukaryotic cell.

euploid An individual with a normal set of chromosomes.

Euryarchaeota A major group of the domain Archaea, members of which are found in different extreme environments. They include methanogens, extreme halophiles, and some extreme thermophiles.

eusocial A form of social organization, observed in some insect species, in which numerous related individuals—a large percentage of them sterile female workers—live and work together in a colony for the reproductive benefit of a single queen and her mate(s).

eutrophic lake A lake that is rich in nutrients and organic matter.

evaporation Heat transfer through the energy required to change a liquid to a gas.

evolutionary developmental biology A field of biology that compares the genes controlling the developmental processes of different animals to determine the evolutionary origin of morphological novelties and developmental processes.

evolutionary divergence A process whereby natural selection or genetic drift causes populations to become more different over time.

exaptation A trait that is adaptive in a context different from the context in which it originally evolved.

Excavata A protist evolutionary group; single-celled animal parasites with greatly reduced mitochondria, or organelles derived from mitochondria, that move by means of flagella, and most of which have a scooped-out feeding apparatus on the ventral surface of the cell.

exchange diffusion *See* **antiport.**

excitatory postsynaptic potential (EPSP) The change in membrane potential caused when a neurotransmitter opens a ligand-gated Na^+ channel and Na^+ enters the cell, making it more likely that the postsynaptic neuron will generate an action potential.

excretion The process that helps maintain the body's water and ion balance while ridding the body of metabolic wastes.

exergonic reaction Reaction that has a negative ΔG because it releases free energy.

exocrine gland A gland that is connected to the epithelium by a duct and that empties its secretion at the epithelial surface.

exocytosis In eukaryotes, the process by which a secretory vesicle fuses with the plasma membrane and releases the vesicle contents to the exterior.

exodermis In the roots of some plants, an outer layer of root cortex that may limit water losses from roots and help regulate the absorption of ions.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

exoenzyme An enzymatic protein released by a bacterium that digests plasma membranes and causes cells of the infected host to rupture and die.

exon An amino acid-coding sequence present in pre-mRNA that is retained in a spliced mRNA that is translated to produce a polypeptide.

exon shuffling Molecular evolutionary process that combines exons of two or more existing genes to produce a gene that encodes a protein with an unprecedented function.

exoskeleton A hard external covering of an animal's body that blocks the passage of water and provides support and protection.

exothermic Referring to a reaction that releases energy, that is, a reaction in which the products have less potential energy than the reactants.

exotic species A nonnative organism.

exotoxin A toxic protein that leaks from or is secreted from a bacterium and interferes with the biochemical processes of body cells in various ways.

experimental data Information that describes the result of a careful manipulation of the system under study.

experimental variable The variable in a scientific study that is manipulated by the experimenter.

exploitative competition Form of competition in which two or more individuals or populations use the same limiting resources.

exponential model of population growth Model that describes unlimited population growth.

expression vector Cloning vector that, in addition to normal features, contains regulatory sequences for transcription and translation of a gene.

extensor muscle A muscle that extends a joint, thereby increasing the angle between the two bones; with a flexor muscle, constitutes the antagonistic pair of muscles that control a joint's movement.

external environment The environment outside of the bodies of multicellular organisms.

external fertilization The process in which sperm and eggs are shed into the surrounding water, occurring in most aquatic invertebrates, bony fishes, and amphibians.

external gill A gill that extends out from the body and lacks a protective covering.

extinction The death of the last individual in a species or the last species in a lineage.

extracellular digestion Digestion that takes place outside body cells, in a pouch or tube enclosed within the body.

extracellular fluid The fluid occupying the spaces between cells in multicellular animals.

extracellular matrix (ECM) A molecular system that supports and protects cells and provides mechanical linkages.

extraembryonic membrane A primary tissue layer extended outside the embryo that conducts nutrients from the yolk to the embryo, exchanges gases with the environment outside the egg, or stores metabolic wastes removed from the embryo.

F factor Plasmid in a donor bacterial cell that confers on that cell the ability to conjugate with a recipient bacterial cell.

F pilus Structure on the cell surface that allows an F^+ donor bacterial cell (a cell containing an F factor) to attach to an F^- recipient bacterial cell (a cell lacking an F factor). Also referred to as a *sex pilus*.

F^- cell Recipient cell in conjugation between bacteria; it lacks an F factor.

F^+ cell Donor cell in conjugation between bacteria; it contains an F factor.

F_1 generation The first generation of offspring from a genetic cross.

F_2 generation The second generation of offspring from a genetic cross produced by interbreeding F_1 individuals.

facilitated diffusion Mechanism by which polar and charged molecules diffuse across membranes with the help of transport proteins.

facilitation hypothesis A hypothesis that explains ecological succession, suggesting that species modify the local environment in ways that make it less suitable for themselves but more suitable for colonization by species typical of the next successional stage.

facultative anaerobe An organism that can live in the presence or absence of oxygen, using oxygen when it is present and living by fermentation under anaerobic conditions.

familial (hereditary) cancer Cancer that runs in a family.

family A Linnaean taxonomic category that ranks below an order and above a genus.

family planning program A program that educates people about ways to produce an optimal family size on an economically feasible schedule.

fast block to polyspermy The barrier set up by the wave of depolarization triggered when sperm and egg fuse, making it impossible for other sperm to enter the egg.

fast muscle fiber A muscle fiber that contracts relatively quickly and powerfully.

fat Neutral lipid that is semisolid at biological temperatures.

fate map Mapping of adult or larval structures onto the region of the embryo from which each structure developed.

fat-soluble vitamin A vitamin that dissolves in liquid fat or fatty oils, in addition to water.

fatty acid One of two components of a neutral lipid, containing a single hydrocarbon chain with a carboxyl group linked at one end.

feather A sturdy, lightweight structure of birds, derived from scales in the skin of their ancestors.

feces Condensed and compacted digestive contents in the large intestine.

feedback inhibition In enzyme reactions, regulation in which the product of a reaction acts as a regulator of the reaction. Also referred to as *end-product inhibition*.

fermentation Process in which electrons carried by NADH are transferred to an organic acceptor molecule rather than to the electron transfer system.

fertilization The fusion of the nuclei of an egg and sperm cell, which initiates development of a new individual.

fetus A developing human from the eighth week of gestation onward, at which point the major organs and organ systems have formed.

fever A condition characterized by a rise in body temperature above the normal range.

fiber In sclerenchyma, an elongated, tapered, thick-walled cell that gives plant tissue its flexible strength.

fibrin A protein necessary for blood clotting; fibrin forms a weblike mesh that traps platelets and red blood cells and holds a clot together.

fibrinogen A plasma protein that plays a central role in the blood-clotting mechanism.

fibroblast The type of cell that secretes most of the collagen and other proteins in the loose connective tissue.

fibronectin A class of glycoproteins that aids in the attachment of cells to the extracellular matrix and helps hold the cells in position.

fibrous connective tissue Tissue in which fibroblasts are sparsely distributed among dense masses of collagen and elastin fibers that are lined up in highly ordered, parallel bundles, producing maximum tensile strength and elasticity.

fibrous root system A root system that consists of branching roots rather than a main taproot; roots tend to spread laterally from the base of the stem.

filament In flowers, the stalk of a stamen, which supports the anther.

filtration The nonselective movement of some water and a number of solutes—ions and small molecules, but not large molecules such as proteins—into the proximal end of the renal tubules through spaces between cells.

first law of thermodynamics The principle that energy can be transferred and transformed but it cannot be created or destroyed.

first messenger The extracellular signal molecule in signal transduction pathways controlled by G-protein–coupled receptors.

fission The mode of asexual reproduction in which the parent separates into two or more offspring of approximately equal size.

fixed action pattern A highly stereotyped instinctive behavior; when triggered by a specific cue, it is performed over and over in almost exactly the same way.

flagellum (plural, *flagella*) A long, threadlike cellular appendage responsible for movement; found in both prokaryotes and eukaryotes, but with different structures and modes of locomotion.

flatulence Gas expelled through the anus.

flexor muscle A muscle that decreases the angle between the two bones at a joint, thereby performing the opposite action to an extensor muscle;

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

with an extensor muscle, constitutes the antagonistic pair of muscles that control a joint's movement.

flower The reproductive structure of angiosperms, consisting of floral parts grouped on a stem; the structure in which seeds develop.

fluid feeder An animal that obtains nourishment by ingesting liquids that contain organic molecules in solution.

fluid mosaic model Model proposing that the membrane consists of a fluid phospholipid bilayer in which proteins are embedded and float freely.

fMRI *See* **functional magnetic resonance imaging.**

follicle cell A cell that grows from ovarian tissue and nourishes the developing egg.

follicle-stimulating hormone (FSH) The pituitary hormone that stimulates oocytes in the ovaries to continue meiosis and become follicles. During follicle enlargement, FSH interacts with luteinizing hormone to stimulate follicular cells to secrete estrogens.

food chain A depiction of the trophic structure of a community; a portrait of who eats whom.

food vacuole A membrane-bound sac used for digestion.

food web A set of interconnected food chains with multiple links.

Foraminifera (forams) A lineage of the Rhizaria protist evolutionary group; heterotrophic marine organisms with shells consisting of organic matter reinforced by calcium carbonate.

forebrain The largest division of the brain, which includes the cerebral cortex and basal ganglia. It is credited with the highest intellectual functions.

foreskin A loose fold of skin that covers the glans of the penis.

formula The name of a molecule written in chemical shorthand.

fossil The remains or traces of an organism of a past geologic age embedded and preserved in Earth's crust.

foundation species A species that defines the nature of a community by creating locally stable environmental conditions.

founder effect An evolutionary phenomenon in which a population that was established by just a few colonizing individuals has only a fraction of the genetic diversity seen in the population from which it was derived.

fovea The small region of the retina around which cones are concentrated in mammals and birds with eyes specialized for daytime vision.

fragmentation A type of vegetative reproduction in plants in which cells or a piece of the parent break off, then develop into new individuals.

frameshift mutation Mutation in a protein-coding gene that causes the reading frame of an mRNA transcribed from the gene to be altered, resulting in the production of a different, and nonfunctional, amino acid sequence in the polypeptide.

free energy The energy in a system that is available to do work.

freeze-fracture technique Technique in which experimenters freeze a block of cells rapidly, then fracture the block to split the lipid bilayer and expose the hydrophobic membrane interior.

frequency-dependent selection A form of natural selection in which rare phenotypes have a selective advantage simply because they are rare.

fruit A mature ovary, often with accessory parts, from a flower.

fruiting body In some fungi, a stalked, spore-producing structure such as a mushroom.

functional genomics The study of the functions of genes and of other parts of the genome.

functional groups The atoms in reactive groups.

functional magnetic resonance imaging (fMRI) A scanning technique for studying activities of the cerebral cortex.

fundamental niche The range of conditions and resources that a population can possibly tolerate and use.

fungal spore In fungi, a haploid reproductive cell that can germinate and produce a mycelium.

furrow In cytokinesis, a groove that girdles the cell and gradually deepens until it cuts the cytoplasm into two parts.

G_0 phase The phase of the cell cycle in eukaryotes in which many cell types stop dividing.

G_1 phase The initial growth stage of the cell cycle in eukaryotes, during which the cell makes proteins and other types of cellular molecules, but not nuclear DNA.

G_2 phase The phase of the cell cycle in eukaryotes during which the cell continues to synthesize proteins and to grow, completing interphase.

gallbladder The organ that stores bile between meals, when no digestion is occurring.

gametangium In certain plants and fungi, a cell or organ in which gametes are produced.

gamete A haploid cell, an egg or sperm. Haploid cells fuse during sexual reproduction to form a diploid zygote.

gametic isolation A prezygotic reproductive isolating mechanism caused by incompatibility between the sperm of one species and the eggs of another; may prevent fertilization.

gametogenesis The formation of male and female gametes.

gametophyte In organisms in which alternation of generations occurs, notably plants and green algae, the multicellular haploid generation that produces gametes. *Compare* **sporophyte.**

ganglion A functional concentration of nervous system tissue composed principally of nerve-cell bodies, usually lying outside the central nervous system.

ganglion cell A type of neuron in the retina of the eye that receives visual information from photoreceptors via various intermediate cells such as bipolar cells, amacrine cells, and horizontal cells.

gap gene In *Drosophila* embryonic development, one of the first activated set of segmentation genes that progressively subdivide the embryo into regions, determining the segments of the embryo and the adult. Gap genes subdivide the embryo along the anterior–posterior axis into broad regions that later develop into several distinct segments.

gap junction Junction that opens direct channels allowing ions and small molecules to pass directly from one cell to another.

gastric glands Glands in the stomach wall that contain cells which secrete some of the products needed to digest food.

gastric juice A substance secreted by the stomach that contains the digestive enzyme pepsin.

gastric pits Entrances to gastric glands.

gastrin A hormone secreted in response to stimulation of chemoreceptors in the stomach by the presence of food molecules, particularly proteins.

gastroesophageal sphincter Ring of muscle at the junction of the esophagus and the stomach that controls the movement of a bolus of food into the stomach.

gastrovascular cavity A saclike body cavity with a single opening, a mouth, which serves both digestive and circulatory functions.

gastrula The developmental stage resulting when the cells of the blastula migrate and divide once cleavage is complete.

gastrulation The second major process of early development in most animals, which produces an embryo with three distinct primary tissue layers.

gated channel Ion transporter in a membrane that switches between open, closed, or intermediate states.

gemma (plural, *gemmae*) Small cell mass that forms in cuplike growths on a thallus.

gene A unit containing the code for a protein molecule or one of its parts, or for functioning RNA molecules such as tRNA and rRNA.

gene cloning DNA cloning when it involves a gene.

gene duplication Any process that produces two identical copies of a gene in an organism's genome. It is the simplest and most common mechanism for the evolution of new genes.

gene flow The transfer of genes from one population to another through the movement of individuals or their gametes.

gene pool The sum of all alleles at all gene loci in all individuals in a population.

gene therapy Correction of genetic disorders using genetic engineering techniques.

gene-for-gene recognition A mechanism in which plants can detect an attack by a specific pathogen; the product of a specific plant gene interacts with the product of a specific pathogen gene, triggering the plant's defensive response.

general transcription factor (basal transcription factor) In eukaryotes, a protein that binds to the promoter of a gene in the area of the TATA box and recruits and orients RNA polymerase II to initiate transcription at the correct place.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

generalized compartment model A model used to describe nutrient cycling in which two criteria—organic versus inorganic nutrients and available versus unavailable nutrients—define four compartments where nutrients accumulate.

generalized transduction Transfer of bacterial genes between bacteria using virulent phages that have incorporated random DNA fragments of the bacterial genome.

generation time The average time between the birth of an organism and the birth of its offspring.

genetic code The nucleotide information that specifies the amino acid sequence of a polypeptide.

genetic counseling Counseling that allows prospective parents to assess the possibility that they might have a child affected by a genetic disorder.

genetic drift Random fluctuations in allele frequencies as a result of chance events; usually reduces genetic variation in a population.

genetic engineering The use of DNA technologies to alter genes for practical purposes.

genetic equilibrium The point at which neither the allele frequencies nor the genotype frequencies in a population change in succeeding generations.

genetic recombinants Nonparental combinations of alleles. In eukaryotes they result from crossing-over in meiosis.

genetic recombination The process by which the combinations of alleles for different genes in two parental individuals become shuffled into new combinations in offspring individuals.

genetic screening Biochemical or molecular tests for identifying inherited disorders after a child is born.

genetically modified organism (GMO) A transgenic organism.

genomic imprinting Pattern of inheritance in which the expression of a nuclear gene is based on whether an individual organism inherits the gene from the male or female parent.

genomic library A set of clones that contains a copy of every DNA sequence in a genome.

genotype The genetic constitution of an organism in terms of its genes and alleles.

genotype frequency The percentage of individuals in a population possessing a particular genotype.

genus A Linnaean taxonomic category ranking below a family and above a species.

geographical range The overall spatial boundaries within which a population lives.

germ cell An animal cell that is set aside early in embryonic development and gives rise to the gametes.

germ layers The three primary cell layers of the embryo: the outer ectoderm, the inner endoderm, and the mesoderm between the ectoderm and the endoderm.

germ-line cells Cells that develop into sperm or eggs.

germ-line gene therapy Experiment in which a gene is introduced into germ-line cells of an animal to correct a genetic disorder.

gestation The period of mammalian development in which the embryo develops in the uterus of the mother.

gibberellin Any of a large family of plant hormones that regulate aspects of growth, including cell elongation.

gill A respiratory organ formed as evagination of the body that extends outward into the respiratory medium.

gill arch One of the series of curved supporting structures between the slits in the pharynx of a chordate.

gill slit One of the openings in the pharynx of a chordate through which water passes out of the pharynx.

Ginkgophyta A plant phylum with a single living species, the ginkgo (or maiden-hair) tree.

gizzard The part of the digestive tube that grinds ingested material into fine particles by muscular contractions of the wall.

gland A cell or group of cells that produces and releases substances nearby, in another part of the body, or to the outside.

glans A soft, caplike structure at the end of the penis, containing most of the nerve endings producing erotic sensations.

glial cell A nonneuronal cell contained in the nervous tissue that physically supports and provides nutrients to neurons, provides electrical insulation between them, and scavenges cellular debris and foreign matter.

globulin A plasma protein that transports lipids (including cholesterol) and fat-soluble vitamins; a specialized subgroup of globulins, the immunoglobulins, constitute antibodies and other molecules contributing to the immune response.

glomerular filtration The process by which plasma filters through the glomerular capillaries into Bowman's capsule as blood flows through the glomerulus; it is the first step of urine formation.

glomerulus A ball of blood capillaries surrounded by Bowman's capsule in the human nephron.

glucagon A pancreatic hormone with effects opposite to those of insulin: it stimulates glycogen, fat, and protein degradation.

glucocorticoid A steroid hormone secreted by the adrenal cortex that helps maintain the blood concentration of glucose and other fuel molecules.

glucose-dependent insulinotropic peptide (GIP) Hormone released in response to a meal entering the digestive tract that triggers insulin release from the pancreas.

glycocalyx A carbohydrate coat covering the cell surface.

glycogen Energy-providing carbohydrates stored in animal cells.

glycolipid A lipid molecule with carbohydrate groups attached.

glycolysis Stage of cellular respiration in which sugars such as glucose are partially oxidized and broken down into smaller molecules.

glycoprotein A protein with carbohydrate groups attached.

glycosidic bond Bond formed by the linkage of two α-glucose molecules with oxygen as a bridge between a carbon of the first glucose unit and a carbon of the second glucose unit.

Gnathostomata The group of vertebrates with moveable jaws.

golden algae *See* **Chrysophyta.**

Golgi complex In eukaryotes, the organelle responsible for the final modification, sorting, and distribution of proteins and lipids.

Golgi tendon organ A proprioceptor of tendons.

gonad A specialized gamete-producing organ in which the germ cells collect. Gonads are the primary source of sex hormones in vertebrates: ovaries in the female and testes in the male.

gonadotropin A hormone that regulates the activity of the gonads (ovaries and testes).

gonadotropin-releasing hormone (GnRH) A tropic hormone secreted by the hypothalamus that causes the pituitary to make luteinizing hormone (LH) and follicle-stimulating hormone (FSH).

G-protein–coupled receptor In signal transduction, a surface receptor that responds to a signal by activating a G protein.

graded potential A change in membrane potential that does not necessarily trigger an action potential.

gradualism The view that Earth and its living systems changed slowly over its history.

gradualist hypothesis The hypothesis that large changes in either geological features or biological lineages result from the slow, continuous accumulation of small changes over time.

Gram stain technique A technique of staining bacteria to distinguish between types of bacteria with different cell wall compositions.

Gram-negative Describing bacteria that do not retain the stain used in the Gram stain technique.

Gram-positive Describing bacteria that appear purple when stained using the Gram stain technique.

granum Structure in the chloroplasts of higher plants formed by thylakoids stacked one on top of another.

gravitropism A directional growth response to Earth's gravitational pull that is induced by mechanical and hormonal influences.

gray crescent A crescent-shaped region of the underlying cytoplasm at the side opposite the point of sperm entry exposed after fertilization when the pigmented layer of cytoplasm rotates toward the site of sperm entry.

gray matter Areas of densely packed nerve cell bodies and dendrites in the brain and spinal cord.

greater vestibular gland One of two glands located slightly below and to the left and right of the opening of the vagina in women. They secrete mucus that provides lubrication, especially when the woman is sexually aroused.

green algae *See* **Chlorophyta.**

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

greenhouse effect A phenomenon in which certain gases foster the accumulation of heat in the lower atmosphere, maintaining warm temperatures on Earth.

gross primary productivity The rate at which producers convert solar energy into chemical energy.

ground meristem The primary meristematic tissue in plants that gives rise to ground tissues, mostly parenchyma.

ground tissue system One of the three basic tissue systems in plants; includes all tissues other than dermal and vascular tissues.

growth factor A molecule (typically a peptide hormone) that stimulates cell division of a target cell.

growth hormone (GH) A hormone that stimulates cell division, protein synthesis, and bone growth in children and adolescents, thereby causing body growth.

growth-inhibiting factor A molecule that inhibits cell division of a target cell.

guanine A purine that base-pairs with cytosine in nucleic acids.

guard cell Either of a pair of specialized crescent-shaped cells that control the opening and closing of stomata in plant tissue.

guttation The exudation of water from leaves as a result of strong root pressure.

gymnosperm A seed plant that produces "naked" seeds not enclosed in an ovary.

H^+ pump *See* **proton pump.**

habitat The specific environment in which a population lives, as characterized by its biotic and abiotic features.

habitat fragmentation A process in which remaining areas of intact habitat are reduced to small, isolated patches.

habituation The learned loss of responsiveness to stimuli.

half-life The time it takes for half of a given amount of a radioisotope to decay.

haplodiploidy A pattern of sex determination in insects in which females are diploid and males are haploid.

haploid An organism or cell with only one copy of each type of chromosome in its nuclei.

Hardy–Weinberg principle An evolutionary rule of thumb that specifies the conditions under which a population of diploid organisms achieves genetic equilibrium.

haustorium (plural, *haustoria*) The hyphal tip of a parasitic fungus that penetrates a host plant and absorbs nutrients from it; likewise in parasitic flowering plants, a root that can penetrate a host's tissues and absorb nutrients.

head The anteriormost part of an organism's body, containing the brain, sensory structures, and feeding apparatus. For a bacteriophage, the usually polyhedral part of the virus containing the genetic material.

head–foot In mollusks, the region of the body that provides the major means of locomotion and contains concentrations of nervous system tissues and sense organs.

heart The muscular organ that pumps fluid through the circulatory system.

heartwood The inner core of a woody stem; composed of dry tissue and nonliving cells that no longer transport water and solutes and may store resins, tannins, and other defensive compounds.

heat of vaporization The heat required to give water molecules enough energy of motion to break loose from liquid water and form a gas.

heat-shock protein (HSP) Any of a group of chaperone proteins that are present in all cells in all life forms. They are induced when a cell undergoes various types of environmental stresses such as heat, cold, and oxygen deprivation.

heavy chain The heavier of the two types of polypeptide chains that are found in immunoglobulin and antibody molecules.

helical virus A virus in which the protein subunits of the coat assemble in a rodlike spiral around the genome.

helper T cell A clonal cell that assists with the activation of B cells.

hemolymph The circulatory fluid of invertebrates with open circulatory systems, including mollusks and arthropods.

hepatic portal vein The blood vessel that leads to capillary networks in the liver.

Hepatophyta The phylum that includes liverworts and their bryophyte relatives.

herbicide A compound that, at proper concentration, kills plants.

herbivore An animal that obtains energy and nutrients primarily by eating plants.

herbivory The process in which herbivores consume plants.

hermaphroditism The mechanism in which both mature egg-producing and mature sperm-producing tissue are present in the same individual.

heterochrony Changes in the relative rate of development of morphological characters.

heterogametic sex The sex that produces two types of gametes with respect to the sex chromosomes.

heterosporous Producing two types of spores, "male" microspores and "female" megaspores.

heterotroph An organism that acquires energy and nutrients by eating other organisms or their remains.

heterozygote An individual with two different alleles of a gene.

heterozygote advantage An evolutionary circumstance in which individuals that are heterozygous at a particular locus have higher relative fitness than either homozygote.

heterozygous State of possessing two different alleles of a gene.

Hfr cell A special donor cell that can transfer genes on a bacterial chromosome to a recipient bacterium.

hibernation Extended torpor during winter.

high-throughput technique A method that facilitates the handling of many samples simultaneously, such as DNA molecules for sequencing or genes for analysis.

hindbrain The lower area of the brain that includes the brain stem, medulla oblongata, and pons.

hippocampus A gray-matter center that is involved in sending information.

histamine An inflammatory signaling molecule.

histone A small, positively charged (basic) protein that is complexed with DNA in the chromosomes of eukaryotes.

histone code A regulatory mechanism for altering chromatin structure and, therefore, gene activity, based on signals in histone tails represented by chemical modification patterns.

historical biogeography The study of the geographical distributions of plants and animals in relation to their evolutionary history.

homeobox A region of a homeotic gene that corresponds to an amino acid section of the homeodomain.

homeodomain An encoded transcription factor of each protein that binds to a region in the promoters of the genes whose transcription it regulates.

homeostasis A steady internal condition maintained by responses that compensate for changes in the external environment.

homeostatic control system The processes and activities responsible for homeostasis.

homeotic gene Any of the family of genes that determines overall body plan (the structure of body parts) during embryonic development.

hominin A member of a monophyletic group of primates, characterized by an erect bipedal stance, that includes modern humans and their recent ancestors.

Hominoidea The monophyletic group of primates that includes apes and humans.

homogametic sex The sex that produces only one type of gamete with respect to the sex chromosomes.

homologies Characteristics shared by a set of species because they inherited them from their common ancestor.

homologous chromosomes The two chromosomes of each pair in a diploid cell—one of the pair derives from the maternal parent and the other derives from the paternal parent. Homologous chromosomes have the same genes, in the same order, in their DNA.

homologous traits Characteristics that are similar in two species because they inherited the genetic basis of the trait from their common ancestor.

homoplasies Characteristics shared by a set of species, often because they live in similar environments, but not present in their common ancestor; often the product of convergent evolution.

homosporous Producing only one type of spore.

homozygote An individual with two copies of the same allele.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

homozygous State of possessing two copies of the same allele.

horizon A noticeable layer of soil, such as topsoil, having a distinct texture and composition that varies with soil type.

horizontal cell A type of neuron that forms lateral connections among photoreceptor cells in the retina of the eye.

horizontal gene transfer Movement of genetic material between organisms other than by descent.

hormone A signaling molecule secreted by a cell that can alter the activities of any cell with receptors for it; in animals, typically a molecule produced by one tissue and transported via the bloodstream to another specific tissue to alter its physiological activity.

host A species that is fed on by a parasite.

host race A population of insects that may be reproductively isolated from other populations of the same species as a consequence of their adaptation to feed on a specific host plant species.

***Hox* gene** A type of homeotic gene that controls an organism's overall body plan.

human chorionic gonadotropin (hCG) A hormone that keeps the corpus luteum in the ovary from breaking down.

human immunodeficiency virus (HIV) A retrovirus that causes acquired immunodeficiency syndrome (AIDS).

humoral immunity *See* **antibody-mediated immunity.**

humus The organic component of soil remaining after decomposition of plants and animals, animal droppings, and other organic matter.

hybrid breakdown A postzygotic reproductive isolating mechanism in which hybrids are capable of reproducing, but their offspring have either reduced fertility or reduced viability.

hybrid inviability A postzygotic reproductive isolating mechanism in which a hybrid individual has a low probability of survival to reproductive age.

hybrid sterility A postzygotic reproductive isolating mechanism in which hybrid offspring cannot form functional gametes.

hybrid zone A geographical area where the hybrid offspring of two divergent populations or species are common.

hybridoma A B cell that has been induced to fuse with a cancerous lymphocyte called a *myeloma cell,* forming a single, composite cell.

hydration layer A surface coat of water molecules that covers other polar and charged molecules and ions.

hydrocarbon Molecule consisting of carbon linked only to hydrogen atoms.

hydrogen bond Noncovalent bond formed by unequal electron sharing between hydrogen atoms and oxygen, nitrogen, or sulfur atoms.

hydrologic alterations Human-induced changes in the pathways through which water moves in the hydrologic cycle.

hydrologic cycle The global cycling of water between the ocean, the atmosphere, land, freshwater ecosystems, and living organisms.

hydrolysis Reaction in which the components of a water molecule are added to functional groups as molecules are broken into smaller subunits.

hydrophilic In chemistry and biology, referring to polar molecules that associate readily with water.

hydrophobic In chemistry and biology, referring to nonpolar substances that are excluded by water and other polar molecules.

hydroponic culture A method of growing plants not in soil but with the roots bathed in a solution that contains water and mineral nutrients.

hydrosphere The component of the biosphere that encompasses all the waters on Earth, including oceans, rivers, and polar ice caps.

hydrostatic skeleton A structure consisting of muscles and fluid that, by themselves, provide support for the animal or part of the animal; no rigid support, such as a bone, is involved.

hydroxyl group Group consisting of an oxygen atom linked to a hydrogen atom on one side and to a carbon chain on the other side.

hymen A thin flap of tissue that partially covers the opening of the vagina.

hyperpolarized The condition of a neuron when its membrane potential is more negative than the resting value.

hypersensitive response A plant defense that physically cordons off an infection site by surrounding it with dead cells.

hypertension Commonly called *high blood pressure,* a medical condition in which blood pressure is chronically elevated above normal values.

hyperthermia The condition resulting when the heat gain of the body is too great to be counteracted.

hypertonic Solution containing dissolved substances at higher concentrations than the cells it surrounds.

hypha (plural, *hyphae*) Any of the threadlike filaments that form the mycelium of a fungus.

hypoblast The bottom layer of a blastodisc.

hypocotyl The region of a plant embryo's vertical axis between the cotyledons and the radicle.

hypodermis The innermost layer of the skin that contains larger blood vessels and additional reinforcing connective tissue.

hypolimnion The deep water of the profundal zone of a lake.

hypothalamus The portion of the brain that contains centers regulating basic homeostatic functions of the body and contributing to the release of hormones.

hypothermia A condition in which the core temperature falls below normal for a prolonged period.

hypothesis A tentative explanation for an observation, phenomenon, or scientific problem that can be tested by further investigation.

hypotonic Solution containing dissolved substances at lower concentrations than the cells it surrounds.

ice lattice A rigid, crystalline structure formed when a water molecule in ice forms four hydrogen bonds with neighboring molecules.

IgA The class of antibodies found mainly in secretions at particular locations in the body; IgA functions to bind to surface groups on pathogens and block their attachment to body surfaces.

IgD The class of antibodies that occurs with IgM as a receptor on the surfaces of B cells; the function of IgD is uncertain.

IgE The class of antibodies secreted by plasma cells of the skin and tissues lining the gastrointestinal tract and respiratory tract that binds to basophils and mast cells to trigger the release of histamine, thereby causing an inflammatory response.

IGF *See* **insulin-like growth factor.**

IgG The most abundant antibody type circulating in the blood and lymphatic system that is involved in primary and secondary immune responses.

IgM The first antibody type secreted by B cells in a primary immune response.

imbibition The movement of water into a seed as the water molecules are attracted to hydrophilic groups of stored proteins; the first step in germination.

immigration Movement of organisms into a population.

immune response The defensive reactions of the immune system.

immune system The body's system of defenses against disease, composed of certain white blood cells and antibodies.

immunoglobulin A specific protein substance produced by plasma cells to aid in fighting infection.

immunological memory The capacity of the immune system to respond more rapidly and vigorously to the second contact with a specific antigen than to the primary contact.

immunological tolerance The process that protects the body's own molecules from attack by the immune system.

imperfect flower A type of incomplete flower that has stamens or carpels, but not both.

imprinting The process of learning the identity of a caretaker and potential future mate during a critical period early in life.

inbreeding A special form of nonrandom mating in which genetically related individuals mate with each other.

incisors Flattened, chisel-shaped teeth of mammals, located at the front of the mouth, that are used to nip or cut food.

incomplete dominance Condition in which the effects of recessive alleles can be detected to some extent in heterozygotes.

incomplete flower A flower lacking one or more of the four floral whorls.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

incomplete metamorphosis In certain insects, a life cycle characterized by the absence of a pupal stage between the immature and adult stages.

incurrent siphon A muscular tube that brings water containing oxygen and food into the body of an invertebrate.

incus The second of the three sound-conducting middle ear bones in vertebrates, located between the malleus and the stapes.

independent assortment Mendel's principle that the alleles of the genes that govern two characters assort independently during formation of gametes. Mechanistically this is the case because any combination of chromosomes may be segregated to the spindle poles during meiosis I.

indeterminate cleavage A type of cleavage, observed in many deuterostomes, in which the developmental fates of the first few cells produced by mitosis are not determined as soon as cells are produced.

indeterminate growth Growth that is not limited by an organism's genetic program, so that the organism grows for as long as it lives; typical of many plants. *Compare* **determinate growth.**

inducer Concerning regulation of gene expression in bacteria, a molecule that turns on the transcription of the genes in an operon.

inducible operon Operon whose expression is increased by an inducer molecule.

induction A mechanism in which one group of cells (the inducer cells) causes or influences another nearby group of cells (the responder cells) to follow a particular developmental pathway.

infection thread In the formation of root nodules on nitrogen-fixing plants, the tube formed by the plasma membrane of root hair cells as bacteria enter the cell.

infertility The inability for the female of a couple to get pregnant after 12 months of frequent, contraceptive-free intercourse.

inflammation The heat, pain, redness, and swelling that occur at the site of an infection.

ingestion The feeding methods used to take food into the digestive cavity.

inheritance The transmission of DNA (that is, genetic information) from one generation to the next.

inhibin A peptide that, in females, is an inhibitor of FSH secretion from the pituitary thereby diminishing the signal for follicular growth. In males, inhibin inhibits FSH secretion from the pituitary, thereby decreasing spermatogenesis.

inhibiting hormone (IH) A hormone released by the hypothalamus that inhibits the secretion of a particular anterior pituitary hormone.

inhibition hypothesis A hypothesis suggesting that new species are prevented from occupying a community by whatever species are already present.

inhibitory postsynaptic potential (IPSP) A change in membrane potential caused when hyperpolarization occurs, pushing the neuron farther from threshold.

initial A plant cell that remains permanently as part of a meristem and gives rise to daughter cells that differentiate into specialized cell types.

initiation In transcription, the step in which the molecular machinery that carries out transcription assembles at the promoter and begins synthesizing an RNA copy of the gene. In translation, the step in which the translation components assemble on the start codon of the mRNA.

initiation factor (IF) A protein that aids an initiation step of translation.

initiator codon *See* **start codon.**

innate immune system A nonspecific line of defense against pathogens that includes inflammation, which creates internal conditions that inhibit or kill many pathogens, and specialized cells that engulf or kill pathogens or infected body cells. The innate system is found in all animals and is one of two components of the immune system in vertebrates.

innate immunity The initial response by the body to eliminate cellular pathogens that involves mechanisms of the innate immune system.

inner boundary membrane Membrane lying just inside the outer boundary membrane of a chloroplast, enclosing the stroma.

inner cell mass The dense mass of cells within the blastocyst that will become the embryo.

inner ear That part of the ear, particularly the cochlea, that converts mechanical vibrations (sound) into neural messages that are sent to the brain.

inner mitochondrial membrane Membrane surrounding the mitochondrial matrix.

inorganic molecule Molecule without carbon atoms in its structure.

inositol triphosphate (IP_3) In particular signal transduction pathways, a second messenger that activates transport proteins in the endoplasmic reticulum to release Ca^{2+} into the cytoplasm. IP_3 is involved in one of two major G-protein–coupled receptor–response pathways.

insertion sequence A transposable element that contains only genes for its transposition.

instinctive behavior A genetically "programmed" response that appears in complete and functional form the first time it is used.

insulin A hormone secreted by beta cells in the islets, acting mainly on cells of nonworking skeletal muscles, liver cells, and adipose tissue (fat) to lower blood glucose, fatty acid, and amino acids levels, and promote the storage of those molecules.

insulin-like growth factor (IGF) A peptide released by target tissues in response to binding by growth hormone that directly stimulates growth processes.

integral protein Protein embedded in a phospholipid bilayer.

integration The third component of neural signaling involving the sorting and interpretation of neural messages and the determination of the appropriate response(s).

integrator In homeostatic feedback, the control center that compares a detected environmental change with a set point.

integument Skin.

intercalated disk The joining point between two cells in cardiac muscle.

interference competition Form of competition in which individuals fight over resources or otherwise harm each other directly.

interferon A cytokine produced by infected host cells affected by viral dsRNA, which acts both on the infected cell that produces it, an autocrine effect, and on neighboring uninfected cells, a paracrine effect.

interkinesis A brief interphase separating the two meiotic divisions.

intermediate disturbance hypothesis Hypothesis proposing that species richness is greatest in communities that experience fairly frequent disturbances of moderate intensity.

intermediate filament A cytoskeletal filament about 10 nm in diameter that provides mechanical strength to cells in tissues.

intermediate-day plant A plant that flowers only when day length falls between the values for long-day and short-day plants.

internal environment The fluid within an organism that supplies all the needs of individual cells.

internal fertilization The process in which sperm are released by the male close to or inside the entrance of the reproductive tract of the female.

internal gill A gill located within the body that has a cover providing physical protection for the gills. Water must be brought to internal gills.

interneuron A neuron that integrates information to formulate an appropriate response.

internode The region between two nodes on a plant stem.

interphase The first stage of the mitotic cell cycle, during which the cell grows and replicates its DNA before undergoing mitosis and cytokinesis.

interspecific competition The competition for resources between species.

interstitial fluid The fluid occupying the spaces between cells in multicellular animals.

intertidal zone The shoreline that is alternately submerged and exposed by tides.

intestinal villus A microscopic, fingerlike extension in the lining of the small intestine.

intestine The portion of digestive system where organic matter is hydrolyzed by enzymes secreted into the digestive tube. As muscular contractions of the intestinal wall move the mixture along, cells lining the intestine absorb the molecular subunits produced by digestion.

intracellular digestion The process in which cells take in food particles by endocytosis.

intraspecific competition The dependence of two or more individuals in a population on the same limiting resource.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

intrinsic rate of increase The maximum possible per capita population growth rate in a population living under ideal conditions.

intron A non-protein-coding sequence that interrupts the protein-coding sequence in a eukaryotic gene. Introns are removed by splicing in the processing of pre-mRNA to mRNA.

invagination The process in which cells changing shape and pushing inward from the surface produce an indentation, such as the dorsal lip of the blastopore.

inversion Chromosomal alteration that occurs if a broken segment reattaches to the same chromosome from which it was lost, but in reversed orientation, so that the order of genes in the segment is reversed with respect to the other genes of the chromosome.

invertebrate An animal without a vertebral column.

involution The process by which cells migrate into the blastopore.

ion A positively or negatively charged atom.

ionic bond Bond that results from electrical attractions between atoms that have lost or gained electrons.

ionotropic neurotransmitter receptor A receptor in the postsynaptic membrane to which a neurotransmitter binds directly, causing an associated ion channel gate to open or close thereby altering the flow of a specific ion or ions in the postsynaptic cell.

iris Of the eye, the colored muscular membrane that lies behind the cornea and in front of the lens, which by opening or closing determines the size of the pupil and hence the amount of light entering the eye.

islets of Langerhans Endocrine cells that secrete the peptide hormones insulin and glucagon into the bloodstream.

isomers Two or more molecules with the same chemical formula but different molecular structures.

isotonic Equal concentration of water inside and outside cells.

isotope A distinct form of the atoms of an element, with the same number of protons but different number of neutrons.

jasmonate Any of a group of plant hormones that help regulate aspects of growth and responses to stress, including attacks by predators and pathogens.

juvenile hormone (JH) A peptide hormone secreted by the corpora allata, a pair of glands just behind the brain in insects.

juxtaglomerular apparatus A structure in the kidney near a point where the distal convoluted tubule contacts the afferent arteriole carrying blood to the glomerulus; specialized tubule cells in the juxtaglomerular apparatus monitor the salt level of the fluid flowing past them in the tubule.

karyogamy In plants, the fusion of two sexually compatible haploid nuclei after cell fusion (plasmogamy).

karyotype A characteristic of a species consisting of the shapes and sizes of all the chromosomes at metaphase.

keeled sternum The ventrally extended breastbone of a bird to which the flight muscles attach.

ketone Molecule in which the carbonyl group is linked to a carbon atom in the interior of a carbon chain.

keystone species A species that has a greater effect on community structure than its numbers might suggest.

kilocalorie (kcal) The scientific unit equivalent to a Calorie and equal to 1,000 small calories.

kin selection An explanation for altruistic behavior to close relatives, allowing them to produce proportionately more surviving copies of the altruist's genes than the altruist might otherwise have produced on its own.

kinesis A change in the rate of movement or the frequency of turning movements in response to environmental stimuli.

kinetic energy The energy of motion.

kinetochore A specialized structure consisting of proteins attached to a centromere that mediates the attachment and movement of chromosomes along the mitotic spindle.

Kinetoplastids A lineage of the Euglenozoa subgroup of the Excavata protist evolutionary group; nonphotosynthetic, heterotrophic cells that live as animal parasites and that contain a single mitochondrion with a large DNA–protein deposit called a kinetoplast.

kingdom A Linnaean taxonomic category that ranks below a domain and above a phylum.

Kingdom Animalia The taxonomic kingdom that includes all living and extinct animals.

Kingdom Fungi The taxonomic kingdom that includes all living or extinct fungi.

Kingdom Plantae The taxonomic kingdom encompassing all living or extinct plants.

Korarchaeota A group of the domain Archaea consisting of one living species, with other members represented in sequences in environmental samples. This group diverged very early in the evolution of the Archaea.

Krebs cycle *See* **citric acid cycle.**

***K*-selected species** Long-lived species that thrive in more stable environments.

labia majora A pair of fleshy, fat-padded folds that partially cover the labia minora.

labia minora Two folds of tissue that run from front to rear on either side of the opening to the vagina.

lactate fermentation Reaction in which pyruvate is converted into lactate.

lactose intolerance The unpleasant intestinal symptoms that result when an individual loses the capacity to synthesize lactase, the enzyme that breaks down the milk sugar.

lagging strand The new DNA strand synthesized discontinuously during replication in the direction opposite to that of DNA unwinding.

lagging strand template The DNA template strand for the lagging strand.

landscape ecology The field that examines how large-scale ecological factors—such as the distribution of plants, topography, and human activity—influence local populations and communities.

larva A sexually immature stage in the life cycle of many animals that is morphologically distinct from the adult.

larynx The voice box.

latent state The time during which a pathogen such as a virus remains in an infected organism in an inactive form and cannot be isolated and identified.

lateral bud A bud on the side of a plant stem from which a branch may grow.

lateral geniculate nuclei Clusters of neurons located in the thalamus that receive visual information from the optic nerves and send it on to the visual cortex.

lateral inhibition Visual processing in which lateral movement of signals from a rod or cone proceeds to a horizontal cell and continues to bipolar cells with which the horizontal cell makes inhibitory connections, serving both to sharpen the edges of objects and enhance contrast in an image.

lateral line system The complex of mechanoreceptors along the sides of some fishes and aquatic amphibians that detect vibrations in the water.

lateral meristem A plant meristem that gives rise to secondary tissue growth. *Compare* **primary meristem.**

lateral root A root that extends away from the main root (or taproot).

lateralization A phenomenon in which some brain functions are more localized in one of the two hemispheres.

lateral-line system The complex of organs and sensory receptors along the sides of many fishes and amphibians that detects vibrations in water.

leaching The process by which soluble materials in soil are washed into a lower layer of soil or are dissolved and carried away by water.

leading strand The new DNA strand synthesized during replication in the direction of DNA unwinding.

leading strand template The DNA template strand for the leading strand.

leaf primordium A lateral outgrowth from the apical meristem that develops into a young leaf.

learned behavior A response of an animal that is dependent on having a particular kind of experience during development.

learning A process in which experiences stored in memory change the behavioral responses of an animal.

leghemoglobin An iron-containing, red-pigmented protein produced in root nodules during the symbiotic association between *Bradyrhizobium* or *Rhizobium* and legumes.

lek A display ground where males each possess a small territory from which they court attentive females.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

lens The transparent, biconvex intraocular tissue that helps bring rays of light to a focus on the retina.

Lepidosauromorpha A monophyletic lineage of diapsids that includes both marine and terrestrial animals, represented today by sphenodontids, lizards, and snakes.

leukocyte A white blood cell, which eliminates dead and dying cells from the body, removes cellular debris, and participates in defending the body against invading organisms.

Leydig cell A cell that produces the male sex hormones.

lichen A single vegetative body that is the result of an association between a fungus and a photosynthetic partner, often an alga.

life cycle The sequential stages through which individuals develop, grow, maintain themselves, and reproduce.

life history The lifetime pattern of growth, maturation, and reproduction that is characteristic of a population or species.

life table A chart that summarizes the demographic characteristics of a population.

ligament A fibrous connective tissue that connects bones to each other at a joint.

ligation The process of sealing two DNA molecules together with DNA ligase to produce a recombinant DNA molecule.

light chain The lighter of the two types of polypeptide chains found in immunoglobulin and antibody molecules.

light microscope Microscope that uses light to illuminate the specimen.

light-dependent reaction The first stage of photosynthesis, in which the energy of sunlight is absorbed and converted into chemical energy in the form of ATP and NADPH.

light-independent reaction The second stage of photosynthesis, in which electrons are used as a source of energy to convert inorganic CO_2 to an organic form. Also referred to as the *Calvin cycle.*

lignification The deposition of lignin in plant cell walls; it anchors the cellulose fibers in the walls, making them stronger and more rigid, and protects the other wall components from physical or chemical damage.

lignin A tough, rather inert polymer that strengthens the secondary walls of various plant cells and thus helps vascular plants to grow taller and stay erect on land.

limbic system A functional network formed by parts of the thalamus, hypothalamus, and basal nuclei, along with other nearby gray-matter centers—the amygdala, hippocampus, and olfactory bulbs—sometimes called the "emotional brain."

limiting nutrient An element in short supply within an ecosystem, the shortage of which limits productivity.

limnetic zone The sunlit, open water in a lake, beyond the zone where plants rooted in the bottom can grow.

linkage The phenomenon of genes being located on the same chromosome.

linkage map Map of a chromosome showing the relative locations of genes based on recombination frequencies.

linked genes Genes on the same chromosome.

linker A short segment of DNA extending between one nucleosome and the next in a eukaryotic chromosome.

lipase A pancreatic enzyme that hydrolyzes fats.

lipopolysaccharide A large molecule that consists of a lipid and a carbohydrate joined by a covalent bond.

lithosphere The component of the biosphere that includes the rocks, sediments, and soils of the crust.

littoral zone The shallow, sunlit water near the shore of a lake or pond.

liver A large organ whose many functions include aiding in digestion, removing toxins from the body, and regulating the chemicals in the blood.

loam Any well-aerated soil composed of a mixture of sand, clay, silt, and organic matter.

local homeostatic controls Controls that operate only within an organ where a change in the internal environment needs to be addressed.

local inflammation Inflammation that occurs at the site of an infection.

locus The particular site on a chromosome at which a gene is located.

logistic model of population growth Model of population growth that assumes that a population's per capita growth rate decreases as the population gets larger.

long-day plant A plant that flowers in spring when dark periods become shorter and day length becomes longer.

long-term memory Memory that stores information from days to years or even for life.

long-term potentiation A long-lasting increase in the strength of synaptic connections in activated neural pathways following brief periods of repeated stimulation.

loop of Henle A U-shaped bend of the proximal convoluted tubule.

loose connective tissue A tissue formed of sparsely distributed cells surrounded by a more or less open network of collagen and other glycoprotein fibers.

lophophore The circular or U-shaped fold with one or two rows of hollow, ciliated tentacles that surrounds the mouth of brachiopods, bryozoans, and phoronids and is used to gather food.

lumen The inside of the digestive tube.

lung One of a pair of invaginated respiratory surfaces, buried in the body interior where they are less susceptible to drying out; the organs of respiration in mammals, birds, reptiles, and most amphibians.

luteinizing hormone (LH) A hormone secreted by the pituitary that stimulates the growth and maturation of eggs in females and the secretion of testosterone in males.

Lycophyta The plant phylum that includes club mosses and their close relatives.

lymph The interstitial fluid picked up by the lymphatic system.

lymph node One of many small, bean-shaped organs spaced along the lymph vessels that contain macrophages and other leukocytes that attack invading disease organisms.

lymphatic system An accessory system of vessels and organs that helps balance the fluid content of the blood and surrounding tissues and participates in the body's defenses against invading disease organisms.

lymphocyte A leukocyte that carries out most of its activities in tissues and organs of the lymphatic system. Lymphocytes play major roles in immune responses.

lysogenic cycle Cycle in which the DNA of the bacteriophage is integrated into the DNA of the host bacterial cell and may remain for many generations.

lysosome Membrane-bound vesicle containing hydrolytic enzymes for the digestion of many complex molecules.

lytic cycle The series of events from infection of one bacterial cell by a phage through the release of progeny phages from lysed cells.

M phase–promoting factor (MPF) A complex of M cyclin and cyclin-dependent kinase 1 (Cdk1). The complex initiates mitosis and orchestrates some of its key events.

macroevolution Large-scale evolutionary patterns in the history of life, producing major changes in species and higher taxonomic groups.

macronucleus In ciliophorans, a single large nucleus that develops from a micronucleus but loses all genes except those required for basic "housekeeping" functions of the cell and for ribosomal RNAs.

macronutrient In humans, a mineral required in amounts ranging from 50 mg to more than 1 gram per day. In plants, a nutrient needed in large amounts for normal growth and development.

macrophage A phagocyte that takes part in nonspecific defenses and adaptive immunity.

magnetoreceptor A receptor found in some animals that navigate long distances which allows them to detect and use Earth's magnetic field as a source of directional information.

magnification The ratio of an object as viewed to its real size.

magnoliids An angiosperm group that includes magnolias, laurels, and avocados; they are more closely related to monocots than to eudicots.

major histocompatibility complex A large cluster of genes encoding the MHC proteins.

malleus The outermost of the sound-conducting bones of the middle ear in vertebrates.

malnutrition A condition resulting from a diet in which intake of organic fuels is inadequate or whose assimilation of such fuels is abnormal

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(= **undernutrition**), or in which there is excessive intake of specific nutrients (= **overnutrition**).

Malpighian tubule The main organ of excretion and osmoregulation in insects, helping them to maintain water and electrolyte balance.

mammary glands Specialized organs of female mammals that produce energy-rich milk, a watery mixture of fats, sugars, proteins, vitamins, and minerals.

mantle One or two folds of the body wall that lines the shell and secretes the substance that forms the shell in mollusks.

map unit The unit of a linkage map, equivalent to a recombination frequency of 1%. Also referred to as a *centimorgan*.

maritime climate Climate tempered by ocean winds.

marsupium An external pouch on the abdomen of many female marsupials, containing the mammary glands, and within which the young continue to develop after birth.

mass The amount of matter in an object.

mass extinctions The disappearance of a large number of species in a relatively short period of geological time.

mass number The total number of protons and neutrons in the atomic nucleus.

mast cell A type of cell dispersed through connective tissue that releases histamine when activated by the death of cells, caused by a pathogen at an infection site.

maternal chromosome The chromosome derived from the female parent of an organism.

maternal inheritance A type of uniparental inheritance in which all progeny (both males and females) have the phenotype of the female parent.

maternal-effect gene One of a class of genes that regulate the expression of other genes expressed by the mother during oogenesis and that control the polarity of the egg and, therefore, of the embryo.

mating The pairing of a male and a female for the purpose of sexual reproduction.

mating systems The social systems describing how males and females pair up.

mating type A genetically defined strain of an organism (such as a fungus) that can only mate with an organism of the opposite mating type; mating types are often designated + and −.

matter Anything that occupies space and has mass.

maximum likelihood methods A statistical technique that compares alternative phylogenetic trees with specific models of evolutionary change.

mechanical isolation A prezygotic reproductive isolating mechanism caused by differences in the structure of reproductive organs or other body parts.

mechanical processing In the digestive tube, the process of chewing, grinding, and tearing food chunks into smaller pieces.

mechanoreceptor A sensory receptor that detects mechanical energy, such as changes in pressure, body position, or acceleration. The auditory receptors in the ears are examples of mechanoreceptors.

medusa The tentacled, usually bell-shaped, free-swimming sexual stage in the life cycle of a coelenterate.

megapascal A unit of pressure used to measure water potential.

megaspore A plant spore that develops into a female gametophyte; usually larger than a microspore.

meiosis The division of diploid cells to haploid progeny, consisting of two sequential rounds of nuclear and cellular division.

meiosis I The first division of the meiotic cell cycle in which homologous chromosomes pair and undergo an exchange of chromosome segments, and then the homologous chromosomes separate, resulting in two cells, each with the haploid number of chromosomes and with each chromosome still consisting of two chromatids.

meiosis II The second division of the meiotic cell cycle in which the sister chromatids in each of the two cells produced by meiosis I separate and segregate into different cells, resulting in four cells each with the haploid number of chromosomes.

melanocyte-stimulating hormone (MSH) A hormone secreted by the anterior pituitary that controls the degree of pigmentation in melanocytes.

melatonin A peptide hormone secreted by the pineal gland that helps maintain daily biorhythms.

membrane attack complexes (MAC) An abnormal activation of the complement (protein) portion of the blood, forming a cascade reaction that brings blood proteins together, binds them to the cell wall, and then inserts them through the cell membrane.

membrane potential An electrical voltage that measures the potential inside a cell membrane relative to the fluid just outside; it is negative under resting conditions and becomes positive during an action potential.

memory The storage and retrieval of a sensory or motor experience, or a thought.

memory B cell In antibody-mediated immunity, a long-lived cell expressing an antibody on its surface that can bind to a specific antigen. A memory B cell is activated the next time the antigen is encountered, producing a rapid secondary immune response.

memory cell An activated lymphocyte that circulates in the blood and lymph, ready to initiate a rapid immune response on subsequent exposure to the same antigen.

memory cytotoxic T cells Cells differentiated from cytotoxic T cells that are stored for subsequent cell-mediated immunity involving the same antigens.

memory helper T cell In cell-mediated immunity, a long-lived cell differentiated from a helper T cell, which remains in an inactive state in the lymphatic system after an immune reaction has run its course and ready to be activated on subsequent exposure to the same antigen.

meninges Three layers of connective tissue that surround and protect the spinal cord and brain.

menstrual cycle A cycle of approximately 1 month in the human female during which an egg is released from an ovary and the uterus is prepared to receive the fertilized egg; if fertilization does not occur, the endometrium breaks down, which releases blood and tissue breakdown products from the uterus to the outside through the vagina.

meristem An undifferentiated, permanently embryonic plant tissue that gives rise to new cells forming tissues and organs.

mesenteries Sheets of loose connective tissue, covered on both surfaces with epithelial cells, which suspend the abdominal organs in the coelom and provide lubricated, smooth surfaces that prevent chafing or abrasion between adjacent structures as the body moves.

mesoderm The middle layer of the three primary germ layers of an animal embryo, from which the muscular, skeletal, vascular, and connective tissues develop.

mesohyl The gelatinous middle layer of cells lining the body cavity of a sponge.

mesophyll The ground tissue located between the two outer leaf tissues, composed of loosely packed parenchyma cells that contain chloroplasts.

messenger RNA (mRNA) An RNA molecule that serves as a template for protein synthesis.

metabolism The biochemical reactions that allow a cell or organism to extract energy from its surroundings and use that energy to maintain itself, grow, and reproduce.

metabotropic neurotransmitter receptor A receptor in the postsynaptic membrane, typically of the G-protein–coupled receptor type, to which a neurotransmitter binds as a first messenger, activating the receptor and triggering generation of a second messenger that brings about changes in ion-conducting channels in the membrane.

metagenomics Analysis of DNA sequences of the genomes in entire communities of microbes that have been isolated from the environment.

Metamonada (metamonads) A subgroup of the Excavata protist evolutionary group containing the Diplomonadida and the Parabasala.

metamorphosis A reorganization of the form of certain animals during postembryonic development.

metanephridium The excretory tubule of most annelids and mollusks.

metaphase The phase of mitosis during which the spindle reaches its final form and the spindle microtubules move the chromosomes into alignment at the spindle midpoint.

metapopulation A group of neighboring populations that exchange individuals.

metastasis The spreading of a malignant tumor through the blood system or lymphatic system, forming new tumors at other locations in the body.

micelles The tiny droplets produced when fats are emulsified.

microbody Small, membrane-bound organelle that carries out vital reactions linking metabolic pathways.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

microclimate The abiotic conditions immediately surrounding an organism.

microevolution Small-scale genetic changes within populations, often in response to shifting environmental circumstances or chance events.

microfilament A cytoskeletal filament composed of actin.

microfossil The remains of a cell that has decayed and been filled in by calcium carbonate or silica.

micronucleus In ciliophorans, one or more diploid nuclei that contains a complete complement of genes, functioning primarily in cellular reproduction.

micronutrient Any mineral required by an organism only in trace amounts.

micropyle A small opening at one end of an ovule through which the pollen tube passes before fertilization.

microRNA (miRNA) One of the major types of small regulatory RNAs in eukaryotes involved in RNA interference (RNAi).

microsatellite *See* **short tandem repeat (STR).**

microscope Instrument of microscopy with different magnifications and resolutions of specimens.

microscopy Technique for producing visible images of objects that are too small to be seen by the human eye.

microspore A plant spore from which a male gametophyte develops; usually smaller than a megaspore.

microsporidium (plural, *microsporidia*) A fungal parasite of animals; many mycologists believe they make up a possible sixth phylum within the Kingdom Fungi.

microtubule A cytoskeletal component formed by the polymerization of tubulin into rigid, hollow rods about 25 nm in diameter.

microtubule organizing center (MTOC) An anchoring point near the center of a eukaryotic cell from which most microtubules extend outward.

microvilli Fingerlike projections forming a brush border in epithelial cells that cover the villi.

midbrain The uppermost of the three segments of the brainstem, serving primarily as an intermediary between the rest of the brain and the spinal cord.

middle ear The air-filled cavity containing three small, interconnected bones: the malleus, incus, and stapes.

middle lamella Layer of gel-like polysaccharides that holds together walls of adjacent plant cells.

migration The predictable seasonal movement of animals from the area where they are born to a distant and initially unfamiliar destination, returning to their birth site later.

mimic The species in Batesian mimicry that resembles the model.

mimicry A form of defense in which one species evolves an appearance resembling that of another.

mineralocorticoid A steroid hormone secreted by the adrenal cortex that regulates the levels of Na^+ and K^+ in the blood and extracellular fluid.

minimal medium A growth medium containing the minimal ingredients that enable a nonmutant organism, such as *E. coli,* to grow.

minimum viable population size The smallest population size that is likely to survive both predictable and unpredictable environmental variation.

miRNA-induced silencing complex (miRISC) Protein complex containing an miRNA that binds to sequences in the 3′ UTRs of target mRNAs, resulting in either inhibition of translation of the mRNAs or their degradation.

mismatch repair Repair system that removes mismatched bases from newly synthesized DNA strands.

missense mutation A base-pair substitution mutation in a protein-coding gene that results in a different amino acid in the encoded polypeptide than the normal one.

mitochondrial electron transfer system Series of electron carriers that alternately pick up and release electrons, ultimately transferring them to their final acceptor, oxygen.

mitochondrial matrix The innermost compartment of the mitochondrion.

mitochondrion Membrane-bound organelle responsible for synthesis of most of the ATP in eukaryotic cells.

mitosis Nuclear division that produces daughter nuclei that are exact genetic copies of the parental nucleus.

model The species in Batesian mimicry that is resembled by the mimic.

model organism An organism with characteristics that make it a particularly useful subject of research because it is likely to produce results widely applicable to other organisms.

modern synthesis A unified theory of evolution developed in the middle of the twentieth century.

molarity (*M*) The number of moles of a substance dissolved in 1 L of solution.

molars Posteriormost teeth of mammals, with a broad chewing surface for grinding food.

mold Asexual, spore-producing stage of many multicellular fungi.

mole (mol) Amount of substance that contains as many atoms or molecules as there are atoms in exactly 12 g of carbon-12, which is 6.022×10^{23}.

molecular clock A technique for dating the time of divergence of two species or lineages, based on the number of molecular sequence differences between them.

molecular phylogenetics Approach of using DNA or amino acid sequence comparisons to determine evolutionary relationships among organisms.

molecular weight The weight of a molecule in grams, equal to the total mass number of its atoms.

molecule A unit composed of atoms combined chemically in fixed numbers and ratios.

molt-inhibiting hormone (MIH) A peptide neurohormone secreted by a gland in the eye stalks of crustaceans that inhibits ecdysone secretion.

monoclonal antibody An antibody that reacts only against the same segment (epitope) of a single antigen.

monocot A plant belonging to the Monocotyledones, one of the two major classes of angiosperms; monocot embryos have a single seed leaf (cotyledon) and pollen grains with a single groove.

monocyte A type of leukocyte that enters damaged tissue from the bloodstream through the endothelial wall of the blood vessel.

monoecious Having both "male" flowers (which possess only stamens) and "female" flowers (which possess only carpels).

monogamy A mating system in which one male and one female form a long-term association.

monohybrid An F_1 heterozygote produced from a genetic cross that involves a single character.

monohybrid cross A genetic cross between two individuals that are each heterozygous for the same pair of alleles.

monophyletic taxon A group of organisms that includes a single ancestral species and all of its descendants.

monoploid An individual with one set of chromosomes instead of the usual two.

monosaccharides The smallest carbohydrates, containing three to seven carbon atoms.

monotreme A lineage of mammals that lay eggs instead of bearing live young.

monounsaturated Fatty acids with one double bond.

monsoon cycle A wind pattern that brings seasonally heavy rain to a region by blowing moisture-laden air from the sea to the land.

morphogenesis Orderly, genetically programmed changes in the size, shape, and proportion of body parts of an organism; the process by which specialized tissues and organs form.

morphological species concept The concept that all individuals of a species share measurable traits that distinguish them from individuals of other species.

morphology The form or shape of an organism, or of a part of an organism.

morula The first stage of animal development, a solid ball or layer of blastomeres.

motif A highly specialized region in a protein produced by the three-dimensional arrangement of amino acid chains within and between domains.

motile Capable of self-propelled movement.

motor neuron An efferent neuron that carries signals to skeletal muscle.

motor unit A block of muscle fibers that is controlled by branches of the axon of a single efferent neuron.

mRNA splicing Process that removes introns from pre-mRNAs and joins exons together.

mucosa The lining of the gut that contains epithelial and glandular cells.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

mucous cells Cells of gastric pits that secrete alkaline mucus, which protects the mucosal layer of the stomach.

Müllerian duct The bipotential primitive duct associated with the gonads that leads to a cloaca.

Müllerian mimicry A form of defense in which two or more unpalatable species share a similar appearance.

multicellular organism Individual consisting of interdependent cells.

multigene family A family of homologous genes in a genome. The members of a multigene family have all evolved from one ancestral gene, and therefore have similar DNA sequences and produce proteins with similar structures and functions.

multiple alleles More than two different alleles of a gene.

multiple sclerosis An autoimmune disease resulting from an attack against a protein of the myelin sheaths insulating the surfaces of neurons.

multipotent In development, referring to cells derived from pluripotent cells; multipotent cells give rise to cells with particular functions.

muscle fiber A bundle of elongated, cylindrical cells that make up skeletal muscle.

muscle tissue Cells that have the ability to contract (shorten) forcibly.

muscle twitch A single, weak contraction of a muscle fiber.

muscularis The muscular coat of a hollow organ or tubular structure.

mutation A spontaneous and heritable change in DNA.

mutualism A symbiotic interaction between species in which both partners benefit.

mycelium A network of branching hyphae that constitutes the body of a multicellular fungus.

mycobiont The fungal component of a lichen.

mycorrhiza A mutualistic symbiosis in which fungal hyphae associate intimately with plant roots.

myofibril A cylindrical contractile element about 1 mm in diameter that runs lengthwise inside the muscle fiber cell.

myogenic heart A heart that maintains its contraction rhythm with no requirement for signals from the nervous system.

myoglobin An oxygen-storing protein closely related to hemoglobin.

myosin A protein that interacts with the protein actin to cause muscle contraction.

Na^+/K^+-ATPase *See* **Na^+/K^+ pump.**

Na^+/K^+ pump Pump that pushes 3 Na^+ out of the cell and 2 K^+ into the cell in the same pumping cycle. Also referred to as the *sodium–potassium pump* or as *Na^+/K^+-ATPase*.

Nanoarchaeota A group of the domain Archaea consisting of one living species that lives as a symbiont and species represented by DNA samples.

nastic movement In plants, a reversible response to nondirectional stimuli, such as mechanical pressure or humidity.

natural history The branch of biology that examines the form and variety of organisms in their natural environments.

natural killer (NK) cell A type of lymphocyte that destroys virus-infected cells.

natural selection The evolutionary process by which alleles that increase the likelihood of survival and the reproductive output of the individuals that carry them become more common in subsequent generations.

natural theology A belief that knowledge of God may be acquired through the study of natural phenomena.

navigation A wayfinding mechanism in which an animal moves toward a specific destination, using both a compass and a "mental map" of where it is in relation to the destination.

negative feedback The primary mechanism of homeostasis, in which a stimulus—a change in the external or internal environment—triggers a response that compensates for the environmental change.

negative pressure breathing Muscular contractions that expand the lungs, lowering the pressure of the air in the lungs and causing air to be pulled inward.

nekton Animals that can actively swim against water currents.

nematocyst A coiled thread, encapsulated in a cnidocyte, that cnidarians fire at prey or predators, sometimes releasing a toxin through its tip.

nephron A specialized excretory tubule that contributes to osmoregulation and carries out excretion, found in all vertebrates.

neritic zone The shallow water of the oceans above the continental shelves.

nerve A bundle of axons enclosed in connective tissue and all following the same pathway.

nerve cord A bundle of nerves that extends from the central ganglia to the rest of the body, connected to smaller nerves.

nerve net A simple nervous system that coordinates responses to stimuli but has no central control organ, or brain.

nervous tissue Tissue that contains neurons, which serve as lines of communication and control between body parts.

net primary productivity The chemical energy remaining in an ecosystem after a producer's cellular respiration is deducted from the gross primary productivity.

neural circuit A connection between axon terminals of one neuron and the dendrites or cell body of a second neuron; typically a neural circuit consists of an afferent (sensory) neuron connected to one or more interneurons, and an efferent neuron.

neural crest A band of cells that arises early in the embryonic development of vertebrates near the region where the neural tube pinches off from the ectoderm; later, the cells migrate and develop into unique structures.

neural plate Ectoderm thickened and flattened into a longitudinal band, induced by notochord cells.

neural signaling The process by which an animal responds appropriately to a stimulus.

neural tube A hollow tube in vertebrate embryos that develops into the brain, spinal cord, spinal nerves, and spinal column.

neurogenic heart A heart that beats under the control of signals from the nervous system.

neuromuscular junction The junction between a nerve fiber and the muscle it supplies.

neuron An electrically active cell of the nervous system responsible for controlling behavior and body functions.

neuroscience The integrated study of the structure, function, and development of the nervous system.

neurosecretory neuron A neuron that releases a neurohormone into the circulatory system when appropriately stimulated.

neurotransmitter A chemical released by an axon terminal at a chemical synapse.

neurulation The process in vertebrates by which organogenesis begins with development of the nervous system from ectoderm.

neutral lipid Energy-storing molecule consisting of a glycerol backbone and three fatty acid chains.

neutral variation hypothesis An evolutionary hypothesis that some variation at gene loci coding for enzymes and other soluble proteins is neither favored nor eliminated by natural selection.

neutralization One of two important mechanisms that clear foreign antigens from the body; toxins produced by an invading pathogen are inactivated (neutralized) by antibodies.

neutron Uncharged particle in the nucleus of an atom.

neutrophil A type of phagocytic leukocyte that attaches to blood vessel walls in massive numbers when attracted to the infection site by chemokines.

nicotinamide adenine dinucleotide (NAD^+) A coenzyme that serves as an electron carrier.

nitrification A metabolic process in which certain soil bacteria convert ammonia or ammonium ions into nitrites that are then converted by other bacteria to nitrates, a form usable by plants.

nitrogen cycle A biogeochemical cycle that moves nitrogen between the huge atmospheric pool of gaseous molecular nitrogen and several much smaller pools of nitrogen-containing compounds in soils, marine and freshwater ecosystems, and living organisms.

nitrogen fixation A metabolic process in which certain bacteria and cyanobacteria convert molecular nitrogen into ammonia and ammonium ions, forms usable by plants.

nitrogenous base A nitrogen-containing molecule with the properties of a base.

nociceptor A sensory receptor that detects tissue damage or noxious chemicals; their activity

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

registers as pain. In systematics, the point of intersection of two branches of a phylogenetic tree.

node In plants, the point on a stem where one or more leaves are attached.

node of Ranvier The gap between two Schwann cells, which exposes the axon membrane directly to extracellular fluids.

noncoding RNA gene A gene encoding an RNA that is not translated; that is, a gene other than a protein-coding gene.

noncompetitive inhibition Inhibition of an enzyme reaction by an inhibitor molecule that binds to the enzyme at a site other than the active site and, therefore, does not compete directly with the substrate for binding to the active site.

noncyclic electron flow Pathway in photosynthesis in which electrons travel in a one-way direction from H_2O to $NADP^+$.

nondisjunction The failure of homologous pairs to separate during the first meiotic division or of chromatids to separate during the second meiotic division.

nonhistone protein All the proteins associated with DNA in a eukaryotic chromosome that are not histones.

nonpolar association Association that occurs when nonpolar molecules clump together.

nonpolar covalent bond Bond in which electrons are shared equally.

nonsense codon *See* **stop codon.**

nonsense mutation A base-pair substitution mutation in a gene in which the base-pair change results in a change from a sense codon to a nonsense codon in the mRNA. The polypeptide translated from the mRNA is shorter than the normal polypeptide because of the mutation.

nonshivering thermogenesis The generation of heat by oxidative mechanisms in nonmuscle tissue throughout the body.

nonvascular plant *See* **bryophyte.**

norepinephrine A nontropic amine hormone secreted by the adrenal medulla.

northern blot analysis Method of analysis in which RNA molecules extracted from cells or a tissue are separated by size using electrophoresis, transferred to a filter paper, and then probed to reveal the presence of particular RNAs.

notochord A flexible rodlike structure, constructed of fluid-filled cells surrounded by tough connective tissue, which supports a chordate embryo from head to tail.

N-terminal end The end of a polypeptide chain with an $—NH_3^+$ group.

nuclear envelope In eukaryotes, membranes separating the nucleus from the cytoplasm.

Nucleariidae (nucleariids) A protist group consistsing of heterotrophic, predominantly spherical amoebae with radiating, fine pseudopods that are not supported by microtubules. Nucleariids are a subgroup of the opisthokonts and are more closely related to fungi than to animals.

nuclear localization signal A short amino acid sequence in a protein that directs the protein to the nucleus.

nuclear pore complex A large, octagonally symmetrical, cylindrical structure that functions to exchange molecules between the nucleus and cytoplasm and prevents the transport of material not meant to cross the nuclear membrane. A nuclear pore—a channel through the complex—is the path for the exchange of molecules.

nucleoid The central region of a prokaryotic cell with no boundary membrane separating it from the cytoplasm, where DNA replication and RNA transcription occur.

nucleolus The nuclear site of rRNA transcription, processing, and ribosome assembly in eukaryotes.

nucleoplasm The liquid or semiliquid substance within the nucleus.

nucleoside Chemical structure containing only a nitrogenous base and a five-carbon sugar.

nucleosome The basic structural unit of chromatin in eukaryotes, consisting of DNA wrapped around a histone core.

nucleosome core particle An eight-protein particle formed by the combination of two molecules each of H2A, H2B, H3, and H4, around which DNA winds for almost two turns.

nucleosome remodeling complex Multiprotein complex that uses the energy of ATP hydrolysis to slide a nucleosome along the DNA of a eukaryotic chromosome to expose the promoter of a gene, or to restructure the nucleosome without moving it to allow transcription factors to bind.

nucleotide The monomer of nucleic acids consisting of a five-carbon sugar, a nitrogenous base, and a phosphate.

nucleus The central region of eukaryotic cells, separated by membranes from the surrounding cytoplasm, where DNA replication and messenger RNA transcription occur. In the nervous system, a nucleus is a concentration of nerve cells within the central nervous system that have related functions.

null hypothesis A statement of what would be seen if the hypothesis being tested were wrong.

null model A conceptual model that predicts what one would see if a particular factor had no effect.

nutrition The processes by which an organism takes in, digests, absorbs, and converts food into organic compounds.

obligate aerobe A microorganism that uses oxygen for cellular respiration and requires oxygen in its surroundings to support growth.

obligate anaerobe A microorganism that cannot use oxygen and can grow only in the absence of oxygen.

observational data Basic information on biological structures or the details of biological processes.

oceanic zone The deep ocean water beyond the continental shelves.

ocellus (plural, *ocelli*) The simplest eye, which detects light but does not form an image.

oil Neutral lipid that is liquid at biological temperatures.

Okazaki fragments The short lengths of lagging strand DNA produced by discontinuous replication.

olfactory bulb A gray-matter center that relay inputs from odor receptors to both the cerebral cortex and the limbic system.

oligodendrocyte A type of glial cell that populates the CNS and is responsible for producing myelin.

oligosaccharin A complex carbohydrate that in plants serves as a signaling molecule and as a defense against pathogens.

oligotrophic lake A lake that is poor in nutrients and organic matter, but rich in oxygen.

omasum One of the four stomach chambers of a ruminant; in this chamber, water is absorbed from the mass of digesting material.

ommatidium (plural, *ommatidia*) A faceted visual unit of a compound eye.

omnivore An animal that feeds at several trophic levels, consuming plants, animals, and other sources of organic matter.

oncogene A gene capable of inducing one or more characteristics of cancer cells.

one gene–one enzyme hypothesis Hypothesis showing the direct relationship between genes and enzymes.

one gene–one polypeptide hypothesis Restatement of the one gene–one enzyme hypothesis, taking into account that some proteins consist of more than one polypeptide and not all proteins are enzymes.

oocyte A developing gamete that becomes an ootid at the end of meiosis.

oogenesis The process of producing eggs.

oogonium A cell that enters meiosis and gives rise to gametes, produced by mitotic divisions of the germ cells in females.

Oomycota (water molds, white rusts, and downy mildews) A lineage of the Stramenopila subgroup of the Chromalveolata protist evolutionary group; funguslike organisms that lack chloroplasts and live as heterotrophs.

open circulatory system An arrangement of internal transport in some invertebrates in which the vascular fluid, hemolymph, is released into sinuses, bathing organs directly, and is not always retained within vessels.

open reading frame (ORF) Segment of a protein-coding gene or an mRNA transcribed from such a gene that involves a start codon separated by a multiple of three nucleotides from one of the stop codons. The ORF is a potential polypeptide-coding sequence.

operant conditioning A form of associative learning in which animals learn to link a voluntary activity, an operant, with its favorable consequences, the reinforcement.

operator A DNA regulatory sequence that controls transcription of an operon.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

operculum A lid or flap of the bone serving as the gill cover in some fishes.

operon A cluster of prokaryotic genes organized into a single transcription unit and their associated regulatory sequences.

Opisthokonta (opisthokonts) A protist evolutionary group; a broad group of eukaryotes in which a single posterior flagellum is found at some stage in the life cycle.

opsin One of several different proteins that bond covalently with the light-absorbing pigment of rods and cones (retinal).

optic chiasm Location just behind the eyes where the optic nerves converge before entering the base of the brain, a portion of each optic nerve crossing over to the opposite side.

optical isomers *See* **enantiomers.**

optimal foraging theory A set of mathematical models that predict the diet choices of animals as they encounter a range of potential food items.

oral hood Soft fleshy structure at the anterior end of a cephalochordate that frames the opening of the mouth.

orbital The region of space where the electron "lives" most of the time.

order A Linnaean taxonomic category of organisms that ranks above a family and below a class.

organ Two or more different tissues integrated into a structure that carries out a specific function.

organ of Corti An organ within the cochlear duct that contains the sensory hair cells detecting sound vibrations transmitted to the inner ear.

organ system The coordinated activities of two or more organs to carry out a major body function such as movement, digestion, or reproduction.

organelles The nucleus and other specialized internal structures and compartments of eukaryotic cells.

organic acid (carboxylic acid) Acid for which the characteristic functional group is a carboxyl group (—COOH).

organic molecule Molecule based on carbon.

organismal ecology An ecological discipline in which researchers study the genetic, biochemical, physiological, morphological, and behavioral adaptations of organisms to their abiotic environments.

organogenesis The development of the major organ systems, giving rise to a free-living individual with the body organization characteristic of its species.

oriented cell division Cell division in different planes; establishes the overall shape of a plant organ.

origin of replication A specific region at which DNA replication commences. Bacterial chromosomes have single origins of replication (*ori*) whereas eukaryotic chromosomes have multiple origins.

orthogenesis An obsolete theory that evolution is goal oriented, striving to perfect organisms.

oscula One or more openings in a sponge through which water is expelled.

osmoconformer An animal in which the osmolarity of the cellular and extracellular solutions matches the osmolarity of the environment.

osmolarity The total solute concentration of a solution, measured in osmoles—the number of solute molecules and ions (in moles)—per liter of solution.

osmoreceptor A sensory receptor in the hypothalamus that responds to changes in the osmolarity of the fluid surrounding it, which reflects the osmolarity generally of the body fluids.

osmoregulation The regulation of water and ion balance.

osmoregulator An animal that uses control mechanisms to keep the osmolarity of cellular and extracellular fluids the same, but at levels that may differ from the osmolarity of the surroundings.

osmosis The passive transport of water across a selectively permeable membrane in response to solute concentration gradients, a pressure gradient, or both.

osmotic pressure A state of dynamic equilibrium in which the pressure of the solution on one side of a selectively permeable membrane exactly balances the tendency of water molecules to diffuse passively from the other side of the membrane due to a concentration gradient.

osteoblast A cell that produces the collagen and mineral of bone.

osteoclast A cell that removes bone minerals and recycles them through the bloodstream.

osteocyte A mature bone cell.

osteon The structural unit of bone, consisting of a minute central canal surrounded by osteocytes embedded in concentric layers of mineral matter.

ostracoderm One of an assortment of extinct, jawless fishes that were covered with bony armor.

otolith One of many small crystals of calcium carbonate embedded in the otolithic membrane of the hair cells.

outer boundary membrane A smooth membrane that surrounds a chloroplast, enclosing the stroma.

outer ear The external structure of the ear, consisting of the pinna and meatus.

outer membrane In Gram-negative bacteria, an additional boundary membrane that covers the peptidoglycan layer of the cell wall.

outer mitochondrial membrane The smooth membrane covering the outside of a mitochondrion.

outgroup comparison A technique used to identify ancestral and derived characters by comparing the group under study to more distantly related species that are not otherwise included in the analysis.

ova *See* **ovum.**

oval window An opening in the bony wall that separates the middle ear from the inner ear.

ovarian cycle The cyclic events in the ovary leading to ovulation.

ovary In animals, the female gonad, which produces female gametes and reproductive hormones. In flowering plants, the enlarged base of a carpel in which one or more ovules develop into seeds.

overexploitation The excessive harvesting of an animal or plant species, potentially leading to its extinction.

overnutrition A form of malnutrition. The condition caused by excessive intake of specific nutrients.

oviduct The tube through which the egg moves from the ovary to the outside of the body.

oviparous Referring to animals that lay eggs containing the nutrients needed for development of the embryo outside the mother's body.

ovoviviparous Referring to animals in which fertilized eggs are retained within the body and the embryo develops using nutrients provided by the egg; eggs hatch inside the mother.

ovulation The process in which oocytes are released into the oviducts as immature eggs.

ovule In plants, the structure in a carpel in which a female gametophyte develops and fertilization takes place.

ovum (plural, *ova*) A female sex cell, or egg.

oxidation The partial or full loss of electrons from a substance.

oxidative phosphorylation Synthesis of ATP in which ATP synthase uses an H^+ gradient built by the electron transfer system as the energy source to make the ATP.

oxidized Substance—the electron donor—from which the electrons are lost during oxidation.

oxytocin A hormone that stimulates the ejection of milk from the mammary glands of a nursing mother.

P generation The parental individuals used in an initial genetic cross.

P site The site in the ribosome where the tRNA carrying the growing polypeptide chain is bound during translation.

pacemaker cell A specialized cardiac muscle cell in the upper wall of the right atrium that sets the rate of contraction in the heart.

paedomorphosis A common form of heterochrony in which juvenile characteristics are retained in a reproductive adult.

pairing Process in meiosis in which homologous chromosomes come together and pair. Also referred to as *synapsis*.

pair-rule gene In *Drosophila* embryonic development, one of the second activated set of segmentation genes that progressively subdivide the embryo into regions, determining the segments of the embryo and the adult. Pair-rule genes control the division of the embryo into units of two segments each.

paleobiology The study of ancient organisms.

pancreas A mixed gland composed of an exocrine portion that secretes digestive enzymes into the small intestine and an endocrine portion, the islets of Langerhans, that secretes insulin and glucagon.

pancreatic enzymes Digestive enzymes secreted by exocrine cells in the pancreas into ducts that empty into the lumen of the duodenum.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

parapatric speciation Speciation between populations with adjacent geographical distributions.

paraphyletic taxon A group of organisms that includes an ancestral species and some, but not all, of its descendants.

parapodia Fleshy lateral extensions of the body wall of aquatic annelids, used for locomotion and gas exchange.

parasite An organism that feeds on the tissues of or otherwise exploits its host.

parasitism A symbiotic interaction in which one species, the parasite, uses another, the host, in a way that is harmful to the host.

parasitoid An insect species in which a female lays eggs in the larva or pupa of another insect species, and her young consume the tissues of the living host.

parasympathetic division The division of the autonomic nervous system that predominates during quiet, low-stress situations, such as while relaxing.

parathyroid gland One of a pair of glands that produce parathyroid hormone (PTH) (found only in tetrapod vertebrates).

parathyroid hormone (PTH) The hormone secreted by the parathyroid glands in response to a fall in blood Ca^{2+} levels.

parenchyma A ground tissue with cells having a thin primary wall, which is pliable and permeable to water. Parenchyma cells may be specialized for photosynthesis, storage, secretion, or other tasks.

parental Phenotypes identical to the original parental individuals.

parental investment The time and energy devoted to the production and rearing of offspring.

parietal cells Cells of gastric glands that secrete H^+ and Cl^-, which combine to form HCl in the lumen of the stomach.

parthenogenesis A mode of asexual reproduction in which animals produce offspring by the growth and development of an egg without fertilization.

partial diploid A condition in which part of the genome of a haploid organism is diploid. Recipients in bacterial conjugation between an Hfr and an F^- cell become partial diploids for part of the Hfr bacterial chromosome.

partial pressure In a mixture of gases, the pressure of each individual gas.

parturition The process of giving birth.

passive immunity The acquisition of antibodies as a result of direct transfer from another person.

passive parental care The amount of energy invested in offspring—in the form of the energy stored in eggs or seeds or energy transferred to developing young through a placenta—before they are born.

passive transport The transport of substances across cell membranes without expenditure of energy, as in diffusion.

paternal chromosome The chromosome derived from the male parent of an organism.

pathogenesis-related (PR) protein A hydrolytic enzyme that breaks down components of a pathogen's cell wall.

pattern formation The arrangement of organs and body structures in their proper three-dimensional relationships.

pectoral girdle A bony or cartilaginous structure in vertebrates that supports and is attached to the forelimbs.

pedicellariae Small pincers at the base of short spines in starfishes and sea urchins.

pedigree Chart that shows all parents and offspring for as many generations as possible, the sex of individuals in the different generations, and the presence or absence of a trait of interest.

pelagic province The open water in the oceans.

pellicle A layer of supportive protein fibers located inside the cell, just under the plasma membrane, providing strength and flexibility instead of a cell wall.

pelvic girdle A bony or cartilaginous structure in vertebrates that supports and is attached to the hind limbs.

pepsin An enzyme made in the stomach that breaks down proteins.

pepsinogen The inactive precursor molecule for pepsin.

peptic ulcer Lesion in the stomach wall resulting from attack by HCl and pepsin.

peptide bond A link formed by a dehydration synthesis reaction between the —NH_2 group of one amino acid and the —COOH group of a second.

peptidoglycan A polymeric substance formed from a polysaccharide backbone tied together by short polypeptides, which is the primary structural molecule of bacterial cell walls.

peptidyl transferase An enzyme that catalyzes the reaction in which an amino acid is cleaved from the tRNA in the P site of the ribosome and forms a peptide bond with the amino acid on the tRNA in the A site of the ribosome.

peptidyl–tRNA A tRNA linked to a growing polypeptide chain containing two or more amino acids.

per capita growth rate The difference between the per capita birth rate and the per capita death rate of a population.

perception The conscious awareness of our external and internal environments derived from the processing of sensory input.

perennial A plant in which vegetative growth and reproduction continue year after year.

perfect flower A flower that has both male (stamen) and female (carpel) sexual organs.

perfusion The flow of blood or other body fluids on the internal side of the respiratory surface.

pericarp The fruit wall.

pericycle A tissue of plant roots, located between the endodermis and the phloem, which gives rise to lateral roots.

periderm The outermost portion of bark; consists of cork, cork cambium, and secondary cortex.

peripheral nervous system (PNS) All nerve roots and nerves (motor and sensory) that supply the muscles of the body and transmit information about sensation (including pain) to the central nervous system.

peripheral protein Protein held to membrane surfaces by noncovalent bonds formed with the polar parts of integral membrane proteins or membrane lipids.

peristalsis The rippling motion of muscles in the intestine or other tubular organs characterized by the alternate contraction and relaxation of the muscles that propel the contents onward.

peritoneum The thin tissue derived from mesoderm that lines the abdominal wall and covers most of the organs in the abdomen.

peritubular capillary A capillary of the network surrounding the glomerulus.

permafrost Perpetually frozen ground below the topsoil.

peroxisome Microbody that produces hydrogen peroxide as a by-product.

PET *See* **positron emission tomography.**

petal Part of the corolla of a flower, often brightly colored.

petiole The stalk by which a leaf is attached to a stem.

pH scale The numerical scale used by scientists to measure acidity.

Phaeophyta (brown algae) A lineage of the Stramenopila subgroup of the Chromalveolata evolutionary subgroup; photosynthetic autotrophs that range from microscopic forms to giant kelps.

phage *See* **bacteriophage.**

phagocytosis Process in which some types of cells engulf bacteria or other cellular debris to break them down.

pharyngeal arches Embryonic features of all vertebrates; they contribute to the formation of the face, neck, mouth, larynx, and pharynx.

pharynx The throat. In some invertebrates, a protrusible tube used to bring food into the mouth for passage to the gastrovascular cavity; in mammals, the common pathway for air entering the larynx and food entering the esophagus.

phenotype The observable or measurable (biochemical, molecular) characteristics of an organism that are produced by an interaction between the genotype and the environment.

phenotypic variation Differences in appearance or function between individual organisms.

pheromone A distinctive volatile chemical released in minute amounts to influence the behavior of members of the same species.

phloem The food-conducting tissue of a vascular plant.

phloem sap The solution of water and organic compounds that flows rapidly through the sieve tubes of plants.

phosphate group Group consisting of a central phosphorus atom held in four linkages: two that bind —OH groups to the central phosphorus atom,

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

a third that binds an oxygen atom to the central phosphorus atom, and a fourth that links the phosphate group to an oxygen atom.

phosphodiester bond The linkage of nucleotides in polynucleotide chains by a bridging phosphate group between the 5′ carbon of one sugar and the 3′ carbon of the next sugar in line.

phospholipid A phosphate-containing lipid.

phosphorus cycle A biogeochemical cycle in which weathering and erosion carry phosphate ions from rocks to soil and into streams and rivers, which eventually transport them to the ocean, where they are slowly incorporated into rocks.

phosphorylation The addition of a phosphate group to a molecule.

photic zone Surface water of a lake or ocean that sunlight penetrates.

photoautotroph Photosynthetic organism that uses light as its energy source and carbon dioxide as its carbon source.

photobiont The photosynthetic component of a lichen.

photoheterotroph An organism that uses light as the ultimate energy source but obtains carbon in organic form rather than as carbon dioxide.

photoperiodism The response of plants to changes in the relative lengths of light and dark periods in their environment during each 24-hour period.

photophosphorylation The synthesis of ATP coupled to the transfer of electrons energized by photons of light.

photopigment Light-absorbing pigment.

photopsin One of three photopigments in which retinal is combined with different opsins.

photoreceptor A sensory receptor that detects the energy of light.

photorespiration A process that metabolizes a by-product of photosynthesis.

photosynthesis The conversion of light energy to chemical energy in the form of sugar and other organic molecules.

photosystem A large complex into which the light-absorbing pigments for photosynthesis are organized with proteins and other molecules.

photosystem I In photosynthesis, a protein complex in the thylakoid membrane that uses energy absorbed from sunlight to synthesize NADPH.

photosystem II In photosynthesis, a protein complex in the thylakoid membrane that uses energy absorbed from sunlight to synthesize ATP.

phototroph An organism that obtains energy from light.

phototropism The tendency of a plant shoot to bend toward a source of light.

phyletic gradualism hypothesis The hypothesis that most morphological change occurs gradually over long periods of time.

PhyloCode A formal set of rules governing phylogenetic nomenclature.

phylogenetic species concept A concept that seeks to delineate species as the smallest aggregate population that can be united by shared derived characters.

phylogenetic tree A branching diagram depicting the evolutionary relationships of groups of organisms.

phylogeny The evolutionary history of a group of organisms.

phylum (plural, *phyla*) A major Linnaean division of a kingdom, ranking above a class.

physical barriers The first of three lines of defense that humans and other mammals have against threats of pathogens; parts of the organism that physically block access to a pathogen. Examples are skin and epithelial surfaces covering internal body cavities and ducts. Physical barriers are not part of the immune system.

physiological respiration The process by which animals exchange gases with their surroundings—how they take in oxygen from the outside environment and deliver it to body cells, and remove carbon dioxide from body cells and deliver it to the environment.

physiology The study of the functions of organisms—the physico-chemical processes of organisms.

phytoalexin A biochemical that functions as an antibiotic in plants.

phytochrome A blue-green pigmented plant chromoprotein involved in the regulation of light-dependent growth processes.

phytoplankton Microscopic, free-flowing aquatic plants and protists.

phytosterol A sterol that occurs in plant cell membranes.

piloting A wayfinding mechanism in which animals use familiar landmarks to guide their journey.

pilus (plural, *pili*) A hair or hairlike appendage on the surface of a prokaryote.

pinacoderm In sponges, an unstratified outer layer of cells.

pineal gland A light-sensitive, melatonin-secreting gland that regulates some biological rhythms.

pinna The external structure of the outer ear, which concentrates and focuses sound waves.

pinocytosis *See* **bulk-phase endocytosis.**

pith The soft, spongelike, central cylinder of plant stems, composed mainly of parenchyma.

pituitary A gland consisting mostly of two fused lobes suspended just below the hypothalamus by a slender stalk of tissue that contains both neurons and blood vessels; it interacts with the hypothalamus to control many physiological functions, including the activity of some other glands.

placenta A specialized temporary organ that connects the embryo and fetus with the uterus in mammals, mediating the delivery of oxygen and nutrients.

plasma The clear, yellowish fluid portion of the blood in which cells are suspended. Plasma consists of water, glucose and other sugars, amino acids, plasma proteins, dissolved gases, ions, lipids, vitamins, hormones and other signal molecules, and metabolic wastes.

plasma cell A large antibody-producing cell that develops from B cells.

plasma membrane The outer limit of the cytoplasm responsible for the regulation of substances moving into and out of cells.

plasmid A DNA molecule in the cytoplasm of certain prokaryotes, which often contains genes with functions that supplement those in the nucleoid and which can replicate independently of the nucleoid DNA and be passed along during cell division.

plasmodesma (plural, *plasmodesmata*) A minute channel that perforates a cell wall and contains extensions of the cytoplasm that directly connect adjacent plant cells.

plasmodial slime mold A slime mold of the class Myxomycetes.

plasmodium The composite mass of plasmodial slime molds consisting of individual nuclei suspended in a common cytoplasm surrounded by a single plasma membrane.

plasmogamy The sexual stage of fungi during which the cytoplasms of two genetically different partners fuse.

plasmolysis Condition due to outward osmotic movement of water, in which plant cells shrink so much that they retract from their walls.

plastids A family of plant organelles that includes chloroplasts, amyloplasts, and chromoplasts.

plastron The ventral part of the shell of a turtle.

plate tectonics The geological theory describing how Earth's crust is broken into irregularly shaped plates of rock that float on its semisolid mantle.

platelet An oval or rounded cell fragment enclosed in its own plasma membrane, which is found in the blood; they are produced in red bone marrow by the division of stem cells and contain enzymes and other factors that take part in blood clotting.

pleiotropy Condition in which single genes affect more than one character of an organism.

pleura The double layer of epithelial tissue covering the lungs.

ploidy The number of chromosome sets of a cell or species.

plumule The rudimentary terminal bud of a plant embryo located at the end of the hypocotyl, consisting of the epicotyl and a cluster of tiny foliage leaves.

pluripotent In development, referring to cells derived from totipotent cells; pluripotent cells can give rise to most adult cell types.

polar association Association that occurs when polar molecules attract and align themselves with other polar molecules and with charged ions and molecules.

polar body A nonfunctional cell produced in oogenesis.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

polar covalent bond Bond in which electrons are shared unequally.

polar nucleus In the embryo sac of a flowering plant, one of two nuclei that migrate into the center of the sac, become housed in a central cell, and eventually give rise to endosperm.

polar transport Unidirectional movement of a substance from one end of a cell (or other structure) to the other.

polarity The unequal distribution of yolk and other components in a mature egg.

pollen grain The male gametophyte of a seed plant.

pollen sac The microsporangium of a seed plant, in which pollen develops.

pollen tube A tube that grows from a germinating pollen grain and carries sperm cells to the ovary.

pollination The transfer of pollen to a seed plant's female reproductive parts by air currents or on the bodies of animal pollinators.

pollutant Materials or energy in a form or quantity that organisms do not usually encounter.

poly(A) polymerase The enzyme in eukaryotes that adds a chain of adenine nucleotides—the poly(A) tail—to the cleaved 3′ end of a pre-mRNA.

poly(A) tail The string of A nucleotides added posttranscriptionally to the 3′ end of a cleaved pre-mRNA molecule and retained in the mRNA produced from it that enables the mRNA to be translated efficiently and protects it from attack by RNA-digesting enzymes in the cytoplasm.

polyadenylation signal Sequence near the 3′ end of a eukaryotic gene which, in the pre-mRNA transcript of the gene, specifies where the transcript should be cleaved. Once cleaved, a poly(A) tail is added to the 3′ end of the RNA.

polyandry A polygamous mating system in which one female mates with multiple males.

polygamy A mating system in which either males or females may have many mating partners.

polygenic inheritance Inheritance in which several to many different genes contribute to the same character.

polygyny A polygamous mating system in which one male mates with many females.

polyhedral virus A virus in which the coat proteins form triangular units that fit together like the parts of a geodesic sphere.

polymerase chain reaction (PCR) Process that amplifies a specific DNA sequence from a DNA mixture to an extremely large number of copies.

polymorphism The existence of discrete variants of a character among individuals in a population.

polyp The tentacled, usually sessile stage in the life cycle of a coelenterate.

polypeptide The chain of amino acids formed by sequential peptide bonds.

polyphyletic taxon A group of organisms that belong to different evolutionary lineages and do not share a recent common ancestor.

polyploid An individual with one or more extra copies of the entire haploid complement of chromosomes.

polyploidy The condition of having one or more extra copies of the entire haploid complement of chromosomes.

polysaccharide Chain with more than 10 linked monosaccharide subunits.

polysome The entire structure of an mRNA molecule and the multiple associated ribosomes that are translating it simultaneously.

polyunsaturated Fatty acid with more than one double bond.

population All the individuals of a single species that live together in the same place and time.

population bottleneck An evolutionary event that occurs when a stressful factor reduces population size greatly and eliminates some alleles from a population.

population density The number of individuals per unit area or per unit volume of habitat.

population dynamics Changes in the characteristics of populations through time or over space.

population ecology The ecological discipline that focuses on how a population's size and other characteristics change in space and time.

population genetics The branch of science that studies the prevalence and variation in genes among populations of individuals.

population size The number of individuals in a population at a specified time.

population viability analysis A mathematical analysis used by conservation biologists to determine the minimum viable population size for threatened or endangered species.

positive feedback A mechanism that intensifies or adds to a change in internal or external environmental condition.

positive pressure breathing A gulping or swallowing motion that forces air into the lungs.

positron emission tomography (PET) A scanning technique for studying activities of the cerebral cortex.

posterior Indicating the tail end of an animal.

posterior pituitary The neural portion of the pituitary, which stores and releases two hormones made by the hypothalamus, antidiuretic hormone and oxytocin.

postsynaptic cell The neuron or the surface of an effector after a synapse that receives the signal from the presynaptic cell.

posttranslational import A mechanism by which proteins are sorted to their final cellular locations in a eukaryotic cell after they have been made on free ribosomes in the cytosol.

postzygotic isolating mechanism A reproductive isolating mechanism that acts after zygote formation.

potential energy Stored energy.

predation The interaction between animals and the animal prey they consume.

prediction A statement about what the researcher expects to happen to one variable if another variable changes.

pregnancy The period of mammalian development in which the embryo develops in the uterus of the mother.

premolars Teeth located in pairs on each side of the upper and lower jaws of mammals, positioned behind the canines and in front of the molars.

pre-mRNA (precursor-mRNA) The primary transcript of a eukaryotic protein-coding gene, which is processed to form messenger RNA.

prenatal diagnosis Techniques in which cells derived from a developing embryo or its surrounding tissues or fluids are tested for the presence of mutant alleles or chromosomal alterations.

prepuce Foreskin; a loose fold of skin that covers the glans of the penis.

pressure flow mechanism In vascular plants, pressure that builds up at the source end of a sieve tube system and pushes solutes by bulk flow toward a sink, where they are removed.

presynaptic cell The neuron with an axon terminal on one side of the synapse that transmits the signal across the synapse to the dendrite or cell body of the postsynaptic cell.

prezygotic isolating mechanism A reproductive isolating mechanism that acts before the production of a zygote, or fertilized egg.

primary active transport Transport in which the same protein that transports a substance also hydrolyzes ATP to power the transport directly.

primary cell layers The ectoderm, mesoderm, and endoderm layers that form the embryonic tissues.

primary cell wall The initial cell wall laid down by a plant cell.

primary consumer An herbivore, a member of the second trophic level.

primary endosymbiosis In the model for the origin of plastids in eukaryotes, the first event in which a eukaryotic cell engulfed a photosynthetic cyanobacterium.

primary growth The growth of plant tissues derived from apical meristems. *Compare* **secondary growth.**

primary immune response The response of the immune system to the first challenge by an antigen.

primary meristem Root and shoot apical meristems, from which a plant's primary tissues develop. *Compare* **lateral meristem.**

primary motor area The area of the cerebral cortex that runs in a band just in front of the primary somatosensory area and is responsible for voluntary movement.

primary plant body The portion of a plant that is made up of primary tissues.

primary producer An autotroph, usually a photosynthetic organism, a member of the first trophic level.

primary somatosensory area The area of the cerebral cortex that runs in a band across the parietal lobes of the brain and registers information on touch, pain, temperature, and pressure.

primary structure The sequence of amino acids in a protein.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

primary succession Predictable change in species composition of an ecological community that develops on bare ground.

primary tissue A plant tissue that develops from an apical meristem.

primase An enzyme that assembles the primer for a new DNA strand during DNA replication.

primer A short nucleotide chain made of RNA that is laid down as the first series of nucleotides in a new DNA strand, or made of DNA for use in the polymerase chain reaction (PCR).

primitive groove In development of birds, the sunken midline of the primitive streak that acts as a conduit for migrating cells to move into the blastocoel.

primitive streak In development of birds, the thickened region of the embryo produced by cells of the epiblast streaming toward the midline of the blastodisc.

Principle of Independent Assortment Mendel's principle that the alleles of the genes that govern two characters assort independently during formation of gametes.

principle of parsimony A principle of systematic biology that states that a particular trait is unlikely to evolve independently in separate evolutionary lineages.

Principle of Segregation Mendel's principle that the pairs of alleles that control a character segregate as gametes are formed, with half the gametes carrying one allele, and the other half carrying the other allele.

prion An infectious agent that contains only protein and does not include a nucleic acid molecule.

probability The possibility that an outcome will occur if it is a matter of chance.

procambium The primary meristem of a plant that develops into primary vascular tissue.

product An atom or molecule leaving a chemical reaction.

product rule Mathematical rule in which the final probability is found by multiplying individual probabilities.

profundal zone The perpetually dark layer below the limnetic zone in a lake.

progesterone A female sex hormone that stimulates growth of the uterine lining and inhibits contractions of the uterus.

progestin A class of sex hormones synthesized by the gonads of vertebrates and active predominantly in females.

prokaryote Organism in which the DNA is suspended in the cell interior without separation from other cellular components by a discrete membrane.

prokaryotic chromosome The genetic material of prokaryotes, in most cases a single, circular DNA molecule.

prolactin (PRL) A peptide hormone secreted by the anterior pituitary that stimulates breast development and milk secretion in mammals.

prometaphase A transition period between prophase and metaphase during which the microtubules of the mitotic spindle attach to the kinetochores and the chromosomes shuffle until they align in the center of the cell.

promiscuity A mating system in which individuals do not form close pair bonds, and both males and females mate with multiple partners.

promoter The site to which RNA polymerase binds (prokaryotes) or to which general transcription factors bind and recruit RNA polymerase (eukaryotes) for initiating transcription of a gene.

promoter proximal element Regulatory sequence within the promoter proximal region, a region upstream of the promoter of a eukaryotic protein-coding gene. Regulatory proteins bind to promoter proximal elements and stimulate or inhibit the rate of transcription initiation.

promoter proximal region Upstream of a eukaryotic gene, a region containing regulatory sequences—promoter proximal elements—for transcription called promoter proximal elements.

proofreading mechanism Mechanism during DNA replication in which DNA polymerase backs up and removes a mispaired nucleotide from a newly synthesized DNA strand and then adds the correct nucleotide to the growing chain.

prophage A viral genome inserted in the host cell DNA.

prophase The beginning phase of mitosis during which the duplicated chromosomes within the nucleus condense from a greatly extended state into compact, rodlike structures.

proprioceptor A mechanoreceptor that detects stimuli used in the CNS to maintain body balance and equilibrium and to monitor the position of the head and limbs.

prostaglandin One of a group of local regulators derived from fatty acids that are involved in paracrine and autocrine regulation.

prostate gland An accessory sex gland in males that adds a thin, milky fluid to the semen and adjusts the pH of the semen to the level of acidity best tolerated by sperm.

proteasome Large cytoplasmic protein complex in eukaryotic cells that degrades ubiquitinylated proteins.

protein Molecules that carry out most of the activities of life, including the synthesis of all other biological molecules. A protein consists of one or more polypeptides depending on the protein.

protein chip *See* **protein microarray.**

protein kinase Enzyme that transfers a phosphate group from ATP to one or more sites on particular proteins.

protein microarray Similar in concept to a DNA microarray, a solid surface with a microscopic grid with thousands of spaces containing probes for analyzing the proteome, the complete set of proteins encoded by the genome of an organism. Also referred to as a *protein chip*.

protein phosphatase Enzyme that removes phosphate groups from target proteins.

protein-coding gene A gene encoding a protein.

proteome The complete set of proteins that can be expressed by the genome of an organism.

proteomics The study of the proteome.

prothoracicotropic hormone (PTTH) A peptide hormone secreted by neurosecretory neurons in the brains of insects that is one of the hormones regulating molting and metamorphosis.

protists A diverse and polyphyletic group of single-celled and multicellular eukaryotic species.

protocell A primitive cell-like structure that has some of the properties of life and that might have been the precursor of cells.

protoderm The primary meristem that will produce stem epidermis.

proton Positively charged particle in the nucleus of an atom.

proton pump Pump that moves hydrogen ions across membranes and pushes hydrogen ions across the plasma membrane from the cytoplasm to the cell exterior. Also referred to as H^+ *pump*.

protonema The structure that arises when a liverwort or moss spore germinates and eventually gives rise to a mature gametophyte.

protonephridium The simplest form of invertebrate excretory tubule.

proton-motive force Stored energy that contributes to ATP synthesis, as well as to the cotransport of substances to and from mitochondria.

proto-oncogene A gene that encodes various kinds of proteins that stimulate cell division. Mutated proto-oncogenes—oncogenes—contribute to the development of cancer.

protoplast The cytoplasm, organelles, and plasma membrane of a plant cell.

protoplast fusion A plant breeding process in which protoplasts are fused into a single cell.

provirus DNA copy of a retrovirus RNA genome that becomes inserted into host DNA.

proximal convoluted tubule The tubule between the Bowman's capsule and the loop of Henle in the nephron of the kidney, which carries and processes the filtrate.

pseudocoelom A fluid- or organ-filled body cavity between the gut (a derivative of endoderm) and the muscles of the body wall (a derivative of mesoderm).

pseudocoelomate A body plan of bilaterally symmetrical animals with a body cavity that lacks a complete lining derived from mesoderm.

pseudopod (plural, *pseudopodia*) A temporary cytoplasmic extension of a cell.

pseudogene A gene that is very similar to a functional gene at the DNA sequence level but that has one or more inactivating mutations that prevent it from producing a functional gene product.

psychrophile An archaean or bacterium that grows optimally at temperatures in the range −10°C to −20°C.

Pterophyta The plant phylum of ferns and their close relatives.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

pulmocutaneous circuit In amphibians, the branch of a double blood circuit that receives deoxygenated blood and moves it to the skin and lungs or gills.

pulmonary arteries The arteries from the right ventricle of the heart that lead to the lungs.

pulmonary circuit The circuit of the cardiovascular system that supplies the lungs.

pulmonary veins The veins that carry oxygenated blood from the lungs to the right atrium of the heart.

pulse The measurable rate of ventricular contraction of the heart detected at the peak of high pressure in an artery.

pulvinus (plural, *pulvini*) A jointlike, thickened pad of tissue at the base of a leaf or petiole; flexes when the leaf makes nastic movements.

punctuated equilibrium hypothesis The evolutionary hypothesis that most morphological variation arises rapidly during speciation events in isolated populations at the edge of a species' geographical distribution.

Punnett square Method for determining the genotypes and phenotypes of offspring and their expected proportions by combining gametes and their probabilities of occurrence in a matrix table.

pupa The nonfeeding stage between the larva and adult in the complete metamorphosis of some insects, during which the larval tissues are completely reorganized within a protective cocoon or hardened case.

pupil The dark center in the middle of the iris through which light passes to the back of the eye.

purine A type of nitrogenous base with two carbon–nitrogen rings.

pyloric sphincter The muscular ring at the junction between the stomach and small intestine that controls the flow of materials from the stomach.

pyramid of biomass A diagram that illustrates differences in standing crop biomass in a series of trophic levels.

pyramid of energy A diagram that illustrates the amount of energy that flows through a series of trophic levels.

pyramid of numbers A diagram that illustrates the number of individual organisms present in a series of trophic levels.

pyrimidine A type of nitrogenous base with one carbon–nitrogen ring.

pyrogens Chemicals released by macrophages in response to infection that stimulate prostaglandin release from the hypothalamus thereby leading to an increase in body temperature (fever).

pyruvate oxidation (pyruvic acid oxidation) Stage of cellular respiration in which the three-carbon molecule pyruvate is converted into a two-carbon acetyl group that is completely oxidized to carbon dioxide.

qualitative variation Variation that exists in two or more discrete states, with intermediate forms often being absent.

quantitative trait A character that displays a continuous distribution of the phenotype involved, typically resulting from several to many contributing genes.

quantitative trait loci (QTLs) The individual genes that contribute to a quantitative trait.

quantitative variation Variation that is measured on a continuum (such as height in human beings) rather than in discrete units or categories.

quaternary structure The arrangement of polypeptide chains in a protein that contains more than one chain.

quiescent center A region in a root apical meristem where there is no cell division.

***R* gene** A resistance gene in a plant; dominant *R* alleles confer enhanced resistance to plant pathogens.

R plasmid A bacterial plasmid containing genes that provide resistance to unfavorable conditions.

radial cleavage A cleavage pattern in deuterostomes in which newly formed cells lie directly above and below other cells of the embryo.

radial symmetry A body plan of organisms in which structures are arranged regularly around a central axis, like spokes radiating out from the center of a wheel.

radiation The transfer of heat energy as electromagnetic radiation.

radicle The rudimentary root of a plant embryo.

radioactivity The giving off of particles of matter and energy by decaying nuclei.

radioisotope An unstable, radioactive isotope.

Radiolaria (radiolarians) A lineage of the Rhizaria protist evolutionary group; characterized by axopods, slender, raylike strands of cytoplasm supported internally by long bundles of microtubules.

radiometric dating A dating method that uses measurements of certain radioactive isotopes to calculate the absolute ages in years of rocks and minerals.

radula The tooth-lined "tongue" of mollusks that scrapes food into small particles or drills through the shells of prey.

rain shadow An area of reduced precipitation on the leeward side of a mountain.

random coil An arrangement of the amino acid chain providing flexible regions that allow sections of the chain to bend.

random dispersion A pattern of distribution in which the individuals in a population are distributed unpredictably in their habitat.

rapid eye movement (REM) sleep The period during deep sleep when the delta wave pattern is replaced by rapid, irregular beta waves characteristic of the waking state. The person's heartbeat and breathing rate increase, the limbs twitch, and the eyes move rapidly behind the closed eyelids.

reabsorption The process in which some molecules (for example, glucose and amino acids) and ions are transported by the transport epithelium back into the body fluid (animals with open circulatory systems) or into the blood in capillaries surrounding the tubules (animals with closed circulatory systems) as the filtered solution moves through the excretory tubule.

reactants The atoms or molecules entering a chemical reaction.

reaction center Part of photosystems I and II in chloroplasts of plants. In the light-dependent reactions of photosynthesis, the reaction center receives light energy absorbed by the antenna complex in the same photosystem.

reading frame The series of codons for a polypeptide encoded by the mRNA.

realized niche The range of resources and environmental conditions actually used by a population in nature.

receptacle The expanded tip of a flower stalk that bears floral organs.

reception In signal transduction, the binding of a signal molecule with a specific receptor in a target cell. In neural signaling, the first of four components in which a stimulus is detected by specialized sensory receptors.

receptive field The region surrounding a receptor within which the receptor responds to a stimulus.

receptor potential The change in membrane potential exhibited by a sensory receptor in response to a stimulus in its receptive field.

receptor protein Protein that recognizes and binds molecules from other cells that act as chemical signals.

receptor tyrosine kinase In signal transduction, a surface receptor with built-in protein kinase activity.

receptor-mediated endocytosis The selective uptake of macromolecules that bind to cell surface receptors concentrated in clathrin-coated pits.

recessive An allele that is masked by a dominant allele.

reciprocal altruism Form of altruistic behavior in which individuals help nonrelatives if they are likely to return the favor in the future.

reciprocal cross A genetic cross in which the two parents are switched with respect to which trait is associated with each sex.

recognition protein Protein in the plasma membrane that identifies a cell as part of the same individual or as foreign.

recombinant Phenotype with a different combination of traits from those of the original parents.

recombinant chromosomes Chromosomes that contain nonparental combinations of alleles. In eukaryotes they are generated by crossing-over in meiosis.

recombinant DNA DNA from two or more different sources joined together.

recombination *See* **genetic recombination.**

recombination frequency In the construction of linkage maps of diploid eukaryotic organisms, the percentage of testcross progeny that are recombinants.

rectum The final segment of the large intestine.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

red tide A growth in dinoflagellate populations that causes red, orange, or brown discoloration of coastal ocean waters.

redox reaction Coupled oxidation–reduction reaction in which electrons are removed from a donor molecule and simultaneously added to an acceptor molecule.

reduced Substance—the electron acceptor—that gains electrons during reduction.

reduction The partial or full gain of electrons to a substance.

reflex A programmed movement that takes place without conscious effort, such as the sudden withdrawal of a hand from a hot surface.

refractory period A period that begins at the peak of an action potential and lasts a few milliseconds, during which the threshold required for generation of an action potential is much higher than normal.

regulators Animals that maintain factors of the internal environment in a relatively constant state.

regulatory gene Gene that encodes a protein that regulates the expression of a structural gene or genes.

regulatory protein DNA-binding protein that binds to a regulatory sequence and affects the expression of an associated gene or genes.

regulatory sequence DNA sequence involved in the regulation of a gene or genes to which a regulatory protein binds to control the transcription of the gene or genes.

reinforcement The enhancement of reproductive isolation that had begun to develop while populations were geographically separated.

relative abundance The relative commonness of populations within a community.

relative fitness The number of surviving offspring that an individual produces compared with the number left by others in the population.

release The process in which urine is released into the environment from the distal end of the excretory tubule.

release factor A protein that recognizes stop codons in the A site of a ribosome translating an mRNA and terminates translation. Also referred to as the *termination factor.*

releasing hormone (RH) A peptide neurohormone that control the secretion of hormones from the anterior pituitary.

renal artery An artery that carries bodily fluids into the kidney.

renal cortex The outer region of the mammalian kidney that surrounds the renal medulla.

renal medulla The inner region of the mammalian kidney.

renal pelvis The central cavity in the kidney where urine drains from collecting ducts.

renal vein The vein that routes filtered blood away from the kidney.

renaturation The reformation of a denatured protein into its folded, functional state.

renin An enzyme secreted by cells in the juxtaglomerular apparatus into the bloodstream that converts a blood protein into the peptide hormone angiotensin.

renin-angiotensin-aldosterone system (RAAS) The most important hormonal system involved in regulation of Na^+ in mammals.

replica plating Technique for identifying and counting genetic recombinants in conjugation, transformation, or transduction experiments in which the colony pattern on a plate containing solid growth medium is pressed onto sterile velveteen and transferred to other plates containing different combinations of nutrients.

replicates Multiple subjects that receive either the same experimental treatment or the same control treatment.

replication bubble The two Y-shaped replication forks joined together at the tops of the Ys after DNA is unwound at an origin of replication.

replication fork The region of DNA synthesis where the parental strands separate and two new daughter strands elongate.

repressible operon Operon whose expression is prevented by a repressor molecule.

repressor A regulatory protein that prevents the operon genes from being expressed.

reproduction The process in which parents produce offspring.

reproductive isolating mechanism A biological characteristic that prevents the gene pools of two species from mixing.

reproductive strategy One of a set of behaviors that lead to reproductive success.

residual volume The air that remains in lungs after exhalation.

resilin An elastic protein related to elastin, found only in insects and some crustaceans.

resolution The minimum distance two points in a specimen can be separated and still be seen as two points.

resource partitioning The use of different resources or the use of resources in different ways by species living in the same place.

respiratory medium The environmental source of O_2 and the "sink" for released CO_2. For aquatic animals, the respiratory medium is water; for terrestrial animals, it is air.

respiratory surface A layer of epithelial cells that provides the interface between the body and the respiratory medium.

respiratory system All the parts of the body involved in exchanging air between the external environment and the blood.

response In signal transduction, the last stage in which the transduced signal causes the cell to change according to the signal and to the receptors on the cell. In neural signaling, the fourth and last component involving the action resulting from the integration of neural messages.

resting potential A steady negative membrane potential exhibited by the membrane of a neuron that is not stimulated—that is, not conducting an impulse.

restriction endonuclease (restriction enzyme) An enzyme that cuts DNA at a specific sequence.

restriction fragment A DNA fragment produced by cutting a long DNA molecule with a restriction enzyme.

restriction fragment length polymorphisms When comparing different individuals, restriction enzyme–generated DNA fragments of different lengths from the same region of the genome.

reticular activating system *See* **ascending reticular formation.**

reticular formation A complex network of interconnected neurons that runs through the length of the brain stem, connecting to the thalamus at the anterior end and to the spinal cord at the posterior end.

reticulum One of the four chambers of the stomach of a ruminant; in this chamber, fermentation reactions by symbiotic microorganisms begin digesting boluses of swallowed plant matter.

retina A light-sensitive membrane lining the posterior part of the inside of the eye.

retrotransposon A transposable element that transposes via an intermediate RNA copy of the transposable element.

retrovirus A virus with an RNA genome that replicates via a DNA intermediate.

reverse transcriptase An enzyme that uses RNA as a template to make a DNA copy of the retrotransposon. Reverse transcriptase is used to make DNA copies of RNA in test tube reactions.

reversible The term indicating that a reaction may go from left to right or from right to left, depending on conditions.

rheumatoid arthritis An autoimmune disease that results by a self-attack on connective tissues, particularly in the joints, causing pain and inflammation.

Rhizaria (rhizarians) A protist evolutionary group; amoebas with filamentous pseudopods.

rhizome A horizontal, modified stem that can penetrate a substrate and anchor the plant.

Rhodophyta (red algae) A lineage of the Archaeplastida protist evolutionary group; mostly free-living autotrophic marine seaweeds.

rhodopsin A photopigment consisting of retinal bound covalently to an opsin protein.

ribonucleic acid (RNA) A polymer assembled from repeating nucleotide monomers in which the five-carbon sugar is ribose. Cellular RNAs include mRNA (which is translated to produce a polypeptide), tRNA (which brings an amino acid to the ribosome for assembly into a polypeptide during translation), and rRNA (which is a structural component of ribosomes). The genetic material of some viruses is RNA.

ribonucleotide Nucleotide containing ribose as the sugar; ribonucleotides are components of RNA.

ribose A five-carbon sugar to which the nitrogenous bases in nucleotides link covalently.

ribosomal RNA (rRNA) The RNA component of ribosomes.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ribosome A ribonucleoprotein particle that carries out protein synthesis by translating mRNA into chains of amino acids.

ribosome binding site In translation initiation in prokaryotes, a sequence just upstream of the start codon that directs the small ribosomal subunit to bind and orient correctly for the complete ribosome to assemble and start translating in the correct spot.

ribozyme An RNA-based catalyst that is part of the biochemical machinery of all cells.

ring species A species with a geographical distribution that forms a ring around uninhabitable terrain.

RNA *See* **ribonucleic acid.**

RNA interference (RNAi) The phenomenon of silencing a gene posttranscriptionally by a small, single-stranded RNA that is complementary to part of an mRNA.

RNA polymerase An enzyme that catalyzes the assembly of ribonucleotides into an RNA strand.

RNA world model A model which states that the first genes and enzymes were RNA molecules.

rod In the vertebrate eye, a type of photoreceptor in the retina that is specialized for detection of light at low intensities.

root An anchoring structure in land plants that also absorbs water and nutrients and (in some plant species) stores food.

root cap A dome-shaped cell mass that forms a protective covering over the apical meristem in the tip of a plant root.

root hair A tubular outgrowth of the outer wall of a root epidermal cell; root hairs absorb much of a plant's water and minerals from the soil.

root nodule A localized swelling on a root in which symbiotic nitrogen-fixing bacteria reside.

root pressure The pressure that develops in plant roots as the result of osmosis, forcing xylem sap upward and out through leaves. *See also* **guttation.**

root primordium A rudimentary root.

root system An underground (or submerged) network of roots with a large surface area that favors the rapid uptake of soil water and dissolved mineral ions.

rough ER Endoplasmic reticulum with many ribosomes studding its outer surface.

round window A thin membrane that faces the middle ear.

***r*-selected species** A short-lived species adapted to function well in a rapidly changing environment.

RuBP carboxylase/oxygenase (rubisco) An enzyme that catalyzes the key reaction of the Calvin cycle, carbon fixation, in which CO_2 combines with RuBP (ribulose 1,5-bisphosphate) to form 3-phosphoglycerate.

rumen One of the four chambers of the stomach of a ruminant; in this chamber, fermentation reactions by symbiotic microorganisms begin digesting boluses of swallowed plant matter.

ruminant An animal that has a complex, four-chambered stomach.

S phase The phase of the eukaryotic cell cycle during which DNA replication occurs.

saccule Saclike, fluid-filled structure that is part of the vestibular apparatus. With the utricle, provides information about the up–down position of the head, as well as changes in the rate of linear movement of the head.

salicylic acid (SA) In plants, a chemical synthesized following a wound that has multiple roles in plant defenses, including interaction with jasmonates in signaling cascades.

salivary amylase A substance that hydrolyzes starches to the disaccharide maltose.

salivary gland A gland that secretes saliva through a duct on the inside of the cheek or under the tongue; the saliva lubricates food and begins digestion.

salt marsh A tidal wetland dominated by emergent grasses and reeds.

saltatory conduction A mechanism that allows small-diameter axons to conduct impulses rapidly.

saprobe An organism nourished by dead or decaying organic matter.

sapwood The newly formed outer wood located between heartwood and the vascular cambium. Compared with heartwood, it is wet, lighter in color, and not as strong.

sarcomere The basic unit of contraction in a myofibril.

sarcoplasmic reticulum In vertebrate muscle fibers, a complex system of vesicles modified from the smooth endoplasmic reticulum that encircles the sarcomeres. The sarcoplasmic reticulum is part of the pathway for the stimulation of muscle contraction by neural signals.

saturated enzymes Enzymes for which increases in substrate concentration have no effect on the reaction rate.

saturated fatty acid Fatty acid with only single bonds linking the carbon atoms.

savanna A biome comprising grasslands with few trees, which grows in areas adjacent to tropical deciduous forests.

schizocoelom In protostomes, the body cavity that develops as inner and outer layers of mesoderm separate.

Schwann cell A type of glial cell in the PNS that wraps nerve fibers with myelin and also secretes regulatory factors.

scientific method An investigative approach in which scientists make observations about the natural world, develop working explanations about what they observe, and then test those explanations by collecting more information.

scientific name A two-part name identifying the genus to which a species belongs and designating a particular species within that genus.

scientific theory A broadly applicable idea or hypothesis that has been confirmed by every conceivable test.

sclereid A type of sclerenchyma cell; sclereids typically are short and have thick, lignified walls.

sclerenchyma A ground tissue in which cells develop thick secondary walls, which commonly are lignified and perforated by pits through which water can pass.

scrotum The baglike sac in which the testes are suspended in many mammals.

scutellum The shield-shaped cotyledon of a grass.

second law of thermodynamics Principle that for any process in which a system changes from an initial to a final state, the total disorder of the system and its surroundings always increases.

second messenger In particular signal transduction pathways, an internal, nonprotein signal molecule that directly or indirectly activates protein kinases, which elicit the cellular response.

secondary active transport Transport indirectly driven by ATP hydrolysis.

secondary cell wall A layer added to the cell wall of plants that is more rigid and may become many times thicker than the primary cell wall.

secondary consumer A carnivore that feeds on herbivores, a member of the third trophic level.

secondary endosymbiosis In the model for the origin of plastids in eukaryotes, the second event, in which a nonphotosynthetic eukaryote engulfed a photosynthetic eukaryote.

secondary growth Plant growth that originates at lateral meristems and increases the diameter of older roots and stems. *Compare* **primary growth.**

secondary immune response The rapid immune response that occurs during the second (and subsequent) encounters of the immune system of a mammal with a specific antigen.

secondary plant body The part of a plant made up of tissues that develop from lateral meristems.

secondary productivity Energy stored in new consumer biomass as energy is transferred from producers to consumers.

secondary structure Regions of alpha helix, beta strand, or random coil in a polypeptide chain.

secondary succession Predictable changes in species composition in an ecological community that develops after existing vegetation is destroyed or disrupted by an environmental disturbance.

secondary tissue In plants, the tissue that develops from lateral meristems.

secretin Hormone released into the bloodstream from glandular cells in the small intestine in response to stimulation by acidic chyme.

secretion A selective process in which specific small molecules and ions are transported from the body fluids (in animals with open circulatory systems) or blood (in animals with closed circulatory systems) into the excretory tubules.

secretory vesicle Vesicle that transports proteins to the plasma membrane.

seed The structure that forms when an ovule matures after a pollen grain reaches it and a sperm fertilizes the egg.

seed coat The outer protective covering of a seed.

segment polarity gene In *Drosophila* embryonic development, one of the third activated set of

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

segmentation genes that progressively subdivide the embryo into regions, determining the segments of the embryo and the adult. Segment polarity genes set the boundaries and anterior–posterior axis of each segment in the embryo, thereby determining the regions that become segments of larvae and adults.

segmentation The production of body parts and some organ systems in repeating units.

segmentation genes Genes that work sequentially, progressively subdividing the embryo into regions, determining the segments of the embryo and the adult.

segregation The separation of the pairs of alleles that control a character as gametes are formed.

selective cell adhesion A mechanism in which cells make and break specific connections to other cells or to the extracellular matrix.

selectively neutral *See* **neutral variation hypothesis.**

selectively permeable Membranes that selectively allow, impede, or block the passage of atoms and molecules.

self-fertilization (self-pollination) Fertilization in which sperm nuclei in pollen fertilize egg cells of the same plant.

self-incompatibility In plants, the inability of a plant's pollen to fertilize ovules of the same plant.

semen The secretions of several accessory glands in which sperm are mixed before ejaculation.

semicircular canal Fluid-filled structures that are part of the vestibular apparatus. The three semicircular canals are positioned at angles corresponding to the three planes of space and detect rotational (spinning) motions.

semiconservative replication The process of DNA replication in which the two parental strands separate and each serves as a template for the synthesis of new progeny double-stranded DNA molecules.

seminal fluid Fluid secreted by the seminal vesicles that contains prostaglandins, which when ejaculated into the female trigger contractions of the female reproductive tract that help move the sperm into and through the uterus.

seminal vesicle A vesicle that secretes seminal fluid.

seminiferous tubule One of the tiny tubes in the testes where sperm cells are produced, grow, and mature.

senescence The biologically complex process of aging in mature organisms that leads to the death of cells and eventually the whole organism.

sense codon A codon that specifies an amino acid.

sensitization Increased responsiveness to mild stimuli after experiencing a strong stimulus; one of the simplest forms of memory.

sensor A tissue or organ that detects a change in an external or internal factor such as pH, temperature, or the concentration of a molecule such as glucose.

sensory adaptation A condition in which the effect of a stimulus is reduced if it continues at a constant level.

sensory neuron A neuron that transmits stimuli collected by the sensory receptors to interneurons.

sensory receptor A receptor formed by the dendrites of afferent neurons, or by specialized receptor cells making synapses with afferent neurons that pick up information about the external and internal environments of the animal.

sensory transduction The conversion of a stimulus into a change in membrane potential.

sepal One of the separate, usually green parts forming the calyx of a flower.

septum (plural, *septa*) A thin partition or cross wall that separates body segments.

sequential hermaphroditism The form of hermaphroditism in which individuals change from one sex to the other.

serosa The serous membrane: a thin membrane lining the closed cavities of the body; has two layers with a space between that is filled with serous fluid.

Sertoli cell One of the supportive cells that completely surrounds developing spermatocytes in the seminiferous tubules. Follicle-stimulating hormone stimulates Sertoli cells to secrete a protein and other molecules that are required for spermatogenesis.

sessile Unable to move from one place to another.

set point The level at which the condition controlled by a homeostatic pathway is to be maintained.

seta (plural, *setae*) A chitin-reinforced bristle that protrudes outward from the body wall in some annelid worms.

sex chromosomes Chromosomes that are different in male and female individuals of the same species.

sex pilus *See* **F pilus.**

sex ratio The relative proportions of males and females in a population.

sex-linked gene Gene located on a sex chromosome.

sexual dimorphism Differences in the size or appearance of males and females.

sexual reproduction The mode of reproduction in which male and female parents produce offspring through the union of egg and sperm generated by meiosis.

sexual selection A form of natural selection established by male competition for access to females and by the females' choice of mates.

shells *See* **energy levels.**

shoot system The stems and leaves of a plant.

short tandem repeat (STR) Short 2- to 6-bp DNA sequence repeated in series.

short-day plant A plant that flowers in late summer or early autumn when dark periods become longer and light periods become shorter.

short-term memory Memory that stores information for seconds.

sieve tube A series of phloem cells joined end to end, forming a long tube through which nutrients are transported; a feature mainly of flowering plants.

sieve tube member Any of the main conducting cells of phloem that connect end to end, forming a sieve tube.

sign stimulus A simple cue that triggers a fixed action pattern.

signal peptide A short segment of amino acids to which the signal recognition particle binds, temporarily blocking further translation. A signal peptide is found on polypeptides that are sorted to the endoplasmic reticulum. Also referred to as *signal sequence.*

signal recognition particle (SRP) Protein-RNA complex that binds to signal sequences and targets polypeptide chains to the endoplasmic reticulum.

signal sequence *See* **signal peptide.**

signal transduction The series of events by which a signal molecule released from a controlling cell causes a response (affects the function) of target cells with receptors for the signal. Target cells process the signal in the three sequential steps of reception, transduction, and response.

silencing Phenomenon in which methylation of cytosines in eukaryotic promoters inhibits transcription and turns the genes off.

silent mutation A base-pair substitution mutation in a protein-coding gene that does not alter the amino acid specified by the gene.

simple diffusion Mechanism by which certain small substances diffuse through the lipid part of a biological membrane.

simple fruit A fruit that develops from a single ovary; in many of them at least one layer of the pericarp is fleshy.

simulation modeling An analytical method in which researchers gather detailed information about a system and then create a series of mathematical equations that predict how the components of the system interact and respond to change.

simultaneous hermaphroditism A form of hermaphroditism in which individuals develop functional ovaries and testes at the same time.

single-lens eye An eye type that works by changing the amount of light allowed to enter into the eye and by focusing this incoming light with a lens.

single-stranded binding protein (SSB) Protein that coats single-stranded segments of DNA, stabilizing the DNA for the replication process.

sink Any region of a plant where organic substances are being unloaded from the phloem and used or stored.

sink population In metapopulation analysis, a population that routinely declines in size after being replenished by immigrants from a source population.

sinoatrial node (SA node) The region of the heart that controls the rate and timing of cardiac muscle cell contraction.

sinus A body space that surrounds an organ.

siRNA-induced silencing complex (siRISC) Protein complex containing an siRNA that binds to a sequence in a target RNA resulting in cleavage of that RNA.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

sister chromatid One of two exact copies of a chromosome duplicated during replication.

sister clades Two evolutionary lineages (that is, clades) that emerge from the same node in a phylogenetic tree.

sister species Two species that are descended from the same recent ancestral species.

skeletal muscle A muscle that connects to bones of the skeleton, typically made up of long and cylindrical cells that contain many nuclei.

sliding DNA clamp A protein that encircles the DNA and binds to the DNA polymerase to tether the enzyme to the template, thereby making replication more efficient.

slime layer A coat typically composed of polysaccharides that is loosely associated with bacterial cells.

slime molds Members of the Amoebozoa; heterotrophic protists that, at some stage of their life cycle, exist as individuals that move by amoeboid motion but that exist in more complex forms the remainder of the time.

slow block to polyspermy The process in which enzymes released from cortical granules alter the egg coats within minutes after fertilization, so that no other sperm can attach and penetrate to the egg.

slow muscle fiber A muscle fiber that contracts relatively slowly and with low intensity.

small interfering RNA (siRNA) One of the major types of small, single-stranded regulatory RNAs in eukaryotes involved in RNA interference (RNAi).

small ribonucleoprotein particle A complex of RNA and proteins.

smooth ER Endoplasmic reticulum with no ribosomes attached to its membrane surfaces. Smooth ER has various functions, including synthesis of lipids that become part of cell membranes.

smooth muscle A relatively small and spindle-shaped muscle cell in which actin and myosin molecules are arranged in a loose network rather than in bundles.

social behavior The interactions that animals have with other members of their species.

sodium–potassium pump *See* **Na^+/K^+ pump.**

soil solution A combination of water and dissolved substances that coats soil particles and partially fills pore spaces.

solenoid *See* **30-nm chromatin fiber.**

solute The molecules of a substance dissolved in water.

solution Substance formed when molecules and ions separate and are suspended individually, surrounded by water molecules.

solvent The water in a solution in which the hydration layer prevents polar molecules or ions from reassociating.

somaclonal selection A procedure in which somatic embryos derived from tissue culture are screened to identify those having desired characteristics, such as disease resistance.

somatic cell Any of the cells of an organism's body other than reproductive cells.

somatic embryo A plant embryo that is genetically identical to the parent because it arose through asexual means.

somatic gene therapy Gene therapy in which genes are introduced into somatic cells.

somatic nervous system A subdivision of the peripheral nervous system controlling body movements that are primarily conscious and voluntary.

somites Paired blocks of mesoderm cells along the vertebrate body axis that form during early vertebrate development and differentiate into dermal skin, bone, and muscle.

soredium (plural, *soredia*) A specialized cell cluster produced by lichens, consisting of a mass of algal cells surrounded by fungal hyphae; soredia function like reproductive spores and can give rise to a new lichen.

sorus (plural, *sori*) A cluster of sporangia on the underside of a fern frond; reproductive spores arise by meiosis inside each sporangium.

source In plants, any region (such as a leaf) where organic substances are being loaded into the sieve tube system of phloem.

source population In metapopulation analyses, a population that is either stable or increasing in size.

Southern blot analysis Technique in which labeled probes are used to detect specific DNA fragments that have been separated by gel electrophoresis.

spatial summation The summation of EPSPs produced by firing of different presynaptic neurons.

specialized transduction Transfer of bacterial genes between bacteria using temperate phages that have incorporated fragments of the bacterial genome as they make the transition from the lysogenic cycle to the lytic cycle.

speciation The process of species formation.

species A group of populations in which the individuals are so closely related in structure, biochemistry, and behavior that they can successfully interbreed.

species cluster A group of closely related species recently descended from a common ancestor.

species composition The particular combination of species that occupy a site.

species diversity A community characteristic defined by species richness and the relative abundance of species.

species richness The number of species that live within an ecological community.

specific epithet The species name in a binomial.

specific heat The amount of heat required to increase the temperature of a given quantity of water.

spermatocyte A developing gamete that becomes a spermatid at the end of meiosis.

spermatogenesis The process of producing sperm.

spermatogonium (plural, *spermatogonia*) A cell that enters meiosis and gives rise to gametes, produced by mitotic divisions of the germ cells in males.

spermatozoan Also called *sperm;* a haploid cell that develops into a mature sperm cell when meiosis is complete.

sphincter A powerful ring of smooth muscle that forms a valve between major regions of the digestive tract.

spinal cord A column of nervous tissue located within the vertebral column and directly connected to the brain.

spinal nerve A nerve that carries signals between the spinal cord and the body trunk and limbs.

spindle The structure that separates sister chromatids and moves them to opposite spindle poles.

spindle pole One of the pair of centrosomes in a cell undergoing mitosis from which bundles of microtubules radiate to form the part of the spindle from that pole.

spinneret A modified abdominal appendage from which spiders secrete silk threads.

spiracle An opening in the chitinous exoskeleton of an insect through which air enters and leaves the tracheal system.

spiral cleavage The cleavage pattern in many protostomes in which newly produced cells lie in the space between the two cells immediately below them.

spiral organ *See* **organ of Corti.**

spiral valve A corkscrew-shaped fold of mucous membrane in the digestive system of elasmobranchs, which slows the passage of material and increases the surface area available for digestion and absorption.

spirillum (plural, *spirilla*) Any flagellated aerobic bacterium twisted helically like a corkscrew.

spliceosome A complex formed between the pre-mRNA and small ribonucleoprotein particles, in which mRNA splicing takes place.

spongocoel The central cavity in a sponge.

spontaneous reaction Chemical or physical reaction that occurs without outside help.

sporadic (nonhereditary) cancer Cancer that is not inherited.

sporangium (plural, *sporangia*) A single-celled or multicellular structure in fungi and plants in which spores are produced.

spore A haploid reproductive structure, usually a single cell, that can develop into a new individual without fusing with another cell; found in plants, fungi, and certain protists.

sporophyll A specialized leaf that bears sporangia (spore-producing structures).

sporophyte An individual of the diploid generation produced through fertilization in organisms that undergo alternation of generations; it produces haploid spores.

sporopollenin A tough polymer in the walls of spores and pollen grains, the presence of which helps such structures resist decay.

spring overturn The mixing of surface water with deep water in a lake or pond, causing oxygen at the surface to move to the bottom, and nutrients from the bottom to move to the surface.

SRP (signal recognition particle) receptor A protein on the membrane of the endoplasmic reticulum that binds the signal recognition particle.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

stability The ability of a community to maintain its species composition and relative abundances when environmental disturbances eliminate some species from the community.

stabilizing selection A type of natural selection in which individuals expressing intermediate phenotypes have the highest relative fitness.

stamen A "male" reproductive organ in flowers, consisting of an anther (pollen producer) and a slender filament.

standing crop biomass The total dry weight of plants present in an ecosystem at a given time.

stapes The smallest of three sound-conducting bones in the middle ear of tetrapod vertebrates.

starch A storage polysaccharide in plants consisting of branched or unbranched chains of glucose subunits.

start codon The first codon read in an mRNA in translation—AUG. Also referred to as the *initiator codon.*

statocyst A mechanoreceptor in invertebrates that senses gravity and motion using statoliths.

statolith A movable starch- or carbonate-containing stonelike body involved in sensing gravitational pull.

stele The central core of vascular tissue in roots and shoots of vascular plants; it consists of the xylem and phloem together with supporting tissues.

stem cells Cells capable of undergoing many divisions in an unspecialized, undifferentiated state and that also have the ability to differentiate into specialized cell types.

stereocilia Microvilli covering the surface of hair cells clustered in the base of neuromasts.

stereoisomers Molecules that are mirror images of one another are an example of stereoisomers.

steroid A type of lipid derived from cholesterol.

steroid hormone receptor Internal receptor that turns on specific genes when it is activated by binding a signal molecule.

steroid hormone response element The DNA sequence to which the hormone-receptor complex binds.

sterol Steroid with a single polar —OH group linked to one end of the ring framework and a complex, nonpolar hydrocarbon chain at the other end.

sticky end End of a DNA fragment generated by digestion with a restriction enzyme, with a single-stranded structure that can form hydrogen bonds with a complementary sticky end on any other DNA molecule cut with the same enzyme.

stigma The receptive end of a carpel where deposited pollen germinates.

stimulus A component of a negative feedback control system maintaining homeostasis, specifically an environmental change that triggers a response.

stoma (plural, *stomata*) The opening between a pair of guard cells in the epidermis of a plant leaf or stem, through which gases and water vapor pass.

stomach The portion of the digestive system in which food is stored and digestion begins.

stomach ulcer *See* **peptic ulcer.**

stop codon A codon that does not specify amino acids. The three nonsense codons are UAG, UAA, and UGA. Also referred to as the *nonsense codon* and *termination codon.*

Stramenopila (stramenopiles) A subgroup of the Chromalveolata protist evolutionary group; protists with two different flagella, one with hollow tripartite projections, and one that is plain.

stratification Horizontal layering of sedimentary rocks beneath the soil surface.

strict aerobe Cell with an absolute requirement for oxygen to survive, unable to live solely by fermentations.

strict anaerobe Organism in which fermentation is the only source of ATP.

strobilus *See* **cone.**

structural gene Gene that encodes a protein that has a function other than gene regulation.

structural isomers Two molecules with the same chemical formula but atoms that are arranged in different ways.

style The slender stalk of a carpel situated between the ovary and the stigma in plants.

submucosa A thick layer of elastic connective tissue that contains neuron networks and blood and lymph vessels.

subsoil The region of soil beneath topsoil, which contains relatively little organic matter.

subspecies A taxonomic subdivision of a species.

substrate The particular reacting molecule or molecular group that an enzyme catalyzes.

substrate-level phosphorylation An enzyme-catalyzed reaction that transfers a phosphate group from a substrate to ADP.

sugar–phosphate backbone Structure in a polynucleotide chain that is formed when deoxyribose sugars (in DNA) or ribose sugars (in RNA) are linked by phosphate groups in an alternating sugar–phosphate–sugar–phosphate pattern.

sulfhydryl group Group that works as a molecular fastener, consisting of a sulfur atom linked on one side to a hydrogen atom and on the other side to a carbon chain.

sum rule Mathematical rule in which final probability is found by summing individual probabilities.

surface tension The force that places surface water molecules under tension, making them more resistant to separation than the underlying water molecules.

survivorship curve Graphic display of the rate of survival of individuals over a species' life span.

suspension feeder An animal that ingests small food items suspended in water.

suspensor In seed plants, a stalklike row of cells that develops from a zygote and helps position the embryo close to the nourishing endosperm.

swallowing reflex The involuntary action produced by contractions of muscles in the walls of the pharynx that direct food into the esophagus.

swim bladder A gas-filled internal organ that helps bony fishes maintain buoyancy.

symbiosis An interspecific interaction in which the ecological relations of two or more species are intimately tied together.

symmetry Exact correspondence of form and constituent configuration on opposite sides of a dividing line or plane.

sympathetic division Division of the autonomic nervous system that predominates in situations involving stress, danger, excitement, or strenuous physical activity.

sympatric speciation Speciation that occurs without the geographical isolation of populations.

symplastic pathway The route taken by water that moves through the cytoplasm of plant cells (the symplast). *Compare* **apoplastic pathway.**

symport The transport of two molecules in the same direction across a membrane. Also referred to as *cotransport.*

synapomorphy A derived character state found in two or more species.

synapse A site where a neuron makes a communicating connection with another neuron or an effector such as a muscle fiber or gland.

synapsida A lineage of amniotes that have one bony temporal arch near the back of the skull; includes mammals.

synapsis *See* **pairing.**

synaptic cleft A narrow gap that separates the plasma membranes of the presynaptic and postsynaptic cells.

synaptonemal complex A protein framework that tightly holds together homologous chromosomes as they pair.

systematics The branch of biology that studies the diversity of life and its evolutionary relationships.

systemic acquired resistance A plant defense response to microbial invasion; defensive chemicals including salicylic acid may spread throughout a plant, rendering healthy tissues less vulnerable to infection.

systemic circuit In amphibians, the branch of a double blood circuit that receives oxygenated blood and provides the blood supply for most of the tissues and cells of a body.

systemic homeostatic controls Controls that are initiated outside of an organ or organ system to control that organ's or organ system's activity.

systemic inflammation Inflammation that occurs throughout the body.

systemic lupus erythematosus (lupus) An autoimmune disease caused by production of a wide variety of anti-self antibodies against blood cells, blood platelets, and internal cell structures and molecules such as mitochondria and proteins associated with the DNA in the cell nucleus; characterized by anemia and problems with blood circulation and kidney function.

systemin A plant peptide hormone that functions in defense responses to wounds.

systems biology An area of biology that studies the organism as a whole to unravel the integrated and interacting network of genes, proteins, and biochemical reactions responsible for life.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

systole The period of contraction and emptying of the heart.

systolic blood pressure The peak of high blood pressure in the cardiac cycle that occurs as the heart ventricles contract and move blood outward through the arteries.

T (transverse) tubule The tubule that passes in a transverse manner from the sarcolemma across a myofibril of striated muscle.

T cell A lymphocyte produced by the division of stem cells in the bone marrow and then released into the blood and carried to the thymus. T cells participate in adaptive immunity.

tactile signal A means of animal communication in which the signaler uses touch to convey a message to the signal receiver.

taiga *See* **boreal forest.**

tandem duplication Duplicate genes clustered together in the same region of the same chromosome. Unequal crossing-over produces such an arrangement.

taproot system A root system consisting of a single main root from which lateral roots can extend; often stores starch.

target site The location in a genome to which a transposable element moves when it transposes.

taxis A behavioral response that is directed either toward or away from a specific stimulus.

taxon (plural, *taxa*) A name designating a group of organisms included within a category in the Linnaean taxonomic hierarchy.

taxonomic hierarchy A system of classification based on arranging organisms into ever more inclusive categories.

taxonomy The science of the classification of organisms into an ordered system that indicates natural relationships.

T-cell receptor (TCR) A receptor that covers the plasma membrane of a T cell, specific for a particular antigen.

tectorial membrane A membrane that extends the length of the cochlear canal of the inner ear in which the stereocilia of the sensory hair cells of the organ of Corti are embedded.

telomerase An enzyme that adds telomere repeats to chromosome ends.

telomeres Repeats of simple-sequence DNA that maintain the ends of linear chromosomes.

telophase The final phase of mitosis, during which the spindle disassembles, the chromosomes decondense, and the nuclei reform.

temperate bacteriophage Bacteriophage that may enter an inactive phase (lysogenic cycle) in which the host cell replicates and passes on the bacteriophage DNA for generations before the phage becomes active and kills the host (lytic cycle).

temperate deciduous forest A forested biome found at low to middle altitudes at temperate latitudes, with warm summers, cold winters, and annual precipitation between 75 and 250 cm.

temperate grassland A nonforested biome that stretches across the interiors of most continents, where winters are cold and snowy and summers are warm and fairly dry.

temperate rainforest A coniferous forest biome supported by heavy rain and fog, which grows where winters are mild and wet and the summers are cool.

template A nucleotide chain used in DNA replication for the assembly of a complementary chain.

template strand The DNA strand that is copied into an RNA molecule during gene transcription.

temporal fenestrae Openings near the back of the skull in some amniote vertebrates.

temporal isolation A prezygotic reproductive isolating mechanism in which species live in the same habitat but breed at different times of day or different times of year.

temporal summation The summation of several EPSPs produced by successive firing of a single presynaptic neuron over a short period of time.

tendon A type of fibrous connective tissue that attaches muscles to bones.

terminal bud A bud that develops at the apex of a shoot.

termination In transcription, the step in which transcription ends and the RNA transcript and RNA polymerase (RNA polymerase II in the case of eukaryotes) are released from the DNA template. In translation, the step in which the translation complex disassembles after the last amino acid of the polypeptide specified by the mRNA has been added to the polypeptide.

termination codon *See* **stop codon.**

termination factor *See* **release factor.**

terminator Specific DNA sequence for a gene that signals the end of transcription of a gene. Terminators are common for prokaryotic genes.

territory A plot of habitat, defended by an individual male or a breeding pair of animals, within which the territory holders have exclusive access to food and other necessary resources.

tertiary consumer A carnivore that feeds on other carnivores, a member of the fourth trophic level.

tertiary structure The overall three-dimensional folding of a polypeptide chain.

testcross A genetic cross between an individual with the dominant phenotype and a homozygous recessive individual.

testis (plural, *testes*) The male gonad. In male vertebrates, they secrete androgens and steroid hormones that stimulate and control the development and maintenance of male reproductive systems.

testosterone A hormone produced by the testes, responsible for the development of male secondary sex characteristics and the functioning of the male reproductive organs.

tetanus A situation in which a muscle fiber cannot relax at all between stimuli, and twitch summation produces a peak level of continuous contraction.

tetrad Homologous pair of eukaryotic chromosomes during the first meiotic division consisting of four chromatids.

Tetrapoda A monophyletic lineage of vertebrates that includes animals having four feet, legs, or leglike appendages.

T-even bacteriophage Virulent bacteriophages, T2, T4, and T6, that have been valuable for genetic studies of bacteriophage structure and function.

thalamus A major switchboard of the brain that receives sensory information and relays it to the regions of the cerebral cortex concerned with motor responses to sensory information of that type.

thallus A plant body not differentiated into stems, roots, or leaves.

Thaumarchaeota A group of the domain Archaea consisting of four living species, all of which are mesophilic, chemoautotraphic ammonia oxidizers, and other members represented by DNA sequences in environmental samples.

thermal acclimatization A set of physiological changes in ectotherms in response to seasonal shifts in environmental temperature, allowing the animals to attain good physiological performance at both winter and summer temperatures.

thermocline The narrow depth range in a lake where water temperature changes abruptly at the boundary between the epilimnion and the hypolimnion.

thermodynamics The study of the energy flow during chemical and physical reactions.

thermoreceptor A sensory receptor that detects the flow of heat energy.

thermoregulation The control of body temperature.

thick filament A type of filament in striated muscle composed of myosin molecules; they interact with thin filaments to shorten muscle fibers during contraction.

thigmomorphogenesis A plant response to a mechanical disturbance, such as frequent strong winds; includes inhibition of cellular elongation and production of thick-walled supportive tissue.

thigmotropism Growth in response to contact with a solid object.

thin filament A type of filament in striated muscle composed of actin, tropomyosin, and troponin molecules; they interact with thick filaments to shorten muscle fibers during contraction.

thorax The central part of an animal's body, between the head and the abdomen.

thorn forest A forested biome that grows at the arid borders of true savanna, where large mammals are less abundant.

threshold potential In signal conduction by neurons, the membrane potential at which the action potential fires.

thymine A pyrimidine that base-pairs with adenine.

thymus An organ of the lymphatic system that plays a role in filtering viruses, bacteria, damaged cells, and cellular debris from the lymph and

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

bloodstream, and in defending the body against infection and cancer.

thyroid gland A gland located beneath the voice box (larynx) that secretes hormones regulating growth and metabolism.

thyroid-stimulating hormone (TSH) A hormone that stimulates the thyroid gland to grow in size and secrete thyroid hormones.

thyroxine (T_4) The main hormone of the thyroid gland, responsible for controlling the rate of metabolism in the body.

Ti (tumor-inducing) plasmid A plasmid used to make transgenic plants.

tidal volume The volume of air entering and leaving the lungs during inhalation and exhalation.

tight junction Region of tight connection between membranes of adjacent cells.

time lag The delayed response of organisms to changes in environmental conditions.

tissue A group of cells and intercellular substances with the same structure that function as a unit to carry out one or more specialized tasks.

tolerance hypothesis Hypothesis asserting that ecological succession proceeds because competitively superior species replace competitively inferior ones.

tonicity The effect a solution has on a cell when the solution surrounds it.

tonoplast The membrane that surrounds the central vacuole in a plant cell.

topoisomerase An enzyme that relieves the overtwisting and strain of DNA ahead of the replication fork.

topsoil The rich upper layer of soil where most plant roots are located; it generally consists of sand, clay particles, and humus.

torpor A sleeplike state produced when a lowered set point greatly reduces the energy required to maintain body temperature, accompanied by reductions in metabolic, nervous, and physical activity.

torsion The realignment of body parts in gastropod mollusks that is independent of shell coiling.

totipotent Having the capacity to produce cells that can develop into or generate a new organism or body part.

trace element An element that occurs in organisms in very small quantities (less than 0.01%); in nutrition, a mineral required by organisms only in small amounts.

tracer Isotope used to label molecules so that they can be tracked as they pass through biochemical reactions.

trachea In insects, an extensively branched, air-conducting tube formed by invagination of the outer epidermis of the animal, and reinforced by rings of chitin. In vertebrates, the windpipe, which branches into the bronchi.

tracheal system A branching network of tubes that carries air from small openings in the exoskeleton of an insect to tissues throughout its body.

tracheid A conducting cell of xylem, usually elongated and tapered.

tracheophyte A plant with xylem, phloem, and usually well-developed roots, stems, and leaves.

traditional systematics An approach to systematics that uses phenotypic similarities and differences to infer evolutionary relationships, grouping together species that share both ancestral and derived characters.

trait One of the forms of a genetic character.

transcription The mechanism by which the information encoded in DNA is made into a complementary RNA copy.

transcription factor (TF) In eukaryotes, the proteins required for RNA polymerase to initiate transcription or that regulate that process. One class of transcription factors recognizes and binds to the promoter in the area of the TATA box and then recruit RNA polymerase.

transcription initiation complex Combination of general transcription factors with RNA polymerase II.

transcription unit A region of DNA that transcribes a single primary transcript.

transcriptional regulation The fundamental level of control of gene expression that determines which genes are transcribed into mRNA.

transduction In cell signaling, the process of changing a signal into the form necessary to cause the cellular response. In prokaryotes, the process in which DNA is transferred from donor to recipient bacterial cells by an infecting bacteriophage.

transfer cell Any of the specialized cells that form when large amounts of solutes must be loaded or unloaded into the phloem; they facilitate the short-distance transport of organic solutes from the apoplast into the symplast.

transfer RNA (tRNA) The RNA that brings amino acids to the ribosome for addition to the polypeptide chain.

transformation The conversion of the hereditary type of a cell by the uptake of DNA released by the breakdown of another cell.

transgene A gene introduced into an organism by genetic manipulation to alter its genotype.

transgenic An organism that has been modified to contain genetic information from an external source.

transition state An intermediate arrangement of atoms and bonds that both the reactants and the products of a reaction can assume.

transit sequence Short amino acid sequence on a protein that serves to direct the protein to the appropriate organelle (other than the nucleus or ER) in a eukaryotic cell.

translation The use of the information encoded in mRNA to assemble amino acids into a polypeptide.

translocation In genetics, a chromosomal alteration that occurs if a broken segment is attached to a different, nonhomologous chromosome. In vascular plants, the long-distance transport of substances by xylem and phloem.

transmembrane pathway The path followed by water when it enters root cells by crossing the cells' plasma membranes.

transmission The second component of neural signaling involving the sending of a message along a neuron, and then to another neuron or to a muscle or gland.

transpiration The evaporation of water from a plant, principally from the leaves.

transport The controlled movement of ions and molecules from one side of a membrane to the other.

transport epithelium A layer of cells with specialized transport proteins in their plasma membranes.

transport protein A protein embedded in the cell membrane that forms a channel allowing selected polar molecules and ions to pass across the membrane.

transposable element (TE) A sequence of DNA that can move from one place to another within the genome of a cell.

transposase An enzyme that catalyzes some of the reactions inserting or removing the transposable element from the DNA.

transposition The movement of a transposable element from one site to another in a genome.

transposon A bacterial transposable element with an inverted repeat sequence at each end enclosing a central region with one or more genes.

tricarboxylic acid cycle *See* **citric acid cycle.**

trichocyst A dartlike protein thread that can be discharged from a surface organelle for defense or to capture prey.

trichome A single-celled or multicellular outgrowth of the plant epidermis; examples include root hairs and leaf trichomes that resemble hairs.

triglyceride A nonpolar compound produced when a fatty acid binds by a dehydration synthesis reaction at each of glycerol's three —OH-bearing sites.

triiodothyronine (T_3) A hormone secreted by the thyroid gland that regulates metabolism.

trimester A division of human gestation, three months in length.

triploblastic An animal body plan in which adult structures arise from three primary germ layers, endoderm, mesoderm, and ectoderm.

trochophore The small, free-swimming, ciliated aquatic larva of various invertebrates, including certain mollusks and annelids.

trophic cascade The effects of predator–prey interactions that reverberate through other population interactions at two or more trophic levels in an ecosystem.

trophic level A position in a food chain or web that defines the feeding habits of organisms.

trophoblast The outer single layer of cells of the blastocyst.

tropical deciduous forest A tropical forest biome that occurs where winter drought reduces photosynthesis, and most trees drop their leaves seasonally.

tropical forest Any forest that grows between the Tropics of Capricorn and Cancer, a region charac-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

terized by high temperature and rainfall and thin, nutrient-poor topsoil.

tropical montane forest A tropical forest biome of short trees, which are frequently enveloped in mist; also known as a "cloud forest."

tropical rainforest A dense tropical forest biome that grows where some rain falls every month, mean annual rainfall exceeds 250 cm, mean annual temperature is at least 25°C, and humidity is above 80%.

tropics The latitudes between 23.5° N and 23.5° S, the Tropics of Cancer and Capricorn.

tropism The turning or bending of an organism or one of its parts toward or away from an external stimulus, such as light, heat, or gravity.

true-breeding Individual that passes traits without change from one generation to the next.

trypsin A digestive enzyme that digests peptides to produce small peptides.

tubular reabsorption The selective process in which some molecules and ions are transported by the transport epithelium from the lumen of the tubule back into the extracellular fluid and eventually into the blood as the solution produced by filtration moves through an excretory tubule.

tubular secretion The selective process in which specific small molecules and ions are transported from the extracellular fluid and blood into an excretory tubule.

tumor Tissue mass that results with differentiated cells of complex multicellular organisms deviate from their normal genetic program and being to grow and divide.

tumor-suppressor gene A gene that encodes proteins that inhibit cell division.

turgor pressure The internal hydrostatic pressure within plant cells.

turnover rate The rate at which one generation of producers in an ecosystem is replaced by the next.

tympanic membrane Also called the *eardrum,* a sheet of tissue forming the boundary between the outer ear and the middle ear that vibrates in response to sound waves that move through the auditory canal.

tympanum A thin membrane in the auditory canal that vibrates back and forth when struck by sound waves.

umbilical cord A long tissue with blood vessels linking the embryo and the placenta.

umbilicus Navel; the scar left when the short length of umbilical cord still attached to the infant after birth dries and shrivels within a few days.

undernutrition A form of malnutrition. A condition in animals in which intake of organic fuels is inadequate, or whose assimilation of such fuels is abnormal.

undulating membrane In parabasalid protists, a finlike structure formed by a flagellum buried in a fold of the cytoplasm that facilitates movement through thick and viscous fluids; an expansion of the plasma membrane in some flagellates that is usually associated with a flagellum.

unequal crossing-over The rare phenomenon in meiosis in which, instead of crossing-over occurring at the exact same point on each homolog of a homologous pair of chromosomes, crossing-over occurs at different points.

unicellular organism Individual consisting of a single cell.

uniform dispersion A pattern of distribution in which the individuals in a population are evenly spaced in their habitat.

uniformitarianism The concept that the geological processes that sculpted Earth's surface over long periods of time—such as volcanic eruptions, earthquakes, erosion, and the formation and movement of glaciers—are exactly the same as the processes observed today.

Unikonta (unikonts) Eukaryotes with a single flagellum.

uniparental inheritance A pattern of inheritance in which all progeny (both males and females) have the phenotype of only one of the parents.

universal A feature of the nucleic acid code, with the same codons specifying the same amino acids in all living organisms.

unreduced gamete A gamete that contains the same number of chromosomes as a somatic cell.

unsaturated fatty acid Fatty acid with one or more double bonds linking the carbons.

ureter The tube through which urine flows from the renal pelvis to the urinary bladder.

urethra The tube through which urine leaves the bladder. In most animals, the urethra opens to the outside.

urinary bladder A storage sac located outside the kidneys.

uterine cycle The menstrual cycle.

uterus A specialized saclike organ, in which the embryo develops in viviparous animals.

utricle Saclike, fluid-filled structure that is part of the vestibular apparatus. With the saccule, provides information about the up–down position of the head, as well as changes in the rate of linear movement of the head.

vaccination The process of administering a weakened form of a disease to patients as a means of giving them immunity to a more serious form of the disease.

vagina The muscular canal that leads from the cervix to the exterior.

valence electron An electron in the outermost energy level of an atom.

Van der Waals forces Weak molecular attractions over short distances.

variable An environmental factor that may differ among places or an organismal characteristic that may differ among individuals.

variable (V) region For the light and heavy polypeptides of a particular type of antibody, the regions that have different amino acids sequences from molecule to molecule.

vas deferens The tube through which sperm travel from the epididymis to the urethra in the male reproductive system.

vascular bundle A cord of plant vascular tissue; often multistranded with both xylem and phloem.

vascular cambium A lateral meristem that produces secondary vascular tissues in plants.

vascular plant *See* **tracheophyte.**

vascular tissue system One of the three tissue systems in plants that provide the foundation for plant organs; it consists of transport tubes for water and nutrients.

vegetal pole The end of the egg opposite the animal pole, which typically gives rise to internal structures such as the gut and the posterior end of the embryo.

vegetative reproduction Asexual reproduction in plants by which new individuals arise (or are created) without seeds or spores; examples include fragmentation from the parent plant or the use of cuttings by gardeners.

vein In a plant, a vascular bundle that forms part of the branching network of conducting and supporting tissues in a leaf or other expanded plant organ. In an animal, a vessel that carries the blood back to the heart.

ventilation The flow of the respiratory medium (air or water, depending on the animal) over the respiratory surface.

ventral Indicating the lower or "belly" side of an animal.

ventricle In the brain, an irregularly shaped cavity containing cerebrospinal fluid. In the heart, a chamber that pumps blood out of the heart.

venule A capillary that merges into the small veins leaving an organ.

vernalization The stimulation of flowering by a period of low temperature.

vertebrae The series of bones that form the vertebral column of vertebrate animals.

vertebral column The series of vertebrae that surrounds and protects the dorsal nerve cord and forms the supporting axis of the body.

vertebrate A member of the monophyletic group of tetrapod animals that possess a vertebral column.

vesicle A small, membrane-bound compartment that transfers substances between parts of the endomembrane system.

vessel In plants, one of the tubular conducting structures of xylem, typically several centimeters long; most angiosperms and some other vascular plants have xylem vessels.

vessel member Any of the short cells joined end to end in tubelike columns in xylem.

vestibular apparatus The specialized sensory structure of the inner ear of most terrestrial vertebrates that is responsible for detecting rotational movement of the head and provides information about the up–down positioning of the head as well as changes in the rate of linear movement of the head. The vestibular apparatus consists of three semicircular canals, the utricle, and the saccule.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

vestigial structure An anatomical feature of living organisms that no longer retains its function.

vibrio Any of various short, motile, S-shaped or comma-shaped bacteria of the genus *Vibrio*.

vicariance The fragmentation of a continuous geographical distribution by nonbiological factors.

virion A complete virus particle.

viroid A plant pathogen that consists of strands or circles of RNA, smaller than any viral DNA or RNA molecule, that have no protein coat.

virulent bacteriophage Bacteriophage that kills its host bacterial cells during each cycle of infection.

virus An infectious agent that contains either DNA or RNA surrounded by a protein coat.

visceral mass In mollusks, the region of the body containing the internal organs.

visual signal A means of communication in which animals use facial expressions or body language to send messages to other individuals.

vital capacity The maximum tidal volume of air that an individual can inhale and exhale.

vitamin An organic molecule required in small quantities that the animal cannot synthesize for itself.

vitamin D A steroidlike molecule that increases the absorption of Ca^{2+} and phosphates from ingested food by promoting the synthesis of a calcium-binding protein in the intestine; it also increases the release of Ca^{2+} from bone in response to PTH.

vitelline coat A gel-like matrix of proteins, glycoproteins, or polysaccharides immediately outside the plasma membrane of an egg cell.

vitreous humor The jellylike substance that fills the main chamber of the eye, between the lens and the retina.

viviparous Referring to animals that retain the embryo within the mother's body and nourish it during at least early embryo development.

voltage-gated ion channel A membrane-embedded protein that opens and closes as the membrane potential changes.

vulva The external female sex organs.

water lattice An arrangement formed when a water molecule in liquid water establishes an average of 3.4 hydrogen bonds with its neighbors.

water molds *See* **Oomycota.**

water potential The potential energy of water, representing the difference in free energy between pure water and water in cells and solutions; it is the driving force for osmosis.

watershed An area of land from which precipitation drains into a single stream or river.

water-soluble vitamin A vitamin with a high proportion of oxygen and nitrogen able to form hydrogen bonds with water.

wax A substance insoluble in water that is formed when fatty acids combine with long-chain alcohols or hydrocarbon structures.

weight A measure of the pull of gravity on an object.

wetland A highly productive ecotone often at the border between a freshwater biome and a terrestrial biome.

white blood cell *See* **leukocyte.**

white matter The myelinated axons that surround the gray matter of the central nervous system.

white rusts *See* **Oomycota.**

wilting The drooping of leaves and stems caused by a loss of turgor.

wobble hypothesis Hypothesis stating that the complete set of 61 sense codons can be read by fewer than 61 distinct tRNAs because of particular pairing properties of the bases in the anticodons.

Wolffian duct A bipotential primitive duct associated with the gonads that leads to a cloaca.

wood The secondary xylem of trees and shrubs, lying under the bark and consisting largely of cellulose and lignin.

X chromosome Sex chromosome that occurs paired in female cells and single in male cells.

X-linked gene A gene on the X chromosome.

X-linked inheritance The pattern of inheritance of an X-linked gene.

X-linked recessive inheritance Pattern in which displayed traits are due to inheritance of recessive alleles carried on the X chromosome.

X-ray diffraction Method for deducing the position of atoms in a molecule.

xylem The plant vascular tissue that distributes water and nutrients.

xylem sap The dilute solution of water and solutes that flows in the xylem.

Y chromosome Sex chromosome that is paired with an X chromosome in male cells.

yeast A single-celled fungus that reproduces by budding or fission.

yolk The portion of an egg that serves as the main energy source for the embryo.

yolk sac In an amniote egg, an extraembryonic membrane that encloses the yolk.

zero population growth A circumstance in which the birth rate of a population equals the death rate.

zona pellucida A gel-like matrix of proteins, glycoproteins, or polysaccharides immediately outside the plasma membrane of the egg cell.

zone of cell division The region in a growing root that consists of the root apical meristem and the actively dividing cells behind it.

zone of elongation The region in a root where newly formed cells grow and elongate.

zone of maturation The region in a root above the zone of elongation where cells do not increase in length but may differentiate further and take on specialized roles.

zooplankton Small, usually microscopic, animals that float in aquatic habitats.

zygospore A multinucleate, thick-walled sexual spore formed in zygomycete fungi (Zygomycota).

zygote A fertilized egg.

Electron acceptor, 162, 163–164
Electron carrier
cytochrome, 189, 189i, 190i, 192i
ferredoxin, 190i, 191, 192i
flavin adenine dinucleotide, 168–169, 170i–173i, 171, 173, 175–176, 175i
NADPH, 183i, 184–185, 189, 189i, 190i, 191–193, 195i, 196, 198
nicotinamide adenine dinucleotide, 164i, 166, 166i, 167i–173i, 168–169, 173, 175i, 176–178
in photosynthesis, 189, 190i, 191, 192i
plastocyanin, 190i, 191, 192i
plastoquinone, 190i, 191, 192i
Electron donor, 162
Electron flow
cyclic, 191–192, 192i
electron transfer system, 164i, 165, 172i, 173, 173i, 175–176
to final electron acceptors, 163–164
linear, 189i, 191
oxidation-reduction (redox) reactions, 162–163, 163i
Electron microscope, **92**
Electron microscopy, 93i
Electron transfer system, 164i, 165, **165,** 171, 172i, 173i, 175–176
in photosynthesis, 189, 189i, 190i, 191
Electronegativity, **30**
Electrophoresis, agarose gel, 399, 400i
Electrophysiology, 981
Electroporation, 375
Electroreceptor, **719,** 939
Element
chemical symbols, 24, 24t
defined, **23**
proportions in living organisms, 23, 23i
structure of, 24
trace, 23
Elephant, 445, 452–453
Elephantiasis, 686, 686i
Elimination, **1047**
Elk *(Cervus elaphus),* 943
Ellis-van Crevald syndrome, 465, 470
Elm *(Ulmus),* 769i
Elongation, in translation, **324,** 325–326, 326i
Elongation factor (EF), **325,** 326i
Embden, Gustav, 165
Embden-Meyerhof pathway, 165. *See also* Glycolysis
Embryo
animal (*See* Animal development)
defined, **671**
plant
development, 818–819, 819i, 826–832
seed germination, 821–822, 822i, 823i
somatic, 824, 825i

Light
absorption in photosynthesis, 185–189, 185i, 186i, 187i, 188i
fluorescence, 186
induction of stomata opening, 784–785
visible spectrum, 185, 186i
Light chain, antibody, **1009,** 1009i
Light-dependent reactions of photosynthesis, **183,** 183i, 184, 185–192, 188i, 189i, 190i, 192i
Light-harvesting complex, 188
Light-independent reactions, **183,** 183i, 184, 193–196, 195i
Light microscope, **91**–92, 93i
Lignification, **749,** 754
Lignin, 112, **613,** 614
Lijam, Nardos, 1283
Likens, Gene, 1243
Lilac *(Syringa vulgaris),* 862i
Limbic system, 911i, **912**
Limbs, evolution of, 722, 722i
Limiting nutrient, **1234**
Limnetic zone, **1162,** 1163i
Limulus polyphemus, 697i
Linear electron flow, **191,** 198i
LINEs. *See* Long Interspersed Elements
Linkage, **262**–266, 263i, 265i, 266i
Linkage map, **264**–265, 266i
Linked genes, **262**–266, 263i, 265i, 266i
Linker, DNA, **305,** 305i
Linnaeus, Carolus, 440, 529–530
Linoleic acid, 1048
Linolenic acid, 1048
Linum insertion sequence-1 (LIS-1), 863
Lion–tiger hybrids, 484
Lipase, 1046, 1053i, **1057,** 1058i
Lipid bilayer assembly, protocell, 557–558, 557i
Lipids, 50–55
defined, **50**
fatty acids, 50–52, 51i
membrane, 120–121, 121i, 122i, 123–124
neutral, 50–53
phospholipids, 53, 53i
steroids, 54–55, 54i
triglyceride, 50, 51, 51i, 52i
waxes, 52–53
Lipopolysaccharide, **570,** 581
Lipoprotein, 52, 54, 62, 136, 1057
Lipoprotein lipase, 1065–1066
Liposomes, 949
Lipotyphla, 734, 736i
LIS-1 (*Linum* insertion sequence-1), 863
Listeria monocytogenes, 115
Lithium, 153
Lithosphere, **1146**
Litt, Amy, 645
Littoral zone, **1162,** 1163i
Liver, 1049i, 1056i, **1057,** 1058
Liverwort, 619, 619i
Living systems, characteristics of, 2–6
chemical instructions, 3–4, 3i
energy and matter cycling, 4, 5i
evolution of populations, 5–6
metabolic activity, 4, 4i
organization, 2–3, 2i
reproduction and development, 5, 6i
response to environmental change, 4–5
Lizard
description, 727–728, 728i
ectothermy in, 1086, 1087, 1087i, 1088
iguana, 2i
as model research organism, 728, 729
predation on spiders, 1187–1188, 1188i
temperature regulation, 15–17, 17i
thermoregulation, 1152–1153, 1153i
Loam, **798,** 800t
Lobaria verrucosa, 665i
Lobe-finned fish, 721, 721i
Lobster, 698, 698i
Local homeostatic controls, **878**
Local inflammation, **1005**
Local regulation, 142, 945
Locus, **251,** 251i
Locust *(Locusta migratoria),* 1186, 1186i
Locust *(Schistocerca gregaria),* 423
Lodgepole pine *(Pinus contorta),* 666i
Loewi, Otto, 887i
Loggerhead sea turtles *(Caretta caretta),* 939, 939i
Logistic model of population growth, 1182–1184, **1183,** 1183i, 1184t, 1185i
Lohmann, Kenneth, 939, 939i
Long-day plant, **859**–860, 860i
Long Interspersed Elements (LINEs), 537
Long-tailed widowbird *(Euplectes progne),* 470, 471i
Long-term memory, **916,** 918
Long-term potentiation, **916,** 917
Loop of Henle, **1075,** 1075i, 1076i, 1077–1078, 1077t
Loose connective tissue, **872,** 873i
Lophophore, 677, **683,** 683i
Lophotrochozoa, 677, 683–692
feeding structure, 683, 683i
phyla
Annelida, 690–692, 691i, 692i
Brachiopoda, 683i, 684
Ectoprocta, 683, 683i
Mollusca, 687–690, 688i–690i
Nemertea, 686–687, 687i
Phoronida, 683i, 684
Platyhelminthes, 684–685, 684i, 685i, 686
Rotifera, 685–686, 687i
Loreau, Michel, 667
Lorenz, Konrad, 1279, 1284, 1284i
Lorises, 736
Losos, Jon, 729
Lotic system, 1161
Lotka, Alfred J., 1203
Lotus *(Nelumbo lutea),* 822
Low-density lipoprotein (LDL), 52, 136, 137, 1065–1066
Lubchenco, Jane, 1215, 1215i
Luciferase, 594, 1078–1079, 1134
Luciferin, 594
Lucy (hominid fossil), 740, 741i
Ludwig, Stephen, 155
Luft, Rolf, 161
Luft syndrome, 161
Lumbricus, 692i
Lumen, digestive tube, **1047**
Luna moth, 700i
Lungfish, 721i, 1029
Lungs, **1025,** 1026i, 1029–1033, 1030i, 1031i, 1032i
Lupine *(Lupinus arcticus),* 822
Luteal phase, 1105, 1106i
Luteinizing hormone (LH), 951t, **952,** 953i, 958, **1105,** 1106i, 1107, 1109–1110, 1109i, 1113
Lycophyta, **622,** 622t
Lycophytes, 622, 622t, 623, 623i, 626–627
Lycopodium, 623, 623i

Z line, 967i, 968, 968i
Z scheme, 191
Zeatin, 846
Zebra finch *(Taeniopygia guttata),* 1285, 1285i, 1286, 1286i
Zebra mussel *(Dreissina polymorpha),* 1230
Zebrafish *(Danio rerio),* 205, 205i, 523
Zebroid, 486, 486i
Zenk gene, 1285, 1285i
Zero population growth, **1182,** 1193
Zhang, Billiang, 85
Zhang, GuangJun, 523
Zinc, as plant micronutrient, 796t
Zinc finger, 348, 348i
Zinder, Norton, 375
Zona pellucida, **1100,** 1100i, 1102i, 1110, 1114, 1128, 1129i, 1130i
Zonation
intertidal, 1166, 1166i
lake, 1162–1163, 1163i
ocean, 1164–1165, 1165i
Zone of cell division, **766,** 766i
Zone of elongation, **766,** 766i
Zone of maturation, **766,** 766i
Zooplankton
defined, **590**
open ocean, 1167
as primary consumers, 1238
ZW sex-determination system, 1141
Zygomycota (zygomycetes), 655t, 657–658, 657i, 658i
Zygospore, 657, 657i, **658**
Zygote, **225,** 227, 235, 242, 355
angiosperm, 812, 818, 819i
defined, **671**
fungal, 653–654, 653i

Experimental Research

Figure	Description	Page
1.15	Hypothetical Experiment Illustrating the Use of Control Treatment and Replicates	16
3.24	Anfinsen's Experiment Demonstrating That the Amino Acid Sequence of a Protein Specifies Its Tertiary Structure	61
5.11	Discovery of the Nuclear Localization Signal	101
6.6	The Frye–Edidin Experiment Demonstrating That the Phospholipid Bilayer Is Fluid	124
7.2	Sutherland's Experiments Discovering a Second Messenger Molecule	144
8.15	The Racker and Stoeckenius Experiment Demonstrating That an H^+ Gradient Powers ATP Synthesis by ATP Synthase	174
10.12	Movement of Chromosomes during Anaphase of Mitosis	215
10.14	Demonstrating the Existence of Molecules Controlling the Cell Cycle by Cell Fusion	216
12.5	The Principle of Segregation: Inheritance of Flower Color in Garden Peas	244
12.8	Testing the Predicted Outcomes of Genetic Crosses	247
12.9	The Principle of Independent Assortment	248
12.13	Experiment Showing Incomplete Dominance of a Trait	253
13.2	Evidence for Gene Linkage	263
13.8	Evidence for Sex-Linked Genes	269
14.2	Griffith's Experiment with Virulent and Nonvirulent Strains of *Streptococcus pneumoniae*	288
14.3	The Hershey and Chase Experiment Demonstrating That DNA Is the Hereditary Molecule	289
14.9	The Meselson and Stahl Experiment Demonstrating the Semiconservative Model for DNA Replication to Be Correct	294
15.2	Relationship between Genes and Enzymes	312
17.1	Genetic Recombination in Bacteria	371
18.14	The First Cloning of a Mammal	408
20.12	How Exposure to Insecticide Fosters the Evolution of Insecticide Resistance	449
21.6	Using Artificial Selection to Demonstrate That Activity Level in Mice Has a Genetic Basis	459
21.13	Sexual Selection in Action	471
21.16	Demonstration of Frequency-Dependent Selection	474

Experimental Research

25.2	The Miller–Urey Apparatus Demonstrating That Organic Molecules Can Be Synthesized Spontaneously under Conditions Simulating Primordial Earth	556
26.13	Demonstration of the Bacterial Cause of Peptic Ulcers	579
27.11	The Evolutionary History of Diatoms as Revealed by Genome Analysis	597
29.14	Analyzing Phytochromes to Explore Angiosperm Evolution	640
34.12	Translocation Pressure	787
36.24	Probing the Roles of Floral Organ Identity Genes	832
37.3	The Darwins' Experiments on Phototropism	841
39.7	Demonstration of Chemical Transmission of Nerve Impulses at Synapses	887
40.13	Investigating the Functions of the Cerebral Hemispheres	915
42.5	Demonstration That Binding of Epinephrine to β-Adrenergic Receptors Triggers a Signal Transduction Pathway within Cells	949
43.4	The Sliding Filament Model of Muscle Contraction	969
44.18	Demonstration of a Vasodilatory Signal Molecule	996
46.14	Demonstration of a Molecular Basis for High-Altitude Adaptation in Deer Mice	1038
47.21	Association of Intestinal Bacteria Populations with Obesity in Humans	1064
48.12	ADH-Stimulated Water Reabsorption in the Kidney Collecting Duct	1082
49.13	Vocal Cues of Ovulation in Human Females	1107
50.18	Demonstrating the Selective Adhesion Properties of Cells	1137
50.20	Spemann and Mangold's Experiment Demonstrating Induction in Embryos	1139
51.25	What Causes Lake Eutrophication?	1164
52.17	Evaluating Density-Dependent Interactions between Species	1188
53.8	Gause's Experiments on Interspecific Competition in *Paramecium*	1204
53.12	Demonstration of Competition between Two Species of Barnacles	1206
53.23	Effect of a Predator on the Species Richness of Its Prey	1214
53.24	The Complex Effects of an Herbivorous Snail on Algal Species Richness	1215

Experimental Research

54.11	A Trophic Cascade in Salt Marshes	1240
55.6	Predation on Songbird Nests in Forests and Forest Fragments	1259
55.18	Effect of Landscape Corridors on Plant Species Richness in Habitat Fragments	1271
56.2	The Role of Sign Stimuli in Parent–Offspring Interactions	1281
56.10	Effects of the Social Environment on Brain Anatomy and Chemistry	1288
56.13	Experimental Analysis of the Indigo Bunting's Star Compass	1290

Observational Research

Figure	Description	Page
1.16	A Field Study Using a Null Hypothesis	17
21.10	Do Humans Experience Stabilizing Selection?	468
21.11	How Opposing Forces of Directional Selection Produce Stabilizing Selection	469
21.15	Habitat Variation in Color and Striping Patterns of European Garden Snails	473
22.13	Evidence for Reproductive Isolation in Bent Grass	490
22.18	Chromosomal Similarities and Differences among the Great Apes	495
23.19	Evidence of Phyletic Gradualism	517
23.20	Evidence of a Punctuated Pattern of Morphological Change	518
23.23	Paedomorphosis in *Delphinium* Flowers	520
24.14	Do Molecular Clocks Tick at a Constant Rate?	545
51.9	How Do Lizards Compensate for Altitudinal Variation in Environmental Temperature?	1153
52.19	Do Immigrants from Source Populations Prevent Extinction of Sink Populations of the Bay Checkerspot Butterfly?	1190
54.7	What Is the Pattern of Energy Flow within the Silver Springs Ecosystem?	1236

Research Methods

Figure	Description	Page
1.14	The Scientific Method	14
5.4	Light and Electron Microscopy	93
5.8	Cell Fractionation	97
6.7	Freeze Fracture	125
10.7	Preparing a Human Karyotype	211
12.3	Making a Genetic Cross between Two Pea Plants	241
17.5	Replica Plating	376
18.3	Cloning a Gene of Interest in a Plasmid Cloning Vector	395
18.4	Synthesis of DNA from mRNA Using Reverse Transcriptase	396
18.5	DNA Hybridization to Identify a DNA Sequence of Interest	397
18.6	The Polymerase Chain Reaction (PCR)	398
18.7	Separation of DNA Fragments by Agarose Gel Electrophoresis	400
18.9	Southern Blot Analysis	402
18.12	Introduction of Genes into Mouse Embryos Using Embryonic Germ-Line Cells	406
18.15	Using the Ti Plasmid of *Agrobacterium tumefaciens* to Produce Transgenic Plants	409
19.1	Whole-Genome Shotgun Sequencing	418
19.2	Dideoxy (Sanger) Method for DNA Sequencing	419
19.3	Illumina/Solexa Method for DNA Sequencing	420
19.8	DNA Microarray Analysis of Gene Expression Levels	429
23.4	Radiometric Dating	504
24.11	Using Cladistics to Construct a Phylogenetic Tree	540
24.13	Using Genetic Distances to Construct a Phylogenetic Tree	544
35.2	Hydroponic Culture	795
36.18	Plant Cell Culture	825
39.8	Measuring Membrane Potential	888
45.9	Production of Monoclonal Antibodies	1016
52.3	Using Mark-Release-Recapture to Estimate Population Size	1174
56.27	Calculating Degrees of Relatedness	1301
