DNA Technologies Are Used in Molecular Testing for Many Human Genetic Diseases

Many human genetic diseases are caused by defects in enzymes or other proteins that result from mutations at the DNA level. Once scientists have identified the specific mutations responsible for human genetic diseases, they can often use DNA technologies to develop molecular tests for those diseases. One example is sickle-cell anemia (see *Why It Matters* in Chapter 12 and Sections 12.2 and 13.4). People with sickle-cell anemia are homozygous for a DNA mutation that affects hemoglobin, the oxygen-carrying molecule of the blood. Hemoglobin consists of two copies each of the α-globin and β-globin polypeptides. The mutation, which is in the β-globin gene, alters one amino acid in the polypeptide. As a consequence, the function of hemoglobin is significantly impaired in individuals homozygous for the mutation (who have sickle-cell anemia), and mildly impaired in individuals heterozygous for the mutation (who have sickle-cell trait).

Three restriction sites for *Mst*II are associated with the normal β-globin gene, two within the coding sequence of the gene and one upstream of the gene. The sickle-cell mutation eliminates the middle site of the three **(Figure 18.8)**. Cutting the β-globin gene with *Mst*II produces two DNA fragments from the normal gene and one fragment from the mutated gene. Restriction enzyme-generated DNA fragments of different lengths from the same region of the genome, such as in this example, are known as **restriction fragment length polymorphisms** (**RFLPs,** pronounced "riff-lips").

RFLPs can be analyzed using a hybridization-based method called **Southern blot analysis** (named after its inventor, researcher Edwin Southern) **(Figure 18.9).** In this technique, genomic DNA is digested with a restriction enzyme, and the DNA fragments are separated using agarose gel electrophoresis. The fragments are then transferred—blotted—to a nylon membrane, and a labeled probe is used to identify a DNA sequence of interest from among the many thousands of fragments on the nylon membrane. As shown in Figure 18.9 for the sickle-cell anemia example, the DNA bands visualized after hybridization indicate the allele or alleles present in each individual.

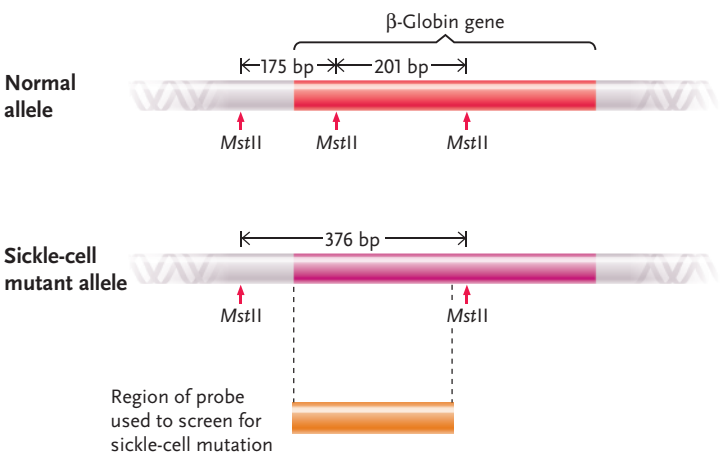

FIGURE 18.8 Restriction site differences between the normal and sickle-cell mutant alleles of the β-globin gene. The figure shows a DNA segment that can be used as a probe to identify these alleles in a subsequent probe-based analysis (see Figure 18.9).

© Cengage Learning 2014

A technique called **northern blot analysis** is very similar to Southern blot analysis but is used to study RNA rather than DNA. (The name is a play on words on Southern's name.) In northern blot analysis, RNA molecules extracted from cells or a tissue are separated by size using electrophoresis and then transferred to a filter paper. Hybridization with a labeled probe reveals the RNAs that were present, both their size and concentration. Northern blot analysis is useful, for example, for determining the size of an mRNA encoded by a gene or for quantifying the expression of a gene in different tissues or at different stages of development.

Restriction enzyme digestion and Southern blot analysis may be used to test for a number of human genetic diseases, including phenylketonuria and Duchenne muscular dystrophy (see Section 13.4). In some cases, restriction enzyme digestion is combined with PCR for a quicker, easier analysis because there is no need for a probe or Southern blotting. With that approach, the gene or region of the gene with the restriction enzyme variation is amplified using PCR, and then the amplified DNA is cut with the diagnostic restriction enzyme. Amplification produces enough DNA so that separation by size using agarose gel electrophoresis produces clearly visible bands, positioned according to fragment length. Researchers can then determine whether the fragment lengths match a normal or abnormal RFLP pattern.

DNA Fingerprinting Is Used to Identify Human Individuals as well as Individuals of Other Species

Just as each human has a unique set of fingerprints, each also has unique combinations and variations of DNA sequences (with the exception of identical twins) known as *DNA fingerprints.* **DNA fingerprinting** is a technique used to distinguish between individuals of the same species using DNA samples. Invented by Sir Alec Jeffreys in 1984, DNA fingerprinting has become a mainstream technique for distinguishing human individuals, notably in forensics and paternity testing. The technique is applicable to all kinds of organisms. We focus on humans in the following discussion.

DNA FINGERPRINTING PRINCIPLES In DNA fingerprinting, molecular techniques, typically PCR, are used to analyze DNA variations at various loci in the genome. In the United States, 13 loci in noncoding regions of the genome are the standards for PCR analysis. Each locus is an example of a **short tandem repeat (STR)** sequence (also called a **microsatellite**), meaning that it has a short 2 to 6 bp sequence

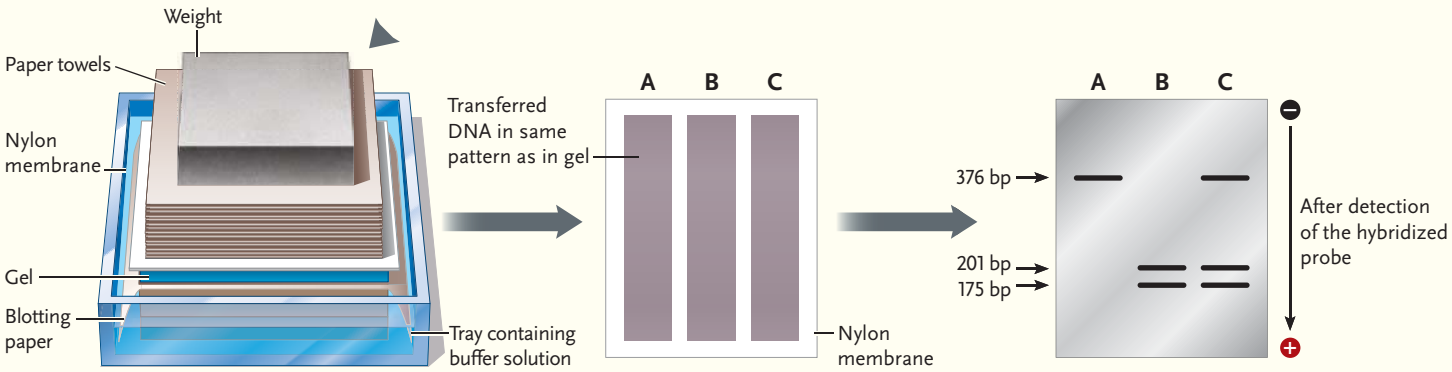
Southern Blot Analysis



Purpose: The Southern blot technique allows researchers to identify DNA fragments of interest after separating DNA fragments on a gel. One application is to compare different samples of genomic DNA cut with a restriction enzyme to detect specific restriction fragment length polymorphisms. Here the technique is used to distinguish between individuals with sickle-cell anemia, individuals with sickle-cell trait, and normal individuals.

Protocol:

1. Isolate genomic DNA and digest with *Mst*II. Here, genomic DNA is from three individuals: **A,** sickle-cell anemia (homozygous for the sickle-cell mutant allele); **B,** normal (homozygous for the normal allele); and **C,** sickle-cell trait (heterozygous for sickle-cell mutant allele).

2. Separate the DNA fragments by agarose gel electrophoresis. The thousands of differently sized DNA fragments produce a smear of DNA down the length of each lane in the gel, which are seen after staining the DNA (see Figure 18.7.)

3. Hybridization with a labeled DNA probe to identify DNA fragments of interest cannot be done directly with an agarose gel. Edward Southern devised a method to transfer the DNA fragments from a gel to a nylon membrane. First, treat the gel with a solution to denature the DNA into single strands. Next, place the gel on a piece of blotting paper with ends of the paper in the buffer solution and place the membrane on top of the gel. Capillary action wicks the buffer solution in the tray up the blotting paper, through the gel and membrane, and into the weighted stack of paper towels on top of the gel. The movement of the solution transfers—blots—the single-stranded DNA fragments to the membrane, where they stick. The pattern of DNA fragments is the same as it was in the gel.

4. Use DNA hybridization with a labeled probe to focus on a particular region of the genome. That is, incubate a labeled, single-stranded probe with the membrane and detect hybridization of the probe with DNA fragments on the membrane. For a radioactive probe, place the membrane against X-ray film, which, after development will show a band or bands where the probe hybridized. In this experiment, the probe is a cloned piece of DNA from the area shown in Figure 18.8 (the β-globin gene), that can bind to all three of the *Mst*II fragments of interest.

Interpreting the Results: The hybridization result indicates that the probe has identified a very specific DNA fragment or fragments in the digested genomic DNA. The RFLPs for the β-globin gene can be seen in Figure 18.8. DNA from the sickle-cell anemia individual **(A)** cut with *Mst*II results in a single band of 376 bp detected by the probe, whereas DNA from the normal individual **(B)** results in two bands, of 201 bp and 175 bp. DNA from a sickle-cell trait heterozygote **(C)** results in three bands, of 376 bp (from the sickle-cell mutant allele), and 201 bp and 175 bp (both from the normal allele). This type of analysis in general is useful for distinguishing normal and mutant alleles of genes where the mutation involved alters a restriction site.

of DNA repeated in series. Each locus has a different repeated sequence, and the number of repeats varies among individuals in a population. For example, one STR locus has the sequence 5′-AGAT-3′ repeated between 8 and 20 times. As a further source of variation, a given individual is either homozygous or heterozygous for an STR allele; perhaps you are homozygous for an 11-repeat allele, or heterozygous for a 9-repeat allele and a 15-repeat allele. Likely your DNA fingerprint for this locus is different from most of the others in your class. Because each individual has an essentially unique combination of alleles (identical twins are the exception), analysis of multiple STR loci can discriminate between DNA of different individuals and, therefore potentially identify individuals on the basis of DNA analysis. **Figure 18.10** illustrates how PCR is used to obtain a DNA fingerprint for a theoretical STR locus with three alleles of 9, 11, and 15 tandem repeats.

DNA FINGERPRINTING IN FORENSICS DNA fingerprints are used routinely to identify criminals or eliminate innocent persons as suspects in legal proceedings. For example, a DNA fingerprint prepared from a hair found at the scene of a crime, or from a semen sample, might be compared with the DNA fingerprint of a suspect to link the suspect with the crime. Or, a DNA fingerprint of blood found on a suspect's clothing or possessions might be compared with the DNA fingerprint of a victim. Typically, the evidence is presented in terms of the probability that the particular DNA sample could have come from a random individual. Hence the media report probability values, such as one in several million, or in several billion, that a person other than the accused could have left his or her DNA at the crime scene.

Although courts initially met with legal challenges to the admissibility of DNA fingerprints, experience has shown that they are highly dependable as a line of evidence if DNA samples are collected and prepared with care, and if a sufficient number of loci which have variable numbers of DNA repeat sequences are examined. There is always concern, though, about the possibility of contamination of the sample with DNA from another source during the path from the crime scene to the forensic laboratory for analysis. Moreover, in some cases criminals themselves have planted fake DNA samples at crime scenes to confuse the investigation.

DNA fingerprinting has been used extensively to identify a criminal or rule out a suspect. For example, in a case in England, the DNA fingerprints of more than 5,000 men were made using blood and saliva samples during an investigation of the rape and murder of two teenage girls in 1983 and 1986. The results led to the release of a man wrongly imprisoned for the crimes—the first person exonerated by DNA fingerprinting evidence. But no DNA fingerprints matched the DNA at the

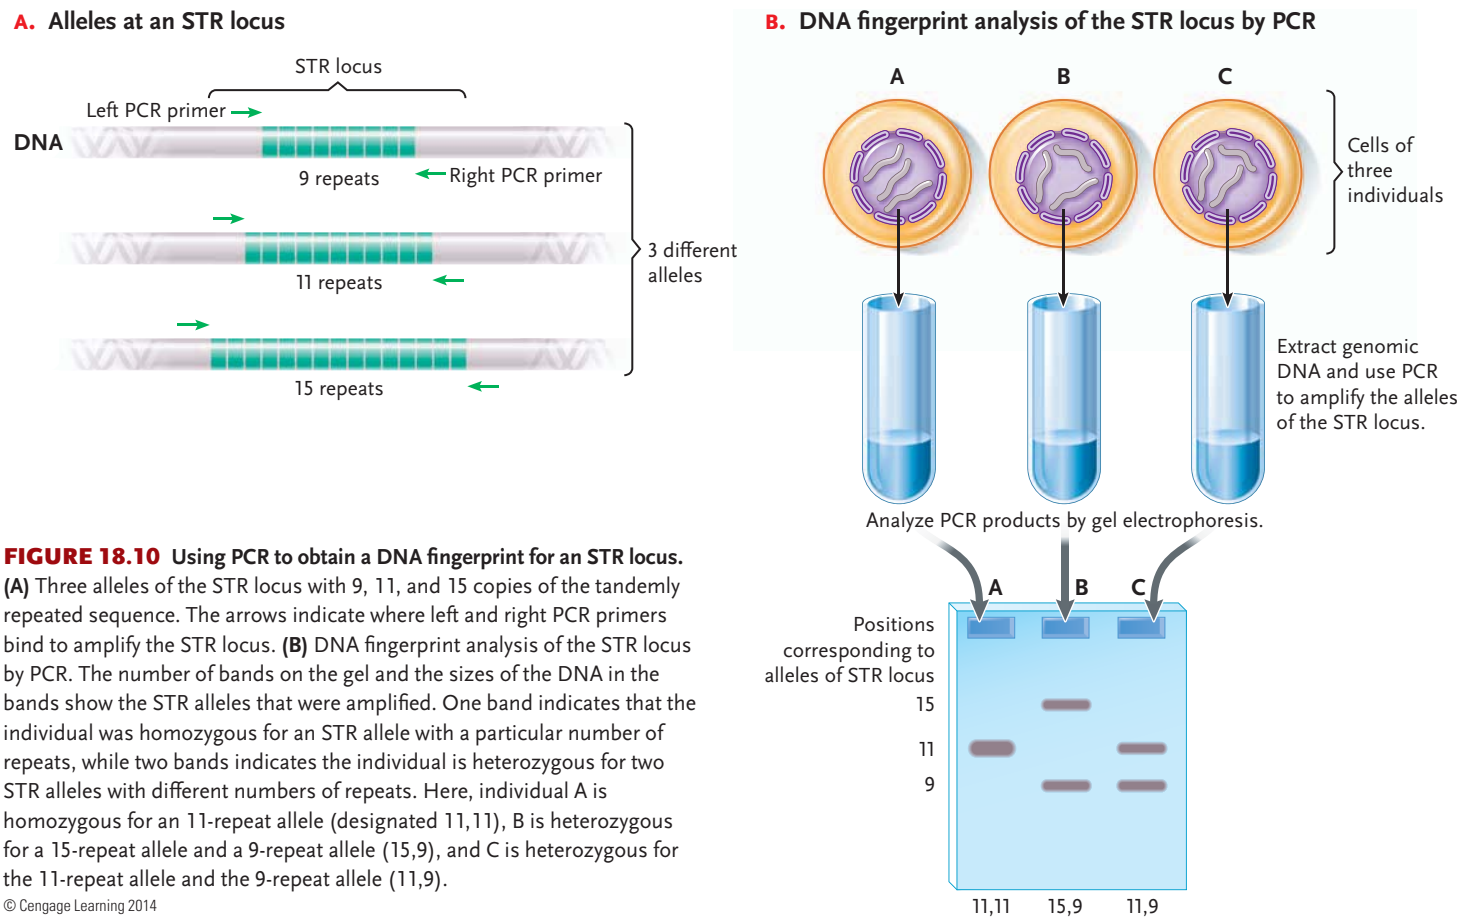

FIGURE 18.10 **Using PCR to obtain a DNA fingerprint for an STR locus.** **(A)** Three alleles of the STR locus with 9, 11, and 15 copies of the tandemly repeated sequence. The arrows indicate where left and right PCR primers bind to amplify the STR locus. **(B)** DNA fingerprint analysis of the STR locus by PCR. The number of bands on the gel and the sizes of the DNA in the bands show the STR alleles that were amplified. One band indicates that the individual was homozygous for an STR allele with a particular number of repeats, while two bands indicates the individual is heterozygous for two STR alleles with different numbers of repeats. Here, individual A is homozygous for an 11-repeat allele (designated 11,11), B is heterozygous for a 15-repeat allele and a 9-repeat allele (15,9), and C is heterozygous for the 11-repeat allele and the 9-repeat allele (11,9).

crime scene. Then a woman overheard a colleague at work saying that he had given his samples in the name of his friend, Colin Pitchfork. Pitchfork was arrested, and his DNA fingerprint subsequently was shown to match the DNA at the crime scene. In 1988 he was convicted of the murders, the first conviction on the basis of DNA evidence. The application of DNA fingerprinting techniques to stored forensic samples has also led to the release of a number of persons wrongly convicted for rape or murder.

DNA FINGERPRINTING IN TESTING PATERNITY AND ESTABLISHING ANCESTRY DNA fingerprints are also widely used as evidence of paternity because parents and their children share common alleles in their DNA fingerprints. That is, each child receives one allele of each locus from one parent and the other allele from the other parent. A comparison of DNA fingerprints for a number of loci can prove almost infallibly whether a child has been fathered or mothered by a given person. DNA fingerprints have also been used for other investigations, such as confirming that remains discovered in a remote region of Russia were actually those of Czar Nicholas II and members of his family, murdered in 1918 during the Russian revolution.

DNA fingerprinting is also used widely in studies of other organisms, including other animals, plants, and bacteria. Examples include testing for pathogenic *E. coli* in food sources such as hamburger meat, investigating cases of wildlife poaching, detecting genetically modified organisms among living organisms or in food, and comparing the DNA of ancient organisms with present-day descendants.

Genetic Engineering Uses DNA Technologies to Alter the Genes of a Cell or Organism

We have seen the many ways scientists use DNA technologies to ask, and answer, questions that were once completely inaccessible. Genetic engineering goes beyond gathering information; it is the use of DNA technologies to modify genes of a cell or organism. The goals of genetic engineering include using prokaryotes, fungi, animals, and plants as factories for the production of proteins needed in medicine and scientific research; correcting hereditary disorders; and improving animals and crop plants of agricultural importance. In many of these areas, genetic engineering has already been highly successful. The successes and potential benefits of genetic engineering, however, are tempered by ethical and social concerns about its use, along with the fear that the methods may produce toxic or damaging foods, or release dangerous and uncontrollable organisms to the environment.

Genetic engineering uses DNA technologies of the kind discussed already in this chapter. DNA—perhaps a modified gene—is introduced into target cells of an organism where that gene is then expressed. In effect, the genotype of the organism is altered by the addition of the gene. Organisms that have undergone a gene transfer are called **transgenic,** meaning that they have been modified to contain genetic information—the **transgene**—from an external source.

The following sections discuss some applications of the genetic engineering of bacteria, animals, and plants.

GENETIC ENGINEERING OF BACTERIA TO PRODUCE PROTEINS

Transgenic bacteria have been made, for example, to synthesize proteins for medical applications, break down toxic wastes such as oil spills, produce industrial chemicals such as alcohols, and process minerals. *E. coli* is the organism of choice for many of these applications of DNA technologies.

Figure 18.11 shows how *E. coli* can be engineered to make a protein from a foreign source. First, the gene for the protein is cloned from the appropriate organism. Then the gene is inserted into an **expression vector,** which is a cloning vector that has extra features, namely the regulatory sequences that allow transcription and translation of a gene. For a bacterial expression vector, this means having a promoter and a transcription terminator that are recognized by the *E. coli* transcriptional machinery, and having the ribosome binding site needed for the bacterial ribosome to recognize the start codon of the transgene (see Section 15.4). The regulatory sequences flank a cluster of restriction sites that are used for cloning so that the inserted gene is placed correctly for transcription and translation when the recombinant plasmid is transformed into *E. coli*.

As was mentioned earlier while discussing DNA libraries, a cDNA copy of a eukaryotic gene is used when we want to use bacteria to express the protein encoded by the gene (see Figure 18.11). This is because a eukaryotic protein-coding gene typically contains introns, which bacteria cannot remove when they transcribe such a gene. However, the eukaryotic mRNA that is copied by reverse transcriptase to synthesize cDNA has no introns; thus, when that cDNA is expressed in bacteria, it can be transcribed and translated to make the encoded eukaryotic protein. The protein is either extracted from the bacterial cells and purified or, if the protein is secreted, it is purified from the culture medium.

Expression vectors are available for a number of organisms. They vary in the regulatory sequences they contain and the selectable marker they carry so that the host organism transformed with the vector carrying a gene of interest can be detected and the host can express that gene.

For example, genetic engineering has been used to produce *E. coli* bacteria that make the human hormone insulin; the commercial product is called Humulin. Insulin is required by persons with some forms of diabetes. Humulin is a perfect copy of the human insulin hormone. Many other proteins, including human growth hormone to treat human growth disorders, tissue plasminogen activator to dissolve blood clots that cause heart attacks, and a vaccine against foot-and-mouth disease of cattle and other cloven-hoofed animals (a highly contagious and sometimes fatal viral disease), have been developed for commercial production in bacteria using similar methods.

A concern is that genetically engineered bacteria may be released accidentally into the environment where possible adverse effects of the organisms are currently unknown. Scientists minimize the danger of accidental release by growing the bacteria in laboratories that follow appropriate biosafety protocols. In addition, the bacterial strains typically used are genetic mutants that cannot survive outside the growth media used in the laboratory.

GENETIC ENGINEERING OF ANIMALS Many animals, including fruit flies, fish, mice, pigs, sheep, goats, and cows, have been altered successfully by genetic engineering. Typically the organism has been altered to express a transgene, which means using an expression vector with the appropriate molecular features for gene expression in that organism. There are many purposes for these alterations, including basic research, correcting genetic disorders in humans and other mammals, and producing pharmaceutically important proteins.

Genetic Engineering Methods for Animals. Several methods are used to introduce a gene of interest into animal cells. The gene may be introduced into **germ-line cells,** which develop into sperm or eggs and thus enable the introduced gene to be passed from generation to generation. Or the gene may be introduced into **somatic** ("body") **cells,** differentiated cells that are not part of lines producing sperm or eggs, in which case the gene is not transmitted from generation to generation.

Germ-line cells of embryos are often used as targets for introducing genes, particularly in mammals other than humans **(Figure 18.12).** The treated cells are then cultured in quantity and reintroduced into early embryos. If the technique is successful, some of the introduced cells become founders of cell lines that develop into eggs or sperm with the desired genetic information integrated into their DNA. Individuals produced by crosses using the engineered eggs and sperm then contain the introduced sequences in all of their cells. Several genes have been introduced into the germ lines of mice by this approach, resulting in permanent, heritable changes in the engineered individuals.

A related technique involves introducing desired genes into **stem cells,** which are cells capable of undergoing many divisions in an unspecialized, undifferentiated state, but which also have the ability to differentiate into specialized cell types. In mammals, *embryonic stem cells* are found in a mass of cells inside an early-stage embryo (the blastocyst) (see Figure 18.12, step 3, and Figure 50.12) and can differentiate into all of the tissue types of the embryo, whereas *adult stem cells* function to replace specialized cells in various tissues and organs. In mice and other non-human mammals, transgenes are introduced into embryonic stem cells, which are then injected into early-stage embryos as in Figure 18.12 (step 3). The stem cells then differentiate into a variety of tissues along with cells of the embryo itself, including sperm and egg cells. Males and females are then bred, leading to offspring that are either homozygotes, containing two copies of the introduced gene, or heterozygotes, containing one introduced gene and one gene that was native to the embryo receiving the engineered stem cells.

Introduction of genes into stem cells has been done mostly in mice. One of the highly useful results is the production of a

FIGURE 18.12 **Research Method**

Introduction of Genes into Mouse Embryos Using Embryonic Germ-Line Cells

Purpose: To make a transgenic animal that can transmit the transgene to offspring. The embryonic germ-line cells that receive the transgene develop into the reproductive cells of the animal.

Protocol:

Outcome: The result of the breeding is some offspring in which all cells are transgenic—a genetically engineered animal has been produced.

© Cengage Learning 2014

knockout mouse, a homozygous recessive that has two copies of a gene each altered to a nonfunctional state. The effect of the missing gene's activity on the knockout mouse is a clue to the normal function of the gene. Knockout mice also are used to model some human genetic diseases.

For introducing genes into somatic cells, typically somatic cells are removed from the body, cultured, and then transformed with an expression vector containing the transgene. The modified cells are then reintroduced into the body where the transgene functions. Because germ cells and their products are not involved, the transgene remains in the engineered individual and is not passed to offspring.

Gene Therapy: Correcting Genetic Disorders. The path to **gene therapy**—correcting genetic disorders—in humans began with experiments using mice. In 1982, Richard Palmiter at the University of Washington, Ralph Brinster of the University of Pennsylvania, and their colleagues injected a growth hormone gene from rats into fertilized mouse eggs and implanted the eggs into a surrogate mother. Some normal-sized mouse pups were produced that grew faster than normal and became about twice the size of their normal litter mates: they were *giant mice* **(Figure 18.13).**

Palmiter and Brinster next attempted to cure a genetic disorder by gene therapy. In this experiment, they constructed transgenic mice in which a normal copy of the rat growth hormone gene was added to mutant mice known as little, genotype *lit/lit.* This mouse mutant is about one-half normal size due to decreased levels of growth hormone gene expression and of growth hormone itself. The transgenic mice grew faster than *lit/lit* and reached a size about three times that of mutant mice. In fact, because regulation of expression of the rat growth hormone in the transgenic mice is not under normal control, the transgenic mice grow to be slightly larger than even normal mice. Overall the results showed that the genetic defect in those mice had been corrected, at least partially.

This sort of experiment, in which a gene is introduced into germ-line cells of an animal to correct a genetic disorder, is **germ-line gene therapy.** For ethical reasons, germ-line gene therapy is not permitted with humans. Instead, humans are treated with **somatic gene therapy,** in which genes are introduced into somatic cells (as described in the previous section).

The first successful use of somatic gene therapy with a human subject who had a genetic disorder was carried out in the 1990s by W. French Anderson and his colleagues at the National Institutes of Health (NIH). The subject was a young girl with *adenosine deaminase deficiency (ADA).* Without the adenosine

FIGURE 18.13 A genetically engineered giant mouse (right) produced by the introduction of a rat growth hormone gene into the animal. A mouse of normal size is on the left.

deaminase enzyme, white blood cells cannot mature (see Chapter 45). In the absence of normally functioning white blood cells, the body's immune response is so deficient that most children with ADA die of infections before reaching puberty. The researchers were successful in introducing a functional ADA gene into mature white blood cells isolated from the patient. Those cells were reintroduced into the girl, and expression of the ADA gene provided a temporary cure for her ADA deficiency. The cure was not permanent because mature white blood cells, produced by differentiation of stem cells in the bone marrow, are nondividing cells with a finite life time. Therefore, the somatic gene therapy procedure has to be repeated every few months. The subject of this example still receives periodic gene therapy to maintain the necessary levels of the ADA enzyme in her blood. In addition, she receives direct doses of the normal enzyme.

Despite enormous efforts, human somatic gene therapy has not been the panacea people expected. Relatively little progress has been made since the first gene therapy clinical trial for ADA deficiency, and, in fact, there have been major setbacks. In 1999, for example, a teenage patient in a somatic gene therapy trial died as a result of a severe immune response to the viral vector used to introduce a normal gene to correct his genetic deficiency. Furthermore, some children in gene therapy trials using retrovirus vectors to introduce genes into blood stem cells have developed a leukemia-like condition. Research and clinical trials continue as scientists try to circumvent the difficulties.

Turning Domestic Animals into Protein Factories. Another successful application of genetic engineering turns animals into pharmaceutical factories for the production of proteins required to treat human diseases or other medical conditions. Most of these *pharming* projects, as they are called, engineer the animals to produce the desired proteins in milk, making the isolation and purification of the proteins easy, as well as harmless to the animals. ("Pharming" is a word made up from "farming" and "pharmaceuticals.")

One of the first successful applications of this approach was carried out with transgenic sheep that produce a protein required for normal blood clotting in humans. The protein, called a *clotting factor,* is deficient in persons with one form of hemophilia. (The genetics of hemophilia is described in Section 13.2.) These people require frequent injections of the factor to avoid bleeding to death from even minor injuries. Using DNA cloning techniques, researchers joined the gene encoding the normal form of the clotting factor to the promoter sequences of the β-lactoglobulin gene, which encodes a protein secreted in milk, and introduced it into fertilized eggs. Those cells were implanted into a surrogate mother, and the transgenic sheep born were allowed to mature. The β-lactoglobulin promoter controlling the clotting factor gene became activated in mammary gland cells of females. The clotting factor produced was secreted into the milk from which it could be collected and purified.

Other similar projects are being done to produce particular proteins in transgenic mammals. These include a protein to treat cystic fibrosis, collagen to correct scars and wrinkles, human milk proteins to be added to infant formulas, and normal hemoglobin for use as an additive to blood transfusions.

Producing Animal Clones. Making transgenic mammals is expensive and inefficient. And, because only one copy of the transgene typically becomes incorporated into the treated cell, not all progeny of a transgenic animal inherit that gene. Scientists reasoned that an alternative to breeding a valuable transgenic mammal to produce progeny with the transgene would be to clone the mammal. Each clone would be identical to the original, including the expression of the transgene. That this is possible was shown when two Scottish scientists, Ian Wilmut of the Roslin Institute and Keith Campbell of PPL Therapeutics, Roslin, Scotland, announced in 1997 that they were successful in cloning a sheep using a single somatic cell taken from an adult sheep **(Figure 18.14)**—Dolly, the first cloned mammal.

After the successful cloning experiment that produced Dolly, many other mammals have been cloned, including mice, goats, pigs, monkeys, rabbits, dogs, a male calf appropriately named Gene, and a domestic calico cat called *CC* (for *Copy Cat*).

Cloning farm animals has been so successful that several commercial enterprises now provide cloned copies of champion animals. One example is a clone of an American Holstein cow, Zita, who was the U.S. national champion milk producer for many years.

The cloning of domestic animals has its drawbacks. Many cloning attempts fail, leading to the death of the transplanted embryos. Cloned animals often suffer from conditions such as birth defects and poor lung development. Genes may be lost during the cloning process or may be expressed abnormally in the cloned animal. For example, molecular studies have shown

FIGURE 18.14 **Experimental Research**

The First Cloning of a Mammal

Question: Does the nucleus of an adult mammal contain all the genetic information to specify a new organism? In other words, can mammals be cloned starting with adult cells?

Experiment: Ian Wilmut, Keith Campbell, and their colleagues fused a mammary gland cell from an adult sheep with an unfertilized egg cell from which the nucleus had been removed and tested whether that fused cell could produce a lamb.

Result: Dolly was born and grew normally. She was white-faced—a clone of the donor ewe. DNA fingerprinting using STR loci showed her DNA matched that of the donor ewe and neither the ewe who donated the egg, nor the ewe who was the surrogate mother.

Conclusion: An adult nucleus of a mammal contains all the genetic material necessary to direct the development of a normal new organism, a clone of the original. Dolly was the first cloned mammal. The success rate for Wilmut and Campbell's experiment was very low—Dolly represented less than 0.4% of the fused cells they made—but its significance was huge.

THINK LIKE A SCIENTIST Why was it important that the donor ewe and surrogate mother be sheep of different kinds?

that the expression of perhaps hundreds of genes in the genomes of clones is regulated abnormally.

GENETIC ENGINEERING OF PLANTS Genetic engineering of plants has led to increased resistance to pests and disease; greater tolerance to heat, drought, and salinity; larger crop yields; faster growth; and resistance to herbicides. Another aim is to produce seeds with higher levels of amino acids. The essential amino acid lysine, for example, is present only in limited quantities in cereal grains such as wheat, rice, oats, barley, and corn; the seeds of legumes such as beans, peas, lentils, soybeans, and peanuts are deficient in the essential amino acids methionine or cysteine. Increasing the amounts of the deficient amino acids in plant seeds by genetic engineering would greatly improve the diet of domestic animals and human populations that rely on seeds as a primary food source. Efforts are also under way to increase the vitamin and mineral content of crop plants.

Other possibilities for plant genetic engineering include plant pharming to produce pharmaceutical products. Plants are ideal for this purpose, because they are primary producers at the bottom rung of the food chain and can be grown in huge numbers with maximum conservation of the sun's energy that is captured in photosynthesis.

Some plants, such as *Arabidopsis thaliana* (thale cress), tobacco, potato, cabbage, and carrot, have special advantages for genetic engineering because individual cells can be removed from an adult, altered by the introduction of a desired gene, and then grown in cultures into a multicellular mass of cloned cells called a *callus*. Subsequently, roots, stems, and leaves develop in the callus, forming a young plant that can then be cultivated by standard methods. Each cell in the plant contains the introduced gene. The gametes produced by the transgenic plants can then be used in crosses to produce offspring, some of which will have the transgene, as in the similar animal experiments.

Methods Used to Insert Genes into Plants. Genes are inserted into plant cells by several techniques. A commonly used method takes advantage of properties of a bacterium,

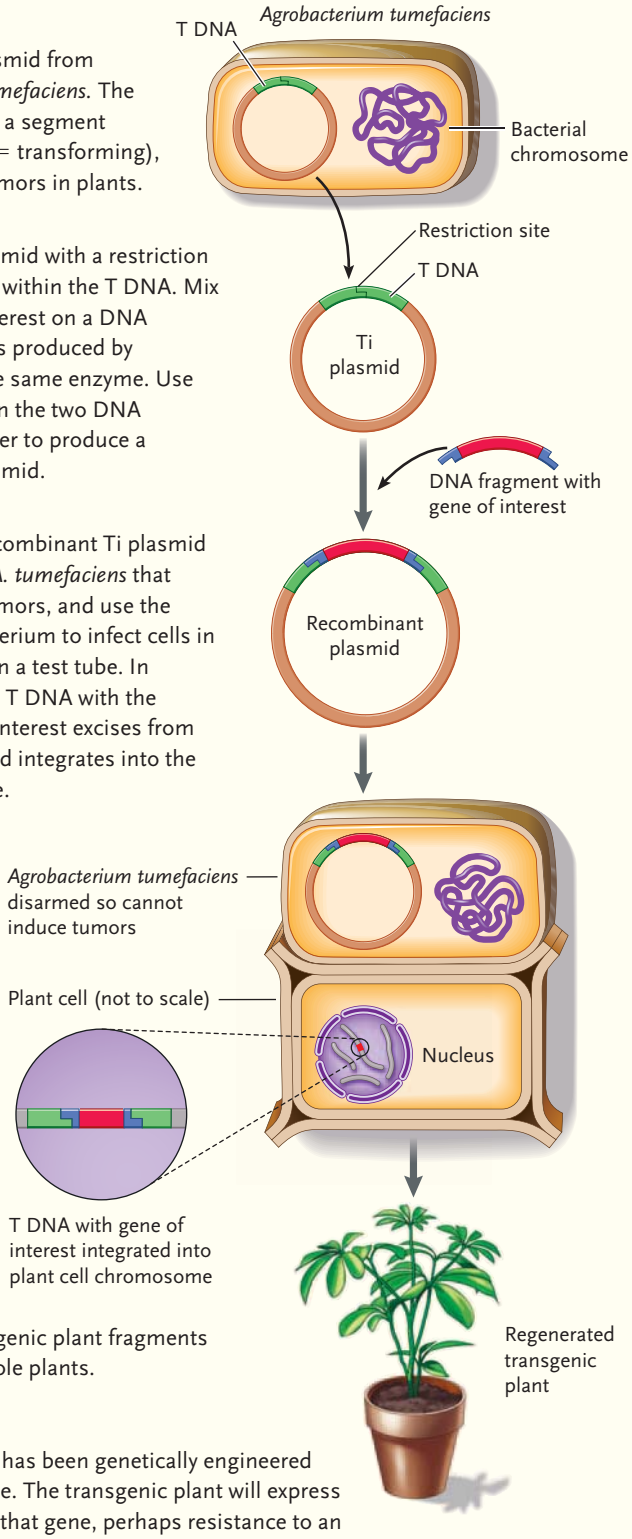
FIGURE 18.15 **Research Method**

Using the Ti Plasmid of *Agrobacterium tumefaciens* to Produce Transgenic Plants

Purpose: To make transgenic plants. This technique is one way to introduce a transgene into a plant for genetic engineering purposes.



Protocol:

1. Isolate the Ti plasmid from *Agrobacterium tumefaciens*. The plasmid contains a segment called T DNA (T = transforming), which induces tumors in plants.

2. Digest the Ti plasmid with a restriction enzyme that cuts within the T DNA. Mix with a gene of interest on a DNA fragment that was produced by digesting with the same enzyme. Use DNA ligase to join the two DNA molecules together to produce a recombinant plasmid.

3. Transform the recombinant Ti plasmid into a disarmed *A. tumefaciens* that cannot induce tumors, and use the transformed bacterium to infect cells in plant fragments in a test tube. In infected cells, the T DNA with the inserted gene of interest excises from the Ti plasmid and integrates into the plant cell genome.

4. Culture the transgenic plant fragments to regenerate whole plants.

Outcome: The plant has been genetically engineered to contain a new gene. The transgenic plant will express a new trait based on that gene, perhaps resistance to an herbicide or production of an insect toxin, according to the goal of the experiment.

© Cengage Learning 2014

Agrobacterium tumefaciens, which causes crown gall disease. Crown gall disease is characterized by bulbous, irregular growths—tumors, essentially—that develop at wound sites on the trunks and limbs of deciduous trees. *A. tumefaciens* contains a large, circular plasmid called the **Ti (tumor-inducing) plasmid (Figure 18.15).** The interaction between the bacterium and a plant cell it infects stimulates the excision of a segment of the Ti plasmid called *T DNA* (for transforming DNA), which then integrates into the plant cell's genome. Genes on the T DNA are then expressed; the products stimulate the transformed cell to grow and divide, producing a tumor. The tumors provide essential nutrients for the bacterium. The Ti plasmid is used as a vector for making transgenic plants, in much the same way as cloning vectors introduce genes into bacteria.

Successful Plant Genetic Engineering Projects. The most widespread application of genetic engineering of plants involves the production of transgenic crops. Thousands of such crops have been developed and field tested, and many have been approved for commercial use. If you examine the processed, plant-based foods sold at a national supermarket chain, you will likely find that at least two-thirds contain transgenic plants.

In many cases, plants are modified to make them resistant to insect pests, viruses, or herbicides. Crops that have been modified for insect resistance include corn, cotton, and potatoes. The most common approach to making plants resistant to insects is to introduce the gene from the bacterium *Bacillus thuringiensis* that encodes the *Bt* toxin, a natural pesticide. This toxin has been used in powder form to kill insects in agriculture for many years, and now transgenic plants making their own *Bt* toxin are resistant to specific groups of insects that feed on them. Millions of acres of crop plants planted in the United States, amounting to about 70% of the nation's agricultural acreage, are now *Bt*-engineered varieties.

Virus infections cause enormous crop losses worldwide. Virus-resistant transgenic crops would be highly valuable in agriculture. There is some promise in this area. By some unknown process, transgenic plants expressing certain viral proteins become resistant to infections by whole viruses that contain those same proteins. Two virus-resistant, genetically modified crops made so far are papaya and squash.

Several crops have also been engineered to become resistant to herbicides. For example, *glyphosate* (commonly known by its brand name,

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).

Roundup) is a potent herbicide that is widely used in weed control. The herbicide works by inhibiting a particular enzyme in the chloroplast. Unfortunately, it also kills crops. But transgenic crops have been made in which a bacterial form of the chloroplast enzyme was added to the plants. The bacteria-derived enzyme is not affected by Roundup, and farmers who use these herbicide-resistant crops can spray fields of crops to kill weeds without killing the crops. Now most of the corn, soybean, and cotton plants grown in the United States and many other countries are glyphosate-resistant ("Roundup-ready") varieties that were produced by genetic engineering.

Crop plants are also being engineered to alter their nutritional qualities. For example, a strain of rice plants has been produced with seeds rich in β-carotene, a precursor of vitamin A **(Figure 18.16).** The new rice, which is given a yellow or golden color by its carotene content, may provide improved nutrition for the billions of people that depend on rice as a diet staple. In particular, the rice may help improve the nutrition of children younger than five years of age in southeast Asia, 70% of whom suffer from impaired vision because of vitamin A deficiency. *Insights from the Molecular Revolution* describes an experiment in which rice plants were genetically engineered to develop resistance to a damaging bacterial blight.

Plant pharming is also an active area in both university research labs and biotechnology companies. Plant pharming involves the engineering of transgenic plants to produce medically valuable products. The approach is one described earlier: the gene for the product is cloned into an expression vector, in this case one with a promoter active in plants, and the recombinant DNA molecule is introduced into plants. Products under development include vaccines for various bacterial and viral diseases, protease inhibitors to treat or prevent virus infections, collagen to treat scars and wrinkles, and the protein aprotinin, which is used to reduce bleeding and clotting during heart surgery.

In contrast to modifying animals by genetic engineering techniques, genetically altered plants have been widely developed and appear to have become mainstays of agriculture. But, as the next section discusses, both animal and plant genetic engineering have not proceeded without concerns.

FIGURE 18.16 Rice genetically engineered to contain β-carotene.

DNA Technologies and Genetic Engineering Are a Subject of Public Concern

When recombinant DNA technology was developed in the early 1970s, researchers were concerned that a bacterium carrying a recombinant DNA molecule might escape into the environment, transfer the recombinant molecule to other bacteria, and produce new, potentially harmful, strains. To address this, and other concerns, the U.S. scientists who developed the technology drew up comprehensive safety guidelines for recombinant DNA research in the United States. Since that time, countless thousands of experiments involving recombinant DNA molecules have shown that recombinant DNA manipulations can be done safely. Over time, therefore, the recombinant DNA guidelines have become more relaxed. Nonetheless, stringent regulations still exist for certain areas of recombinant DNA research that pose significant risk, such as cloning genes from highly pathogenic bacteria or viruses, or gene therapy experiments.

Guidelines for genetic engineering also extend to research in several areas that have been the subject of public concern and debate. While the public is concerned little about genetically engineered microorganisms, for example those cleaning up oil spills and hazardous chemicals, it is concerned about possible problems with **genetically modified organisms (GMOs)** used as food. A GMO is a transgenic organism; the majority of GMOs are crop plants. Issues of concern include the safety of GMO-containing food, and the possible adverse effects of the GMOs on the environment, such as by interbreeding with natural species or by harming beneficial insect species. One example of the latter concern was whether *Bt*-expressing corn would have adverse effects on monarch butterflies that fed on the pollen of the plants. The most recent of a series of independent studies investigating this possibility has indicated that the risk to the butterflies from *Bt* toxin is extremely low.

More broadly, different countries have reacted to GMOs in different ways. In the United States, transgenic crops are planted widely. Before commercialization, such GMOs are evaluated for potential risk by appropriate government regulatory agencies, including the NIH, Food and Drug Administration (FDA), Department of Agriculture, and Environmental Protection Agency (EPA). Usually, the opposition to GMOs has come from particular activist and consumer groups.

Political opposition to GMOs has been greater in Europe, dampening the use of transgenic crop plants in the fields and GMOs in food. In 1999, the European Union (EU) imposed a 6-year moratorium on all GMOs. More recently, the EU has decided that using genetic engineering in agriculture and food production is permissible provided the GMO or food containing it is safe for humans, animals, and the environment.

Globally, an international agreement, the **Cartagena Protocol on Biosafety,** "promotes biosafety by establishing

Rice Blight: Engineering rice for resistance to the disease

Rice is common in the diet of the entire human population; for one-third of humanity, more than 2 billion people, it is the primary nutrient source. Worldwide, 560 million tons of rice are produced annually.

This major human staple is threatened by a rice blight caused by the bacterium *Xanthomonas oryzae.* Rice plants infected by the bacterium turn yellow and wilt **(Figure);** in many Asian and African rice fields, as much as half of the crop is lost to the bacterial blight. Some wild forms of rice, which are not usable as crop plants, have a natural resistance to the *Xanthomonas* blight, but no cultivated variety is resistant.

Research Goal

To develop a blight-resistant rice strain using a genetic engineering approach.

Experiments

Pamela Ronald and her colleagues at the University of California, Davis used genetic engineering techniques to produce a blight-resistant rice strain. They were aided by the results of genetic experiments in which a gene, *Xa21,* was identified that confers resistance to *Xanthomonas* in a wild rice.

Ronald and her coworkers cloned the *Xa21* gene following these steps:

1. Genetic crosses showed that *Xa21* is located near several known genes, including one that was very close.
2. The DNA of the known gene was used as a probe to find nearby sequences in a genomic library of the resistant wild rice genome. The probe identified 16 DNA chromosome fragments in the library.
3. To determine which fragments included the *Xa21* gene, the researchers introduced each fragment individually into rice crop plants that were susceptible to *Xanthomonas* infection. Out of 1,500 plants that incorporated the fragments, 50 plants, all containing the same 9,600-bp fragment, became resistant to the blight. These plants were the first rice crop plants to be engineered successfully to resist *Xanthomonas* infections.
4. The researchers analyzed the 9,600-base-pair fragment further to identify and isolate the resistance gene from the fragment.

Conclusion

The sequence of the *Xa21* gene revealed that it encodes a plasma membrane receptor protein which in some way triggers an internal cellular response on exposure to *Xanthomonas.* The response alters cell structure or biochemistry to inhibit growth of the bacterium.

Ronald and her coworkers then introduced the *Xa21* gene successfully into three varieties of rice that are widely grown as crops in Asia and Africa. Those varieties became resistant to the bacterial blight, thereby showing that expression of the *Xa21* gene is sufficient to confer resistance.

THINK LIKE A SCIENTIST The *Xa21* gene encodes a plasma membrane receptor. How could that knowledge inform future research on controlling blight?

Source: W.-Y. Song et al. 1995. A receptor kinase-like protein encoded by the rice disease resistance gene, *Xa21. Science* 270:1804–1806.

practical rules and procedures for the safe transfer [between countries], handling and use of GMOs." Separate procedures have been set up for GMOs that are to be introduced into the environment and those that are to be used as food or feed or for processing. By July 2012, 163 countries had ratified the Protocol; the United States was not one of them.

In sum, the use of DNA technologies in biotechnology has the potential for tremendous benefits to humankind. Such experimentation is not without risk, and so for each experiment, researchers must assess that risk and make a judgment about whether to proceed and, if so, how to do so safely. Furthermore, agreed-upon guidelines and protocols should ensure a level of biosafety that is acceptable to researchers, consumers, politicians, and governments.

In this chapter you have learned about how individual genes can be isolated and manipulated using various DNA technologies. But a gene is just a part of a genome. Researchers also want to know about the set of genes in a complete genome, and how genes and their gene products work together in networks to control life. They also want to know more generally about the organization of the genome with respect to both genes and nongene sequences. Genomes and proteomes (the complete sets of proteins expressed by a genomes) are the subjects of the next chapter.

STUDY BREAK 18.2

1. What are the principles of DNA fingerprinting?
2. What is a transgenic organism?
3. What is the difference between using germ-line cells and somatic cells for gene therapy?

THINK OUTSIDE THE BOOK

Individually or collaboratively, investigate how it can be determined experimentally that processed foods that contain plant material contain transgenic plants. List the steps you would take to investigate whether a can of corn from a supermarket contains genetically modified corn.

UNANSWERED QUESTIONS

What are scientists aiming for with "targeted gene therapy"?

The molecular basis of inherited disease resides in your genes. Thus, it is not surprising that gene therapy has evoked such excitement in the field of molecular medicine. Gene therapy is defined as the use of nucleic acid sequences (DNA or RNA) to treat inherited or acquired disease. Gene therapy for monogenic diseases (diseases caused by a single defective gene) has begun to demonstrate great promise. For example, gene therapy for a form of congenital blindness (called Leber congenital amaurosis) has restored vision to blind children. This shot in the arm for the field has renewed enthusiasm for gene therapy of other monogenic diseases such as cystic fibrosis (CF)—a devastating disease caused by a single gene defect in a chloride channel called the cystic fibrosis transmembrane conductance regulator (CFTR) that leads to chronic bacterial infections in the lung (see Chapter 6 *Why It Matters,* and Section 13.4). How can scientists approach gene therapy of CF? What cells in the lung must scientists target to treat this disease? Can gene therapy cure CF? These and other questions about gene therapy for CF are common to a myriad of other genetic diseases and patients' lives are depending on rapid answers. Our work at the University of Iowa focuses on obtaining answers to these questions needed to treat CF using gene therapy.

What are the cellular targets for gene therapy?

The cellular targets for gene therapy of any genetic disease are informed by a basic understanding of how the defective gene product (or protein) produces disease at the cellular and organ level. Using CF as an example, we know the defective gene encodes a chloride channel (CFTR; see Figure 6.1) that is expressed in a variety of cell types in the lung and airways. However, researchers still do not know which of these cell types must be targeted by gene therapy to treat the disease effectively. Defective innate immunity in CF may involve cells lining the surface of the airways and/or mucous-producing cells underneath the airways. Do both of these cellular compartments need to be targeted by gene therapy to reverse CF lung disease? The answer to this question resides in research that bridges gene therapy and the mechanisms of disease progression.

Tissues within the body are made from a complex assortment of unique cell types. These cells perform unique differentiated functions and organize into distinct groups of specialized cell types that act together to perform unique functions in a given organ. Typically, each group has unique microenvironments that house stem cells (called stem cell niches), which replace differentiated cell types within the trophic unit following normal cell turnover or injury. Often, these stem cells lie dormant until a signal from the microenvironment tells them to divide. In the lung, four unique stem cell niches have been identified, each being potentially important targets for gene therapy of CF and other lung diseases. To achieve lasting disease correction, scientists must target the adult stem cells that replace terminally differentiated cell types throughout the patient's lifetime. Therapeutic genes that incorporate within the genome of tissue-specific stem cells will potentially persist indefinitely.

How do scientists deliver genes to treat disease?

Conceptually, gene therapy consists of two strategies: 1) *gene addition,* which incorporates an additional gene into target cells; and 2) *gene correction,* which corrects the gene mutation that exists in the target cells. Although more challenging, the second approach is considered the "Holy Grail" of gene therapy because it corrects the cause of disease—the DNA mutation itself. Viral gene delivery is generally the most efficient means of delivering genetic payloads to cells and thus is the approach used in most current clinical gene therapy trials. In this method, scientists remove most (or all) viral genes from the virus and replace them with the therapeutic gene of interest. Although viruses are generally efficient at gene addition, they can cause the host to mount an immune response. Thus, important areas of research are directed at generating recombinant viruses that can escape the immune response and/or improve efficiency of gene delivery through an increased understanding of viral infection. Certain viruses also have the capability of correcting a gene mutation through homologous recombination, while others insert randomly into the genome, both mechanisms allow therapeutic DNA to persist if stem cells are targeted.

THINK LIKE A SCIENTIST Future gene therapy research must bridge the fields of stem cell biology, disease pathophysiology, virology, immunology, and homologous recombination. Tissue-specific stem cells are important targets of gene therapy, but they are often found in protective microenvironments with unique biologic properties.

Why do you think biological systems have evolved to sequester tissue-specific stem cells into constrained locations?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

18.1 DNA Cloning

- Producing multiple copies of genes by cloning is a common first step for studying the structure and function of genes, or for manipulating genes. Cloning involves cutting genomic DNA and a cloning vector with the same restriction enzyme, joining the fragments to produce recombinant plasmids, and introducing those plasmids into a living cell such as a bacterium, where replication of the plasmid takes place (Figures 18.1–18.3).
- A clone containing a gene of interest may be identified among a population of clones by using DNA hybridization with a labeled nucleic acid probe (Figure 18.5).
- A genomic library is a collection of clones that contains a copy of every DNA sequence in the genome. A cDNA (complementary DNA) library is the entire collection of cloned cDNAs made from the mRNAs isolated from a cell. A cDNA library contains only sequences from the genes that are active in the cell when the mRNAs are isolated.
- PCR amplifies a specific target sequence in DNA, such as a gene, which is defined by a pair of primers. PCR increases DNA quantities by successive cycles of denaturing the template DNA, annealing the primers, and extending the primers in a DNA synthesis reaction catalyzed by DNA polymerase. With each cycle of PCR, the amount of DNA doubles (Figure 18.6).

18.2 Applications of DNA Technologies

- Recombinant DNA and PCR techniques are used in DNA molecular testing for human genetic disease mutations. One approach exploits restriction site differences between normal and mutant alleles of a gene that create restriction fragment length polymorphisms (RFLPs) which are detectable by DNA hybridization with a labeled nucleic acid probe (Figures 18.8 and 18.9).
- Human DNA fingerprints are produced from a number of loci in the genome characterized by short, tandemly repeated sequences that vary in number in all individuals (except identical twins). To produce a DNA fingerprint, the PCR is used to amplify the region of genomic DNA for each locus, and the lengths of the PCR products indicate the alleles an individual has for the repeated sequences at each locus. DNA fingerprints are widely used to establish paternity, ancestry, or criminal guilt (Figure 18.10).
- Genetic engineering is the introduction of new genes or genetic information to alter the genetic makeup of humans, other animals, plants, and microorganisms such as bacteria and yeast. Genetic engineering primarily aims to correct hereditary defects, improve domestic animals and crop plants, and provide proteins for medicine, research, and other applications (Figures 18.11–18.13 and 18.15).
- Genetic engineering has enormous potential for research and applications in medicine, agriculture, and industry. Potential risks include unintended damage to living organisms or to the environment.

UNDERSTAND & APPLY

Test Your Knowledge

1. A complementary DNA library (cDNA) and a genomic library are similar in that both:
   a. use bacteria to make eukaryotic proteins.
   b. provide information on whether genes are active.
   c. contain all of the DNA of an organism cut into pieces.
   d. clone mRNA.
   e. depend on cloning in a living cell to produce multiple copies of the DNA of interest.
2. Why do the cDNA libraries produced from two different cell types in the human body often contain different cDNAs?
   a. Because different expression vectors must be used to insert cDNAs into different cell types.
   b. Because different cell types contain different numbers of chromosomes.
   c. Because different cell types contain different genomic DNA sequences.
   d. Because different genes are transcribed in different cell types.
   e. Because different cell types contain different restriction enzymes.
3. The point at which a restriction enzyme cuts DNA is determined by
   a. the sequence of nucleotides.
   b. the length of the DNA molecule.
   c. whether it is closer to the 5′ end or 3′ end of the DNA molecule.
   d. the number of copies of the DNA molecule in a bacterial cell.
   e. the location of a start codon in a gene.
4. Restriction endonucleases, ligases, plasmids, *E. coli,* electrophoretic gels, and a bacterial gene resistant to an antibiotic are all required for:
   a. dideoxyribonucleotide analysis.
   b. PCR.
   c. DNA cloning.
   d. DNA fingerprinting.
   e. DNA sequencing.
5. After a polymerase chain reaction (PCR), agarose gel electrophoresis is often used to:
   a. amplify the DNA.
   b. convert cDNA into genomic DNA.
   c. convert cDNA into messenger RNA.
   d. verify that the desired DNA sequence has been amplified.
   e. synthesize primer DNA molecules.
6. Restriction fragment length polymorphisms (RFLPs):
   a. are produced by reaction with restriction endonucleases and are detected by Southern blot analysis.
   b. are of the same length for mutant and normal β-globin alleles.
   c. determine the sequence of bases in a DNA fragment.
   d. have in their middle short fragments of DNA that are palindromic.
   e. are used as vectors.
7. DNA fingerprinting, which is often used in forensics, paternity testing, and for establishing ancestry:
   a. compares one stretch of the same DNA between two or more people.
   b. measures different lengths of DNA from many repeating noncoding regions.
   c. requires the largest DNA lengths to run the greatest distance on a gel.
   d. requires amplification after the gels are run.
   e. can easily differentiate DNA between identical twins.
8. Which of the following is needed both in using bacteria to produce proteins and in genetic engineering of human cells?
   a. DNA fingerprinting based on microsatellite sequences
   b. insertion of a transgene into an expression vector
   c. restriction fragment length polymorphism (RFLP)
   d. screening of a cDNA library by DNA hybridization
   e. antibiotic resistance
9. Dolly, a sheep, was an example of reproductive (germ-line) cloning. Required to perform this process was:
   a. implantation of uterine cells from one strain into the mammary gland of another.
   b. fusion of the mammary cell from one strain with an enucleated egg of another strain.
   c. fusion of an egg from one strain with the egg of a different strain.
   d. fusion of an embryonic diploid cell with an adult haploid cell.
   e. fusion of two nucleated mammary cells from two different strains.
10. Which of the following is *not* true of somatic cell gene therapy?
    a. White blood cells can be used.
    b. Somatic cells are cultured, and the desired DNA is introduced into them.
    c. Cells with the introduced DNA are returned to the body.
    d. The technique is still very experimental.
    e. The inserted genes are passed to the offspring.

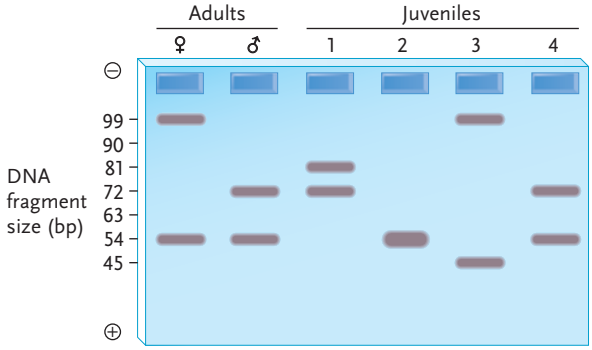
Discuss the Concepts



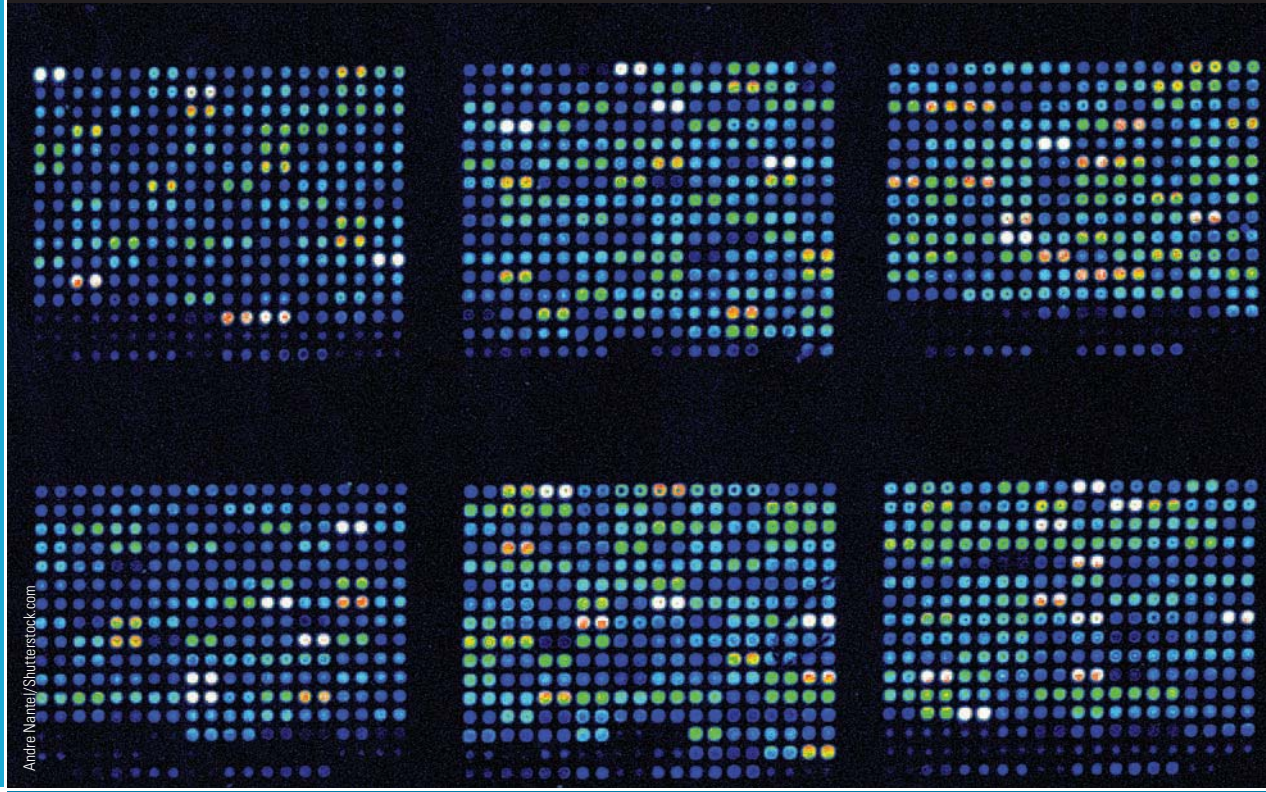
1. What should juries know to be able to interpret DNA evidence? Why might juries sometimes ignore DNA evidence?
2. A forensic scientist obtained a small DNA sample from a crime scene. In order to examine the sample, he increased its quantity by cycling the sample through the polymerase chain reaction. He estimated that there were 50,000 copies of the DNA in his original sample. Derive a simple formula and calculate the number of copies he will have after 15 cycles of the PCR.

Design an Experiment

Suppose a biotechnology company has developed a GMO, a transgenic plant that expresses *Bt* toxin. The company sells its seeds to a farmer under the condition that the farmer may plant the seed, but not collect seed from the plants that grow and use it to produce crops in the subsequent season. The seeds are expensive, and the farmer buys seeds from the company only once. How could the company show experimentally that the farmer has violated the agreement and is using seeds collected from the first crop to grow the next crop?

Interpret the Data

You learned in the chapter that an STR locus is a locus where alleles differ in the number of copies of a short, tandemly repeated DNA sequence. PCR is used to determine the number of alleles present, as shown by the size of the DNA fragment amplified. In the **Figure** to the right are the results of PCR analysis for STR alleles at a locus where the repeat unit length is 9 bp, and alleles are known that have 5 to 11 copies of the repeat. Given the STR alleles present in the adults, state whether each of the four juveniles could or could not be an offspring of those two adults. Explain your answers.



© Cengage Learning 2014

Apply Evolutionary Thinking

In PCR, researchers use a heat-stable form of DNA polymerase from microorganisms that are able to grow in extremely high temperatures. Given what you learned in Chapter 3 about protein folding, and in Chapter 4 about the effects of temperature on enzymes, would you predict that the amino acids of heat-stable DNA polymerase enzymes would have evolved so they can form stronger chemical attractions with each other, or weaker chemical attractions? Explain your answer.

19.2 Genome Sequence Determination and Annotation
19.3 Determining the Functions of the Genes in a Genome
19.4 Genome Evolution

Genomes and Proteomes

Why it matters . . . The 1000 Genomes Project (www.1000genomes.org), initiated in 2008, is an international collaborative research effort to find and catalog genetic variation in human genomes. As its name suggests, the Project intends to sequence the genomes of over 1,000 unidentified individuals from around the world. The sequencing data will be valuable in highly focused medical research, as well as in basic research. One interesting research study done as part of the Project analyzed the mutations each of us receives from our parents. As you learned in Chapters 12 and 13, mutations in the germline cells (sperm and egg) of a parent are inherited. Those mutations fall into two groups: mutations inherited by the parent, and new mutations that occur in the germline. In the study, researchers compared the genomes of two parent–offspring trios. They identified 49 and 35 mutations in the two offspring that must have originated as new mutations in their parents' germlines. Let that sink in: we have numerous mutations in our genomes that our parents do not have. Most interestingly, in one family, 92% of the new mutations were from the paternal germline, whereas in the other family 64% of the new mutations were from the maternal germline. These results mean that there is considerable variation in mutation rates within and between families. While this is a relatively limited study (as it only can be at the moment given the limited availability of complete genomes of families to study), nonetheless the results are provocative.

The 1000 Genomes Project research exemplifies the field of **genomics,** the characterization of whole genomes, including their structures (sequences), functions, and evolution. In this chapter, you will learn about genomics and some of the information that has come from genome analysis. You will also learn about **proteomics,** the study of the **proteome,** which is the complete set of proteins that can be produced by a genome. Proteomics involves characterizing the structures and functions of all expressed proteins of an organism, and the interactions among proteins in the cell. The chapter

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

also discusses how comparisons of genome sequences have contributed to our understanding of genome evolution.

19.1 Genomics: An Overview

As defined in *Why It Matters,* genomics is the characterization of whole genomes, including their structures (sequences), functions, and evolution. Having the complete sequence of a genome makes it possible to study the complete set of genes in an organism or a virus, as well as other important sequences of their genomes. Understanding the structures and functions of all the genes in an organism or virus will give us a complete blueprint of the information for the development, structure and function of that organism's life or for that virus's infection cycle. That is an exciting prospect, but we are not there yet.

Before we go further, let us be sure we are clear about genes. As you learned in Chapter 15, some genes encode proteins. Protein-coding genes are the main focus of our discussions. Other so-called noncoding RNA genes are transcribed to produce RNAs that function without being translated into proteins. They include genes for tRNAs, rRNAs, snRNAs, and miRNAs.

Fundamental to genomics is determining the DNA sequences of organismal genomes and the DNA or RNA sequences of viral genomes. We focus here on the DNA genomes of organisms, though most of the techniques described in this chapter have also been applied to the study of viral genomes. Modern DNA sequencing techniques are advances on methods used to analyze the sequences of cloned DNA sequences and DNA sequences amplified by PCR (see Section 18.1). Having the complete sequence of a genome enables researchers to study the organization of genes in the genome as a whole, and to determine how genes function together in networks to control life.

Of natural interest to us is the human genome. The complete sequencing of the approximately 3 billion base-pair human genome—the Human Genome Project (HGP)—began in 1990. The task was completed in 2003 by an international consortium of researchers and by a private company, Celera Genomics (headed by J. Craig Venter). As part of the official HGP, the genomes of several important model organisms commonly used in genetic studies were sequenced for purposes of comparison: *E. coli* (representing prokaryotes); the yeast *Saccharomyces cerevisiae* (representing single-celled eukaryotes); *Drosophila melanogaster* and *Caenorhabditis elegans* (the fruit fly and a nematode worm, representing multicellular invertebrate animals); and *Mus musculus* (the mouse, representing nonhuman mammals). The sequences of the genomes of many organisms and viruses not part of the official Human Genome Project, including plants, have since been completed or are in progress.

A vast amount of DNA sequence data has been generated by genome sequencing projects. For those sequences to be useful, they need to be available centrally for access by all researchers. DNA sequences from genome sequencing projects are deposited into databases that are publicly available via the Internet. For example, GenBank® is an "annotated collection of all publicly available DNA sequences" at the National Institutes of Health (NIH). The Internet link is http://www.ncbi.nlm.nih.gov/genbank/. Currently there are over 150 billion bases in the DNA sequence records at GenBank®. Computational tools at NCBI GenBank® enable researchers, and others, such as students like yourself, to perform various analyses with the sequence data.

Many other genomics databases are accessible using the Internet, with sequence data organized in different ways (perform an Internet search for "DNA sequence database"). For example, there are organism-specific sequence databases as well as databases that include summaries of particular genomics studies. The databases are available for individual researchers to use and also for collaborative efforts involving researchers all over the world. One of the main benefits of collaborative research of this kind is that researchers with different specialities can tackle a particular question or questions at a genomic or multigenomic level.

Genomics consists of three main areas of study:

1. *Genome sequence determination and annotation,* which means obtaining the sequences of complete genomes, and analyzing them to locate putative protein-coding and noncoding RNA genes and other functionally important sequences in the genome.
2. *Determining the functions of genes* (a somewhat outdated term for this is *functional genomics*), which means using genome sequence data as a basis to study and understand the functions of genes and other parts of the genome. With respect to genes, this includes developing an understanding of how their expression is regulated. For protein-coding genes it also includes determining what proteins they encode, and how those proteins function in the organism's metabolic processes.
3. *Studying how genomes have evolved,* which means comparing genome sequence data to develop an understanding of how genes, particularly protein-coding genes, originated and genes and genomes changed over evolutionary time. Studies of genome sequences or large parts of genome sequences for a number of organisms represent an area of genomics known as **comparative genomics.**

Advances in each of these areas of study are accelerating as techniques are developed and improved for automating experimental procedures and more sophisticated computer algorithms for data analysis are generated. Methods that facilitate the handling of many samples simultaneously, whether those samples are DNA molecules for sequencing or genes for analysis, are called **high-throughput techniques.** The next three sections of the chapter discuss each of the three areas of genomics in turn.

STUDY BREAK 19.1

What additional biological questions can be answered if one has the complete sequence of an organism's genome as compared with the sequences of individual genes?

FIGURE 19.1 Research Method

Whole-Genome Shotgun Sequencing

Purpose: Obtain the complete sequence of the genome of an organism.

Protocol:

3. Enter the DNA sequences of the fragments into a computer, and use the computer to assemble overlapping sequences into the continuous sequence of each chromosome of the organism. This technique is analogous to taking 10 copies of a book that has been torn randomly into smaller sets of a few pages each and, by matching overlapping pages of the leaflets, assembling a complete copy of the book with the pages in the correct order.

Interpreting the Results: The method generates the complete sequence of the genome of an organism.

19.2 Genome Sequence Determination and Annotation

Genome sequence determination and annotation means obtaining the sequence of bases in a genome using DNA sequencing techniques, and then analyzing the sequence data using computer-based approaches to identify genes and other sequences of interest, which include gene regulatory sequences, origins of replication, repetitive sequences, and transposable elements.

Genome Analysis Begins with DNA Sequencing

DNA sequencing was developed in the late 1970s by Allan M. Maxam, a graduate student, and his mentor, Walter Gilbert of Harvard University. A few years later, Frederick Sanger of Cambridge University designed a method that became the one commonly used in research. Gilbert and Sanger were awarded a Nobel Prize in 1980. DNA sequencing technology has evolved since its development, and particularly rapidly in the past few years.

WHOLE-GENOME SHOTGUN SEQUENCING

Before we discuss methods of DNA sequencing, let us consider the strategy generally used to determine the sequence of a genome, **whole-genome shotgun sequencing (Figure 19.1).** In this method, genomic DNA is isolated and purified, and that DNA is broken into thousands to millions of random, overlapping fragments. Each fragment is amplified to produce many copies, and then the sequence of the fragment is determined. The entire genome sequence is then assembled using computer algorithms that search for the sequence overlaps between fragments and stitch together the sequence reads to produce longer contiguous sequences.

DNA SEQUENCING METHODS

All DNA sequencing methods have in common the following steps: (1) DNA purification; (2) DNA fragmentation; (3) amplification of fragments; (4) sequencing each fragment; and (5) assembly of fragment sequences into genome sequences. The methods differ in how the amplification is done, the lengths of the fragments, how many fragments are sequenced simultaneously, and how the sequencing reactions themselves are done.

For decades the method devised by Frederick Sanger was by far the most common DNA sequencing technique used. The Sanger method is a DNA synthesis-based method for DNA sequencing. It is based on the properties of nucleotides known as *dideoxyribonucleotides,* which have a —H on the 3′ carbon of the deoxyribose sugar instead of the —OH found in normal deoxyribonucleotides; therefore, the method, explained in **Figure 19.2,** is also called *dideoxy sequencing.*

In recent years the dideoxy sequencing method has been replaced largely, but not completely, by faster, cheaper, and

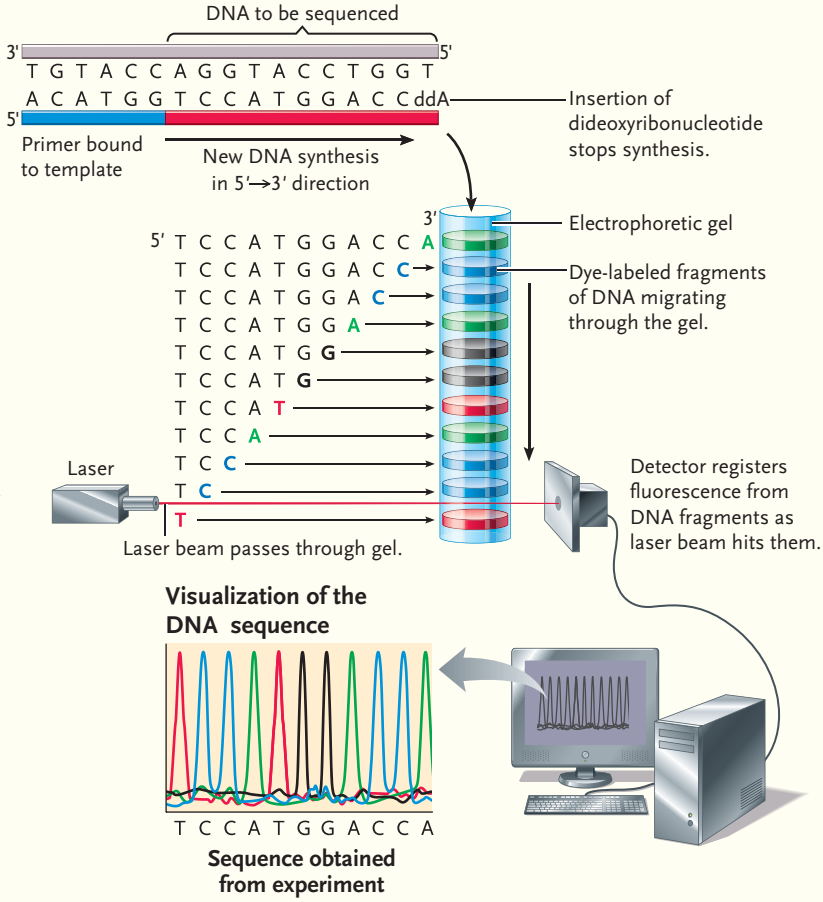
Dideoxy (Sanger) Method for DNA Sequencing

Purpose: Obtain the sequence of a piece of DNA, such as in gene sequencing or genome sequencing. The method is shown here with a typical automated sequencing system.



Protocol:

1. A dideoxy sequencing reaction contains: (1) the fragment of DNA to be sequenced (denatured to single strands); (2) a DNA primer that will bind to the 3′ end of the sequence to be determined; (3) a mixture of the four deoxyribonucleotide precursors for DNA synthesis; (4) a mixture of the four dideoxyribonucleotide (dd) precursors, at about 1/100th of the concentration of the deoxyribonucleotides, each labeled with a different fluorescent molecule; and (5) DNA polymerase to catalyze the DNA synthesis reaction.

2. DNA polymerase synthesizes the new DNA strand in the 5′→3′ direction starting at the 3′ end of the primer. New synthesis continues until a dideoxyribonucleotide is incorporated randomly into the DNA. The dideoxyribonucleotide acts as a *terminator* for DNA synthesis because it has no 3′-OH group for the addition of the next base (see Section 14.3). For a large population of template DNA strands, the dideoxy sequencing reaction produces a series of new strands, with lengths from one on up. At the 3′ end of each new strand is the fluorescently labeled dideoxyribonucleotide that terminated the synthesis.

3. The labeled strands are separated by electrophoresis using a polyacrylamide gel prepared in a capillary tube. The principle of separation is the same as for agarose gel electrophoresis (see Figure 18.7), but this gel can discriminate between DNA strands that differ in length by one nucleotide. As the bands of DNA fragments move near the bottom of the tube, a laser beam shining through the gel excites the fluorescent labels on each DNA fragment. The fluorescence is registered by a detector, with the wavelength of the fluorescence indicating whether ddA, ddT, ddG or ddC is at the end of the fragment in each case.

Interpreting the Results: The data from the laser system are sent to a computer that interprets which of the four possible fluorescent labels is at the end of each DNA strand. The results show, on a computer screen or in printouts, colors for the labels as the DNA bands passed the detector. The sequence of the newly synthesized DNA, which is complementary to the template strand, is read from left (5′) to right (3′). (The sequence shown here begins after the primer.)

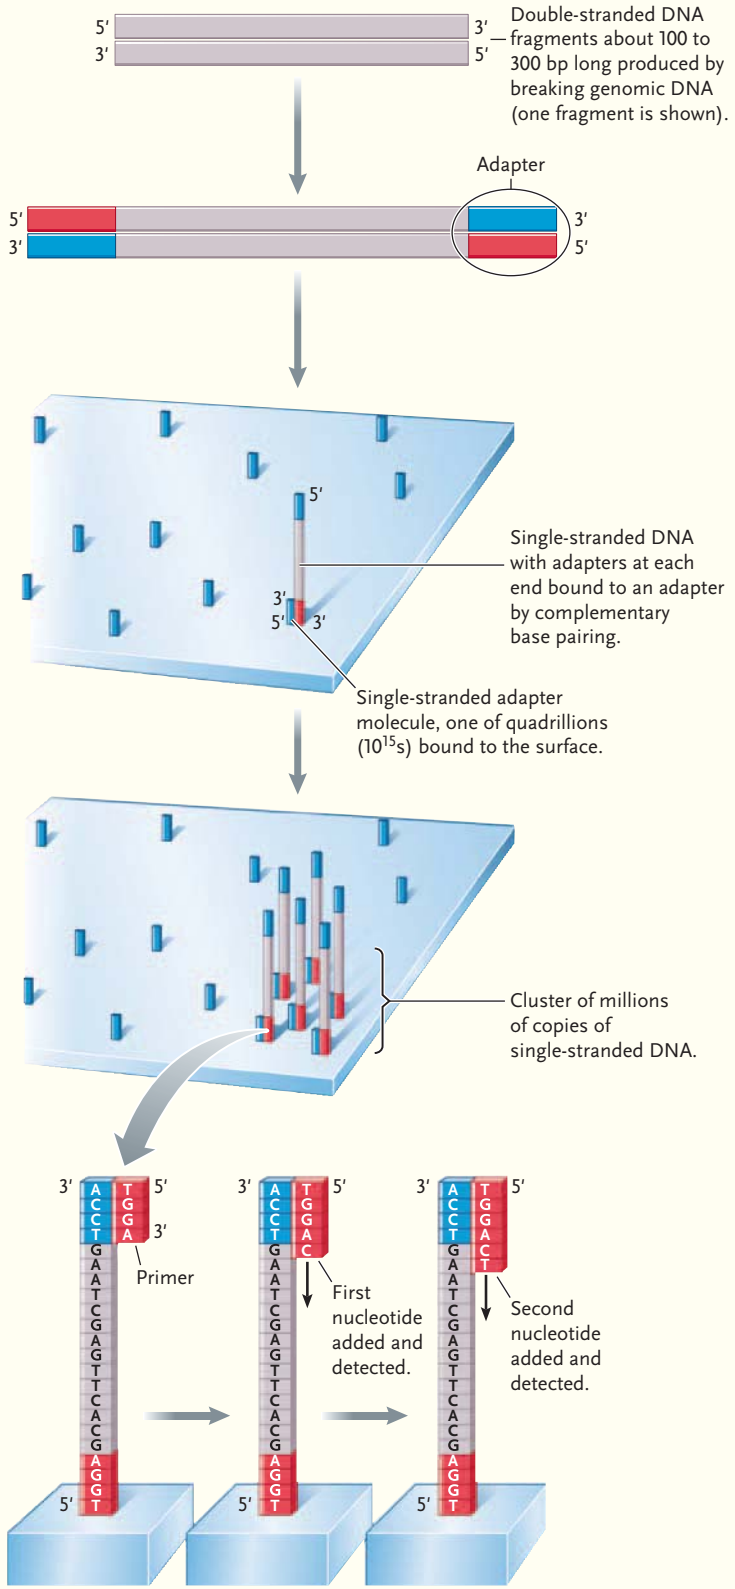
Illumina/Solexa Method for DNA Sequencing

Purpose: Automated, massively parallel sequencing of up to a billion DNA fragments.

Protocol:



1. DNA ligase attaches short double-stranded DNA adapter molecules to each end of 100 to 300-bp genomic DNA fragments.

2. The DNA fragments are denatured to single strands which are added to a cell in an automated machine through which liquid can flow. Over the glass surface of the cell are bound about one quadrillion (1×10^{15}) single-stranded adapter molecules that have complementary sequences to those of the adapters added to the DNA in step 1. Each DNA fragment to be sequenced binds to one of the glass-bound adapter molecules by complementary base pairing. The massive number of glass-bound adapters allows many DNA strands to be sequenced simultaneously.

3. An amplification process generates millions of copies of each of the DNA fragments that bound initially to one of the glass-bound adapters, clustered around the place on the cell where that DNA bound. Up to one billion different clusters can be produced in the sequencing cell simultaneously.

4. The DNA fragments are now ready for synthesis-based DNA sequencing. One fragment is shown for the sequencing steps.

5. DNA primers are added to the cell. A primer anneals to each DNA strand (it is the complementary strand to the adapter sequence at its end) and DNA synthesis is done in a cyclic manner one nucleotide at a time using four different fluorescently labeled DNA nucleotide precursors. Each time a labeled nucleotide is added, synthesis stops and the machine uses laser technology to measure the fluorescence so as to identify the base added. That base is the same for all strands in a cluster. By repeated cycles of addition of a nucleotide and laser detection, the sequence of the strand is obtained. Up to about 100 bases of each fragment can be sequenced.

Interpreting the Results: The DNA sequence obtained is complementary to the initial single-stranded DNA strand that paired with the glass-bound adapter. The DNA sequence data from all of the clusters of DNA fragments are analyzed by computer to determine overlaps between fragments and, by the principles described in Figure 19.2, the complete sequence of a genome is assembled.

more automated techniques. In general, these newer high-throughput techniques have decreased sequencing costs by reducing the preparatory steps, automating more of the process, and sequencing up to a billion different DNA fragments in parallel.

Figure 19.3 outlines a next-generation DNA sequencing technique that is widely used in genome sequencing projects, the DNA synthesis-based Illumina/Solexa method. This is an example of *massively parallel DNA sequencing,* because up to one billion different DNA fragments can be sequenced simultaneously.

As a result of the lower cost of sequencing, and the automated massively parallel DNA sequencing methods that are used, the genomes of many species beyond those targeted in the Human Genome Project have been determined. **Table 19.1** summarizes the number of whole genomes sequenced from organisms of the different domains of life. The cost of DNA sequencing is now low enough that sequencing a complete human genome costs only a few thousand dollars. This makes it feasible to sequence thousands of individual human genomes, to learn more about what makes us human and what is responsible for human variation. We are perhaps not too far from the scenario where your own genome sequence may be used to help physicians personalize medical treatments to your specific genetic makeup.

Genome Sequences Are Annotated to Identify Genes and Other Sequences of Importance

A raw genome sequence is simply a string of A, T, G, and C letters; it tells us practically nothing about the organism from which it derives, other than the total length of its genome. Therefore, once the complete sequence of a genome has been determined, the next step is *annotation,* the identification of functionally important features in the genome. These include:

- Protein-coding genes.
- Noncoding RNA genes. As mentioned earlier, "noncoding" means that the RNA transcript of the gene is not translated. Rather, the transcript is the functional product of the gene. Noncoding genes include genes for tRNAs, rRNAs, and snRNAs (see Chapter 15), and genes for microRNAs (miRNAs; see Chapter 16).
- Regulatory sequences associated with genes (see Chapter 16).
- Origins of replication (see Chapter 14).
- Transposable elements and sequences related to them (see Chapter 15).
- Pseudogenes. A **pseudogene** is very similar to a functional gene at the DNA sequence level, but one or more inactivating mutations have changed the gene so that it can no longer produce a functional gene product. Most pseudogenes are derived from protein-coding genes and they are recognized by their sequence similarities to functional genes.
- Short repetitive sequences. These are sequences that are repeated a few too many times in the genome. The short tandem repeat (STR) sequences discussed in Section 18.2 are examples of short repetitive sequences.

Annotation is performed by researchers in the field of **bioinformatics,** which is the application of mathematics and computer science to extract information from biological data, including those related to genome structure and function. More broadly, the term bioinformatics may be used to include the experimental work that generates such data. For example, bioinformatics scientists predict the structure and function of gene products and postulate evolutionary relationships of sequences, which are issues for functional and comparative genomics, respectively.

Some examples of genome annotation are illustrated in the following subsections. Protein-coding genes are the focus because they are of particular interest in genome analysis.

IDENTIFYING OPEN READING FRAMES BY COMPUTER SEARCH OF GENOME SEQUENCES

Proteins are specified in mRNA molecules by a series of codons starting with the initiation codon AUG and ending with one of the three termination codons, UAG, UAA, or UGA. The span of codons from start to stop codon is called an **open reading frame (ORF),** and ORFs that are longer than 100 codons almost always indicate the presence of a protein-coding gene. Computer algorithms are used to identify possible protein-coding genes in a genome sequence by

FIGURE 19.4 **The six reading frames of double-stranded DNA.** In this particular sequence, one of them is an open reading frame (ORF).
© Cengage Learning 2014

searching for ORFs. In a DNA sequence, this means searching for ATG, separated from a stop codon (TAG, TAA, or TGA) by a multiple of three nucleotides. The search is complicated because which of the two DNA strands is the template strand for transcription is gene-specific. Theoretically, then, each DNA sequence has six reading frames for the three-letter genetic code, three on one strand and three on the other strand, and an ORF can be in any one of those frames. This is illustrated in **Figure 19.4** for a theoretical 30-nucleotide segment of DNA. Note that each single-stranded DNA sequence generated by DNA sequencing can be used to infer the sequence of the complementary DNA strand. If an ORF is present in a particular DNA sequence, it will be in one of those frames.

We can start looking for an ORF going in the 5′-to-3′ direction in the top strand of Figure 19.4, starting at the leftmost A nucleotide. In this case, reading in groups of three nucleotides will lead you to the TAG at the right end, which is the stop codon. We have found an ORF in the sequence, and it is coded by the entire length of top strand. However, if instead we start looking for an open reading frame in the top strand starting at either the second nucleotide (the T) or the third nucleotide (the G), we do not find a start codon so we have not found an ORF. For the bottom strand, none of the three frames has a start codon. Computer algorithms can search easily for ORFs in all six reading frames of a DNA sequence.

Searching for protein-coding ORFs is straightforward in prokaryotic genomes because few genes have introns. Eukaryotic protein-coding genes typically have introns and therefore more sophisticated algorithms must be used to identify such genes. For example, the algorithms may search for particular characteristics of protein-coding genes, such as junctions between exons and introns, sequences that are characteristic of eukaryotic promoters, and overrepresentation of certain three-base codons relative to others.

Computer identification typically is the first step in identifying protein-coding genes. However, other evidence is needed before biologists are confident that the sequence they have annotated is a functioning protein-coding gene. Two approaches to obtain such evidence are described in the next two subsections.

IDENTIFYING PROTEIN-CODING GENES BY SEQUENCE SIMILARITY SEARCHES

One way of testing whether candidate protein-coding genes found by searching for ORFs are functioning protein-coding genes is by comparing their sequences with known, identified and verified genes in databases. This is a *sequence similarity search.* Such searches can be done using an Internet browser to access the computer programs and the databases. For example, to use the BLAST (Basic Local Alignment Search Tool) program at the National Center for Biotechnology Information (http://blast.ncbi.nlm.nih.gov), a researcher pastes the putative ORF DNA sequence, or the amino acid sequence of the protein it would encode, into a browser window and sets the program to begin searching. The BLAST program searches the databases of known sequences and returns the best matches, if any. The matches are listed in order, from the closest match to the least likely match. Finding a known gene's sequence that matches the putative ORF sequence closely would be good evidence that the ORF is in fact a protein-coding gene and that it encodes a protein functionally related to that of the matching gene sequence. The principle here is that genes of living organisms tend to be similar to each other because they have evolved from ancestral genes in ancestral organisms. Genes that have highly conserved sequences because they have evolved from a gene in a common ancestor are called **homologous genes.** For example, if a gene in the mouse has been characterized experimentally and its sequence is known, and that gene is evolutionarily conserved in mammals, there should be a match for that gene in the human genome sequence.

With sequence similarity searches, ORFs can be sorted into ones with known and unknown functions. For the latter, experiments are required to show whether they are real protein-coding genes and, if so, what their functions are. For example, analysis of the human genome sequence initially identified more than a thousand putative protein-coding genes with no sequence similarities to known genes. Most of these function-unknown genes have now been shown to be pseudogenes. Such uncertainty makes it difficult to determine the exact number of protein-coding genes in a genome just from its sequence.

IDENTIFYING PROTEIN-CODING GENES FROM SEQUENCES OF GENE TRANSCRIPTS

The gold standard for identifying protein-coding genes in a genome sequence is the demonstration that the sequences are transcribed in cells to make mRNAs. One approach to do this makes use of the sequences of transcripts represented in cDNA libraries. Recall from Section 18.1 that a cDNA library is made starting with mRNA molecules isolated from a cell. If the mRNA molecules are isolated under different conditions and from different cell types in a multicellular organism, they will represent the activity of many of the organism's protein-coding genes. However, protein-coding genes that are rarely transcribed or that produce very few mRNA molecules are likely to be missed by this approach.

The single-stranded mRNA molecules are converted to double-stranded DNA molecules using reverse transcriptase, and those DNA molecules are cloned to produce the cDNA library. Some part of each cloned mRNA (as cDNA) is sequenced using a sequencing primer that pairs with the DNA just adja-

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

cent to the inserted cDNA fragment in the clone. Using computer algorithms, each cDNA sequence is compared with the genome sequence of the organism to map the location of the sequence and, therefore, the protein-coding gene from which the original transcript was derived.

This approach is also useful for cataloging transcripts in humans and other eukaryotes to identify which genes are alternatively spliced. Recall from Section 16.3 that alternative splicing of pre-mRNA transcripts of protein-coding genes produces different mRNAs by using different splice sites that may remove different combinations of exons, or modify their lengths. The resulting mRNAs are translated to produce a family of related proteins having various combinations of amino acid sequences derived from the remaining exons.

Genome Landscapes Vary Markedly in Size, Gene Number, and Gene Density

With many genomes now sequenced, researchers can compare them to learn about genome sizes, the number of protein-coding genes, and the density of those genes (how widely spaced they are). A vast amount of new information is available about genome landscapes. Here we will present some broad brush strokes and then provide a more detailed description of the *E. coli* genome and the human genome, as examples of prokaryote and eukaryote genomes, respectively.

GENOME SIZES OF VIRUSES, BACTERIA, ARCHAEA, AND EUKARYA **Figure 19.5** shows the ranges of genome sizes for viruses, bacteria, archaea, and different groups of eukaryotes; and **Table 19.2** gives examples of genome sizes and the number of protein-coding genes for some bacteria, archaea, and eukaryotes. We can arrive at some general conclusions about the data. Members of both the Domain Bacteria and Domain Archaea have genomes that vary widely in size. In addition, their genes are densely packed in their genomes, with little noncoding space between them. Thus, the larger genomes of organisms in these two domains tend to reflect increased gene number. For example, in the Bacteria, *Mycoplasma genitalium* has a genome size of 0.58 Mb with 475 protein-coding genes (and 43 noncoding RNA genes), and *E. coli* has a genome size of 4.6 Mb with 4,146 protein-coding genes (and 176 noncoding RNA genes). In the Archaea, *Thermoplasma acidophilum* has a genome size of 1.56 Mb with 1,484 protein-coding genes, and *Methanosarcina thermophila* has a genome size of 5.75 Mb with 4,540 protein-

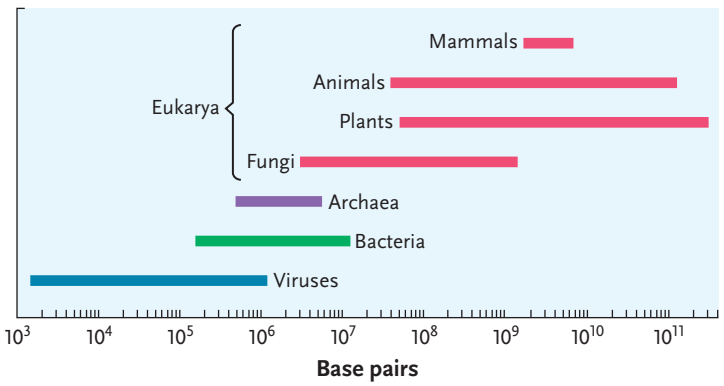

FIGURE 19.5 Ranges of genome sizes for viruses, bacteria, archaea, and eukaryotes. Note that the Domain Archaea has not been studied as extensively as the Domain Bacteria, so there may be representatives with substantially larger or smaller genomes than the range given.

TABLE 19.2 Genome Sizes and Estimated Number of Protein-Coding Genes for Selected Members of Domains Bacteria, Archaea, and Eukarya

Domain and Organism	Genome Size (Mb)	Protein-Coding Genes
Bacteria		
Mycoplasma genitalium	0.58	475
Escherichia coli	4.6	4,146
Archaea		
Thermoplasma acidophilum	1.56	1,484
Methanosarcina acetivorans	5.75	4,540
Eukarya		
Protists		
Tetrahymena thermophila (a ciliated protist)	146	>20,000
Fungi		
Saccharomyces cerevisiae (a budding yeast)	12.1	~6,000
Neurospora crassa (orange bread mold)	40	~10,100
Plants		
Arabidopsis thaliana (thale cress)	120	~26,000
Oryza sativa (rice)	411	~56,000
Invertebrates		
Caenorhabditis elegans (a nematode worm)	100	~20,000
Drosophila melanogaster (fruit fly)	165	~13,700
Vertebrates		
Takifugu rubripes (pufferfish)	393	~27,000
Mus musculus (mouse)	2,600	~22,000
Homo sapiens (human)	3,200	~20,500

coding genes. More broadly, bacteria and archaea have a fairly consistent density of about 900 genes for every Mb of DNA.

Members of the domain Eukarya vary markedly in form and complexity, and their genomes also show great differences in size. For example, budding yeast, *Saccharomyces cerevisiae,* has a 12.1-Mb genome that is about 0.4% the size of the 3,200-Mb human genome, yet humans, with ~20,500 protein-coding genes, have only a little more than three times the number found in yeast, which has ~6,000 protein-coding genes.

There are no clear rules relating organism complexity and genome size. For instance, the fruit fly, *Drosophila melanogaster,* and the locust, *Schistocerca gregaria,* have similar physiological complexity, but the genome of the locust is 9,300 Mb, which is 52 times the size of the 165-Mb fruit fly genome (and almost three times the size of the human genome). Even within a genus there is not necessarily a consistency. For example, there is a 50-fold variation in the genome size of *Allium* species, which contains onions, leeks, shallots, and garlic. Even among vertebrates, there is great variation in genome size. The pufferfish, *Takifugu rubripes,* for example, has a 393-Mb genome, whereas the genomes of the mouse and humans are about seven times larger. And yet, the pufferfish, with ~27,000 protein-coding genes, has more protein-coding genes than either the mouse (~22,000 genes) or the human (~20,500). Clearly the genes are spaced more closely in the pufferfish genome than they are in either the mouse or human genomes. But the human genome is by no means the largest among eukaryotes; the genomes of some amphibians and some ferns are about 200 times larger. In general, though, all genes are packed less densely in eukaryotes than they are in prokaryotes, with protein-coding gene density ranging from 500 per Mb (yeast) to fewer than 10 per Mb (humans and other mammals). However, there is no uniformity in the packing, as the pufferfish–mammal comparison shows.

It is important to think critically about the data presented for gene numbers in a genome. As you have learned, the determination of the protein-coding gene number involves both computer and experimental analysis. The outcomes of those analyses are therefore estimates of the number of genes present. Only when an entire genome has been studied experimentally to characterize every gene it contains can we be certain of an organism's exact gene number. For example, you have just learned that the estimated number of protein-coding genes is ~22,000 in the mouse genome and ~20,500 in the human genome. The numbers are not precise. Rather, at this point they likely reflect different extents of progress in annotating the two genomes, and not that 2,000 more protein-coding genes are required necessarily to be a mouse compared to being a human.

A. Map of the circular *E. coli* K12 genome showing the genes transcribed clockwise (blue) and the genes transcribed counterclockwise (orange) and the location of the origin of replication.

B. Detail of a 10-kb region of the *E. coli* K12 genome, from about 3:30 on the genome "clock."

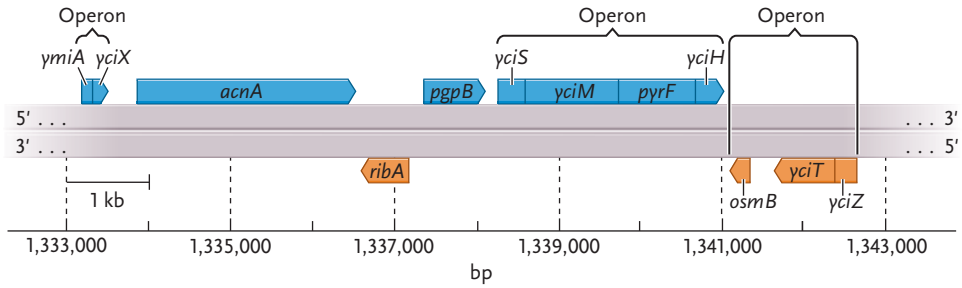

FIGURE 19.6 **The genome of *E. coli*, laboratory strain K12.**

© Cengage Learning 2014

PROFILE OF THE *E. coli* GENOME *E. coli* is one of the most intensively studied model organisms, and the genome of laboratory strain K12 is one of the best annotated. In many ways, *E. coli* has a typical bacterial genome, with the vast majority of its genes on a single circular chromosome with one origin of replication **(Figure 19.6A),** and the remainder of its genes on one or more plasmids, each of which is much smaller than the circular chromosome. With about 4.6 Mb and about 4,146 protein-coding genes, the *E. coli* K12 genome is in the middle range, sizewise, of bacterial genomes (see Figure 19.5). The noncoding genes are those for rRNAs and tRNAs. There are a small number of transposable elements and repetitive sequences.

Figure 19.6B shows a close up of a 10-kb segment of the *E. coli* genome containing a number of protein-coding genes to illustrate the following characteristics:

- The genes are close together, with little space in between. Promoters for the genes are located immediately upstream of each transcription unit (not shown in the figure).

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Some of the genes are transcribed in the left-to-right direction (using the bottom strand as the template), whereas the others are transcribed in the right-to-left direction (using the top strand as the template). (The two template strands are transcribed in different directions because the two DNA molecules in a double helix are antiparallel; see Chapter 14.)
- Some genes are single transcription units, whereas others are organized into operons (see Chapter 16). In the genome as a whole, about one-half of protein-coding genes are organized into operons.
- The genes vary in length, reflecting the lengths of their encoded proteins.

Table 19.3 summarizes some of what has been learned about the *E. coli* K12 genome to date with respect to its physical aspects, genes, and gene products.

Other bacterial genomes may be larger or smaller than the *E. coli* K12 genome, but their genome landscapes are similar to that of *E. coli* in several ways. For example, typically there is one origin of replication, 85% to 92% of the DNA codes for proteins, there is a mixture of operons and single-gene transcription units, some genes are transcribed using one DNA strand as the template whereas others are transcribed using the other strand, and there are relatively few transposable elements or repetitive sequences.

TABLE 19.3 Comparison of the *E. coli* K12 and Human Genomes

Property	*E. coli* K12 genome	*H. sapiens* genome
Chromosomes	1 circular (plus plasmids)	23 linear (pairs in diploid cells)[a]
Nucleotides	4.64 Mb	3,100 Mb
Protein-coding genes	4,146	~20,500
Noncoding RNA genes	176	~12,000
% coding DNA	88%	1.2%
Protein-coding genes per Mb	894	7
Introns per average gene	0	8
Average polypeptide size	330 amino acids	430 amino acids

[a]There are 24 different human chromosomes: 22 autosomes, and the X and Y chromosomes. Each individual has 23 pairs of chromosomes.

© Cengage Learning 2014

PROFILE OF THE HUMAN GENOME At about 3.2 billion base pairs, the human genome is about 700 times longer than the *E. coli* genome. Each human individual has 23 pairs of chromosomes. Men have 24 different chromosomes, the 22 autosomes and the X and Y chromosomes, whereas women have 23 different chromosomes, the 22 autosomes and the X chromosome. **Figure 19.7A** displays the complete set of human chromosomes, depicting the banding patterns that help researchers identify regions of chromosomes. (Figure 10.7 shows the banding patterns of stained human chromosomes.) **Figure 19.7B** shows chromosome 6 in more detail and then a close-up of a 100-kb segment of the long arm of that chromosome to show the protein-coding genes it contains. Compare this figure with Figure 19.6B, which

shows a 10-kb segment of the *E. coli* chromosome and note the following:

- Genes are relatively far apart, with a large amount of space in between. That is, even though the human genome segment shown is ten times longer than the *E. coli* segment shown in Figure 19.6.B, it contains only two protein-coding genes. Each of these genes consists of transcription units that are far longer than the genes in *E. coli,* largely because they consist of about 95% introns and 5% exons. The right-hand gene in Figure 19.7B illustrates at the DNA level the alternative splicing variants for that gene; note the different exons for the three gene drawings. (Alternative splicing is described in Section 16.3.)
- As in the genomes of other organisms, some genes are transcribed in the left-to-right direction and others in the right-to-left direction. For the particular segment shown in Figure 19.7B, both genes are transcribed in the right-to-left direction.
- All the genes are single transcription units. Eukaryotic genes are rarely organized in operons.

Table 19.3 summarizes some of what researchers have learned about the human genome to date with respect to its physical aspects, genes, and gene products. Some of the key features of the human genome are:

- There are about 20,500 protein-coding genes. On average, there are 9 to 10 exons per gene, with some human genes consisting of a single exon and others having over 100 exons. Introns make up about 95% of the average transcription unit. Since about 2% of the genome consists of protein-coding sequences, introns represent about 20% to 25% of the human genome.
- On average, more than 20 regulatory sequences are associated with each protein-coding gene. Those sequences are distributed over thousands to tens of thousands of base pairs upstream and downstream of each gene, as well as being scattered within introns. The regulatory sequences are widely scattered within regions that encompass 15% to 25% of the human genome.
- There are about 9,000 noncoding RNA genes, which include genes for rRNA, tRNA, small nuclear RNA, and microRNAs (see Chapter 15 and Section 16.3).
- There are thousands of pseudogenes.
- About 45% of the genome consists of transposable element sequences (see Section 15.5). Only a tiny fraction of those transposable elements are functionally active. The others are inactive, being the transposable element version of pseudogenes.
- The genome contains a variety of short, repeated sequences, including those at the centromeres and telomeres, as well as others scattered throughout the rest of the chromosome.
- Replication begins at hundreds to thousands of origins of replication per chromosome. However, there are no consistent, sequence-specific replication origins as is found in bacteria and yeast.

Up to this point, we have focused on the features of the enormous portion of the human genome encoded within the linear chromosomes of the cell's nucleus. It is also important to remember that in a eukaryote, each mitochondrion also contains a circular mitochondrial genome, or mtDNA. The human mtDNA is 16.6 kb, much smaller than even a prokaryotic genome. Its 37 genes (13 of them are protein-coding) perform essential functions related to cellular respiration. In addition, photosynthetic eukaryotes, including plants and algae, have a separate circular genome up to several hundred thousand bases in each of their chloroplasts: the cpDNA. Not surprisingly, this genome contains genes involved in photosynthesis.

Other mammalian genomes are very much like the human genome. But for other eukaryotes generally, particular features can vary considerably. For example, eukaryote genomes range from having a very low percentage of protein-coding DNA as in mammals to almost as high a percentage as is seen for prokaryotes.

2. **What are the key sequences identified by genome annotation?**
3. **How are possible protein-coding genes identified in a genome sequence of a bacterium? Of a mammal?**
4. **What general differences are there in the genome landscapes of prokaryotes and eukaryotes?**

19.3 Determining the Functions of the Genes in a Genome

Once a genome is annotated, the next step is to use the genome sequence data to understand the functions of genes and other parts of the genome. "Gene function" is considered broadly here to include regulation of gene expression, the products genes encode, and the role of those products in the function of the organism. For protein-coding genes, the gene products are proteins. We study proteins to understand their structure and function, and to discover how they interact with other proteins and other nonprotein molecules in the cell and how those complexes are important functionally for the organism.

We also need to determine what genes there are for noncoding RNAs in the genome, and what the functions of the RNAs are. Several of the noncoding RNA genes can be assigned functions based on evolutionary conservation principles; that is, by looking for sequence similarity with known gene sequences. An example is the rRNA genes. However, identifying and determining the functions of miRNA genes is more challenging in part because of their diversity of sequences. In this section, we focus on protein-coding genes, again because of the importance of their products in controlling the functions of cells and, therefore, of organisms. Determining the functions

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

of protein-coding genes typically relies on computer analysis and on laboratory experiments. The following presents examples of those approaches.

Gene Function May be Assigned by a Sequence Similarity Search of Sequence Databases

You learned earlier that a DNA sequence can be identified as a likely protein-coding gene by using a sequence similarity search of sequences in databases. This approach can also be used to assign the function of a gene. A high degree of similarity between the sequence of a candidate gene of unknown function and the sequence of a gene of known function likely indicates that both sequences evolved from a gene in a common ancestor and that their sequences in the present day have been conserved significantly because they code for proteins that have similar functions. As explained earlier, genes with highly conserved sequences as a result of divergence from a common ancestral gene are homologous genes.

Using sequence similarity searches to determine if a candidate gene and a known gene are homologous is by far the most common method for assigning the functions of genes. Experimental investigation of the functions of genes is considerably more expensive and time-consuming than DNA sequence comparisons; therefore, it is not feasible to repeat experiments in every species whose genome is sequenced. As a result, experimental data are available only for a small fraction of organisms. And because the functions of homologous protein-coding genes are so well conserved during the evolution of organisms, information about the function of a gene in one well-studied species very often applies to the homologous genes in another.

In some cases, the outcome of a sequence similarity search will indicate that the entire candidate gene's sequence is homologous to a known gene's sequence. In other cases, only part of the candidate gene sequence may match closely a sequence in a known gene. Typically this result indicates that the candidate gene encodes a protein with a domain that is related evolutionarily to a domain-encoding region of the known gene. (Protein domains are discussed in Section 3.4 and in the Genome Evolution section later in this chapter.)

Gene Function May be Assigned Using Evidence from Protein Structure

Since the structure of a protein determines its function and the structures and functions of many proteins are known, similarity between the structure of a protein determined for a newly identified gene and a characterized protein will indicate a likely function of the protein product of that gene. (How protein structure may be determined is described later in this section.) However, isolating and purifying a protein and determining its structure experimentally is expensive; therefore, that approach is used for only a small fraction of identified genes.

Gene Function May be Determined Using Experiments That Alter the Expression of a Gene

If a researcher can determine how the phenotype of a cell or organism is affected when the expression of a gene is turned off, or reduced significantly, functional properties of the encoded protein may be inferred. In a simple example, if cells grow larger, the gene may be involved in regulating cell size.

Two main kinds of manipulations are used to turn off or reduce significantly the expression of a gene in genome-scale experiments—gene knockout and gene knockdown:

1. *Gene knockout.* In this approach, researchers replace a normal gene on its chromosome with a defective gene that cannot express a functional protein. Usually, the replacement lacks the ORF that encodes the gene's protein product. In effect, this is a deletion mutation that has been engineered genetically. A deletion mutation is a *null mutation* because there is zero expression of the gene's protein product. For a haploid organism, there is only one copy of each gene to knock out, whereas in diploid organisms both copies of each gene must be knocked out. On a genomic scale, experimental manipulations can be done to knockout each gene systematically one by one. The phenotypic consequences of zero expression of each gene can then be ascertained. Major projects have been done, or are being done, to knock out systematically the function of each gene in the genomes of several organisms, including yeast, the fruit fly, the nematode worm, and the mouse (knockout mice were introduced in Section 18.2).
2. *Gene knockdown.* Knocking down a gene's expression typically is done using RNA interference (RNAi). As discussed in Section 16.3, RNAi reduces the expression of a gene at the translation level. In RNAi, a small regulatory RNA (like a natural miRNA) is transcribed from an expression plasmid introduced into the cell. The sequence of that regulatory RNA forms complementary base pairs with the mRNA of a gene of interest. The base pairing triggers the RNAi molecular mechanisms (see Figure 16.14), which knocks down the expression of the gene by causing degradation of that gene's mRNA or by blocking its translation. For example, RNAi has been used to knock down gene expression of each of the approximately 20,000 genes of the nematode worm one by one. The advantage of RNAi in comparison to gene knockouts is that the decrease in function of a gene can be temporary.

Characterizing genes by studying the effects on phenotype of knockouts or knockdowns can be very expensive and time-consuming. In a genome-wide study, thousands of knockout or knockdown strains have to be engineered genetically, and then each one has to be screened for a battery of possible phenotypic changes. The most ambitious studies of this kind have examined hundreds of phenotypes for each gene, which is only a fraction of the phenotypes that could be characterized. To make this approach really productive in the future will require

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

further development of high-throughput methods that automate the measurement of phenotypic changes.

The study of gene function by identifying changes in phenotypes is called **phenomics.** Knowing the phenotypic effects of knocking out or knocking down a gene usually only gives general information about the function of a gene. But that information is useful for follow-up experiments on the specific protein involved.

Transcriptomics Determines at the Genome Level When and Where Genes Are Transcribed

Some genes are transcribed in all cell types, whereas others are transcribed only when and where they are needed (see Chapter 16). Determining when and where genes are transcribed can shed light on their function. For instance, a researcher might be interested in determining at a genomic scale the gene expression patterns in different cell types, at different stages of embryonic development, at different points of the cell division cycle, or in response to mutation or changes in the environment. A medical example, for instance, would be identifying gene expression differences between normal cells and cells that have become cancerous. The experimental analysis itself may be qualitative—analyzing whether or not genes are expressed—or quantitative—analyzing how the level of expression of genes varies.

The complete set of transcripts in a cell is called the **transcriptome,** and the study of the transcriptome is called **transcriptomics.** Transcriptomics includes cataloging transcripts, and quantifying the changes in expression levels of each transcript during development, in different cell types, under different physiological conditions, and with other variations.

Analysis of transcriptomes is done using high-throughput hybridization or, increasingly, by sequence-based approaches. A hybridization-based approach uses **DNA microarrays,** also called **DNA chips.** The surface of a DNA microarray is divided into a microscopic grid of about 60,000 spaces. On each space of the grid, a computerized system deposits a microscopic spot containing about 10,000,000 copies of a DNA probe that is about 20 nucleotides long.

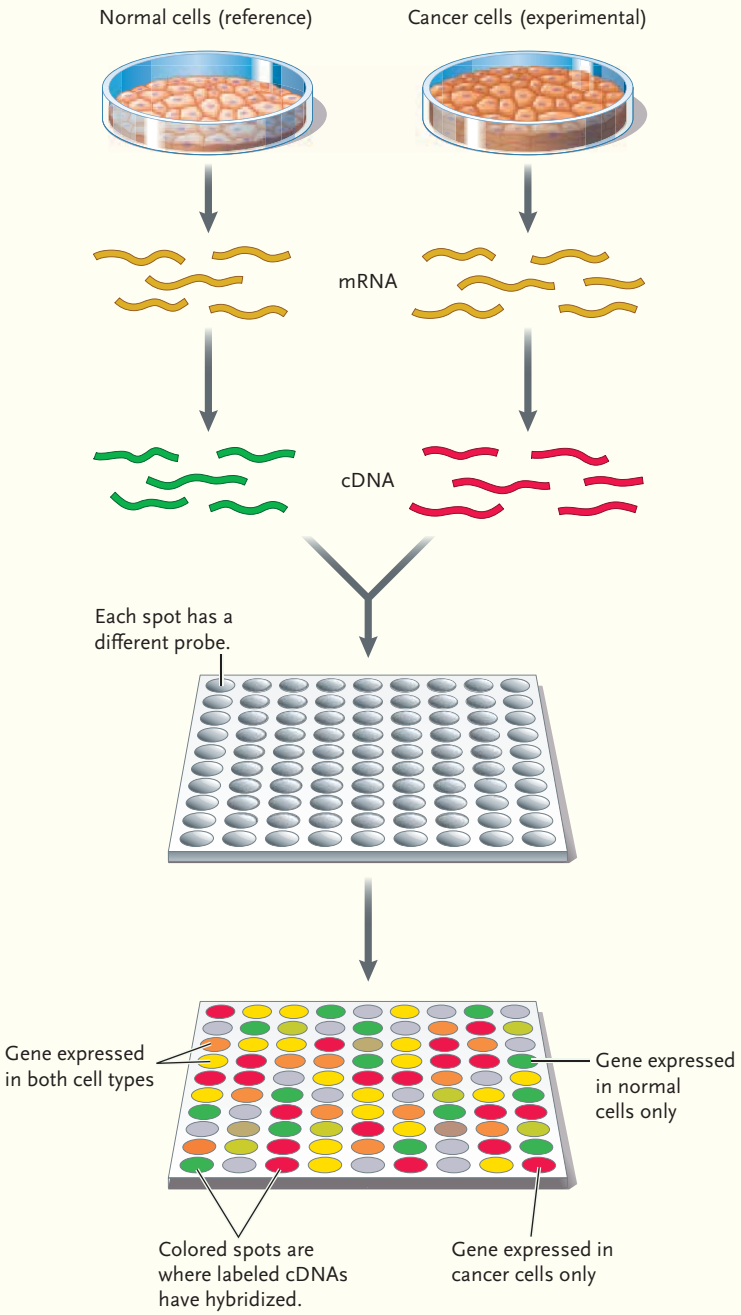
Studies of gene activity using DNA microarrays involve comparing gene expression under a defined experimental condition with expression under a reference (control) condition. As a theoretical example, **Figure 19.8** shows how a DNA microarray can be used to compare gene expression patterns in normal cells and cancer cells in humans. mRNAs are isolated from each cell type and cDNAs are made from them, incorporating different fluorescent labels: green for one cDNA, red for the other. The two cDNAs are mixed and added to the DNA microarray, where they hybridize with whichever spots on the microarray contain complementary DNA probes. A laser excites the fluorescent labels and the resulting green and red fluorescence is detected and quantified, enabling a researcher to see which genes are expressed in the cells. This technique is semiquantitative because it is also able to quantify differences in gene expression between the two cell types approximately (see *Interpreting the Results* in the figure).

In cancer research, for example, microarray analysis has been used to diagnose a particular cancer type, thereby potentially informing physicians about appropriate treatments. That is, many cancers can be identified based on **signature genes** which are key genes whose expression changes in a way that correlates with a normal cell becoming a cancer cell. *Diffuse large B-cell lymphoma* (DLBCL) is the most common type of non-Hodgkin's lymphoma, a type of cancer of the lymphatic system. Some patients respond to chemotherapy treatment, resulting in prolonged survival, whereas the remainder do not respond to such treatment and show no greater survival than untreated patients. DNA microarray-based transcriptome analysis of DLBCLs in a group of patients showed that the gene expression profile in chemotherapy-responsive tumors is different from that in chemotherapy-nonresponsive tumors. This result indicates that there are two subtypes of DLBCL. Identifying by DNA microarray analysis which type of DLBCL a patient has can, therefore, inform physicians as to the most effective treatment regimen. If the DLBCL is a responder, then chemotherapy is the best approach. If the DLBCL is a nonresponder based on the gene expression profile, then more aggressive treatments can be done.

Other examples of DNA microarray analysis include screening individuals for mutations associated with genetic diseases (such as breast cancer), and studying changing gene expression profiles during *Drosophila* development, when a gingivitis-causing bacterium grows under different conditions (see *Insights from the Molecular Revolution* in Chapter 26), during flower development in plants (see *Focus on Basic Research* in Chapter 37), and when sea urchin larvae are living under different pH conditions (see *Insights from the Molecular Revolution* in Chapter 54).

A newer, sequence-based approach to analyze transcriptomes is **RNA-seq** (whole-transcriptome sequencing). This technique uses high-throughput sequencing of cDNAs to identify and quantify RNA transcripts in a sample. For transcriptomic analysis of protein-coding genes using RNA-seq, mRNAs are isolated and converted to cDNAs (see Figure 18.4). About 30 to 400 nucleotides of each cDNA are sequenced using high-throughput techniques, and the results are aligned with the genome sequence of the organism under study. A single RNA-seq study can identify over 100,000 sequence reads, each one of which indicates the presence of a specific mRNA in the cells being studied. While a relatively new technique, RNA-seq rapidly is becoming the replacement for DNA microarrays in transcriptomics, because of its decreasing cost and its greater precision for quantifying transcripts.

Proteomics Is the Characterization of All Expressed Proteins



Genome research also includes analysis of the proteins encoded by a genome, for proteins are largely responsible for cell function and, therefore, for most of the functions of an organism. The term **proteome** has been coined to refer to the complete set of proteins that can be expressed by an organism's genome. A *cellular proteome* is a subset of those proteins—the collection of

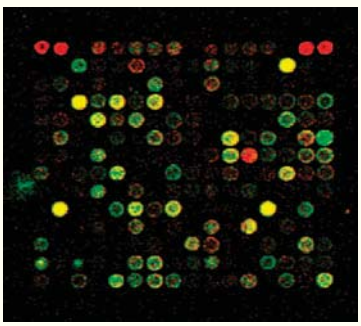
DNA Microarray Analysis of Gene Expression Levels

Purpose: DNA microarrays can be used in various experiments, including comparing the levels of gene expression in two different tissues, as illustrated here. The power of the technique is that the entire set of genes in a genome can be analyzed simultaneously.

Protocol:



1. Isolate mRNAs from a control cell type (here, normal human cells) and an experimental cell type (here, human cancer cells).

2. Prepare cDNA libraries from each mRNA sample. For the normal cell (control) library use nucleotides with a green fluorescent label, and for the cancer cell (experimental) library use nucleotides with a red fluorescent label.

3. Denature the cDNAs to single strands, mix them, and pump them across the surface of a DNA microarray containing a set of single-stranded probes representing every protein-coding gene in the human genome. The probes are spotted on the surface, with each spot containing a probe for a different gene. Allow the labeled cDNAs to hybridize with the gene probes on the surface of the chip, and then wash excess cDNAs off.

4. Locate and quantify the fluorescence of the labels on the hybridized cDNAs with a laser detection system.

Actual DNA microarray result

Courtesy Ludwig Institute for Cancer Research

Interpreting the Results: The colored spots on the microarray indicate where the labeled cDNAs have bound to the gene probes attached to the chip and, therefore, which genes were active in normal and/or cancer cells. Moreover, we can quantify the gene expression in the two cell types by the color detected. A purely green spot indicates the gene was active in the normal cell, but not in the cancer cell. A purely red spot indicates the gene was active in the cancer cell, but not in the normal cell. A yellow spot indicates the gene was equally active in the two cell types, and other colors tell us the relative levels of gene expression in the two cell types. For this particular experiment, we would be able to see how many genes have altered expression in the cancer cells, and exactly how their expression was changed.

proteins found in a particular cell type under a particular set of environmental conditions.

The study of the proteome is the field of **proteomics.** The number of possible proteins encoded by the genome is larger than the number of protein-coding genes in the genome, at least in eukaryotes. In eukaryotes, alternative splicing of gene transcripts and variation in protein processing means that expression of a gene may yield more than one protein product. The number of different proteins an organism can produce typically far exceeds the number of protein-coding genes.

Proteomics has three major goals: (1) to determine the structures and functions of all proteins; (2) to determine the location of each protein within or outside the cell; and (3) to identify physical interactions among proteins.

DETERMINING PROTEIN STRUCTURE Protein structure may be determined as follows:

Clone the coding sequence of the gene into an expression vector (see Section 18.2)
↓
Transform the cloned gene into a host to express the protein
↓
Purify the protein
↓
Determine the structure of the protein using X-ray crystallography or nuclear magnetic resonance (NMR)

Protein structure may also be predicted nonexperimentally using computer algorithms based on the known chemistry of amino acids and how they interact.

DETERMINING THE LOCATIONS OF PROTEINS IN CELLS The location of a protein in a cell is important because it is key to its function. The cellular location of a protein can be studied by tagging the protein in some way, and then visualizing the location of the tag microscopically. Different tags are used for visualization using light microscopy or electron microscopy.

IDENTIFYING INTERACTIONS AMONG PROTEINS Many proteins function by interacting with other proteins. In some cases, proteins (actually polypeptides) interact to form the quaternary structure—and therefore the functional form—of a protein (see Section 3.4). Many multi-polypeptide proteins exist, and you have encountered several in this book, for example: (1) hemoglobin is a four-polypeptide protein consisting of two α-globin polypeptides and two β-globin polypeptides and four associated heme groups (see Figure 3.20); (2) RuBP carboxylase/oxygenase (rubisco), the first enzyme of the light-independent reactions of photosynthesis (see Section 9.3), consists of eight copies of a large polypeptide and eight copies of a small polypeptide (see figure in *Insights from the Molecular Revolution,* Chapter 9); and (3) the Lac repressor protein that controls the expression of the *lac* operon in *E. coli* (see Section 16.1) consists of four copies of the same polypeptide.

In other interactions among proteins, the interaction is not permanent, but instead serves to affect the function of one or other of the partners in the interaction. For example, in Chapter 7 you were introduced to protein kinases—enzymes that transfer a phosphate group from ATP to one or more sites on particular target proteins as part of a signal transduction pathway. The phosphorylation of the target proteins occurs as a result of the interaction between the enzymatic protein and each target protein. Once the target protein is phosphorylated, the two proteins no longer interact. Understanding the interactions among proteins is important, then, to help us understand how proteins work individually and together to determine the phenotype of a cell.

Thousands of interactions have been identified experimentally for a variety of organisms. The interaction data are assembled to produce protein-interaction networks, the analysis of which is informing us about the details and complexities of the functions of proteins in cells. **Figure 19.9** shows part of a protein-interaction network centered on the human protein, β-catenin (cadherin-associated protein; the central CTNNB1 sphere in the figure). β-Catenin is involved in the formation of adherens junctions (a type of cell junction; see Section 5.5) in epithelial cells where it links α-catenin (CTNNA1 in the figure) with E-cadherin (CDH1 in the figure; cadherins are discussed in Chapter 50). It also plays a key role in a signaling pathway that is important, for example, in regulating how cell fate is decided during development. Interactions with, for example, APC, LEF1, TCF4, and TCF7L2 occur as part of that signaling pathway's operation.

Just as for genomic DNA sequences, information about various properties of each protein are placed in databases, for example Entrez (http://www.ncbi.nlm.nih.gov) and UniProt

(http://www.uniprot.org), to create a dossier of that protein that is available to researchers worldwide.

CHARACTERIZING PROTEIN FUNCTION Through various approaches, researchers learn about the functions of proteins. **Figure 19.10A** shows an example of what we have learned about the functions of human protein-coding genes with respect to protein classes, and **Figure 19.10B** shows the functions of human protein-coding genes with respect to the biological processes involving those proteins.

STUDY BREAK 19.3

1. **What are the ways by which the function of a gene identified in a genome sequence may be assigned?**
2. **How would you determine how a steroid hormone affects gene expression in human tissue culture cells?**
3. **What is the proteome, and what are the major goals of proteomics?**

THINK OUTSIDE THE BOOK

Earlier in the chapter we mentioned the fact that cloned animals may have many genes whose expression is abnormal compared to gene expression in a noncloned animal. Individually or collaboratively, outline the steps you would take experimentally to determine, on a genome-wide scale, if genes are abnormally expressed in a cloned mammal. Your answer should include how the experiment reveals both qualitative and quantitative differences in gene expression.

19.4 Genome Evolution

DNA genomes with protein-coding genes are thought to have evolved over 3.5 billion years ago, by the time of the earliest fossil microorganisms that have been discovered (see Chapter 25). Those early cells probably had at most a few hundred protein-coding genes. New genes evolved as life evolved and became more complex, so that most present-day organisms have thousands or tens of thousands of protein-coding genes. In this section you will learn how genes and genomes have evolved, and how genome sequences inform us about the evolutionary history of life.

Comparative Genomics Reveals the Evolutionary History of Genes and Genomes

Understanding how genes evolved and how genomes evolved are major goals of the field of *comparative genomics*. Because the genes in present-day genomes evolved from ancestral genes that were in the genomes of organisms living millions-to-billions of years ago, we can trace the evolutionary history of genes by comparing the genomes of different groups of present-day organisms. From such comparisons, we can estimate when new genes first appeared in ancient organisms, describe how they changed over time, and gain insights into what molecular processes cause new genes to evolve in the first place.

Comparative genomics has shown that some genes are found in the genomes of almost all present-day organisms. Examples are genes involved in core biological processes like transcription and protein synthesis, including genes for some subunits of RNA polymerase, genes for many of the proteins that make up part of the structure of a ribosome, and most of the aminoacyl–tRNA synthetase enzymes that attach amino acids to transfer RNA molecules. The proteins coded for by these genes not only perform the same function in every organism, but they are also related evolutionarily. This conclusion strongly suggests that the single-celled common ancestor of all living organisms had those genes in its genome, and that those genes have been passed down through the generations for billions of years.

Most genes do not appear in the genomes of all organisms but have a more restricted distribution. There are eukaryote-specific genes, bacteria-specific genes, archaea-specific genes,

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

animal-specific genes, plant-specific genes, primate-specific genes, human-specific genes, and so on. For example, mitosis and meiosis genes are eukaryote-specific genes, genes for flowers are plant-specific, and some genes related to brain function are primate-specific.

Analyzing the evolutionary history of genes provides valuable information about how life evolved on the molecular level. For example, by comparing the functions of almost 4,000 evolutionarily related groups of genes in 100 genomes of bacteria, archaea, and eukaryotes, researchers have identified a period about three billion years ago when many new genes evolved. By analyzing the functions of these new genes, the researchers concluded that many of the new genes evolved as adaptations to changes in the amount of oxygen in Earth's atmosphere, following the development of the oxygen-producing photosynthetic reactions (see Chapter 9).

Comparative genomics has also been applied to understanding human evolution. (Human evolution is discussed in Section 32.13.) The human genome was the first mammalian genome sequenced, and researchers now have the sequences of hundreds of human genomes to study and compare to discover what makes us human and what is responsible for human variation. We also have over 40 other mammalian genomes to compare with the human genome. These include genomes of primate species that are closely related to humans, such as the common chimpanzee and the mountain gorilla, as well as less closely related mammals, such as the cow and the duck-billed platypus. Comparing the human genome with the genomes of other primates reveals which features are common to all of these primates and which are unique to humans. The human and chimpanzee genomes are strikingly similar, with 96% DNA sequence identity across the entire genome. The annotation of the chimpanzee genome is not yet complete, but it is likely that these two species share virtually all of their genes, so the genomic changes that occurred in human evolution probably involved only subtle mutations in the protein-coding sequences of genes, and mutations to regulatory sequences that determine how and when each gene is expressed (see Chapter 16). By contrast, comparisons of primate genomes with those of other mammals have identified new genes that evolved only in primates. Further studies of the functions of these genes may shed light on how primates evolved the characteristics that distinguish them from other mammals (see Chapter 32). And, interestingly, the primate-specific genes in the human genome contain the highest fraction of disease-related genes—19.4%—of any group of genes.

DNA microarrays and RNA-seq (see Section 19.3) have been used to compare which genes are transcribed in which parts of the brain in humans, chimpanzees, and rhesus monkeys. Certain groups of genes are expressed in the brain only during embryonic and early postnatal development. In both chimpanzees and rhesus monkeys, many genes involved in the formation of new synapses (communicating junctions between neurons: see Chapter 39) are transcribed only in the first year after birth, while in humans expression of these genes continues up to age five. These differences are most prominent in the prefrontal cortex, which is an area of the brain involved in complex decision-making (see Chapter 40). These comparative findings provide clues to how our species evolved enhanced learning abilities.

Comparative genomics also provides information about how the arrangement of genes on chromosomes has evolved. In Section 13.3 you learned about chromosomal mutations that occur when part of a chromosome is translocated to another chromosome, or inverted in place. Nondisjunction in meiosis can also cause entire chromosomes to be duplicated (see Figure 13.13). Such chromosomal mutations are uncommon, and usually they are harmful. But when a nonharmful chromosomal mutation occurs and spreads to all members of a species, the order of genes on the chromosomes of that species may then be different from the order in closely related species. Comparing the genomes of a range of related species reveals that, over the course of hundreds of millions of years of biological evolution, pieces of chromosomes have changed places repeatedly by translocation and inversion, rearranging the genes on chromosomes like shuffling a deck of cards (see Figure 22.18). Even so, the chromosomal arrangement of some genes is preserved after all this reshuffling, even in distantly related organisms. For example, comparisons of the human genome with the genomes of distantly related animals such as insects and sea anemones reveal blocks of homologous genes that are on the same chromosome and arranged in the same order in all of these species. This means that the order of these genes on the chromosome has been preserved from the time that all of these species evolved from a common ancestor, even though that common ancestor lived over 500 million years ago.

New Genes Evolve by Duplication and Exon Shuffling

The evolution of a new gene is a rare event—much less common than a mutation in an existing gene. But, nonetheless, over millions of years of biological evolution many new genes have been produced. For example, a comparison of genome sequences among four species in the *Drosophila* genus of fruit flies identified over 200 genes that had evolved in just the past 13 million years (a comparatively short time in evolutionary history).

Throughout the history of life on Earth, the evolution of new biological functions has almost always involved the evolution of new genes. For example, photosynthesis became possible only with the evolution of genes coding for proteins that could harness the energy in photons to synthesize ATP and electron carrier molecules. And comparative analysis of mammalian genomes has revealed genes involved in milk production and other biological functions found only in mammals. Evolutionary biologists have described a number of molecular mechanisms to explain where these new genes come from. The most common molecular mechanism to explain the origin of new genes is *gene duplication,* which produces *multigene families* after a series of duplications of genes that all derive from the same ancestral gene. New *types* of genes are produced by a process called *exon shuffling,* which combines parts of two or more genes.

GENE DUPLICATION **Gene duplication** is any process that produces two identical copies of a gene in an organism's genome. Genes can be duplicated either by *unequal crossing-over* of homologous chromosomes during meiosis, or as a result of the replication of transposable elements (see Section 15.5).

Unequal crossing-over is the rare phenomenon in meiosis in which, instead of crossing-over occurring at the exact same point on each homolog of a homologous pair of chromosomes **(Figure 19.11A),** crossing-over occurs at different points **(Figure 19.11B).** The result of unequal crossing-over is that one of the recombinant chromosomes is missing one or more genes, while the other has duplicate copies of those genes. Unequal crossing-over produces **tandem duplication** of genes with the duplicate copies clustered together in the same region of the same chromosome.

Gene duplication may occur when a transposable element copies itself and splices the DNA copies elsewhere in a genome. (Transposable element movement is discussed in Section 15.5.) Rarely, transposable elements copy adjacent DNA in addition to their own, producing duplicate copies of any genes in that DNA. This produces **dispersed duplication** of genes, meaning that the copies of the gene are found in different places in the genome—often on two different chromosomes.

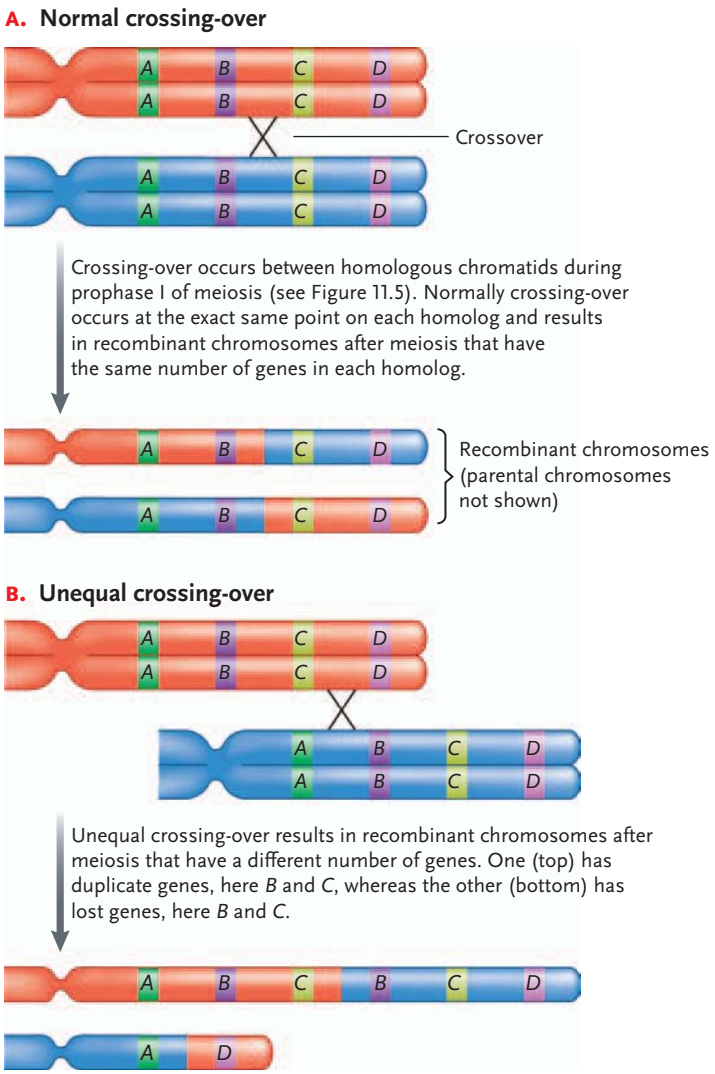

FIGURE 19.11 Duplication of genes by unequal crossing-over.

© Cengage Learning 2014

At first, the duplicate copies of a gene have the same protein-coding sequences and encode identical proteins. The two genes are functionally redundant, meaning that one could be eliminated from the genome with no loss of biological functionality. Often, one of the redundant copies is mutated into a pseudogene, or lost by deletion. But if both genes remain functional, they will evolve slowly in different ways, as different mutations occur in each gene. Mutations in regulatory sequences may change how each duplicate gene is regulated, or mutations in protein-coding sequences may change the functional properties of the proteins produced by each gene. Over many generations, this evolutionary process can produce two homologous genes with similar but distinct functions.

For example, nitric oxide synthase enzymes catalyze a reaction that produces nitric oxide (NO), a molecule that cells use to communicate with each other (see Section 44.5 for an example). In the human genome, there are three genes for different nitric oxide synthase enzymes. One gene is expressed only in neurons, another only in the endothelial cells lining blood vessels (see Chapter 44), and the third in the liver and in a type of white blood cell called a macrophage (see Chapter 45). Homologs of all three of these genes are found in other mammalian genomes as well as in the genomes of birds and reptiles, so the gene duplications by which these genes evolved must have happened over 200 million years ago. Evolution of tissue-specific expression patterns for each gene must have involved mutations to regulatory sequences that control transcription. The evolution of these genes also involved mutations to the protein-coding sequences, causing the proteins to have subtly different structures and functions. For example, the neuronal and endothelial nitric oxide synthase enzymes are regulated by Ca^{2+} ions, while the third enzyme is not. The three genes are found on three different chromosomes in the human genome, which suggests that they evolved by dispersed duplication.

PRODUCTION OF MULTIGENE FAMILIES Gene duplication is often followed by further duplication of one or both of the original duplicates. When this happens repeatedly over millions of years, a family of homologous genes called a **multigene family** evolves. The nitric oxide synthase enzymes described above are a small gene family, with three members in the human genome. Other multigene families contain tens to hundreds of genes. The members of a multigene family all evolve from one ancestral gene, and therefore have similar DNA sequences and produce proteins with similar structures and functions. But because different mutations occur in each member of a multigene family, the genes gradually evolve subtly different characteristics.

Let us consider the *OPT/YSL* multigene family of the plant, *Arabidopsis thaliana,* as an example. The proteins coded for by these genes are oligopeptide transporters that shuttle short peptide molecules across cell membranes. This multigene family is

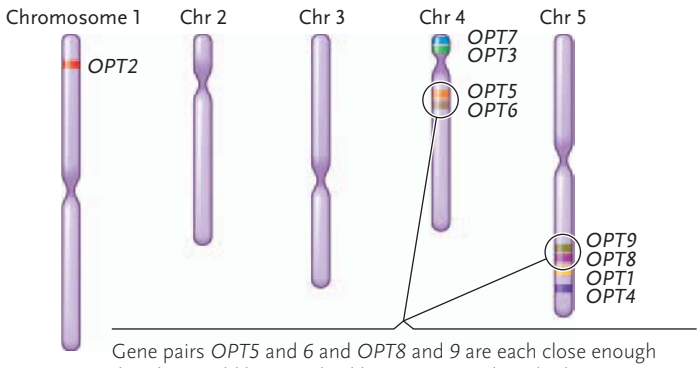
© Cengage Learning 2014

found in other plant genomes as well as in the genomes of fungi and other eukaryotes. By comparing DNA sequences of *OPT/YSL* genes in the genomes of plants and other organisms, researchers have concluded that, hundreds of millions of years ago, and before the evolution of the plant kingdom, a gene duplication produced the ancestral *OPT* gene and the ancestral *YSL* gene. Mutations in each gene caused them to encode proteins specialized for transporting different oligopeptides. A series of more recent gene duplications occurred since the evolution of plants, but well before the evolution of *Arabidopsis thaliana*. Each duplicate gene in this family accumulated different mutations, producing the functionally diverse set of *OPT* genes and *YSL* genes now found in *Arabidopsis thaliana* and other plants.

Figure 19.12A illustrates the family relationships among the *OPT/YSL* genes using a phylogenetic tree, much as a family tree illustrates relationships in a human family (see Chapter 24 for more information on how phylogenetic trees are constructed). **Figure 19.12B** shows the distribution of the *OPT* genes on *Arabidopsis thaliana* chromosomes and outlines the possible evolutionary history of some of those genes.



A. Family tree showing evolutionary relationships among *OPT* and *YSL* genes

Genes *OPT1–OPT9* are all descendants of the ancestral *OPT* gene. An early duplication within this gene subfamily produced two genes, one an ancestor of *OPT1* and *OPT5* and the other an ancestor of the other seven *OPT* genes. A subsequent gene duplication in the latter group produced the ancestor of *OPT2*, *4*, and *6–9*, and the ancestor of *OPT3*.

Genes *YSL1–9* are all descendants of the ancestral *YSL* gene. An early duplication within this gene subfamily produced two genes, one an ancestor of *YSL5*, *7*, and *8* and the other an ancestor of the other six *YSL* genes. A subsequent gene duplication in the latter group produced the ancestor of *YSL1–3* and *9*, and the ancestor of *YSL4* and *6*.

B. Distribution of *OPT* genes on chromosomes in the *Arabidopsis thaliana* genome

Gene pairs *OPT5* and *6* and *OPT8* and *9* are each close enough that they could have evolved by a recent tandem duplication. But only *OPT8* and *9* are near relatives in the *OPT* gene family tree (part **A** of figure). Therefore, we can hypothesize that *OPT8* and *9* likely resulted from a fairly recent tandem duplication, whereas *OPT6* is a dispersed duplicate of another *OPT* gene.

The oligopeptide transporter gene family in *Arabidopsis thaliana* is larger than the nitric oxide synthase gene family in the human genome, but other multigene families are even larger. For example, some families of transcription factor proteins and membrane-bound receptor proteins include hundreds of genes. Some of the larger multigene families have members in all kingdoms of eukaryotes, or even in all three domains of living organisms. Such families each evolved from an ancestral gene that first appeared billions of years ago.

EXON SHUFFLING The new genes produced by gene duplication evolve distinct functions, but they retain the same general function as other members of the multigene family into which they have been "born," so to speak. Our examples have illustrated that. By contrast, **exon shuffling**—the duplication and rearrangement of exons—is a molecular evolutionary process that combines exons of two or more existing genes, to produce a gene that encodes a protein with an unprecedented function.

Remember from Section 15.3 that many protein-coding genes in eukaryotes contain introns, sequences that do not encode amino acids. The introns are present in the pre-mRNA transcripts of such genes but, by RNA processing, the introns are removed while the exons—the sequences encoding amino acids in the pre-mRNAs—are spliced together to make the mature mRNAs. In many genes, the junctions between exons fall at points within the protein-coding sequence between major functional regions in the protein. These functional regions correspond to the domains into which many proteins are divided (see Section 3.4).

Exon shuffling can occur in the following way. When a piece of DNA is cut out of a chromosome and reinserted else-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

where in the genome (through the activity of a transposable element, for example), the ends of the piece of DNA that moves may occur within the introns of a gene, causing one or more whole exons to be inserted somewhere else in a chromosome. If those exons are inserted into an intron in another gene, the amino acid sequence encoded by those exons may be added to the amino acid sequence of the encoded protein. Such a transfer of DNA can produce a new gene, coding for a protein that has one or more domains added to the other domains that it already had.

An exon shuffling event occurred very early in the evolution of animals (at least 700 million years ago) that produced a new gene coding for a protein that plays a key role in signaling between cells in animal tissues. Evidence for this exon shuffling event comes from comparing the genome sequence of the choanoflagellate *Monosiga brevicollis* with the sequences of a number of animal genomes, including *Homo sapiens*. Choanoflagellates (see Sections 27.2 and 31.1) are single-celled or colonial protists that are thought to be related evolutionarily to animals. The evolution of multicellularity in the first animals is thought to have involved molecular mechanisms that enabled choanoflagellate-like cells to attach to and communicate with one another, so they could then specialize in performing different functions.

Figure 19.13 shows the exon shuffling event. It involves the Notch family of proteins, which are multidomain, membrane-spanning proteins. The human Notch1 protein, encoded by the *NOTCH1* gene, contains a transmembrane (TM) region, 36 copies of an EGF domain, three copies of an NL domain, and six copies of an ankyrin domain. The TM region anchors the Notch1 protein in the plasma membrane. The three domains are key to the protein's function. The part of the protein that is outside the cell membrane includes the EGF and NL domains, which enables a Notch protein in one cell to bind to other proteins in adjacent cells in a tissue. The ankyrin domains within the cell enable it to attach to the microfilaments that make up part of the cytoskeleton (see Section 5.3).

Figure 19.13 also shows three different genes in the *Monosiga brevicollis* genome, one with a sequence encoding EGF domains, a second with a sequence encoding NL domains, and a third with a sequence encoding ankyrin domains. However, this organism lacks a gene homologous to the gene for the Notch protein. Researchers have hypothesized that, through exon shuffling early in animal evolution, the sequences coding for the EGF, NL, and ankyrin domains in the three genes were combined in one gene, producing the ancestor of the *NOTCH* gene family. At some point, a duplication of the sequence coding for one NL domain occurred, since the *Monosiga brevicollis* gene has sequences coding for only two copies of that domain while animal genes for Notch proteins have sequences coding for three copies.

The genes produced by gene duplication typically encode functional proteins because they are duplicates of an existing functional gene. Most instances of exon shuffling theoretically should produce nonfunctional proteins, because an existing functional protein is interrupted by one or more domains from an unrelated protein. But in a small number of cases, proteins produced by exon shuffling combine the functions of two or more proteins in a new and useful way, like the assembly of the gene for the Notch signaling protein (see Figure 19.13). Interest-

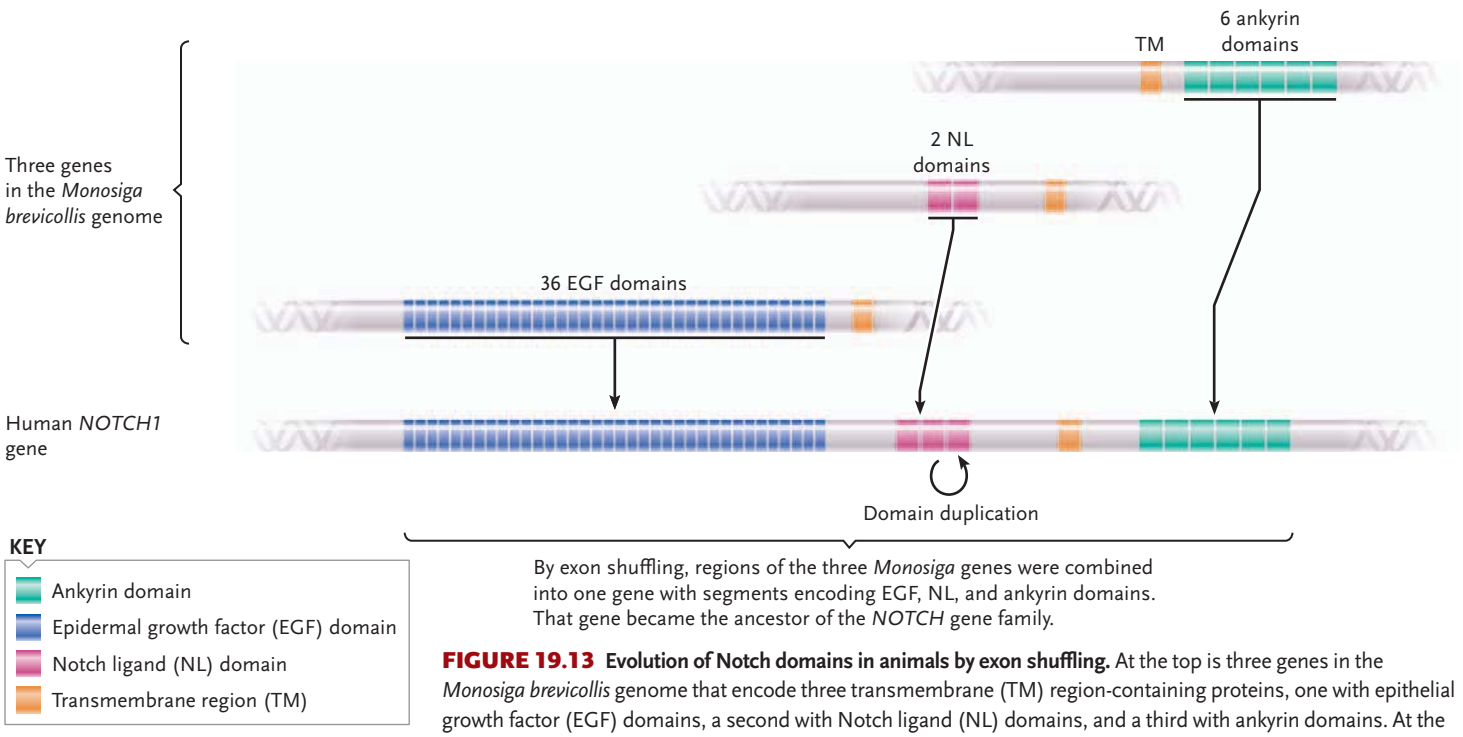

FIGURE 19.13 Evolution of Notch domains in animals by exon shuffling. At the top is three genes in the *Monosiga brevicollis* genome that encode three transmembrane (TM) region-containing proteins, one with epithelial growth factor (EGF) domains, a second with Notch ligand (NL) domains, and a third with ankyrin domains. At the bottom is the human *NOTCH1* gene, which encodes a protein with EFG, NL, and ankyrin domains.

ingly exon shuffling is thought to account for perhaps 1/3 of newly evolved genes. The genes that are produced by exon shuffling have more novel functions than those produced by gene duplication. In cases like the Notch protein, they become the ancestors of multigene families that evolve through subsequent gene duplications.

The domain structures of proteins in humans and other organisms provide evidence of how common exon shuffling has been in the evolution of proteins. The most widely used domains are found in thousands of different proteins, in dozens of different combinations with other domains.

STUDY BREAK 19.4

1. **What molecular mechanisms cause tandem duplication of genes and dispersed duplication of genes?**
2. **Why do new genes produced by exon shuffling have more novel functions than new genes produced by gene duplication?**

UNANSWERED QUESTIONS

It is well known that individuals respond differently to medications. For example, a blood pressure lowering medication may effectively lower blood pressure in one patient, have no effect on blood pressure in another patient, and cause intolerable adverse effects in a third patient. Factors such as age, weight, or liver and kidney function may influence response to medication. However, it remains difficult to predict how effective or safe a drug will be for a particular patient based on these factors alone. In clinical medicine, a trial-and-error approach is often used for drug therapy—several drugs or drug doses may be tried before finding the drug and dose that produces optimal response with acceptable tolerability.

Genes encoding proteins involved in the metabolism and transport of a drug through the body and for proteins at the drug target site may greatly influence drug response. Genes involved in disease progression or phenotype may also influence how well a drug works. How can molecular approaches be used to personalize drug therapy? The answer to that question may well come from the field of pharmacogenomics. Pharmacogenomics is the study of how genes affect individual responses to drug therapy. The goal is to choose the most appropriate drug, drug dose, and treatment duration for a particular patient based on genetic information.

How can pharmacogenomics be used to optimize therapy for blood clots?

Prescribed to prevent the formation of blood clots in the circulatory system, the drug warfarin ranks among the top 50 most commonly prescribed drugs in the United States. Because it inhibits the blood from clotting, warfarin also increases the chance of bleeding. The risk for bleeding increases when the warfarin dose is too high, while the risk for clotting increases when the dose is too low. The dose of warfarin needed to prevent clotting without significantly increasing the chance for bleeding is highly variable among patients, with doses ranging by as much as 20-fold. Age, body size, other diseases the person may have, and medications the person may be taking, all influence the dose of warfarin a person needs. However, considering age, body size, and clinical factors alone is not enough to choose the right warfarin dose for a given patient. Genes encoding for proteins involved in warfarin metabolism (pharmacokinetics) and mechanism of action (pharmacodynamics) are now known to influence warfarin dose requirements. Our group is working with other research groups from around the world to study variations in a person's genome that affect the dose of warfarin that he or she needs. The goal is to develop an algorithm, or equation, for dosing warfarin that includes both genetic and clinical factors and accurately predicts warfarin dose requirements for persons of various racial and ethnic backgrounds.

THINK LIKE A SCIENTIST What are the ethical implications of pharmacogenomics if the genes in question are associated with disease risk as well as drug response? What are the ethical implications of pharmacogenomics if a patient possesses a genotype predictive of poor drug response and there are no alternative treatments available?

Larisa H. Cavallari

Larisa H. Cavallari is an Associate Professor in the Department of Pharmacy Practice at the University of Illinois at Chicago. She is involved in both clinical and basic science research focusing on genetic contributions to cardiovascular drug response. REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

19.1 Genomics: An Overview

- Genomics is the characterization of whole genomes, including their structures (sequences), functions, and evolution.
- Genome sequence data are in databases that may be accessed by researchers worldwide.
- Genomics consists of three main areas of study: genome sequence determination and annotation, the determination of complete genome sequences and identification of putative genes and other important sequences; functional genomics, the study of the functions of genes and other parts of the genome; and comparative genomics, the comparison of entire genomes of parts of them to understand evolutionary relationships and basic biological similarities and differences among species.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

19.2 Genome Sequence Determination and Annotation

- The whole-genome shotgun method of sequencing a genome involves breaking up the entire genome into random, overlapping fragments, cloning each fragment, determining the sequence of the fragment in each clone, and using computer algorithms to assemble overlapping sequences into the sequence of the complete genome (Figure 19.1).
- DNA sequencing methods involve DNA purification; DNA fragmentation; amplification of fragments; sequencing each fragment; and assembly of fragment sequences into longer sequences, such as those of a genome (Figures 19.2 and 19.3).
- Once the complete sequence of a genome has been determined, it is annotated to identify key sequences, including protein-coding genes, noncoding RNA genes, regulatory sequences associated with genes, origins of replication, transposable elements, pseudogenes, and short repetitive sequences. Annotation of a genome is the task of researchers in bioinformatics.
- Identifying protein-coding genes in a genome sequence can be done by using a computer search for open reading frames, by searching databases for sequence similarity to genes of known function, and (the gold standard) by studying gene transcripts.
- Complete genome sequences have been obtained for many viruses, a large number of prokaryotes, and many eukaryotes, including the human. For organismal genomes, those of bacteria and archaea are generally smaller than those of eukaryotes and their genes are densely packed in their genomes with little noncoding space in between them. Prokaryotic genes are organized either into single transcription units or into operons. Genomes of eukaryotes vary greatly in size, but there is no correlation between genome size and type of organism. Gene density also varies, but in general it is significantly less than is seen for prokaryotic genes. Eukaryotic genes are organized into single transcription units (Figures 19.5–19.7; Tables 19.2 and 19.3).

19.3 Determining the Functions of the Genes in a Genome

- The function of a protein-coding gene may be assigned by a sequence similarity search of sequence databases, by using evidence from protein structure, or by using knockout or knockdown experiments that alter the expression of a gene.
- Transcriptomics is the study at the genome level of when and where genes are transcribed. One experimental method for studying the transcription of all or many of the genes in a genome simultaneously is the DNA microarray (DNA chip); this technique can generate qualitative information about gene transcription, such as the similarities and differences in gene expression in two cell types or in two developmental stages, as well as quantitative information about the relative levels of gene transcription (Figure 19.8).
- Proteomics is the characterization of the complete set of proteins in an organism or in a particular cell type. Protein numbers, protein structures, protein functions, protein locations, and protein interactions are all topics of proteomics (Figures 19.9 and 19.10).

19.4 Genome Evolution

- Comparative genomics traces the evolution of genomes by analyzing similarities and differences in DNA sequences in the genomes of present-day organisms.
- Comparative analysis reveals how homologous protein-coding genes have evolved in groups of organisms, how regulation of gene expression has evolved through mutations in the regulatory sequences of genes, and how chromosome structure has evolved as parts of one chromosome have broken off and been attached to other chromosomes.
- New genes evolve by tandem duplication when chromosomes cross over unequally in meiosis, producing a chromosome containing two copies of the DNA coding for one or more genes (Figure 19.11). New genes evolve by dispersed duplication when transposable elements copy DNA coding for one or more genes, and insert it at another location in the genome.
- Duplicate copies of genes evolve distinct functions as different mutations occur in the two copies. Mutations in protein-coding sequences produce proteins with slightly different structures, while mutations in regulatory sequences cause the genes to be expressed in different cell types and in response to different stimuli.
- Repeated cycles of duplication followed by mutation produce multigene families, which are collections of homologous genes that code for similar but functionally distinct proteins. The largest multigene families comprise hundreds of different genes (Figure 19.12).
- Exon shuffling produces functionally novel proteins by combining parts of two or more different genes. When exons that code for one or more domains of a protein are copied from one gene and inserted into the protein-coding sequence of another gene, those domains are added to the structure of the protein coded for by that gene. Adding new domains to a protein gives the protein new molecular functionalities (Figure 19.13).

UNDERSTAND & APPLY

Test Your Knowledge

1. Why is the Solexa/Illumina DNA sequencing method faster and less expensive than the Sanger method?
   a. It sequences longer fragments of DNA.
   b. It sequences more DNA fragments at the same time.
   c. It does not require the use of fluorescent markers.
   d. It does not require amplification of DNA fragments before sequencing.
   e. It does not require the use of computer algorithms to find places where sequence fragments overlap.
2. How do pseudogenes differ from genes?
   a. They are not transcribed.
   b. They contain longer open reading frames (ORFs).
   c. They do not have introns.
   d. They use a different genetic code.
   e. Their protein-coding sequence contains more than one start codon.
3. What is the main reason that searching for open reading frames (ORFs) is more useful for annotating prokaryote protein-coding genes than it is for annotating eukaryote protein-coding genes?
   a. Eukaryote protein-coding genes contain introns.
   b. The density of protein-coding genes is much higher in eukaryote genomes.
   c. In most prokaryotes, all of the protein-coding genes are located on a single circular chromosome.
   d. Prokaryotes use a different genetic code than eukaryotes.
   e. Prokaryotic protein-coding genes are much longer than eukaryotic protein-coding genes.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

4. Which of the following is true about genome size?
   a. Bacteria have genomes that vary widely in size.
   b. The human genome is the largest among eukaryotes.
   c. Organisms with large genomes are always more complex than organisms with small genomes.
   d. As genome size increases in a lineage, the number of genes also always increases.
   e. The smallest known cellular genome is found in a species of Archaea.
5. Which of the following statements about the *E. coli* genome is false?
   a. Most of the genes are located on one circular chromosome.
   b. It has a much higher gene density than the human genome.
   c. It contains fewer genes than the human genome.
   d. All of the genes are transcribed from the same template strand of the DNA double helix.
   e. About half of the genes in the *E. coli* genome are grouped with other genes in operons.
6. Which of the following does *not* characterize the human genome?
   a. Introns occupy 20% to 25% of the genome.
   b. The protein-coding sequences occupy about 2% of the genome.
   c. About 45% of the genome consists of transposable element sequences.
   d. The genome sequence is comprised of approximately 30 million base pairs.
   e. Human cells have about 20,500 different protein-coding genes.
7. About 95% of the average human transcription unit consists of:
   a. short repeat sequences.
   b. protein-coding sequences.
   c. regulatory sequences.
   d. introns.
   e. origins of replication.
8. When the DNA sequences of two protein-coding genes are similar, but only for part of the protein-coding sequence, that suggests:
   a. the two proteins have one or more domains in common.
   b. the two proteins were produced by duplication of an ancestral gene.
   c. the two proteins perform the same function.
   d. one of the two genes is actually a pseudogene.
   e. both genes are pseudogenes.
9. When two protein-coding genes have very similar nucleotide sequences and are located right next to each other on a chromosome, we can hypothesize that:
   a. one of them is a duplicate of the other, copied by a retrotransposon.
   b. they are nonhomologous.
   c. one of them is a pseudogene.
   d. they were produced by unequal crossing-over.
   e. they are transcribed in the same cell types.
10. The proteins coded for by genes in a multigene family begin to evolve distinct functions when:
    a. gene duplication occurs.
    b. exon shuffling occurs.
    c. the genes are expressed by transcription and translation.
    d. different mutations occur in each protein-coding sequence.
    e. the two proteins evolve so they have the same three-dimensional structure.

Discuss the Concepts

1. Why are high-throughput techniques used so much in genomics research? Give examples from Chapter 19 of different uses of high-throughput techniques.
2. Why does the Sanger DNA sequencing method work best when the concentration of dideoxyribonucleotides is much less than the concentration of deoxyribonucleotides? If you wanted to adjust the reaction mixture to produce a greater number of very long complementary sequence fragments, how would you change the relative concentration of dideoxyribonucleotides, and why?
3. Which of the methods for annotating protein-coding genes would you expect to do the best job of distinguishing functioning genes from pseudogenes, and why?
4. The genome of the yeast *Saccharomyces cerevisiae* is only about 0.4% the size of the human genome, yet it contains about 30% as many genes as are in the human genome. Given that, which of the features of the human genome would you expect to find many fewer of in the yeast genome?
5. How does sequencing the genomes of a greater number of animal species help in annotating and determining the functions of human protein-coding genes?

Design an Experiment

You are studying the molecular mechanisms of sex determination in fruit flies *(Drosophila melanogaster)*. How can you determine which genes are expressed at higher levels in male *Drosophila* embryos and which genes are expressed at higher levels in female *Drosophila* embryos? Once you have identified sex-specific genes, what further experiments could you do to test what effects they have on the development of *Drosophila* sex organs?

Interpret the Data

Below is a sequence of 540 bases from a genome. What information would you use to find the beginnings and ends of open reading frames? How many open reading frames can you find in this sequence? Which open reading frame is likely to represent a protein-coding sequence, and why? Which are probably not functioning protein-coding sequences, and why? Note: for simplicity's sake, analyze only this one strand of the DNA double helix, reading from left to right, so you will only be analyzing three of the six reading frames shown in Figure 19.4.

STUDY OUTLINE

20.1 Recognition of Evolutionary Change
20.2 Darwin's Journeys
20.3 Evolutionary Biology since Darwin

Development of Evolutionary Thought

Why it matters . . . On June 18, 1858, Charles Darwin received the shock of his life. Alfred Russel Wallace, a young naturalist working in the Asian tropics, solicited Darwin's opinion of a manuscript he had written about how species change through time. Darwin quickly realized that Wallace had independently described a mechanism for biological evolution that was nearly identical to the one he had been studying for more than 20 years, but had not yet described in print.

Like researchers today, scientists in the nineteenth century had to publish their work quickly to establish the "priority" on which their scientific reputations were made. Darwin's friend and colleague, the geologist Charles Lyell, had encouraged him to publish a preliminary essay on evolution two years before Wallace's letter arrived. But Darwin procrastinated, and because Wallace was the first to prepare his work for publication, Darwin feared that history would credit the younger man with these new ideas. Despite his anxiety, Darwin forwarded Wallace's manuscript to Lyell, who passed it along to the botanist Joseph Hooker. Lyell and Hooker engineered a solution that gave credit to both men **(Figure 20.1).** On July 1, 1858, papers by Darwin and Wallace were presented to the Linnaean Society of London, a prestigious scientific organization.

Darwin worked feverishly after this harrowing experience, and his now-famous book, *On the Origin of Species by Means of Natural Selection,* was published on November 24, 1859. The first printing of 1,250 copies sold out in one day. Today, we honor

Darwin for developing the seminal idea about how biological evolution occurs and for accumulating and documenting vast quantities of evidence over decades of study.

In *The Origin,* Darwin proposed that natural mechanisms produce and transform the diversity of life on Earth. His concept of evolution still forms the unifying intellectual paradigm within which all biological research is undertaken. Even when researchers do not address explicitly evolutionary questions, their observations, theories, hypotheses, and experiments are formulated with the implicit knowledge that all forms of life are related and have evolved from ancestral forms.

Biological evolution occurs in populations when specific *processes* cause the genomes of organisms to differ from those of their ancestors. These genetic changes, and the phenotypic modifications they cause, are the *products* of evolution. By studying the products of evolution, biologists strive to understand the processes that cause evolutionary change.

The theory of evolution is so widely accepted that most people cannot think about the biological world in any other way. But the biological changes implied by Darwin's ideas and by modern evolutionary theory had not been included in earlier European worldviews.

20.1 Recognition of Evolutionary Change

The historical development of evolutionary theory is a fascinating tale of scientists struggling to reconcile evidence of change with a prevailing philosophy that change was impossible in a perfectly created universe.

Europeans Integrated Ideas from Ancient Greek Philosophy into Christian Doctrine

The Greek philosopher Aristotle (384–322 B.C.) was a keen observer of nature; he is generally considered to have been the first student of **natural history,** the branch of biology that examines the form and variety of organisms in their natural environments. Aristotle believed that both inanimate objects and living species had fixed characteristics. Careful study of their differences and similarities enabled him to create a ladder-like classification of nature, from the simplest to the most complex forms: minerals ranked below plants, plants below animals, animals below humans, and humans below the gods of the spiritual realm.

By the fourteenth century, Europeans had merged Aristotle's classification system with the biblical account of creation: each organism had been specially created by God; species could never change or become extinct; and new species could never arise. Biological research became dominated by **natural theology,** which sought to name and catalog all of God's creation. Careful study of each species would identify its position and purpose in the *Scala Naturae,* or Great Chain of Being, as Aristotle's ladder of life was called. In the eighteenth century, the Swedish botanist Carolus Linnaeus (1707–1778), who developed the science of **taxonomy,** the branch of biology that classifies organisms (see Chapter 24), undertook this important work *ad majorem Dei gloriam* ("for the greater glory of God").

Scholars also used a literal interpretation of scripture to date the time of creation precisely. By tabulating the human generations described in the Bible, they determined that the creation had occurred around 4000 B.C., making Earth a bit less than 6,000 years old—hardly old enough for much change to have taken place.

Scientists Slowly Became Aware of Change in the Natural World

Modern science came of age in the fifteenth through eighteenth centuries. The English philosopher and statesman Sir Francis Bacon (1561–1626) established the importance of observation, experimentation, and inductive reasoning. Other scientists, notably Nicolaus Copernicus (1473–1543), Galileo Galilei (1564–1642), René Descartes (1596–1650), and Sir Isaac Newton (1643–1727), proposed mechanistic theories to explain physical events. In addition, three new disciplines—biogeography, comparative morphology, and geology—promoted a growing awareness of change.

QUESTIONS ABOUT BIOGEOGRAPHY As long as naturalists encountered organisms only from Europe and surrounding lands, the task of understanding the *Scala Naturae* was manageable. But global explorations in the fifteenth through seventeenth centuries provided naturalists with thousands of unknown plants and animals from Asia, Africa, the Pacific Islands, and the Americas. Although some were similar to European species, others were new and very strange.

Studies of the world distribution of plants and animals, now called **biogeography,** raised puzzling questions. Was there no limit to the number of species created by God? Where did all these species fit in the *Scala Naturae*? If they had all been created in the Garden of Eden, why did some species have limited geographical distributions, whereas others were widespread? And why were some species found in Africa or Asia different from those found in Europe, whereas other species from far-flung locations were similar to each other **(Figure 20.2)**?

QUESTIONS ABOUT COMPARATIVE MORPHOLOGY When biologists began to compare the **morphology** (anatomical structure) of organisms, they discovered interesting similarities and differences. For example, the front legs of pigs, the flippers of dolphins, and the wings of bats differ markedly in size, shape, and function **(Figure 20.3).** But these appendages have similar locations in the animals' bodies; all are constructed of bones, muscles, and skin; and all develop similarly in the animals' embryos. If these limbs were specially created for different means of locomotion, naturalists wondered, why didn't the Creator use entirely different materials and structures for walking, swimming, and flying?

Natural theologians countered this argument by stating that the body plans were perfect, and there was no need to invent a new plan for every species. But a French scientist, George-Louis Leclerc (1707–1788), le Comte (Count) de Buffon, was still puzzled by the existence of body parts with no apparent function. For example, he noted that the feet of pigs and some other mammals have two toes that never touch the ground (pig digits 2 and 5 in Figure 20.3). If each species was anatomically perfect for its particular way of life, Buffon asked, why did useless structures exist?

Buffon proposed that some animals must have *changed* since their creation; he suggested that **vestigial structures,** the useless parts we observe today, must have functioned in ancestral organisms. Buffon offered no explanation of how functional structures became vestigial, but he clearly recognized that some species were "conceived by Nature and produced by Time."

QUESTIONS ABOUT FOSSILS By the mid-eighteenth century, geologists were mapping the stratification, or horizontal layering, of sedimentary rocks beneath the soil surface (see Figure 23.2). Different layers held different kinds of **fossils** (*fossilis* = dug up). Relatively small and simple fossils appeared in the deepest layers. Fossils in the layers above them were more complex. Those in the uppermost layers often resembled living organisms. Moreover, fossils found in any particular layer were often similar, even if they were collected from geographically separated sites. What were these fossils, and why did they vary more from one layer of rock to another than from one geographical region to another?

Some scientists suggested that fossils were the remains of extinct organisms—but natural theology did not allow extinction. Thomas Jefferson, the third president of the United States and an amateur fossil hunter, thought that fossils were the remains of species that were now extremely rare; he believed that nature could not have "permitted any one race of her animals to become extinct" or "formed any link in her great works so weak [as] to be broken." He even asked Lewis and Clark to keep an eye out for giant ground sloths, now known to be extinct, during their exploration of the Pacific Northwest.

Georges Cuvier (1769–1832), a French zoologist and a founder of comparative morphology, as well as **paleobiology** (the study of ancient organisms), realized that the layers of fossils represented organisms that had lived at successive times in the past. He suggested that the abrupt changes between geological strata marked dramatic shifts in ancient environments. Cuvier and his followers developed the theory of **catastrophism,** reasoning that each layer of fossils represented the remains of organisms that had died in a local catastrophe, such as a flood. Somewhat different species then recolonized the area, and when another catastrophe struck, they formed a different set of fossils in the next, higher layer of rock.

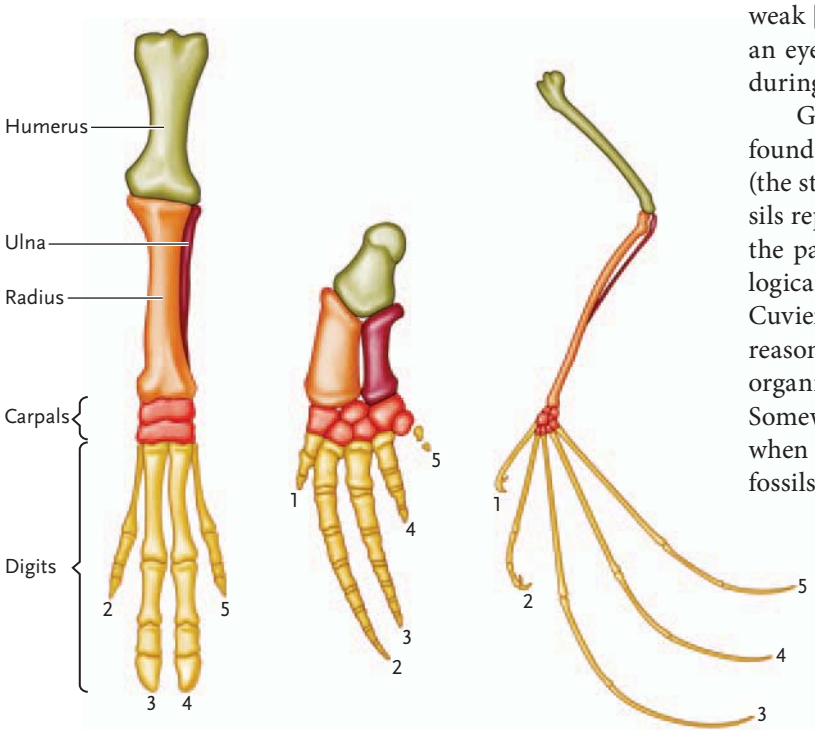

FIGURE 20.3 **Mammalian forelimbs and locomotion.** Pigs use their legs to walk or run, dolphins use their flippers to swim, and bats use their wings to fly. Homologous (equivalent) bones are pictured in the same color, and digits (fingers) are numbered; pigs have lost the first digit over evolutionary time. (Limbs are not drawn to scale.)

Lamarck Developed an Early Theory of Biological Evolution

A contemporary of Cuvier and a student of Buffon, Jean Baptiste de Lamarck (1744–1829) proposed the first comprehensive theory of biological evolution that was based on specific mechanisms. He proposed that a metaphysical "perfecting principle" caused organisms to become better suited to their environments. Simple organisms evolved into more complex ones, moving up the ladder of life, and microscopic organisms were replaced at the bottom of the ladder by spontaneous generation.

Lamarck theorized that two mechanisms fostered evolutionary change. According to his *principle of use and disuse,* body parts grow in proportion to how much they are used, as anyone who "pumps iron" well knows. Conversely, structures that are not often used get weaker and shrink, as do the muscles of an arm immobilized in a cast. According to his second principle, the *inheritance of acquired characteristics,* changes that an animal acquires during its lifetime are inherited by its offspring. Thus, Lamarck argued that long-legged wading birds, such as herons **(Figure 20.4),** are descended from short-legged ancestors that stretched their legs to stay dry while feeding in shallow water. Their offspring inherited slightly longer legs, and after many generations, their legs became extremely long.

Today, we know that Lamarck's proposed mechanisms do not cause evolutionary change. Although muscles do grow larger through continued use, most structures do not respond in the way Lamarck predicted. Moreover, structural changes acquired during an organism's lifetime are not inherited by the next generation. Even in his own day, Lamarck's ideas were not widely accepted.

© McPHOTO/AgeFotostock

FIGURE 20.4 A great blue heron *(Ardea herodias).* Like many other wading birds, herons have long, stilt-like legs. Lamarck hypothesized that as wading birds stretched their legs to keep their bodies dry while feeding, successive generations of their offspring would have progressively longer legs.

Despite the shortcomings of his theory, Lamarck made four tremendously important contributions to the development of an evolutionary worldview. First, he proposed that all species change through time. Second, he recognized that new characteristics are passed from one generation to the next. Third, he suggested that organisms change in response to their environments. And fourth, he hypothesized the existence of specific mechanisms that fostered evolutionary change. All four of these ideas became cornerstones of Darwin's evolutionary theory, although he proposed a different mechanism, natural selection, as the cause of evolutionary change. Perhaps Lamarck's most important contribution was that he fostered discussion. By the mid-nineteenth century, most educated Europeans were talking about evolutionary change, whether they believed in it or not.

Geologists Recognized That Earth Had Changed over Time

In 1795, the Scottish geologist James Hutton (1726–1797) argued that slow and continuous physical processes, *acting over long periods of time,* produced Earth's major geological features; for example, the movement of water in a river slowly erodes the land and deposits sediments near the mouth of the river. Given enough time, erosion creates deep canyons, and sedimentation creates thick topsoil on flood plains. Hutton's **gradualism,** the view that Earth changed *slowly* over its history, contrasted sharply with Cuvier's catastrophism.

The English geologist Charles Lyell (1797–1875) championed and extended Hutton's ideas in an influential series of books, *Principles of Geology.* Lyell argued that the geological processes that sculpted Earth's surface over long periods of time—such as volcanic eruptions, earthquakes, erosion, and the formation and movement of glaciers—are exactly the same as the processes observed today. This concept, called **uniformitarianism,** undermined any remaining notions of an unchanging Earth. Also, because geological processes proceed very slowly, it must have taken millions of years, not just a few thousand, to mold the landscape into its current configuration.

1. **Why did the existence of vestigial structures make Buffon question the idea that living systems never changed?**
2. **What were Lamarck's contributions to an evolutionary worldview?**
3. **How do the concepts of gradualism and uniformitarianism in geology undermine the belief that Earth is only about 6,000 years old?**

20.2 Darwin's Journeys

In 1831, in the midst of this intellectual ferment, young Charles Darwin wondered what to do with his life. Raised in a wealthy English household, he had always collected shells and studied

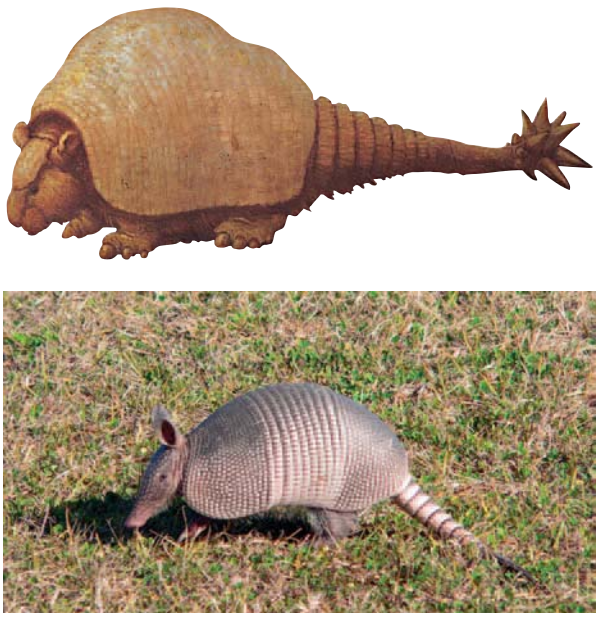
the habits of insects and birds; he preferred hunting and fishing to classical studies. Despite his lackluster performance as a student, Darwin was expected to continue the family tradition of practicing medicine. But after two years, he abandoned his medical studies at the University of Edinburgh. Instead, he followed his interest in natural history despite the objections of his father, who reputedly told him, "You care for nothing but shooting, dogs, and rat-catching and you will be a disgrace to yourself and all of your family."

At the suggestion of his father, Darwin studied for a career as a clergyman, earning a degree from Cambridge University. There, he found a mentor in the Reverend John Henslow, a leading botanist, who arranged for Darwin to travel as the captain's dining companion aboard H.M.S. *Beagle,* a naval surveying ship. Darwin thus embarked on a sea voyage and an intellectual journey that altered the foundations of modern thought.

FIGURE 20.5 **Darwin's voyage.** H.M.S. *Beagle* circumnavigated the globe between 1831 and 1836.

© Cengage Learning 2014

Darwin Saw the World on the Voyage of the *Beagle*



The *Beagle* sailed southwest to map the coastline of South America and then circumnavigated the globe **(Figure 20.5).** When the ship's naturalist quit his post mid-journey, Darwin replaced him in an unofficial capacity. For nearly five years Darwin toured the world, and because he suffered from seasickness, he seized every chance to go ashore. He collected plants and animals in Brazilian rain forests and fossils in Patagonia. He hiked the grasslands of the Pampas and climbed the Andes in Chile. Armed with Henslow's parting gift, the first volume of Lyell's *Principles of Geology,* Darwin was primed to apply gradualism and uniformitarianism to the living world.

WHAT DARWIN SAW When he began his travels, Darwin had no clue that biological evolution had produced the mind-boggling variety of species that he would encounter. Three broad sets of observations later helped him unravel the mystery of evolutionary change.

First, while exploring along the coast of Argentina, Darwin discovered fossils that often resembled organisms inhabiting the same region today. For example, despite an enormous size difference, living armadillos and fossilized glyptodonts had similar body armor, but they were unlike any other species known to science **(Figure 20.6).** If both species had been created at the same time and both were found in South America, why didn't glyptodonts live alongside armadillos? Darwin later wondered whether armadillos might be living relatives of the now-extinct glyptodonts.

Second, Darwin observed that the animals he encountered in different South American habitats clearly resembled each other, but they differed from species that occupied similar habitats in Europe. For example, he noted that nutria *(Myocastor coypus),* a semiaquatic rodent native to South America, bore a closer resemblance to other rodents from the mountains or grasslands of that continent than it did to the beaver *(Castor fiber),* a semiaquatic rodent native to Europe **(Figure 20.7).** Why did animals from markedly different South American environments resemble each other so closely? Why did animals that lived in similar environments on separate continents look so different? Darwin later understood that animals in South America resembled each other because they had inherited their similarities from a common ancestor.

Third, Darwin observed fascinating patterns in the distributions of species on the Galápagos Islands **(Figure 20.8).** There he found strange and wonderful creatures, including giant tortoises and lizards that dove into the sea to feed on algae. Darwin quickly noted that the animals on different islands varied slightly in form. Indeed, experienced sailors could easily identify a tortoise's island of origin by the shape of its shell. More-

over, many species resembled those on the distant South American mainland. Why did so many different organisms occupy one small island cluster, and why did these species resemble others from the nearest continent? Darwin later hypothesized that the plants and animals of the Galápagos Islands were descended from South American ancestors, and that each species had changed after being isolated on a particular island.

DARWIN'S REFLECTIONS AFTER HIS VOYAGE The *Beagle* returned to England in 1836, and Darwin began his first notebook on the "transmutation of species" the following year. He realized that changes in species over time provided the only plausible explanation for his observations.

A diverse group of finches from the Galápagos Islands **(Figure 20.9)** provided the single greatest spark for Darwin's work. He had noticed great variability in the shapes of their bills, but he had incorrectly assumed that birds on different islands belonged to the same species. Thus, he had not recorded the island where he had captured each specimen. Luckily, the *Beagle's* captain, Robert Fitzroy, had more thoroughly documented his own collection, allowing Darwin to study the relationships and geographical distributions of a dozen species. As Darwin re-

viewed the data, he began to focus on two aspects of a general problem. Why were the finches on a particular island slightly different from those on nearby islands, and how did all these different species arise?

Darwin Used Common Knowledge and Several Inferences to Develop His Theory

With a substantial inheritance, and burdened by chronic illness, Darwin led a reclusive life as he embarked on an intellectual journey every bit as exciting as his voyage on the *Beagle* (see *Focus on Basic Research*). His lifetime goal was to accumulate evidence of evolutionary change and identify the mechanism that caused it.

SELECTIVE BREEDING AND HEREDITY

Having grown up in the country, Darwin was well aware that "like begets like"; that is, offspring frequently resemble their parents. Plant breeders and animal breeders had applied this basic truth of inheritance for thousands of years. By selectively breeding individuals with desired characteristics, they enhanced those traits in future generations.

Farmers use selective breeding to improve domesticated plants and animals. If one cow produces more milk than any other, the farmer selectively breeds her (rather than others), hoping that her offspring will also be good milk producers. Although the mechanism of heredity was not yet understood, this principle had been applied countless times to produce bigger beets, plumper pigs, and prize-winning pigeons (see Figure 1.8). Darwin was well aware of this process, which he called **artificial selection,** but he puzzled over how it could operate in nature.

THE STRUGGLE FOR EXISTENCE

Darwin had a revelation about how selective breeding could occur naturally when he read the famous publication by Thomas Malthus, *Essay on the Principles of Population.* Malthus, an English clergyman and economist, was worried about the fate of the nation's poor. England's population was growing much faster than its agricultural capacity, and with individuals competing for limited food resources, some would inevitably starve.

Darwin applied Malthus's argument to organisms in nature. Species typically produce many more offspring than are needed to replace the parent generation, yet the world is not overrun with sunflowers, tortoises, or bears. Darwin even calculated that, if its reproduction went unchecked, a single pair of elephants, the slowest breeding animal known, would leave roughly 19 million descendants after only 750 years. Happily for us (and all other species that might get underfoot), the world is not so crowded with elephants. Instead, some members of every population survive and reproduce, whereas others die without reproducing.

DARWIN'S INFERENCES

Darwin's discovery of a mechanism for evolutionary change required him to infer the nature of a process that no one had envisioned, much less documented **(Figure 20.10).** First, individuals within populations vary in size, form, color, behavior, and other characteristics. Second, many of these variations are hereditary. What if variations in hereditary traits enabled some individuals to survive and reproduce more than others? Organisms with such advantageous traits would leave many offspring, whereas those that lacked such traits would die leaving few, if any, descendants. Thus, advantageous hereditary traits would become more common in the next generation. If the next generation was subjected to the same process of selection, the traits would be even more common in the third generation. Because this process is analogous to artificial selection, Darwin called it **natural selection.**

As an evolutionary mechanism, natural selection favors **adaptive traits,** genetically based characteristics that make or-

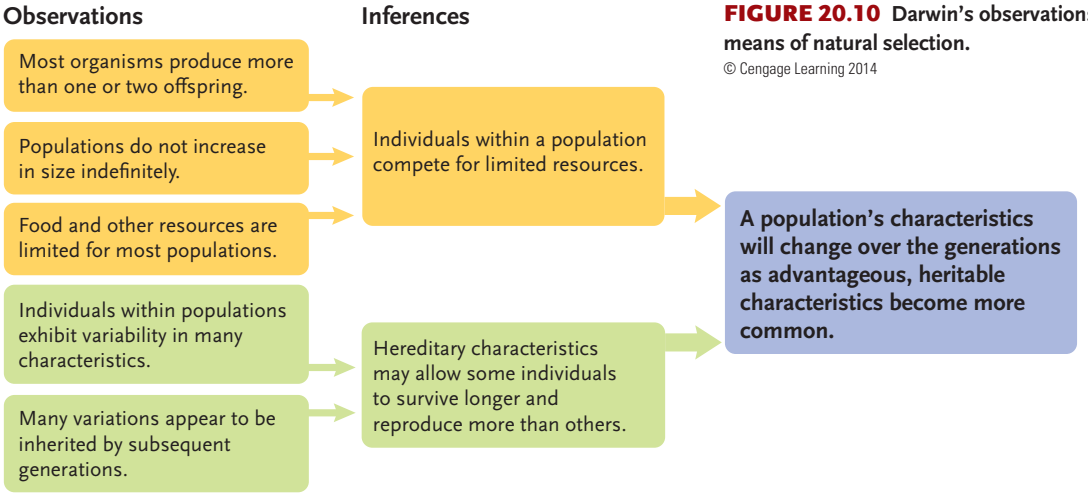

FIGURE 20.10 **Darwin's observations and inferences about evolution by means of natural selection.**

© Cengage Learning 2014

ganisms more likely to survive and reproduce. And by favoring individuals that are well adapted to the environments in which they live, natural selection causes species to change through time. As shown in Figure 20.9, each species of Galápagos finch has a distinctive bill. Variations in bill size and shape make some birds better adapted for crushing seeds and others for capturing insects. Imagine an island where large seeds were the only food available; individuals with a stout bill would be more likely to survive and reproduce than would birds with slender bills. These favored individuals would pass the genes that produce stout bills to their descendants, and after many generations, their bills might resemble those of *Geospiza magnirostris* (see Figure 20.9C). Natural selection also changes nonmorphologic characteristics of populations; for example, insect populations that are exposed to insecticides develop resistance to these toxic chemicals over time (see Figure 20.12).

Darwin realized that natural selection could also account for striking differences between populations and, given enough time, for the production of new species. For example, suppose that small insects were the only food available to finches on a different island. Birds with long, thin bills might be favored by natural selection, and the population of finches might eventually possess a bill shaped like that of *Certhidea olivacea* (see Figure 20.9A). If we apply parallel reasoning to the many characteristics that affect survival and reproduction, natural selection would cause the populations to become more different over time, a process called **evolutionary divergence.**

Darwin's Theory Revolutionized the Way We Think about the Living World

It would be hard to overestimate the impact of Darwin's theory on Western thought. In *The Origin,* Darwin proposed a logical mechanism for evolutionary change and provided enough supporting evidence to convince the educated public.

Darwin argued that all the organisms that have ever lived arose through **descent with modification,** the evolutionary alteration and diversification of ancestral species. He envisioned this pattern of descent as a tree growing through time **(Figure 20.11).** The base of the trunk represents the ancestor of all organisms. Branching points above it represent the evolutionary divergence of ancestors into their descendants. Each limb represents a body plan suitable for a particular way of life; smaller branches represent more narrowly defined groups of organisms; and the uppermost twigs represent living species. Biologists still apply this analogy today when analyzing the Tree of Life (see Figure 1.11 and Chapter 24).

Darwin proposed natural selection as the mechanism that drives evolutionary change. In fact, most of *The Origin* was an explanation of how natural selection acted on the variability within groups of organisms, preserving advantageous traits and eliminating disadvantageous ones.

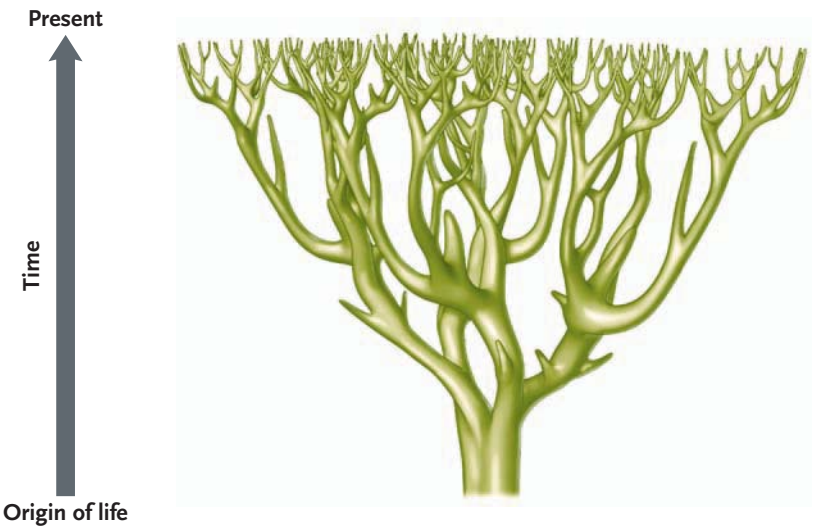

FIGURE 20.11 **The Tree of Life.** Darwin envisioned the history of life as a tree. Branching points represent the origins of new lineages; branches that do not reach the top represent extinct groups.

Charles Darwin's Life as a Scientist

Darwin's observations during the voyage of H.M.S. *Beagle* convinced him that species change through time, and that natural processes produced Earth's biodiversity. He spent the rest of his life gathering data to test his ideas and unravel the workings of natural selection.

Shortly after the *Beagle* returned to England in 1836, Darwin started to publish the geological and biological research that he had undertaken during the voyage. This task took him 10 years to complete—twice as long as the journey itself. The results of these efforts were numerous articles and several books, including the now famous *Journal of the Voyage of the Beagle,* published in 1839.

After preparing a sketch of his ideas about evolution in 1844, Darwin was puzzled by one species of barnacle, a small marine invertebrate, which he had collected in Chile. Over the next eight years he studied more than 10,000 barnacle specimens and revised their entire classification. Although colleagues viewed this study as a strange diversion from his work on evolution, the project honed Darwin's observational skills and provided a test case in which he could apply his ideas about descent with modification to a large and diverse group of organisms. He published four volumes about barnacles in 1854.

While studying barnacles, Darwin continued to think about "the species question." He kept notebooks about variation in plants and animals, focusing on variation that was amplified by selective breeding. He was a tireless collector of facts, which he sought from every possible source. He badgered dog breeders, horse farmers, and horticulturists with long lists of questions about their work. His enthusiasm was infectious, and workers throughout the world supplied him with data and specimens. Darwin was also an eager and skilled experimentalist, and he took up pigeon breeding, marveling at the huge variety of morphological traits that he and other breeders could produce. In the late 1850s, a communication from Alfred Russel Wallace (see *Why It Matters*) forced him to complete *The Origin,* which revolutionized the study of biology.

Even after *The Origin* was published, Darwin continued to gather facts and write about evolution, working almost to the day he died in 1882 at age 74. He published a detailed analysis of how earthworms improve the soil *(The Formation of Vegetable Mould through the Action of Worms)* and wrote books on several botanical topics, among them plants that eat animals *(Insectivorous Plants),* and the tendency of plants to grow toward sunlight *(The Power of Movement in Plants).* Darwin's work always had an evolutionary focus, however, and he produced several revisions of *The Origin,* as well as books on artificial selection *(Variation of Animals and Plants under Domestication),* human ancestry *(The Descent of Man),* and animal behavior *(The Expression of the Emotions in Men and Animals).*

William Perlman/Star Ledger/Corbis

Darwin's study. Darwin undertook most of his life's work in this room at Down House. He hesitated to discard old papers and specimens, believing that he would find a use for them as soon as they were carried away in the trash.

Four characteristics distinguish Darwin's theory from earlier explanations of biological diversity and adaptive traits:

1. Darwin provided purely physical, rather than spiritual, explanations for the origins of biological diversity.
2. Darwin recognized that evolutionary change occurs in groups of organisms, rather than in individuals: some members of a group survive and reproduce more successfully than others.
3. Darwin described evolution as a multistage process: variations arise within groups, natural selection eliminates unsuccessful variations, and the next generation inherits successful variations.
4. Like Lamarck, Darwin understood that evolution occurs because some organisms function better than others *in a particular environment.*

What is most amazing about Darwin's intellectual achievement is that he knew nothing about genetics (see Chapter 12). Thus, he had no clear idea of how variation arose or how it was passed from one generation to the next.

Evolution was a popular topic in Victorian England, and Darwin's theory was both praised and ridiculed. Although he had not speculated about the evolution of humans in *The Origin,* many readers were quick to extrapolate Darwin's ideas to our own species. Needless to say, certain influential Victorians were not amused by the suggestion that humans and apes share a common ancestry.

Nevertheless, Darwin's painstaking logic and careful documentation convinced most readers that evolution really does take place. Thomas Huxley, so staunch an advocate that he was known as "Darwin's bulldog," summed up the reaction of many when he quipped that the theory was so obvious, once articulated, that he was surprised he had not thought of it himself.

Darwin's vision of common ancestry quickly became the intellectual framework for nearly all biological research. Many readers, however, did not readily accept the mechanism of natural selection. The major stumbling block was that Darwin had not provided any plausible theory of heredity.

STUDY BREAK 20.2

1. What observations that Darwin made on his round-the-world voyage influenced his later thoughts about evolution?
2. How did Darwin's understanding of artificial selection enable him to envision the process of natural selection?
3. What were the four great intellectual triumphs of Darwin's theory?

THINK OUTSIDE THE BOOK

Find a copy of *On the Origin of Species by Means of Natural Selection* in a library or bookstore or online, and read a chapter or two. How did Darwin's careful observation of organisms allow him to draw conclusions? Do you think that straightforward observation still has a role in twenty-first–century science?

20.3 Evolutionary Biology since Darwin

Although Gregor Mendel published his work on genetics in 1866, it was not well known in England until 1900. At that time, scientists perceived a fundamental conflict between Darwin's and Mendel's theories. One problem was that Darwin had used complex characteristics, such as the structure of bird bills, to illustrate how natural selection worked. We now know that several genes often control such traits (see Section 12.2). By contrast, Mendel had studied simpler characteristics, such as the height of pea plants. A single gene often controls simple traits, which is one reason Mendel could interpret his experimental results so clearly. Biologists had a hard time applying Mendel's straightforward experimental results to Darwin's complex examples.

A second problem arose because Darwin believed that biological evolution occurred gradually over many generations. However, early twentieth-century geneticists, focusing on simple traits such as those Mendel had studied, sometimes observed very rapid and dramatic changes in certain characteristics. A widely accepted theory, *mutationism,* suggested that evolution occurred in spurts, induced by the chance appearance of "hopeful monsters," rather than by gradual change.

The Modern Synthesis Created a Unified Theory of Evolution

In the early twentieth century, Thomas Hunt Morgan of Columbia University discerned that genes are carried on chromosomes. His experiments, described in Chapter 13, enabled geneticists and mathematicians to forge a critical link between Darwin's and Mendel's ideas. The new discipline, **population genetics,** recognized the importance of genetic variation as the raw material of evolution. Population geneticists constructed mathematical models, which applied equally well to simple and complex traits, to predict how natural selection and other processes influence a population's genetics.

In the 1930s and 1940s, a unified theory of evolution, the **modern synthesis,** integrated data from biogeography, comparative morphology, comparative embryology, paleontology, and taxonomy within an evolutionary framework. The authors of the modern synthesis focused on evolutionary change within populations, and although they considered natural selection the primary mechanism of evolution, they acknowledged the importance of other processes. Proponents of the modern synthesis also embraced Darwin's idea of gradualism and de-emphasized the significance of mutations that changed traits suddenly and dramatically.

The modern synthesis also tried to link the two levels of evolutionary change that Darwin had identified: microevolution and macroevolution. **Microevolution** describes the small-scale genetic changes that populations undergo, often in response to shifting environmental circumstances; a small evolutionary shift in the size of the bill of a finch species is an example of microevolution (see Chapter 21). **Macroevolution** describes larger-scale evolutionary changes observed in species and more inclusive groups. According to the modern synthesis, macroevolution results from the gradual accumulation of microevolutionary changes; researchers have recently begun to unravel the genetic mechanisms that establish a relationship between these two levels of evolutionary change (see Chapter 23).

Research in Many Fields Has Provided Evidence of Evolutionary Change

Since the emergence of the modern synthesis, scientists have assembled a huge and compelling body of evidence from many biological disciplines indicating that biological evolution is a fact of life on Earth.

ADAPTATION BY NATURAL SELECTION Biologists interpret the products of natural selection as evolutionary adaptations. For example, the wings of birds, which have been modified by evolutionary processes over millions of years, have an obvious function that helps these animals survive and reproduce. In Units 5 and 6 of this book, you will encounter many examples of adaptive structures in plants and animals that have been modeled by natural selection. Sometimes, however, natural selection operates on a short time scale, as illustrated by the development of pesticide resistance in insects. When we first use a new pesticide, a low concentration often kills a large percentage of the pests. However, just by chance, a few insects may have genetic characteristics that confer resistance to the poison. These indi-

FIGURE 20.12 **Experimental Research**

How Exposure to Insecticide Fosters the Evolution of Insecticide Resistance

Question: Does exposure to insecticide foster the evolution of insecticide resistance in insect populations?

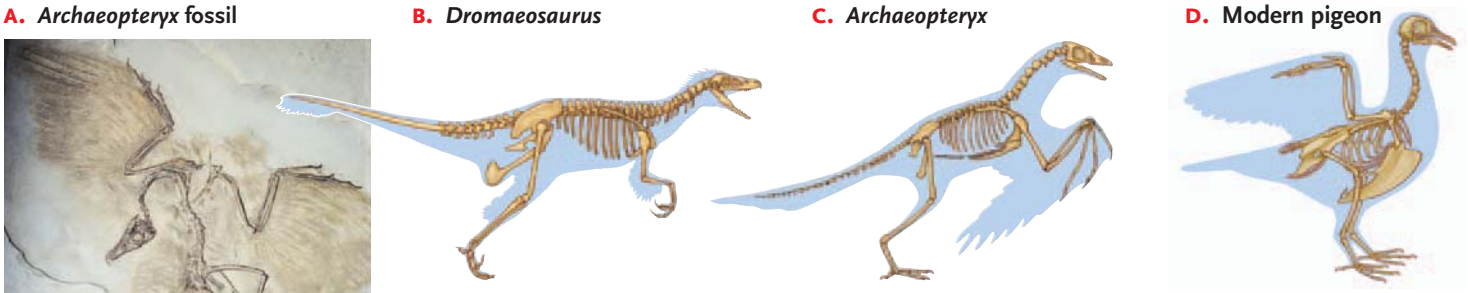
Experiment: Researchers studied samples of wild mosquitoes *(Anopheles culicifacies)* captured at a small village in India, where public health officials frequently sprayed the insecticide dichloro-diphenyl-trichloroethane (DDT) to control these pests. For each test, the researchers exposed samples of mosquitoes to a 4% concentration of DDT for 1 hour and then measured the percentage that died during the next 24 hours. Tests were repeated 12 months and 16 months after the first experiment.

Results: Over the course of the experiment, smaller and smaller percentages of the mosquitoes died after their exposure to the test concentration of the insecticide.

Conclusion: When public health officials used DDT indiscriminately, they created an environment in which natural selection favored DDT-resistant individuals. Exposure to DDT therefore fostered the evolution of an adaptive resistance to DDT in the mosquito population.

THINK LIKE A SCIENTIST What effect would the continued use of DDT be likely to have on the mosquitoes' susceptibility to that chemical?

Source: A.M. Shalaby. 1968. Susceptibility studies on *Anopheles culicifacies* with DDT and Dieldrin in Gujarat state, India. *Journal of Economic Entomology* 61:533–541.



viduals survive and produce offspring, many of which inherit the resistance. As a result, a given concentration of the poison kills a smaller percentage of insects in the next generation, and over time, the entire population may become highly resistant **(Figure 20.12).**

THE FOSSIL RECORD Because evolution results from the modification of existing species, Darwin's theory proposes that all species that have ever lived are genetically related. The fossil record documents such continuity in morphological characteristics, providing clear evidence of ongoing change in **biological lineages,** evolutionary sequences of ancestral organisms and their descendants (see Chapter 23). For example, the evolution of modern birds can be traced from a dinosaur ancestor through fossils such as *Archaeopteryx lithographica* **(Figure 20.13).** This species, discovered only two years after *The Origin* was published, resembled both dinosaurs and birds. Like the small carnivorous dinosaur *Dromaeosaurus, Archaeopteryx* walked on its hind legs and had teeth, long fingers with claws on its forelimbs, and a long, bony tail. Like modern birds, it had enlarged flight feathers on its forelimbs. Recently discovered fossils reveal that many bird ancestors were feathered (discussed further in Chapter 23).

HISTORICAL BIOGEOGRAPHY Analyses of **historical biogeography,** the study of the geographical distributions of plants and animals in relation to their evolutionary history, are generally consistent with Darwin's theory of evolution. Species on oceanic islands often closely resemble species on the nearest mainland, suggesting that the island and mainland species share a common ancestry. Moreover, species on a continental land mass are clearly related to one another and are often distinct from those on other continents. For example, monkeys in South America have long, prehensile tails and broad noses, traits that they inherited from a shared South American ancestor. By contrast, monkeys in Africa and Asia evolved from a different common ancestor in the Old World, and their shorter tails and narrower noses distinguish them from their American cousins.

COMPARATIVE MORPHOLOGY Other evidence of evolution comes from **comparative morphology,** analyses of the structure of living and extinct organisms. Such analyses are based on the comparison of **homologous traits,** characteristics that are similar in two species because they inherited the genetic basis of the trait

from their common ancestor. For example, the forelimbs of all four-legged vertebrates are homologous because they evolved from a common ancestor with a forelimb composed of the same component parts (see Figure 20.3, which shows homologous bones in the same color). Even though the shapes of the bones are different in pigs, dolphins, and bats, similarities in the three limbs are apparent. The differences in structural details arose over evolutionary time, allowing pigs to walk, dolphins to swim, and bats to fly. The arms of humans and the wings of birds are constructed of comparable elements, suggesting that they, too, share a common ancestor with the three species that are illustrated.

Molecular Techniques Extend the Achievements of the Modern Synthesis

Molecular techniques provide biologists with powerful tools for exploring all aspects of life—and evolutionary biology is no exception. In this section, we describe two examples that illustrate how molecular techniques have furthered our understanding of evolution since the modern synthesis was articulated.

HOW SNAKES LOST THEIR LEGS

From Darwin's time until the mid-twentieth century, biologists tried to discern the evolutionary history of animals by comparing their embryos and patterns of development **(Figure 20.14).** The early embryos of related species are often strikingly similar, but morphological differences appear as the embryos grow and develop their adult forms (see Chapter 50). For example, the early embryos of most four-legged vertebrates (such as lizards, mammals, and birds) develop "limb buds" from which the legs or wings typical of each species later grow. Forelimbs and their supporting structures grow at the base of the neck, just in front of the ribcage, and hindlimbs grow right behind the ribcage (Figure 20.14A). Similarities in the limb buds and the positions of the limbs in these animals provide evidence of their descent from a shared ancestor. Differences in their adult structures are caused by additional genetic instructions that have evolved over time.

However, most snakes—which are very closely related to lizards—show no traces of limbs or necks; their ribcages are positioned right behind their heads (Figure 20.14B). The fossil record shows us that snakes evolved from four-legged ancestors in stages: early snakes had small hindlimbs, and the most recently evolved snakes have no limbs at all. Only the most ancient living snakes, pythons and boas, have any traces of limbs—vestigial hindlimbs, which appear as a pair of tiny claw-like structures near the base of the tail (Figure 20.14C). Observational studies of their embryos reveal that most living snakes never develop limb buds; by contrast, pythons and boas develop hind limb buds, which grow only slightly as the animal develops.

How did pythons, and presumably all other snakes, lose their necks and forelimbs? Although many genes control the differences in the adult forelimbs among species (see Figure 20.3), research reported in the 1990s revealed that two regulatory genes, *Hoxc6* and *Hoxc8,* determine whether forelimbs or ribs grow at a particular site along an animal's backbone. The *Hox* genes either activate or suppress other genes that direct the development of these structures. Forelimbs—but not ribs—grow just in front of the tissues where only *Hoxc6* is expressed. By contrast, ribs—but not forelimbs—grow where both *Hoxc6* and *Hoxc8* are expressed. In chickens and other vertebrates with four limbs, only *Hoxc6* is expressed just in front of the ribcage, and forelimbs grow nearby (Figure 20.14D).

In 1999, Martin J. Cohn of the University of Reading and Cheryll Tickle of University College London reported that in pythons (primitive snakes), both *Hoxc6* and *Hoxc8* are expressed all along the backbone, beginning at the base of the skull; as a result, a python's ribcage develops right behind its head, and no limb buds or forelimbs develop (Figure 20.14E). Thus, snakes have no forelimbs or necks because a mutation causes the expression of *Hoxc8* to extend into a more forward region of the animal's body. All descendants of the ancestor with that original mutation now lack necks and forelimbs. Cohn and Tickle's research also suggests that the second stage in snake

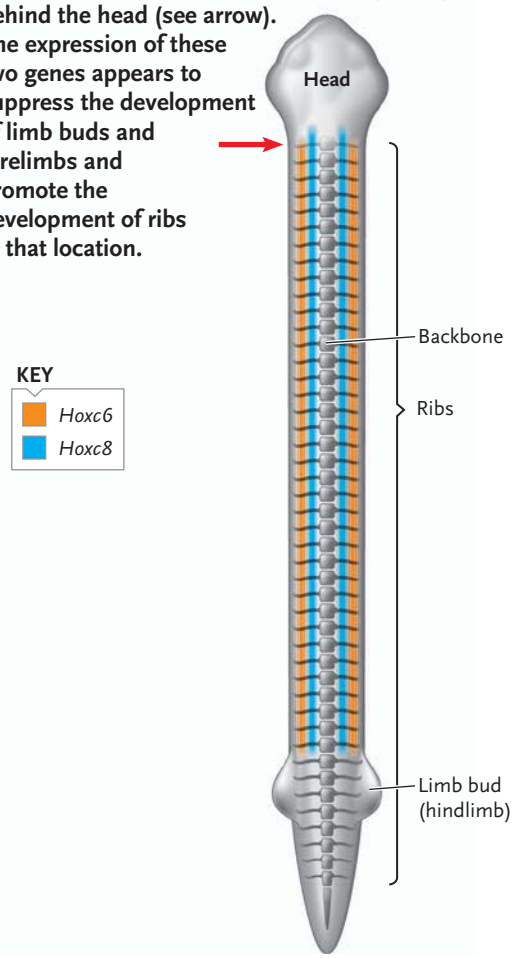
C. Some primitive snakes, like this ball python (*Python regius*), have vestigial hindlimbs, visible as a pair of claw-like mating spurs near the base of the tail.



argonaut/Shutterstock.com

D. Molecular analyses reveal that the expression of *Hoxc6*, but not *Hoxc8*, at the base of the neck in a chick embryo (see arrow) causes limb buds and forelimbs to develop nearby.

E. In pythons, both *Hoxc6* and *Hoxc8* are expressed alongside the backbone, beginning just behind the head (see arrow). The expression of these two genes appears to suppress the development of limb buds and forelimbs and promote the development of ribs at that location.

SUMMARY New molecular techniques from evolutionary developmental biology, coupled with traditional embryological observations, solved a long-standing evolutionary mystery. Evolutionary changes in the spatial pattern of gene expression caused the loss of forelimbs in snakes.

THINK LIKE A SCIENTIST This research identifies the genetic mechanism underlying the loss of forelimbs in snakes, but why might natural selection have favored this anatomical change?

© Cengage Learning 2014

evolution, the reduction or complete absence of hindlimbs, is caused by other genetic variations that appeared some time after the altered expression pattern of *Hoxc8*. Thus, molecular research has identified the genetic changes that caused snakes to lose their forelimbs and necks before losing their hindlimbs.

THE WOOLLY MAMMOTH'S CLOSEST LIVING RELATIVE Evolutionary biologists now routinely compare the genetic sequences of different species to determine their evolutionary relationships (see Chapter 24). The process is straightforward as long as researchers can collect small tissue samples from which they extract DNA. For

Asian Elephant or African Elephant: Which is the woolly mammoth's closest living relative?

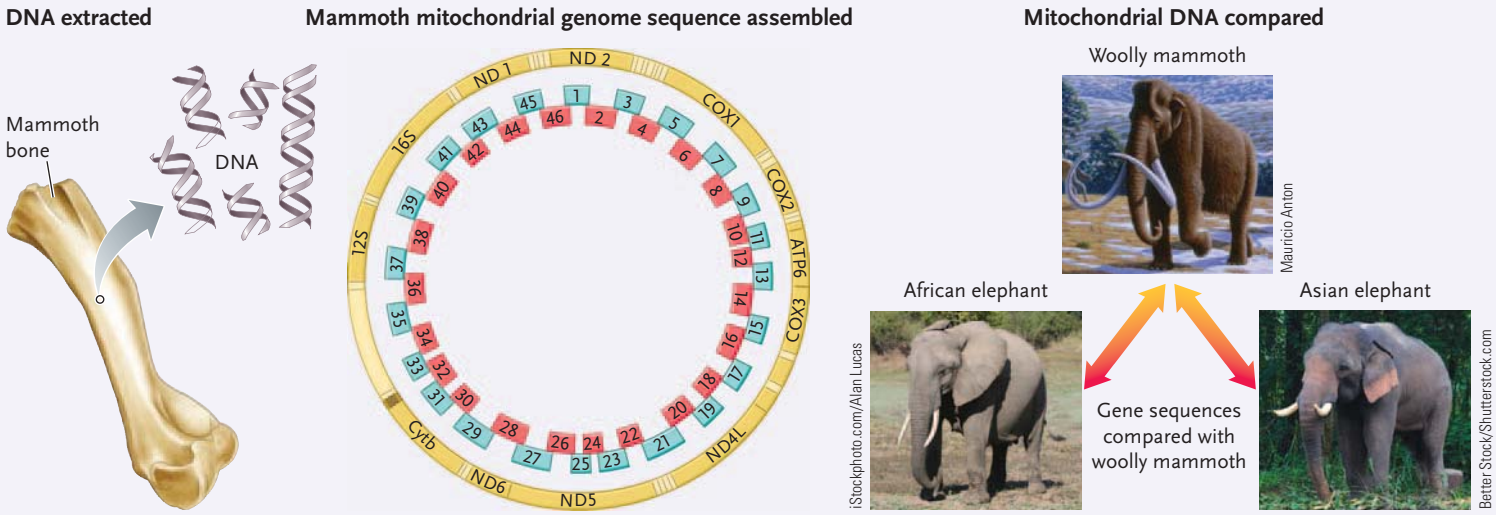
Recent technical innovations now allow biologists to extract DNA from some fossils of extinct organisms, providing answers to long-puzzling questions. Based on morphological evidence, paleobiologists suspected that woolly mammoths *(Mammuthus primigenius)* were more closely related to living Asian elephants *(Elephas maximus)* than to living African elephants *(Loxodonta africana)*. When they recovered samples of mammoth DNA, researchers knew they could settle the matter.

Research Question

Were woolly mammoths genetically more similar to Asian elephants than to African elephants?

Experiment

Svante Pääbo and his colleagues at the Max Planck Institute for Evolutionary Anthropology, Leipzig, Germany, and collaborating researchers at three other institutions in England, Germany, and the United States, used molecular techniques—specifically, PCR amplification, cloning, and sequencing of mitochondrial DNA (see Chapter 18)—to answer the question **(Figure).**



1. They extracted DNA from a mammoth bone, estimated to be between 11,900 and 13,400 years old, from Berelek, Yakutia (in Siberia).
2. Based on known mitochondrial DNA sequences from the African and Asian elephant, they designed and synthesized 46 pairs of PCR primers. Assuming homology with the elephant sequences, these primer pairs were predicted to amplify the entire circular mitochondrial genome of the mammoth (yellow circle) as overlapping DNA fragments. All of the primer pairs were used in a single PCR, and the resulting amplified DNA fragments were cloned and sequenced. Based on their overlaps, the sequences could be arranged in a circle (blue and red), which showed that the researchers had succeeded in amplifying the entire mitochondrial genome.
3. Using computer algorithms, this mitochondrial DNA was compared with the mitochondrial genomes of Asian and African elephants.

Conclusion

The mammoth DNA sequences were more similar to those from the Asian elephant than those from the African elephant. Thus, Asian elephants are the woolly mammoth's closest living relatives. This conclusion makes biogeographic sense because woolly mammoths and Asian elephants occupied the same land mass (that is, Asia), whereas African elephants live on a different continent.

THINK LIKE A SCIENTIST How does the conclusion from this experiment match some of the observations Darwin made while traveling the globe on H.M.S *Beagle*?

many years, paleobiologists could not use these techniques to determine the evolutionary relationships between extinct organisms and those living today because they could not obtain the necessary samples from fossilized material. Sequencing the DNA of extinct organisms was the "holy grail" of paleobiology.

Recent advances in molecular techniques now allow researchers to sequence DNA preserved in some fossils of extinct organisms. In a study published in 2006, Hendrick Poinar of McMaster University and colleagues at other institutions sequenced 13 million base pairs of mitochondrial and nuclear DNA extracted from the jawbone of a woolly mammoth *(Mammuthus primigenius)*, a species that has been extinct for at least 4,000 years **(Figure 20.15).** The mammoth, which died 27,000 years ago, had been preserved in a frigid Siberian ice cave. When the researchers compared its DNA sequences to those from a living African elephant *(Loxodonta africana)*, they discovered that more than 98% of the sequence was identical in the two species, confirming their close evolutionary relationship. *Insights from the Molecular Revolution* describes an-

other study, published the same year, in which several European researchers analyzed the complete mitochondrial genome sequence of a woolly mammoth and compared it to the sequences from two living elephant species.

Some People Misinterpret the Theory of Evolution

The theory of evolution has always been a contentious subject because it challenges deeply held traditional views of how living organisms originated. Many of Darwin's contemporaries were dismayed by the suggestion that all organisms share a common ancestry. Some people even misinterpreted this assertion as "humans evolved from chimpanzees or gorillas." But the theory of evolution makes no such claims. Instead, it suggests that humans and apes are descended from an apelike common ancestor (see Section 32.13). In other words, an ancient population of organisms left descendants, which now include the living species of apes, as well as our own species. Moreover, the theory recognizes that evolution is an ongoing process: humans and apes have been evolving up until this very moment and will continue to evolve for as long as their descendants persist.

Early in the twentieth century, some scientists embraced the notion of **orthogenesis,** or progressive, goal-oriented evolution. This idea, derived from the *Scala Naturae,* suggests that evolution produces new species with the goal of improvement. We now know that evolution proceeds as an ongoing process of dynamic adjustment, not toward any fixed goal. Natural selection preserves the genes of organisms that function well in particular environments, but it cannot predict future environmental change. Imagine a population of plants with genes that affect how well they function under wet versus dry conditions. After a five-year drought, the population would include mostly dry-adapted plants. If a series of wet years follows the drought, these plants will be poorly adapted to the altered conditions. The process that favored drought-adapted plants operated under the prevailing dry conditions, not in anticipation of how conditions might change in the future.

Evolution is the core theory of modern biology because its explanatory power touches on every aspect of the living world. The application of molecular techniques to the study of evolutionary biology has greatly enhanced our knowledge. In the remaining chapters of this unit, you will discover how contemporary evolutionary theory explains changes at every level of biological organization, from adaptive modifications within populations (see Chapter 21), to the evolution of new species (see Chapter 22), major patterns in the history of life (see Chapter 23), and unraveling the evolutionary history of all organisms on Earth (see Chapter 24). Moreover, we will revisit many concepts from evolutionary biology in the discussions of biodiversity, the structure and function of plants and animals, and ecology and behavior in subsequent units.

STUDY BREAK 20.3

1. What two problems slowed the acceptance of Darwin's theory among scientists?
2. What is the difference between microevolution and macroevolution?
3. What types of data provide evidence that evolution has adapted organisms to their environments and promoted the diversification of species?

THINK OUTSIDE THE BOOK

Find examples from popular publications or advertisements for consumer products that misrepresent the theory of biological evolution. Explain how the theory is misrepresented.

UNANSWERED QUESTIONS

What determines whether a species adapts to a changing environment or becomes extinct?

Natural selection has produced marvelous adaptations in every species on Earth, and we know that evolutionary adaptation to certain environmental changes has allowed many species to persist. But we also know that more than 99% of the species that have ever lived became extinct, evidently because they failed to adapt to changes in climate, natural competitors or enemies, or other environmental factors. But what kinds of genetic variation are required for adaptation, and what kinds of characteristics must evolve to allow survival? This is a critical question today, because human activities are changing environments so rapidly and drastically that many species face the threat of extinction. Can aquatic species adapt to various kinds of water pollution? Can animals and plants that lived in prairies adapt to different habitats now that most prairies have been destroyed?

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Is adaptation by natural selection responsible for most of the genetic differences between species?

New genetic variations sometimes become more common within populations or species because the proteins for which they code are advantageous and preserved by natural selection. But biologists who study molecular evolution have discovered that a large part of the genome in most organisms (about 98% of the human genome, for example) does not code for proteins and therefore appears to have no function. If this observation is generally correct, why do the noncoding parts of genomes exist? Are evolutionary changes in noncoding regions and the differences in noncoding sequences among species adaptive? For example, only about 1% of the DNA base pairs differ between human and chimpanzee genomes—but this amounts to about 34 million base-pair differences altogether, at least 60,000 of which alter the amino acid sequences of proteins. How can we determine which of these differences are adaptive and which differences underlie the unique characteristics of humans?

How do pathways of embryonic development evolve?

The characteristics of adult organisms are the product of developmental events, starting with the fertilized egg, that include growth in size, changes in the shape of various body parts, and the differentiation of cell types. These processes are largely controlled by genes, with input from the environment. Although biologists are beginning to learn how the genetic foundations of developmental processes evolve, many questions remain. For example, how do genetic changes induce differences in the branching patterns of antlers among species of deer, or differences in the length of the tails of monkeys and apes (including humans), or differences in the number and size of scales among species of lizards? We know that the proteins forming the lens of the eye are actually enzymes that play different roles in other cells, and that they have been "recruited" to form the lens, but what mechanisms induce them to assume this new role? And why do different enzymes form the lenses in eyes of birds and mammals? Evolutionary developmental biology, which is discussed in Chapter 23, is one of the most active, exciting fields in biology at this time.

THINK LIKE A SCIENTIST As our production of carbon dioxide increases Earth's average temperature faster than ever before, will Arctic species be able to adapt to changes in climate?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

20.1 Recognition of Evolutionary Change

- Ancient Greek philosophers classified the natural world, ranking inanimate objects and living organisms from simple to complex.
- Natural theologians believed that all species were specially created and perfectly adapted; that existing species do not change or become extinct; and that new species do not arise. Studies in biogeography, comparative morphology, and paleontology led scientists to question whether species change through time (Figures 20.2 and 20.3).
- Lamarck proposed that species evolved into more complex forms that functioned better in their environments. He hypothesized that structures in an organism changed when they were used, and that those changes were inherited by the organism's offspring (Figure 20.4). Experiments have refuted Lamarck's proposed mechanisms.
- Two geologists, Hutton and Lyell, recognized that major features on Earth were created by the long-term action of the very slow geological processes that scientists observe today. Their insights suggested that Earth was much older than natural theologians had supposed.

Animation: Evolution of limb bones

20.2 Darwin's Journeys

- Darwin's observations during his voyage on the *Beagle* provided much of the data and inspiration for the development of his theory of evolution (Figures 20.5–20.8).
- Darwin based the theory of evolution by means of natural selection on three inferences: (1) individuals within a population compete for limited resources, (2) hereditary characteristics allow some individuals to survive longer and reproduce more than others, and (3) a population's characteristics change over time as advantageous heritable characteristics become more common (Figure 20.10).
- Darwin also proposed that the accumulation of differences fostered by natural selection could cause populations to diverge over time. Such evolutionary divergence can lead to the production of new species, which can, in turn, give rise to new evolutionary lineages (Figures 20.9 and 20.11).

Animation: Finches of the Galápagos

Animation: The Galápagos Islands

20.3 Evolutionary Biology since Darwin

- Scientists working in population genetics developed theories of evolutionary change by integrating Darwin's ideas with Mendel's research on genetics.
- In the 1930s and 1940s, the modern synthesis provided a unified view of evolution that drew on studies from many biological disciplines. It emphasized evolution within populations, the central role of variation in the evolutionary process, and the gradualism of evolutionary change.
- Studies of adaptation, the fossil record, historical biogeography, and comparative morphology provide compelling evidence of evolutionary change (Figures 20.12 and 20.13).
- Molecular techniques have extended the achievements of the modern synthesis, allowing precise analysis of the genetic basis of evolutionary change (Figure 20.14) and the genetic relatedness of living and extinct organisms (Figure 20.15).

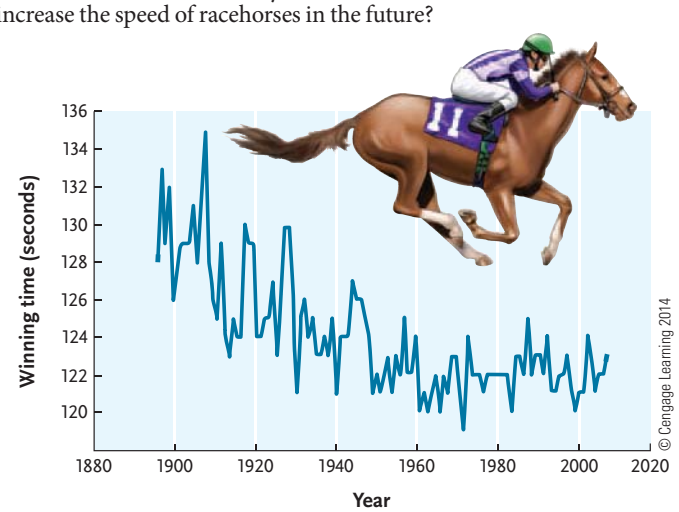
UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following statements about evolutionary studies is *not* true?
   a. Biologists study the products of evolution to understand the processes causing it.
   b. Biologists design molecular experiments to examine evolutionary processes operating over short time periods.
   c. Biologists study the inheritance of characteristics that a parent acquired during its lifetime.
   d. Biologists study variation in homologous structures among related organisms.
   e. Biologists examine why a huge variety of species may inhabit a small island cluster.
2. Which of the following ideas is *not* included in Darwin's theory?
   a. All organisms that have ever existed arose through evolutionary modifications of ancestral species.
   b. The great variety of species alive today resulted from the diversification of ancestral species.
   c. Natural selection drives some evolutionary change.
   d. Natural selection preserves advantageous traits.
   e. Natural selection eliminates adaptive traits.
3. The "father" of taxonomy is:
   a. Charles Darwin.
   b. Charles Lyell.
   c. Alfred Wallace.
   d. Carolus Linnaeus.
   e. Jean Baptiste de Lamarck.
4. The wings of birds, the legs of pigs, and the flippers of dolphins provide examples of:
   a. vestigial structures.
   b. homologous structures.
   c. acquired characteristics.
   d. artificial selection.
   e. uniformitarianism.
5. Which of the following statements is *not* compatible with Darwin's theory?
   a. All organisms have arisen by descent with modification.
   b. Evolution has altered and diversified ancestral species.
   c. Evolution occurs in individuals rather than in groups.
   d. Natural selection eliminates unsuccessful variations.
   e. Evolution occurs because some individuals function better than others in a particular environment.
6. Which of the following does *not* contribute to the study of evolution?
   a. population genetics
   b. inheritance of acquired characteristics
   c. the fossil record
   d. DNA sequencing
   e. comparative morphology
7. Which of the following could be an example of microevolution?
   a. a slight change in a bird population's color due to a small genetic change in the population
   b. large differences between fossils found near the ground surface and those found in deep rock layers
   c. the sudden disappearance of an entire genus
   d. the direct evolutionary link between living primates and humans
   e. a flood that drowns all members of a population
8. Which of the following ideas proposed by Lamarck was *not* included in Darwin's theory?
   a. Organisms change in response to their environments.
   b. Changes that an organism acquires during its lifetime are passed to its offspring.
   c. All species change with time.
   d. New variations may be passed from one generation to the next.
   e. Specific mechanisms cause evolutionary change.
9. Medical advances now allow many people who suffer from genetic diseases to survive and reproduce. These advances:
   a. refute Darwin's theory.
   b. support Lamarck's theory.
   c. disprove descent with modification.
   d. reduce the effects of natural selection.
   e. eliminate adaptive traits.
10. The belief that evolution is progressive or goal-oriented is called:
    a. gradualism.
    b. uniformitarianism.
    c. taxonomy.
    d. orthogenesis.
    e. the modern synthesis.

Discuss the Concepts



1. Explain why the characteristics we see in living organisms adapt them to the environments in which their ancestors lived rather than to the environments in which they live today.
2. Imagine a population of mice that includes both brown and black individuals. They live in a habitat with brown soil, where predatory hawks can see black mice more easily than they can see brown ones. Design a study that would allow you to determine whether the brown mice are better adapted to this environment than the black mice.

Design an Experiment

Design an experiment to test Lamarck's hypothesis that characteristics acquired during an organism's lifetime are inherited by their offspring. (You may wish to review the components of a well-designed experiment in Chapter 1 before formulating your answer.) Can you think of examples of acquired characteristics that are *not* inherited by offspring?

Interpret the Data

For centuries, animal breeders have used artificial selection to increase the speed of racehorses. The results of such efforts are illustrated in a graph that identifies how quickly winning horses ran the 1 1/4 mile track at the Kentucky Derby, a famous race held annually at Churchill Downs, Kentucky. (The time it takes a horse to run a track of fixed length is inversely proportional to the horse's speed.) Based on the data in the graph, has artificial selection increased the speed of horses consistently between 1900 and 2000? Do you think that artificial selection can increase the speed of racehorses in the future?

Apply Evolutionary Thinking

Identify three discoveries or inventions that have changed how humans are affected by natural selection. Describe in detail how each discovery influences survival or reproduction in our species.

21.5 Adaptation and Evolutionary Constraints

Microevolution: Genetic Changes within Populations

Why it matters . . . On November 28, 1942, at the height of American involvement in World War II, a disastrous fire killed more than 400 people in Boston's Cocoanut Grove nightclub. Many more would have died later but for a new experimental drug, penicillin. A product of *Penicillium* mold, penicillin fought the usually fatal infections of *Staphylococcus aureus,* a bacterium that enters the body through damaged skin. Penicillin was the first antibiotic drug based on a naturally occurring substance that kills bacteria.

Until the disaster at the Cocoanut Grove, the production and use of penicillin had been a closely guarded military secret. But after its public debut, the pharmaceutical industry hailed penicillin as a wonder drug, promoting its use for the treatment of the many diseases caused by infectious microorganisms. Penicillin became widely available as an over-the-counter remedy, and Americans dosed themselves with it, hoping to cure all sorts of ills **(Figure 21.1).** But in 1945, Sir Alexander Fleming, the scientist who discovered penicillin, predicted that some bacteria could survive low doses, and that the offspring of those germs would be more resistant to its effects. In 1946—just four years after penicillin's use in Boston—14% of the *Staphylococcus* strains isolated from patients in a London hospital were resistant. By 1950, more than half the strains were resistant.

Scientists have discovered numerous antibiotics since the 1940s, and many strains of bacteria have developed resistance to these drugs. In fact, according to the Centers for Disease Control and Prevention, between 30,000 and 40,000 Americans die each year from infections caused by antibiotic-resistant bacteria.

How do bacteria become resistant to antibiotics? The genomes of bacteria—like those of all other organisms—vary among individuals, and some bacteria have genetic traits that allow them to withstand attack by antibiotics. When we administer antibiotics to an infected patient,

FIGURE 21.1 Selling penicillin. This ad, from a 1944 issue of *Life* magazine, credits penicillin with saving the lives of wounded soldiers.

we create an environment favoring bacteria that are even slightly resistant to the drug. The surviving bacteria reproduce, and resistant microorganisms—along with the genes that confer antibiotic resistance—become more common in later generations. In other words, bacterial strains adapt to the presence of antibiotics in their environment through the evolutionary process of selection. Our use of antibiotics is comparable to artificial selection by plant and animal breeders (see Chapter 20), but when we use antibiotics, we inadvertently select for the success of the organisms we are trying to eradicate.

The evolution of antibiotic resistance in bacteria is an example of **microevolution,** which is a heritable change in the genetics of a population. A **population** of organisms includes all the individuals of a single species that live together in the same place and time. Today, when scientists study microevolution, they analyze variations—the differences between individuals—in natural populations and determine how and why these variations are inherited. Darwin recognized the importance of heritable variation within populations; he also realized that natural selection can change the pattern of variation in a population from one generation to the next. Scientists have since learned that microevolutionary change results from several processes, not just natural selection, and that sometimes these processes counteract each other.

In this chapter, we first examine the extensive variation that exists within natural populations. We then take a detailed look at the most important processes that alter genetic variation within populations, causing microevolutionary change. Finally, we consider how microevolution can fine-tune the functioning of populations within their environments.

21.1 Variation in Natural Populations

In some species, individuals vary dramatically in appearance, but in most species, the members of a population look pretty much alike **(Figure 21.2).** However, even those that look alike, such as the *Cerion* snails on the right in Figure 21.2, are not identical. With a scale and ruler, you could detect differences in their weight as well as in the length and diameter of their shells. With suitable techniques, you could also document variations in their individual biochemistry, physiology, internal anatomy, and behavior. All of these are examples of **phenotypic variation,** differences in appearance or function that are passed from generation to generation.

Evolutionary Biologists Describe and Quantify Phenotypic Variation

Darwin's theory recognized the importance of heritable phenotypic variation, and today, microevolutionary studies often begin by assessing phenotypic variation within populations. Most characters exhibit **quantitative variation:** individuals differ in small, incremental ways. If you weighed everyone in your biology class, for example, you would see that weight varies almost continuously from your lightest to your heaviest classmate. Humans also exhibit quantitative variation in the length of their toes, the number of hairs on their heads, and their height, as discussed in Section 12.2.

We usually display data on quantitative variation in a bar graph or, if the sample is large enough, as a curve **(Figure 21.3).** The width of the curve is proportional to the variability—the

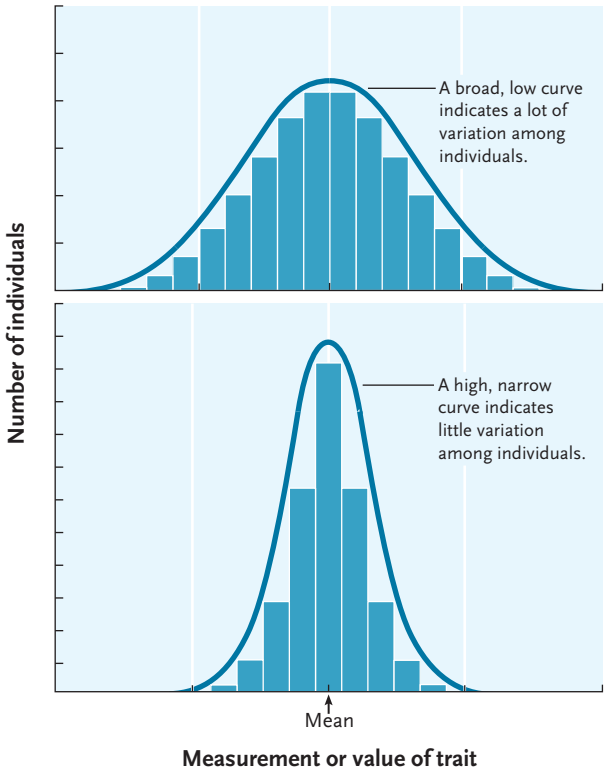

FIGURE 21.3 **Quantitative variation.** Many traits vary continuously among members of a population, and a bar graph of the data often approximates a bell-shaped curve. The mean defines the average value of the trait in the population, and the width of the curve is proportional to the variability among individuals.

© Cengage Learning 2014

amount of variation—among individuals, and the *mean* describes the average value of the character. As you will see shortly, natural selection often changes the mean value of a character or its variability within populations.

Other characters, like those Mendel studied (see Section 12.1), exhibit **qualitative variation:** they exist in two or more discrete states, and intermediate forms are often absent. Snow geese, for example, have *either* blue *or* white feathers **(Figure 21.4).** The existence of discrete variants of a character is called a **polymorphism** (*poly* = many, *morphos* = form); we describe such traits as *polymorphic*. The *Cepaea nemoralis* snail shells in Figure 21.2A are polymorphic in background color, number of stripes, and color of stripes. Biochemical polymorphisms, like the human A, B, AB, and O blood types (described in Section 12.2), are also common.

We describe phenotypic polymorphisms quantitatively by calculating the percentage or *frequency* of each trait. For example, if you counted 123 blue snow geese and 369 white ones in a population of 492 geese, the frequency of the blue phenotype would be 123/492 or 0.25, and the frequency of the white phenotype would be 369/492 or 0.75.

FIGURE 21.4 **Qualitative variation.** Individual snow geese *(Chen caerulescens)* are either blue or white. Although both colors are present in many populations, geese tend to associate with others of the same color.

Phenotypic Variation Can Have Genetic and Environmental Causes

Phenotypic variation within populations may be caused by genetic differences between individuals, by differences in the environmental factors that individuals experience, or by an interaction between genetics and the environment. As a result, genetic and phenotypic variations may not be perfectly correlated. Under some circumstances, organisms with different genotypes exhibit the same phenotype. For example, the black coloration of some rock pocket mice from Arizona is caused by certain mutations in the *Mc1r* gene (see Section 1.2); but black rock pocket mice from New Mexico do not share those mutations—that is, they have different genotypes—even though they exhibit the same phenotype. Conversely, organisms with the same genotype sometimes exhibit different phenotypes. For example, the acidity of soil influences flower color in some plants **(Figure 21.5).**

Knowing whether phenotypic variation is caused by genetic differences, environmental factors, or an interaction of the two is important because *only genetically based variation is subject to evolutionary change.* Moreover, knowing the causes of phenotypic variation has important practical applications. Suppose, for

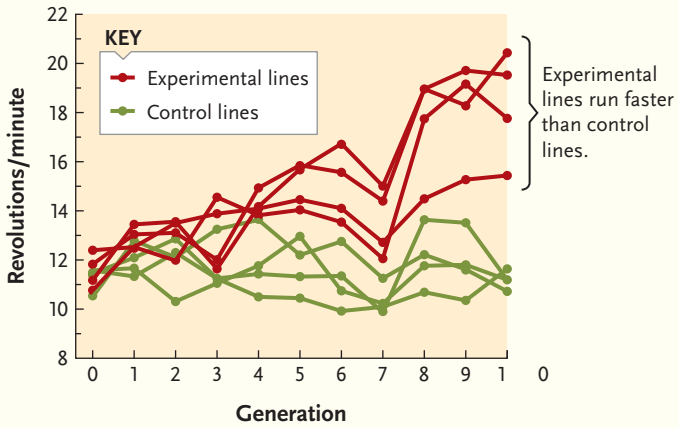
Using Artificial Selection to Demonstrate That Activity Level in Mice Has a Genetic Basis

Question: Do observed differences in activity level among house mice have a genetic basis?



Experiment: Swallow, Carter, and Garland knew that a phenotypic character responds to artificial selection only if it has a genetic, rather than an environmental, basis. In an experiment with house mice *(Mus domesticus)*, they selected for the phenotypic character of increased wheel-running activity. In four experimental lines, they bred those mice that ran the most. Four other lines, in which breeders were selected at random with respect to activity level, served as controls.

Results: After 10 generations of artificial selection, mice in the experimental lines ran longer distances and ran faster than mice in the control lines. Thus, artificial selection on wheel-running activity in house mice increased **(A)** the distance that mice run per day and **(B)** their average speed. The data illustrate responses of females in four experimental lines and four control lines. Males showed similar responses.

A. Distance run

B. Average speed

With kind permission from Springer Science+Business Media: J. G. Swallow, P. A. Carter, and T. Garland, Jr. 1998. Artificial selection for increased wheel-running behavior in house mice. *Behavior Genetics* 28:227–237.

Conclusion: Because the two measures of activity level responded to artificial selection, researchers concluded that variation in this behavioral character has a genetic basis.

THINK LIKE A SCIENTIST Do the data presented in the graphs suggest that continued artificial selection would further increase the distance that the experimental lines run or their average speed?

Source: J. G. Swallow, P. A. Carter, and T. Garland, Jr. 1998. Artificial selection for increased wheel-running behavior in house mice. *Behavior Genetics* 28:227–237.

example, that one field of wheat produced more grain than another. If a difference in the availability of nutrients or water caused the difference in yield, a farmer might choose to fertilize or irrigate the less productive field. But if the difference in productivity resulted from genetic differences between plants in the two fields, a farmer might plant only the more productive genotype. Because environmental factors can influence the expression of genes, an organism's phenotype is frequently the product of an interaction between its genotype and its environment. In our hypothetical example, the farmer may maximize yield by fertilizing and irrigating the more productive genotype of wheat.

How can we determine whether phenotypic variation is caused by environmental factors or by genetic differences? We can test for an environmental cause experimentally by changing one environmental variable and measuring the effects on genetically similar subjects. You can try this yourself by growing some cuttings from an ivy plant in shade and other cuttings from the same plant in full sun. Although they all have the same genotype, the cuttings grown in sun will produce smaller leaves and shorter stems.

Breeding experiments can demonstrate the genetic basis of phenotypic variation. For example, Mendel inferred the genetic basis of qualitative traits, such as flower color in peas, by crossing plants with different phenotypes. Although simple crosses will not reveal the genetic basis of variations in quantitative traits, these characteristics will respond to artificial selection if the variation has some genetic basis. For example, researchers observed that individual house mice *(Mus domesticus)* differ in activity levels, as measured by how much they use an exercise wheel and how fast they run. John G. Swallow and his colleagues at the University of Wisconsin, Madison, used artificial selection to produce lines of mice that exhibit increased wheel-running behavior, demonstrating that the observed differences in these two aspects of activity level have a genetic basis **(Figure 21.6).**

Breeding experiments are not always practical, however, particularly for organisms with long generation times. Ethical concerns also render these techniques unthinkable for humans. Instead, researchers sometimes study the inheritance of particular traits by analyzing genealogical pedigrees, as discussed in Section 13.2, but this approach often provides poor results for analyses of complex traits.

Several Processes Generate Genetic Variation

Genetic variation, the raw material molded by microevolutionary processes, has two potential sources: the production of new alleles and the rearrangement of existing alleles. Most new alleles probably arise from small-scale mutations in DNA (described later in this chapter). The rearrangement of existing alleles into new combinations can result from larger scale changes in chromosome structure or number and from several forms of genetic recombination, including crossing over between homologous chromosomes during meiosis, independent assortment of nonhomologous chromosomes during meiosis, and random fertilizations between genetically different sperm and eggs.

The shuffling of *existing* alleles into new combinations can produce an extraordinary number of novel genotypes in the next generation. By one estimate, more than 10^{600} combinations of alleles are possible in human gametes, yet there are fewer than 10^{10} humans alive today. So unless you have an identical twin, it is extremely unlikely that another person with your genotype has ever lived or ever will.

Populations Often Contain Substantial Genetic Variation

How much genetic variation actually exists within populations? In the 1960s, evolutionary biologists began to use gel electrophoresis (see Figure 18.7) to identify biochemical polymorphisms in diverse organisms. This technique separates two or more forms of a given protein if they differ significantly in shape, mass, or net electrical charge. The identification of a protein polymorphism allowed researchers to infer genetic variation at the locus coding for that protein. This approach revealed much more genetic variation in natural populations than anyone had imagined. For example, nearly half the loci surveyed in many populations of plants and invertebrates are polymorphic. Advances in molecular biology now allow scientists to survey genetic variation directly, and researchers have accumulated an astounding knowledge of the structure of DNA and its nucleotide sequences. In general, studies of chromosomal and mitochondrial DNA suggest that every locus exhibits some variability in its nucleotide sequence among individuals from a single population, between populations of the same species, and between related species. However, some variations detected in the protein-coding regions of DNA may not affect phenotypes because, as explained in Section 15.1, they do not change the amino acid sequences of the proteins for which the genes code.

STUDY BREAK 21.1

1. If a population of skunks includes some individuals with stripes and others with spots, would you describe the variation as quantitative or qualitative?
2. In the experiment on house mice described in Figure 21.6, how did researchers demonstrate that variations in activity level had a genetic basis?
3. What factors contribute to phenotypic variation in a population?

THINK OUTSIDE THE BOOK

Go to a local park, field, or woodland and choose a population of plants or animals to observe. Make a list of the characteristics that show phenotypic variation in this population, describe their patterns of variation, and identify whether each characteristic exhibits quantitative or qualitative variation.

21.2 Population Genetics

To predict how certain factors may influence genetic variation, population geneticists first describe the genetic structure of a population. They then create hypotheses, formalized in mathematical models, to describe how evolutionary processes may change the genetic structure under specified conditions. Finally, researchers test the predictions of these models to evaluate the ideas about evolution that are embodied within them.

All Populations Have a Genetic Structure

Populations are made up of individuals, each with its own genotype. In diploid organisms, which have pairs of homologous chromosomes, an individual's genotype includes two copies of every gene. The sum of all gene copies at all gene loci in all individuals is called the population's **gene pool.**

To describe the structure of a gene pool, scientists first identify the genotypes in a representative sample and calculate **genotype frequencies,** the percentages of individuals possessing each genotype. Knowing that each diploid organism has two copies of each gene (either two copies of the same allele or two different alleles), a scientist can then calculate **allele frequencies,** the relative abundances of the different alleles. For a gene with two alleles, scientists use the symbol p to identify the frequency of one allele, and q the frequency of the other.

The calculation of genotype and allele frequencies for the two alleles at the gene locus governing flower color in snapdragons (genus *Antirrhinum*) is straightforward **(Table 21.1).** This locus is easy to study because it exhibits incomplete dominance (see Section 12.2). Individuals that are homozygous for the C^R allele (C^RC^R) have red flowers; those homozygous for the C^W allele (C^WC^W) have white flowers; and heterozygotes (C^RC^W) have pink flowers. Genotype frequencies represent how the C^R and C^W alleles are distributed among individuals. In this example, examination of the plants reveals that 45% of individuals have the C^RC^R genotype, 50% have the heterozygous C^RC^W genotype, and

TABLE 21.1 Calculation of Genotype Frequencies and Allele Frequencies for the Snapdragon Flower Color Locus

Because each diploid individual has two alleles at each gene locus, the entire sample of 1,000 individuals has a total of 2,000 alleles at the *C* locus.

Flower Color Phenotype	Genotype	Number of Individuals	Genotype Frequency[1]	Total Number of C^R Alleles[2]	Total Number of C^W Alleles[2]
Red	C^RC^R	450	450/1,000 = 0.45	2 × 450 = 900	0 × 450 = 0
Pink	C^RC^W	500	500/1,000 = 0.50	1 × 500 = 500	1 × 500 = 500
White	C^WC^W	50	50/1,000 = 0.05	0 × 50 = 0	2 × 50 = 100
	Total	1,000	0.45 + 0.50 + 0.05 = 1.0	1,400	600

Calculate allele frequencies using the total of 1,400 + 600 = 2,000 alleles in the sample:

p = frequency of C^R allele = 1,400/2,000 = 0.7

q = frequency of C^W allele = 600/2,000 = 0.3

$p + q = 0.7 + 0.3 = 1.0$

[1]Genotype frequency = the number of individuals possessing a particular genotype divided by the total number of individuals in the sample.

[2]Total number of C^R or C^W alleles = the number of C^R or C^W alleles present in one individual with a particular genotype multiplied by the number of individuals with that genotype.

© Cengage Learning 2014

the remaining 5% have the C^WC^W genotype. Allele frequencies represent the commonness or rarity of each allele in the gene pool. As calculated in the table, 70% of the alleles in the population are C^R and 30% are C^W. Remember that for a gene locus with two alleles, there are three genotype frequencies, but only two allele frequencies (p and q). The sum of the three genotype frequencies must equal 1; so must the sum of the two allele frequencies.

The Hardy–Weinberg Principle Is a Null Model That Defines How Evolution Does Not Occur

When designing experiments, scientists often use control treatments to evaluate the effect of a particular factor: the control tells us what we would see if the experimental treatment had no effect. As you may recall from the hypothetical example presented in Chapter 1 (see Figure 1.15), to determine whether fertilizer has an effect on plant growth, you must compare the growth of fertilized plants (the experimental treatment) to the growth of plants that received no fertilizer (the control treatment). However, in studies that use observational rather than experimental data, there is often no suitable control. In such cases, investigators develop conceptual models, called **null models,** which predict what they would see if a particular factor had no effect. Null models serve as theoretical reference points against which observations can be evaluated.

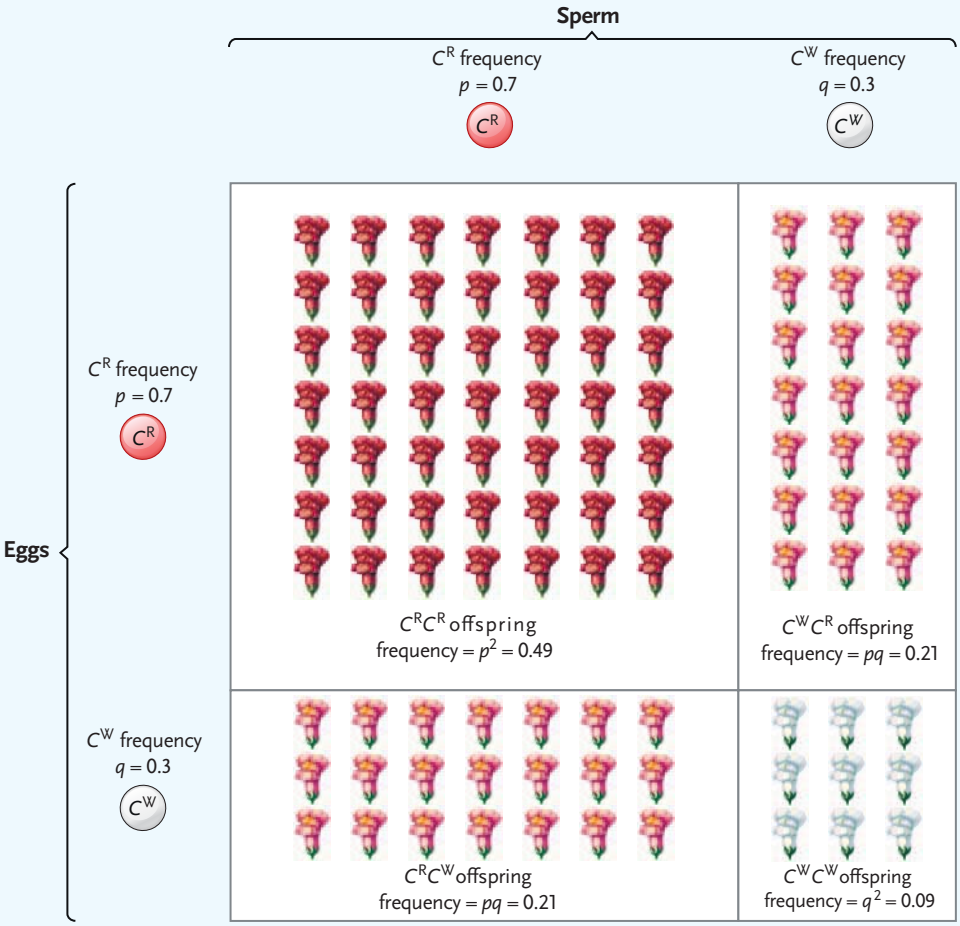
Early in the twentieth century, geneticists were puzzled by the persistence of recessive traits because they assumed that natural selection replaced recessive or rare alleles with dominant or common ones. An English mathematician, G. H. Hardy, and a German physician, Wilhelm Weinberg, tackled this problem independently in 1908. Their analysis, now known as the **Hardy–Weinberg principle,** specifies the conditions under which a population of diploid organisms achieves **genetic equilibrium,** the point at which neither allele frequencies nor genotype frequencies change in succeeding generations. Their work also showed that dominant alleles need not replace recessive ones, and that the shuffling of genes in sexual reproduction does not in itself cause the gene pool to change.

The Hardy–Weinberg principle describes how genotype frequencies are established in sexually reproducing organisms. According to this mathematical model, genetic equilibrium is possible only if *all* of the following conditions are met:

1. No mutations are occurring.
2. The population is closed to migration from other populations.
3. The population is infinitely large.
4. All genotypes in the population survive and reproduce equally well.
5. Individuals in the population mate randomly with respect to genotypes.

If the conditions of the model are met, the allele frequencies of the population will never change, and the genotype frequencies will stop changing after one generation. In short, under these restrictive conditions, microevolution will *not* occur (see *Focus on Basic Research* on pp. 462–463). The Hardy–Weinberg principle is thus a null model that serves as a reference point for evaluating the circumstances under which evolution *may* occur.

If a population's genotype frequencies do not match the predictions of this model or if its allele frequencies change over time, microevolution may be occurring. Determining which of the model's conditions are *not* met is a first step in understanding how and why the gene pool is changing.



STUDY BREAK 21.2

1. **What is the difference between the genotype frequencies and the allele frequencies in a population?**
2. **Why is the Hardy–Weinberg principle considered a null model of evolution?**
3. **If the conditions of the Hardy–Weinberg principle are met, when will genotype frequencies stop changing?**

Using the Hardy–Weinberg Principle

To see how the Hardy–Weinberg principle can be applied, we will analyze the snapdragon flower color locus, using the hypothetical population of 1,000 plants described in Table 21.1. This locus includes two alleles—C^R (with its frequency designated as p) and C^W (with its frequency designated as q)—and three genotypes—homozygous C^RC^R, heterozygous C^RC^W, and homozygous C^WC^W. Table 21.1 lists the number of plants with each genotype: 450 have red flowers (C^RC^R), 500 have pink flowers (C^RC^W), and 50 have white flowers (C^WC^W). It also shows the calculation of both the genotype frequencies (C^RC^R = 0.45, C^RC^W = 0.50, and C^WC^W = 0.05) and the allele frequencies (p = 0.7 and q = 0.3) for the population.

Let's assume for simplicity that each individual produces only two gametes and that both gametes contribute to the production of offspring. This assumption is unrealistic, of course, but it meets the Hardy–Weinberg requirement that all individuals in the population contribute equally to the next generation. In each parent, the two alleles segregate and end up in different gametes:

450 C^RC^R individuals produce → 900 C^R gametes

500 C^RC^W individuals produce → 500 C^R gametes + 500 C^W gametes

50 C^WC^W individuals produce → 100 C^W gametes

© Cengage Learning 2014

21.3 The Agents of Microevolution

A population's allele frequencies will change over time if one or more conditions of the Hardy–Weinberg model are violated. In this section, we describe the processes that foster microevolutionary change—mutation, gene flow, genetic drift, natural selection, and nonrandom mating—which are summarized in **Table 21.2.**

Mutations Create New Genetic Variations

A **mutation** is a spontaneous and heritable change in DNA. Mutations are rare events: roughly one gamete in 100,000 to one in 1 million will include a new mutation at a particular gene locus. New mutations are so infrequent, in fact, that they exert little or no immediate effect on allele frequencies in most populations. But over evolutionary time scales, their numbers are significant—mutations have been accumulating in biological lineages for billions of years. And because it creates entirely new genetic variations, *mutation is a major source of heritable variation.*

For most animals, only mutations in the germ line (the cell lineage that produces gametes) are heritable; mutations in other cell lineages have no direct effect on the next generation. In plants, however, mutations may occur in meristem cells, which eventually produce flowers as well as nonreproductive structures (see Chapter 33); in such cases, a mutation may be passed to the next generation and ultimately influence the gene pool.

Deleterious mutations alter an individual's structure, function, or behavior in harmful ways. In mammals, for example, a protein called collagen is an essential component of most extracellular structures. Several simple mutations in humans cause forms of Ehlers–Danlos syndrome, a disruption of collagen synthesis that may result in loose skin, weak joints, or sudden death from the rupture of major blood vessels, the colon, or the uterus.

Lethal mutations can cause great harm to organisms carrying them. If a lethal allele is dominant, both homozygous and

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

You can readily see that 1,400 of the 2,000 total gametes carry the C^R allele and 600 carry the C^W allele. The frequency of C^R gametes is 1,400/2,000 or 0.7, which is equal to *p;* the frequency of C^W gametes is 600/2,000 or 0.3, which is equal to *q*. Thus, the allele frequencies in the gametes are exactly the same as the allele frequencies in the parent generation—it could not be otherwise because each gamete carries one allele at each locus.

Now assume that these gametes, both sperm and eggs, encounter each other at random. In other words, individuals reproduce without regard to the genotype of a potential mate. We can visualize the process of random mating in the mating table on the left.

We can also describe the consequences of random mating—$(p + q)$ sperm fertilizing $(p + q)$ eggs—with an equation that predicts the genotype frequencies in the offspring generation:

$$(p + q) \times (p + q) = p^2 + 2pq + q^2$$

If the population is at genetic equilibrium for this locus, p^2 is the predicted frequency of the C^RC^R genotype; $2pq$, the predicted frequency of the C^RC^W genotype; and q^2, the predicted frequency of the C^WC^W genotype. Using the gamete frequencies determined above, we can calculate the predicted genotype frequencies in the next generation:

frequency of $C^RC^R = p^2 = (0.7 \times 0.7) = 0.49$

frequency of $C^RC^W = 2pq = 2(0.7 \times 0.3) = 0.42$

frequency of $C^WC^W = q^2 = (0.3 \times 0.3) = 0.09$

Notice that the predicted genotype frequencies in the offspring generation have changed from the genotype frequencies in the parent generation: the frequency of heterozygous individuals has decreased, and the frequencies of both types of homozygous individuals have increased. This result occurred because the starting population was *not in equilibrium* at this gene locus. In other words, the distribution of parent genotypes did not conform to the predicted $p^2 + 2pq + q^2$ distribution.

The 2,000 gametes in our hypothetical population produced 1,000 offspring. Using the genotype frequencies we just calculated, we can predict how many offspring will carry each genotype:

490 red (C^RC^R)
420 pink (C^RC^W)
90 white (C^WC^W)

In a real study, we would examine the offspring to see how well their numbers match these predictions.

What about the allele frequencies in the offspring? The Hardy–Weinberg principle predicts that they did not change. Let's calculate them and see. Using the method shown in Table 21.1 and the prime symbol (′) to indicate offspring allele frequencies:

$p' = ([2 \times 490] + 420)/2{,}000 = 1{,}400/2{,}000 = 0.7$

$q' = ([2 \times 90] + 420)/2{,}000 = 600/2{,}000 = 0.3$

You can see from this calculation that the allele frequencies did not change from one generation to the next, even though the alleles were rearranged to produce different proportions of the three genotypes. Thus, the population is now at genetic equilibrium for the flower color locus; neither the genotype frequencies nor the allele frequencies will change in succeeding generations as long as the population meets the conditions specified in the Hardy–Weinberg model.

To verify this, you can calculate the allele frequencies of the gametes for this offspring generation and predict the genotype frequencies and allele frequencies for a third generation. You could continue calculating until you ran out of either paper or patience, but these frequencies will not change.

Researchers use calculations like these to determine whether an actual population is near its predicted genetic equilibrium for one or more gene loci. When they discover that a population is not at equilibrium, they infer that microevolution is occurring and can investigate the factors that might be responsible.

heterozygous carriers will, by definition, die from its effects; if recessive, it kills only homozygous recessive individuals. Any lethal mutation that causes an individual to die before it reproduces is eliminated from the population.

Neutral mutations are neither harmful nor helpful. Because of the degeneracy of the genetic code, several codons with different nucleotides in the third position may specify the same amino acid in the construction of a polypeptide chain (see Section 15.1). As a result, some DNA sequence changes—especially those in the third nucleotide of the codon—do not alter the amino acid sequence of the protein under construction. Not surprisingly, mutations at the third position appear to persist longer in populations than those at the first two positions. In other instances, mutations that change the amino acid sequence in a protein or even an organism's phenotype may have no influence on its survival and reproduction. A neutral mutation might even prove to be beneficial later if the environment changes.

Sometimes a change in DNA produces an *advantageous mutation,* which confers some benefit on an individual that carries it. However slight the advantage, natural selection may preserve the new allele and even increase its frequency over time. Once the mutation has been passed to a new generation, other agents of microevolution determine its long-term fate.

Gene Flow Introduces Novel Genetic Variants into Populations

Organisms or their gametes (for example, pollen) sometimes move from one population to another. If the immigrants reproduce, they may introduce novel alleles into a population, shifting its allele and genotype frequencies away from the values predicted by the Hardy–Weinberg model. This phenomenon, called **gene flow,** violates the Hardy–Weinberg requirement that populations must be closed to migration.

TABLE 21.2 Agents of Microevolutionary Change

Agent	Definition	Effect on Genetic Variation
Mutation	Heritable change in DNA	Introduces new genetic variation into population; does not change allele frequencies quickly
Gene flow	Change in allele frequencies as individuals join a population and reproduce	May introduce genetic variation from another population
Genetic drift	Random changes in allele frequencies caused by chance events	Reduces genetic variation, especially in small populations; can eliminate rare alleles
Natural selection	Differential survivorship or reproduction of individuals with different genotypes	One allele can replace another or allelic variation can be preserved
Nonrandom mating	Choice of mates based on their phenotypes and genotypes	Does not directly affect allele frequencies, but usually prevents genetic equilibrium

FIGURE 21.7 Gene flow. Blue jays *(Cyanocitta cristata)* serve as agents of gene flow for oaks (genus *Quercus*) when the birds carry acorns from one oak population to another. An uneaten acorn may germinate and contribute to the gene pool of the population into which it was carried.

Gene flow is common in some animal species. For example, young male baboons typically move from one local population to another after experiencing aggressive behavior by older males. And many marine invertebrates disperse long distances as larvae carried by ocean currents.

Dispersal agents, such as pollen-carrying wind or seed-carrying animals, are responsible for gene flow in most plant populations. For example, blue jays foster gene flow among populations of oaks by carrying acorns from nut-bearing trees to their winter caches, which may be as much as a mile away **(Figure 21.7).** Transported acorns that go uneaten may germinate and contribute to the gene pool of a neighboring oak population.

The movement of individuals from one population to another is not sufficient to foster gene flow between two populations. The immigrants must also reproduce in the population they join, thereby contributing to its gene pool. In the San Francisco Bay area, for example, Bay checkerspot butterflies *(Euphydryas editha bayensis)* rarely move from one population to another because they are poor fliers (see Figure 52.19). But when adult females do change populations, it is often late in the breeding season, and their offspring have virtually no chance of finding enough food to mature. Thus, many immigrant females do not foster gene flow because they do not contribute to the gene pool of the population they join.

The evolutionary importance of gene flow depends on the degree of genetic differentiation between populations and the rate of gene flow between them. If two gene pools are very different, a little gene flow may increase genetic variability within the population that receives immigrants, and it will make the two populations more similar. But if populations are already genetically similar, even lots of gene flow will have little effect.

Genetic Drift Reduces Genetic Variability within Populations

Chance events sometimes cause the allele frequencies in a population to change unpredictably. This phenomenon, known as **genetic drift,** has especially dramatic effects on small populations, which clearly violate the Hardy–Weinberg assumption of infinitely large population size.

A simple analogy clarifies why genetic drift is more pronounced in small populations than in large ones. When individuals reproduce, male and female gametes often pair up randomly, as though the allele in any particular sperm or ovum was determined by a coin toss. Imagine that "heads" specifies the *R* allele and that "tails" specifies the *r* allele. If the two alleles are equally common (that is, their frequencies, *p* and *q*, are both equal to 0.5), heads should be as likely an outcome as tails. But if you toss the coin 20 or 30 times to simulate random mating in a small population, you won't often see a 50:50 ratio of heads and tails. Sometimes heads will predominate and sometimes tails will—just by chance. Tossing the coin 500 times to simulate random mating in a somewhat larger population is more likely to produce a 50:50 ratio of heads and tails. And if you tossed the coin 5,000 times, you would get even closer to a 50:50 ratio.

Chance deviations from expected results—which cause genetic drift—occur whenever organisms engage in sexual reproduction, simply because their population sizes are not infinitely large. But genetic drift is particularly common in small

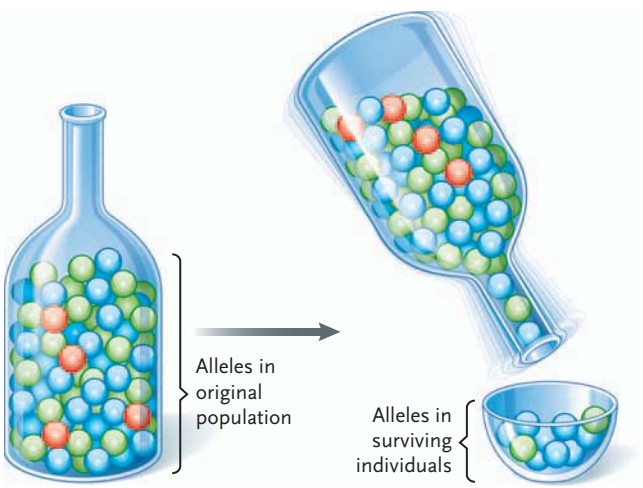
populations because only a few individuals contribute to the gene pool and because any given allele may be present in very few individuals.



Genetic drift generally leads to the loss of alleles and reduced genetic variability; it therefore causes allele and genotype frequencies to differ from those predicted by the Hardy–Weinberg model. Two general circumstances, population bottlenecks and founder effects, often foster genetic drift.

POPULATION BOTTLENECKS On occasion, a stressful factor such as disease, starvation, or drought kills a large proportion of the individuals in a population, producing a **population bottleneck,** a dramatic reduction in population size. This cause of genetic drift greatly reduces genetic variation even if the population numbers later rebound **(Figure 21.8).**

In the late nineteenth century, for example, hunters nearly wiped out northern elephant seals *(Mirounga angustirostris)* along the Pacific coast of North America. Since the 1880s, when the species received protected status, the population has increased to more than 30,000, all descended from a group of about 20 survivors. Today the population exhibits no variation in 24 proteins studied by gel electrophoresis. This low level of genetic variation, which is unique among seal species, is consistent with the hypothesis that genetic drift eliminated many alleles when the population experienced the bottleneck.

FOUNDER EFFECT When a few individuals colonize a distant locality and start a new population, they carry only a small sample of the parent population's genetic variation. By chance, some alleles may be totally missing from the new population, whereas other alleles that were rare "back home" might occur at relatively high frequencies. This change in the gene pool is called the **founder effect.**

The human medical literature provides some of the best-documented examples of the founder effect. The Old Order Amish, an essentially closed religious community in Lancaster County, Pennsylvania, have an exceptionally high incidence of Ellis–van Creveld syndrome, a genetic disorder caused by a recessive allele. In the homozygous state, the allele produces dwarfism, shortened limbs, and polydactyly (extra fingers). Genetic analysis suggests that, although this syndrome affects less than 1% of the Amish in Lancaster County, as many as 13% may be heterozygous carriers of the allele. All of the individuals exhibiting the syndrome are descended from one couple who helped found the community in the mid-1700s.

The gene pool of the original population, represented by a bottle filled with colored marbles, includes a locus with three alleles. Two of the alleles, represented by blue and green marbles, occur at high frequency; the third allele, represented by red marbles, occurs at low frequency.

If an environmental event randomly kills a large number of individuals in the population, the drastic reduction in population size is described as a population bottleneck. The process is analogous to shaking only a few of the marbles—the survivors—through the neck of the bottle. As a consequence of chance events associated with population bottlenecks, surviving individuals may not have the same allele frequencies as the original population. Rare alleles are inevitably lost.

FIGURE 21.8
Population bottlenecks, genetic drift, and the loss of genetic variability.

CONSERVATION IMPLICATIONS Genetic drift has important implications for conservation biology. By definition, endangered species experience severe population bottlenecks, which result in the loss of genetic variability. Moreover, the small number of individuals available for captive breeding programs may not fully represent a species' genetic diversity. Without such variation, no matter how large a population may become in the future, it will be less resistant to diseases or less able to cope with environmental change.

For example, scientists believe that an environmental catastrophe produced a bottleneck in the African cheetah *(Acinonyx jubatus)* population 10,000 years ago. Cheetahs today are remarkably uniform in genetic make-up. Their populations are highly susceptible to diseases; males also have a high proportion of sperm cell abnormalities and a reduced reproductive capacity. Thus, limited genetic variation, as well as small numbers, threatens populations of endangered species. *Insights from the Molecular Revolution* describes techniques used to determine whether hunting has had the same effect on humpback whales.

Natural Selection Shapes Genetic Variability by Favoring Some Traits over Others

The Hardy–Weinberg model requires all genotypes in a population to survive and reproduce equally well. But as you know from reading Section 20.2, heritable traits enable some individuals to survive better and reproduce more than others. **Natural selection** is the process by which such traits become more common in subsequent generations. Thus, natural selection violates a requirement of the Hardy–Weinberg equilibrium and causes allele and genotype frequencies to differ from those predicted by the model.

Although natural selection can change allele frequencies in a population, *it is the phenotype of an individual organism, rather than any particular allele, that is successful or not.* When individuals survive and reproduce, their alleles—both favorable and unfavorable—are passed to the next generation. Of course, an organism with harmful or lethal dominant al-

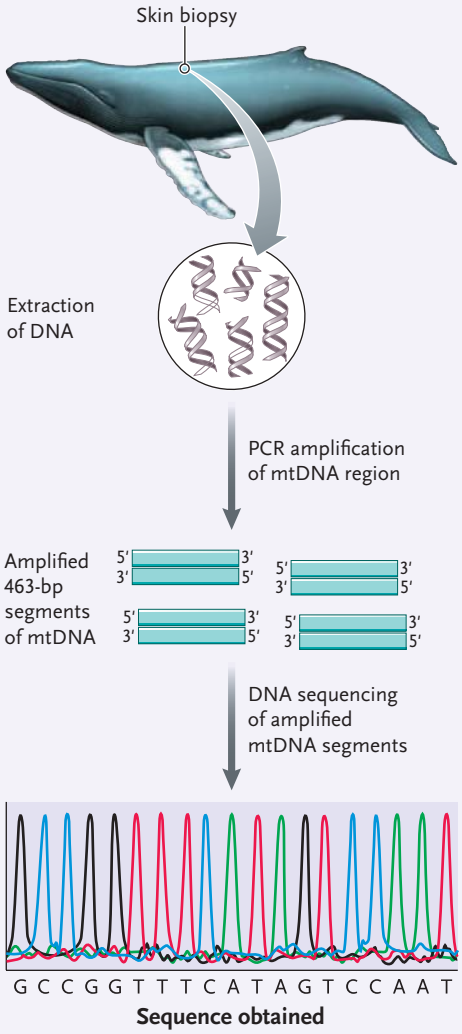
Back from the Brink: Did humpback whales lose genetic variability when they squeezed through a population bottleneck?



As a result of more than 250 years of commercial whaling, humpback whales *(Megaptera novaeangliae)* experienced a disastrous population decline—from about 125,000 to 5,000 individuals. After an international agreement limited whaling in 1966, humpbacks have rebounded strongly; about 80,000 individuals now form three distinct populations in the North Atlantic, North Pacific, and Southern oceans. Yet, conservation biologists wondered if the population bottleneck may have reduced their genetic variability. Such a loss could have adverse effects on the population's reproductive capacity, resistance to disease, and ability to survive unfavorable environmental changes.

Research Question

Do populations of humpback whales exhibit reduced genetic variability as a result of the population bottleneck they experienced before 1966?

Experiment

In the early 1990s, about 25 years after the ban on whaling took effect, a large group of researchers working in Hawaii, the continental United States, Australia, South Africa, Canada, Mexico, and the Dominican Republic measured genetic variability in surviving humpback populations. They studied mitochondrial DNA (mtDNA) because it is small, easily extracted and identified, and almost all of its variability comes from chance mutations that occur at a steady rate (rather than from genetic recombination; see Section 13.5). Except for variations produced by mutation that occurred after the population bottleneck—which can be estimated from the mutation rate and subtracted from the total variation detected—the variability in mtDNA should reflect the level present in the population during the bottleneck.

The researchers used biopsy darts to obtain skin samples from 90 humpback whales distributed among the three populations. They extracted DNA from each sample and used the polymerase chain reaction (PCR; see Figure 18.6) to amplify a 463-base pair segment of mtDNA that includes most of the variable nucleotide positions. They then determined the DNA sequences of the PCR products. (DNA sequencing is described in Section 19.2.)

Results

The researchers were surprised to find that the mtDNA sequence variation was relatively high in most of their sample. However, a subpopulation of the North Pacific population near Hawaii showed no variability at all in the mtDNA segment examined. One possible hypothesis for this result is that the Hawaiian subpopulation originated recently, perhaps during the twentieth century. There is indirect support for that idea: whaling records from the nineteenth century list no humpback sightings around Hawaii, and the native Hawaiian people have no legends or words describing whales of the humpback type (baleen whales). Perhaps the Hawaiian subpopulation was started by a few whales with limited genetic variability, an example of the founder effect.

Conclusion

With the exception of this Hawaiian subpopulation, humpback whales appear to have retained genetic variability comparable to that seen in other animals. Humpbacks have a potential life span of about 50 years. Thus, some individuals still alive at the time of the study had been born before the most intense period of commercial hunting in the mid-twentieth century; those individuals provided a reservoir of genetic variability from the old populations. These results suggest that the hunting ban came just in time to prevent a significant loss of genetic variability in humpback whales.

THINK LIKE A SCIENTIST If the ban on whaling had taken effect in 2000 instead of 1966, how much genetic variability do you think we would find in populations of humpback whales today?

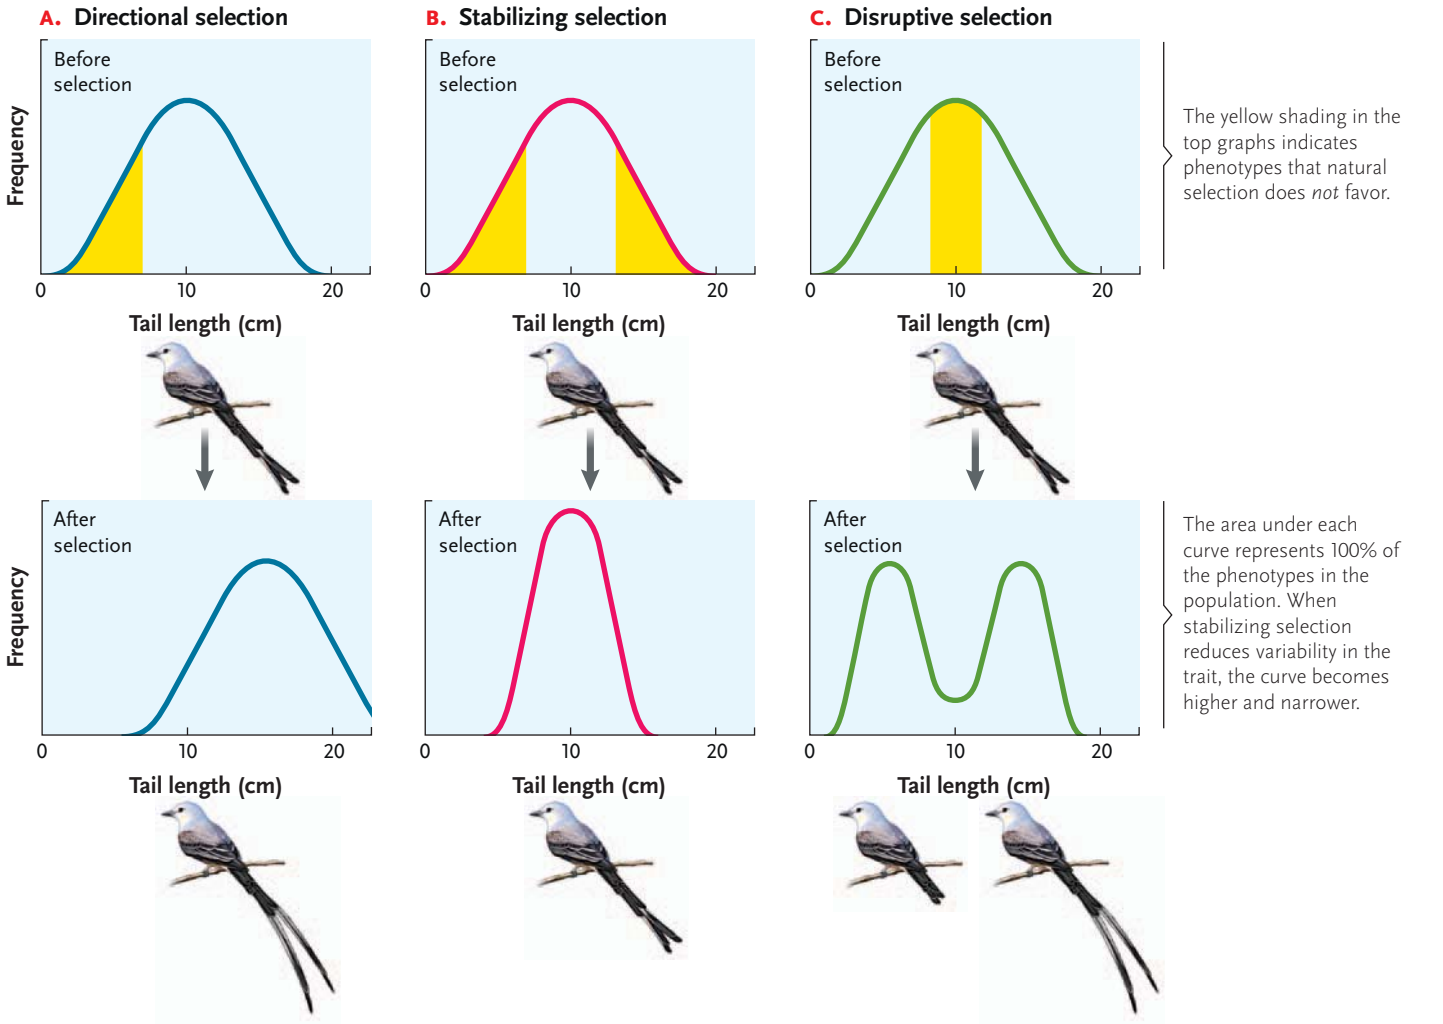
leles will probably die before reproducing, and all the alleles it carries will share that unhappy fate, even those that are advantageous.



To evaluate reproductive success, evolutionary biologists consider **relative fitness,** the number of surviving offspring that an individual produces compared with the number left by others in the population. Thus, a particular allele will increase in frequency in the next generation if individuals carrying that allele leave *more* offspring than individuals carrying other alleles. Differences in the *relative* success of individuals are the essence of natural selection.

Natural selection tests fitness differences at nearly every stage of an organism's life cycle. One plant may be fitter than others in the population because its seeds survive colder conditions, be-

CLOSER LOOK **FIGURE 21.9 Three modes of natural selection.**

A hypothetical example using tail length of birds as the quantitative trait subject to selection.

SUMMARY Directional selection shifts the mean phenotype toward the end of the distribution favored by natural selection. After selection has operated, the average tail length in the population has increased.

Stabilizing selection favors the mean phenotype over extreme phenotypes. After selection has operated, the mean tail length has not changed, but the variability in tail length among individuals in the population has decreased.

Disruptive selection decreases the frequency of the mean phenotype, but increases the frequencies of extreme phenotypes. After selection, the mean tail length may be unchanged, but the variability in tail length among individuals has increased.

THINK LIKE A SCIENTIST

cause the arrangement of its leaves captures sunlight more efficiently, or because its flowers are more attractive to pollinators. However, natural selection exerts little or no effect on traits that appear during an individual's postreproductive life. For example, Huntington disease, a dominant-allele disorder that first strikes humans after the age of 40, is not subject to strong selection. Carriers of the disease-causing allele can reproduce before the onset of the condition, passing it to the next generation.

Biologists measure the effects of natural selection on phenotypic variation by recording changes in the mean and variability of characters over time (see Figure 21.3). Three modes of natural selection have been identified: directional selection, stabilizing selection, and disruptive selection **(Figure 21.9).**

DIRECTIONAL SELECTION Traits undergo **directional selection** when individuals near one end of the phenotypic spectrum have the highest relative fitness. Directional selection shifts a trait away from the existing mean and toward the favored extreme (see Figure 21.9A). After selection, the trait's mean value is higher or lower than before, and variability in the trait may be reduced.

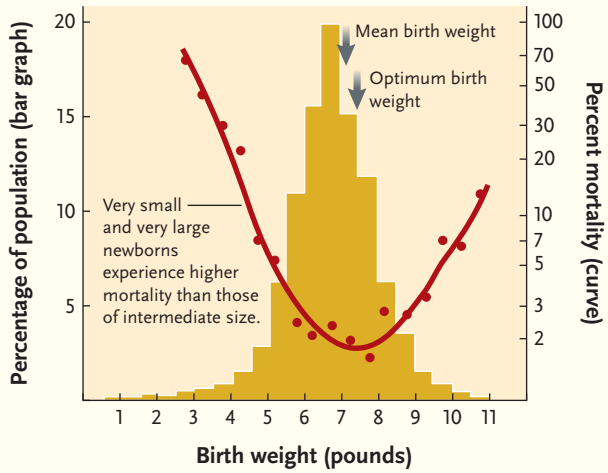
FIGURE 21.10 **Observational Research**



Do Humans Experience Stabilizing Selection?

Hypothesis: Human birth weight has been adjusted by natural selection.

Null Hypothesis: Natural selection has not affected human birth weight.

Method: Geneticists Luigi Cavalli-Sforza and Sir Walter Bodmer of Stanford University collected data on the variability in human birth weight, a character exhibiting quantitative variation, and on the mortality rates of babies born at different weights. They then searched for a relationship between birth weight and mortality rate by plotting both data sets on the same graph. A lack of correlation between birth weight and mortality rate would support the null hypothesis.

Results: When birth weight (the bar graph) and mortality rate (the curve) are plotted together, the mean birth weight is seen to be very close to the optimum birth weight (the weight at which mortality is lowest). The two data sets also show that few babies are born at the very low weights and very high weights associated with high mortality.

L. L. Cavalli-Sforza and W. F. Bodmer. 1971. *The Genetics of Human Populations.* Freeman, San Francisco. Reprinted by permission of John Wiley and Sons.

Conclusion: The shapes and positions of the birth weight bar graph and the mortality rate curve suggest that stabilizing selection has adjusted human birth weight to an average of 7 to 8 pounds.

THINK LIKE A SCIENTIST Having multiple births (that is, carrying three or more children in the same pregnancy) is historically very rare in humans. Why might natural selection have selected against a genetic predisposition for multiple births?

Source: L. L. Cavalli-Sforza and W. F. Bodmer. 1971. *The Genetics of Human Populations.* Freeman, San Francisco.

Directional selection is extremely common. For example, predatory fish promote directional selection for larger body size in guppies when they selectively feed on the smallest individuals in a guppy population (see *Focus on Basic Research* in Chapter 52). And most cases of artificial selection, including the experiment on the activity levels of house mice described above, are directional, aimed at increasing or decreasing specific phenotypic traits. Humans routinely use directional selection to produce domestic animals and crops with desired characteristics, such as the small size of Chihuahuas and the intense "bite" of chili peppers.

STABILIZING SELECTION Traits undergo **stabilizing selection** when individuals expressing intermediate phenotypes have the highest relative fitness (see Figure 21.9B). By eliminating phenotypic extremes, stabilizing selection reduces genetic and phenotypic variation and increases the frequency of intermediate phenotypes. Stabilizing selection is probably the most common mode of natural selection, affecting many familiar traits. For example, very small and very large human newborns are less likely to survive than those born at an intermediate weight **(Figure 21.10).**

Warren G. Abrahamson and Arthur E. Weis of Bucknell University have shown that opposing forces of directional selection can sometimes produce an overall pattern of stabilizing selection **(Figure 21.11).**

The gallmaking fly *(Eurosta solidaginis)* is a small insect that feeds on the tall goldenrod plant *(Solidago altissima).* When a fly larva hatches from its egg, it bores into a goldenrod stem, and the plant responds by producing a spherical growth deformity called a gall. The larva feeds on plant tissues inside the gall. Galls vary dramatically in size; genetic experiments indicate that gall size is a heritable trait of the fly, although plant genotype also has an effect.

Fly larvae inside galls are subjected to two opposing patterns of directional selection. On one hand, a tiny wasp *(Eurytoma gigantea)* parasitizes gallmaking flies by laying eggs in fly larvae inside their galls. After hatching, the young wasps feed on the fly larvae, killing them in the process. However, adult wasps are so small that they cannot easily penetrate the thick walls of a large gall; they generally lay eggs in fly larvae occupying small galls. Thus, wasps establish directional selection favoring flies that produce large galls, which are less likely to be parasitized. On the other hand, several bird species open galls to feed on mature fly larvae; these predators preferentially open large galls, fostering directional selection in favor of small galls.

In about one-third of the populations surveyed in central Pennsylvania, wasps and birds attacked galls with equal frequency, and flies producing galls of intermediate size had the highest survival rate. The smallest and largest galls—as well as the genetic predisposition to make very small or very large galls—were eliminated from the population.

DISRUPTIVE SELECTION Traits undergo **disruptive selection** when extreme phenotypes have higher relative fitness than intermediate phenotypes (see Figure 21.9C). Thus, alleles producing extreme phenotypes become more common, promoting polymorphism. Under natural conditions, disruptive selection is much less common than directional selection and stabilizing selection.

FIGURE 21.11 **Observational Research**

How Opposing Forces of Directional Selection Produce Stabilizing Selection

Hypothesis: The size of galls made by larvae of the gallmaking fly *(Eurosta solidaginis)* is governed by conflicting selection pressures established by parasitic wasps and predatory birds.

Prediction: If parasitic wasps and predatory birds exert selection for different sizes of galls made by gallmaking fly larvae, fly populations that suffer from wasp parasitism and bird predation will make galls of intermediate size.

Method: Abrahamson and his colleagues surveyed galls made by the larvae of the gallmaking fly in Pennsylvania. They measured the diameters of the galls they encountered, and, for those galls in which the larvae had died, they determined whether they had been killed by a parasitic wasp or a predatory bird, such as the downy woodpecker.

Results: Tiny wasps are more likely to parasitize gallmaking fly larvae inside small galls **(C),** fostering directional selection in favor of large galls. By contrast, birds usually feed on fly larvae inside large galls **(D),** fostering directional selection in favor of small galls. These opposing patterns of directional selection create stabilizing selection for the size of galls that the fly larvae make **(E).**

Conclusion: Because wasps preferentially parasitize fly larvae in small galls and birds preferentially eat fly larvae in large galls, the opposing forces of directional selection establish an overall pattern of stabilizing selection in favor of medium-sized galls.

THINK LIKE A SCIENTIST As you will learn in Chapter 55, human activities are causing many North American bird populations to decline in numbers. What effect would declining bird populations be likely to have on the sizes of galls made by gallmaking flies?

Geospiza conirostris

Krystyna Szulecka/Alamy

Birds with long bills open cactus fruits to feed on the fleshy pulp.

Birds with intermediate bills may be favored during nondrought years when many types of food are available.

Birds with deep bills strip bark from trees to locate insects.

Peter and Rosemary Grant of Princeton University, the world's experts on the ecology and evolution of the Galápagos finches, have analyzed a likely case of disruptive selection on the size and shape of the bill in a population of cactus finches *(Geospiza conirostris)* on the island of Genovesa. During normal weather cycles, the finches feed on ripe cactus fruits, seeds, and exposed insects. During drought years, when food is scarce, they also search for insects by stripping bark from the branches of bushes and trees.

During the long drought of 1977, about 70% of the cactus finches on Genovesa died; the survivors exhibited unusually high variability in their bills **(Figure 21.12).** The researchers suggested that this morphological variability allowed birds to specialize on particular foods. Birds that stripped bark from branches to look for insects had particularly deep bills, and birds that opened cactus fruits to feed on the fleshy interior had especially long bills. Thus, birds with extreme bill phenotypes appeared to feed more efficiently on specific resources, establishing disruptive selection on the size and shape of their bills. The selection may be particularly strong when drought limits the variety and overall availability of food. However, intermediate bill morphologies may be favored during nondrought years when insects and small seeds are abundant.

Sexual Selection Often Exaggerates Showy Structures in Males

Darwin hypothesized that a special process, which he called **sexual selection,** has fostered the evolution of showy structures—such as brightly colored feathers, long tails, or impressive antlers—as well as elaborate courtship behavior in the males of many animal species. Sexual selection encompasses two related processes. As the result of *intersexual selection* (that is, selection based on the interactions between males and females), males produce these otherwise useless structures simply because females find them irresistibly attractive. Under *intrasexual selection* (that is, selection based on the interactions between members of the same sex), males use their large body size, antlers, or tusks to intimidate, injure, or kill rival males. In many species, sexual selection is the most probable cause of **sexual dimorphism,** differences in the size or appearance of males and females.

Like directional selection, sexual selection pushes phenotypes toward one extreme. But the products of sexual selection are sometimes bizarre—such as the ridiculously long tail feathers of male African widowbirds. How could evolutionary processes favor such elaborate structures, which are costly to produce? Research by Malte Andersson of the University of Gothenburg, Sweden, suggests that the males' long tail feathers are a product of intersexual selection because females are more strongly attracted to males with long tails than to males with short tails, while tail length had no effect on a male's ability to compete with other males for space in the habitat **(Figure 21.13).** Behavioral aspects of sexual selection are described further in Chapter 56.

Nonrandom Mating Can Influence Genotype Frequencies

The Hardy–Weinberg model requires individuals to select mates randomly with respect to their genotypes. This requirement is, in fact, often met; humans, for example, generally marry one another in total ignorance of their genotypes for digestive enzymes or blood types.

Nevertheless, many organisms mate nonrandomly, selecting a mate with a particular phenotype and underlying genotype. Snow geese, for example, usually select mates of their own color, and a tall woman is more likely to marry a tall man than a short man. If no one phenotype is preferred by all potential mates, nonrandom mating does not change allele frequencies by establishing selection for one phenotype over another. But because individuals with similar genetically based phenotypes mate with each other, the next generation will contain fewer heterozygous offspring—and more homozygous offspring—than the Hardy–Weinberg model predicts.

Inbreeding is a special form of nonrandom mating in which genetically related individuals mate with each other. Self-fertilization in plants (see Chapter 36) and a few animals (see Chapter 49) is an extreme example of inbreeding because offspring are produced from the gametes of a single parent. However, other organisms that live in small, relatively closed populations often mate with related individuals. Because relatives often carry the same alleles, inbreeding generally increases the frequency of homozygous genotypes and decreases the frequency of heterozygotes. Thus, recessive phenotypes are often expressed.

For example, the high incidence of Ellis–van Creveld syndrome among the Old Order Amish population, mentioned earlier, is caused by inbreeding. Although the founder effect originally established the disease-causing allele in this population, inbreeding increases the likelihood that it will be expressed. Most human societies discourage matings between genetically

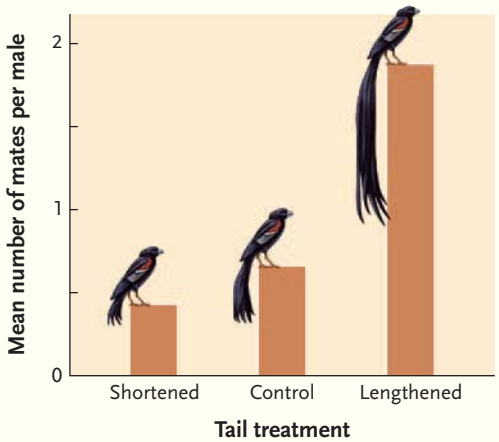
FIGURE 21.13 Experimental Research

Sexual Selection in Action



Question: Is the long tail of the male long-tailed widowbird *(Euplectes progne)* the product of intrasexual selection, intersexual selection, or both?

Experiment: Andersson counted the number of females that associated with individual male widowbirds in the grasslands of Kenya. He then shortened the tails of some males by cutting the feathers, lengthened the tails of others by gluing feather extensions to their tails, and left a third group essentially unaltered as a control. One month later, he again counted the number of females associating with each male and compared the results from the three groups.

Results: Males with experimentally lengthened tails attracted more than twice as many mates as males in the control group, and males with experimentally shortened tails attracted fewer. Andersson observed no differences in the ability of altered males and control group males to maintain their display areas.

Francois Loubser/Shutterstock.com

Conclusion: Female widowbirds clearly prefer males with experimentally lengthened tails to those with normal tails or experimentally shortened tails. Tail length had no obvious effect on the interactions between males. Thus, the long tail of male widowbirds is the product of intersexual selection.

THINK LIKE A SCIENTIST Which experimental treatment had the greater effect on the number of females with which male widowbirds mated?

close relatives, thereby reducing inbreeding and the inevitable production of recessive homozygotes that inbreeding causes.

STUDY BREAK 21.3

1. Which agents of microevolution tend to increase genetic variation within populations, and which ones tend to decrease it?
2. Which mode of natural selection increases the representation of the average phenotype in a population?
3. In what way is sexual selection like directional selection?

THINK OUTSIDE THE BOOK

Search the Internet for examples of diseases or unusual phenotypes caused by inbreeding in specific human populations. Have human geneticists discovered the molecular basis of these conditions?

21.4 Maintaining Genetic and Phenotypic Variation

Evolutionary biologists continue to discover extraordinary amounts of genetic and phenotypic variation in most natural populations. How can so much variation persist in the face of stabilizing selection and genetic drift?

Diploidy Can Hide Recessive Alleles from the Action of Natural Selection

The diploid condition reduces the effectiveness of natural selection in eliminating harmful recessive alleles from a population. Although such alleles are disadvantageous in the homozygous state, they may have little or no effect on heterozygotes. Thus, recessive alleles can be protected from natural selection by the phenotypic expression of the dominant allele.

TABLE 21.3 Masking of Recessive Alleles in Diploid Organisms

When a recessive allele is common in a population (top of table), most copies of the allele are present in homozygotes. But when the allele is rare (bottom of table), most copies of it exist in heterozygotes. Thus, rare alleles that are completely recessive are protected from the action of natural selection because they are masked by dominant alleles in heterozygous individuals.

Frequency of Allele *a*	Genotype Frequencies*			% of Allele *a* Copies in	
	AA	*Aa*	*aa*	*Aa*	*aa*
0.99	0.0001	0.0198	0.9801	1	99

In most cases, the masking of recessive alleles in heterozygotes makes it almost impossible to eliminate them completely through selective breeding. Experimentally, we can prevent homozygous recessive organisms from mating. But, as the frequency of a recessive allele decreases, an increasing proportion of its remaining copies is "hidden" in heterozygotes **(Table 21.3).** Thus, the diploid state preserves recessive alleles at low frequencies, at least in large populations. In small populations, a combination of natural selection and genetic drift can eliminate harmful recessive alleles.

Natural Selection Can Maintain Balanced Polymorphisms

A **balanced polymorphism** is one in which two or more phenotypes are maintained in fairly stable proportions over many generations. Natural selection preserves balanced polymorphisms when heterozygotes have higher relative fitness, when different alleles are favored in different environments, and when the rarity of a phenotype provides an advantage.

HETEROZYGOTE ADVANTAGE A balanced polymorphism can be maintained by **heterozygote advantage,** when heterozygotes have higher relative fitness than either homozygote. As Darwin first discovered in his experiments on corn, the offspring of crosses between two homozygous strains of the same species often exhibit a robustness described as "hybrid vigor." Apparently, being heterozygous at many gene loci provides some advantage, perhaps by allowing organisms to respond effectively to environmental variation.

The best-documented example of heterozygote advantage with reference to a specific gene locus is the maintenance of the *HbS* (sickle) allele, which codes for a defective form of hemoglobin in humans. As you learned in Chapter 12, hemoglobin is an oxygen-transporting molecule in red blood cells. The hemoglobin produced by the *HbS* allele differs from normal hemoglobin (coded by the *HbA* allele) by just one amino acid. In *HbS*/*HbS* homozygotes, the faulty hemoglobin forms long, fibrous chains under low oxygen conditions, causing red blood cells to assume a sickle shape (as shown in Figure 12.1). Homozygous *HbS*/*HbS* individuals often die of sickle-cell disease before reproducing, yet in tropical and subtropical Africa, *HbS*/*HbA* heterozygotes make up nearly 25% of many populations.

Why is the harmful allele maintained at such high frequency in some populations? It turns out that sickle-cell disease is common in regions where malarial parasites infect red blood cells in humans **(Figure 21.14).** When heterozygous *HbA*/*HbS* individuals contract malaria, their in-

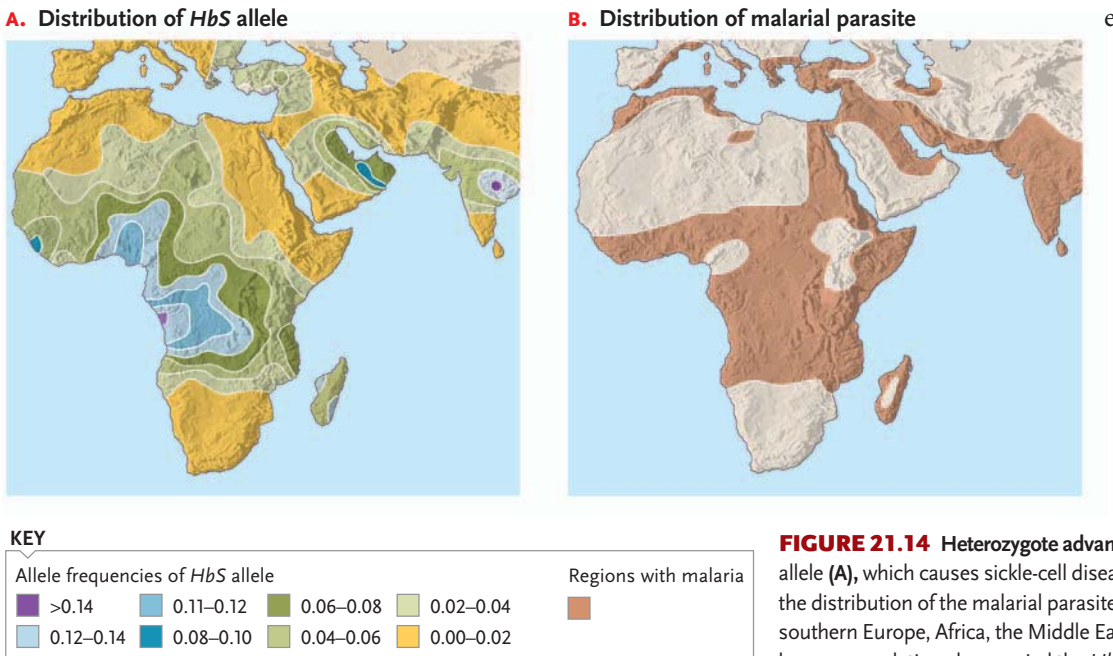

FIGURE 21.14 Heterozygote advantage. The distribution of the *HbS* allele **(A),** which causes sickle-cell disease in homozygotes, roughly matches the distribution of the malarial parasite *Plasmodium falciparum* **(B)** in southern Europe, Africa, the Middle East, and India. Gene flow among human populations has carried the *HbS* allele to some malaria-free regions.

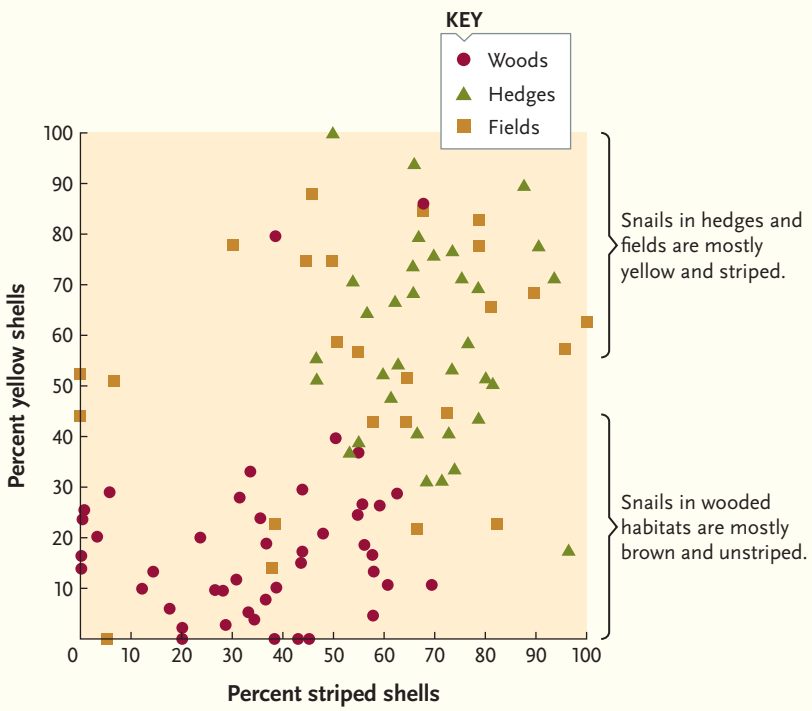
FIGURE 21.15 **Observational Research**



Habitat Variation in Color and Striping Patterns of European Garden Snails

Hypothesis: Birds and other visual predators are more likely to find snails that are not well camouflaged in their habitats than snails that blend in with their habitats.

Prediction: Genetically based variations in the shell color and striping patterns of the European garden snail *(Cepaea nemoralis)* will differ substantially between local populations of snails that live in different types of vegetation.

Method: British researchers A. J. Cain and P. M. Shepard surveyed the distribution of color and striping patterns of snails in many local populations. They plotted the data on a graph showing the percentage of snails with yellow shells versus the percentage of snails with striped shells, noting the vegetation type where each local population lived.

Results: The shell color and striping patterns of snails living in a particular vegetation type tend to be clustered on the graph, reflecting phenotypic differences that enable the snails to be camouflaged in different habitats. Thus, the alleles that control these characters vary from one local population to another.

Conclusion: Variations in the color and striping patterns on the shells of European garden snails allow most snails to be camouflaged in whatever habitat they occupy. Because these traits are genetically based, the frequencies of the alleles that control them also differ among snails living in different vegetation types. Natural selection therefore favors different alleles in different local populations, maintaining genetic variability in populations that span several vegetation types.

THINK LIKE A SCIENTIST Do the data in the graph suggest that populations of snails in wooded habitats include *only* snails with brown, unstriped shells and that populations of snails in hedges and fields include *only* snails with yellow striped shells?

fected red blood cells assume the same sickle shape as those of homozygous *HbS*/*HbS* individuals. The sickled cells lose potassium, killing the parasites, which limits their spread within the infected individual. Heterozygous individuals often survive malaria because the parasites do not multiply quickly inside them, their immune systems can effectively fight the infection, and they retain a large population of uninfected red blood cells. Homozygous *HbA*/*HbA* individuals are also subject to malarial infection, but because their infected cells do not sickle, the parasites multiply rapidly, causing a severe infection with a high mortality rate.

Therefore, *HbA*/*HbS* heterozygotes have greater resistance to malaria and are more likely to survive severe infections in areas where malaria is prevalent. Natural selection preserves the *HbS* allele in these populations because heterozygotes in malaria-prone areas have higher relative fitness than homozygotes for the normal *HbA* allele.

SELECTION IN VARYING ENVIRONMENTS Genetic variability can also be maintained within a population when different alleles are favored in different places or at different times. For example, the shells of European garden snails range in color from nearly white to pink, yellow, or brown, and may be patterned by one to five stripes of varying color (see Figure 21.2A). This polymorphism, which is relatively stable through time, is controlled by several gene loci. The variability in color and striping pattern can be partially explained by selection for camouflage in different habitats.

Predation by song thrushes *(Turdus ericetorum)* is a major agent of selection on the color and pattern of these snails in England. When a thrush finds a snail, it smacks it against a rock to break the shell. The bird eats the snail, but leaves the shell near its "anvil." Researchers used the broken shells near an anvil to compare the phenotypes of captured snails to a random sample of the entire snail population. Their analyses indicated that thrushes are visual predators, usually capturing snails that are easy to find. Thus, well-camouflaged snails survive, and the alleles that specify their phenotypes increase in frequency.

The success of camouflage varies with habitat, however; local subpopulations of the snail, which occupy different habitats, often differ markedly in shell color and pattern. The predators eliminate the most conspicuous individuals in each habitat; thus, natural selection differs from place to place **(Figure 21.15).** In woods where the ground is covered with dead leaves, snails with unstriped pink or brown shells predominate. In hedges and fields, where the vegetation includes thin stems and grass, snails with striped yellow shells are the most common. In populations that span

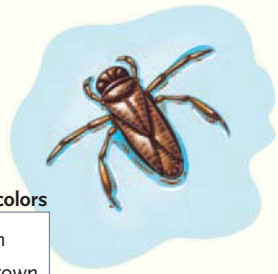

FIGURE 21.16 **Experimental Research**

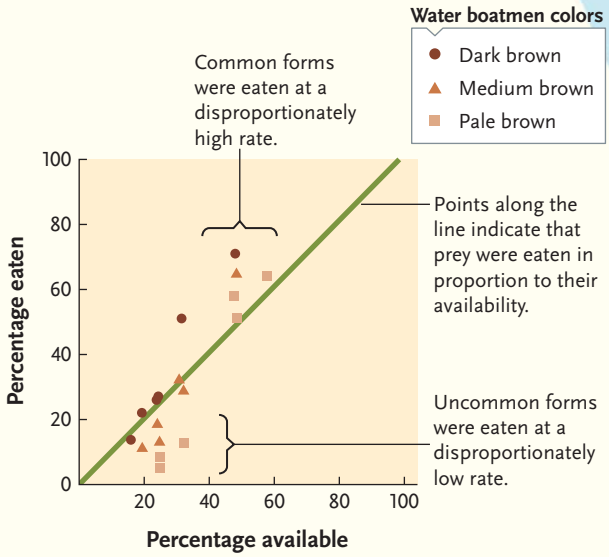

Demonstration of Frequency-Dependent Selection

Question: How does the frequency of a prey type influence the likelihood that it will be captured by predators?

Experiment: Water boatmen *(Sigara distincta)* occur in three color forms, which vary in the effectiveness of their camouflage. Researchers offered different proportions of the three color forms to predatory fishes in the laboratory and recorded how many of each form were eaten.

Result: When all three phenotypes were available, predatory fishes consumed a disproportionately large number of the most common form, thereby reducing its frequency in the population.

B. Clarke. 1962. Balanced polymorphism and the diversity of sympatric species. *Systematics Association Publications* 4:47–70. Reprinted by permission of The Systematics Association.

Conclusion: Predators tend to feed disproportionately on whatever form of their prey is most abundant, thereby reducing its frequency in the prey population.

THINK LIKE A SCIENTIST Do the data in the graph indicate that predatory fishes had a preference for one color form of water boatman over the other color forms?

Source: B. Clarke. 1962. Balanced polymorphism and the diversity of sympatric species. *Systematics Association Publications* 4:47–70.

several habitats, selection preserves different alleles in different places, thus maintaining variability in the population as a whole.

FREQUENCY-DEPENDENT SELECTION Sometimes, genetic variability is maintained in a population simply because rare phenotypes—whatever they happen to be—have higher relative fitness than more common phenotypes. The rare phenotype will increase in frequency until it becomes so common that it loses its advantage. Such phenomena are examples of **frequency-dependent selection** because the selective advantage enjoyed by a particular phenotype depends on its frequency in the population.

Predator–prey interactions can establish frequency-dependent selection because predators often focus their attention on the most common types of prey (see Chapter 53). For example, the aquatic insects called water boatmen *(Sigara distincta)* occur in three different shades of brown. When all three shades are available at moderate frequencies, fish preferentially feed on the darkest individuals, which are the least camouflaged. But if any one phenotype is very common, fish will learn to focus their attention on that phenotype, consuming it in disproportionately large numbers **(Figure 21.16).**

Some Genetic Variations May Be Selectively Neutral

Many biologists believe that some genetic variations are neither preserved nor eliminated by natural selection. According to the **neutral variation hypothesis,** some of the genetic variation at loci coding for enzymes and other soluble proteins is **selectively neutral.** Even if various alleles code for slightly different amino acid sequences in proteins, the different forms of the proteins may function equally well. In those cases, natural selection would not favor some alleles over others.

Biologists who support the neutral variation hypothesis do not question the role of natural selection in producing complex anatomical structures or useful biochemical traits. They also recognize that selection reduces the frequency of harmful alleles. But they argue that we should not simply assume that every genetic variant that persists in a population has been preserved by natural selection. In practice, it is often very difficult to test the neutral variation hypothesis because the fitness effects of different alleles are often subtle and can vary with small changes in the environment.

The neutral variation hypothesis helps to explain why we see different levels of genetic variation in different populations. It proposes that genetic variation is directly proportional to a population's size and the length of time over which variations have accumulated. Small populations experience fewer mutations than large populations simply because they include fewer replicating genomes. Small populations also lose rare alleles more readily through genetic drift. Thus, small populations should exhibit less genetic variation than large ones, and a population, like the northern elephant seals, that has experienced a recent population bottleneck should exhibit an exceptionally low level of genetic variation. These predictions of the neutral variation hypothesis are generally supported by empirical data.

STUDY BREAK 21.4

1. How does the diploid condition protect harmful recessive alleles from natural selection?
2. What is a balanced polymorphism?
3. Why is the allele that causes sickle-cell disease very rare in human populations that are native to northern Europe?

21.5 Adaptation and Evolutionary Constraints

Although natural selection preserves alleles that confer high relative fitness on the individuals that carry them, researchers are cautious about interpreting the benefits that particular traits may provide.

Scientists Construct Hypotheses about the Evolution of Adaptive Traits

An **adaptive trait** is any product of natural selection that increases the relative fitness of an organism in its environment. **Adaptation** is the accumulation of adaptive traits over time, and most chapters of this book describe examples that range across all levels of biological organization, from the molecular to the ecological. For example, the change in the oxygen-binding capacity of hemoglobin in response to carbon dioxide concentration, the water-retaining structures and special photosynthetic pathways of desert plants, and the warning coloration of poisonous animals can all be interpreted as adaptive traits.

In fact, we can concoct an adaptive explanation for almost any characteristic we observe in nature. But such explanations are just fanciful stories unless they are framed as testable hypotheses about the relative fitness of different phenotypes and genotypes. Unfortunately, evolutionary biologists cannot always conduct straightforward experiments because they sometimes study traits that do not vary much within a population or species. In such cases, they may compare variations of a trait in closely related species living in different environments. For example, one can test how the traits of desert plants are adaptive by comparing them to traits in related species from moister habitats.

When biologists try to unravel how and why a particular characteristic evolved, they must also remember that a trait they observe today may have had a different function in the past. For example, the structure of the shoulder joint in birds allows them to move their wings first upward and backward and then downward and forward during flapping flight. But analyses of the fossil record reveal that this adaptation, which is essential for flight, did not originate in birds: some predatory nonflying dinosaurs, including the ancestors of birds, had a similarly constructed shoulder joint. Researchers hypothesize that these fast-running predators may have struck at prey with a flapping motion similar to that used by modern birds. Thus, the structure of the shoulder may have evolved first as an adaptation for capturing prey, and only later proved useful for flapping flight. This hypothesis—however plausible it may be—cannot be tested by direct experimentation because the nonflying ancestors of birds have been extinct for millions of years. Instead, evolutionary biologists must use anatomical studies of birds and their ancestors as well as theoretical models about the mechanics of movement to challenge and refine the hypothesis.

Finally, although evolution has produced all the characteristics of organisms, not all are necessarily adaptive. Some traits may be the products of chance events and genetic drift. Others are produced by alleles that were selected for unrelated reasons (see Section 12.2). And still other characteristics result from the action of basic physical laws. For example, the seeds of many plants fall to the ground when they mature, reflecting the inevitable effect of gravity.

Several Factors Constrain Adaptive Evolution

When we analyze the structure and functions of an organism, we often marvel at how well adapted it is to its environment and mode of life. However, the adaptive traits of most organisms are compromises produced by competing selection pressures. Sea turtles, for example, must lay their eggs on beaches because their embryos cannot acquire oxygen under water. Although flippers allow females to crawl to nesting sites on beaches, they are not ideally suited for terrestrial locomotion. Their structure reflects their primary function, swimming.

Moreover, no organism can be perfectly adapted to its environment because environments change over time. When selection occurs in a population, it preserves alleles that are successful under the prevailing environmental conditions. Thus, each generation is adapted to the environmental conditions under which its parents lived. If the environment changes from one generation to the next, adaptation will always lag behind.

Another constraint on the evolution of adaptive traits is historical. Natural selection is not an engineer that designs new organisms from scratch. Instead, it acts on new mutations and existing genetic variation. Because new mutations are fairly rare, natural selection works primarily with alleles that have been present for many generations. Thus, adaptive changes in the morphology of an organism are often based on small modifications of existing structures. The bipedal (two-footed) posture of humans, for example, evolved from the quadrupedal (four-footed) posture of our ancestors. Natural selection did not produce an entirely new skeletal design to accompany this radical behavioral shift. Instead, existing characteristics of the spinal column and the musculature of the legs and back were modified, albeit imperfectly, for an upright stance.

The agents of evolution cause microevolutionary changes in the gene pools of populations. In the next chapter, we ex-

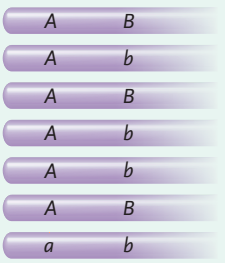
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

amine how microevolution in different populations can cause their gene pools to diverge. The extent of genetic divergence is sometimes sufficient to cause the populations to evolve into different species.

STUDY BREAK 21.5



1. How can a biologist test whether a trait is adaptive?
2. Why are most organisms adapted to the environments in which their parents lived?

UNANSWERED QUESTIONS

What are the evolutionary forces affecting molecular variation within populations?

This question may sound like a simple restatement of the entire chapter you have just read, but it is one of the *fundamental* questions in population genetics today—and we have only begun to scratch its surface. The Hardy–Weinberg principle provides a useful null hypothesis, but since we know that evolution happens routinely, that null hypothesis is very frequently rejected. Recent studies have attempted to address this question using theoretical models, extensive DNA sequence data, and detailed measurements of recombination rate.

Recombination generates new variation, and, most important, it causes the evolutionary forces acting on some genes to become independent of forces acting on other genes. Let's imagine that genes *A* and *B* are on the same chromosome, as shown in this depiction of chromosomes sampled from different individuals within a population:

© Cengage Learning 2014

Gene *B* has two alleles (*B* and *b*), but they have no phenotypic effect, and natural selection does not act on them. Suppose that a new advantageous allele at gene *A* (designated *a*) arises in one chromosome. If there is no recombination between genes *A* and *B,* then as allele *a* spreads in the population by selection, so too will allele *b,* even though there was no selection directly favoring the *b* allele. This effect of selection on nearby genes is called a *selective sweep.* By contrast, if genes *A* and *B* frequently recombine, then allele *a* may not remain associated with allele *b.* Under frequent recombination, the spread of allele *a* may have little or no effect on gene *B:* sometimes *a* will be associated with *b,* but at other times *a* will be associated with *B.*

In the 1990s, evolutionary geneticists were greatly excited by several studies that identified a strong and positive relationship between the recombination rate between particular genes and the amount of genetic variation within those genes. In other words, genes that experienced a lot of recombination also exhibited a great deal of variability. This relationship is consistent with the hypothesis that natural selection often occurs throughout the genome—new advantageous alleles arise frequently, and the impact of their "sweeps" is proportional to their recombination rates. This relationship between recombination and genetic variation was first documented in *Drosophila* (fruit flies) by Chip Aquadro and his team at Cornell University, but it has since been demonstrated in humans and various plants. Hence, this pattern appears to be very general.

However, our initial interpretation may be too simplistic. Brian Charlesworth, then at the University of Chicago, suggested that the observed pattern may result from the frequent appearance of detrimental mutations that eliminate variation in regions of low recombination—called *background selection*—rather than from sweeps associated with the spread of advantageous alleles. Given that detrimental mutations arise far more frequently than advantageous ones, background selection surely explains some of this general pattern, and perhaps much of it.

An alternative hypothesis that may explain the relationship between recombination rate and genetic variation suggests that recombination rate and the level of genetic variation may be mechanistically connected. The connection may be direct if recombination itself induces mutations, resulting in higher mutation rates in regions of high recombination. Or the connection may be indirect: recombination rate is related to the base composition in specific regions of the genome, and base composition influences mutation rates. In 2006, Chris Spencer and his colleagues at Oxford University examined the impact of recombination rates on patterns of nucleotide variation at a very fine scale across the human genome. They found that recombination rates had very local effects on variation, an observation that is consistent with the hypothesis of a mechanistic connection between recombination and mutation rate; their results are not consistent with explanations involving natural selection.

Although biologists first thought that the observed relationship between recombination rate and genetic variation had solved questions about the evolutionary forces that affect molecular variation, this observation has become a puzzle in and of itself. Many researchers continue to address this question, now using whole-genome sequences and theoretical and empirical tools for estimating recombination rates. Evolutionary biologists know that the "final answer" will be that all of the processes described above contribute to this relationship, but knowing their specific contributions will help us understand how, how much, and what kinds of natural selection shape variation within genomes.

THINK LIKE A SCIENTIST If recombination itself induces mutations, should genes in regions of high recombination have many differences or few differences when the sequences of these genes are compared among closely related species? Does this test suggest a means for evaluating whether recombination rate and genetic variation are connected mechanistically or connected by the action of natural selection?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

21.1 Variation in Natural Populations

- Phenotypic traits exhibit either quantitative or qualitative variation within populations (Figures 21.2 and 21.3).
- Genetic variation, environmental factors, or an interaction between the two cause phenotypic variation within populations (Figures 21.4 and 21.5). Only genetically based phenotypic variation is heritable and subject to evolutionary change.
- Genetic variation arises within populations largely through mutation and genetic recombination. Artificial selection experiments and analyses of protein and DNA sequences reveal that most populations include significant genetic variation (Figure 21.6).

21.2 Population Genetics

- All the gene copies in a population comprise its gene pool, which can be described in terms of allele frequencies and genotype frequencies (Table 21.1).
- The Hardy–Weinberg principle of genetic equilibrium is a null model that describes the conditions under which microevolution, a change in allele frequencies through time, will not take place. Microevolution occurs in populations when the restrictive requirements of the model are not met.

Animation: How to find out if a population is evolving

21.3 The Agents of Microevolution

- Several processes cause microevolution in populations (Table 21.2). Mutation introduces completely new genetic variation. Gene flow carries novel genetic variation into a population through the arrival and reproduction of immigrants (Figure 21.7). Genetic drift causes random changes in allele frequencies, especially in small populations (Figure 21.8). Natural selection occurs when the genotypes of some individuals enable them to survive and reproduce more than others.
- Natural selection alters phenotypic variation in three ways (Figure 21.9). Directional selection increases or decreases the mean value of a trait, shifting it toward a phenotypic extreme. Stabilizing selection increases the frequency of the mean phenotype and reduces variability in the trait (Figures 21.10 and 21.11). Disruptive selection increases the frequencies of extreme phenotypes and decreases the frequency of intermediate phenotypes (Figure 21.12).
- Sexual selection promotes the evolution of exaggerated structures and behaviors (Figure 21.13).
- Although nonrandom mating does not change allele frequencies, it can produce more homozygotic and fewer heterozygotic genotypes than the Hardy–Weinberg model predicts.

Animation: Disruptive selection among African finches

Animation: Simulation of genetic drift

Animation: Directional selection

Animation: Disruptive selection

Animation: Change in moth population

Animation: Stabilizing selection

21.4 Maintaining Genetic and Phenotypic Variation

- Diploidy can maintain genetic variation in a population if recessive alleles are not expressed in heterozygotes and are thus hidden from natural selection (Table 21.3).
- Polymorphisms are maintained in populations when heterozygotes have higher relative fitness than both homozygotes (Figure 21.14), when natural selection occurs in variable environments (Figure 21.15), or when the relative fitness of a phenotype varies with its frequency in the population (Figure 21.16).
- The neutral variation hypothesis proposes that many genetic variations are selectively neutral, conferring neither advantages nor disadvantages on the individuals that carry them. It explains why large populations and those that have not experienced a recent population bottleneck exhibit the highest levels of genetic variation.

21.5 Adaptation and Evolutionary Constraints

- Adaptive traits increase the relative fitness of individuals carrying them. Adaptive explanations of traits must be framed as testable hypotheses.
- Natural selection cannot result in perfectly adapted organisms because most adaptive traits represent compromises among conflicting needs, because most environments change constantly, and because natural selection can affect only existing genetic variation.

Animation: Adaptation to what?

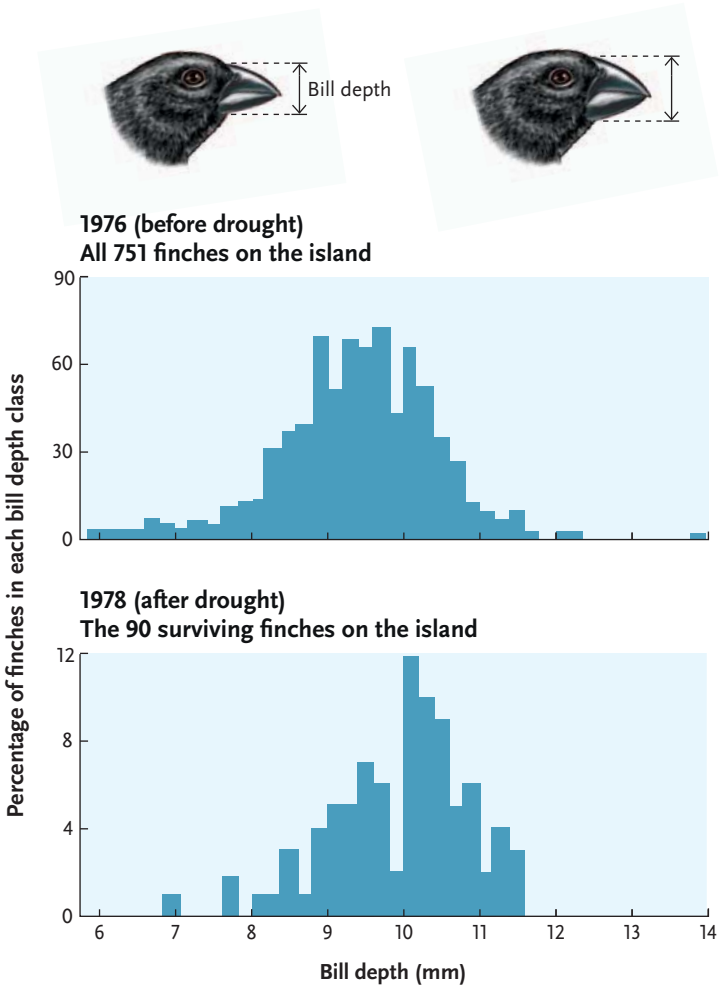
3. If the genotype frequencies in a population are 0.60 *AA,* 0.20 *Aa,* and 0.20 *aa,* and if the requirements of the Hardy–Weinberg principle apply, the genotype frequencies in the offspring generation will be:
   a. 0.60 *AA,* 0.20 *Aa,* 0.20 *aa.*
   b. 0.36 *AA,* 0.60 *Aa,* 0.04 *aa.*
   c. 0.49 *AA,* 0.42 *Aa,* 0.09 *aa.*
   d. 0.70 *AA,* 0.00 *Aa,* 0.30 *aa.*
   e. 0.64 *AA,* 0.32 *Aa,* 0.04 *aa.*
4. The reason spontaneous mutations do not have an immediate effect on allele frequencies in a large population is that:
   a. mutations are random events, and mutations may be either beneficial or harmful.
   b. mutations usually occur in males and have little effect on eggs.
   c. many mutations exert their effects after an organism has stopped reproducing.
   d. mutations are so rare that mutated alleles are greatly outnumbered by nonmutated alleles.
   e. most mutations do not change the amino acid sequence of a protein.
5. The phenomenon in which chance events cause unpredictable changes in allele frequencies is called:
   a. gene flow.
   b. genetic drift.
   c. inbreeding.
   d. balanced polymorphism.
   e. stabilizing selection.
6. An Eastern European immigrant carrying the allele for Tay-Sachs disease settled in a small village on the St. Lawrence River. Many generations later, the frequency of the allele in that village is statistically higher than it is in the immigrant's homeland. The high frequency of the allele in the village probably provides an example of:
   a. natural selection.
   b. the concept of relative fitness.
   c. the Hardy–Weinberg genetic equilibrium.
   d. phenotypic variation.
   e. the founder effect.
7. If a storm kills many small sparrows in a population, but only a few medium-sized and large ones, which type of selection is probably operating?
   a. directional selection
   b. stabilizing selection
   c. disruptive selection
   d. intersexual selection
   e. intrasexual selection
8. Which of the following phenomena explains why the allele for sickle-cell hemoglobin is common in some tropical and subtropical areas where the malaria parasite is prevalent?
   a. balanced polymorphism
   b. heterozygote advantage
   c. sexual dimorphism
   d. neutral selection
   e. stabilizing selection
9. The neutral variation hypothesis proposes that:
   a. complex structures in most organisms have not been fostered by natural selection.
   b. most mutations have a strongly harmful effect.
   c. some mutations are not affected by natural selection.
   d. natural selection cannot counteract the action of gene flow.
   e. large populations are subject to stronger natural selection than small populations.
10. Phenotypic characteristics that increase the fitness of individuals are called:
   a. mutations.
   b. founder effects.
   c. heterozygote advantages.
   d. adaptive traits.
   e. polymorphisms.

Discuss the Concepts

1. Most large commercial farms routinely administer antibiotics to farm animals to prevent the rapid spread of diseases through a flock or herd. Explain why you think that this practice is either wise or unwise.
2. Many human diseases are caused by recessive alleles that are not expressed in heterozygotes. Some people think that eugenics—the selective breeding of humans to eliminate undesirable genetic traits—provides a way for us to rid our populations of such harmful alleles. Explain why eugenics cannot eliminate such genetic traits from human populations.
3. Using two types of beans to represent two alleles at the same gene locus, design an exercise to illustrate how population size affects genetic drift.
4. In what ways are the effects of sexual selection, disruptive selection, and nonrandom mating different? How are they similar?



Design an Experiment

Design an experiment to test the hypothesis that the differences in size among adult guppies are determined by the amount of food they eat rather than by genetic factors.

Interpret the Data

Peter and Rosemary Grant of Princeton University have studied the ecology and evolution of finches on the Galápagos Islands since the early 1970s. They have shown that finches with large bills (as measured by bill depth; see **Figure**) can eat both small seeds and large seeds, but finches with small bills can only eat small seeds. In 1977, a severe drought on the island of Daphne Major reduced seed production by plants. After the birds consumed whatever small seeds they found, only large seeds were still available. The resulting food shortage killed a majority of the medium ground finches *(Geospiza fortis)* on Daphne Major; their population plummeted from 751 in 1976 to just 90 in 1978. The Grants' research also documented a change in the distributions of bill depths in the birds from 1976 to 1978, as illustrated in the graphs to the right. In light of what you now know about the relationship between bill size and food size for these birds, interpret the change illustrated in the graph. What type of natural selection does this example illustrate?

Apply Evolutionary Thinking

Captive breeding programs for endangered species often have access to a limited supply of animals for a breeding stock. As a result, their offspring are at risk of being highly inbred. Why and how might zoological gardens and conservation organizations avoid or minimize inbreeding?

Speciation

FIGURE 22.1 Birds of paradise. A male Count Raggi's bird of paradise *(Paradisaea raggiana)* tries to attract the attention of a female (not pictured) with his showy plumage and conspicuous display. There are 43 known bird of paradise species, 35 of them found only on the island of New Guinea.

Why it matters . . . In 1927, nearly 100 years after Darwin boarded the *Beagle,* a young German naturalist named Ernst Mayr embarked on his own journey, to the highlands of New Guinea. He was searching for rare "birds of paradise" **(Figure 22.1).** These birds were known in Europe only through their ornate and colorful feathers, which were used to decorate ladies' hats. On his trek through the remote Arfak Mountains, Mayr identified 137 bird species (including many birds of paradise) based on differences in their size, plumage, color, and other external characteristics.

To Mayr's surprise, the native Papuans—who were untrained in the ways of Western science, but who hunted these birds for food and feathers—had their own names for 136 of the 137 species he had identified. The close match between the two lists confirmed Mayr's belief that the *species* is a fundamental level of organization in nature. Each species has a unique combination of genes underlying its distinctive appearance and habits. Thus, people who observe them closely—whether indigenous hunters or Western scientists—can often distinguish one species from another.

Mayr also discovered some remarkable patterns in the geographical distributions of the bird species in New Guinea. For example, each mountain range he explored was home to some species that lived nowhere else. Closely related species often lived on different mountaintops, separated by deep valleys of unsuitable habitat. In 1942, Mayr published the book *Systematics and the Origin of Species,* in which he described the role of geography in the evolution of new species; the book quickly became a cornerstone of the modern synthesis (which was outlined in Section 20.3).

What mechanisms produce distinct species? As you discovered in Chapter 21, microevolutionary processes alter the pattern and extent of genetic and phenotypic variation within populations. When these processes differ between populations, the populations will diverge genetically, and they may eventually become so different that we recognize them as distinct species. Although Darwin's famous book was titled *On the Origin of Species,* he didn't dwell on the question of *how* new species arise. But the concept of **speciation**—the process of species formation—was implicit in his insight that similar species often share inherited characteristics and a common ancestry. Darwin also recognized that "descent with modification" had generated the amazing diversity of organisms on Earth.

Today evolutionary biologists view speciation as a *process,* a series of events that occur through time. However, they usually study the *products* of speciation, species that are alive today. Because they can rarely witness the process of speciation from start to finish, scientists make inferences about it by studying organisms in various stages of species formation. In this chapter, we consider four major topics: how biologists define and recognize species; how species maintain their genetic identity; how the geographical distributions of organisms influence speciation; and how different genetic mechanisms produce new species.

22.1 What Is a Species?

Like the hunters of the Arfak Mountains, most of us recognize the different species that we encounter every day. We can distinguish a cat from a dog and sunflowers from roses. The concept of species is based on our perception that Earth's biological diversity is packaged in discrete, recognizable units, and not as a continuum of forms grading into one another. As biologists have learned more about evolutionary processes—and the dazzling biodiversity those processes have produced—they have developed a variety of complementary species concepts.

The Morphological Species Concept Is a Practical Way to Identify Species

Biologists often describe new species on the basis of visible anatomical characteristics, a process that dates back to Linnaeus' classification of organisms in the eighteenth century (described in Chapter 24). This approach is based on the **morphological species concept,** the idea that all individuals of a species share measurable traits that distinguish them from individuals of other species.

The morphological species concept has many practical applications. For example, paleobiologists use morphological criteria to identify the species of fossilized organisms (see Chapter 23). And because we can observe the external traits of organisms in nature, field guides to plants and animals list diagnostic (that is, distinguishing) physical characters that allow us to recognize them **(Figure 22.2).**

Nevertheless, relying exclusively on morphology to identify species can present problems. Consider the variation in the shells of the European garden snail (*Cepaea nemoralis;* shown earlier, in Figure 21.2). How could anyone imagine that so variable a collection of shells represents just one species of snail? Conversely, morphology does not help us distinguish some closely related species that are nearly identical in appearance. Finally, morphological species definitions tell us little about the evolutionary processes that produce new species.

The Biological Species Concept Is Based on Reproductive Characteristics

The **biological species concept** emphasizes the dynamic nature of species. Ernst Mayr defined biological species as "groups of . . . interbreeding natural populations that are reproductively isolated from [do not produce fertile offspring with] other such groups." The concept is based on reproductive criteria and is easy to apply, at least in principle: if the members of two populations interbreed and produce fertile offspring *under natural conditions,* they belong to the same species; their fertile offspring will, in turn, produce the next generation of that species. If two populations do not interbreed in nature, or fail to produce fertile offspring when they do, they belong to different species.

The biological species concept defines species in terms of population genetics and evolutionary theory. The first half of Mayr's definition notes the genetic *cohesiveness* of species: populations of the same species experience gene flow, which mixes their genetic material. Thus, we can think of a species as one large gene pool, which may be subdivided into local populations.

The second part of the biological species concept emphasizes the genetic *distinctness* of each species. Because populations of different species are reproductively isolated, they cannot exchange genetic information. In fact, the process of speciation is frequently defined as the evolution of reproductive isolation between populations.

The biological species concept also explains why individuals of a species generally look alike: members of the same gene pool share genetic traits that determine their appearance. Individuals of different species generally do not resemble one another as closely because they share fewer genetic characteristics. In practice, biologists often still use similarities or differences in morphological traits as convenient markers of genetic similarity or reproductive isolation.

However, the biological species concept does not apply to the many forms of life that reproduce asexually, including most

bacteria; some protists, fungi, and plants; and a few animals. In these species, individuals don't interbreed, so it is pointless to ask whether different populations do. Similarly, we cannot use the biological species concept to study extinct organisms, because we have little or no data on their specific reproductive habits. These species must all be defined using morphological or biochemical criteria. Yet, despite its limitations, the biological species concept currently provides the best evolutionary definition of a sexually reproducing species.

The Phylogenetic Species Concept Focuses on Evolutionary History

Recognizing the limitations of the biological species concept, biologists have developed dozens of other ways to define a species. A widely accepted alternative is the **phylogenetic species concept.** Using both morphological and genetic sequence data, scientists first reconstruct the evolutionary tree for the organisms of interest. They then define a phylogenetic species as a cluster of populations—the tiniest twigs on this part of the Tree of Life—that emerge from the same small branch. Thus, a phylogenetic species comprises populations that share a recent evolutionary history. We will consider this approach for understanding the evolutionary relationships of organisms in Chapter 24.

One advantage of the phylogenetic species concept is that biologists can apply it to any group of organisms, including species that have long been extinct, as well as living organisms that reproduce asexually. Proponents of this approach also argue that the morphological and genetic distinctions between organisms on different branches of the Tree of Life reflect the absence of gene flow between them—one of the key requirements of the biological species definition. Nevertheless, because detailed evolutionary histories have been described for relatively few groups of organisms, biologists are not yet able to apply the phylogenetic species concept to all forms of life. As noted in *Unanswered Questions* for Chapter 24, continued research on the details of evolutionary relationships will increase this concept's usefulness in the future.

Many Species Exhibit Substantial Geographical Variation

Just as individuals within populations exhibit genotypic and phenotypic variation (see Section 21.1, Figures 21.2 and 21.15), populations within species also differ both genetically and phenotypically. Neighboring populations often have shared characteristics because they live in similar environments, exchange individuals, and experience comparable patterns of natural selection. Widely separated populations, by contrast, may live under different conditions and experience different patterns of selection; because gene flow is less likely to occur between distant populations, their gene pools and phenotypes often differ.

When geographically separated populations of a species exhibit dramatic, easily recognized phenotypic variation, biologists may identify them as different **subspecies (Figure 22.3),** which are local variants of a species. Individuals from different subspecies usually interbreed where their geographical distributions meet, and their offspring often exhibit intermediate phenotypes. Biologists sometimes use the word "race" as shorthand for the term "subspecies."

Various patterns of geographical variation—as well as analyses of how the variation may relate to climatic or habitat variation—have provided great insight into the speciation process. Two of the best-studied patterns are *ring species* and *clinal variation.*

RING SPECIES Some plant and animal species have a ring-shaped geographical distribution that surrounds uninhabitable terrain. Adjacent populations of these **ring species** can exchange genetic material directly, but gene flow between distant populations occurs only through the intermediary populations.

The lungless salamander *Ensatina eschscholtzii,* an example of a ring species, is widely distributed in the coastal mountains and the Sierra Nevada of California, but it cannot survive in the hot, dry Central Valley **(Figure 22.4).** Seven subspecies differ in biochemical traits, color, size, and ecology. Individuals from adjacent subspecies often interbreed where their geographical distributions overlap, and intermediate phenotypes are fairly common.

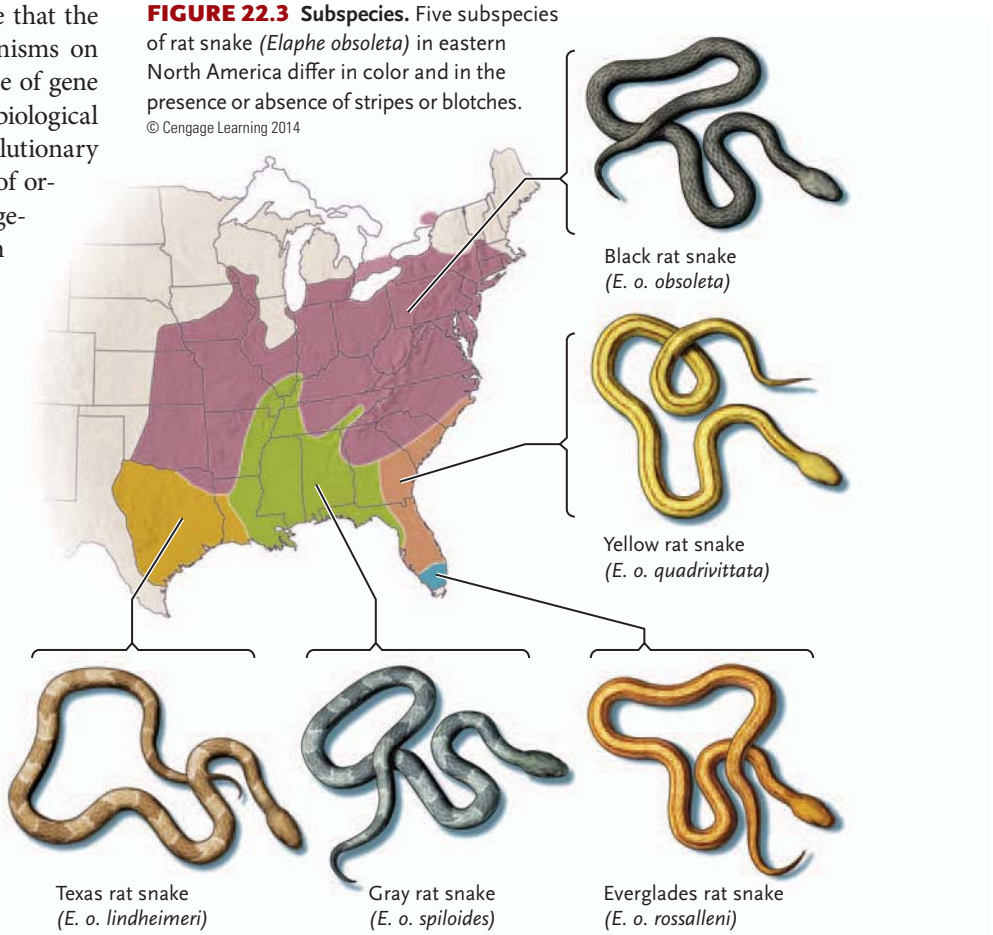

FIGURE 22.3 Subspecies. Five subspecies of rat snake *(Elaphe obsoleta)* in eastern North America differ in color and in the presence or absence of stripes or blotches.

But at the southern end of the Central Valley, adjacent subspecies rarely interbreed. Apparently, they have differentiated to such an extent that they can no longer exchange genetic material directly.

Are the southernmost populations of this salamander subspecies or different species? A biologist who saw *only* the southern populations, which coexist without interbreeding, might define them as separate species. However, they still have the potential to exchange genetic material through the intervening populations that form the ring. Hence, biologists recognize these populations as belonging to the same species. Most likely, the southern subspecies are in an intermediate stage of species formation.

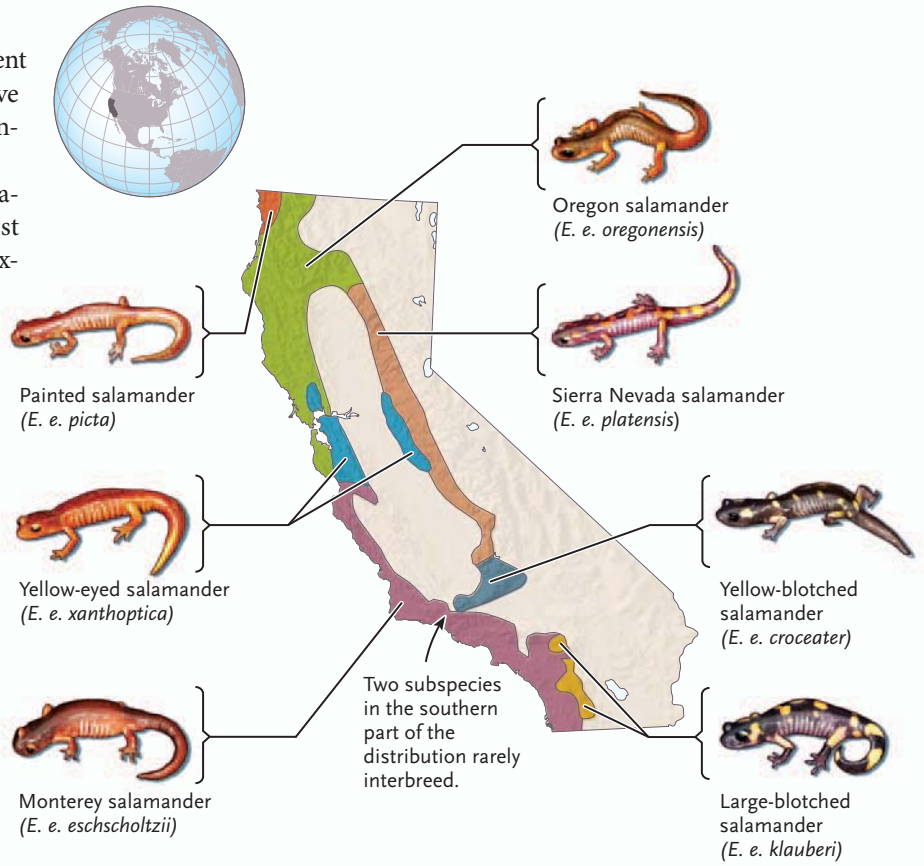

FIGURE 22.4 **Ring species.** Six of the seven subspecies of the salamander *Ensatina eschscholtzii* are distributed in a ring around California's Central Valley. Subspecies often interbreed where their geographical distributions overlap. However, the two subspecies that nearly close the ring in the south (marked with an arrow), the Monterey salamander and the yellow-blotched salamander, rarely interbreed.

CLINAL VARIATION When a species is distributed over a large, environmentally diverse area, some traits may exhibit a **cline,** a pattern of smooth variation along a geographical gradient. For example, many birds and mammals in the northern hemisphere show clinal variation in body size **(Figure 22.5)** and the relative length of their appendages. In general, populations living in colder environments have larger bodies and shorter appendages, a pattern that is usually interpreted as a mechanism to conserve body heat (see Chapter 48).

Clinal variation usually results from gene flow between adjacent populations that are each adapting to slightly different conditions. However, if populations at opposite ends of a cline are separated by great distances, they may exchange very little genetic material through reproduction. Thus, when a cline extends over a large geographical gradient, distant populations may be genetically and morphologically distinct.

Despite the geographical variation that many species exhibit, even closely related species are genetically and morphologically different from each other. In the next section, we consider the mechanisms that maintain the genetic distinctness of closely related species by preventing their gene pools from mixing.

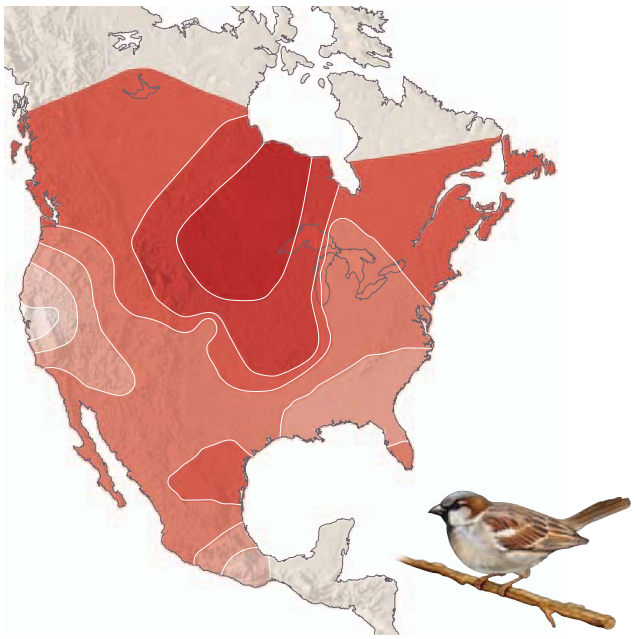

FIGURE 22.5 **Clinal variation.** House sparrows *(Passer domesticus)* exhibit clinal variation in overall body size, which was summarized from measurements of 16 skeletal features. Darker shading in the map indicates larger size.

22.2 Maintaining Reproductive Isolation

Reproductive isolation is central to the biological species concept. A **reproductive isolating mechanism** is any biological characteristic that prevents the gene pools of two species from mixing. Biologists classify reproductive isolating mechanisms into two categories (summarized in **Table 22.1**): **prezygotic isolating mechanisms** exert their effects before the production of a zygote, or fertilized egg, and **postzygotic isolating mechanisms** operate after zygote formation. These isolating mechanisms are not mutually exclusive; two or more of them may operate simultaneously.

Prezygotic Isolating Mechanisms Prevent the Production of Hybrid Individuals

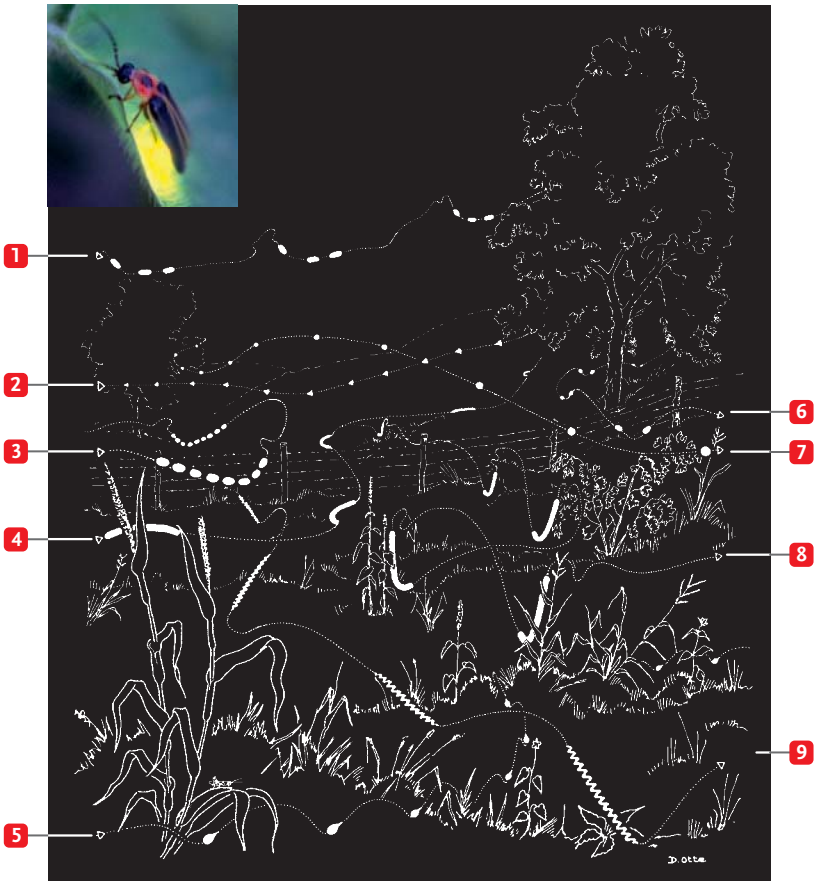
Biologists have identified five mechanisms that can prevent interspecific (between species) matings or fertilizations, and thus prevent the production of hybrid offspring (that is, the offspring of a between-species mating). These five prezygotic mechanisms are *ecological, temporal, behavioral, mechanical,* and *gametic isolation.*

Species living in the same geographical region may experience **ecological isolation** if they live in different habitats. For example, lions and tigers were both common in India until the mid-nineteenth century, when hunters virtually exterminated the Asian lions. However, because lions live in open grasslands and tigers in dense forests, the two species did not encounter one another and did not interbreed. Lion-tiger hybrids are sometimes born in captivity, but they do not occur under natural conditions.

TABLE 22.1 Isolating Mechanisms

Timing Relative to Fertilization	Mechanism	Mode of Action
Prezygotic ("premating") mechanisms	Ecological isolation	Species live in different habitats
	Temporal isolation	Species breed at different times
	Behavioral isolation	Species cannot communicate
	Mechanical isolation	Species cannot physically mate
	Gametic isolation	Species have nonmatching receptors on gametes
Postzygotic ("postmating") mechanisms	Hybrid inviability	Hybrid offspring do not complete development
	Hybrid sterility	Hybrid offspring cannot produce gametes
	Hybrid breakdown	Hybrid offspring have reduced survival or fertility

© Cengage Learning 2014



Species living in the same habitat can experience **temporal isolation** if they mate at different times of day or different times of year. For example, the fruit flies *Drosophila persimilis* and *Drosophila pseudoobscura* overlap extensively in their geographical distributions, but they do not interbreed, in part because *D. persimilis* mates in the morning and *D. pseudoobscura* in the afternoon. Similarly, two species of pine in California are reproductively isolated where their geographical distributions overlap: even though both rely on the wind to carry male gametes (pollen grains) to female gametes (ova) in other cones, *Pinus radiata* releases pollen in February and *Pinus muricata* releases pollen in April.

Many animals rely on specific signals, which may differ dramatically between species, to identify the species of a potential mate. **Behavioral isolation** results when the signals used by one species are not recognized by another. For example, female birds rely on the song, color, and displays of males to identify members of their own species. Similarly, female fireflies identify males by their flashing patterns **(Figure 22.6).** These behaviors (collectively called *courtship displays*) are often so complicated that signals sent by one species are like a foreign language that another species simply does not understand.

Mate choice by females and sexual selection (discussed in Section 21.3) generally drive the evolution of mate recognition signals. Females often spend substantial energy in reproduction, and choosing an appropriate mate—that is, a male of her own species—is critically important for the production of successful young. By contrast, a female that mates with a male from a different species is unlikely to leave any surviving offspring at all. Over time, the number of males with recognizable traits, as well as the number of females able to recognize the traits, increases in the population.

Differences in the structure of reproductive organs or other body parts—**mechanical isolation**—may prevent individuals of different species from interbreeding. In particular, many plants have anatomical features that allow only certain pollinators, usually particular bird or insect species, to collect and distribute pollen (see Chapter 29). For example, the flowers and nectar of two native California plants, the purple monkey-flower *(Mimulus lewisii)* and the scarlet monkey-flower *(Mimulus cardinalis),* attract different animal pollinators **(Figure 22.7).** *Mimulus lewisii* is pollinated by bumblebees. It has shallow purple flowers with broad petals that provide a landing platform for the bees. Bright yellow streaks on the petals serve as "nectar guides," directing bumblebees to the short nectar tube and reproductive parts, which are located among the petals. Bees enter the flowers to drink their concentrated nectar, and they pick up and deliver pollen as their legs and bodies brush against the reproductive parts of the flowers. *Mimulus cardinalis,* by contrast, is pollinated by hummingbirds. It has long red flowers with no yellow streaks, and the reproductive parts extend above the petals. The red color attracts hummingbirds but lies outside the color range detected by bumblebees. The nectar of *M. cardinalis* is more di-

FIGURE 22.7 **Mechanical reproductive isolation.** Because of differences in floral structure, two species of monkey-flower attract different animal pollinators. *Mimulus lewisii* attracts bumblebees, and *Mimulus cardinalis* attracts hummingbirds.

lute than that of *M. lewisii* but is produced in much greater quantity, making it easier for hummingbirds to ingest. When a hummingbird visits *M. cardinalis* flowers, it pushes its long bill down the nectar tube, and its forehead touches the reproductive parts, picking up and delivering pollen. Recent research has demonstrated that where the two monkey-flower species grow side-by-side, animal pollinators restrict their visits to either one species or the other 98% of the time, providing nearly complete reproductive isolation.

Even when individuals of different species mate, **gametic isolation,** an incompatibility between the sperm of one species and the eggs of another, may prevent fertilization. Many marine invertebrates release gametes into the environment for external fertilization. The sperm and eggs of each species recognize one another's complementary surface proteins (see Chapter 49), but the surface proteins on the gametes of different species don't match. In animals with internal fertilization, sperm of one species may not survive and function within the reproductive tract of another. Interspecific matings between some *Drosophila* species, for example, induce a reaction in the female's reproductive tract that blocks "foreign" sperm from reaching eggs. Parallel physiological incompatibilities between a pollen tube and a stigma prevent interspecific fertilization in some plants.

Postzygotic Isolating Mechanisms Reduce the Success of Hybrid Individuals

If prezygotic isolating mechanisms between two closely related species are incomplete or ineffective, sperm from one species sometimes fertilizes an egg of the other species. In such cases the two species will be reproductively isolated if their offspring, called interspecific (between species) hybrids, have lower fitness than those produced by intraspecific (within species) matings. Three postzygotic isolating mechanisms—*hybrid inviability, hybrid sterility,* and *hybrid breakdown*—can reduce the fitness of hybrid individuals.

Many genes govern the complex processes that transform a zygote into a mature organism. Hybrid individuals have two sets of developmental instructions, one from each parent species, which may not interact properly for the successful completion of embryonic development. As a result, hybrid organisms frequently die as embryos or at an early age, a phenomenon called **hybrid inviability.** For example, domestic sheep and goats can mate and fertilize one another's ova, but the hybrid embryos always die before coming to term, presumably because the developmental programs of the two parent species are incompatible.

Although some hybrids between closely related species develop into healthy and vigorous adults, they may not produce functional gametes. This **hybrid sterility** often results when the parent species differ in the number or structure of their chro-

Jen and Des Bartlett/Bruce Coleman USA

FIGURE 22.8 **Interspecific hybrids.** Horses and zebroids (hybrid offspring of horses and zebras) run in a mixed herd. Zebroids are usually sterile.

mosomes, which cannot pair properly during meiosis. Such hybrids have zero fitness because they leave no descendants. The most familiar example is a mule, the product of mating between a female horse ($2n = 64$) and a male donkey ($2n = 62$). Zebroids, the offspring of matings between horses and zebras, are also usually sterile **(Figure 22.8).**

Some first-generation hybrids (F_1; see Section 12.1) are healthy and fully fertile. They can breed with other hybrids and with both parental species. However, the second generation (F_2), produced by matings between F_1 hybrids, or between F_1 hybrids and either parental species, may exhibit reduced survival or fertility, a phenomenon known as **hybrid breakdown.** For example, experimental crosses between *Drosophila* species may produce functional hybrids, but their offspring experience a high rate of chromosomal abnormalities and harmful types of genetic recombination. Thus, reproductive isolation is maintained between the species because there is little long-term mixing of their gene pools.

STUDY BREAK 22.2

1. **What is the difference between prezygotic and postzygotic isolating mechanisms?**
2. **When a male duck of one species performed a courtship display to a female of another species, she interpreted his behavior as aggressive rather than amorous. What type of reproductive isolating mechanism does this scenario illustrate?**

22.3 The Geography of Speciation

As Ernst Mayr recognized, geography has a huge impact on whether gene pools have the opportunity to mix. Biologists define three modes of speciation, based on the geographical relationship of populations as they become reproductively isolated: *allopatric speciation* (*allo* = different, *patria* = homeland), *parapatric speciation* (*para* = beside), and *sympatric speciation* (*sym* = together).

Allopatric Speciation Occurs between Geographically Separated Populations

Allopatric speciation may take place when a physical barrier subdivides a large population or when a small population becomes separated from a species' main geographical distribution. Allopatric speciation occurs in two stages. First, two populations become *geographically* separated, preventing gene flow between them. Then, as the populations experience distinct mutations as well as different patterns of natural selection and genetic drift, they may accumulate genetic differences that isolate them *reproductively.* Allopatric speciation is probably the most common mode of speciation in large animals.

Geographical separation sometimes occurs when a barrier divides a large population into two or more units **(Figure 22.9).** For example, hurricanes may create new channels that divide low coastal islands and the populations inhabiting them. Uplifting mountains or landmasses as well as rivers or advancing glaciers can also produce barriers that subdivide populations. The uplift of the Isthmus of Panama, caused by movements of Earth's crust about 5 million years ago, separated a once-

FIGURE 22.9 **The model of allopatric speciation and secondary contact.**

© Cengage Learning 2014

1 At first, a population is distributed over a large geographical area. A river flows along one edge of the population's geographical range.

2 A geographical change, such as a change in the river's course, separates the original population, creating a barrier to gene flow.

3 In the absence of gene flow, the separated populations evolve independently and diverge into different species.

4 When the river later changes course again, allowing individuals of the two species to come into secondary contact, they do not interbreed.

FIGURE 22.11 Evolution of a species cluster on an archipelago. Letters identify four islands in a hypothetical archipelago, and colored dots represent different species. The ancestor of all the species is represented by black dots on the mainland. At the end of the process, islands A and B are each occupied by two species, and islands C and D are each occupied by one species, all of which evolved on the islands.
© Cengage Learning 2014

continuous shallow sea into the eastern tropical Pacific Ocean and the western tropical Atlantic Ocean. Populations of marine organisms were subdivided by this event. In the tropical Atlantic Ocean, populations experienced patterns of mutation, natural selection, and genetic drift that were different from those experienced by populations in the tropical Pacific Ocean. As a result, the populations diverged genetically, and pairs of closely related species now live on either side of this divide **(Figure 22.10).**

In other cases, small populations may become isolated at the edge of a species' geographical distribution. Such peripheral populations often differ genetically from the central population because they are adapted to somewhat different environments. Once a small population is isolated, founder effects and small population size may promote genetic drift (see page 464), and natural selection may favor the evolution of distinctive traits. If the isolated population experiences limited gene flow from the parent population, these agents of evolution will foster genetic differentiation between them. In time, the accumulated genetic differences may lead to reproductive isolation.

Populations established by colonization of oceanic islands represent extreme examples of this phenomenon. The founder effect makes the populations genetically distinct. And on oceanic archipelagos, such as the Galápagos and Hawaiian islands, individuals from one island may colonize nearby islands, founding populations that differentiate into distinct species. Each island may experience multiple invasions, and the process may be repeated many times within the archipelago, leading to the evolution of a **species cluster,** a group of closely related species recently descended from a common ancestor **(Figure 22.11).** Sometimes a species cluster can evolve relatively quickly; for example, the nearly 800 species of fruit flies now living on the Hawaiian Islands (described in *Focus on Basic Research*) evolved in less than 5 million years, an average of just over 6,000 years per species.

Speciation in Hawaiian Fruit Flies

The islands of the Hawaiian archipelago have been geographically isolated throughout their history, lying at least 3,200 km (approximately 2,000 miles) from the nearest continents or other islands **(Figure 1).** Built by undersea volcanic eruptions over millions of years, they emerged from northwest to southeast: Kauai is at least 5 million years old, and Hawaii, the "Big Island," is less than 1 million years old. Individual islands differ in maximum elevation and include diverse habitats, from sparse, dry vegetation to lush, wet forests.

Resident species must have arrived from distant mainland localities or evolved on the islands from colonizing ancestors. The islands' isolation, different ages, and geographical and ecological complexity allowed repeated interisland colonizations followed by allopatric speciation events. Thus, it is not surprising that species clusters have evolved in several groups of organisms (including flowering plants, insects, and birds).

Nearly 800 species of Hawaiian fruit flies, most of which live on only one island, have been discovered. Biologists used many characters to identify the different species, including external and internal anatomy, cell structure, chromosome structure, ecology, and mating behavior. Their data suggest that the vast majority of native Hawaiian species arose from a single ancestral species that colonized the archipelago long ago, probably from eastern Asia. After repeated speciation events, the fruit flies of the Hawaiian Islands represent more than 25% of all known fruit fly species.

Hampton Carson, of the University of Hawaii, spearheaded studies on the evolutionary relationships of Hawaiian fruit flies. He and his colleagues gathered data on hundreds of fly species—a daunting task. Most species of fruit flies are sexually dimorphic. The females of different species may be similar in appearance, but the males of even closely related species differ in virtually every aspect of their external anatomy: body size, head shape, and the structure of their eyes, antennae, mouthparts, bristles, legs, and wings. Their mating behavior and choice of mating sites also vary dramatically.

Nevertheless, closely related species on different islands occupy comparable habitats and associate with related plant species. Carson suggested that speciation in these flies resulted from the evolution of different genetically determined *mating systems,* the behaviors and morphological characteristics that males display when seeking a mate. The mating systems serve as prezygotic isolating mechanisms.

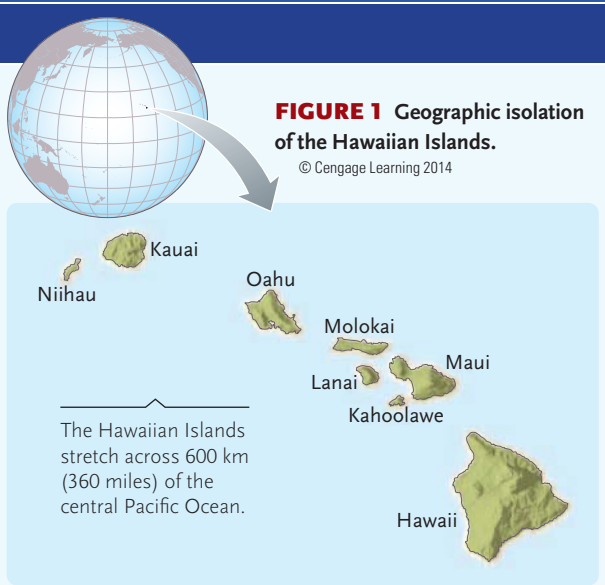

FIGURE 1 **Geographic isolation of the Hawaiian Islands.**

The 100 or more species of "picture-wing" *Drosophila,* relatively large flies with patterns on their wings, illustrate the evolution of a species cluster. Carson and his colleagues used similarities and differences in the banding patterns on the flies' giant salivary chromosomes (described in *Focus on Model Research Organisms* in Chapter 13), to trace the evolutionary origin of species on the younger islands by identifying their closest relatives on the older islands. Their analysis of 26 species on Hawaii, the youngest island, suggested that flies from the older islands colonized Hawaii at least 19 different times, and each founder population evolved into a new species there. Additional species apparently evolved when lava flows on Hawaii subdivided existing populations.

Among the picture-wing fruit flies, some interspecies matings result in hybrid sterility or hybrid breakdown. But for most species, prezygotic reproductive isolation is maintained by differences in their mating systems. For example, *Drosophila silvestris* and *Drosophila heteroneura,* which produce healthy and fertile hybrids in the laboratory, have similar geographical distributions; however, differences in courtship behavior and in the shape of the males' heads, a characteristic that females use to recognize males of their own species **(Figure 2),** keep these two species reproductively isolated. In nature, they hybridize only in one small geographical area.

The work of Carson and his colleagues suggests that most speciation in Hawaiian *Drosophila* has resulted from founder effects and genetic drift. When a fertile female—or a small group of males and females—moves to a new island, this founding population responds to novel selection pressures in its new environment. Sexual selection then exaggerates distinctive morphological and behavioral characteristics, maintaining the population's reproductive isolation from its new neighbors. The tremendous variety of Hawaiian fruit flies has undoubtedly been produced by repeated colonizations of newer islands by flies from older islands and by the back-colonization of older islands by newly evolved species. Thus, they represent what evolutionary biologists describe as an *adaptive radiation,* a cluster of closely related species that are ecologically different (as described further in Chapter 23).

FIGURE 22.12 Hybrid zones. Males of the Bullock's oriole and Baltimore oriole differ in color and courtship song. The populations have maintained a hybrid zone for hundreds of years, and once were considered subspecies of the same species. The American Ornithologists' Union recognized them as separate species in 1997. They now hybridize less frequently than they once did, leading some researchers to suggest that their reproductive isolation evolved recently.

© Cengage Learning 2014

Sometimes, allopatric populations reestablish contact when a geographical barrier is eliminated or breached (see Figure 22.9, step 4). This *secondary contact* provides a test of whether or not the populations have diverged into separate species. If their gene pools did not differentiate much during geographical separation, the populations will interbreed and merge. But if the populations have differentiated enough to be reproductively isolated, they have become separate species.

During the early stages of secondary contact, prezygotic reproductive isolation may be incomplete. Some members of each population may mate with individuals from the other, producing viable, fertile offspring in areas called **hybrid zones.** Although some hybrid zones have persisted for hundreds or thousands of years **(Figure 22.12),** they are generally narrow, and ecological or geographical factors maintain the separation of the gene pools for the majority of individuals in both species.

If postzygotic isolating mechanisms cause hybrid offspring to have lower fitness than those produced within each population, natural selection will promote the evolution of prezygotic isolating mechanisms, favoring individuals that mate only with members of their own population. Recent studies of *Drosophila* suggest that this phenomenon, called **reinforcement,** enhances reproductive isolation that had begun to develop while the populations were geographically separated.

Parapatric Speciation May Occur between Adjacent Populations

Sometimes a single species is distributed across a discontinuity in environmental conditions, such as a major change in soil type. Although organisms on one side of the discontinuity may interbreed freely with those on the other side, natural selection may favor different alleles on either side, limiting gene flow. In such cases, **parapatric speciation**—speciation arising between adjacent populations—may occur if hybrid offspring have low relative fitness.

Some strains of bent grass *(Agrostis tenuis),* a common pasture plant in Great Britain, have the physiological ability to grow on mine tailings, where the soil is heavily polluted by copper or other metals. Plants of the copper-tolerant strains grow well on polluted soils, but plants of the pasture strain do not. Conversely, copper-tolerant plants don't survive as well as pasture plants on unpolluted soils. These strains often grow within a few meters of each other where polluted and unpolluted soils form an intricate environmental mosaic. Because bent grass is wind-pollinated, pollen is readily transferred from one strain to another. Laboratory tests showed that the strains are fully interfertile. However, copper-tolerant plants flower about one week earlier than nearby pasture plants, which promotes prezygotic (temporal) isolation of the two strains **(Figure 22.13).** If the flowering times become further separated, the two strains may attain complete reproductive isolation and become separate species.

Some biologists argue that the places where parapatric populations of bent grass interbreed are really hybrid zones where previously allopatric populations have established secondary contact. Unfortunately, there is no way to determine whether the hybridizing populations were parapatric or allopatric in the past. Thus, a thorough evaluation of the parapatric speciation hypothesis must await the development of techniques that enable biologists to distinguish clearly between the products of allopatric and parapatric speciation.

Sympatric Speciation Occurs within One Continuously Distributed Population

In **sympatric speciation,** reproductive isolation evolves between distinct subgroups that arise within one population. Models of sympatric speciation do not require that the populations be either geographically or environmentally separated as their gene pools diverge. We examine below general models of sympatric speciation in animals and plants; the genetic basis of sympatric speciation is one of the topics we consider in the next section.

Insects that feed on just one or two plant species are among the animals most likely to evolve by sympatric speciation. These insects generally carry out most important life cycle activities on or near their "host" plants. Adults mate on the host plant; females lay their eggs on it; and larvae feed on the host plant's tissues, eventually developing into adults, which initiate another round of the life cycle. Host plant choice is genetically determined in many

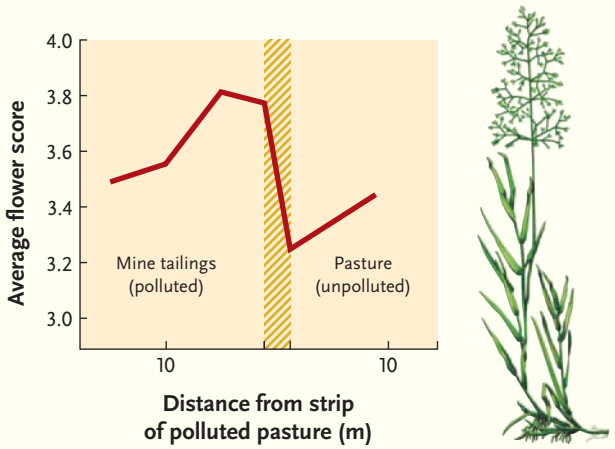
FIGURE 22.13 **Observational Research**

Evidence for Reproductive Isolation in Bent Grass



Question: Do adjacent populations of bent grass living on different soil types exhibit signs of reproductive isolation?

Hypothesis: Adjacent populations of bent grass *(Agrostis tenuis)* flower at slightly different times, which could foster prezygotic reproductive isolation between them.

Prediction: On any given summer day, the flowers in one population will be more mature (thus, being pollinated earlier) than flowers in the adjacent population.

Method: On a late summer day in 1965, Thomas McNeilly and Janis Antonovics of University College of North Wales compared the flowers of bent grass growing on polluted soil at a copper mine with the flowers of plants growing on unpolluted soil in a nearby pasture. A meter-wide stretch of polluted pasture (indicated by cross-hatching in the graph) formed a boundary between the two populations. Researchers assigned a score to every flower, with immature flowers scored as 3 and mature flowers as 4.

Results: On the day that they were surveyed, flowers of the copper-tolerant plants had higher scores, indicating that they were more mature—and thus would complete pollination earlier—than the flowers of the pasture plants.

Conclusion: Because adjacent populations of bent grass flower at slightly different times, temporal reproductive isolation may be developing between them.

THINK LIKE A SCIENTIST If bent grass were insect pollinated instead of being wind pollinated, would the observed difference in the timing of flower maturation still establish temporal reproductive isolation between the two strains?

FIGURE 22.14 Sympatric speciation in animals. Male and female apple maggots *(Rhagoletis pomonella)* court on a hawthorn leaf. The female will later lay her eggs on the fruit, and the offspring will feed, mate, and lay their eggs on hawthorns as well.

insect species. In others, individuals associate with the host plant species they ate as larvae.

Theoretically, a genetic mutation could suddenly change some insects' choice of host plant. Mutant individuals would shift their life cycle activities to the new host, and then interact primarily with others preferring the same new host, an example of ecological isolation. These individuals would collectively form a separate subpopulation, called a **host race.** Reproductive isolation could evolve between different host races if the individuals of each host race are more likely to mate with members of their own host race than with members of another. Some biologists criticize this model, however, because it assumes that the genes controlling two traits, the insects' host plant choice and their mating preferences, change simultaneously. Moreover, host plant choice is controlled by multiple gene loci in some insect species, and it is clearly influenced by prior experience in others.

The apple maggot *(Rhagoletis pomonella)* is the most thoroughly studied example of possible sympatric speciation in animals **(Figure 22.14).** This fly's natural host plant in eastern North America is the hawthorn (*Crataegus* species), but at least two host races have appeared in the past 150 years. The larvae of a new host race were first discovered feeding on apples in New York State in the 1860s. In the 1960s, a cherry-feeding host race appeared in Wisconsin.

Genetic analyses have shown that variations at just a few gene loci underlie differences in the feeding preferences of *Rhagoletis* host races; other genetic differences cause the host races to develop at different rates. Moreover, adults of the three races mate during different summer months. Nevertheless, individuals show no particular preference for mates of their own host race, at least under simplified laboratory conditions. Thus, although behavioral isolation has not developed between races, ecological and temporal isolation may separate adults in nature. Researchers are still not certain that the different host races are reproductively isolated under natural conditions.

In 2010, Andrew P. Michel of the University of Notre Dame and colleagues elsewhere in the United States and Germany published a genomic analysis of the apple- and hawthorn-feeding races of *Rhagoletis.* Their results suggest that over the past 150 years, the two races have diverged at many loci in their genomes—not just at the loci that influence food choice and developmental rate—and that the divergence has largely been driven by nat-

ural selection. Ongoing genetic divergence may prevent them from interbreeding in the future.

Sympatric speciation often occurs in plants through a genetic phenomenon, **polyploidy,** in which an individual has one or more *extra* copies of the entire haploid complement of chromosomes (see Section 13.3). Polyploidy can lead to speciation because these large-scale genetic changes may prevent polyploid individuals from breeding with individuals of the parent species. Nearly half of all flowering plant species are polyploid, including many important crops and ornamental species. The genetic mechanisms that produce polyploid individuals in plant populations are well understood; we describe them in the next section as part of a larger discussion of the genetics of speciation.

STUDY BREAK 22.3

1. What are the two stages required for allopatric speciation?
2. What factor appears to promote parapatric speciation in bent grass?
3. Why might insects from different host races be unlikely to mate with each other?

THINK OUTSIDE THE BOOK

Figure 22.12 presents an example of a hybrid zone between two closely related bird species in North America. Search the biological literature and the Internet for three other examples of hybrid zones in animals. How large are the areas of hybridization? What prezygotic isolating mechanisms prevent the species from interbreeding outside the hybrid zones? Is the frequency of hybrid matings increasing or decreasing through time?

22.4 Genetic Mechanisms of Speciation

What genetic changes lead to reproductive isolation between populations? In this section we examine three genetic mechanisms that can lead to reproductive isolation: *genetic divergence* between allopatric populations, *polyploidy* in sympatric populations, and *chromosome alterations,* which occur independently of the geographical distributions of populations.

Genetic Divergence in Allopatric Populations Can Lead to Speciation

In the absence of gene flow, geographically separated populations inevitably accumulate genetic differences through the action of mutation, genetic drift, and natural selection.

How much genetic divergence is necessary for speciation to occur? To understand the genetic basis of speciation in closely related species, researchers first identify the specific causes of reproductive isolation. They then use standard techniques of genetic analysis along with new molecular approaches such as gene mapping and sequencing to analyze the genetic mechanisms that establish reproductive isolation. As explained in *Insights from the Molecular Revolution,* these techniques now allow researchers to determine the minimum number of genes responsible for reproductive isolation in particular pairs of species.

In cases of postzygotic reproductive isolation, mutations in just a few gene loci can establish reproductive isolation. For example, if two common aquarium fishes, swordtails *(Xiphophorus helleri)* and platys *(Xiphophorus maculatus),* mate, two genes induce the development of lethal tumors in their hybrid offspring. When hybrid sterility is the primary cause of reproductive isolation between *Drosophila* species, at least 5 gene loci are responsible. About 55 gene loci contribute to postzygotic reproductive isolation between the European fire-bellied toad *(Bombina bombina)* and the yellow-bellied toad *(Bombina variegata).*

In cases of prezygotic reproductive isolation, some mechanisms have a surprisingly simple genetic basis. For example, a single mutation reverses the direction of coiling in the shells of some snails (*Bradybaena* species). Snails with shells that coil in opposite directions cannot approach each other closely enough to mate, making reproduction between them mechanically impossible.

Many traits that now function as prezygotic isolating mechanisms may originally have evolved in response to sexual selection (described on page 470). In sexually dimorphic species, this evolutionary process exaggerates showy structures and courtship behaviors in males, the traits that females use to identify appropriate mates. When two populations encounter one another on secondary contact, these traits may also prevent interspecific mating. For example, many closely related duck species exhibit dramatic variation in the appearance of males, but not females **(Figure 22.15),** an almost certain sign of sexual selection. Yet these species hybridize readily in captivity, producing offspring that are both viable and fertile.

Reproductive isolation and speciation in ducks and other sexually dimorphic birds probably results from geographical

Monkey-Flower Speciation: How many genes contribute to reproductive isolation?

Reproductive isolation is the primary criterion that biologists use to distinguish species. As noted earlier, the monkey-flower species *Mimulus lewisii* and *Mimulus cardinalis* experience mechanical reproductive isolation in nature because differences in flower structure keep bumblebees or hummingbirds from carrying pollen from one species to the other (see Figure 22.7). However, the two species are easily crossed in the laboratory and produce fertile F_1 hybrids. The F_2 offspring have flowers with various forms intermediate between the two parental types (see bottom row of **Figure**), suggesting that several gene loci control the traits separating the species.

Research Question

How many gene loci contribute to the differences in flower traits that foster prezygotic reproductive isolation between the two *Mimulus* species?

Experiment

Because little was known about the genetics of the two monkey-flower species, it was not possible to use a direct genetic analysis to identify and map the flower trait genes to the chromosomes. Instead, H. D. ("Toby") Bradshaw and other researchers at the University of Washington used an indirect molecular approach that identified DNA sequence variations (analogous to those used in DNA fingerprinting; see Chapter 18) at various loci in the genome. Just as morphological and biochemical traits vary within a population, DNA sequences vary at particular sites in the genome; and the different DNA sequence alleles can be distinguished using PCR.

The researchers used a random set of 153 DNA sequence variations. They correlated the segregation of those variations with the segregation of flower traits in 93 plants of the F_2 generation. Some of the DNA sequences segregated closely with a particular flower trait. This result indicated that the particular DNA sequence variation locus was very near the gene for that flower trait on the chromosome. In other words, the flower trait locus was identified indirectly through the close linkage between the DNA variation locus and the flower trait locus. But where are the genes? To answer this question, the researchers used the DNA sequences linked to flower trait loci as probes to find the sites on the chromosomes where they originated. (The use of DNA probes to identify complementary DNA in the genome is described in Figure 18.9.) For any given DNA variation locus, once its position on the chromosomes was determined, the investigators knew that the flower trait locus correlated with it must be nearby.

H. D. Bradshaw Jr., S. M. Wilbert, K. G. Otto, and D. W. Schemske. 1995. Genetic mappings of floral traits associated with reproductive isolation in monkey flowers (Mimlus). Nature 376: 762–765.

Results

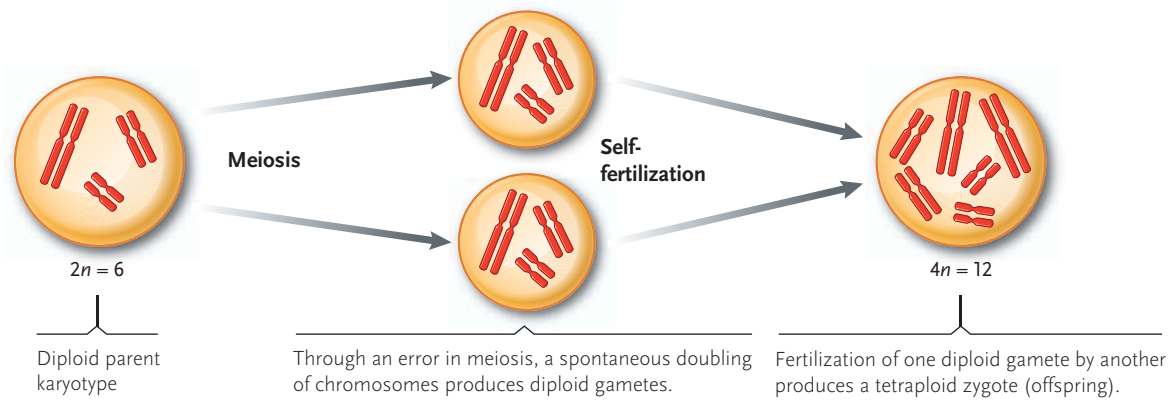
Their results indicate that reproductive isolation of *M. lewisii* and *M. cardinalis* results from differences in eight floral traits: the amount of (1) anthocyanin pigments and (2) carotenoid pigments in petals; (3) flower width; (4) petal width; (5) nectar volume; (6) nectar concentration; and the lengths of the stalks supporting the (7) male and (8) female reproductive parts. Although the investigators could not directly determine the number of genes controlling each trait, the characteristics of the traits, their locations at eight sites on six of the eight chromosomes, and their pattern of inheritance make it most likely that each trait is controlled by a single gene, giving a likely minimum of eight genes.

Conclusion

Mutations in as few as eight genes may have established reproductive isolation between these two species of monkey-flower. Thus, it appears that in some cases surprisingly little genetic change is required for the evolution of a new species. This research was the first in which random differences in DNA sequences were used to answer the fundamental evolutionary question of how much genetic change is needed to produce a new species.

THINK LIKE A SCIENTIST Given what you learned about the two species of monkey-flowers and their pollinators in Section 22.2, explain how differences in the eight floral traits might contribute to reproductive isolation between these two species.

Source: H. D. Bradshaw Jr., S. M. Wilbert, K. G. Otto, and D. W. Schemske. 1995. Genetic mapping of floral traits associated with reproductive isolation in monkey-flowers (*Mimulus*). *Nature* 376:762–765.



© Cengage Learning 2014

isolation and sexual selection on just a few morphological and behavioral characteristics that influence their mating behavior Thus, sometimes the evolution of reproductive isolation may not require much genetic change at all. Indeed, sexual selection appears to increase the rate at which new species arise: bird lineages that are sexually dimorphic generally include more species than do related lineages in which males and females have a similar appearance.

CLOSER LOOK **FIGURE 22.16** Polyploidy in plants.

A. Speciation by autopolyploidy in plants
A spontaneous doubling of chromosomes during meiosis produces diploid gametes. If the plant fertilizes itself, a tetraploid zygote will be produced.

B. Speciation by hybridization and allopolyploidy in plants
A hybrid mating between two species followed by a doubling of chromosomes during mitosis in gametes of the hybrid can instantly create sets of homologous chromosomes. Self-fertilization can then generate polyploid individuals that are reproductively isolated from both parent species.

SUMMARY In both autopolyploidy and allopolyploidy, a spontaneous doubling of chromosome number produces gametes with twice the original number of chromosomes, but the timing of doubling is different. In autopolyploidy, the doubling occurs during a meiotic cell division that produces $2n$ gametes in the parent. In allopolyploidy, the doubling occurs after a hybrid offspring is produced, when some of its cells are undergoing mitosis; meiosis in the polyploid hybrid then produces polyploid gametes.

THINK LIKE A SCIENTIST How many chromosomes would you be likely to find in the allopolyploid hybrid offspring of parents that had $2n = 8$ and $2n = 12$, respectively?

© Cengage Learning 2013

Polyploidy Is a Common Mechanism of Sympatric Speciation in Plants

Polyploidy is common among plants, and it may be an important factor in the evolution of some fish, amphibian, and reptile species. Polyploid individuals can arise from chromosome duplications within a single species (autopolyploidy) or through hybridization of different species (allopolyploidy).

AUTOPOLYPLOIDY In **autopolyploidy (Figure 22.16A),** a diploid ($2n$) individual may produce, for example, tetraploid ($4n$) offspring, each of which has four complete chromosome sets. Auto-

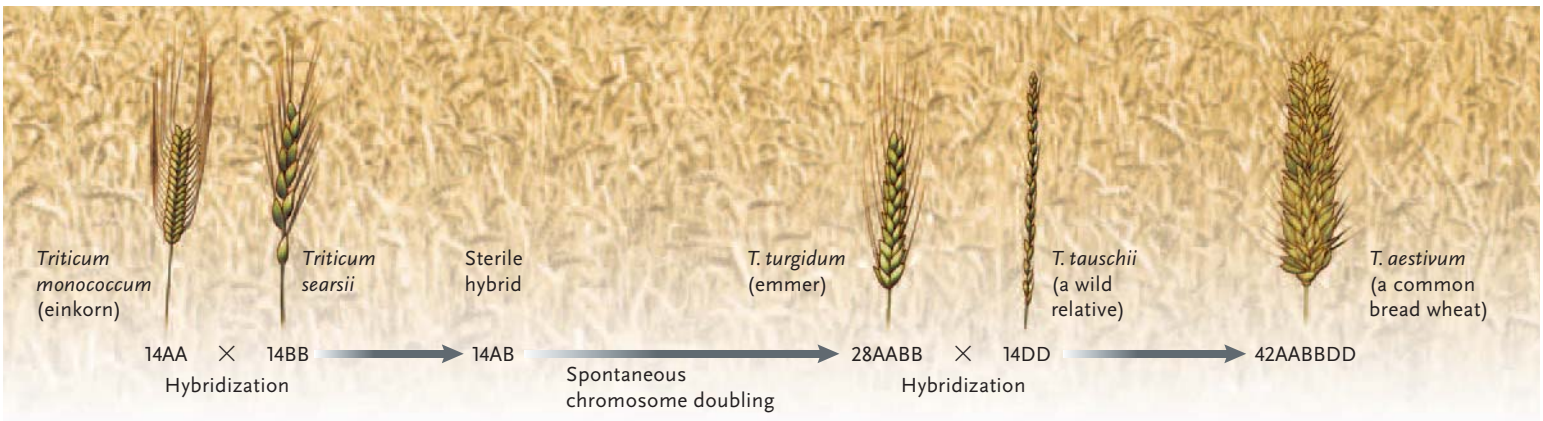
Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

polyploidy often results when gametes, through an error in either mitosis or meiosis, spontaneously receive the same number of chromosomes as a somatic cell. Such gametes are called **unreduced gametes** because their chromosome number has not been reduced compared with that of somatic cells.

Diploid pollen can fertilize the diploid ovules of a self-fertilizing individual, or it may fertilize diploid ovules on another plant with unreduced gametes. The resulting tetraploid offspring can reproduce either by self-pollination or by breeding with other tetraploid individuals. However, a tetraploid plant cannot produce fertile offspring by hybridizing with its diploid parents. The fusion of a diploid gamete with a normal haploid gamete produces a triploid ($3n$) offspring, which is usually sterile because its odd number of chromosomes cannot segregate properly during meiosis. Thus, the tetraploid is reproductively isolated from the original diploid population. Many species of grasses, shrubs, and ornamental plants, including violets, chrysanthemums, and nasturtiums, are autopolyploids, having anywhere from 4 to 20 complete chromosome sets.

ALLOPOLYPLOIDY In **allopolyploidy (Figure 22.16B),** two closely related species hybridize and subsequently form polyploid offspring. Hybrid offspring are sterile if the two parent species have diverged enough that their chromosomes do not pair properly during meiosis. However, if the hybrid's chromosome number is doubled, the chromosome complement of the gametes is also doubled, producing homologous chromosomes that *can* pair during meiosis. The hybrid can then produce polyploid gametes and, through self-fertilization or fertilization with other doubled hybrids, establish a population of a new polyploid species. Compared with speciation by genetic divergence, speciation by allopolyploidy is extremely rapid, causing a new species to arise in one generation without geographical isolation.

Even when sterile, polyploids are often robust, growing larger than either parent species. For that reason, both autopolyploids and allopolyploids have been important to agriculture. For example, the wheat used to make flour *(Triticum aestivum)* has six sets of chromosomes **(Figure 22.17).** Other polyploid crop plants include plantains (cooking bananas), coffee, cotton, potatoes, sugarcane, and tobacco.



Plant breeders often try to increase the probability of forming an allopolyploid by using chemicals that foster nondisjunction of chromosomes during mitosis. In the first such experiment, undertaken in the 1920s, scientists crossed a radish and a cabbage, hoping to develop a plant with both edible roots and leaves. Instead, the new species, *Raphanobrassica,* combined the least desirable characteristics of each parent, growing a cabbage-like root and radishlike leaves. Recent experiments have been more successful. For example, plant scientists have produced an allopolyploid grain, triticale, that has the disease-resistance of its rye parent and the high productivity of its wheat parent.

Chromosome Alterations Can Foster Speciation

Other changes in chromosome structure or number may also foster speciation. Closely related species often have a substantial number of chromosome differences between them, including inversions, translocations, deletions, and duplications (described in Section 13.3). These differences, which may foster postzygotic isolation, can often be identified by comparing the *banding patterns* in stained chromosome preparations from the

FIGURE 22.17 The evolution of wheat. Researchers believe the evolution of common bread wheat resulted from a hybridization between two diploid species, followed by a spontaneous doubling of the hybrid's chromosomes, and a second hybridization between the polyploid hybrid and a third diploid species.

© Cengage Learning 2014

Jose Ignacio/Shutterstock.com

1 Wild diploid wheat, *Triticum monococcum* (einkorn), has two sets of 7 chromosomes (shown above as 14AA). Long ago, einkorn hybridized with *T. searsii*, another wild diploid species that also had two sets of 7 chromosomes (14BB). The resulting hybrid, which had 14 chromosomes (14AB), was sterile because its A chromosomes could not pair with its B chromosomes during meiosis.

2 Between 10,000 and 8,000 years ago, the sterile hybrid experienced a spontaneous doubling of its chromosomes, producing wild emmer (*T. turgidum*). These tetraploid plants had four sets of 7 chromosomes (28AABB) and were fertile. At meiosis, the A chromosomes pair with each other, and the B chromosomes pair with each other.

3 Later, emmer, the tetraploid hybrid (AABB), hybridized with *T. tauschii*, a wild diploid species with two sets of 7 chromosomes (14DD). Their hybrid descendants include common bread wheats, such as *T. aestivum*, a hexaploid that has six sets of 7 chromosomes (42AABBDD).

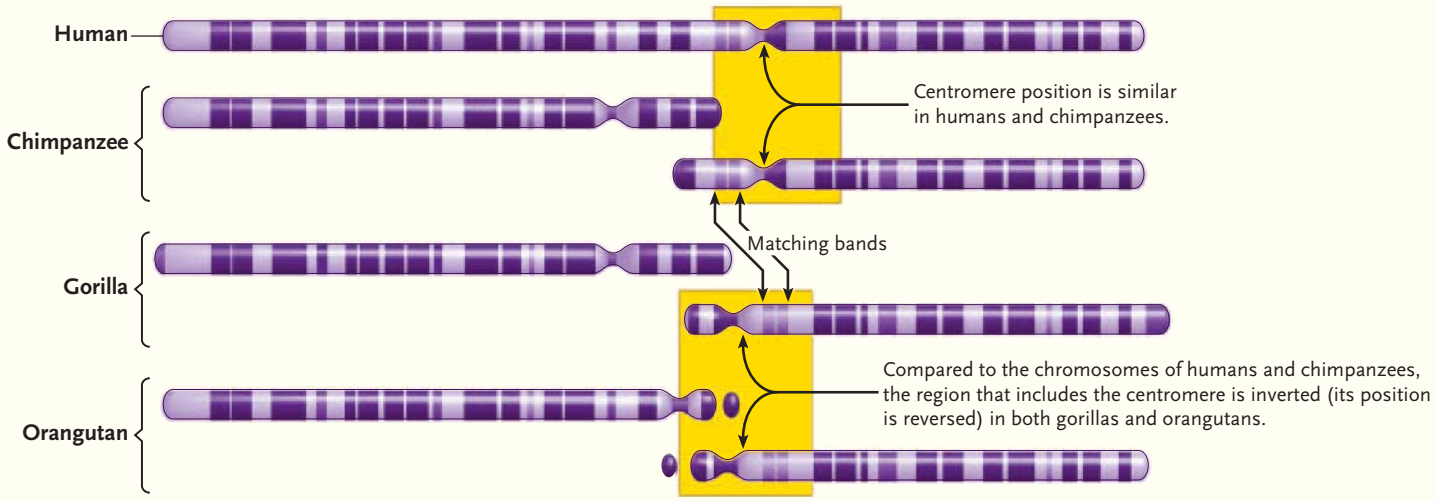
FIGURE 22.18 Observational Research

Chromosomal Similarities and Differences among the Great Apes



Question: Does chromosome structure differ between humans and their closest relatives among the apes?

Hypothesis: Large scale chromosome rearrangements contributed to the development of reproductive isolation between species within the evolutionary lineage that includes humans and apes.

Prediction: Chromosome structure differs markedly between humans and their close relatives among the great apes: chimpanzees, gorillas, and orangutans.

Method: Jorge J. Yunis and Om Prakash of the University of Minnesota Medical School used Giemsa stain to visualize the banding patterns on metaphase chromosome preparations from humans, chimpanzees, gorillas, and orangutans. They identified about 1,000 bands that are present in humans and in the three ape species. By matching the banding patterns on the chromosomes, the researchers verified that they were comparing the same segments of the genomes in the four species. They then searched for similarities and differences in the structure of the chromosomes.

Results: Analysis of human chromosome 2 reveals that it was produced by the fusion of two smaller chromosomes that are still present in the other three species. Although the position of the centromere in human chromosome 2 matches that of the centromere in one of the chimpanzee chromosomes, in gorillas and orangutans it falls within an inverted segment of the chromosome.

Conclusion: Differences in chromosome structure between humans and both gorillas and orangutans are more pronounced than they are between humans and chimpanzees. Structural differences in the chromosomes of these four species may contribute to their reproductive isolation.

THINK LIKE A SCIENTIST Do you think that the differences in chromosome structure between humans and their closest relatives among the apes represent a prezygotic or postzygotic reproductive isolating mechanism?

Source: J. J. Yunis and O. Prakash. 1982. The origin of man: A chromosomal pictorial legacy. *Science* 215:1525–1530.

© Cengage Learning 2014

different species. In all species, banding patterns vary from one chromosome segment to another. When researchers find identical banding patterns in chromosome segments from two or more related species, they know that they are examining comparable portions of the species' genomes. Thus, the banding patterns allow scientists to identify specific chromosome segments and compare their positions in the chromosomes of different species.

The banding patterns of humans and their closest relatives among the apes—chimpanzees, gorillas, and orangutans—reveal that whole sections of chromosomes have been rearranged over evolutionary time **(Figure 22.18).** For example, humans have a diploid complement of 46 chromosomes, whereas chimpanzees, gorillas, and orangutans have 48 chromosomes. The difference can be traced to the fusion (that is, the joining together) of two ancestral chromosomes into chromosome 2 of humans; the ancestral chromosomes are separate in the other three species.

Moreover, banding patterns suggest that the position of the centromere in human chromosome 2 closely matches that of a centromere in one of the chimpanzee chromosomes, reflecting their close evolutionary relationship. But this centromere falls within an inverted region of the chromosome in gorillas and orangutans, reflecting their evolutionary diver-

gence from chimpanzees and humans. (Recall from Section 13.3 that an inverted chromosome segment has a reversed orientation, so the order of genes on it is reversed relative to the order in a segment that is not inverted.) Nevertheless, humans and chimps differ from each other in centromeric inversions in six other chromosomes.

How might such chromosome rearrangements promote speciation? In a paper published in 2003, Arcadi Navarro of the Universitat Pompeu Fabra in Spain and Nick H. Barton of the University of Edinburgh in Scotland compared the rates of evolution in protein-coding genes that lie within rearranged chromosome segments of humans and chimpanzees to those in genes outside the rearranged segments. They discovered that proteins evolved more than twice as quickly in the rearranged chromosome segments. Navarro and Barton reasoned that because chromosome rearrangements inhibit chromosome pairing and recombination during meiosis, new genetic variations favored by natural selection would be conserved within the rearranged segments. These variations accumulate over time, contributing to genetic divergence between populations with the rearrangement and those without it. Thus, chromosome rearrangements can be a trigger for speciation: once a chromosome rearrangement becomes established within a population, that population will diverge more rapidly from populations lacking the rearrangement. The genetic divergence eventually causes reproductive isolation.

Because speciation results from microevolutionary processes that divide one gene pool into two, it is sometimes the first step in the evolution of new biological lineages. In the next chapter we consider the effects of speciation over vast spans of time as we examine paleobiology and patterns of macroevolution. In Unit 4, we further explore the evolution of each of the major lineages in the Tree of Life.

STUDY BREAK 22.4

1. **How can natural selection promote reproductive isolation in allopatric populations?**
2. **How does polyploidy promote speciation in plants?**

UNANSWERED QUESTIONS

Do asexual organisms form species?

As you learned in this chapter, the biological species concept applies only to sexually reproducing organisms because only those organisms can evolve barriers to gene flow (asexual organisms reproduce more or less clonally). Nevertheless, research is starting to show that organisms whose reproduction is almost entirely asexual, such as bacteria, seem to form distinct and discrete clusters in nature. (These clusters could be considered "species.") That is, bacteria and other asexual forms may be as distinct as the species of birds described by Ernst Mayr in New Guinea. Workers are now studying the many species of bacteria in nature (only a small number of which have been discovered) to see if they indeed fall into distinct groups. If they do, then scientists will need a special theory, independent of reproductive isolation, to explain this distinctness. Scientists are now working on theories of whether the existence of discrete ecological niches in nature might explain the possible discreteness of asexual "species."

How often does speciation occur allopatrically versus sympatrically or parapatrically?

Scientists do not know how often speciation occurs between populations that are completely isolated geographically (allopatric speciation), compared to how often it occurs in populations that exchange genes (parapatric or sympatric speciation). The relative frequency of these modes of speciation in nature is an active area of research. The ongoing work includes studies on small, isolated islands: if an invading species divides into two or more species in this situation, it probably did so sympatrically or parapatrically, since geographical isolation of populations in small islands is unlikely. In addition, biologists are reconstructing the evolutionary history of speciation using molecular tools and correlating this history with the species' geographical distributions. If this research were to show, for example, that the most closely related pairs of species always had geographically isolated distributions, it would imply that speciation was usually allopatric. These lines of research should eventually answer the controversial question of the relative frequency of various forms of speciation.

What are the genetic changes underlying speciation?

Biologists know a great deal about the types of reproductive isolation that prevent gene flow between species, but almost nothing about their genetic underpinnings. Which genes control the difference between flower shape in monkey-flower species? Which genes lead to inviability and sterility of *Drosophila* hybrids? Which genes cause species of ducks to preferentially mate with members of their own species over members of other species? Do the genetic changes that lead to reproductive isolation tend to occur repeatedly at the same gene loci in a group of organisms, or at different gene loci? Do the changes occur mostly in protein-coding regions of genes, or in the noncoding regions that control the production of proteins? Were the changes produced by natural selection or by genetic drift? Biologists are now isolating "speciation genes" and sequencing their DNA. With only a handful of such genes known, and all of these causing hybrid sterility or inviability, there will undoubtedly be a lot to learn about the genetics of speciation in the next decade.

THINK LIKE A SCIENTIST Professor Coyne suggested that biologists will need to devise a special theory—or an additional type of species definition—to explain the distinctness of clusters of asexual organisms that are observed in nature. Do you think that this new explanation would be more similar to the morphological species concept or the phylogenetic species concept as described in this chapter?

Jerry Coyne

Jerry Coyne conducts research on speciation and teaches at the University of Chicago. To learn more about his research, go to http://pondside.uchicago.edu/ecol-evol/faculty/coyne_j.html.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

22.1 What Is a Species?

- In practice, most biologists describe, identify, and recognize species on the basis of morphological characteristics that serve as indicators of their genetic similarity to or divergence from other species (Figure 22.2).
- The biological species concept defines species as groups of interbreeding populations that are reproductively isolated from populations of other species in nature. A biological species thus represents a gene pool within which genetic material is potentially shared among populations. The biological species concept cannot be applied to organisms that reproduce only asexually, to those that are extinct, or to geographically separated populations.
- The phylogenetic species concept defines a species as a group of populations with a recently shared evolutionary history.
- Most species exhibit geographical variation of phenotypic and genetic traits. When marked geographical variation in phenotypes is discontinuous, biologists sometimes name subspecies (Figure 22.3). In ring species, populations are distributed in a ring around unsuitable habitat (Figure 22.4). Many species exhibit clinal variation of characteristics, which change smoothly over a geographical gradient (Figure 22.5).

22.2 Maintaining Reproductive Isolation

- Reproductive isolating mechanisms are characteristics that prevent two species from interbreeding (Table 22.1).
- Prezygotic isolating mechanisms either prevent individuals of different species from mating or prevent fertilization between their gametes. Prezygotic isolation occurs because species live in different habitats, breed at different times, use different courtship behavior (Figure 22.6), or differ anatomically (Figure 22.7). Prezygotic isolation can also result from genetic and physiological incompatibilities between male and female gametes.
- Postzygotic isolating mechanisms reduce the fitness of interspecific hybrids through hybrid inviability, hybrid sterility (Figure 22.8), or hybrid breakdown.

Animation: Reproductive isolating mechanisms

Animation: Temporal isolation among cicadas

22.3 The Geography of Speciation

- The model of allopatric speciation proposes that speciation results from divergent evolution in geographically separated populations (Figures 22.9–22.11). If allopatric populations accumulate enough genetic differences, they will be reproductively isolated upon secondary contact. Nevertheless, some species hybridize over small areas of secondary contact (Figure 22.12).
- The model of parapatric speciation suggests that reproductive isolation can evolve between parts of a population that occupy opposite sides of an environmental discontinuity (Figure 22.13).
- A model of sympatric speciation in insects suggests that reproductive isolation may evolve between host races that rarely contact one another under natural conditions (Figure 22.14). Sympatric speciation commonly occurs in flowering plants by allopolyploidy.

Animation: Allopatric speciation on an archipelago

Animation: Models of speciation

22.4 Genetic Mechanisms of Speciation

- Allopatric populations inevitably accumulate genetic differences, some of which contribute to their reproductive isolation. Reproductive isolating mechanisms evolve as by-products of genetic changes that occur during divergence. Prezygotic isolating mechanisms may evolve in populations experiencing secondary contact (Figure 22.15).
- We cannot yet generalize about how many gene loci participate in the process of speciation, but at least several gene loci are usually involved.
- Speciation by polyploidy in flowering plants involves the duplication of an entire chromosome complement through nondisjunction of chromosomes during meiosis or mitosis. Polyploids can arise among the offspring of a single species (autopolyploidy; Figure 22.16A) or, more commonly, after hybridization between closely related species (allopolyploidy; Figures 22.16B and 22.17).
- Chromosome alterations can promote speciation by fostering the genetic divergence of, and reproductive isolation between, populations with different numbers of chromosomes or different chromosome structure (Figure 22.18).

UNDERSTAND & APPLY

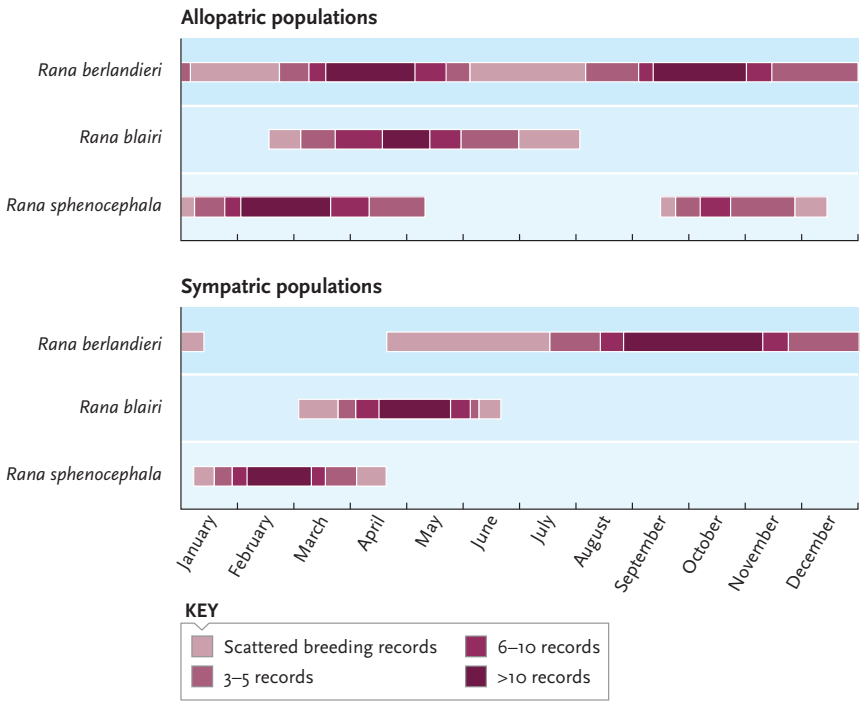
Test Your Knowledge

1. The biological species concept defines species on the basis of:
   a. reproductive characteristics.
   b. biochemical characteristics.
   c. morphological characteristics.
   d. behavioral characteristics.
   e. all of the above.
2. Biologists can apply the biological species concept *only* to species that:
   a. reproduce asexually.
   b. lived in the past.
   c. are allopatric to each other.
   d. hybridize in captivity.
   e. reproduce sexually.
3. A characteristic that exhibits smooth changes in populations distributed along a geographical gradient is called a:
   a. ring species.
   b. hybrid.
   c. cline.
   d. hybrid breakdown.
   e. subspecies.
4. If two species of holly (genus *Ilex*) flower during different months, their gene pools may be kept separate by:
   a. mechanical isolation.
   b. ecological isolation.
   c. gametic isolation.
   d. temporal isolation.
   e. behavioral isolation.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

5. Prezygotic isolating mechanisms:
   a. reduce the fitness of hybrid offspring.
   b. generally prevent individuals of different species from producing zygotes.
   c. are found only in animals.
   d. are found only in plants.
   e. are observed only in organisms that reproduce asexually.
6. In the model of allopatric speciation, the geographical separation of two populations:
   a. is sufficient for speciation to occur.
   b. occurs only after speciation is complete.
   c. allows gene flow between them.
   d. reduces the relative fitness of hybrid offspring.
   e. inhibits gene flow between them.
7. Adjacent populations that produce hybrid offspring with low relative fitness may be undergoing:
   a. clinal isolation.
   b. parapatric speciation.
   c. allopatric speciation.
   d. sympatric speciation.
   e. geographical isolation.
8. An animal breeder, attempting to cross a llama with an alpaca for finer wool, found that the hybrid offspring rarely lived more than a few weeks. This outcome probably resulted from:
   a. genetic drift.
   b. prezygotic reproductive isolation.
   c. postzygotic reproductive isolation.
   d. sympatric speciation.
   e. polyploidy.
9. Which of the following could be an example of allopolyploidy?
   a. One parent has 8 chromosomes, the other has 10, and their offspring have 36.
   b. Gametes and somatic cells have the same number of chromosomes.
   c. Chromosome number increases by one in a gamete and in the offspring it produces.
   d. Chromosome number decreases by one in a gamete and in the offspring it produces.
   e. Chromosome number in the offspring is exactly half of what it is in the parents.
10. Which of the following genetic characteristics is shared by humans and chimpanzees?
   a. They have the same number of chromosomes.
   b. The position of the centromere on human chromosome 2 matches the position of a centromere on a chimpanzee chromosome.
   c. A fusion of ancestral chromosomes formed chromosome 2.
   d. Centromeres on all of their chromosomes fall within inverted chromosome segments.
   e. all of the above

Discuss the Concepts



1. All domestic dogs are classified as members of the species *Canis familiaris*. But it is hard to imagine how a tiny Chihuahua could breed with a gigantic Great Dane. Do you think that artificial selection for different breeds of dogs will eventually create different dog species?
2. Human populations often differ dramatically in external morphological characteristics. On what basis are all human populations classified as a single species?
3. If intermediate populations in a ring species go extinct, eliminating the possibility of gene flow between populations at the two ends of the ring, would you now identify those remaining populations as full species? Explain your answer.

Design an Experiment

Design an experiment to test whether populations of birds on different islands belong to the same species.

Interpret the Data

David Hillis of Baylor University noted that three closely related species of leopard frog (genus *Rana*) exhibit substantial—but not complete—postzygotic reproductive isolation when crossed in the laboratory. Field surveys of numerous populations in Texas and surrounding states revealed that populations of the three species breed at various times during the year. Data on the breeding schedule of both allopatric and sympatric populations of these species are presented in the **Figure** below. Interpret the data in the figure and explain how they may demonstrate that these frogs experience prezygotic reproductive isolation in nature. What type of prezygotic reproductive isolation do the data suggest?

D. M. Hillis. 1981. Premating isolating mechanisms among three species of the *Rana pipiens* complex in Texas and southern Oklahoma. *Copeia* 1981:312–319.

Source: D. M. Hillis. 1981. Premating isolating mechanisms among three species of the *Rana pipiens* complex in Texas and southern Oklahoma. *Copeia* 1981:312–319.

Apply Evolutionary Thinking

How do human activities (such as destruction of natural habitats, diversion of rivers, and the construction of buildings) influence the chances that new species of plants and animals will evolve in the future? Frame your answer in terms of the geographical and genetic factors that foster speciation.

Fossil of a trilobite *(Asaphus kowalewskii)* that lived 490 million years ago.

23

Paleobiology and Macroevolution

Why it matters . . . In a report on the fossil reptiles of Britain, published in April 1842, Sir Richard Owen described fragmentary fossils of three species that another researcher had unearthed in 1818. Recognizing that these gigantic creatures were distinct from lizards and snakes, Owen assigned them to a new group, which he named Dinosauria (*deinos* = terrible; *sauros* = lizards). In 1851, he brought the dinosaurs to the attention of a broader public in a display of the "inhabitants of the ancient world" at the Crystal Palace exhibition in London.

Owen's published accounts and Crystal Palace exhibition models led to a dinosaur craze that still grips scientists and the public today. Dinosaur discoveries continued apace, especially in North America, where the most complete fossils are found. In 1858, a nearly intact skeleton of the duck-billed dinosaur *Hadrosaurus foulkii* was uncovered in New Jersey. Analyses of its leg bones showed clearly that it was bipedal (that is, it stood on its hind legs rather than on all fours), a shocking hypothesis at the time. Ten years later, the specimen was exhibited at the Philadelphia Academy of Science, where it is still on display. The *Hadrosaurus* exhibit tripled attendance at the Philadelphia Academy, setting off a race to uncover other complete dinosaur skeletons. In the late 1870s, abundant fossils turned up in Colorado, Wyoming, and Alberta; and scientists and entrepreneurs scoured the region for fossils that would bring them fame and fortune. Their quest was not unlike the California gold rush of the mid-nineteenth century, with rivals reputedly hijacking one another's fossils and sometimes coming to blows over their ownership.

As natural history museums exhibited these discoveries, a major question plagued preparators (professionals who clean and reassemble fossils) as they mounted the specimens. What did dinosaurs really look like? How did these animals stand when they were alive? How did they hold their heads and tails?

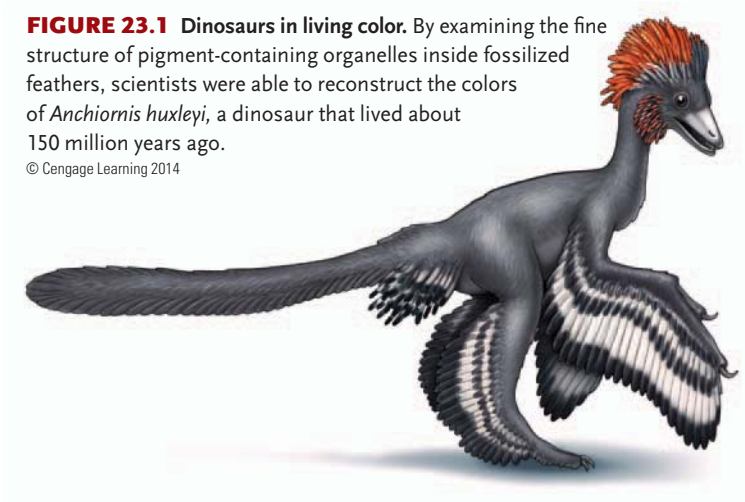

FIGURE 23.1 Dinosaurs in living color. By examining the fine structure of pigment-containing organelles inside fossilized feathers, scientists were able to reconstruct the colors of *Anchiornis huxleyi,* a dinosaur that lived about 150 million years ago.
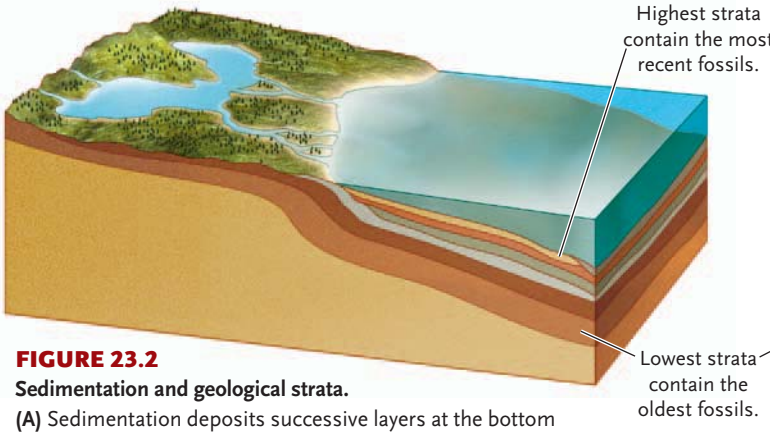
© Cengage Learning 2014

The continued study of dinosaur biology has answered many of these questions. In the 1960s, biologists hypothesized that dinosaurs were very active creatures, like mammals and birds are today. According to this hypothesis, many dinosaurs held their heads up and their tails off the ground; others adopted a bipedal stance. As our knowledge of dinosaurs increased, natural history museums have remounted their specimens and models in more active poses. But one question seemed impossible to answer. Did dinosaurs blend in with their surroundings, or were they brightly colored?

As you will discover later in this chapter, many dinosaurs were feathered, just as birds are today. In 2010, two groups of researchers published analyses of the colors of fossilized feathers from several species of small dinosaurs. Using scanning electron microscopes, the researchers compared the fine structure of melanosomes (pigment-bearing organelles) in the fossilized feathers to those of living birds, allowing them to reconstruct the feather colors of the dinosaurs. One analysis suggests that *Anchiornis huxleyi,* a dinosaur that lived about 150 million years ago in what is now northern China, had gray or black feathers over most of its body, black and white feathers on its limbs, and a crown of red feathers on its head **(Figure 23.1).** These animals must surely have used their colorful feathers in social displays.

This description of a truly remarkable discovery opens our chapter on paleobiology and macroevolution, the large-scale changes in morphology and diversity observed over life's 3.8-billion-year history. Macroevolution has occurred over so vast a span of time and space that the evidence for it is fundamentally different from that for microevolution and speciation. In this chapter we consider what paleobiology and evolutionary developmental biology tell us about macroevolutionary patterns.



23.1 The Fossil Record

Paleobiologists discover, describe, and name new fossil species and analyze the morphology and ecology of extinct organisms. Because fossils provide physical evidence of life in the past, they are a primary source of data about the evolutionary history of many organisms.

Fossils Form When Organisms Are Buried by Sediments or Preserved in Oxygen-Poor Environments

Most fossils form in sedimentary rocks. Rain and runoff constantly erode the land, carrying fine particles of rock and soil downstream to a swamp, a lake, or the sea. Particles settle to the bottom as sediments, forming successive layers, called *strata,* over millions of years **(Figure 23.2).** The weight of newer sediments compresses the older layers beneath them into a solid matrix: sand into sandstone and silt or mud into shale. Fossils form within the layers when the remains of organisms are buried in the accumulating sediments. Because sedimentation superimposes new layers over old ones, the lowest strata in a sedimentary rock formation are usually the oldest and the highest layers are the newest.

The process of fossilization is a race against time because the soft remains of organisms are quickly consumed by scavengers or decomposed by microorganisms. Thus, fossils usually preserve the details of hard structures, such as the bones, teeth, and shells of animals and the wood, leaves, and pollen of plants. During fossilization, dissolved minerals replace some parts molecule by molecule, leaving a fossil made of stone **(Figure 23.3A);** other fossils form as molds, casts, or impressions in material that is later transformed into solid rock **(Figure 23.3B).**

In some environments, the near absence of oxygen prevents decomposition, and even soft-bodied organisms are preserved. Some insects, plants, and tiny lizards and frogs are embedded in amber, the fossilized resin of coniferous trees **(Figure 23.3C).** Other organisms are preserved in glacial ice, coal, tar pits, or the highly acidic water of peat bogs **(Figure 23.3D).** Sometimes organisms are so well preserved that researchers can examine their internal anatomy, cell structure, and even food in their digestive tracts.

These forests lived during the late Triassic period, about 225 million years ago. **(B)** The remains of a fern *(Sphenopteris)* from the Carboniferous period, 300 million years ago, were preserved in coal. **(C)** These 10-million-year-old mosquitoes were trapped in the oozing resin of a coniferous tree and are now encased in amber. **(D)** A frozen baby mammoth that lived about 40,000 years ago was discovered embedded in Siberian permafrost in 1977.

The Fossil Record Provides an Incomplete Portrait of Life in the Past

The 300,000 described fossil species represent less than 1% of all the species that have ever lived. Several factors make the fossil record incomplete. First, soft-bodied organisms do not fossilize as readily as species with hard body parts. Moreover, we are unlikely to find fossilized remains of species that were rare or locally distributed. Finally, fossils rarely form in habitats where sediments do not accumulate, such as mountain forests. The most common fossils are those of hard-bodied, widespread, and abundant organisms that lived in swamps or shallow seas, where sedimentation is ongoing.

Although most fossils are composed of stone, they don't last forever. Many are deformed by pressure from overlying rocks or destroyed by geological disturbances like volcanic eruptions and earthquakes. Once they are exposed on Earth's surface, where scientists are most likely to find them, rain and wind cause them to erode. Because the effects of these destructive processes are additive, old fossils are much less common than those formed more recently.

Scientists Assign Relative and Absolute Dates to Geological Strata and the Fossils They Contain

The sediments found in any one place form distinctive strata (layers) that differ in color, mineral composition, particle size, and thickness (see Figure 23.2B). If they have not been disturbed, the strata are arranged in the order in which they formed, with the youngest layers on top. However, strata are sometimes uplifted, warped, or even inverted by geological processes.

Geologists of the early nineteenth century deduced that the fossils discovered in a particular sedimentary stratum, no matter where on Earth it is found, represent organisms that lived and died at roughly the same time in the past. Because each stratum formed at a specific time, the sequence of fossils in the lowest (oldest) to the highest (newest) strata reveals their *relative ages*. Geologists used the sequence of strata and their distinctive fossil assemblages to establish the geological time scale **(Table 23.1).**

TABLE 23.1 The Geological Time Scale and Major Evolutionary Events

Eon	Era	Period	Epoch	Millions of Years Ago	Major Evolutionary Events
Phanerozoic	Cenozoic	Quaternary	Holocene	0.01	
			Pleistocene		Origin of humans; major glaciations 
		Neogene	Pliocene	2.6	Origin of apelike human ancestors 
			Miocene	5.3	Angiosperms and mammals further diversify and dominate terrestrial habitats  
		Paleogene	Oligocene	23.0	Primates diversify; origin of apes 
			Eocene	33.9	Angiosperms and insects diversify; modern orders of mammals differentiate  
			Paleocene	55.8	Grasslands and deciduous woodlands spread; modern birds, mammals, snakes, pollinating insects diversify; continents approach current positions  
	Mesozoic	Cretaceous		65.5	Angiosperms, insects, marine invertebrates, fishes, dinosaurs diversify; asteroid impact causes mass extinction at end of period, eliminating dinosaurs and many other groups  
		Jurassic		145.5	Gymnosperms abundant in terrestrial habitats; modern fishes diversify; dinosaurs diversify and dominate terrestrial habitats; frogs, salamanders, lizards, and birds appear; continents continue to separate  
		Triassic		201.6	Predatory fishes and reptiles dominate oceans; gymnosperms dominate terrestrial habitats; radiation of dinosaurs; early mammals; Pangaea starts to break up; mass extinction at end of period

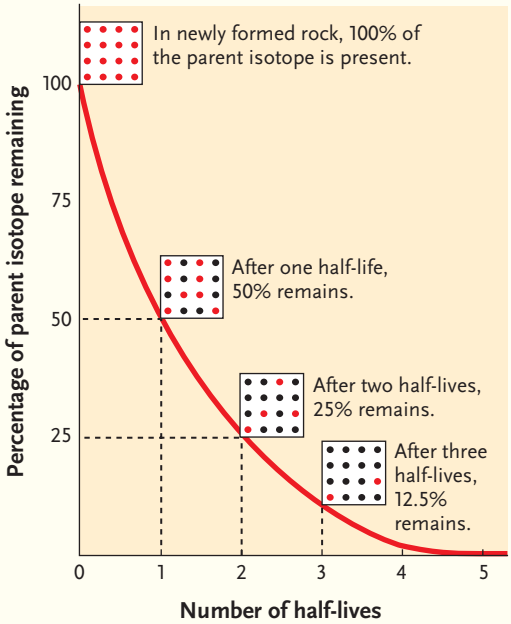
Radiometric Dating

Protocol:

1. Knowing the approximate age of a rock or fossil, select a radioisotope that has an appropriate half-life. Because different radioisotopes have half-lives ranging from seconds to billions of years, it is usually possible to choose one that brackets the estimated age of the sample under study. For example, if you think that your fossil is more than 10 million years old, you might use uranium-235. The half life of ^{235}U, which decays into the lead isotope ^{207}Pb, is about 700 million years. Or if you think that your fossil is less than 70,000 years old, you might select carbon-14. The half-life of ^{14}C, which decays into the nitrogen isotope ^{14}N, is 5,730 years.

Purpose: Radiometric dating allows researchers to estimate the absolute age of a rock sample or fossil.



Radioisotopes Commonly Used in Radiometric Dating

Radioisotope (Unstable)		More Stable Breakdown Product	Half-Life (Years)	Useful Range (Years)
Samarium-147	→	Neodymium-143	106 billion	>100 million
Rubidium-87	→	Strontium-87	48 billion	>10 million
Thorium-232	→	Lead-208	14 billion	>10 million
Uranium-238	→	Lead-206	4.5 billion	>10 million
Uranium-235	→	Lead-207	700 million	>10 million
Potassium-40	→	Argon-40	1.25 billion	>100,000
Carbon-14	→	Nitrogen-14	5,730	<70,000

2. Prepare a sample of the material and measure the quantities of the parent radioisotope and its more stable breakdown product.

Interpreting the Results: Compare the relative quantities of the parent radioisotope and its breakdown product (or some other stable isotope) to determine what percentage of the original parent radioisotope remains in the sample. Then use a graph of radioactive decay for that isotope to determine how many half-lives have passed since the sample formed.

Theory of radiometric dating

Knowing the number of half-lives that have passed allows you to estimate the age of the sample.

Radiometric dating of a fossilized mollusk

A living mollusk absorbed trace amounts of ^{14}C, a rare radioisotope of carbon, and large amounts of ^{12}C, which is the more stable and common isotope of carbon.

When the mollusk died, it was buried in silt and fossilized. From the moment of its death, the ratio of ^{14}C to ^{12}C began to decline through radioactive decay. Because the half-life of ^{14}C is 5,730 years, half of the original ^{14}C was eliminated from the fossil in 5,730 years and half of what remained was eliminated in another 5,730 years.

After the fossil was discovered, a scientist determined that its ^{14}C to ^{12}C ratio was one-eighth (12.5%) of the ^{14}C to ^{12}C ratio in living organisms. Thus, radioactive decay had proceeded for three half-lives—about 17,000 years—since the mollusk's death.

© Cengage Learning 2014

Although the geological time scale provides a relative dating system for sedimentary strata, it does not tell us how old the rocks and fossils actually are. But many rocks contain radioisotopes, which, from the moment they form, begin to break down into other, more stable elements. The breakdown proceeds at a steady rate that is unaffected by chemical reactions or environmental conditions such as temperature or pressure. Using a technique called **radiometric dating,** scientists can estimate the age of a rock by noting how much of an unstable "parent" isotope has decayed to another form. By measuring the relative amounts of the parent radioisotope and its breakdown products and comparing this ratio with the isotope's **half-life**—the time it takes for half of a given amount of radioisotope to decay—researchers can estimate the *absolute age* of the rock **(Figure 23.4).** Table 23.1

presents these age estimates along with the major geological and evolutionary events of each period.

Radiometric dating works best with volcanic rocks, which form when lava cools and solidifies. But most fossils are found in sedimentary rocks. To date a sedimentary fossil, scientists determine the age of volcanic rocks from the same stratum. Using this method, investigators have linked fossils to deposits that are hundreds of millions of years old.

Fossils that still contain organic matter, such as the remains of bones or wood, can be dated directly by measuring their content of the radioactive carbon isotope ^{14}C, which decays to ^{14}N. Living organisms absorb traces of ^{14}C and large quantities of ^{12}C, a stable carbon isotope, from the environment and incorporate them into biological molecules. As long as an organism is alive, its ^{14}C content remains constant because the ratio of ^{14}C to ^{12}C in its tissues is at equilibrium with the ratio in the environment. But as soon as the organism dies, ^{14}C begins its steady radioactive decay. Scientists use the ratio of ^{14}C to ^{12}C in a fossil to determine its age, as explained in Figure 23.4.

To develop a feeling for geological time, imagine the 4.5-billion-year history of Earth scaled onto a calendar year; each day represents a little over 12 million years **(Figure 23.5).** The planet was formed on January 1. Animal life originated in mid-November, dinosaurs lived between December 14 and December 26, and the genus that includes modern humans appeared during the last 4 hours of December 31.

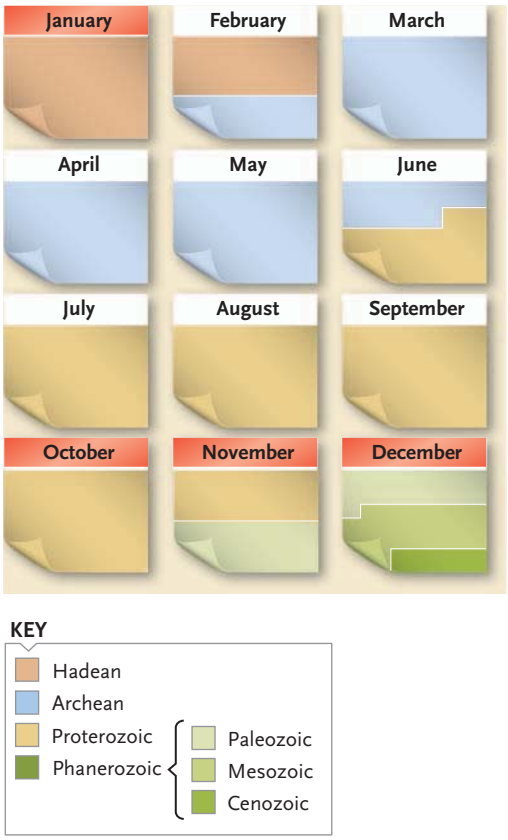

FIGURE 23.5 **A calendar of Earth's history.** Geological time can be scaled onto a calendar year in which each day is a little more than 12 million years.

Fossils Provide Abundant Information about Life in the Past

Although imperfect, the fossil record provides our only direct information about life in the past. Fossilized skeletons, shells, stems, leaves, and flowers tell us about the size and appearance of ancient animals and plants. The fossil record also allows scientists to see how structures were modified as they became adapted for specialized uses (see Figure 21.3). Moreover, fossils chronicle the proliferation and extinction of evolutionary lineages and provide data on their past geographical distributions.

Recent applications of new techniques allow paleobiologists to make truly remarkable discoveries about extinct organisms. For example, researchers appear to have solved a long-standing puzzle about lambeosaurines, a group of huge duck-billed dinosaurs that lived in the swampy habitats of western North America in the late Cretaceous period. The heads of lambeosaurines sported bony crests with gigantic nasal passages. Paleobiologists had proposed that the crests served as weapons in male combat, adornments that attracted mates, snorkels that facilitated breathing underwater, radiators that cooled the dinosaurs' bodies, structures that enhanced the sense of smell, or resonating chambers that produced honking vocalizations. Based on anatomical analyses, researchers accepted the vocalization hypothesis as the most probable: computerized acoustic models predicted that air flowing through the nasal passages would have produced low frequency sounds (30–375 hertz).

But could lambeosaurines hear sounds in that frequency range? In 2009, David Evans of the Royal Ontario Museum in Toronto, Canada, and colleagues in Ohio used computed tomography and 3-D visualization software to scan and reconstruct the interior anatomy of the skulls and brains of several lambeosaurine species **(Figure 23.6).** Their findings indicate that

FIGURE 23.6 **Honking dinosaurs.** Analysis of the sinuses and braincase of lambeosaurines (*Corythosaurus* species) revealed that the nasal passages in their crests served as resonating chambers for the production of low-frequency sounds that their inner ears could detect.

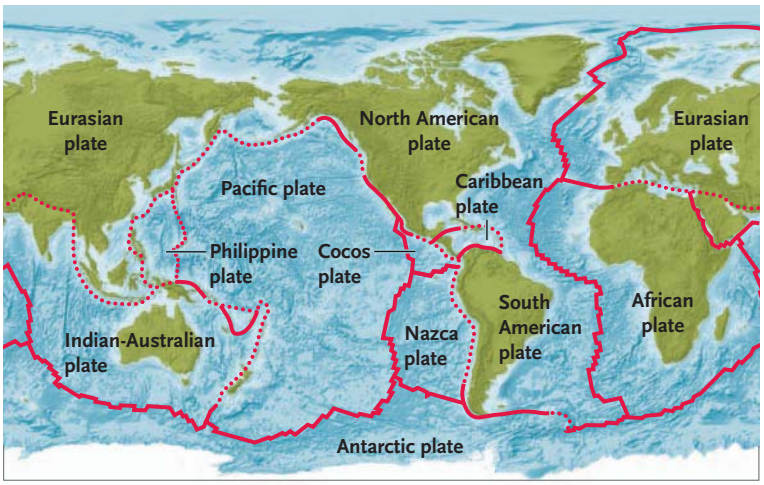
the inner ears of lambeosaurines were attuned to hear low-frequency sounds that matched those predicted by the earlier research. The authors concluded that the elaborate nasal passages in lambeosaurine crests as well as the structure of their inner ears facilitated vocal communication, perhaps between parents and their offspring.

Fossils also provide indirect data about behavior, physiology, and ecology. For example, the fossilized footprints of some dinosaurs suggest that adults surrounded their young when the group moved, possibly to protect them from predators. Complex scrolls of bone in the nasal passages of early mammals suggest that they had a well-developed sense of smell, and fossilized teeth and dung provide data about the diets of extinct animals. The study of fossilized pollen allows paleobiologists to reconstruct the vegetation and climate of ancient sites. The changing arrays of fossils that document biological evolution partly reflect large-scale shifts in Earth's physical environments, a topic that we explore in the next section.

STUDY BREAK 23.1

1. What biological materials are the most likely to fossilize?
2. Why does the fossil record provide an incomplete portrait of life in the past?
3. What sorts of information can paleobiologists discern from the fossil record?

23.2 Earth History



Organisms have interacted constantly with their environments over geological time. These interactions have triggered fundamental changes in Earth's physical environment as well as in the organisms that occupy them. Perhaps the most striking effect of living systems on the physical environment was the development of an oxidizing atmosphere, discussed extensively in Chapter 25. Photosynthesis by prokaryotic organisms increased the concentration of oxygen in the atmosphere, facilitating the evolution of eukaryotic cells and later allowing animals to invade terrestrial habitats. In this section we focus on long-term shifts in geography and climate—as well as some brief but catastrophic events—that have significantly altered the environments where organisms live.

Continental Drift Has Altered the Configuration of Landmasses and Oceans

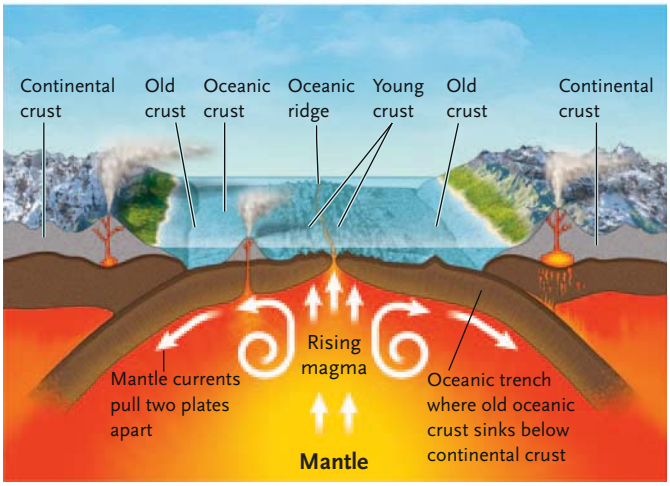
Major geological and climatic shifts occur because the planet's crust is constantly in motion. According to the theory of **plate tectonics,** Earth's crust is broken into irregularly shaped plates of rock—roughly 40 km thick—that float on its semisolid mantle **(Figure 23.7).** Currents in the mantle cause the plates—and the continents embedded in them—to move, a phenomenon called **continental drift.**

Continent-sized landmasses have coalesced and broken apart several times in Earth's history. About 250 million years

A. Earth's crustal plates

KEY
Oceanic ridge ····· Oceanic trench

B. Model of plate tectonics



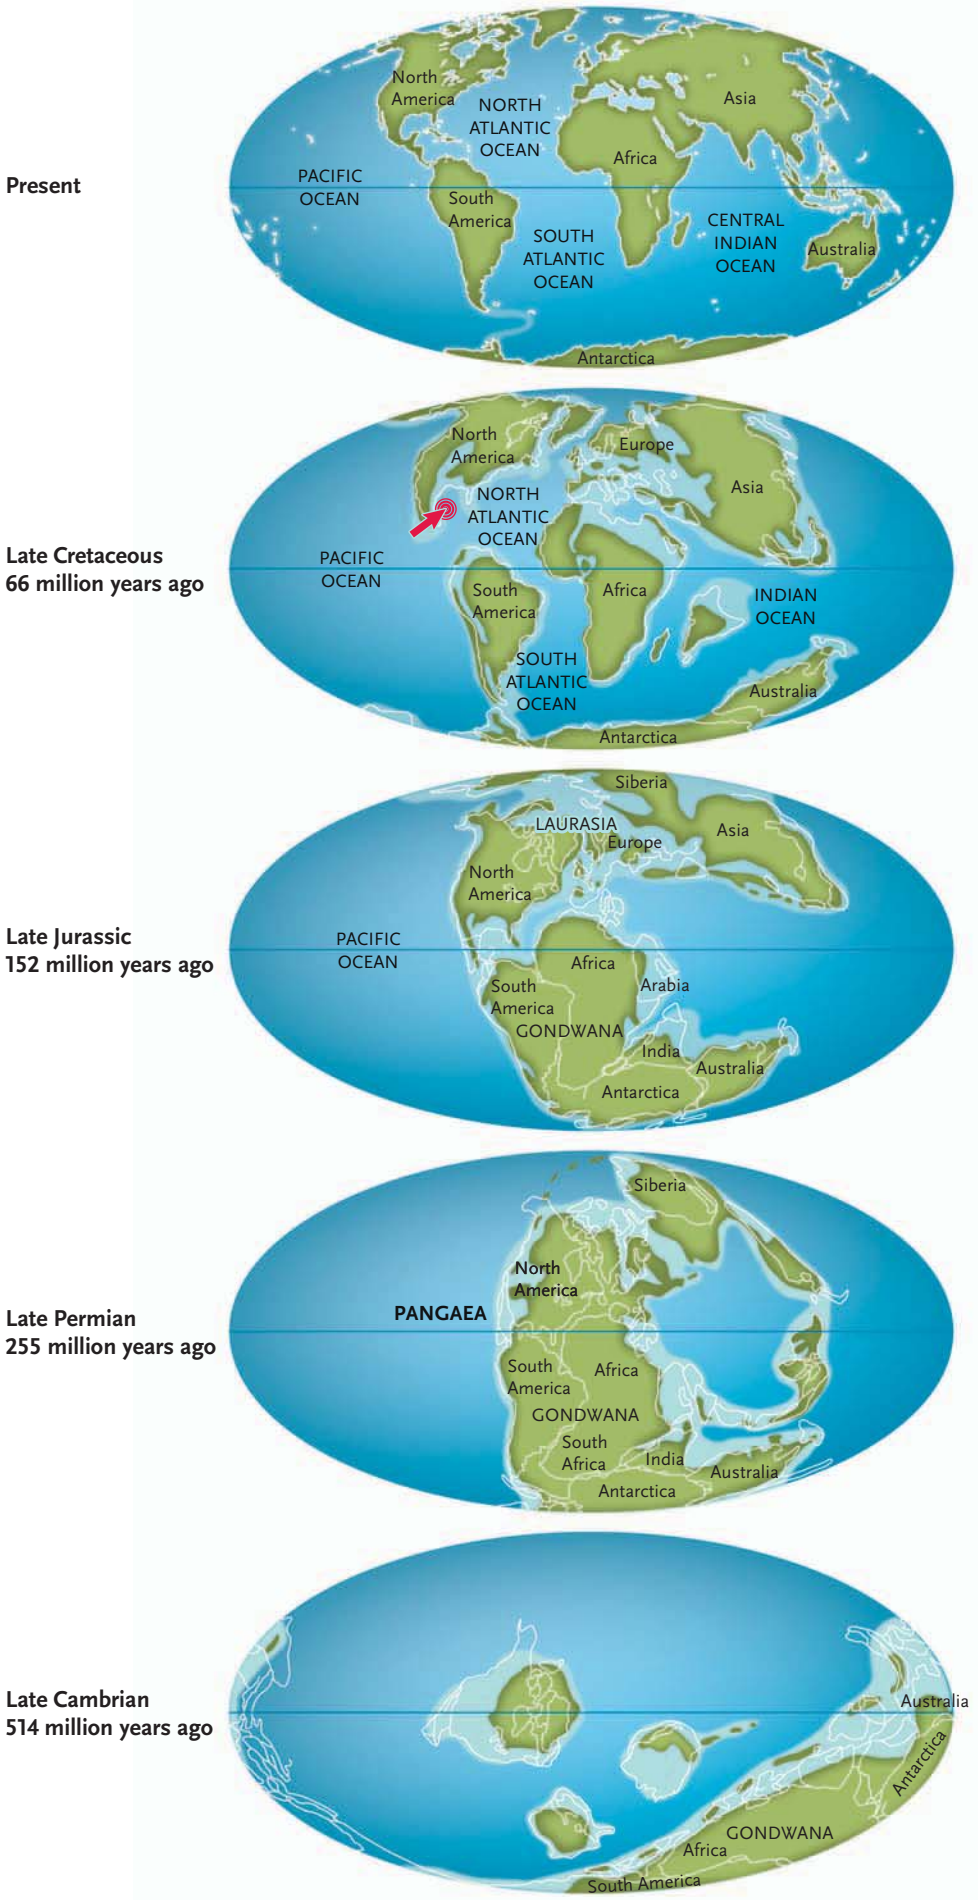


FIGURE 23.7 Plate tectonics. (A) Earth's crust is broken into large, rigid plates. New crust is added at oceanic ridges, and old crust is recycled into the mantle at oceanic trenches. **(B)** Oceanic ridges form where pressure in the mantle forces magma (molten rock) through fissures in the sea floor. Mantle currents pull the plates apart on either side of the ridge, forcing the sea floor to move laterally away from the ridge. This phenomenon, seafloor spreading, is widening the Atlantic Ocean about 3 cm per year. Oceanic trenches form where plates collide. The heavier oceanic crust sinks below the lighter continental crust, and it is recycled into the mantle, a process called subduction. The highest mountain ranges (including the Rockies, Himalayas, Alps, and Andes) formed where subduction uplifted continental crust. Earthquakes and volcanoes are also common near trenches.

FIGURE 23.8 Continental drift. Earth's many landmasses coalesced during the Permian period, forming the supercontinent Pangaea. About 160 million years ago, Pangaea began to separate into a southern continent, Gondwana, and a northern continent, Laurasia. Then Gondwana began to break apart. The landmasses that would form Africa and India pulled away first, opening the South Atlantic and Indian Oceans. Australia separated from Antarctica about 55 million years ago and slowly drifted northward. South America separated from Antarctica shortly thereafter. Laurasia remained nearly intact until 43 million years ago when North America and Greenland both separated from Europe and Asia. Movement of the continents also changed the shapes and the sizes of the oceans.

© Cengage Learning 2014

ago, they merged into a single supercontinent called Pangaea; continental drift later separated Pangaea into a northern continent, Laurasia, and a southern continent, Gondwana. Laurasia and Gondwana subsequently broke into the continents we know today **(Figure 23.8).**

The breakup and separation of the continents had a huge impact on the evolution of terrestrial and aquatic organisms. For example, the widespread distribution of many terrestrial groups on Pangaea was a defining characteristic of the Paleozoic era. But continental drift later established large-scale patterns of geographical isolation. Each continent became a separate arena in which organisms evolved independently of those on other landmasses. Thus, the organisms that live on southern continents, the remnants of Gondwana, are very different from those that live on northern continents, which are the remnants of Laurasia. For example, the large flightless birds known as ratites (pictured in Figure 20.2) occur only in Africa, Australia, South America and on nearby islands; no comparable or closely related species live in Eurasia or North America.

Moreover, the smaller landmasses produced by plate tectonics are surrounded by more extensive coastlines and shallow marine habitats than were the larger continents. Coastal waters have always harbored tremendous bio-

diversity, and as the continents became increasingly separated, the populations living in these shallow seas became geographically isolated from each other. As the continents assumed their present positions at different latitudes, locally distributed organisms diversified and differentiated from those in other regions. Today, shallow marine habitats in the temperate zone are often occupied by giant kelp beds, whereas those in the tropics harbor coral reefs (described further in Chapter 51).

Geological Processes and Unpredictable Events Changed the Environments Where Organisms Lived

Continental drift affected climate, the extent of glaciations, and sea levels, changing the physical environments where organisms live on local, regional, and global scales. Most environmental changes occurred incrementally over millions of years—and millions of generations—but some catastrophes have also had a sudden impact. The combined effects of these changes on biological evolution have been profound.

CLIMATE, GLACIATIONS, AND SEA LEVEL As you will learn in Chapter 51, environmental temperatures vary with latitude: they are lower near the poles than near the equator. As the continents drifted, their latitudinal positions shifted, causing what must have been huge changes in local temperatures. For example, one billion years ago Queensland, Australia, was situated near the North Pole; it then drifted southward for 800 million years, moving to the equator 440 million years ago and to mid-latitudes in the southern hemisphere (40° S latitude) 200 million years ago. It then reversed direction and moved northward to its present position near the equator (12° S).

On a regional level, the sizes of landmasses also have an effect on their climates. Coastal regions generally experience smaller daily and seasonal fluctuations in temperature than interior regions because their proximity to the sea moderates their climate. Whenever landmasses were joined into large continents, vast expanses of the interior landscape must have experienced frigid winters and hot summers. As the landmasses broke up into smaller continents, a larger fraction of the land was close to the sea and its moderating influence.

On a global scale, the overall climate has shifted from warm and wet to cool and dry several times in Earth's history **(Figure 23.9).** The changing positions of continents altered the flow of ocean currents, which, along with small changes in Earth's orbit around the sun, contributed to these climatic shifts. At times when Earth's climate was cooler than it is today, the polar ice caps grew larger. And because much of Earth's water was incorporated into these enormous glaciers, rainfall was greatly reduced and sea level fell dramatically. Between the cold spells, Earth's climate was warmer than it is today. Under those conditions, glaciers retreated, rainfall was luxuriant, temperature differences between equatorial and polar regions were reduced, and sea levels rose.

Changing climate patterns and the accompanying rise or fall of sea level influenced the evolution of living systems. Organisms adapted to the altered conditions, shifted their geographical ranges into suitable environments, or became ex-

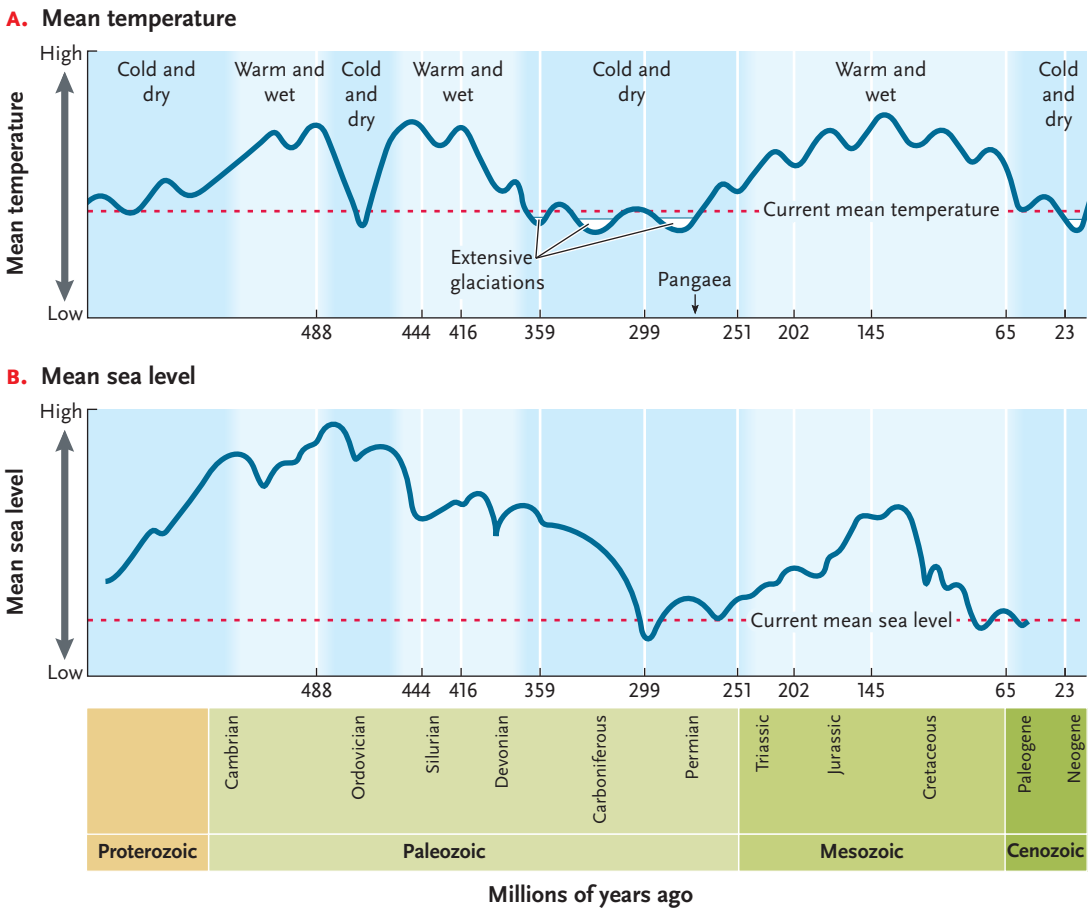

FIGURE 23.9 Variations in climate and sea level. (A) Earth's climate has shifted from cold and dry to warm and wet multiple times in Earth's history. Particularly cold periods were accompanied by extensive glaciation. **(B)** As a result of climatic shifts and continental drift, sea level has often risen and fallen. Large drops in sea level eliminated many near-shore, shallow marine environments.

tinct. Declining sea levels took an especially severe toll on organisms living in shallow marine environments. As their habitats disappeared, many marine species ceased to exist. Nevertheless, some organisms always survived, and their descendants flourished and later diversified in the altered environments.

Today we are living in one of the cooler periods of Earth's history. But human activities, including the combustion of fossil fuels and industrial-scale agriculture, are causing an extraordinarily rapid warming of the atmosphere and oceans. Although Earth's climate has experienced repeated temperature shifts, these changes occurred slowly relative to the lifetimes of individual organisms, and many populations, species, and evolutionary lineages adapted to them. But global climate change is occurring much faster today, and scientists have documented its effects: melting glaciers, rising temperatures, and rising sea level. They have also documented changes in the geographical ranges and breeding schedules of many species. We explore the effects of global climate change more fully in Unit Seven.

VOLCANIC ERUPTIONS AND ASTEROID IMPACTS Sudden, unpredictable events have also changed physical environments on Earth. For example, volcanoes are especially active near oceanic trenches where old crust is recycled into Earth's mantle. Volcanic eruptions often spew enormous quantities of ash and gas into the atmosphere, blocking incoming sunlight. Massive eruptions may cause Earth's surface temperature to decrease several degrees for as long as a year. Other types of tectonic activity also release molten rock on Earth's surface, sometimes with the opposite effect on climate, as you will discover in Section 23.4.

Asteroid strikes have also had devastating effects on living systems. In addition to obliterating a gigantic area around the site of impact, the collisions threw massive amounts of material into the atmosphere, blocking sunlight and potentially altering the planet's climate. As we describe in Section 23.4, these cataclysmic events have sometimes caused many forms of life to disappear over relatively short periods of geological time.

STUDY BREAK 23.2

1. How did continental drift affect the geographical distributions of organisms?
2. What effect did glaciations have on sea level?

THINK OUTSIDE THE BOOK

Search Internet and library resources for information about how continental drift and other major geological phenomena affected the area where you live. At what latitude was your home or university 65 million years ago, 100 million years ago, and 250 million years ago? Was it ever submerged below a shallow sea?

23.3 Historical Biogeography and Convergent Biotas

Continental drift facilitated the diversification of distinct evolutionary lineages in different regions on Earth. In this section we consider the large-scale geographical distributions of organisms.

Historical Biogeography Explains the Broad Geographical Distributions of Organisms

More than a century after Darwin published his observations, the theory of plate tectonics refocused attention on biogeography. Historical biogeographers try to explain how organisms acquired their geographical distributions over evolutionary time.

CONTINUOUS AND DISJUNCT DISTRIBUTIONS Many species have a **continuous distribution:** they live in suitable habitats throughout a geographical area. For example, herring gulls *(Larus argentatus)* live along the coastlines of all northern continents. Continuous distributions, especially in mobile organisms like birds, usually require no special historical explanation.

Other groups exhibit **disjunct distributions,** in which closely related species live in widely separated locations. Two phenomena—dispersal and vicariance—can create disjunct distributions. **Dispersal** is the movement of organisms away from their place of origin; it can produce a disjunct distribution if a new population becomes established on the far side of a geographical barrier. **Vicariance** is the fragmentation of a once-continuous geographical distribution by external factors.

How can researchers determine whether a disjunct distribution is the product of dispersal or vicariance? Analysis of the fossil record for a group of organisms, interpreted in the context of their evolutionary relationships as well as continental drift, can provide an answer. For example, southern beech trees (genus *Nothofagus*) are currently found in Australasia and South America **(Figure 23.10).** (Australasia is the region that includes Australia, New Guinea, New Zealand, and other islands of the South Pacific.) For many years, the genus' distribution only on southern continents and islands has been the classic example of vicariance: the group presumably originated on Gondwana, and its subsequent fragmentation apparently isolated ancestral *Nothofagus* populations on different continents and islands where their descendants live today. The fossil record generally supports that interpretation: researchers have identified fossilized *Nothofagus* pollen, dating from 55 to 34 million years ago, in locations that still formed a nearly contiguous landmass at that time (Figure 23.10C).

However, Lyn G. Cook and Michael D. Crisp of The Australian National University recently undertook a molecular analysis of the relationships and geographical distributions of living *Nothofagus* species. Their research reveals that the genus had a much more complicated biogeographic history. It confirms that the distributions of some *Nothofagus* species in Australia and South America are the products of vicariance: their common ancestor originated on Gondwana *before* the two con-

FIGURE 23.11 **Wallace's biogeographical realms. Each realm contains a distinctive biota.**

© Cengage Learning 2014

tinents separated from each other, and their descendants now live in both places. However, the analysis also suggests that the common ancestor of certain closely related *Nothofagus* species in New Zealand and Australia originated more than 30 million years *after* New Zealand had separated from Australia. Thus, vicariance cannot explain their current distribution. Instead, seeds of these trees must have dispersed across the open ocean from one place to the other. Therefore, both vicariance and dispersal have played important roles in establishing the present geographical distribution of *Nothofagus.*

BIOGEOGRAPHICAL REALMS For species that were widespread in the Mesozoic era, Pangaea's breakup was a powerful vicariant experience. The subsequent geographical isolation of continents fostered the evolution of distinctive regional **biotas.** (The word *biota* refers to all of the organisms living in a region; *fauna* to all of the animals; and *flora* to all of the plants.) Alfred Russel Wallace used the biotas to define six **biogeographical realms,** which we still recognize today **(Figure 23.11).**

The Australian and Neotropical realms, which have been geographically isolated since the Mesozoic, contain many **endemic species** (those that occur nowhere else on Earth). The Australian realm, in particular, has had no complete land connection to any other continent for approximately 55 million years. As a result, Australia's mammalian fauna is unique, made up almost entirely of endemic marsupials (mammals that give birth after a short gestation period and then carry their young in a pouch). Although Eocene fossils of placental mammals (mammals that do not rear their young in a pouch) have been found in Australia, all of them became extinct. The only native placental mammals that live there now are bats and rodents, which apparently dispersed to Australia from either Asia or New Guinea after the marsupial fauna had already diversified there.

The biotas of the Nearctic and Palearctic realms are, by contrast, fairly similar. North America and Eurasia were frequently connected by land bridges: eastern North America was attached to Western Europe until the breakup of Laurasia 43 million years ago, and northwestern North America had periodic contact with northeastern Asia over the Bering land bridge during much of the past 60 million years. As a result, many plant and animal species on these continents are closely related.

Evolution Has Produced Convergent Biotas in Widely Separated Regions

Distantly related species living in different biogeographical realms are sometimes very similar in appearance. For example, the overall form of cactuses in the Americas is extraordinarily similar to that of spurges in Africa **(Figure 23.12).** But these lineages arose independently long after those continents had separated; thus, cactuses and spurges did not inherit their similarities from a shared ancestor. Their overall resemblance is the product of **convergent evolution,** the evolution of similar adaptations in distantly related organisms that occupy similar environments.

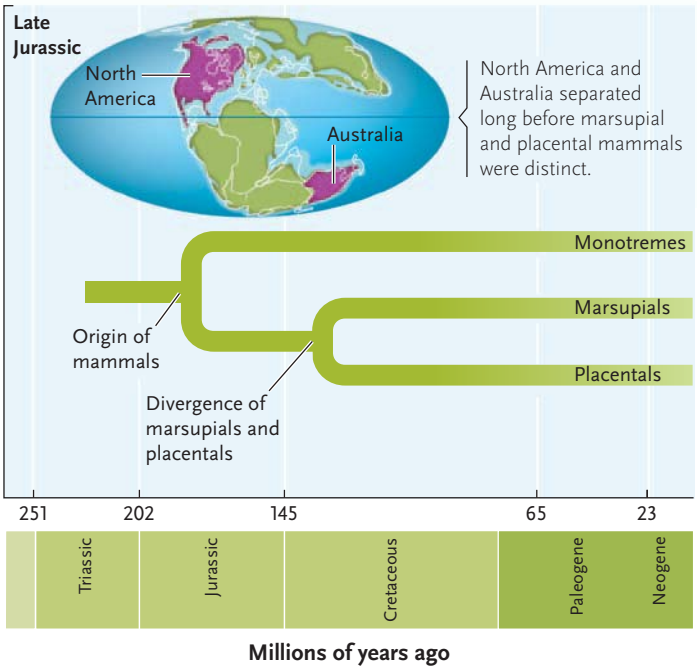

FIGURE 23.12 **Convergent evolution in plants. (A)** North American cactuses (family Cactaceae) are strikingly similar to **(B)** African spurges (family Euphorbiaceae). Convergent evolution adapted both groups to desert environments with thick, water-storing stems, spiny structures that discourage animals from feeding on them, CAM photosynthesis (see Section 9.4), and stomata that open only at night.

Convergent evolution has also fostered morphological similarities in distantly related animals that feed on similar foods and occupy similar habitats in widely separated geographic ranges. Sometimes, large portions of entire faunas develop convergent morphologies. For example, the marsupial mammals of Australia and the placental mammals of North America—groups that arose long after the breakup of Pangaea—include many pairs of morphologically convergent species **(Figure 23.13).** Although the species in each pair differ in most of their anatomical details, their overall appearance and structure are remarkably similar. Biologists interpret these convergent morphologies as evolutionary responses to similar patterns of natural selection in the habitats where these animals live.

STUDY BREAK 23.3

1. **Which type of geographical distribution requires no special explanation?**
2. **Why do distantly related species that live in different biogeographical realms sometimes resemble each other?**

A. Mammals and continental drift

B. Convergence of placental and marsupial mammals

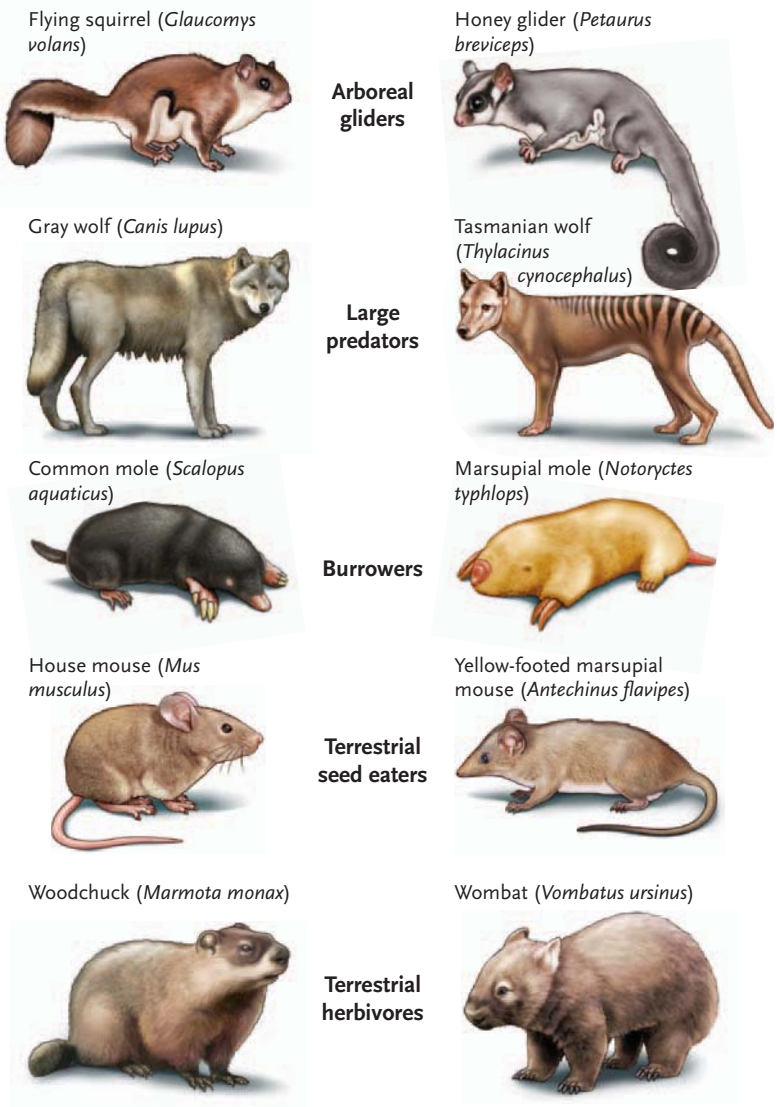

FIGURE 23.13 **Convergent evolution in mammalian faunas. (A)** Two distinctive lineages of mammals, the placentals and the marsupials, diverged after Pangaea had already split into northern and southern continents. **(B)** Thus, biologists conclude that convergent evolution, rather than shared ancestry, produced similar body forms in North American placental mammals (on left) and Australian marsupial mammals (on right). The members of each pair differ in their anatomical details, but their overall forms are similar even though they are only distantly related. Biologists interpret these similarities as convergent adaptations in animals that fulfill similar ecological roles on the two continents.

23.4 The History of Biodiversity

As organisms were isolated on different landmasses or in the seas that surrounded them, the number of species living on Earth—its overall **biodiversity**—changed over time as the result of adaptive radiations and extinctions.

Adaptive Radiations Are Clusters of Related Species with Diverse Ecological Adaptations

In some lineages, rapid speciation produces a cluster of closely related species that occupy different habitats or consume different foods; we describe such a lineage as an **adaptive radiation.** The Galápagos finches **(Figure 23.14)** and the Hawaiian fruit flies described in Chapter 22 are examples of adaptive radiations in animals. Comparable adaptive radiations have also been identified in plants.

Adaptive radiation often occurs after an ancestral species moves into an unfilled **adaptive zone,** a general way of life. Feeding on other marine animals is the adaptive zone that most sharks occupy, and grazing on grass in open habitats is the adaptive zone that living horses exploit. Feeding on plastic in landfills might become an adaptive zone in the future if some organism develops the ability to digest that now-abundant resource.

An organism's move into a new adaptive zone is sometimes triggered by the chance evolution of a key morphological innovation that allows it to use the environment in a unique way. For example, the dehydration-resistant eggs of early reptiles enabled them to complete their life cycle on land, opening terrestrial habitats to them. Similarly, the evolution of flowers that attract insect pollinators was a key innovation in the history of flowering plants.

An adaptive radiation may also be triggered after the demise of a successful group. Mammals, for example, were relatively inconspicuous during their first 150 million years on Earth, presumably because dinosaurs dominated terrestrial habitats. But after dinosaurs declined in the late Mesozoic era, mammals underwent an explosive adaptive radiation. Today they are the dominant vertebrates in many terrestrial habitats.

Extinctions Have Been Common in the History of Life

Biodiversity has not always increased through the history of life. The additions to biodiversity caused by adaptive radiations and other speciation events are counteracted by **extinction,** the death of the last individual in a species or the last species in a lineage. Paleobiologists recognize two distinct patterns of extinction in the fossil record, background extinction and mass extinction.

Species and lineages have been going extinct since life first appeared. We should expect species to disappear at some low rate, the **background extinction rate;** as environments change, poorly adapted organisms will not survive and reproduce. In all likelihood, more than 99.9% of the species that have ever lived are now extinct. David Raup of the University of Chicago has suggested that, on average, as many as 10% of species go extinct every million years and that more than 50% go extinct every 100 million years. Thus, the history of life has been characterized by an ongoing turnover of species.

On at least five occasions, however, extinction rates rose well above the background rate. During these **mass extinctions,** large numbers of species and lineages died out over relatively short periods of geological time **(Figure 23.15).** The Permian extinction was the most severe: more than 85% of the species alive at that time—including all trilobites, many insects and amphibians, and the trees of the coal swamp forests—disappeared forever. During the last mass extinction, at the end of the Cretaceous, half the species on Earth, including most dinosaurs, became extinct. A sixth mass extinction, potentially the largest of all, may be occurring now as a result of global climate change and human degradation of the environment (see Unit Seven).

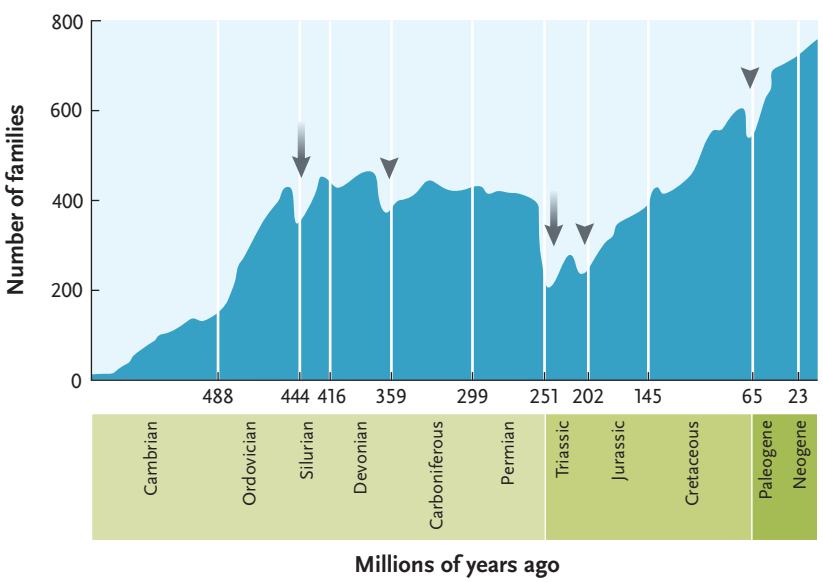

FIGURE 23.15 **Mass extinctions.** Biodiversity, indicated by the height of the dark blue area in the graph, was temporarily reduced by at least five mass extinctions (arrows) during the history of life. The data presented in this graph record the family-level diversity of marine animals. A family is a group of genera descended from a common ancestor.

© Cengage Learning 2014

Different factors were responsible for the five mass extinctions. For example, the Ordovician extinction occurred after Gondwana moved toward the South Pole, triggering a glaciation that cooled the world's climate and lowered sea levels, eliminating many shallow marine environments.

Scientists hypothesize that the massive Permian extinction was caused by a chain of events that resulted in severe climate warming. The trigger was apparently a series of ongoing eruptions that released a flood of molten lava hundreds—or even thousands—of meters thick. Once solidified, the lava formed the "Siberian traps," a rock formation that covers 1.6 million km^2 of northeastern Asia. Scientists estimate that the lava flood released so much carbon dioxide, a greenhouse gas (see Section 54.4), into the atmosphere that it may have increased the average global surface temperature by 6°C. The resulting higher ocean temperature melted frozen submarine deposits of methane, which then bubbled into the atmosphere, causing even more climate warming. Michael J. Benton and Richard J. Twitchett of the University of Bristol, United Kingdom, describe the situation as a "runaway greenhouse" in which global temperature increased so much that organisms simply could not adapt to the change. One hundred million years elapsed before global diversity returned to pre-extinction levels.

Many researchers agree that an asteroid impact was a major cause of the Cretaceous mass extinction. The resulting dust cloud may have blocked the sunlight necessary for photosynthesis, setting up a chain reaction of extinctions that began with microscopic marine organisms. Geological evidence supports this hypothesis. Rocks dating to the end of the Cretaceous period (65 million years ago) contain a highly concentrated layer of iridium, a metal that is rare on Earth but common in asteroids. The impact from an iridium-laden asteroid only 10 km in diameter could have caused an explosion equivalent to that of 100 million megatons of TNT, scattering iridium dust around the world. Geologists have identified the Chicxulub crater, 180 km in diameter, on the edge of Mexico's Yucatán peninsula (see the red arrow in Figure 23.8) as the likely site of the impact.

Biodiversity Has Increased Repeatedly over Evolutionary History

Although mass extinctions temporarily reduce biodiversity, they also create evolutionary opportunities. Some species survive because they have highly adaptive traits, large population sizes, or widespread distributions. And some of the surviving species undergo adaptive radiation, filling adaptive zones that mass extinctions made available.

Sometimes, the success of one lineage comes at the expense of another. Although the diversity of terrestrial vascular plants has increased almost continuously since the Devonian period, this trend includes booms and busts in several lineages **(Figure 23.16).**

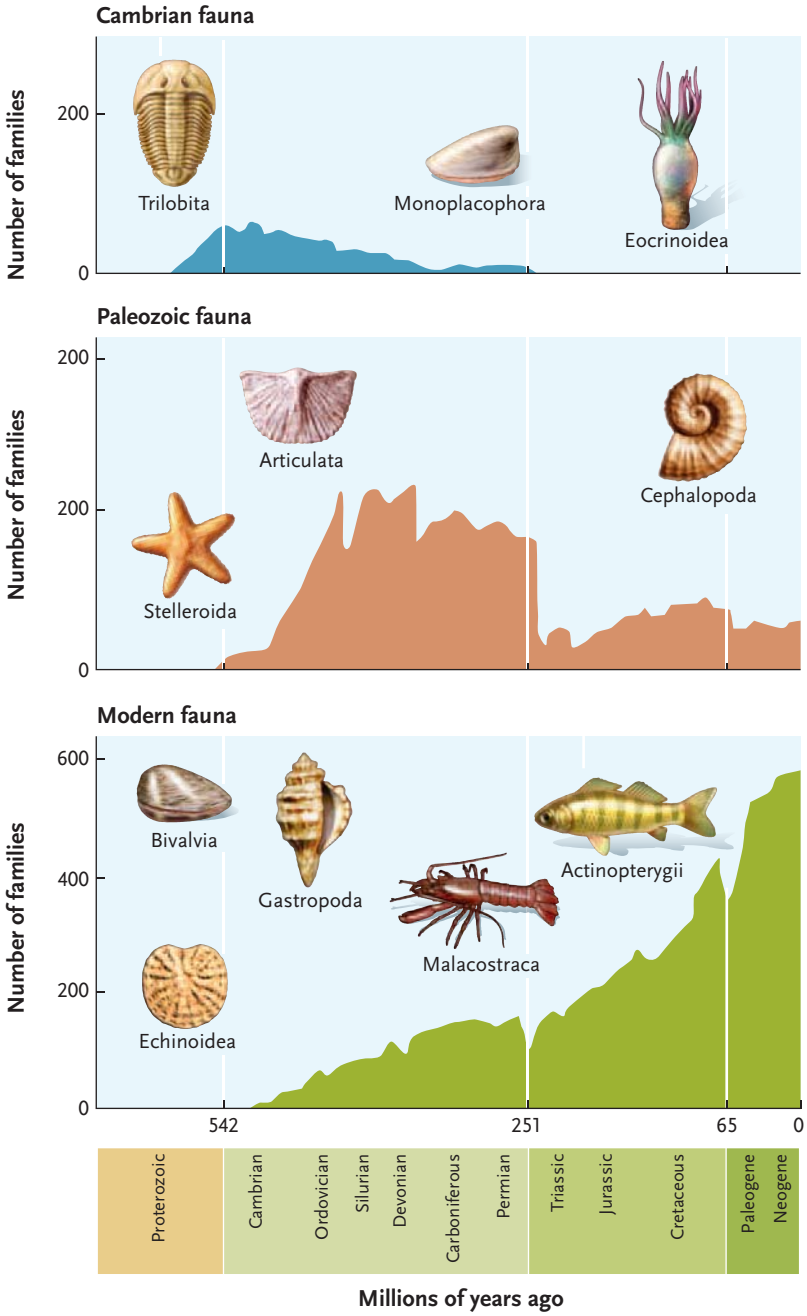

FIGURE 23.17 **History of marine animal diversity.** Marine animals have undergone three major radiations. Few remnants of the Cambrian fauna remain alive today.

© Cengage Learning 2014

Ferns and conifers recovered rapidly after the Permian extinction, maintaining their diversity into the early Cenozoic era. However, angiosperms, which arose and began to diversify in the early Cretaceous period, may have hastened the decline of these groups by replacing them in many environments.

The superb fossil record left by certain marine animals reveals three major periods of adaptive radiation **(Figure 23.17).** The first occurred during the Cambrian, more than 500 million years ago, when many animal phyla, the major categories of animal life, first appeared. Most of these phyla became extinct, and a second wave of radiations established the dominant Paleozoic fauna during the Ordovician period. A third evolutionary fauna diversified in the Triassic period, right after the great Permian extinction; it produced the immediate ancestors of modern marine animals. The diversity of marine animals has increased consistently since the early Triassic, in large measure because of continental drift. As continents and shallow seas became increasingly isolated, regional biotas diversified independently of one another, increasing worldwide biodiversity.

Historical increases in biodiversity can also be attributed to the evolution of ecological interactions. For example, the number of plant species found *within* fossil assemblages has increased over time, suggesting the evolution of mechanisms that allow more species to coexist. In addition, insects continued to diversify dramatically in the Cretaceous period, possibly because the angiosperms created a new adaptive zone for them. New insect species then provided a novel set of pollinators that may have stimulated the radiation of angiosperms. Such long-term evolutionary interactions between ecologically intertwined lineages have played an important role in structuring ecological communities, which are described more fully in Chapter 53.

STUDY BREAK 23.4

1. What factors might allow a population of organisms to occupy a new adaptive zone?
2. What events apparently triggered the mass extinction at the end of the Permian period?
3. When did the first major adaptive radiation of animals occur?

THINK OUTSIDE THE BOOK

You have learned how the geography of the Galápagos and the Hawaiian Islands fostered adaptive radiations in finches and fruit flies. Search Internet or library sources for examples of adaptive radiations in other types of organisms on these archipelagos. Also look for information about the adaptive radiation of mammals on continental land masses. Do adaptive radiations on archipelagos and on continental landmasses differ in substantive ways?

23.5 Interpreting Evolutionary Lineages

As newly discovered fossils demand the reinterpretation of old hypotheses, biologists constantly refine their ideas about the history of life. In this section we describe how our interpretation of evolutionary lineages is constantly changing.

Modern Horses Are Living Representatives of a Once-Diverse Lineage

The earliest known ancestors of modern horses were first identified by Othniel C. Marsh of Yale University just a year after Darwin published *On the Origin of Species.* These early horses, *Hyracotherium,* stood 25 to 50 cm high and weighed no more than 20 kg. Their toes (four on the front feet and three on the hind) were each capped with a tiny hoof, but the animals walked on soft pads as dogs do today. Their faces were short, their teeth were small, and they browsed on soft leaves in woodland habitats.

In 1879, Marsh published his analysis of 55 million years of horse family history. He described the evolution of this group of mammals as a sequence of stages from the tiny *Hyracotherium* through intermediates represented by *Mesohippus, Merychippus,* and *Pliohippus* to the modern *Equus* **(Figure 23.18A).** (Each of these names refers to a genus, a group of closely related species.) Marsh inferred a pattern of descent characterized by gradual, directional evolution in several skeletal features. Changes in the legs and feet allowed horses to run more quickly, and changes in the face and teeth accompanied a switch in diet from soft leaves to tough grasses.

The fossil record for horses is superb, and we now have fossils of more than 100 extinct species from five continents. These data reveal a macroevolutionary history very different from Marsh's interpretation. *Hyracotherium* was not gradually transformed into *Equus* along a linear track. Instead, the evolutionary tree for horses was highly branched **(Figure 23.18B),** and *Hyracotherium's* descendants differed in size, number of toes, tooth structure, and other traits. Although many branches of this lineage lived in the Miocene and Pliocene epochs, all but one are now extinct. The species of the genus *Equus* living today (horses, donkeys, and zebras) are the surviving tips of that one branch.

When we study extinct organisms, we tend to focus on traits that characterize modern species. Marsh, for example, assumed that the differences between *Hyracotherium* and *Equus* were typical of the changes that characterized the group's evolutionary history. But not all fossil horses were larger **(Figure 23.18C),** had fewer toes, or were better adapted to feed on grass than their ancestors.

The Tempo of Morphological Change Varies among Lineages

Analyses of the fossil record indicate that the tempo, or timing, of morphological change varies among lineages. The discovery of transitional fossils provides evidence in support of the **phyletic gradualism hypothesis** (*phylon* = race), which proposes that most morphological change occurs gradually over long periods of time. For example, a study of Ordovician trilobites revealed that the number of "ribs" in their tail region changed continuously over 3 million years. The change was so gradual that a sample from any given stratum was almost always intermediate between samples from the strata just above and below it. The changes in rib number probably evolved without the evolution of new, reproductively isolated species **(Figure 23.19).**

But for most groups of organisms, the fossil record is not nearly as good as it is for horses or trilobites. In fact, the discovery of intermediate or transitional fossils is fairly rare. Instead, most species appear suddenly in a particular layer, persist for some time with little change, and then disappear from the fossil record. Then another species with different traits suddenly appears in the next higher stratum.

In the early 1970s, Niles Eldredge of the American Museum of Natural History and Stephen Jay Gould of Harvard University published an explanation for the absence of transitional forms, or "missing links." Their **punctuated equilibrium hypothesis** suggested that speciation usually occurs in isolated populations at the edge of a species' geographical distribution. Such populations experience substantial genetic drift and distinctive patterns of natural selection (as described in Section 23.3). According to this hypothesis, morphological variations appear rapidly as new species arise; then, most species exhibit long periods of morphological equilibrium (that is, little change in form), punctuated by brief periods of speciation and rapid morphological evolution. Eldridge and Gould further argued that transitional forms live only for short periods of geological time in small, localized populations—the very conditions that discourage broad representation in the fossil record. Darwin himself used this line of reasoning to explain puzzling gaps in the fossil record: new species appear as fossils only after they become abundant and widespread and begin a period of morphological stasis.

Some evolutionists challenged the hypothesis' definition of rapid morphological change, particularly given our inability to resolve time precisely in the fossil record. To a paleobiologist with a geological perspective, "instantaneous" events

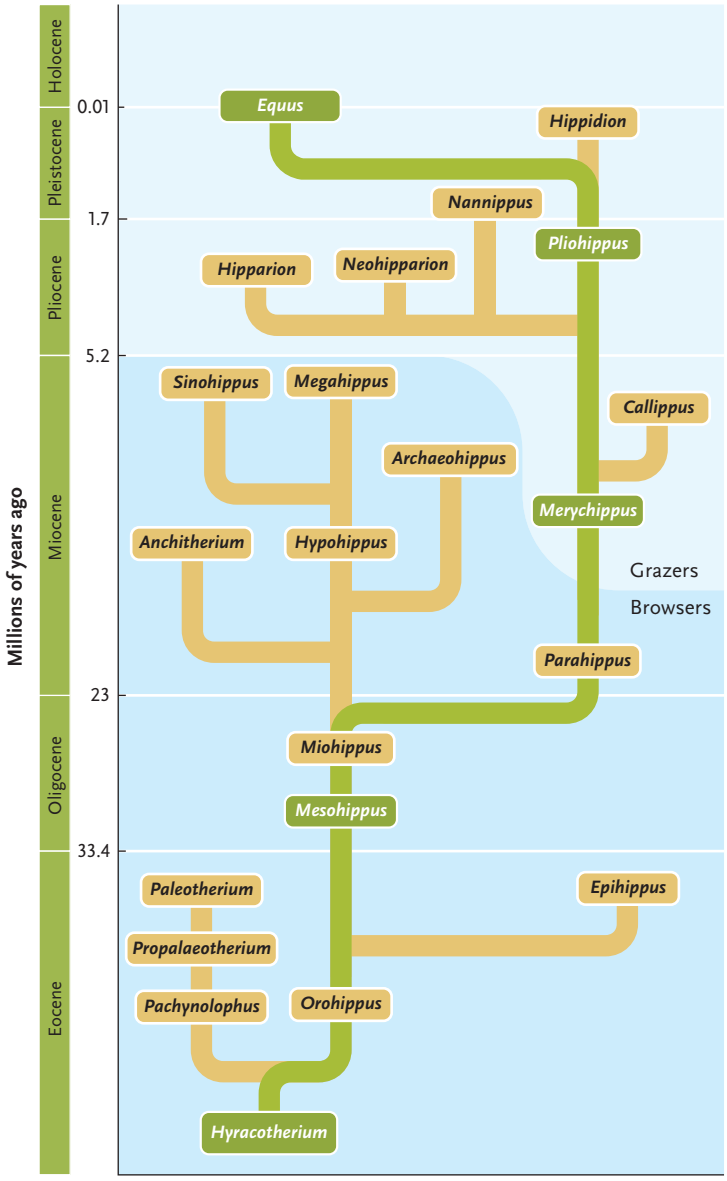
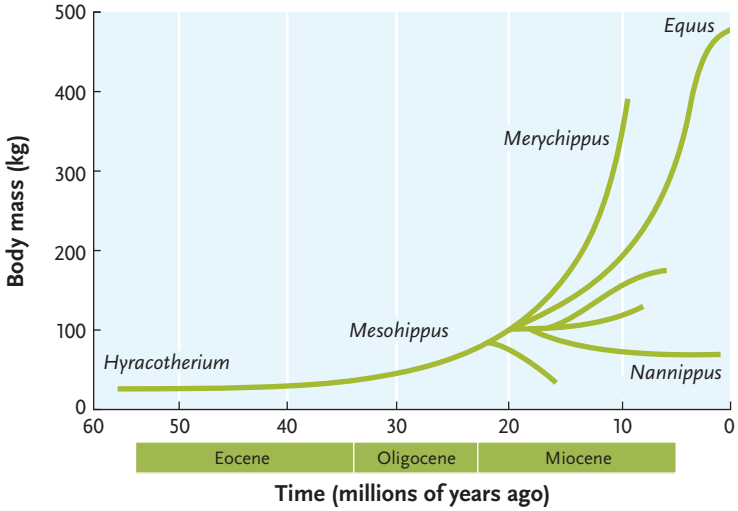
CLOSER LOOK

FIGURE 23.18 Evolving views of horse ancestry.



A. Marsh's reconstruction of horse evolution

Marsh's description of horse evolution focused on increased body size, reduced number of toes, and larger, grinding teeth at the back of the mouth.



B. Modern reconstruction of horse evolution

Recent studies revealed that the horse family includes numerous evolutionary branches with variable morphology. The horses in Marsh's analysis are highlighted in green.

C. Changes in body size of horse species over time

Some branches of the lineage remained as small as the first horses.

SUMMARY The lineage that includes modern horses includes many branches that did not leave any living descendants. If a branch other than *Equus* had survived, Marsh's description of trends in horse evolution would have been very different. All evolutionary lineages have extinct branches, and any attempt to trace a linear evolutionary path—as Marsh did for horses and many people do for humans—imposes artificial order on an inherently disorderly history.

THINK LIKE A SCIENTIST Modern horse breeders have used artificial selection to produce miniature horses that resemble their full-sized ancestors in all respects except body size. Does artificial selection for miniature horses constitute a reversal of the evolutionary trends observed in the horse lineage?

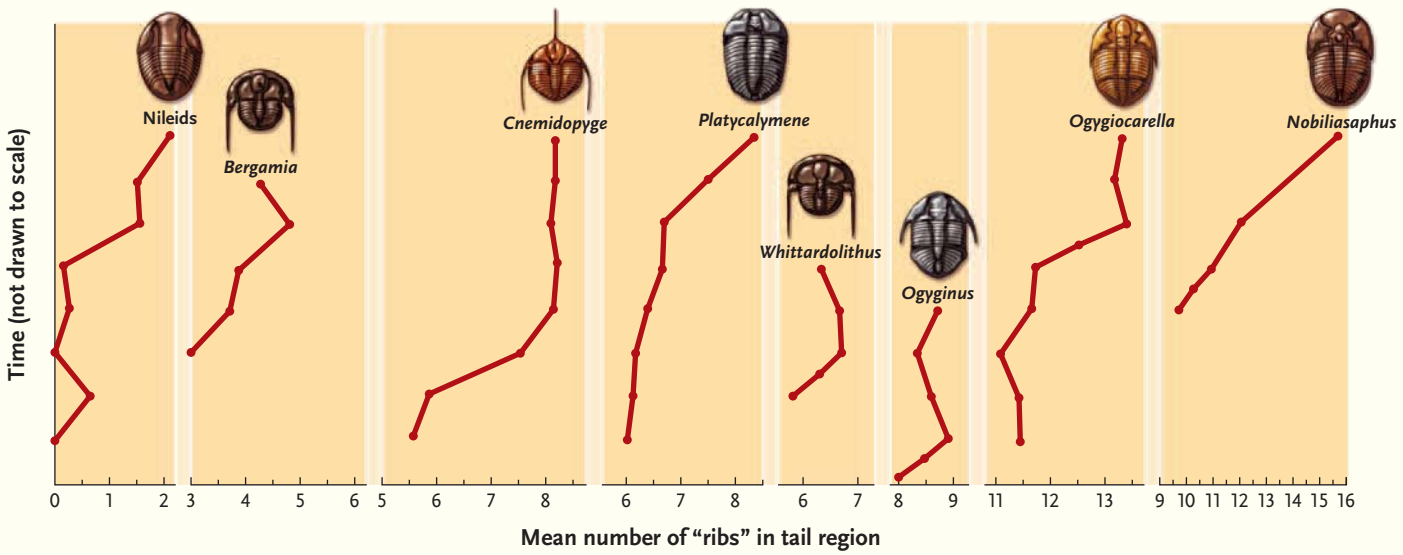
FIGURE 23.19 **Observational Research**



Evidence of Phyletic Gradualism

Hypothesis: The phyletic gradualism hypothesis states that most morphological change within evolutionary lineages results from the accumulation of small, incremental changes over long periods of time.

Prediction: The morphology of fossils from a given stratum will be intermediate between those of fossils from the strata immediately below and above it.

Method: Peter R. Sheldon of Trinity College, Dublin, Ireland, counted the number of "ribs" in the tail region of the exoskeletons of approximately 15,000 trilobite fossils from central Wales, United Kingdom. The fossils had formed over a span of about 3 million years during the Ordovician period. Shelton plotted the mean number of ribs found in successive samples of eight lineages.

Results: Sheldon's data reveal gradual changes in the mean number of "ribs" in these animals with no evidence of speciation.

Reprinted by permission from Macmillan Publishers Ltd: P. R. Sheldon. 1987. Parallel gradualistic evolution of Ordovician trilobites. *Nature* 330:561–563.

Conclusion: Morphological changes in Ordovician trilobites from central Wales are consistent with the predictions of the phyletic gradualism hypothesis.

THINK LIKE A SCIENTIST Do you think that the changes in rib number over time in *Bergamia* and *Ogyginus* are the products of balancing selection, directional selection, or some other agent of evolution?

Source: Grant, Peter R., Ecology and Evolution of Darwin's Finches. © Princeton University Press. Reprinted by permission of Princeton University Press.

occur over tens or hundreds of thousands of years. But to a population geneticist, those time scales may encompass thousands of generations, ample time for gradual microevolutionary change.

Moreover, examples of evolutionary stasis may not be as static as they appear. Alternating periods of directional selection that favor opposite patterns of change could produce the appearance of stasis. For example, if natural selection favored slight increases in body size for 2,000 years and then favored slight decreases for the next 2,000 years, paleobiologists would probably detect no change in body size at all.

Nevertheless, punctuated patterns of evolution have been observed in some groups, such as *Metrarabdotos,* a genus of ectoprocts from the Caribbean Sea. Ectoprocts are small colonial animals that build hard skeletons (see Figure 31.15A), the details of which are well preserved in fossils. Alan Cheetham of the Smithsonian Institution measured the morphological differences between populations of individual *Metrarabdotos* species over time and between ancestral species and their descendants. His results indicate that most species did not change much for millions of years, but new species, which were morphologically different from their ancestors, often appeared suddenly **(Figure 23.20).**

Researchers have found evidence of both gradual and punctuated morphological changes as well as some intermediate patterns. The punctuated equilibrium hypothesis caused a stir when it was first proposed because it challenged long-held assumptions about the tempo of evolution. But its publication rekindled interest in paleobiology and macroevolution, and

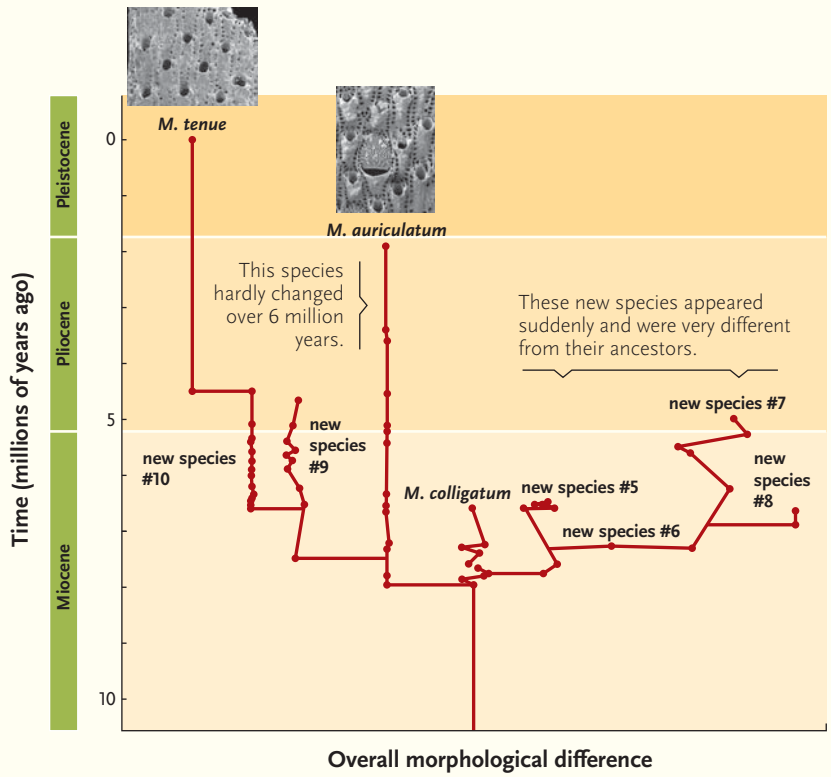
FIGURE 23.20 Observational Research



Evidence of a Punctuated Pattern of Morphological Change

Hypothesis: The punctuated equilibrium hypothesis states that most morphological change within evolutionary lineages appears during speciation.

Prediction: The fossil record will reveal that most species experienced relatively little morphological change for long periods of time, but that new, morphologically distinctive species arose suddenly.

Method: Cheetham examined numerous fossilized samples of populations of a small marine invertebrate, the ectoproct *Metrarabdotos,* from the Dominican Republic. He measured 46 morphological characters in populations representing 18 species and then used a complex statistical analysis to summarize the extent of morphological difference between populations.

Results: The morphology of most *Metrarabdotos* species changed very little over millions of years, but new species, morphologically very different from their ancestors, often appeared suddenly in the fossil record. Each dot in the graph represents a sample of a population from the fossil record. The horizontal axis reflects the overall morphological difference between samples of one species over time or between samples of ancestral species and descendant species.

A. H. Cheetham. 1987. Tempo of evolution in a Neogene bryozoan: Are trends in single morphologic characters misleading? *Paleobiology* 13:286–296. Used with permission of the Paleontological Society.

Conclusion: The *Metrarabdotos* lineage exhibits a pattern of morphological evolution that is consistent with the predictions of the punctuated equilibrium hypothesis.

THINK LIKE A SCIENTIST Which of the *Metrarabdotos* species in the illustration shows some evidence of gradual morphological change?

like any good idea in science, it inspired much new research. Some of the most interesting results have focused on the evolution of morphological novelties, which biologists now analyze with studies in paleontology, embryology, and genetics.

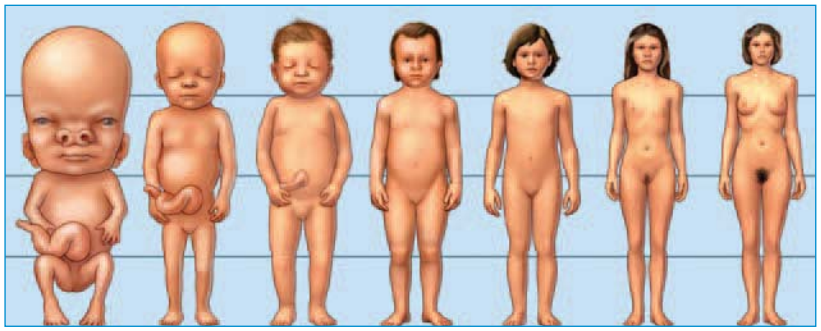
23.6 The Evolution of Morphological Novelties

The fossil record documents the appearance of distinctive morphological novelties, such as the limbs of four-legged vertebrates and the appearance of crests and horns on some dinosaurs. In this section we consider explanations for how such novelties may arise.

Differential Growth of Body Parts and Changes in the Timing of Developmental Events Produce Distinctive Structures

The morphology of individuals sometimes changes over time because of *allometric growth* (*allos* = other; *metron* = measure), the differential growth of body parts. In humans, for example, the relative sizes of different body parts change because human heads, torsos, and limbs grow at different rates **(Figure 23.21A).**

Allometric growth can also establish morphological differences in closely related species. For example, the skulls of chimpanzees and humans are similar in newborns of both species, but markedly different in adults **(Figure 23.21B).** The jaw region of the chimp skull grows much faster than other regions, while the different parts of the human skull all grow at more similar rates. Differences in the adult skulls may therefore simply reflect changes in one or a few genes that regulate the pattern of growth.



Changes in the timing of developmental events, called *heterochrony* (*heteros* = different;

A. Allometric growth in humans

Humans exhibit allometric growth from prenatal development until adulthood. Our heads grow more slowly than other body parts; our legs grow faster.

B. Differential growth in the skulls of chimpanzees and humans

Although the skulls of newborn humans and chimpanzees are remarkably similar, differential patterns of growth make them diverge during development. The jaw of a chimpanzee grows much faster than other regions of the skull. In humans, the different parts of the skull grow at more similar rates.

khronos = time), also cause the morphology of closely related species to differ. **Paedomorphosis** (*paedo-* = child; *morphos* = form or shape), the development of reproductive capability in an organism with juvenile characteristics, is a common form of heterochrony.

Many salamanders, for example, undergo metamorphosis from an aquatic juvenile into a morphologically distinct terrestrial adult. However, populations of several species are paedomorphic—they grow to adult size and become reproductively mature without changing to the adult form **(Figure 23.22).** The evolutionary change causing these differences may be surprisingly simple. In amphibians, including salamanders, the hormone thyroxine induces metamorphosis (see Chapter 42). Paedomorphosis could result from a mutation that either reduces thyroxine production or limits the responsiveness of some developmental processes to thyroxine concentration.

FIGURE 23.22 **Paedomorphosis in salamanders.** Some small-mouthed salamanders *(Ambystoma talpoideum)* undergo metamorphosis, losing their gills and developing lungs (left). Others are paedomorphic: they retain juvenile morphological characteristics, such as gills, after attaining sexual maturity (right).

David Scott/SREL

Changes in developmental rates also influence the morphology of plants **(Figure 23.23).** The flower of a larkspur species, *Delphinium decorum,* includes a ring of petals that guide bees to its nectar tube and structures on which bees can perch. By contrast, *Delphinium nudicaule,* a more recently evolved species, has tight flowers that attract hummingbird pollinators, which can hover in front of the flowers. Slower development in *D. nudicaule* flowers causes the structural difference: a mature flower in the descendant species resembles an unopened (juvenile) flower of the ancestral species.

Morphological Novelties Often Arise as Modifications of Existing Structures

Sometimes a trait that is adaptive in one context is also advantageous under different circumstances. Biologists describe the original version of the trait as an **exaptation** (formerly called a *preadaptation*). Natural selection may then exaggerate the trait or modify it altogether to enhance its new function. Exaptations are just lucky accidents; they never evolve *in anticipation* of future evolutionary needs or benefits.

The forelimbs and feathers of certain dinosaurs provide a good example of an exaptation. Shortly after the first discovery of an *Archaeopteryx* skeleton in 1861, Thomas Henry Huxley, a protégé of Darwin, developed the controversial hypothesis that birds are the living representatives of the theropods, a lineage of bipedal predatory dinosaurs (see Figure 20.13). More than a century passed before John Ostrom of Yale University provided support for Huxley's hypothesis; in 1964, he described a previously unknown theropod dinosaur, *Deinonychus antirrhopus,* with a very birdlike skeleton. But *Archaeopteryx*

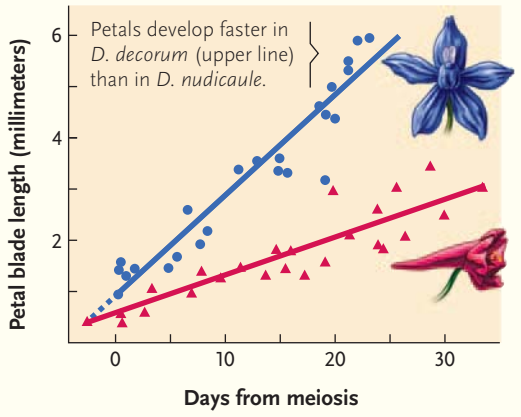
FIGURE 23.23 **Observational Research**

Paedomorphosis in *Delphinium* Flowers

Hypothesis: The narrow tubular shape of the flowers of *Delphinium nudicaule,* which are pollinated by hummingbirds, is the product of paedomorphosis, the retention of juvenile characteristics in a reproductive adult.

Prediction: The flowers of *D. nudicaule* grow more slowly and mature at an earlier stage of development than those of *Delphinium decorum,* a species with broad, open flowers that are pollinated by bees.

D. decorum ***D. nudicaule***



Gary Head

Gary Head

Method: Edward O. Guerrant of the University of California, Berkeley, measured 42 bud and flower characteristics in *D. nudicaule* and *D. decorum* as their flowers developed and used the number of days since the completion of meiosis in pollen grains as a measure of flower maturity. He then used a complex statistical analysis to compare the characteristics of the buds and flowers of both species.

Results: The mature flowers of *D. nudicaule* resemble the buds of both species more closely than they resemble the flowers of *D. decorum.* Although the time required for maturation of the reproductive structures is similar in the two species, the rate of petal growth (measured as petal blade length) is slower in *D. nudicaule.* As a result, the mature flowers of *D. nudicaule* do not open as widely as those of *D. decorum.* Because of these morphological differences, bees can pollinate flowers of *D. decorum,* but they cannot land on the flowers of *D. nudicaule,* which are instead pollinated by hummingbirds.

E. O. Guerrant. 1982. Neotenic evolution of *Delphinium nudicaule* (Ranunculaceae): A hummingbird-pollinated larkspur. *Evolution* 36:699–712. Copyright 1982 Blackwell Publishing Ltd. Reproduced with permission of Blackwell Publishing Ltd.

Conclusion: The narrower and more tubular shape of *D. nudicaule* flowers, which mature at an earlier stage of development than *D. decorum* flowers, is the product of paedomorphosis.

THINK LIKE A SCIENTIST How might the structural difference in the flowers of *D. decorum* and *D. nudicaule* maintain reproductive isolation between the two species?

Source: E. O. Guerrant. 1982. Neotenic evolution of *Delphinium nudicaule* (Ranunculaceae): A hummingbird-pollinated larkspur. *Evolution* 36:699–712.

remained a puzzling creature because of its mix of dinosaurian characteristics—teeth, a flat breastbone, a long tail with many vertebrae, and three clawed fingers on each hand—and avian (that is, birdlike) characteristics—a furcula (wishbone), winglike forelimbs, and feathers. Although *Archaeopteryx* was the only feathered dinosaur-like fossil known at the time, scientists hypothesized that at least some of its dinosaur ancestors must have been feathered as well. Nevertheless, the known fossil record suggested that the transition from dinosaurs to feathered birds was abrupt: feathers were absent in the dinosaur ancestors of birds, but present in what biologists consider the earliest known bird.

Since the early 1990s, however, paleontologists have uncovered a wealth of feathered dinosaur fossils; most have been found in early Cretaceous deposits, dated at 124 million years ago, in northern China. The fossilized dinosaur feathers range from filamentous or downy structures that covered their bodies to long stiff feathers on their forelimbs and tails. One dinosaur species, *Microraptor gui,* had well-developed feathers on all four of its limbs **(Figure 23.24).** Research has confirmed that the feathers in one fossil included β-keratin, the protein found in the feathers of modern birds. Based on this anatomical and biochemical evidence, biologists hypothesize that feathers arose as modifications of ancestral scales in the skin of early dinosaurs. Thus, feathers are not unique to birds. They appeared in bird ancestors, perhaps as a form of insulation or as structures used for social communication; birds merely retain this ancestral characteristic.

But flight requires wings as well as feathers. How did wings and flapping flight evolve from the forelimbs of bipedal dinosaurs? Scientists have proposed two hypotheses to explain the origin of flight in birds, both of which view feathered forelimbs as exaptations. According to the "from the ground up" hypothesis, the dinosaur ancestors of birds were bipedal predators that chased prey on the ground. If they jumped at flying insect prey and used their feathered forelimbs as "fly-swatters," natural selection may have enlarged the forelimbs—along with their muscles and feathers—in stages, first to improve jumping ability and later to power flapping flight. The alternative "from the trees down" hypothesis argues that bird ancestors were at least partially arboreal. If they leapt from limb to limb or from tree to tree to chase prey or escape from predators, feathered forelimbs may have allowed them to glide and extend their jumps. Natural selec-

tion might then have modified these structures and behaviors to improve gliding ability and eventually allow flapping flight.

Evolutionary Developmental Biology May Explain the Sudden Appearance of Some Morphological Novelties

During much of the twentieth century, the evolutionary biologists who studied morphological novelties in extinct and living organisms worked independently of the scientists studying embryonic development. As a result, evolutionary biologists were unable to construct a coherent picture of the specific developmental mechanisms that contributed to morphological innovations. Since the late 1980s, however, advances in molecular genetics have allowed scientists to explore the genomes of organisms in great detail, fostering a new approach to these studies. **Evolutionary developmental biology**—evo-devo, for short—asks how evolutionary changes in the genes regulating embryonic development can lead to the morphological changes that foster adaptive radiations, increasing biodiversity over geological time.

In the life cycle of a multicellular organism, the many different body parts of the adult develop in a highly controlled sequence of steps that is specified by genetic instructions in the single cell of a fertilized egg. Developmental biologists study how regulatory genes control the development of phenotypes and their variations. As described in Section 16.4, **homeotic genes** (described further for plants in Chapter 36) code for transcription factors that bind regulatory sites on DNA, either activating or repressing the expression of other genes that contribute to an organism's form. In the remainder of this chapter, we describe a few intriguing discoveries about the genetic mechanisms that underlie some macroevolutionary changes in animals. You have already encountered one example when you read about the evolution of limblessness in snakes (Section 20.3).

Most Animals Share the Genetic Tool Kit That Regulates Their Development

Comparisons of genome sequence data reveal that most animals, regardless of their complexity or position in the Tree of Life, share a set of several hundred homeotic genes that control their development. Collectively, these genes have been dubbed the "genetic tool kit," because they govern the basic design of the body plan by controlling the activity of thousands of other genes. Some of the tool-kit genes must be at least 500 million years old, because all living animals inherited them from a com-

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

mon ancestor alive at that time. Not surprisingly, their structure does not differ much among the animals that possess them, and they generally play the same role in development for all species. For example, as you learned in Section 16.4, genes in the *Hox* family control the overall body plan of animals, including where appendages—wings in flies and legs in mice—will develop on the animal's body. Some of the same tool-kit genes are also present in plants, fungi, and prokaryotes, suggesting that those genes may date back to the earliest forms of life.

Another example of a highly conserved and widely distributed tool-kit gene, the *Pax-6* gene, triggers the formation of light-sensing organs as diverse as the eye spots in flatworms, the compound eyes of insects and other arthropods, and the camera eyes of vertebrates (see Chapter 41). Like the *Hox* genes, *Pax-6* also codes for a protein that either activates or represses gene transcription. The proteins coded by *Pax-6* in different animals are so similar that when researchers genetically engineered fruit fly larvae to express the *Pax-6* gene taken from a squid or a mouse, the flies responded by developing eyes. The induced eyes were, however, fruit fly eyes—not squid eyes or mouse eyes. Thus, *Pax-6* triggers activity in the fruit fly genes that carry the specific instructions for making an eye typical of that species. Apparently, the ancient genetic sequence for *Pax-6,* the master regulatory gene for eye development, has been conserved over the hundreds of millions of years since the common ancestor of squids, fruit flies, and mice lived.

Evolutionary Changes in Developmental Switches May Account for Much Evolutionary Change

If most animals share the same tool-kit genes, how has evolution produced different body plans among species? What makes a squid, a fruit fly, and a mouse different? Researchers in evo-devo have proposed that morphological differences among species arise when mutations alter the effects of developmental regulatory genes. As described in Chapter 16, the developmental programs of animals involve complex networks of many interacting genes. Varying combinations of tool-kit genes may be expressed at different times and in different body regions. According to this hypothesis, the several hundred tool-kit genes encode proteins that work as either activators or repressors in a multitude of possible combinations. Thus, they can generate an unimaginably large number of different gene expression patterns, each with the potential to alter morphology.

Sean B. Carroll of the Howard Hughes Medical Institute has described the regulatory sites that transcription factors can bind as *switches,* like those we use to turn lights on or off. When a combination of transcription factors turns on a regulatory switch, a gene further downstream (that is, one that is expressed later in time) is activated. When transcription factors turn off a regulatory switch, a downstream gene is inactivated.

Although all the cells in an animal contain exactly the same set of genes, the differential expression of genes in different body regions and at different times during embryonic development causes different structures to be made. Allometric growth can result from evolutionary changes in developmental switches that cause certain body parts to grow faster or larger than others. Similarly, heterochrony can be explained as an evolutionary change in the switches that either delays the development of adult characteristics or speeds up the development of reproductive maturity.

If Carroll's hypothesis is correct, morphological novelties arise when evolutionary changes in developmental switches alter the expression patterns of *existing* genes. This view contrasts markedly with the explanation proposed in the modern synthesis (the unified theory of evolution described in Chapter 20), that most morphological novelties arise as mutations that slowly accumulate in the genes that carry blueprints for building particular structures. According to the modern synthesis, the accumulated mutations eventually create *new* genes that specify the creation of new structures.

Although Carroll's hypothesis proposes a different genetic mechanisms as the basis for evolutionary changes in morphology, mutations in developmental regulatory genes and their effects on morphology are subject to the action of the same microevolutionary processes—natural selection, genetic drift, and gene flow—that influence the frequencies of genotypes and phenotypes in populations. Thus, every morphological change induced by a mutation in a homeotic gene or developmental switch is tested by the success or failure of the individual that carries it.

Numerous studies have shown that changes in the expression of homeotic genes can have dramatic effects on morphology. *Insights from the Molecular Revolution* explains how a change in the timing of the expression of *Hox* genes may have changed the fins of fishes into the limbs of four-legged vertebrates.

In another example, researchers have determined how an adaptive morphological change in a small fish, the three-spined stickleback *(Gasterosteus aculeatus),* results from the deactivation of a homeotic gene. The freshwater stickleback populations in North American lakes are the descendants of marine ancestors that colonized the lakes after the retreat of glaciers between 10,000 and 20,000 years ago. Marine sticklebacks have bony armor along their sides and prominent spines; lake-dwelling sticklebacks have greatly reduced armor and, in many populations, lack spines on their pelvic fins **(Figure 23.25).**

Natural selection has apparently fostered these morphological differences in response to the dominant predators in each habitat. In marine environments, long spines prevent some predatory fishes from swallowing sticklebacks. But long spines are a liability in lakes, where voracious dragonfly larvae grab sticklebacks by their spines and devour them; freshwater sticklebacks that lack spines are more likely to escape from their clutches.

In a paper published in 2004, Michael D. Shapiro of the Stanford University School of Medicine and the Howard Hughes Medical Institute and colleagues at several other institutions described how the presence or absence of spines on the pelvic fins of these fishes is governed by the expression of the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Fancy Footwork from Fins to Fingers

Both fishes and tetrapods (four-footed animals) have two pairs of appendages, one anterior and one posterior. In both groups the appendages develop from buds of mesoderm—the middle of the three primary embryonic tissue layers—that thicken by increased cell division. As the buds elongate, cartilage is deposited at localized centers, where bones later form.

In fishes, the bones that support the fin develop along a central axis from the base to the tip of the fin. Like fins, tetrapod limbs have a central axis, but they also have distal structures, the digits (that is, fingers and toes). In tetrapods, centers of cartilage formation generate both the long bones of the limb and the five digits of the foot.

Groups of homeobox *(Hox)* genes control limb development in all animals with paired anterior and posterior appendages. Researchers have studied the expression of the *Hoxd* genes by using a nucleic acid probe that can pair with mRNA products of the genes, resulting in the generation of a color. The color is visualized under the microscope in embryos at different stages of development to determine where and when gene expression occurs. For tetrapods, genes at the 5′ end of the *Hoxd* cluster—designated 5′ *Hoxd* genes—are expressed in two distinct phases (**Figure,** part A). First, gene activity is restricted to the posterior half of the limb; this period of activity corresponds to development of the long limb bones. Second, the 5′ *Hoxd* genes became active in a band of cells perpendicular to the central axis; the cartilage centers that form the bones of the digits develop in this anterior-posterior band.

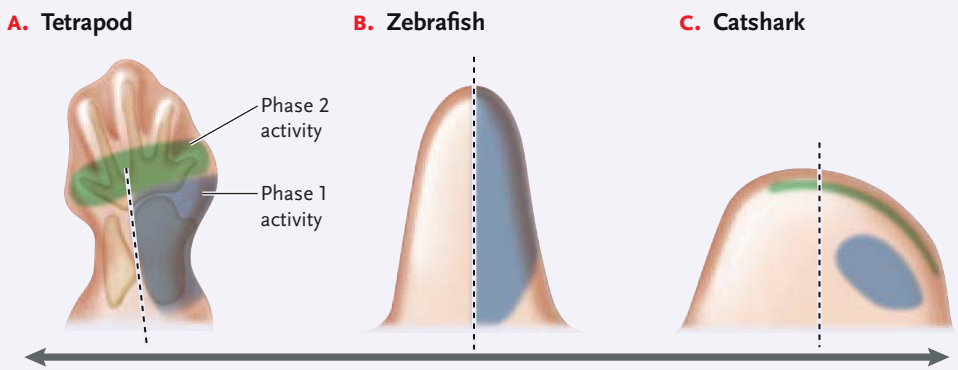
In 1995 Paolo Sordino, Frank van der Hoeven, and Denis Duboule at the University of Geneva in Switzerland published a study on *Hoxd* expression in the zebrafish *Danio rerio* (a common aquarium fish and a model research organism). They found that only a single phase of 5′ *Hoxd* gene activity occurs during zebrafish fin development (**Figure,** part B). Because the second phase of 5′ *Hoxd* gene activity is apparently absent in zebrafishes, they concluded that tetrapod digits must be an entirely novel evolutionary structure fostered by the addition of the second phase of 5′ *Hoxd* gene activity.

Research Question

Is the pattern of 5′ *Hoxd* gene expression seen in zebrafish typical of all fishes? That is, are tetrapods the only vertebrates that have a second phase of 5′ *Hoxd* gene expression?

Experiment

A number of research groups have carried out experiments to answer the question. One study, published in 2007 by Renata Freitas, GuangJun Zhang, and Martin Cohn at the University of Florida, Gainesville, examined the pattern of 5′ *Hoxd* gene expression in developing catshark *(Scyliorhinus canicula)* fins. Catsharks are included in an evolutionary lineage (Chondrichthyes, fishes with cartilaginous skeletons) that predates the lineage that includes zebrafishes (Actinopterygii, ray-finned fishes). Thus, data on fin development in catsharks may portray a more ancient developmental pattern than the one observed in zebrafishes.



Results

Their results showed that in the early stages of catshark fin development, the 5′ *Hoxd* genes are expressed in a phase like that seen during fin development in zebrafish and in the first phase of limb development in tetrapods. Unexpectedly, the researchers observed a *second* phase of expression of two of the 5′ *Hoxd* genes along the distal margin of the catshark fin buds (**Figure,** part C). Strikingly, that second phase of expression is similar to the second phase of 5′ *Hoxd* gene expression in tetrapod limb development.

Conclusion

The second phase of 5′ *Hoxd* gene expression is not uniquely associated with tetrapod limb development, as the earlier zebrafish data had suggested. Indeed, the more recent research suggests that two phases of 5′ *Hoxd* gene expression were present in the common ancestor of sharks, ray-finned fishes, and tetrapods. The authors of the later article hypothesized that digits may have arisen if the *Hoxd* genes in the distal parts of the limb were expressed for a longer period of development in tetrapods than in catsharks. The loss of the second phase of 5′ *Hoxd* gene expression in the zebrafish and their relatives may explain why most ray-finned fishes have a fin skeleton that is much smaller than that of catsharks and their relatives.

THINK LIKE A SCIENTIST The research described above suggests that *Hoxd* genes are expressed for a longer period of time during the development of the limbs in tetrapods than during the development of fins in ray-finned fishes. What general phenomenon does this example at the molecular level illustrate?

During development of the limb and digits in tetrapods, *Hoxd* genes first become active in cells on the posterior side of the limb (blue). Later, these genes are active in a broad band of cells perpendicular to the central axis of the limb (green).

During development of the fin in zebrafish, *Hoxd* genes become active in cells only on the posterior side of the developing fin (blue). Zebrafish exhibit no second phase of *Hoxd* activity in the developing fin.

During development of the fin in catsharks, *Hoxd* genes first become active in cells on the posterior side of the developing fin (blue). Later these genes become active in a very narrow band of cells near the edge of the developing fin (green).

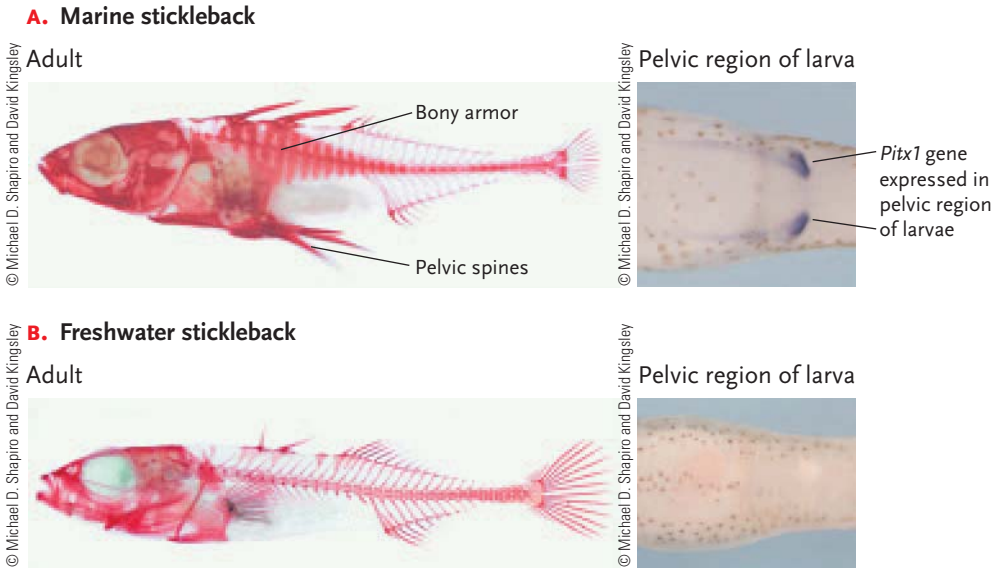

FIGURE 23.25 Sticklebacks with and without pelvic spines. (A) Marine populations of three-spined sticklebacks *(Gasterosteus aculeatus)* have prominent bony plates along their sides and large spines on their dorsal and pelvic fins. The growth of pelvic spines is induced by the expression of the *Pitx1* gene (the purple crescents in the photo on the right) in the pelvic region during embryonic development. **(B)** Many freshwater populations of the same species lack the bony plates and spines. Pelvic spines do not develop in the freshwater sticklebacks because the *Pitx1* gene is not expressed in the pelvic region. Natural selection has apparently fostered these morphological differences in response to the dominant predators in each environment. The skeletons of these specimens, each about 8 cm long, were dyed bright red.

gene *Pitx1*. Pelvic spines are part of the pelvic fin skeleton, the fishes' equivalent of a hind limb. In fact, *Pitx1* also contributes to the development of hind limbs in four-legged vertebrates and to certain glands and sensory organs in the head.

In long-spined marine sticklebacks, *Pitx1* is expressed in the embryonic buds from which pelvic fins develop, promoting the development of spines. But *Pitx1* is not expressed in the fin buds of freshwater sticklebacks; hence, pelvic spines do not develop. However, freshwater sticklebacks have not *lost* the *Pitx1* gene; it is still expressed elsewhere in the fishes' bodies. In a follow-up paper, published in 2009, the Shapiro team reported that the failure of freshwater sticklebacks to express the *Pitx1* gene in the developing pelvic region results from the deletion of a tissue-specific enhancer of hind limb expression; without this enhancer, the *Pitx1* gene is not expressed, and the fishes do not grow pelvic spines.

In the next chapter, we examine how biologists explore the evolutionary relationships among species and how they organize that information into a useful framework for researchers in every biological discipline. In the following unit, we will revisit evo-devo and examine some recent discoveries about how changes in homeotic genes have diversified body plans in the major evolutionary groups of organisms.

STUDY BREAK 23.6

1. **What is the difference between allometry and heterochrony?**
2. **What evidence suggests that many developmental control genes have been conserved by evolution?**
3. **What genetic factor is apparently responsible for the presence or absence of spines in stickleback fish?**

UNANSWERED QUESTIONS

Does morphological evolution always proceed gradually or can it occur in great leaps and bounds?

As you read in this chapter, biologists disagree about whether evolutionary changes in morphology can occur very rapidly. Although biologists have proposed various hypotheses to explain the abrupt changes that we sometimes find in the fossil record, evo-devo studies provide insight into one mechanism for how dramatic changes can arise: the spatial redeployment of homeotic genes. *Homeosis* is defined as the complete replacement of one type of organ with another. In one famous example, a *Hox* gene mutation in *Drosophila* replaces the antennae with legs. If such a mutation were to occur in nature, the organism would probably not have a selective advantage. But what if it did? These kinds of mutant phenotypes first inspired Richard Goldschmidt to develop his idea of the "hopeful monster" early in the twentieth century.

Stephen Jay Gould later revised and updated this idea in the context of his punctuated equilibrium hypothesis about the tempo and mode of evolution. The hypothesis suggests that if, on very rare occasions, truly dramatic morphological changes provide a selective advantage, they may lead to the rapid formation of a new species based on only a few genetic differences. What types of organisms are the most likely to exhibit homeotic change in an evolutionary context? The best candidates are those with highly modular bodies made up of repeating units—like the segments of an insect or the bones in the spine of a vertebrate. Such animals often express different organ identities in different modular units—such as the antennae, claws, and legs of a lobster—and these identities may be redeployed to different positions along the body axis. Plants are among the most modular organisms on Earth. They produce serially repeated structures—a leaf, a bud at the base of the leaf, and a stem—to generate their bodies. Many exciting and promising questions in plant evo-devo relate to how evolutionary homeosis may have generated rapid change in plant morphology.

Has homeosis contributed to the appearance and diversification of the angiosperms?

The sudden appearance of flowering plants, the angiosperms, in the fossil record so puzzled Charles Darwin that he dubbed their evolution an "abominable mystery." How did the gymnosperms, which always bear their male and female reproductive structures separately, give rise to the hermaphroditic (that is, bearing both male and female structures) flower? Our current understanding of the genetics of floral developmental provides a simple solution to this puzzle: the genetic program controlling floral organ identity is homeotic. Thus, it is possible for very simple genetic changes to transform an entirely male set of reproductive organs into a combination of male and female parts. Such models have been outlined by Günter Theissen at the Friedrich-Schiller-Universität Jena in Germany and by David Baum and Lena Hileman at the University of Wisconsin–Madison and the University of Kansas, respectively. In addition to fostering the origin of the angiosperms, homeosis may have played a role in the group's diversification. Commonly observed shifts in the morphology of sepals and petals or in the number of stamens (male reproductive structures) are suggestive of homeotic changes. These examples are more suitable for experimental verification than is the question on the origin of the angiosperms because they are much more recent occurrences. Although these hypotheses are very attractive, they remain to be confirmed through molecular genetic analyses.

THINK LIKE A SCIENTIST One point of disagreement among evolutionary biologists is whether evolutionary changes primarily occur in gene regulatory regions or in the coding regions. Which of these two types of changes do you think is more likely with homeotic evolution?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

23.1 The Fossil Record

- Fossils are the parts of organisms preserved in sedimentary rocks or in oxygen-poor environments (Figures 23.2 and 23.3).
- The fossil record is incomplete because few organisms fossilize completely, because some organisms are more likely to fossilize than others, and because natural processes destroy many fossils.
- Fossils provide a relative dating system, the geological time scale, for the strata in which they occur. Radiometric dating techniques establish the absolute age of rocks and fossils (Figures 23.4 and 23.5, Table 23.1).
- The fossil record provides data on changes in morphology, biogeography, ecology, and the behavior of organisms (Figure 23.6).

Animation: Radiometric dating

Animation: Geologic time scale

Animation: Radioisotope decay

23.2 Earth History

- Earth's crust is composed of plates of solid rock that float on a semisolid mantle (Figure 23.7). New crust is constantly generated and old crust is recycled. Currents in the mantle cause the continents to move over geological time (Figure 23.8). The breakup of the continents profoundly influenced biological evolution by separating populations and creating more shallow marine habitats.
- Continental movements caused variations in climate, the extent of glaciation, and sea levels (Figure 23.9). Asteroid impacts and volcanic eruptions have also influenced Earth's environment, sometimes triggering large-scale extinctions.

Animation: Plate margins

23.3 Historical Biogeography and Convergent Biotas

- Disjunct distributions of species can be produced by dispersal and/or vicariance (Figure 23.10). Dispersal results in a disjunct distribution when a new population is established on the far side of a barrier. Vicariance results in a disjunct distribution when external factors such as continental drift fragment the landscape.
- Continental drift has created six major biogeographical realms, each with a characteristic biota (Figure 23.11).
- Convergent evolution produces similar adaptations in distantly related species that live in similar environments (Figures 23.12 and 23.13).

23.4 The History of Biodiversity

- Adaptive radiation produces morphologically diverse species within lineages (Figure 23.14), increasing biodiversity.
- Extinction decreases species diversity. Mass extinctions have occurred at least five times in the history of life (Figure 23.15). Tectonic activity, climate change, and asteroid strikes are probable causes of mass extinctions.
- Biodiversity has increased repeatedly since life first evolved, partly in response to increased geographical separation of the continents and partly because complex interactions evolve among existing species (Figures 23.16 and 23.17).

Animation: Five major extinctions

Animation: Animal evolution in Phyla

23.5 Interpreting Evolutionary Lineages

- The horse lineage is complex and highly branched. It includes species of various sizes and diverse morphological adaptations (Figure 23.18).
- The tempo of morphological change varies among lineages. Some exhibit a pattern of gradual change through time (Figure 23.19). Other lineages confirm the predictions of the punctuated equilibrium hypothesis (Figure 23.20).

Animation: Evolution of Horses

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

23.6 The Evolution of Morphological Novelties

- Morphological novelties can arise from evolutionary changes in the relative growth rates of body parts (Figure 23.21) or in the timing of developmental events (Figures 23.22 and 23.23).
- Morphological novelties are often modifications of existing structures. An exaptation is a trait that turns out to be useful in a new environmental context even before natural selection refines its form. For example, the feathers and wings of birds evolved from the ancestral feathers and elongated forelimbs of some bipedal dinosaurs (Figure 23.24).
- Evolutionary developmental biology—evo-devo—examines how evolutionary changes in genes that regulate embryonic development can foster changes in body shape and form.
- Most organisms share an ancient tool kit of several hundred genes that regulate the expression of the thousands of genes involved in development. Evolutionary changes in developmental switches may account for many morphological changes. The differential expression of the *Pitx1* gene in sticklebacks determines whether or not a fish grows pelvic spines (Figure 23.25).

Animation: Mutation and proportional changes

UNDERSTAND & APPLY

Test Your Knowledge

1. The fossil record:
   a. provides direct and indirect evidence about life in the past.
   b. shows that all morphological novelties arise rapidly.
   c. provides abundant data about rare species with local distributions.
   d. is equally good for all organisms that ever lived.
   e. provides no evidence about the physiology or behavior of ancient organisms.
2. The absolute age of a geological stratum is determined by:
   a. the thickness of its rocks.
   b. the particle size in its rocks.
   c. the types of fossils found within it.
   d. its position relative to other layers.
   e. radiometric dating techniques.
3. The observation that fossils of *Premedosaurus* are found only in Argentina and Northern Europe provides an example of:
   a. a continuous distribution.
   b. a disjunct distribution.
   c. punctuated equilibrium.
   d. heterochrony.
   e. gradualism.
4. The evolutionary history of horses demonstrates that:
   a. modern horses are the direct, lineal descendants of the earliest horses.
   b. the leg bones of modern horses are more complex than those of the earliest horses.
   c. horses have always had specialized teeth that allow them to feed on tough grasses.
   d. horses diversified greatly, but only a few types survived to the present.
   e. the first horses lived in open, grassy habitats.
5. The punctuated equilibrium hypothesis:
   a. recognizes that morphological evolution may occur slowly or quickly.
   b. suggests that major morphological novelties arise gradually.
   c. may help explain why there are so many "missing links" in the fossil record.
   d. suggests that the fossil record is usually complete.
   e. links mass extinctions to the impact of asteroids striking Earth.
6. Biologists believe that the overall similarities between marsupial mammals in Australia and placental mammals in North America were caused by:
   a. plate tectonics.
   b. dispersal.
   c. convergent evolution.
   d. homeotic genes.
   e. punctuated equilibria.
7. The differential growth of body parts is called:
   a. allometry.
   b. paedomorphosis.
   c. heterochrony.
   d. phyletic gradualism.
   e. evo-devo.
8. Exaptations are traits that:
   a. prepare some organisms for future environmental changes.
   b. appear in lineages as a result of an adaptive radiation.
   c. evolve in anticipation of a species' future needs.
   d. are useful in new situations before natural selection alters them for a new function.
   e. occur in animals, but not in plants.
9. Adaptive radiations often follow mass extinctions because:
   a. mass extinctions limit the impact of paedomorphosis.
   b. mass extinctions foster allometry and heterochrony.
   c. mass extinctions decimate all forms of life on Earth.
   d. species that form transitional fossils often survive mass extinctions.
   e. extinctions open adaptive zones that had been previously occupied.
10. Homeotic genes are defined as genes that:
    a. bind directly to a regulatory site on DNA.
    b. code for transcription factors activating or repressing genes that influence an organism's form.
    c. determine whether or not a morphological innovation leads to an adaptive radiation.
    d. have been inherited from an ancient ancestor by nearly all forms of life.
    e. help biologists differentiate between plants and animals.

Discuss the Concepts

1. Many millions of years from now, continental drift may obliterate the Pacific Ocean, pushing North America into physical contact with Asia. What effects might these events have on the organisms living at that time?
2. One possible measure of a species' evolutionary success is the number of descendant species it produces. Should our species, *Homo sapiens,* be considered successful under this definition?
3. Extinctions are common in the history of life. Why are biologists alarmed by the current wave of extinctions caused by human activity?

Apply Evolutionary Thinking

The geological evolution of Earth has had an obvious effect on biological evolution. You have read about how the release of oxygen by photosynthetic organisms increased atmospheric oxygen concentration. How are human activities changing the physical environment on Earth? What new selection pressures do these environmental alterations establish?

Systematics and Phylogenetics: Revealing the Tree of Life

Why it matters . . . Mention the word "malaria," and people envision the tropics: explorers wander through the jungle in pith helmets and sleep under mosquito netting; clouds of insects hover nearby, ready to infect them with *Plasmodium,* the protistan parasite that causes this disease. You may be surprised to learn, however, that less than 100 years ago, malaria was also a serious threat in the southeastern United States and much of Western Europe.

Scientists puzzled over the cause of malaria for thousands of years. Hippocrates, a Greek physician who worked in the fifth century B.C., knew that people who lived near malodorous marshes often suffered from fevers and swollen spleens. Indeed, the name malaria is derived from the Latin for "bad air." By 1900, scientists had established that mosquitoes, *Plasmodium's* intermediate hosts, transmit the parasite to humans. Mosquitoes breed in standing water, and anyone living nearby is likely to suffer their bites.

Until the 1920s, scientists thought that the mosquito species *Anopheles maculipennis* carried malaria in Europe. But some areas with huge mosquito populations had little human malaria, whereas other areas had relatively few mosquitoes and a high incidence of the disease.

Then, a French researcher reported variation in the mosquitoes, and Dutch scientists identified two forms of the "species," only one of which seemed to carry malaria. The breakthrough came in 1924, when a retired public health inspector in Italy discovered that individual mosquitoes—all thought to be the same species—produced eggs with one of six distinctive surface patterns **(Figure 24.1).**

Further research revealed that the name *Anopheles maculipennis* had been applied to six separate mosquito species. Although the adults of these species are almost indistinguishable, their eggs are clearly different. The species are reproductively isolated from each other, and they differ ecologically: some breed in brackish coastal marshes, others in freshwater inland marshes, and still others

in slow-moving streams. Only some of these species have a preference for human blood, and researchers eventually determined that only three of them routinely transmit malaria to humans.

These discoveries explained why the geographical distributions of mosquitoes and malaria did not always match. And government agencies could finally fight malaria by eradicating the disease-carrying species. Health workers drained marshes to prevent mosquitoes from breeding. They used insecticides to kill mosquito larvae or introduced fish of the genus *Gambusia,* the mosquitofish, which eats them. These targeted control programs were very successful in the early and middle decades of the twentieth century.

Today, with the increased mobility of humans, agricultural products, and other goods, some mosquito species—as well as many other organisms—are invading habitats made more hospitable by global climate change (discussed further in Unit Seven). Some have expanded their geographical ranges substantially: introduced mosquito species have been discovered on all continents except Antarctica. Mosquitoes carry numerous agents of disease, and biologists are now devising new ways to recognize—and eradicate—the species that pose the greatest threats to human welfare.

The historic eradication of malaria in Europe owed a debt to **systematics,** the branch of biology that studies the diversity of life and its evolutionary relationships. Systematic biologists—systematists for short—identify, describe, name, and classify organisms, organizing their observations within a framework that reflects the organisms' evolutionary relationships. In this chapter we briefly describe the traditional approach to classification. We then focus attention on how systematists working today develop hypotheses about the evolutionary relationships of all the branches, twigs, and leaves on the Tree of Life.

From L. W. Hackett, Malaria in Europe, Oxford University Press, 1937

FIGURE 24.1 Eggs of European mosquitoes. Differences in surface patterns on the eggs of *Anopheles* mosquitoes in Europe helped researchers identify six separate species. The adults of all six species look remarkably alike. An adult *Anopheles atroparvus* is illustrated.

24.1 Nomenclature and Classification

The Swedish naturalist Carl von Linné (1707–1778), better known by his Latinized name, Carolus Linnaeus, was the first modern practitioner of **taxonomy,** the science that identifies, names, and classifies new species. A professor at the University of Uppsala, Linnaeus sent ill-prepared students around the world to gather specimens, losing perhaps a third of his followers to the rigors of their expeditions. Although he may not have been a commendable student adviser, Linnaeus developed the basic system of naming and classifying organisms that biologists embraced for two centuries.

Linnaeus Developed the System of Binomial Nomenclature

Linnaeus invented the system of **binomial nomenclature,** in which species are assigned a Latinized two-part name, or **binomial.** The first part of the name identifies a **genus** (plural, *genera*), a group of species with similar characteristics. The second part is the **specific epithet,** or species name. When identifying and naming a new species, Linnaeus used the morphological species concept (described in Section 22.1), assigning the same scientific name to individuals that shared anatomical characteristics.

A combination of the generic name and the specific epithet provides a unique name for every species. For example, *Ursus maritimus* is the polar bear and *Ursus arctos* is the brown bear. By convention, the first letter of a generic name is always capitalized; the specific epithet is never capitalized; and the entire binomial is italicized. In addition, the specific epithet is never used without the full or abbreviated generic name preceding it because the same specific epithet is often given to species in different genera. For instance, *Ursus americanus* is the American black bear, *Homarus americanus* is the Atlantic lobster, and *Bufo americanus* is the American toad. If you were to order just "*americanus*" for dinner, you might be dismayed when your plate arrived—unless you have an adventurous palate!

Nonscientists often use different common names to identify a species. For example, *Bothrops asper,* a poisonous snake native to Central and South America, is called *barba amarilla* (meaning "yellow beard") in some places and *cola blanca* (meaning "white tail") in others; biologists have recorded about 50 local names for this species. Adding to the confusion, the same common name is sometimes used for several different species. Binomials, however, allow people everywhere to discuss organisms unambiguously.

Many binomials are descriptive of the organism or its habitat. *Asparagus horridus,* for example, is a spiny plant. Other species, such as the South American bird *Rhea darwinii,* are named for notable biologists. The naming of newly discovered

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

species follows a formal process of publishing a description of the species in a scientific journal. International commissions meet periodically to settle disputes about scientific names.

Linnaeus Devised the Taxonomic Hierarchy to Organize Information about Species

Linnaeus described and named thousands of species on the basis of their morphological similarities and differences. Keeping track of so many species was no easy task, so he devised a **classification,** a conceptual filing system that arranges organisms into ever more inclusive categories. Linnaeus' classification, called the **taxonomic hierarchy,** includes a nested series of formal categories: domain, kingdom, phylum, class, order, family, genus, species, and subspecies. (You may find it useful to review the traditional taxonomic categories, which were described in Section 1.3 and illustrated in Figure 1.10.) The organisms included within any category of the taxonomic hierarchy compose a **taxon** (plural, *taxa*). Woodpeckers, for example, are a taxon (Picidae) at the family level, and pine trees are a taxon *(Pinus)* at the genus level.

Species that are included in the same taxon at the bottom of the hierarchy (that is, in the same genus or family) generally share many characteristics. By contrast, species that are included in the same taxon only near the top of the hierarchy (that is, the same kingdom or phylum) generally share many fewer characteristics. The hierarchy has been a great convenience for biologists because every taxon is defined by a set of shared characteristics. Thus, when a biologist refers to a member of the family Picidae, all of his or her colleagues understand that the biologist is talking about a medium-sized bird that uses its stout bill to drill holes in tree trunks.

STUDY BREAK 24.1

1. **How does the system of binomial nomenclature minimize ambiguity in the naming and identification of species?**
2. **How does the taxonomic hierarchy help biologists organize information about different species?**

24.2 Phylogenetic Trees

Linnaeus devised the taxonomic hierarchy long before Darwin published his theory of evolution. His goals were to illuminate the details of God's creation and to devise a practical way for naturalists to keep track of their discoveries. But the science of systematics changed in response to Darwin's idea that all organisms in the Tree of Life are descended from a distant common ancestor: systematists began to focus on discovering the evolutionary relationships between groups of organisms.

Systematists Adapted Linnaeus' Approach to a Darwinian Worldview

The taxonomic hierarchy that Linnaeus defined was easily adapted to Darwin's concept of branching evolution, which is itself a hierarchical phenomenon **(Figure 24.2).** As we discussed in Chapters 22 and 23, ancestral species give rise to descendant species through repeated branching of a lineage. Organisms in the same genus generally share a fairly recent common ancestor, whereas those assigned to the same higher taxonomic category, such as a class or phylum, share a common ancestor that lived in the more distant past.

In the second half of the nineteenth century, systematists began to reconstruct the **phylogeny** (that is, the evolutionary history) of organisms. Phylogenies are illustrated in **phylogenetic trees,** which are formal hypotheses that identify likely relationships among species and higher taxonomic groups. And like all hypotheses, they are constantly revised as scientists gather new data.

A Phylogenetic Tree Depicts the Evolutionary History of a Group of Organisms

Contemporary evolutionary biologists construct phylogenetic trees to illustrate the hypothesized evolutionary history of organisms. Researchers tailor the breadth of their analyses to match specific research questions. Thus, some trees might include the evolutionary history of all known organisms, others a small cluster of closely related populations within a species, and still others a group somewhere between those extremes. Regardless of how wide a range of organisms is included, all phylogenetic trees share a specific structure and depict key relationships in similar ways **(Figure 24.3).**

For example, phylogenetic trees are usually drawn along an implicit or explicit time line. In this book, phylogenetic trees are generally depicted vertically; the most ancient organisms and evolutionary events are at the bottom of the tree (often labeled "long ago"), and the most recent are at the top (often labeled "present"). The common ancestor of all species included in the tree is described as the **root** of the tree. In a few cases in this book, trees are presented with the root on the left, with time passing from left to right.

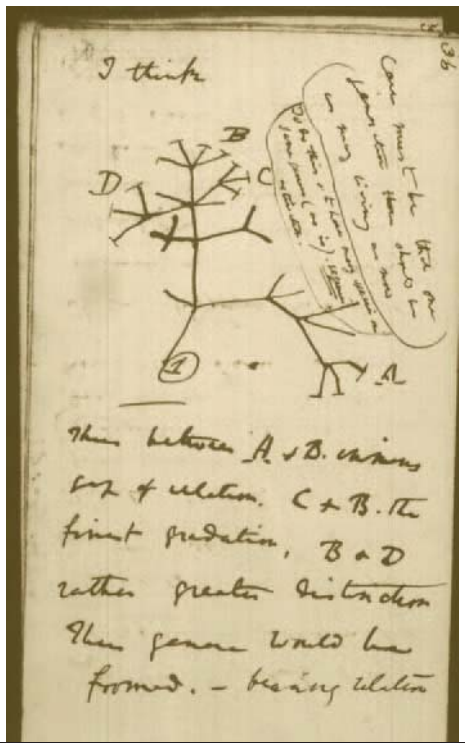

FIGURE 24.2
Darwin and branching evolution. This entry from his notebook on the "transmutation of species" demonstrates that Charles Darwin first thought about the branching pattern of evolution in 1837, more than 20 years before he published *On the Origin of Species.*

As you know from the discussion in Section 23.5, the tempo of evolution varies within and among lineages. In some cases, evolutionary changes may accumulate slowly in a lineage as the environment shifts over time. This pattern of gradual phyletic change is often described as *anagenesis*. If the changes through time are substantial and the fossil record is incomplete, paleontologists who discover morphologically distinct fossils in different strata may assign them different species names and say that "the ancestral species A evolved into the descendant species B." But the production of such "new" species by anagenesis does not increase biodiversity; rather, it is simply the gradual transformation of one "species" into another as its characteristics shifted over time. Anagenesis is often illustrated by a straight line in a phylogenetic tree.

In other circumstances, an ancestral species undergoes speciation, producing two descendant species, both of which are distinct from their common ancestor. This pattern of evolution is described as *cladogenesis,* a process that *does* increase biodiversity. Cladogenesis is depicted in a phylogenetic tree by a branching pattern, with two descendants arising from their common ancestor. When they first emerge, the two branches may represent new species. But as cladogenesis continues repeatedly through evolutionary time—with branches giving rise to branchlets and branchlets to twigs—each of those new species may become the common ancestor of its own many descendants. Thus, each new species produced by cladogenesis has the potential to become the "root" of its own evolutionary lineage.

When describing phylogenetic trees, each branching point is called a **node,** and each evolutionary lineage—a node with all of the branches, branchlets, and twigs that emerge from it—is called a **clade** (*klados* = branch). You can identify a clade on any phylogenetic tree by following a lineage from a node

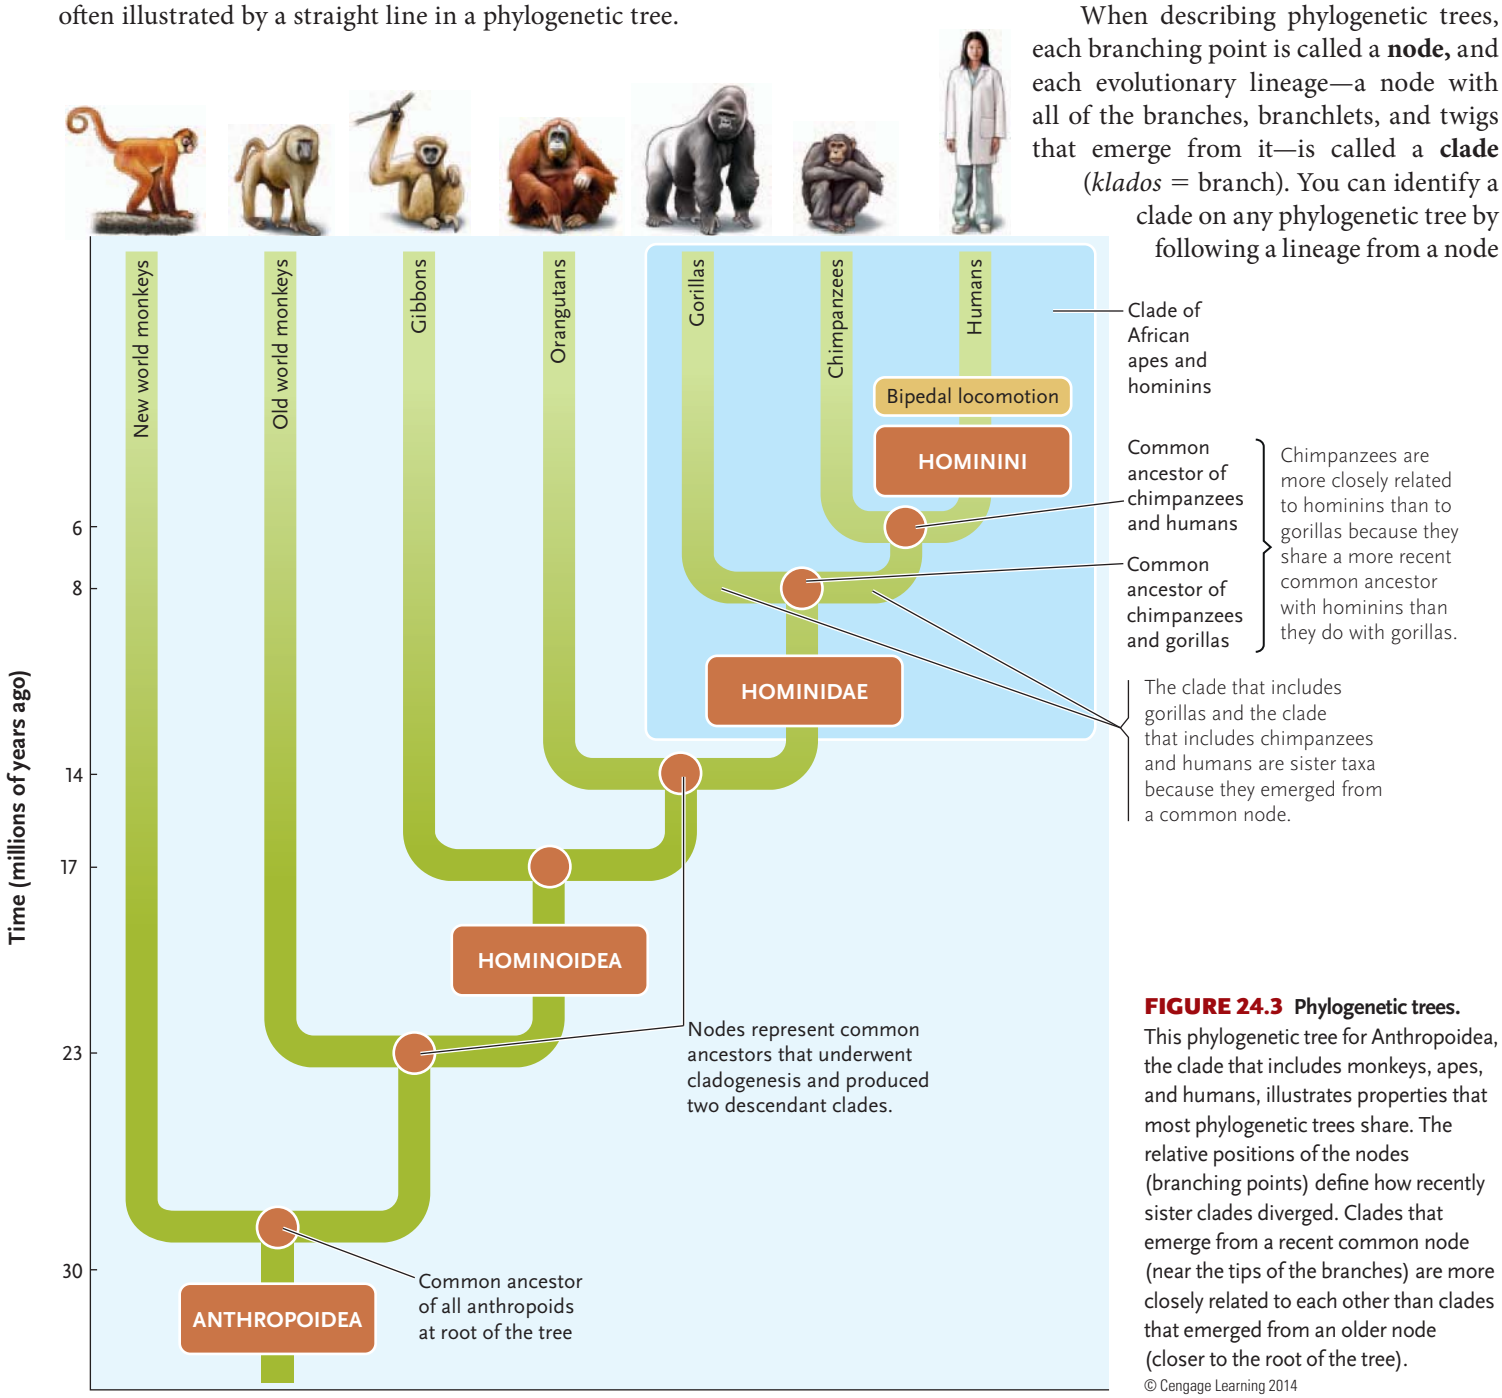

FIGURE 24.3 Phylogenetic trees. This phylogenetic tree for Anthropoidea, the clade that includes monkeys, apes, and humans, illustrates properties that most phylogenetic trees share. The relative positions of the nodes (branching points) define how recently sister clades diverged. Clades that emerge from a recent common node (near the tips of the branches) are more closely related to each other than clades that emerged from an older node (closer to the root of the tree).

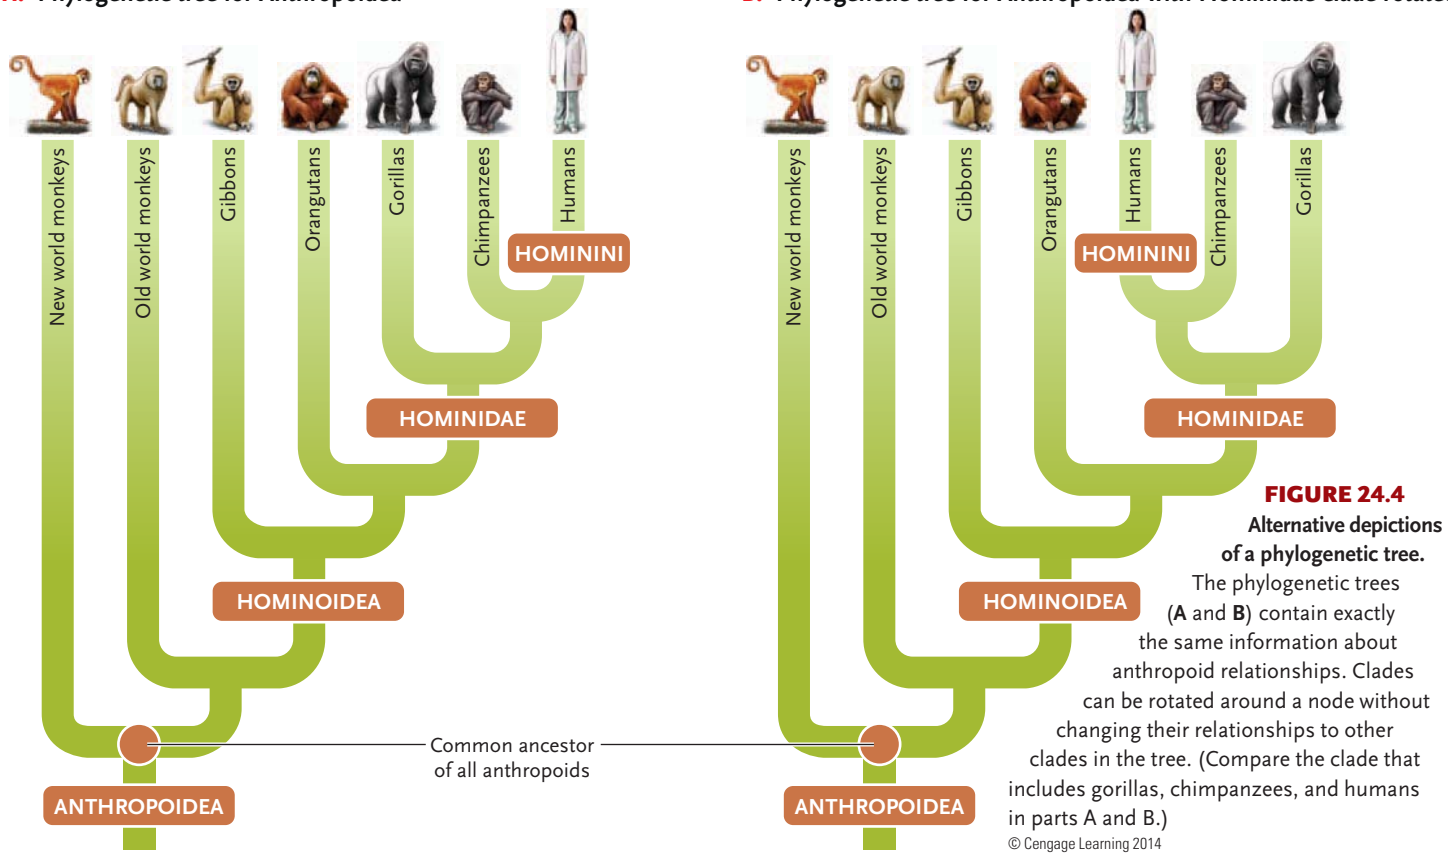

FIGURE 24.4
Alternative depictions of a phylogenetic tree. The phylogenetic trees (**A** and **B**) contain exactly the same information about anthropoid relationships. Clades can be rotated around a node without changing their relationships to other clades in the tree. (Compare the clade that includes gorillas, chimpanzees, and humans in parts A and B.)

© Cengage Learning 2014

to the tips of all of its twigs at the very top of the tree. Some clades, such as Aves (birds), include thousands of species, whereas others, such as *Geospiza* (a genus of ground and cactus finches from the Galápagos Islands), include just a few (see Figure 23.14). Like the taxonomic hierarchy, phylogenetic trees have a nested structure: younger and smaller clades, like the genus *Geospiza,* are nested within larger and older clades, such as Aves. Two clades that emerge from the same node are called **sister clades** (or sister taxa) because they are each other's closest relatives; similarly, two species that emerge from the same node near the very top of the tree are described as **sister species.**

You should keep certain conventions in mind when you read the phylogenetic trees in this text:

1. If a phylogenetic tree includes an explicit time axis, the positions of the nodes reveal when on the geological time scale a clade originated; the length of the vertical branch between nodes indexes how long an ancestral group persisted before it diversified. However, in most of the phylogenetic trees presented in this book, the time scale is not precise; often it is not even specified. Thus, the sequence of nodes only indicates the sequence in which clades appeared, and the lengths of the vertical lines contain no specific information about the time since two clades diverged. When reading a phylogenetic tree, you should always remember that if two species or clades emerge from the same node near the top of the tree, they are closely related. If they emerge from the same node near the bottom of the tree, they are more distantly related.
2. Horizontal spacing between clades in most of this book's phylogenetic trees does not indicate their degree of difference or their degree of relatedness. However, when the horizontal distance between species or clades is meaningful, as it is in the tree for extinct ectoprocts in Figure 23.20, the horizontal axis label, the figure legend, or the text explains how the distances should be interpreted.
3. Most of the nodes in the phylogenetic trees have two branches protruding from them, reflecting the evolution of two descendants from one ancestor. However, for some groups of organisms, biologists have not yet discovered the detailed pattern of branching that produced the diversity of clades living today. In these cases, you may see three or even more branches emerging from a node or from a horizontal branch. Biologists describe these nodes as "unresolved." Hopefully, future research will allow us to portray these evolutionary relationships more precisely.
4. In most phylogenetic trees in this book, the clades have been arranged from oldest on the left to youngest on the right. But any clade can be rotated around a node without changing the meaning of the phylogenetic tree **(Figure 24.4).** When reading a phylogenetic tree, you should focus primarily on which clades share the more recent common ancestors, indicated by the relative positions of the nodes from which they emerge.

Phylogenetic Trees Allow Biologists to Define Evolutionary Classifications

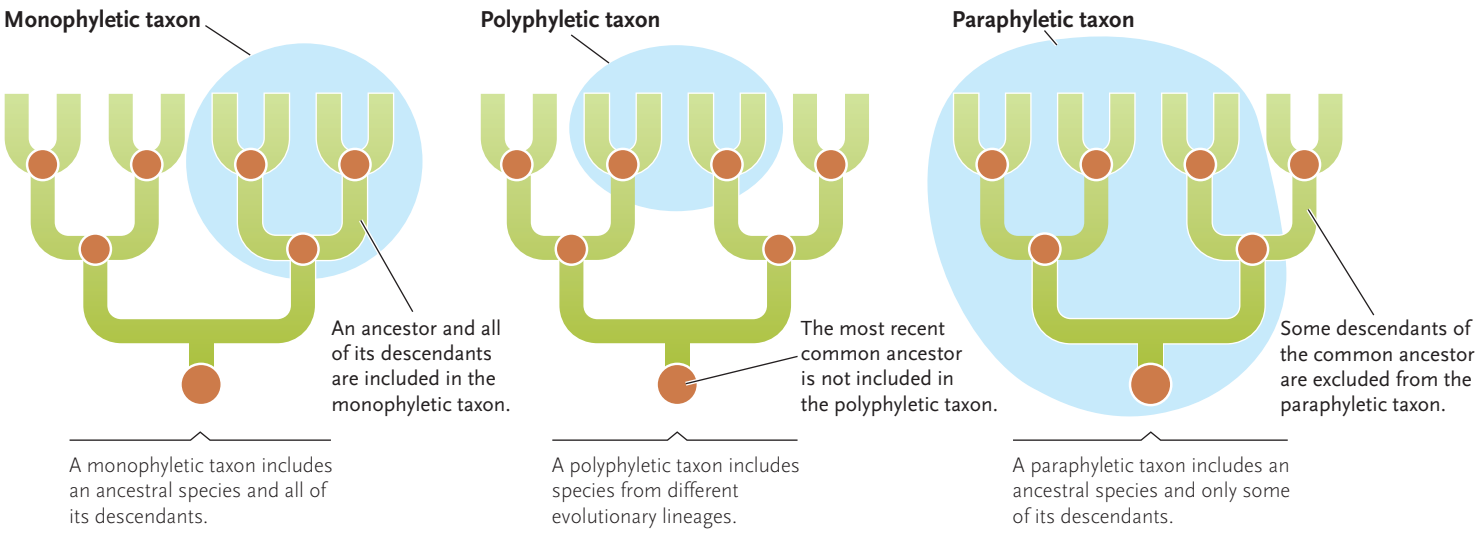
Evolutionary biologists working today want a classification that mirrors the branching patterns of a group's phylogenetic history. When converting a phylogenetic tree into a classification, they try to identify only **monophyletic taxa** or lineages. A monophyletic taxon comprises one clade—an ancestral species (represented by a node) and *all* of its descendants, but no other species **(Figure 24.5).** Monophyletic taxa are defined at every level of the taxonomic hierarchy. For example, biologists consider the Felidae (the traditional family-level taxon that includes all cat species) to be monophyletic: all cat species living on Earth today, from housecats to tigers, are the descendants—and the only living descendants—of a common ancestor that lived about 25 million years ago. Thus, the Felidae is one small, but complete, branch on the Tree of Life. At a much broader scale, the Animalia is a monophyletic taxon (at the traditional kingdom level) that comprises all animals, which are the descendants of one common ancestor. Even if biologists have not yet identified the very first animal in the fossil record, they can infer its existence at the root of the phylogenetic tree for Animalia.

Biologists have not always defined strictly monophyletic taxa. Because of missing data, or as a matter of convenience, they sometimes named taxa that included species from different clades or taxa that included some, but not all, of an ancestral species' descendants. A **polyphyletic taxon** is one that includes organisms from different clades, but not their common ancestor. For example, a taxon that included only birds and bats, two clades of vertebrates that are capable of flight, would be considered polyphyletic because it would not include their last common ancestor, which lived many millions of years before birds and bats first appeared. A **paraphyletic taxon** is one that includes an ancestor and some, *but not all,* of its descendants. For example, people commonly used to define terrestrial dinosaurs and birds as distinct groups. But "terrestrial dinosaurs" was a paraphyletic taxon: as you know from Section 23.6, birds are the descendants of one group of terrestrial dinosaurs. Thus, the monophyletic taxon Dinosauria must include birds as well as their nonflying relatives.

Many of the phylogenetic trees included in this book identify monophyletic taxa with labels on their branches. The names of these clades are identified in capital letters in a bronze-colored plaque; the major characteristics that define major clades are identified in lowercase letters in a tan-colored plaque. As a convenience, some commonly used names for groups that biologists now recognize as paraphyletic are presented in quotation marks in bronze plaques with dashed, rather than solid, borders.

STUDY BREAK 24.2

1. **What is the difference between a phylogenetic tree and a classification?**
2. **What is the difference between a monophyletic taxon, a polyphyletic taxon, and a paraphyletic taxon?**



24.3 Sources of Data for Phylogenetic Analyses

Linnaeus classified organisms on the basis of their morphological similarities and differences—even though he did not understand how those characteristics arose. For example, he defined birds as a class of oviparous ("egg-laying") animals with feathered bodies, two wings, two feet, and a bony beak. No other animals possess all these characteristics, which distinguish birds from "quadrupeds" (his term for mammals), "amphibians" (among which he included reptiles), fishes, insects, and "worms."

Mendel's subsequent work on the heritable basis of morphological variations provided the scientific rationale for this

FIGURE 24.5 Defining taxa in a classification. Although systematists can identify different groups of species in a phylogenetic tree as a taxon, the taxon highlighted in blue on the left is the only monophyletic group.

endeavor: modern systematists infer that morphological differences serve as indicators of underlying genetic differences between species and lineages. Today, with our much deeper understanding of the genetic basis of variation, systematists undertake phylogenetic analyses using a variety of organismal and molecular characters. Indeed, any heritable trait (that is, any trait with a genetic basis) that is intrinsic to the organism can be used in a phylogenetic analysis; phenotypic differences caused by environmental variation (see Section 20.1) are excluded. In this section we first consider a general criterion for evaluating characters and then examine examples of how a few specific types of characters are useful in this effort.

The Analysis of Homologous Characters Sheds Light on Evolutionary Relationships

A basic premise of phylogenetic analyses is that phenotypic similarities between organisms reflect their underlying genetic similarities. As you may recall from Figure 20.3, species that are morphologically similar have often inherited the genetic basis of their resemblance from a common ancestor. Similarities that result from shared ancestry, such as the four limbs of all tetrapod vertebrates, are called **homologies** (or homologous characters). Any trait, from genetic sequences to anatomical structures to mating behaviors, can be described as homologous in two or more species as long as they inherited the trait from their common ancestor.

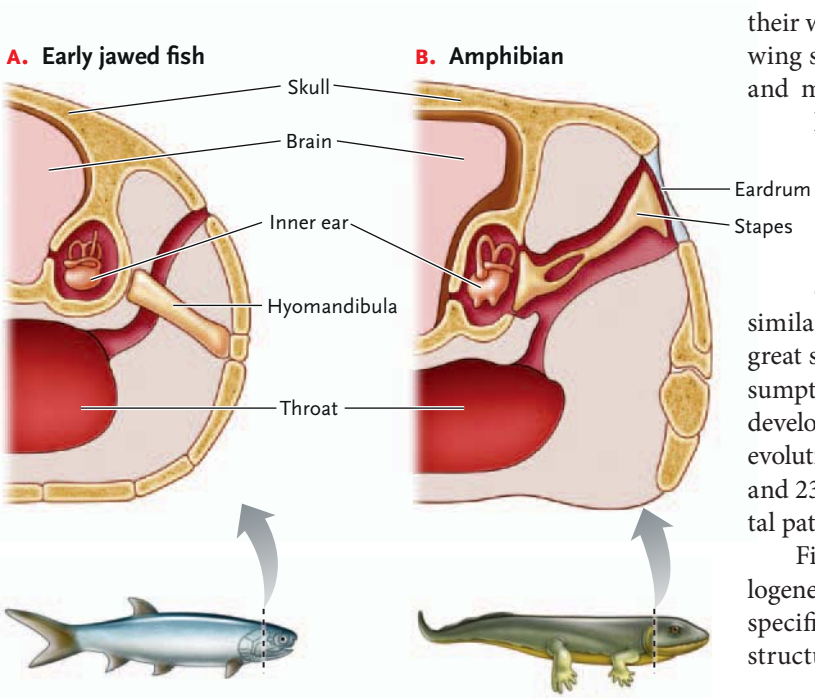

FIGURE 24.6 Homologous bones, different structure and function. The hyomandibula, which braced the jaw joint against the skull in early jawed fishes **(A),** is homologous to the stapes, which transmits sound to the inner ear in the four-legged vertebrates, exemplified here by an early amphibian **(B).** Both large illustrations show a cross section through the head just behind the jaw joint, as depicted in the small illustrations.

© Cengage Learning 2014

Even though characters are homologous, they may differ greatly among species, especially if their function has changed over time. For example, the stapes, a bone in the middle ear of tetrapod vertebrates, evolved from—and is therefore homologous to—the hyomandibula, a bone that supported the jaw joint of early fishes. The ancestral function of the bone is retained in some modern fishes, but its structure, position, and function are different in tetrapods **(Figure 24.6).**

As you know from the discussion of convergent evolution in Section 23.3, organisms that are not closely related sometimes bear a striking resemblance to one another, especially when they are exposed to similar patterns of natural selection. Phenotypic similarities that evolved independently in different lineages are called **homoplasies** (or homoplastic characters). Some biologists use the terms *analogies* or *analogous characters* for homoplastic characters that serve a similar function in different species.

When systematists encounter similar morphological traits, how can they determine whether they are homologous or homoplastic? First, homologous structures are similar in anatomical detail and in their relationship to surrounding structures. For example, the bones in the wings of birds and bats are considered to be homologous **(Figure 24.7).** They include the same structural elements and have similar connections to the rest of the skeleton. Moreover, the fossil record documents that birds and bats inherited the basic skeletal structure of the forelimb from their most recent common ancestor, a tetrapod vertebrate that lived more than 300 million years ago. However, the large flat surfaces of their wings, as well as flying behavior itself, are homoplastic. The wing surfaces are made of different materials—feathers in birds and membranous skin in bats—and their common ancestor, lacking any hint of such structures on its forelimbs, was confined to life on the ground. Thus, for birds and bats, flight and the anatomical structures that produce it are the products of convergent evolution.

Second, in multicellular organisms, homologous characters grow from the same embryonic tissues and in similar ways during development. Systematists have always put great stock in embryological indications of homology on the assumption that evolution has conserved the pattern of embryonic development in related organisms. Indeed, recent discoveries in evolutionary developmental biology (described in Sections 16.4 and 23.6) have revealed that the genetic controls of developmental pathways are very similar across a wide variety of organisms.

Finally, as we will see in Section 24.4, the structure of a phylogenetic tree can reveal whether two or more species inherited specific similarities from a common ancestor. If they did, the structures are homologous; if not, they are homoplastic.

Morphological Characters Provide Abundant Clues to Evolutionary Relationships

Morphological structures often provide useful information for phylogenetic analyses. Structural differences between organisms, which often reflect underlying genetic differences (see

Section 21.1), are easy to measure in preserved or living specimens. Moreover, morphological characteristics are often clearly preserved in the fossil record, allowing the comparison of living species with their extinct relatives. As you discovered in the discussions of dinosaur feathers and the inner ear structure of lambeosaurine dinosaurs in Chapter 23, researchers are applying new techniques, such as computed tomography and electron microscopy, to expand our knowledge of the anatomy of extinct organisms.

The morphological traits that are useful in phylogenetic analyses vary from group to group. In flowering plants, the details of flower anatomy may reveal common ancestry. Among vertebrates, the presence or absence of scales, feathers, and fur as well as the structure of the skull help scientists to reconstruct the evolutionary history of major groups. Sometimes systematists use obscure characters of unknown function. But differences in the number of scales on the backs of lizards or in the curvature of a vein in the wings of bees may be good indicators of the genetic differentiation that accompanied or followed speciation—even if we do not know *why* these differences evolved.

Sometimes characteristics found only in the earliest stages of an organism's life cycle can provide evidence of evolutionary relationships. As described in Chapter 31, analyses of the embryos of vertebrates revealed that they are rather closely related to sea cucumbers, sea stars, and sea urchins and even more closely related to a group of nearly shapeless marine invertebrates called sea squirts or tunicates.

Despite their usefulness, morphological characters alone cannot reveal the details of all evolutionary relationships. For example, some salamander species in North America differ in relatively few morphological features, even when they are genetically, physiologically, and behaviorally distinct. Moreover, researchers cannot easily compare the structures of organisms, such as flatworms and dogs, that share very few morphological traits.

Behavioral Characters Are Useful When Animal Species Are Not Morphologically Distinct

When external morphology cannot be used to differentiate animal species, systematists often examine their behaviors for clues about their relationships. For example, two species of treefrog (*Hyla versicolor* and *H. chrysoscelis*) commonly occur together in forests of the central and eastern United States. Both species have bumpy skin and adhesive pads on their toes that enable them to climb vegetation. They also have gray backs, white bellies, yellowish-orange coloration on their thighs, and large white spots below their eyes. The frogs are so similar that even experts cannot easily tell them apart.

How do we know that these frogs represent two species? During the breeding season, males of each species use a distinctive mating call to attract females **(Figure 24.8).** The difference in calls is a prezygotic reproductive isolating mechanism that prevents females from mating with males of a different species (see

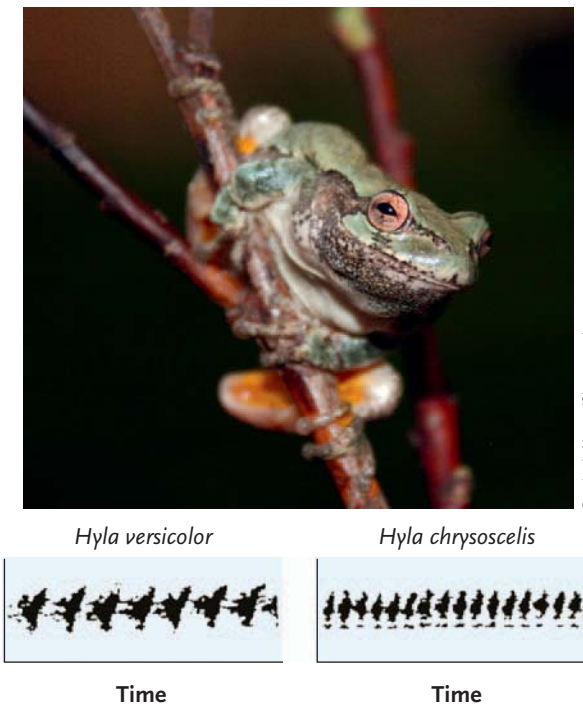

FIGURE 24.8 Morphologically similar frog species. The frogs *Hyla versicolor* and *Hyla chrysoscelis* are so similar in appearance that one photo can depict both species. Male mating calls, visualized in sound spectrograms for the two species, are very different. The spectrograms, which depict call frequency on the vertical axis and time on the horizontal axis, show that *H. chrysoscelis* has a faster trill rate.

Section 22.2). Prezygotic isolating mechanisms are excellent systematic characters because they are often the traits that animals themselves use to recognize members of their own species. The two frog species also differ in chromosome number—*Hyla chrysoscelis* is diploid and *Hyla versicolor* is tetraploid—which is a postzygotic isolating mechanism.

Molecular Sequences Are Now a Commonly Used Source of Phylogenetic Data

For roughly 200 years, systematists building on Linnaeus' work relied on a variety of organismal traits to analyze evolutionary relationships and classify organisms. Today, most systematists conduct phylogenetic analyses using molecular characters, such as the nucleotide base sequences of DNA and RNA. Because DNA is inherited, shared changes in molecular sequences—insertions, deletions, or substitutions—provide clues to the evolutionary relationships of organisms.

The polymerase chain reaction (PCR) makes it easy for researchers to produce numerous copies of specific segments of DNA for analysis (see Section 18.1); the technique is so effective that it allows scientists to sequence minute quantities of DNA taken from dried or preserved specimens in museums and even from some fossils. Technological advances have automated the sequencing process, and researchers use analytical software to compare new data to known sequences filed in online data banks. Nuclear DNA is frequently used in phylogenetic analyses, and the publication of complete genome sequences for an ever-expanding list of organisms allows researchers to undertake broad comparative studies.

Molecular sequences have certain practical advantages over organismal characters. First, they provide abundant data: every base in a nucleic acid can serve as a separate, independent character for analysis. Moreover, because many genes have been conserved by evolution, molecular sequences can be compared between distantly related organisms that share no organismal characteristics. They can also be used to study closely related species with only minor morphological differences. Finally, nucleic acids are not directly affected by the developmental or environmental factors that cause the nongenetic morphological variations described in Section 21.1.

Molecular characters have certain drawbacks, however. For example, only four alternative character states (the four nucleotide bases) exist at each position in a DNA or RNA sequence and only 20 alternative character states (the 20 amino acids) at each position in a protein. (You may want to review Sections 14.2 and 15.1 on the structure of these molecules.)

Because of the limited number of character states, researchers often find it difficult to assess the homology of a nucleotide base substitution that appears at the same position in the DNA of two or more species. For organismal characters, biologists can determine homology by analyzing the characters' embryonic development, details of their function, or their presence in the fossil record. But molecular characters have no embryonic development; biologists still do not understand the functional significance of many molecular differences they discover; and researchers have only recently developed techniques that allow them to sequence DNA found in fossils. Nevertheless, systematists have devised complex statistical tools that allow them to discern whether molecular similarities are likely to be homologous or homoplastic.

Despite their disadvantages, molecular sequences allow researchers to sample the genome directly, and systematists have successfully used sequence data to analyze phylogenetic relationships that organismal characters were unable to resolve. For example, the phylogenetic tree for animals in Figure 31.6 is based on data from several different nucleic acid molecules. *Insights from the Molecular Revolution* describes another example using sequences called transposable elements.

STUDY BREAK 24.3

1. **Why do systematists use homologous characters in their phylogenetic analyses?**
2. **Why are morphological traits often helpful in tracing the long-term evolutionary relationships within a group of organisms?**
3. **What are three advantages of using molecular characters in phylogenetic analyses?**

24.4 Traditional Classification and Paraphyletic Groups

For a century after Darwin published his theory of evolution, systematists followed an approach called **traditional systematics.** Researchers constructed phylogenetic trees and classified organisms by assessing the amount of phenotypic divergence between lineages as well as the patterns of branching evolution that had produced them. In other words, they focused on the products of anagenesis (that is, evolutionary change through the accumulation of new or modified characteristics) as well as the products of cladogenesis (that is, the new species and lineages produced through branching evolution). Thus, their classifications did not always strictly reflect the patterns of branching evolution **(Figure 24.9A).**

For example, the fossil record for tetrapod vertebrates reveals that the amphibian and mammalian lineages each diverged early, followed shortly thereafter by the turtle lineage. (The phylogenetic position of turtles is controversial, as discussed in Chapter 32; here we follow the traditional view based on paleontological evidence.) The remaining organisms then diverged into two groups: one includes living lizards and snakes and another includes living crocodilians and birds. Thus, although crocodilians, with their scaly skin and sprawling posture outwardly resemble lizards, evolutionary biologists have long recognized that crocodilians share a more recent common ancestor with birds.

Even though the phylogenetic tree shows six living clades, the traditional classification recognizes four classes of tetrapod

Evolution of Whales: SINEs yield signs of the LINEs of evolution

The fossil record reveals that whales evolved from terrestrial mammals into streamlined creatures adapted to life in the sea more than 50 million years ago. Using morphological, fossil, and molecular data, researchers have determined that modern cetaceans—whales, dolphins, and porpoises—are closely related to artiodactyls (even-toed ungulates). Systematists now group cetaceans and artiodactyls in the clade Cetartiodactyla, which, in addition to whales and their relatives, includes camels, pigs, ruminants, and hippopotamuses.

Research Question

Which living cetartiodactyls are the closest relatives of whales?

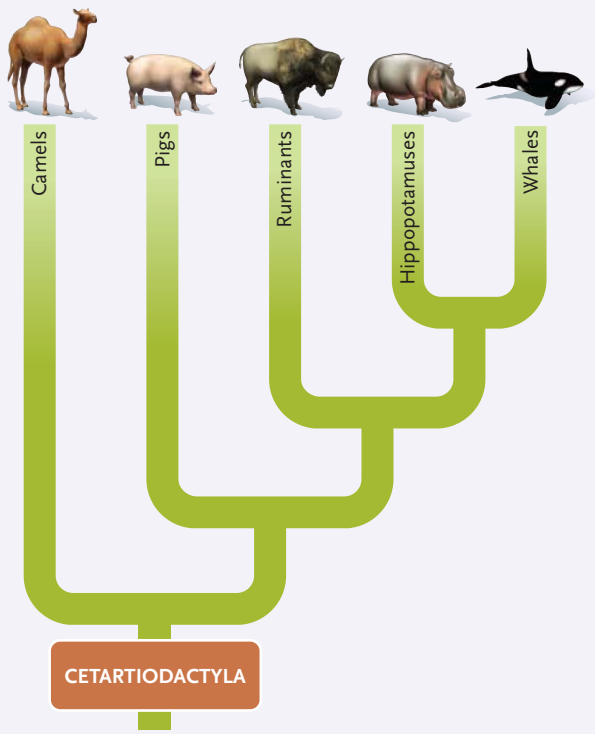
Experiment

A number of research groups have attempted to answer the question using molecular approaches. Norihiro Okada and his research group at the Tokyo Institute of Technology, Yokohama, Japan, and collaborators in the United States used the patterns of locations of transposable elements (TEs) in genomes to determine the evolutionary relationship between living members of the various cetartiodactyl groups. TEs are sequences that can move to new locations in DNA. The type of TEs the researchers studied are retrotransposons, which move by making RNA copies of themselves; the RNA copies then act as templates for making DNA copies, which insert in new locations (see Section 15.5).

Okada and his collaborators analyzed specific representatives of two classes of retrotransposons, SINEs (for *S*hort *IN*terspersed *E*lements) and LINEs (for *L*ong *IN*terspersed *E*lements), which are known to be inserted into particular chromosomal loci. SINEs and LINEs are valuable tools for phylogenetic studies; their pattern of duplication and movement to new locations represent a novel character that is unique to each clade. Once they have inserted themselves into new locations, they are rarely lost. Thus, if SINEs and LINEs occur at the same sites in the nuclear DNA of several species, those species are likely to be members of the same lineage.

To determine whether a chromosomal locus contained the SINE or LINE associated with it, the researchers isolated DNA, amplified the locus using PCR (see Section 18.1), and then used probes—labeled nucleic acid molecules—that could pair specifically with the SINE or LINE of the locus. A signal from the probing indicated that the SINE or LINE was present; no signal indicated the SINE or LINE was absent.

Results



The investigators analyzed 16 retrotransposons in 10 loci in the DNA from living members of all cetartiodactyl groups. Using the patterns of SINEs and LINEs identified in their phylogenetic analysis, the researchers identified the best hypothesis about the evolutionary relationships of the Cetartiodactyla **(Figure).**

Conclusion

As the phylogenetic tree indicates, hippopotamuses are the closest relatives of whales; ruminants (such as cattle and bison) are more distantly related, and pigs and camels even more distantly related. Other phylogenetic analyses based on combined data sets that include morphological characters from extinct and living species as well other molecular characters generally support this conclusion.

THINK LIKE A SCIENTIST Research by Nikaido and colleagues reveals that whales are closely related to hippos and other artiodactyls. But what sorts of morphological changes must the ancestors of whales have undergone as they changed from being wholly terrestrial to wholly aquatic animals?

Source: M. Nikaido et al. 1999. Phylogenetic relationships among cetartiodactyls based on insertions of short and long interspersed elements: Hippopotamuses are the closest extant relatives of whales. *Proceedings of the National Academy of Sciences USA* 96:10261–10266.

© Cengage Learning 2014

vertebrates: Amphibia, Mammalia, Reptilia, and Aves. These groups are given equal ranking because each represents a distinctive body plan and way of life. The traditionally defined taxon Reptilia is clearly paraphyletic because, even though birds share a common ancestor with reptiles, they are placed in a separate taxon. Traditional systematists justify this definition of Reptilia because it includes morphologically similar animals with close evolutionary relationships. Crocodilians are classified with lizards, snakes, and turtles because they share a distant common ancestry and are covered with dry, scaly skin. Traditional systematists also argued that the key innovations initiating the adaptive radiation of birds—a high metabolic rate, wings, and flight—represent such extreme divergence from the ancestral morphology that birds merit recognition as a separate class.

STUDY BREAK 24.4

Why does a classification produced by traditional systematics sometimes include paraphyletic groups?

24.5 The Cladistic Revolution

In the 1950s and 1960s, some researchers criticized the traditional classifications based on two distinct phenomena—branching evolution and morphological divergence—as inherently unclear. How can we tell *why* two groups are classified in the same higher taxon? They may have shared a recent common ancestor, as did lizards and snakes. Alternatively, they may have retained some ancestral characteristics after being separated on different branches of a phylogenetic tree, as is the case for lizards and crocodilians.

To avoid such confusion, many systematists followed the philosophical and analytical lead of Willi Hennig, a German entomologist (that is, a scientist who studies insects), who published an influential book, *Phylogenetic Systematics,* in 1950; its English translation appeared in 1966. Hennig and his followers argued that classifications should be based solely on evolutionary relationships. This approach, which is called **cladistics,** produces phylogenetic hypotheses and classifications that reflect only the branching pattern of evolution; it ignores morphological divergence altogether.

Cladistic Analyses Focus on Recently Evolved Character States

Like traditional systematics, cladistics analyzes the evolutionary relationships among organisms by comparing their organismal and, more recently, genetic characteristics. Each **character** can exist in two or more forms, described as character states. Evolutionary processes change characters over time from an original, **ancestral character state** to a newer, **derived character state.** Characters that were present in the ancestors of a clade are considered ancestral; those that are new in a descendant are considered derived. For example, ancient fishes, which represent the ancestral vertebrates, had fins; but some of their descendants, the tetrapods, which appeared much later in the fossil record,

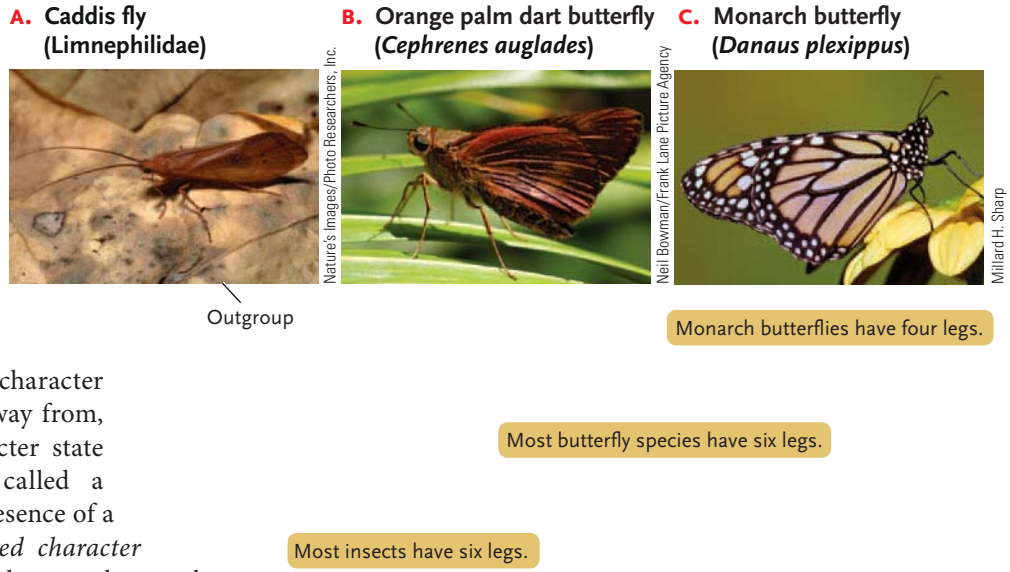

FIGURE 24.10 **Outgroup comparison.** Most adult insects, like **(A)** the caddis fly and **(B)** the orange palm dart butterfly, have six walking legs. This comparison of butterflies with other insects suggests that the four walking legs of **(C)** the monarch butterfly represents the derived character state.
© Cengage Learning 2014

have limbs. In this example, fins are the ancestral character state, and limbs are the derived character state.

In the jargon of cladistics, a derived character state is called an **apomorphy** (*apo* = away from, *morphe* = form), and a derived character state found in two or more species is called a **synapomorphy** (*syn* = together). The presence of a synapomorphy (that is, a *shared derived character state*) among species provides a clue that they may be members of the same clade. As you learned in Section 22.4, morphological innovations often trigger an adaptive radiation. And once a derived character state becomes established in a species, it is likely to be present in that species' descendants. Thus, unless they are lost or replaced by newer characters over evolutionary time, *synapomorphies can serve as markers for monophyletic lineages.*

Systematists define synapomorphies only when comparing character states among species. Thus, any particular character state is derived *only in relation to* an ancestral character state observed in other organisms—either an older version of the character or its absence. For example, most species of animals lack a vertebral column. However, one animal clade—the vertebrates, including fishes, amphibians, reptiles, birds, and mammals—has that structure. Thus, when systematists compare vertebrates to all other animals, the absence of a vertebral column is the ancestral character state and the presence of a vertebral column is derived.

How can systematists distinguish between ancestral and derived character states? In other words, how can they determine the direction in which a character has evolved? The fossil record, if it is detailed enough, can provide unambiguous information. For example, biologists are confident that the presence of a vertebral column is a derived character state because fossils of animals that lived before vertebrates lack that structure.

In the absence of evidence from fossils, systematists frequently use a technique called **outgroup comparison** to identify ancestral and derived character states. Using this approach, systematists compare characters in the *ingroup,* the clade under study, to those in an *outgroup,* a closely related species that is not a member of the clade. Character states observed in the outgroup are considered ancestral, and those observed *only* in the ingroup are considered derived. And because the outgroup and the ingroup are phylogenetically related, outgroup comparison allows researchers to hypothesize the root (that is, the common ancestor shared by the outgroup and the ingroup) of the phylogenetic tree. Most modern butterflies, for example, have six walking legs, but species in two families have four walking legs and two small, nonwalking legs. Which is the ancestral character state, and which is derived? Outgroup comparison with other insects, which are not included in the butterfly clade, demonstrates that most insects have six walking legs as adults; this result suggests that six walking legs is ancestral and four is derived **(Figure 24.10).**

Cladistics Uses Synapomorphies to Reconstruct Evolutionary History and Classify Organisms

Following the cladistic method, biologists construct phylogenetic trees and classifications by grouping together species that *share derived character states.* Ancestral character states, because they are shared by the ingroup and the outgroup, do not help to define the ingroup. For example, mammals are a monophyletic lineage—a clade—because they possess a unique set of synapomorphies: hair, mammary glands, and a reduced number of bones in the lower jaw. The ancestral character states found in mammals, such as a vertebral column and four legs, do not distinguish them from other tetrapod vertebrates. Thus, these shared ancestral character states are not useful in defining the mammal clade.

The results of a cladistic analysis are presented in a phylogenetic tree that illustrates the hypothesized sequence of evolutionary branching that produced the organisms under study **(Figure 24.9B):** a common ancestor is hypothesized at each node, and every branch portrays a strictly monophyletic group. Once a researcher identifies a suitable outgroup and the ancestral and derived character states, a cladistic analysis is straightforward **(Figure 24.11).** The synapomorphies that define each clade are sometimes listed on the branches.

The use of molecular sequence data in phylogenetic analyses relies on the same logic that underlies analyses based on organismal characters, like those considered above: species included within a clade are expected to exhibit more molecular

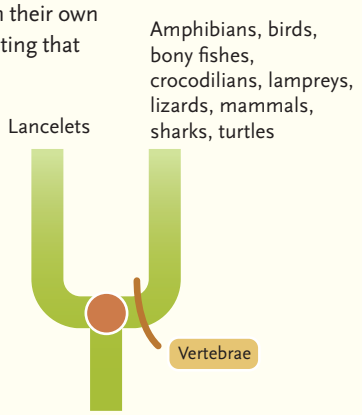
Using Cladistics to Construct a Phylogenetic Tree

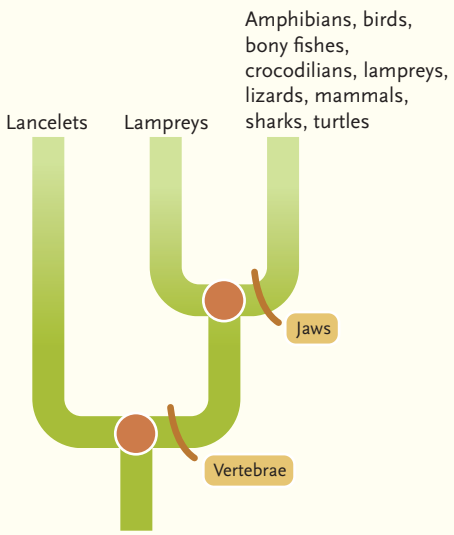
Purpose: Systematists construct phylogenetic trees to visualize hypothesized evolutionary relationships among a group of organisms. The cladistic method requires a researcher to group together organisms that share derived characters states. The derived character states identified in the tan plaques are the synapomorphies that define each clade.

Protocol:



1. *Select the organisms to study.* To demonstrate the method, we develop a phylogenetic tree for the nine groups of living vertebrates: lampreys, sharks (and their relatives), bony fishes (and their relatives), amphibians (frogs and salamanders), turtles, lizards (including snakes), crocodilians (including alligators), birds, and mammals. We also include marine animals called lancelets (Chordata, Cephalochordata) as the outgroup. Lancelets are closely related to, but not included within, the vertebrates (see Chapter 32). The inclusion of an outgroup allows biologists to identify ancestral versus derived character states and root the tree.

2. *Choose the characters on which the phylogenetic tree will be based.* Our simplified example is based on the presence or absence of 10 characters: (1) vertebral column, (2) jaws, (3) swim bladder or lungs, (4) paired limbs (with one bone connecting each limb to the body), (5) extraembryonic membranes (such as the amnion), (6) mammary glands, (7) dry, scaly skin somewhere on the body, (8) two openings on each side near the back of the skull, (9) one opening on each side of the skull in front of the eye, and (10) feathers.



3. *Score the character states in each group.* Because lancelets serve as the outgroup in this analysis, we consider character states observed in lancelets as ancestral; any deviation from the lancelet pattern is considered derived. Because lancelets lack all of the characters in our analysis, the presence of each character is the derived condition. We tabulate data on the distribution of ancestral (−) and derived (+) characters in all species included in the analysis.

	Vertebrae	Jaws	Swim bladder or lungs	Paired limbs	Extraembryonic membranes	Mammary glands	Dry, scaly skin	Two openings at back of skull	One opening in front of eye	Feathers
Lancelets	–	–	–	–	–	–	–	–	–	–
Lampreys	+	–	–	–	–	–	–	–	–	–
Sharks	+	+	–	–	–	–	–	–	–	–
Bony fishes	+	+	+	–	–	–	–	–	–	–
Amphibians	+	+	+	+	–	–	–	–	–	–
Mammals	+	+	+	+	+	+	–	–	–	–
Turtles	+	+	+	+	+	–	+	–	–	–
Lizards	+	+	+	+	+	–	+	+	–	–
Crocodilians	+	+	+	+	+	–	+	+	+	–
Birds	+	+	+	+	+	–	+	+	+	+

4. *Construct the phylogenetic tree from information in the table, grouping organisms that share derived character states.* All groups except lancelets have vertebrae. Thus, we group organisms that share this derived character state on the right-hand branch, identifying them as a monophyletic lineage. Lancelets are on their own branch to the left, indicating that they lack vertebrae.

All of the remaining organisms except lampreys have jaws. (Lancelets also lack jaws, but we have already separated them out, and do not consider them further.) Place all groups with jaws, a derived character state, on the right-hand branch. Lampreys are separated out to the left, because they lack jaws. Again, the branch on the right represents a monophyletic lineage.

synapomorphies than do species from different clades. The comparison of sequences in the ingroup to those in the outgroup may allow a researcher to define ancestral and derived character states.

The classifications produced by cladistic analysis often differ radically from those of traditional systematics (compare Figure 24.9A with Figure 24.9B). Pairs of nested taxa are defined directly from the two-way branching pattern of the phy-

5. *Construct the rest of the phylogenetic tree using the same step-by-step procedure to separate the remaining groups.* In our completed tree, seven groups share a swim bladder or lungs; six share paired limbs; and five have extraembryonic membranes during development. Some groups are distinguished by the unique presence of a derived character state, such as feathers in birds.

Interpreting the Results: Although phylogenetic trees provide information about evolutionary relationships, the common ancestors represented by the branch points are often hypothetical. You can tell from the tree, however, that birds are more closely related to lizards than they are to mammals. Follow the branches of the tree from birds and lizards back to their node. Next, trace the branches of birds and mammals to their node. You can see that the bird–mammal node is closer to the root of the tree than the bird–lizard node is. Nodes that are closer to the bottom of the tree indicate a more distant common ancestry than those closer to the top. Note also that this simplified example produces a phylogenetic tree that is easy to interpret because the data set includes no homoplastic similarities and no conflicting evidence. Most phylogenetic analyses include many such complications.

logenetic tree. Thus, the clade Tetrapoda (the traditional amphibians, reptiles, birds, and mammals) is divided into two taxa, the Amphibia (tetrapods that do not have an amnion, as discussed in Section 32.3) and the Amniota (tetrapods that have an amnion). The Amniota is subdivided into two taxa on the basis of skull morphology and other characteristics: Synapsida (mammals) and Sauropsida (turtles, lizards, snakes, crocodilians, and birds). The Sauropsida is further divided into the Testudomorpha (turtles) and the Diapsida (lizards and snakes, crocodilians, and birds). Finally, the Diapsida is subdivided into two more recently evolved taxa—the Lepidosauromorpha (lizards and snakes) and the Archosauromorpha (crocodilians and birds). Thus, a strictly cladistic classification exactly parallels the pattern of branching evolution that produced the organisms included in the classification. These parallels are the essence and strength of the cladistic method.

Most biologists value the evolutionary focus, clear goals, and precise methods of the cladistic approach. In fact, some systematists advocate abandoning the Linnaean hierarchy for classifying and naming organisms. They propose using a strictly phylogenetic system, called **PhyloCode,** that identifies and names clades instead of pigeonholing organisms into traditional taxonomic categories. This approach is further described in *Unanswered Questions* at the end of this chapter. Although traditional systematics has guided many people's understanding of biological diversity, we use cladistic analyses to describe evolutionary lineages and taxa in the Biodiversity unit that follows this chapter.

Systematists Use Several Techniques to Identify an Optimal Phylogenetic Tree

In practice, most phylogenetic studies are far more complicated than the examples discussed above and in Figure 24.11. Researchers may collect data on hundreds of characters in dozens of species. After scoring each character state as ancestral or derived in every species, a systematist uses one or more computer programs to generate a set of alternative phylogenetic trees. The output of these analyses is often substantial: an analysis of five species can produce 15 possible phylogenetic trees; an analysis of 50 species can produce 3×10^{76}.

Faced with such an unimaginably large number of alternative hypotheses, how does a systematist decide which phylogenetic tree is the "best" representation of a clade's evolutionary history? This problem is complex, because, when evaluating large data sets, we expect to see some similarities that arise when convergent evolution causes distantly related organisms to evolve similar traits independently; because such traits are not synapomorphies, they are false indicators of relatedness that confound the analysis. We also expect to find some differences between closely related organisms if natural selection or some other microevolutionary process caused a derived character state to be reversed or lost. How can we tell which similarities are synapomorphies and which are homoplasies? Researchers use several approaches to sort through the alternatives, two of which we describe below.

PARSIMONY APPROACH Many systematists adopt a philosophical concept, the **principle of parsimony,** to identify the optimal phylogenetic tree. This principle states that the simplest

SUMMARY Based on this set of five characters, the phylogenetic tree with five hypothesized evolutionary changes **(B)** is more parsimonious than the tree that hypothesizes 10 evolutionary changes **(C).** In the absence of additional data, a systematist would accept the more parsimonious tree as the best working hypothesis. (The characters and clades of vascular plants are discussed in detail in Chapter 28.)

THINK LIKE A SCIENTIST Do the five characters in the table provide sufficient information to develop an hypothesis about the evolutionary relationship of cycads and ginkgophytes?

© Cengage Learning 2014

plausible explanation of any phenomenon is the best. If we assume that any complex evolutionary change is an unlikely event, then it is extremely unlikely that the same complex change evolved twice in one lineage. Thus, when the principle is applied to phylogenetic analyses, it suggests that the "best" phylogenetic tree is the one that hypothesizes the smallest number of evolutionary changes needed to account for the distribution of character states within a clade; in effect, this approach minimizes the number of homoplasies (that is, the independent evolution of similar traits) in the tree **(Figure 24.12).** To apply the principle, computer programs evaluate the number of evolutionary changes hypothesized by each phylogenetic tree they generate, and the researcher identifies the one with the fewest hypothesized changes as the most plausible.

The principle of parsimony also allows researchers to identify homologous characters and infer their ancestral and derived states. Once the most parsimonious phylogenetic tree is identified, a researcher can visualize the distribution of derived character states and pinpoint when each derived state evolved.

STATISTICAL APPROACHES When comparing two genome sequences, each base in a strand of DNA can be treated as a character with four possible states (A, G, T, and C). One could perform a parsimony analysis on molecular sequence data, like the one illustrated for morphological data in Figure 24.12, to identify the phylogenetic tree that assumes the fewest mutations. But the application of the parsimony approach to molecular data is complicated by several factors. First, given that there are only four possible character states at each position in a nucleic acid, identical changes in nucleotides often arise independently. Second, segments of DNA that do not code for proteins are less likely than coding regions to be affected by natural selection. As a result, mutations accumulate faster in non-coding regions, causing them to evolve rapidly. Third, because of the degeneracy of the genetic code (described in Section 15.1), mutations in the third codon position do not often influence the amino acid composition of the protein for which a gene codes. As a result, third codon mutations are often selectively neutral (see Section 21.4), and they accumulate more rapidly than do mutations in the first or second positions. Finally, certain nucleotide substitutions are more common than others: transitions (the substitution of a purine for another purine or a pyrimidine for another pyrimidine) occur more frequently than transversions (substitutions between purines and pyrimidines).

To avoid this problem, systematists develop statistical models of evolutionary change that take into account variations in the evolutionary rates at different nucleotide positions or in different genes or species as well as changes in evolutionary rates over time. In one statistical approach, the **maximum likelihood method,** systematists compare alternative trees with specific models about the rates of evolutionary change. The tree that is most likely to have produced the observed distribution of molecular character states is identified as the best hypothesis.

To illustrate how phylogenetic trees are constructed from DNA sequence data, we cite an example using the **genetic distance method,** which calculates the overall proportion of bases that differ between two species. The genetic distance between closely related species is smaller than the genetic distance between distantly related species, because the gene pools of closely related species have accumulated distinctive mutations for a shorter period of time. Systematists can construct a phylogenetic tree from these data by making multiple comparisons of genetic distance between pairs of species and then between groups of species **(Figure 24.13).** Although not as powerful as the maximum likelihood method, the genetic distance method does not depend on assumptions about the evolutionary likelihood of different types of mutations. It also requires much less computing power, which is useful when comparing billions of bases of homologous DNA sequences.

STUDY BREAK 24.5

1. How does outgroup comparison facilitate the identification of ancestral and derived character states?
2. What characteristics are used to group organisms in a cladistic analysis?
3. How is the principle of parsimony applied in phylogenetic analyses?

THINK OUTSIDE THE BOOK

Access the web page for the Tree of Life project at http://www.tolweb.org/tree/. Select a group of animals or plants that is of interest to you, and study the structure of its phylogenetic tree. How many major clades does it include? On the basis of what shared derived characters are those clades defined?

FIGURE 24.13 **Research Method**

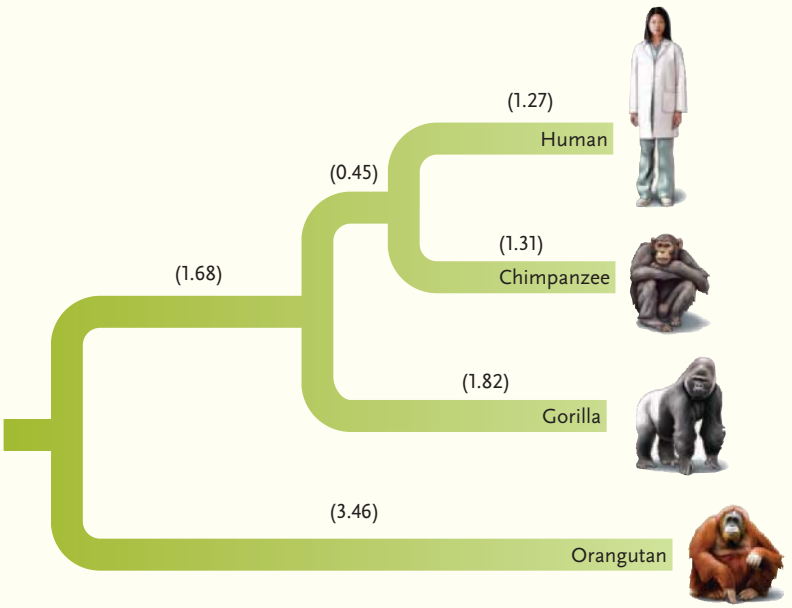
Using Genetic Distances to Construct a Phylogenetic Tree

Purpose: Systematists use data on genetic distances (the overall differences in DNA sequences) among species to reconstruct their phylogenetic tree.

Protocol:

1. Calculate the genetic distance between each pair of species. The genetic distances between humans and three species of great apes are shown in the first table.

	Chimpanzee	Gorilla	Orangutan
Human	1.37	1.75	3.40
Chimpanzee		1.81	3.44
Gorilla			3.50



2. Identify the pair of species with the smallest genetic distance in the first table; in this example, the smallest distance is between chimpanzee and human (genetic distance = 1.37). These two species therefore form a cluster of two closely related species.

3. Calculate the average genetic distances between the chimpanzee-human cluster and each of the other species in the analysis, gorilla and orangutan. For example, the genetic distance between the chimpanzee-human cluster and gorilla is the average of the human-gorilla genetic distance and the chimpanzee-gorilla genetic distance [(1.75 + 1.81)/2 = 1.78]. The newly calculated genetic distances are shown in the second table.

	Gorilla	Orangutan
Chimpanzee–human cluster	1.78	3.42
Gorilla		3.50

4. Identify the two groups (individual species or clusters) with the smallest genetic distance in the second table. In this example, the next smallest genetic distance is between the chimpanzee-human cluster and gorilla (genetic distance = 1.78). Thus, chimpanzee-human-gorilla forms the next cluster, leaving orangutan as the outgroup.

5. Because there are only four species in our example, these genetic distance calculations define the phylogenetic tree shown below. If the analysis included additional species, we would repeat the calculation described in steps 2 to 4 as many times as necessary to complete the phylogenetic tree.

Interpreting the Results: In our phylogenetic tree, the length of each branch reflects the amount of genetic change that has occurred in that branch. A longer branch length indicates that the genome of that species has evolved at a correspondingly higher rate (that is, undergone more evolutionary change since the two sister branches emerged from their common ancestor).

24.6 Phylogenetic Trees as Research Tools

In addition to providing a wealth of information about the patterns of branching evolution across the entire spectrum of living organisms, phylogenetic trees are useful tools that facilitate research in all areas of biology.

Molecular Clocks Estimate the Time of Evolutionary Divergences

Although many biological molecules have been conserved by evolution, different adaptive changes and neutral mutations accumulate in separate lineages from the moment they first diverge. Because mutations that arise in noncoding regions of DNA do not affect protein structure, they are probably not often eliminated by natural selection. If mutations accumulate in these segments at a reasonably constant rate, differences in their DNA sequences can serve as a **molecular clock,** indexing the time at which two species diverged. Large differences imply divergence in the distant past, whereas small differences suggest a more recent common ancestor.

Because different molecules exhibit individual rates of evolutionary change, every molecule is an independent clock, ticking at its own rate. Researchers study different molecules to track evolutionary divergences that occurred at different times in the past. For example, mitochondrial DNA (mtDNA) evolves relatively quickly; it is useful for dating evolutionary diver-

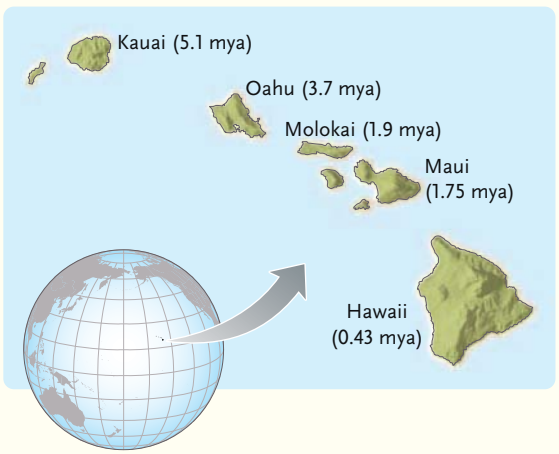
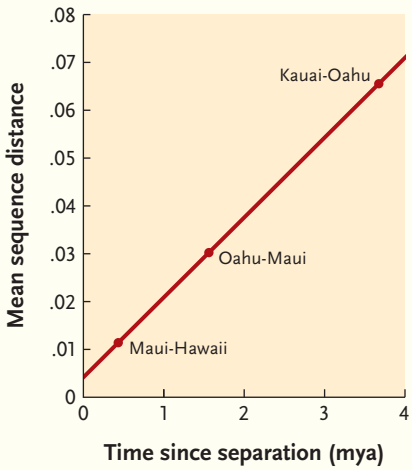
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Do Molecular Clocks Tick at a Constant Rate?



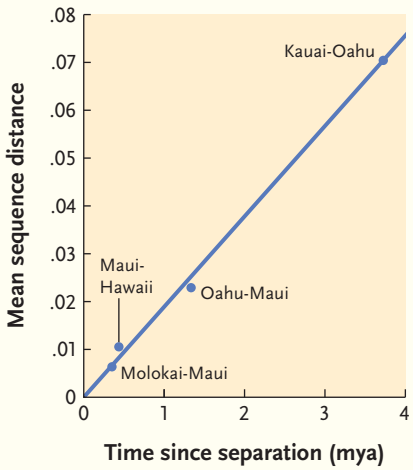
Hypothesis: Some DNA segments accumulate mutations at a constant rate, allowing researchers to use genetic differences between species as molecular clocks.

Prediction: The genetic differences observed between pairs of species will be proportional to the time since they diverged from their common ancestor.



Method: Robert C. Fleischer of the Smithsonian Institution and colleagues at the Smithsonian and Pennsylvania State University compared gene sequences among pairs of related bird species (honeycreepers) and fruit fly species *(Drosophila)* on different Hawaiian Islands. They used radiometric dating of volcanic rocks to estimate the age of each island and used the estimates of island age to measure the divergence time between pairs of species. This approach assumes that birds and flies founded populations on each new island shortly after the island's emergence from the Pacific Ocean and that newly founded populations began to diverge from ancestral populations immediately. Thus, if a population of *Drosophila* now lives on Oahu, the researchers estimate that it diverged from its ancestor 1.6 million years ago, which is the estimated time of Oahu's origin. The researchers plotted a summary statistic of genetic differences between species pairs versus estimated island age to test their hypothesis about constant rates of evolution in the DNA segments they studied.

Results: The extent of genetic difference in the cytochrome *b* sequences of Hawaiian honeycreepers and in the *Yp1* gene sequences of Hawaiian fruit flies is strongly correlated with the time since the members of each species pair were separated. The results indicate that these DNA sequences have evolved at constant rates.



A. Hawaiian Islands (with time of origin)

B. Hawaiian honeycreepers

C. Hawaiian *Drosophila*

Conclusion: Because the gene sequences evolve at a constant rate, they can be used as molecular clocks. Each 0.016 units of genetic difference in the cytochrome *b* sequence in Hawaiian honeycreepers and each 0.019 units of genetic difference in the *Yp1* sequence in Hawaiian *Drosophila* indexes 1 million years of independent evolution.

THINK LIKE A SCIENTIST Which of the two gene sequences surveyed—cytochrome *b* honeycreepers or *Yp1* sequence in *Drosophila*—appears to have evolved more quickly?

Source: R. C. Fleischer et al. 1998. Evolution on a volcanic conveyor belt: using phylogeographic reconstructions and K–Ar-based ages of the Hawaiian Islands to estimate molecular evolutionary rates. *Molecular Ecology* 7:533–545.

© Cengage Learning 2014

gences that occurred within the last few million years. Studies of mtDNA have illuminated aspects of the evolutionary history of humans, as described in Section 32.13. By contrast, chloroplast DNA (cpDNA) and genes that encode ribosomal RNA evolve much more slowly, providing information about divergences that date back hundreds of millions of years.

To calibrate molecular clocks, researchers examine the degree of genetic difference between species in relation to their time of divergence estimated from the fossil record. Alternatively, the clock can be calibrated biogeographically with independent data on when volcanic islands first emerged from the sea or when landmasses separated **(Figure 24.14).**

The reliability of molecular clocks depends on the constancy of evolutionary change in the DNA segment analyzed. Some researchers have noted that even DNA segments that are thought to be selectively neutral may show variable rates of

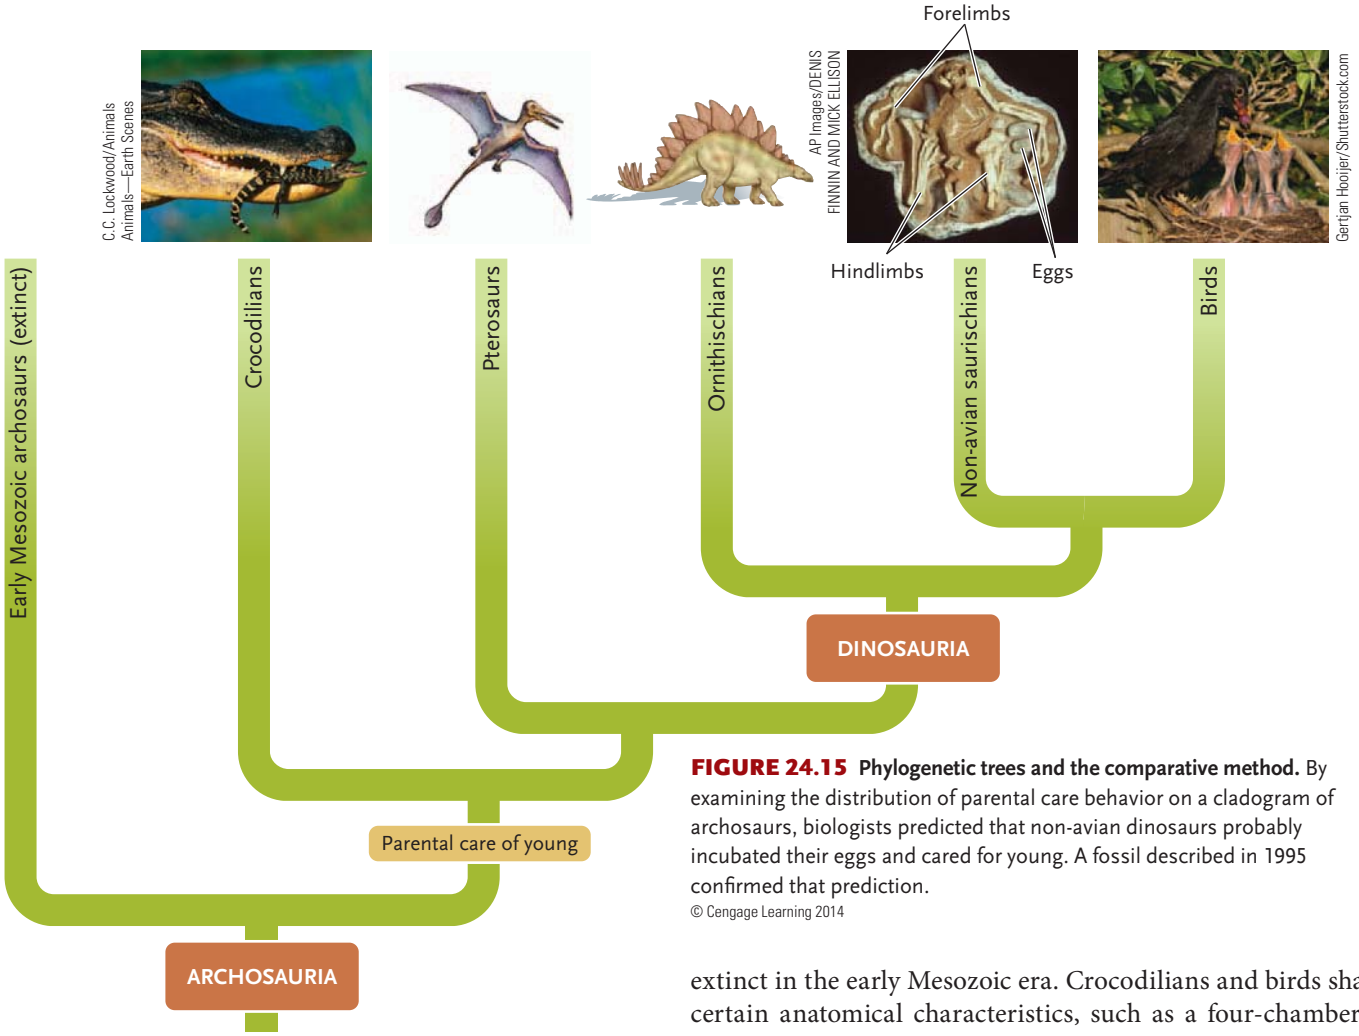

FIGURE 24.15 **Phylogenetic trees and the comparative method.** By examining the distribution of parental care behavior on a cladogram of archosaurs, biologists predicted that non-avian dinosaurs probably incubated their eggs and cared for young. A fossil described in 1995 confirmed that prediction.

© Cengage Learning 2014

evolution. Many factors can influence the rates at which mutations accumulate, and researchers must be cautious when evaluating divergence times estimated with this technique, especially if there are no independent data to corroborate the estimates.

Phylogenetic Trees Allow Biologists to Propose and Test Hypotheses

Accurate phylogenetic trees are essential tools for analyses that biologists describe as the "comparative method." With this approach, researchers compare the characteristics of different species to assess the homology of their similarities and infer where on the phylogenetic tree a particular trait appeared. The comparative method is used to study almost any sort of organismal trait, but in this section we will focus on parental care behavior.

As noted above, birds and crocodilians are included within the Archosauria, a clade that also includes non-avian dinosaurs (that is, extinct terrestrial dinosaurs that are not included within the bird clade), pterosaurs (an extinct group of flying vertebrates, not closely related to bats, with wing surfaces formed by skin), and a number of other groups that became extinct in the early Mesozoic era. Crocodilians and birds share certain anatomical characteristics, such as a four-chambered heart and the one-way flow of air through their lungs. They also share behavioral characteristics, including the production of mating calls (songs in birds and roars in crocodilians), nest-building behavior, and parental care of their young. Female crocodilians guard their nests and keep them moist with urine. They also excavate the nest as the young hatch, and then carry them to standing water. Young stay with their mother for about a year, feeding on scraps of food that fall from her mouth.

Did similar parental care behavior evolve independently in birds and crocodilians, or is it truly a synapomorphy? Did most Mesozoic archosaurs care for their young as birds and crocodilians do today? The comparative method seeks answers to these questions by examining the phylogenetic tree for archosaurs **(Figure 24.15).** As you can readily see, crocodilians and birds lie on widely separated branches of the archosaur tree, with pterosaurs and non-avian dinosaurs positioned between them. The most parsimonious inference about the evolution of parental care behavior is that it evolved once in the common ancestor of crocodilians and birds. If that inference is correct, then non-avian dinosaurs and pterosaurs probably also cared for their young in the nest. Indeed, that prediction was confirmed in 1995, when Mark A. Norell of George Washington University and his colleagues discovered a fossil of a non-avian dinosaur *(Oviraptor)* sitting on a nest full of eggs.

STUDY BREAK 24.6

1. What assumption underlies the use of genetic sequence differences between species as a molecular clock?
2. Are birds more closely related to non-avian dinosaurs or to crocodilians?

24.7 Molecular Phylogenetic Analyses

The application of molecular techniques to phylogenetic analyses has allowed systematic biologists to resolve some evolutionary puzzles that could not be addressed with older techniques. In this section we describe how molecular analyses have enabled public health researchers to identify sources of HIV infection in humans and elucidate the relationships among the three domains of the Tree of Life.

Molecular Phylogenetic Analyses Pinpoint the Origins of Infectious Diseases

Phylogenetic analyses also allow physicians and public health workers to identify the origin of infectious agents and follow their spread through a population. Many pathogenic organisms and viruses mutate as they proliferate, establishing derived character states that are ripe for phylogenetic analysis.

The human immunodeficiency virus (HIV), the agent that causes acquired immunodeficiency syndrome (AIDS) in humans, began to infect large numbers of people in the 1980s. As its devastating effects on humans became apparent, scientists scrambled to discover its origin. Genetic analyses linked it to the lentiviruses, specifically simian immunodeficiency virus (SIV), which infects dozens of monkey species as well as chimpanzees in Africa. Surprisingly, SIV does not cause illness in those animals, perhaps because their populations developed immunity to it after a long period of exposure.

Two distinct strains of HIV infect humans: HIV-1 is common in central Africa, and HIV-2 is common is West Africa. Did these strains evolve within human hosts, or did they exist before the virus was first transmitted to humans? An analysis by Beatrice H. Hahn of the University of Alabama at Birmingham and the Howard Hughes Medical Institute and colleagues at other institutions identified three major clades of SIV. The clade that infects chimpanzees includes HIV-1, and one of the clades that infect monkeys includes HIV-2 **(Figure 23.16).** Thus, the two strains of HIV apparently originated in nonhuman hosts. Scientists suspect that the transmission to humans occurred multiple times when hunters who were butchering bush meat—chimpanzees in central Africa and sooty mangabey monkeys in West Africa—acquired the virus through cuts on their hands.

Analyses of Gene Sequences Have Revealed the Branching Pattern of the Entire Tree of Life

On a very grand scale, molecular phylogenetics has revolutionized our view of the entire Tree of Life. The first efforts to create a phylogenetic tree for all forms of life were based on morphological analyses. However, these analyses did not resolve the branches of the Tree containing prokaryotes, which lack significant structural variability for analysis, or the relationships of those branches to eukaryotes.

In the 1960s and early 1970s, biologists organized living systems into five kingdoms. All prokaryotes were grouped into the kingdom Monera. The eukaryotic organisms were grouped into four kingdoms: Fungi, Plantae, Animalia, and "Protista." The kingdom "Protista" was always recognized as a polyphy-

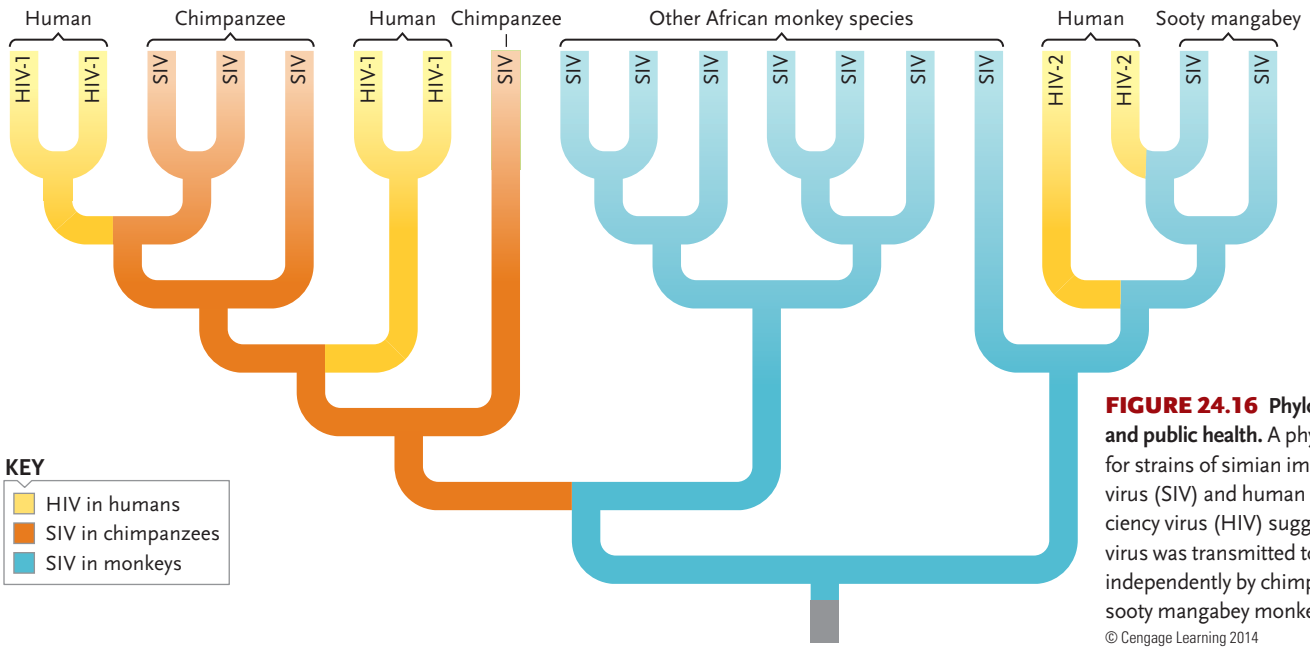

FIGURE 24.16 Phylogenetic trees and public health. A phylogenetic tree for strains of simian immunodeficiency virus (SIV) and human immunodeficiency virus (HIV) suggests that the virus was transmitted to humans independently by chimpanzees and sooty mangabey monkeys.

© Cengage Learning 2014

letic "grab bag" of unicellular or acellular organisms (discussed further in Chapter 27). Unfortunately, phylogenetic analyses based on morphology were unable to sort them into distinct evolutionary lineages.

In the 1970s, biologists realized that molecular phylogenetics provides an alternative approach. They simply needed to identify and analyze molecules that have been conserved by evolution over billions of years. Carl R. Woese, a microbiologist at the University of Illinois at Urbana–Champaign, identified the small subunit of ribosomal RNA (rRNA) as a suitable molecule for analysis. Ribosomes, the structures that translate messenger RNA molecules into proteins (see Section 15.1), are remarkably similar in all forms of life. They are apparently so essential to cellular processes that the genes specifying ribosomal structure exhibit similarities in their nucleotide sequences in organisms as different as bacteria and humans. Thus, it is possible to compare the sequences of these genes in a phylogenetic analysis.

The phylogenetic tree based on rRNA sequences divides living organisms into three primary lineages called domains—Bacteria, Archaea, and Eukarya—which differ in many molecular and cellular characters (**Figure 24.17** and **Table 24.1**). According to this hypothesis, two domains, Bacteria and Archaea, consist of prokaryotic organisms, and one, Eukarya, consists of eukaryotes. Bacteria includes well-known microorganisms. Archaea includes microorganisms that live in physiologically harsh environments, such as hot springs or very salty habitats, as well as less extreme environments. Eukarya includes the familiar animals, plants, and fungi, as well as the many lineages formerly included among the "Protista," which is not a monophyletic group. As the Tree in Figure 24.17 suggests, Archaea and Eukarya are more closely related to each other than either domain is to Bacteria. The next unit of this book is devoted to detailed analyses of the biology and evolutionary relationships between and within these three domains.

Our discussion of phylogenetic analysis has emphasized the importance of direct descent: the transmission of derived traits from ancestors to descendants. But as scientists analyze the complete genome sequences of an ever-growing list of organisms, they are discovering that the three domains in the Tree of Life have not had entirely independent evolutionary

TABLE 24.1 **Some Differences among the Three Domains**

Character	Bacteria	Archaea	Eukarya

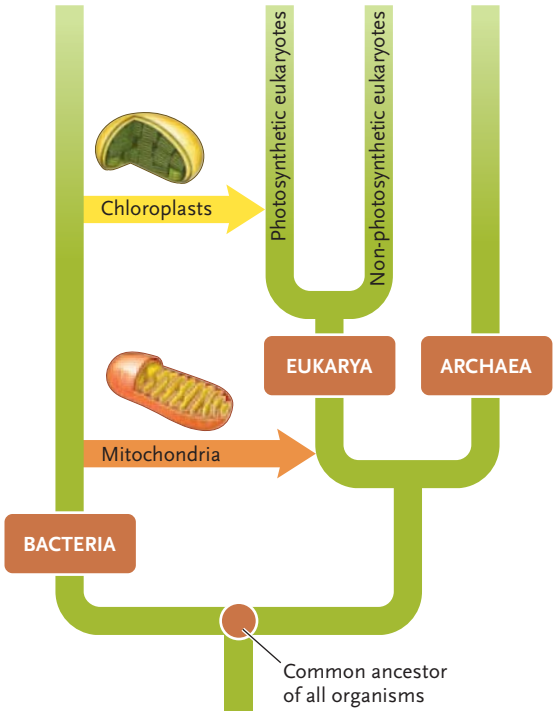

FIGURE 24.18 Horizontal gene transfer. Molecular analyses suggest that horizontal gene transfer from bacteria brought mitochondria to an ancestral eukaryote. A later transfer brought chloroplasts into the cells of some eukaryotes.

© Cengage Learning 2014

histories. Although inheritance from one generation to the next has produced the clades we recognize today, **horizontal gene transfer,** the movement of genetic material from one clade to another, has also been important (discussed further in Chapters 26 and 27). The mechanisms that facilitate horizontal gene transfer include transformation and transduction (discussed in Section 17.1), viral infection, and the incorporation of one organism into another. For example, the genes that regulate metabolism in eukaryotes are more similar to those in Bacteria than to those in Archaea, leading researchers to hypothesize that the mitochondria in eukaryotic cells may have originated when bacterial genes, or entire bacteria, were transferred horizontally into an ancestral eukaryote. The chloroplasts of plants may well have originated in a similar way **(Figure 24.18).** Thus, a more accurate portrait of the evolutionary history of life on Earth may require networklike connections between the three major trunks on the Tree of Life. Researchers are hard at work analyzing these connections.

1. **Did HIV originate in humans, or was the infection acquired from other animals?**
2. **Why was a phylogenetic analysis of prokaryotes based on molecular sequence data more successful than the analysis based on morphological data?**

UNANSWERED QUESTIONS

Should we abandon the traditional Linnaean hierarchy in favor of a more evolutionary classification?

Diligent Kindly Professors Cannot Often Fail Good Students—or some equally silly mnemonic device for remembering the Linnaean taxonomic hierarchy—is all that many students recall about systematics. Even if they remember the underlying rank names—is *G* for "group" or "genus"—they often forget that Linnaeus conceived his system of classification more than a century before Darwin articulated his theory of evolution, which revolutionized our understanding of biological diversity. In the more than 150 years since Darwin published *On the Origin of Species,* systematists have sought not only to categorize life's diversity but, more important, to understand its origins. The broad relevance of studies in systematics has become increasingly clear as biologists have discovered that systematic principles are as important in tracing the emergence and spread of HIV as they are in distinguishing a duck from a dove.

More than a century and a half after it was first published, Darwin's theory has an increasingly revolutionary impact. Perhaps the most striking recent example is a call for the complete abandonment of the Linnaean taxonomic hierarchy. Although biologists thought they had reconciled the perspectives of Darwin and Linnaeus, a growing minority of systematists now believe that any effort to catalog and categorize life's diversity must be explicitly phylogenetic and free of the arbitrary ranks that Linnaeus invented. This movement, which has been codified in the PhyloCode initiative, is fueled largely by newly available molecular data, vastly improved phylogenetic methods, and increasingly fast computers. These advances offer the potential to reconstruct accurate and fully resolved phylogenetic trees at a scale never before possible. For the first time, biologists see real progress in accurately reconstructing the entire Tree of Life. Although we are still far from achieving this goal, every day millions of new, phylogenetically informative DNA fragments are being sequenced and analyzed by thousands of computers running around the clock.

Although PhyloCode's synthesis of taxonomy and evolutionary systematics may be long overdue, this attempted coup is not without controversy. For example, some systematists contend that such a radical revision of our taxonomic system will introduce confusion and instability in the naming of species. Even the revolution's adherents recognize that we still face many challenging limitations to the synthesis between taxonomic practice and Darwinian principles. Nowhere is this more evident than in the definition of species.

During Linnaeus' time, species were viewed as immutable natural types created by God. Darwin, however, formulated his theory on the principle that species change over time. Although the truth of this basic hypothesis is no longer a subject of debate, its practical implications for delimiting species boundaries and understanding how new species form are among the most exciting areas of study in modern systematics. Most practicing systematists view species as real (that is, biologically meaningful) categories, but the criteria for recognizing species vary dramatically among systematists working on different types of organisms (plants versus animals, or organisms that reproduce asexually versus those that

reproduce sexually). Using new molecular tools and sophisticated genetic experiments, evolutionary biologists are beginning to probe the precise genetic basis of species. Over the past decade, a small number of "speciation genes" have been identified; more such discoveries are sure to follow in the coming years. Although many of these studies have been restricted to model research organisms, such as fruit flies, the new tools offered by the fields of genomics and bioinformatics offer the potential to address similar questions in an increasingly broad array of organisms.

Simply put, the systematics of today is not that of your grandparents. Given the enormous challenge involved in categorizing and understanding the origin and evolutionary relationships of millions of species, many additional changes are on the horizon. For the next generation of systematists, however, a better mnemonic to remember may be "Do Keep Probing Charles' *Origin* For Good Systematics."

THINK LIKE A SCIENTIST How easily does the Linnaean system of classification accommodate the phenomenon of horizontal gene transfer? Is a completely phylogenetic view of biodiversity, like PhyloCode, more consistent with the idea that genes have moved horizontally between clades?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

24.1 Nomenclature and Classification

- Linnaeus invented a system of binomial nomenclature in which each species receives a unique two-part name.
- Species are organized into a taxonomic hierarchy, which largely reflects the pattern of branching evolution (Figure 24.2). Species classified in the same lower-level taxon have a more recent common ancestor than species classified in the same higher-level taxon.

24.2 Phylogenetic Trees

- Phylogenetic trees are hypotheses that portray the branching pattern of evolution (Figure 24.3). Most phylogenetic trees have an implicit or explicit time line that indicates the relative times for cladogenesis. Branch points are described as nodes, and monophyletic lineages are called clades. Two lineages that share a node are called sister clades. Clades can be rotated at nodes without changing the meaning of the tree (Figure 24.4).
- Evolutionary biologists define monophyletic taxa directly from the structure of a phylogenetic tree (Figure 24.5). Biologists never intentionally define paraphyletic or polyphyletic taxa.

Animation: Evolutionary tree diagrams

Animation: Primate evolutionary tree

24.3 Sources of Data for Phylogenetic Analyses

- Homologies are characters that two or more descendant species inherited from their common ancestor (Figure 24.6). Homologous structures are similar in anatomical detail, and they often show a similar pattern of embryonic development. Characters that are similar for any other reason are described as homoplasies (Figure 24.7).
- Systematists often use morphological characters in phylogenetic analyses.
- If morphological characters do not distinguish species, behavioral characters may be useful (Figures 24.8).
- Systematists today use genetic sequence data to reconstruct phylogenetic history.

Animation: Evolution of jaws

24.4 Traditional Classification and Paraphyletic Groups

- In traditional systematics, biologists used the similarities and differences between organisms to construct a phylogenetic tree and a classification.
- Traditional classifications sometimes included paraphyletic groups (Figure 24.9A).

24.5 The Cladistic Revolution

- Derived character states can serve as markers of clades.
- Systematists use evidence from the fossil record as well as outgroup comparison to identify which character states are derived and which are ancestral (Figure 24.10).
- Cladistic analyses use synapomorphies (derived character states) to construct phylogenetic hypotheses (Figure 24.9B).
- The construction of a simple using cladistic methods is straightforward (Figure 24.11).
- Systematists use genetic distance data (Figure 24.13), the principle of parsimony (Figure 24.12), and maximum likelihood techniques to evaluate alternate phylogenetic hypotheses.

Animation: Interpreting a cladogram

24.6 Phylogenetic Trees as Research Tools

- If a nucleic acid accumulates mutations at a reasonably constant rate, it can be used as a molecular clock (Figure 24.14).
- Phylogenetic trees allow biologists to propose and test hypotheses about when certain characters evolved (Figure 24.15).

24.7 Molecular Phylogenetic Analyses

- Molecular techniques allow systematists to address questions that they could not have posed in the mid-twentieth century. Phylogenetic analyses are useful tools in medicine because they allow researchers to track the origin and spread of infectious diseases (Figure 24.16).
- Sequence data from the small subunit ribosomal RNA allowed researchers to recognize the three domains of life (Figure 24.17). Horizontal gene transfer complicates our understanding of the history of biodiversity (Figure 24.18).

UNDERSTAND & APPLY

Test Your Knowledge

1. The evolutionary history of a group of organisms is called its:
   a. classification.
   b. taxonomy.
   c. phylogeny.
   d. domain.
   e. outgroup.
2. In the Linnaean hierarchy, the organisms classified within the same taxonomic category are called:
   a. a phylum.
   b. a taxon.
   c. a genus.
   d. a binomial.
   e. an epithet.
3. When systematists study morphological or behavioral traits to reconstruct the evolutionary history of a group of animals, they assume that:
   a. similarities and differences in phenotypic characters reflect underlying genetic similarities and differences.
   b. the animals use exactly the same traits to identify appropriate mates.
   c. differences in these traits caused speciation in the past.
   d. the adaptive value of these traits can be explained.
   e. variations in these traits are produced by environmental effects during development.
4. Which of the following pairs of structures are homoplastic?
   a. the wing skeleton of a bird and the wing skeleton of a bat
   b. the wing of a bird and the wing of a fly
   c. the eye of a fish and the eye of a human
   d. the bones in the foot of a duck and the bones in the foot of a chicken
   e. the toes on the foot of a lizard and the toes on the foot of a human
5. Which of the following does *not* help systematists determine whether a morphological character state is ancestral or derived?
   a. outgroup comparison
   b. patterns of embryonic development
   c. studies of the fossil record
   d. studies of the character in more related species
   e. dating of the character by molecular clocks
6. In a cladistic analysis, a systematist groups together organisms that share:
   a. derived homologous traits.
   b. derived homoplastic traits.
   c. ancestral homologous traits.
   d. ancestral homoplastic traits.
   e. all of the above.
7. A monophyletic taxon is one that includes:
   a. an ancestor and all of its descendants.
   b. an ancestor and some of its descendants.
   c. organisms from different evolutionary lineages.
   d. an ancestor and those descendants that still resemble it.
   e. organisms that resemble each other because they live in similar environments.
8. Which of the following is *not* an advantage of using molecular characters in a systematic analysis?
   a. Molecular characters provide abundant data.
   b. Systematists can compare molecules among species that are morphologically very similar.
   c. Systematists can compare molecules among species that are morphologically very different.
   d. Nucleotide sequences in DNA are generally not influenced by environmental factors.
   e. Systematists can easily determine whether base substitutions in the DNA of two species are synapomorphies.
9. To construct a phylogenetic tree by applying the principles of parsimony to molecular sequence data, one would:
   a. start by making assumptions about variations in the rates at which different DNA segments evolve.
   b. group together organisms that share the largest number of ancestral sequences.
   c. group together organisms that share derived sequences, matching the groups to those defined by morphological characters.
   d. group together organisms that share derived sequences, minimizing the number of hypothesized evolutionary changes.
   e. identify derived sequences by studying the embryology of the organisms.
10. Which of the following underlying assumptions allows differences in a particular molecular sequence to be used as a molecular clock?
    a. The sequence never experiences any mutations.
    b. The sequence codes for a protein.
    c. The sequence accumulates mutations at a reasonably constant rate.
    d. The sequence is part of a mitochondrial gene.
    e. The sequence codes for small subunit ribosomal RNA.

Discuss the Concepts

1. In the past, systematists commonly used the amino acid sequences of proteins and DNA sequences in phylogenetic analyses. Think about the genetic code (Section 15.1), and explain why phylogenetic hypotheses based on DNA sequences may be more accurate than those based on amino acid sequences.
2. Traditional evolutionary systematists identify the Reptilia as one class of vertebrates, even though we know that this taxon is paraphyletic. Describe disadvantages of defining paraphyletic taxa in a classification.
3. The following table provides information about the distribution of ancestral and derived character states for six systematic characters (labeled 1 through 6) in five species (labeled A through E). A "d" means that the species has the derived state, and an "a" means that it has the ancestral state. Construct a phylogenetic tree for the five species using the principle of parsimony; in other words, assume that each derived character state evolved only once in this group of organisms. Mark the branches of the phylogenetic tree to show where each character changed from the ancestral to the derived state.

	Character					
Species	1	2	3	4	5	6
A	a	a	a	a	a	a
B	d	a	a	a	a	d
C	d	d	d	a	a	a
D	d	d	d	a	d	a
E	d	d	a	d	a	a

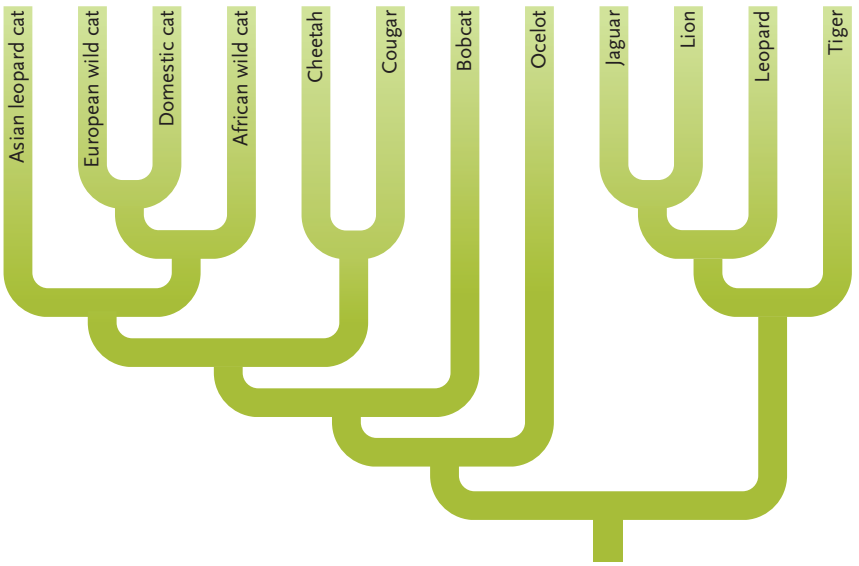
4. Imagine that you are a systematist studying a group of little-known flowering plants. You discover that the phylogenetic tree based on flower morphology differs dramatically from the phylogenetic tree based on DNA sequences. How would you try to resolve the discrepancy? Which tree would you believe is more accurate?
5. Create an imaginary phylogenetic tree for an ancestral species and its 10 descendants. Circle a monophyletic group, a polyphyletic group, and a paraphyletic group on the tree. Explain why the groups you identify match the definitions of the three types of groups.

Design an Experiment

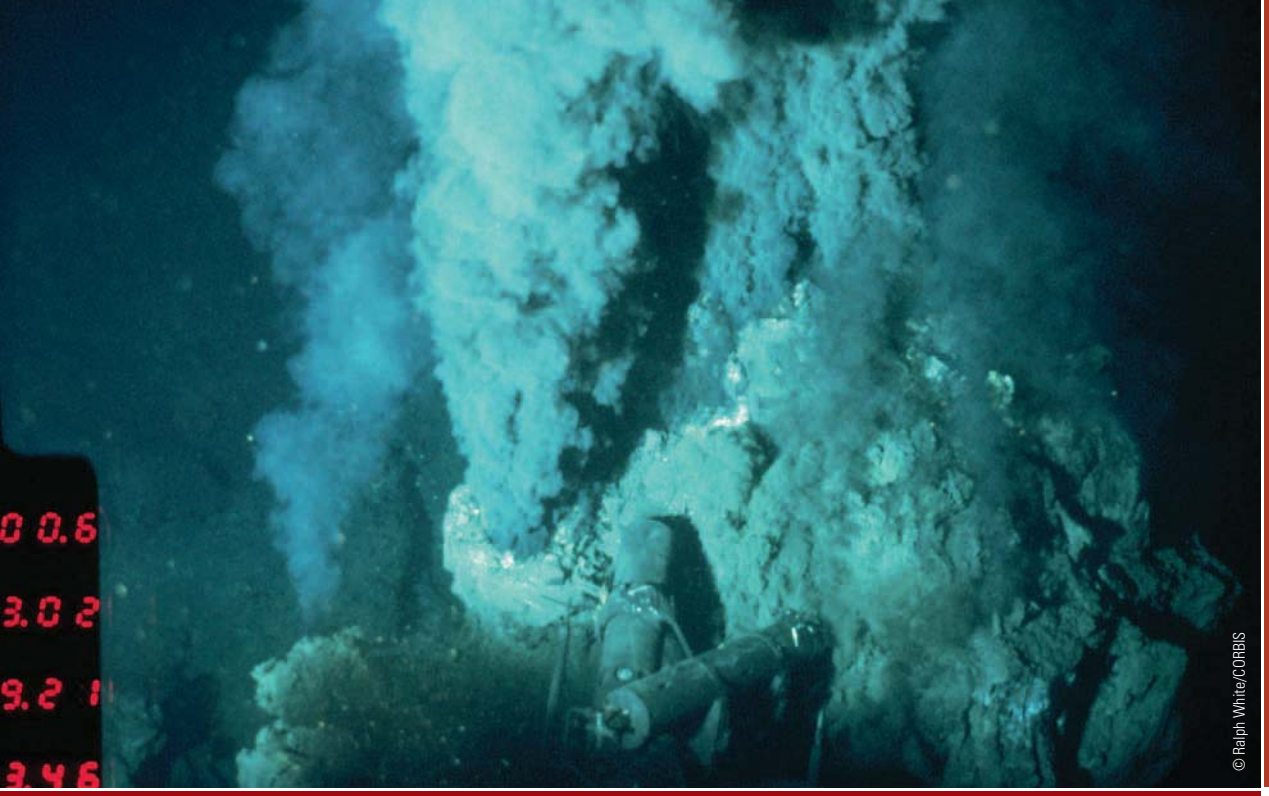


Imagine that you are trying to determine the evolutionary relationships among six groups of animals that look very much alike because they have few measurable morphological characters. What data would you collect to reconstruct their phylogenetic history?

Interpret the Data

The phylogenetic tree for 12 cat species (Felidae) reproduced at right was assembled from molecular sequence data. Which species is the domestic cat's closest relative? Which clade is the sister taxon to tigers? Are bobcats more closely related to cougars or to ocelots?

Apply Evolutionary Thinking



Is the construction of parsimonious phylogenetic trees more consistent with the predictions of the phyletic gradualism hypothesis or the punctuated equilibrium hypothesis of evolutionary change? You may want to review material in Section 23.5 before answering this question.

Black smoker hydrothermal vents on the ocean floor. Many scientists support the theory that life developed near hydrothermal vents, where superheated, mineral-rich water is found.

25

The Origin of Life

STUDY OUTLINE

25.1 The Formation of Molecules Necessary for Life
25.2 The Origin of Cells
25.3 The Origins of Eukaryotic Cells

Why it matters . . . In 1927, Belgian priest and astronomer George Lemaître proposed the Big Bang Theory, which is now the dominant scientific theory about the origin of the universe. According to this theory, an incomprehensibly vast explosion about 14 billion years ago produced the matter and energy of our universe. As the universe expanded, slight variations in temperature and density led to an uneven distribution of matter. Gravitational attraction caused gas to form clouds and then collapse into more concentrated collections of matter. Stars, in which nuclear reactions generated the major elements we find in present-day biological molecules, were formed. Stars that were aging before the birth of our solar system expanded to produce red supergiants, which eventually exploded as supernovae. Such an explosion ejects the contents of a star at near light speed, in effect distributing all the elements of the periodic table across the universe. When our Sun formed, some of the elements coalesced with it and also formed the planets of our solar system. In other words, stardust, the remnants of long-ago stars, is the elemental origin of life on Earth. The origin of cellular life required two other fundamental conditions: a continual source of energy, and a temperature range in which liquid water can form. The continual energy source is, of course, the Sun. The relatively narrow temperature range suitable for life relates to the nature of the Sun, the distance of Earth from the Sun, and the properties of the atmosphere that cause trapping of heat.

Earth is estimated to have formed approximately 4.6 billion years ago. When and how did living cells form from inert materials? Answering these questions is difficult because we must rely on indirect geological evidence, and on experimental data that are open to debate and multiple interpretations.

Figure 25.1 outlines the key events in the origin and early evolution of life, which we will examine in this chapter. The earliest events are uncertain, but probably include the development of

protocells, primitive cell-like structures that have some of the properties of life and that might have been the precursors of cells. Some geological evidence shows that prokaryotic cells were present in the Archaean eon by 3.5 billion years ago (see Table 23.1 for the geological time scale). The activity of photosynthetic prokaryotes generated an oxygen-enriched atmosphere, a condition probably necessary for the development of the first eukaryotic cells. Fossils of cells that resemble modern eukaryotic cells appeared about 1.5 billion years ago.

25.1 The Formation of Molecules Necessary for Life

All present-day living cells have the following characteristics: (1) a boundary membrane separating the cell interior from the exterior; (2) one or more nucleic acid coding molecules located in a nuclear region (a nucleus in eukaryotes and a nucleoid region in prokaryotes); (3) a system using the coded information in the nucleic acids to make proteins and, through them, other biological molecules; and (4) a metabolic system providing energy for these activities. The complexity of these systems makes it highly unlikely that living cells appeared suddenly from nonliving matter. Rather, there must have been a transition from nonliving to living matter, although we lack direct evidence for how it occurred.

Most scientists study the origin of life by assuming that it originated from nonliving matter on Earth, through chemical and physical processes no different from those operating today. Hypotheses made under these assumptions are testable to the extent that the chemical and physical processes can be duplicated in the laboratory.

But some scientists consider a possible extraterrestrial origin of life. Analysis of meteorites has shown that they contain some organic molecules that are characteristic of living organisms. Could a living cell or organism, or perhaps a spore, have arrived in such a way? Most scientists believe it is unlikely that a cell or an organism could have survived a long journey in space, even if protected from radiation, or that it could have survived intense heating while traveling through Earth's atmosphere and the actual impact with Earth. At this point the hypothesis that life arrived on Earth by interplanetary transport is not testable, so it cannot be ruled out. Nonetheless, even if a living organism arrived from space and spawned a population on this planet, life would still have had to arise from nonliving matter in a similar way on the organism's home planet.

Conditions on Primordial Earth Led to the Formation of Organic Molecules

The formation of Earth led to a planet with three layers. In its center is the core, which is surrounded by the mantle. Both the core and the mantle are rich in iron. Surrounding the mantle is the relatively thin crust, which consists mainly of silicates. Volcanic activity on early Earth released gases from the crust and mantle such as CO_2, H_2, and N_2, which helped form the first atmosphere. Water vapor emitted from volcanoes formed the first oceans, lakes, and rivers.

Primordial Earth met several basic conditions necessary for life to begin. Although Earth's gravitational pull was strong enough to retain an atmosphere, it was not strong enough to compress the atmospheric gases into liquid form. Earth's dis-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tance from the Sun was such that, on average, sunlight warmed the surface enough to keep much of the liquid water from freezing, but not enough to boil the water. *Liquid water is essential for the chemistry of biological systems* (see Section 2.4).

In the primordial atmosphere, any molecular oxygen would have reacted with elements of the crust and atmosphere to form oxides. Spontaneous reactions of hydrogen, nitrogen, and carbon would have produced ammonia (NH_3) and methane (CH_4).

As Earth's surface cooled, natural sources of energy caused chemical bonds to break and reform, leading to the formation of organic molecules at about 4.5 billion years ago. In addition to sunlight and electrical discharges during storms and volcanic activity, radioactivity from atomic decay and heat from volcanoes, geysers, and hydrothermal (hot water) vents in the sea floor all acted on the primordial atmosphere and crust—as they still do today. As many as a half-billion years may have passed before the concentrations of organic molecules reached levels where their interactions formed more complex organic substances. We now consider the current thinking about how simple molecules were converted into the key molecules of life.

The Oparin–Haldane Hypothesis Initiated Scientific Investigations into the Origin of Life

Scientific efforts to explain the origin of life began with a major hypothesis proposed independently in the 1920s by two investigators, Aleksandr I. Oparin, a Russian plant biochemist at Moscow State University in Russia, and J. B. S. Haldane, a British geneticist and evolutionary biologist at Cambridge University in England. Their hypothesis rested on the critical assumption that Earth's primordial atmosphere was radically different from today's atmosphere. They proposed that, rather than being an oxygen-rich (oxidizing) atmosphere as it is now, the early atmosphere was a strongly reducing atmosphere, due to the concentration of substances such as hydrogen (H_2), methane (CH_4), ammonia (NH_3), and water, which are *fully reduced*—they contain the maximum possible number of electrons and hydrogens (see Section 8.1). They reasoned that the primordial atmosphere would have had an abundance of electrons and hydrogens for reduction reactions, which could create organic molecules from inorganic elements and compounds. Energy to drive the reductions, according to the hypothesis, came from solar energy and other natural sources such as the electrical energy of lightning in atmospheric storms and from volcanic activity.

The absence of oxygen in the primitive atmosphere is essential to the Oparin–Haldane hypothesis. Oxygen can reverse reductions by removing electrons and hydrogens from organic molecules (see Section 8.1). In other words, if oxygen was present, the newly formed molecules would have been broken down quickly by oxidation.

Oparin and Haldane proposed that reductions occurring on the primordial Earth produced great quantities of organic molecules. The molecules accumulated because the two main routes by which such substances break down today, chemical attack by oxygen and decay by microorganisms, could not take place. According to Oparin and Haldane's hypothesis, the organic substances would have become so concentrated that the oceans and other bodies of water resembled a prebiotic soup. Recent geochemical evidence, however, suggests an alternate mechanism for the formation of organic molecules. According to this evidence, early Earth's oceans actually contained some amount of oxidized forms of nitrogen, sulfur, and iron that were generated by UV radiation that penetrated the atmosphere in the absence of an ozone layer. Those oxidized materials could have reacted with reduced molecules of the crust, releasing energy that could have been used to produce some more complex biomolecules.

In their model, Oparin and Haldane assumed that the highly concentrated organic molecules would tend to aggregate in random combinations and that, by chance, some of the combinations were able to carry out one or more primitive reactions characteristic of life, such as increasing in mass by adding new materials. Later, scientists reasoned that these combinations were able to compete successfully against less efficient combinations for space and materials in an organic soup. As a result, they persisted and became more numerous.

Chemistry Simulation Experiments Support the Oparin–Haldane Hypothesis

In 1953, Stanley L. Miller, a graduate student in Harold Urey's laboratory at the University of Chicago, tested the Oparin–Haldane hypothesis. They created a laboratory simulation of conditions Oparin and Haldane believed existed on early Earth; namely involving a reducing atmosphere consisting of H_2, CH_4, and NH_3, as well as H_2O **(Figure 25.2).** After one week of running the apparatus, as much as 15% of the carbon was now in the form of organic compounds, including amino acids. The significance of the finding at the time was enormous; amino acids, which are essential to cellular life, could be made under the conditions scientists believed existed on early Earth.

The synthesis of complex biological molecules in a reducing atmosphere in the Miller–Urey experiment supported the Oparin–Haldane hypothesis. However, many scientists believe that the atmosphere at the time key organic molecules were formed on early Earth was not reducing. Rather, the atmosphere at that time is thought to have been neutral (neither reducing nor oxidizing), consisting mostly of gases released by volcanic activity, notably CO_2, N_2, CO, and H_2S. Indeed, experiments using these gases in the Miller–Urey apparatus, in addition to the original gases used, resulted in the formation of many other molecules of biological significance. Produced, for example, were all the building blocks of complex biological molecules, including amino acids; fatty acids; the purine and pyrimidine building blocks of nucleic acids; sugars such as glyceraldehyde, ribose, deoxyribose, glucose, and fructose; and phospholipids, which form the lipid bilayers of biological membranes.

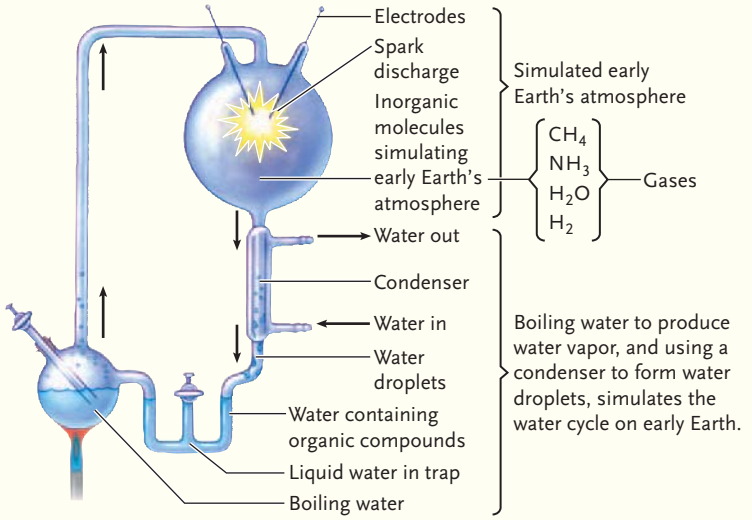

FIGURE 25.2 **Experimental Research**

The Miller–Urey Apparatus Demonstrating That Organic Molecules Can Be Synthesized Spontaneously under Conditions Simulating Primordial Earth

Question: Do chemistry simulation experiments support the Oparin–Haldane hypothesis that reduction reactions on primordial Earth produced organic molecules?

Experiment: Stanley Miller set up an experiment to simulate chemical conditions of early Earth **(Figure).** He placed components of a reducing atmosphere—hydrogen, methane, and ammonia—in a closed apparatus. Water vapor was added to the "atmosphere" by boiling water in one part of the apparatus, and it was removed by cooling and condensation in another part. This simulated the cycle of release of water vapor into the atmosphere, and condensation into water. Miller exposed the gases to an energy source in the form of continuously sparking electrodes to simulate lightning.

~4.5 billion years ago

© Cengage Learning 2014

Results: After running the apparatus for only a week, Miller found a large assortment of organic compounds in the water, including urea, amino acids, and lactic, formic, and acetic acids—as much as 15% of the carbon was now in the form of organic compounds. Two percent of the carbon was in the form of amino acids, which form easily under sufficiently reducing conditions.

Conclusion: The synthesis of organic molecules, including biological molecules, in a reducing atmosphere supported the Oparin–Haldane hypothesis.

THINK LIKE A SCIENTIST What aspect of the Miller–Urey experimental design ruled out the possibility that amino acids were synthesized by living organisms such as bacteria?

Source: S. Miller. 1953. A production of amino acids under possible primitive Earth conditions. *Science* 117:528–529. (Figure redrawn from an original courtesy of S. L. Miller, Copyright 1955 by the American Chemical Society.)

Scientists Have New Theories about the Sites for the Origin of Organic Molecules

Scientists have developed a number of other theories for how organic compounds may have arisen on early Earth. All of the theories have the reasonable assumption of the presence of liquid water. Remember that water is essential for the chemistry of biological systems (see Section 2.4). All of the theories have their advocates and critics. It is fair to say that there are controversial issues in each of them. Two of the theories are outlined here.

One current theory for the origin of life, which has significant support among scientists, is that life developed near hydrothermal vents in the sea floor (see photo on first page of the chapter). Many such vents exist in today's oceans, emitting bursts of mineral-rich water superheated to up to 400°C by submarine volcanoes. Scientists exploring hydrothermal vents find complex ecosystems associated with them.

Life might have originated near oceanic hydrothermal vents because reducing conditions existed there along with an abundance of the chemicals that are essential for life. Even now, there are high levels of hydrogen gas, methane, and ammonia around the vents. Indeed, based on simulation experiments, scientists hypothesize that hydrothermal vents could have produced a lot more organic material than that generated in the Miller–Urey experiment. However, if life did evolve near hydrothermal vents, we would expect many present-day hydrothermal-vent life forms to be ancient. This is not the case; in most cases, these organisms are closely related to modern organisms that do not live in hydrothermal vent environments. Critics of the hydrothermal-vent origin of life theory also argue that the temperature at the vents is too high to permit the origin of life. The critics argue that at the high temperature found at vents, the organic molecules are too unstable and would be destroyed as soon as they form. Supporters of the theory counter that the necessary organic molecules for life form not at the vent itself, but somewhere in the gradient between the hot water at the vent and the near-freezing water surrounding the vent.

Another theory is that some organic compounds had an extraterrestrial origin. (As mentioned earlier, scientists do not believe living cells or organisms of extraterrestrial origin could have survived a journey to Earth.) Indeed, many of the compounds made in the Miller–Urey experiment exist in outer space. For example, a meteorite that fell on Murchison, Australia, in 1969 contained more than 90 amino acids, only 19 of which are found on Earth. Since amino acids appear to be able to survive in outer space, they could potentially have been present when Earth was formed. DNA precursors have also been identified in some me-

teorites. It is possible that other organic compounds arrived by meteor impact, too. Repeated bombardment by meteors occurred during the first period of Earth's existence, the Hadean eon, from 4.6 to 3.85 billion years ago (see Figure 25.1 and Table 23.1), causing a cycle of vaporization of water in the oceans, which then cooled and recondensed.

STUDY BREAK 25.1

1. **Why is the reducing nature of early Earth's atmosphere key to the Oparin–Haldane theory of the origin of molecules necessary for life?**
2. **How do the theories about the sites for the origin of life differ?**

25.2 The Origin of Cells

No matter where organic molecules originated, they do not qualify as life. In this section, we discuss the key stage in the origin of life—the formation of the first cells.

Protocells Formed with Some of the Properties of Life

How did organic building blocks such as amino acids assemble into macromolecules such as proteins and nucleic acids? To answer this question, researchers have proposed and tested several processes. One process is the concentration of subunits by the evaporation of water. Another is *dehydration synthesis (condensation),* in which subunits assemble into larger molecules through removal of the elements of a molecule of water (see Section 3.1). Experiments with these processes under simulated conditions showed that both evaporation and condensation reactions can produce polypeptide chains from amino acids, polysaccharides from glucose and other monosaccharides, and nucleotides and nucleic acids from nitrogenous bases, ribose, and phosphates.

Scientists reason that spontaneous condensations and other reactions produced significant quantities of all the major biological molecules over the hundreds of millions of years following the initial formation of Earth. They hypothesize that the accumulation of organic matter set up the conditions necessary for the next stage, the chance assembly of molecules into aggregations that became membrane-bound to form primitive protocells, perhaps by 4.0 billion years ago **(Figure 25.3A).** Protocells are key to the origin of life, because life depends on reactions occurring in a controlled and sequestered environment, the cell. Researchers have proposed several mechanisms for the assembly of organic molecules into aggregates, each of which has been successfully duplicated in laboratory experiments simulating primordial conditions. Two of those mechanisms are adsorption into clays and lipid bilayer assembly.

EXPERIMENTAL SUPPORT FOR ADSORPTION INTO CLAYS Could clays have provided an ideal environment for molecular aggregation and interaction on the primitive Earth? Clays consist of very thin layers of minerals separated by layers of water only a few nanometers thick. The layered structure readily adsorbs ions and organic molecules and promotes their interactions, including condensations and other assembly reactions. Clays can also store potential energy, and therefore could have channeled some of the energy into reactions taking place between molecules adsorbed to them.

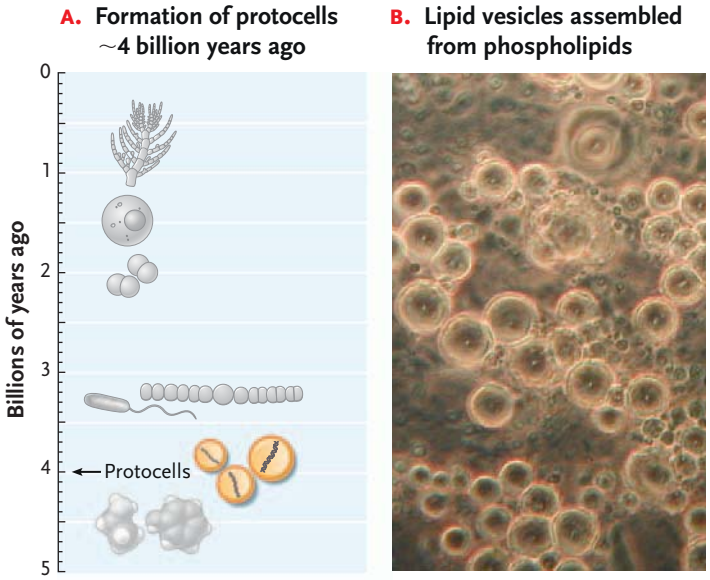

FIGURE 25.3 Protocells. (A) As a key event in the origin of life, protocells are thought to have formed ~4 billion years ago. **(B)** Phase micrograph of lipid vesicles assembled from phospholipids. Structurally, primitive protocells were vesicle-like, with a lipid bilayer membrane surrounding aggregations of major biological molecules.

© Cengage Learning 2014

Several experiments have supported these proposals. For example, in the 1970s Noam Lahav at the Hebrew University of Jerusalem and Sherwood Chang of NASA's Ames Research Center added amino acids to clays and exposed the mixtures to water-content changes and fluctuating temperatures that are likely to occur in a tidal flat. After several cycles of the fluctuating conditions, polypeptides were detected in the clays. Other researchers found that RNA nucleotides linked to phosphate chains could combine into RNA-like molecules in clays. Accumulation of these and other macromolecules in the clays could have provided an environment in which they could react to carry out the first reactions of life.

However, even if molecules became organized in clay and some of the reactions of life commenced, it is not clear how a lipid bilayer membrane could have formed around them. Such a membrane is necessary to organize the molecules into protocells, the presumed precursors of cells. (The biological importance of lipid bilayers and membranes are discussed in Sections 2.4, 3.3, and 6.1.)

EXPERIMENTAL SUPPORT FOR LIPID BILAYER ASSEMBLY In the 1950s, R. J. Goldacre at Chester Beatty Research Institute, London, hypothesized that protocells could have formed starting with lipid bilayers that had assembled spontaneously. In the

1970s, David W. Deamer at the University of California, Davis, and other investigators tested this hypothesis, finding that phospholipids and some other types of lipid molecules could form under simulated conditions. The phospholipids self-assembled readily into bilayers when suspended in water (see Section 6.1). Often, the bilayers rounded up into stable, closed vesicles called liposomes, consisting of a continuous-boundary "membrane" surrounding an inner space **(Figure 25.3B).**

Further tests showed that the bilayers formed in these experiments have many properties of living membranes. For example, they can incorporate proteins onto their surfaces or into the hydrophobic membrane interior and they form vesicles that can trap other substances in the fluid enclosed by the membrane. Potentially, on early Earth, the concentration of organic molecules in such vesicles could have stimulated their expansion in size and fragmentation into smaller vesicles, providing a primitive form of reproduction. These mechanisms of aggregation, as well as others, may have worked separately or together to form protocells.

Researchers continue to experiment on producing protocells in the laboratory as a step toward understanding the transition from the protocell to the living cell. Present-day thinking is that a boundary membrane system must have evolved simultaneously with a genetic information system, rather than one being formed before the other, as some earlier models have proposed. Experimental approaches being used are therefore directed toward generating self-replicating nucleic acid and membrane vesicle systems.

Living Cells May Have Developed from Protocells

Eventually the chemical reactions taking place in the primitive protocells became organized enough to make the transition to living cells. Exactly how this occurred is open to speculation. Two of the critical events necessary for the transition are the development of pathways that captured and harnessed the energy required to drive molecular synthesis, and the development of a system for the storage, replication, and translation of information for protein synthesis. Remember that proteins are the catalysts for most cellular reactions. How the information system developed is crucial to our understanding of the origin of life. The development of energy-harnessing reaction pathways is not well understood. Here we focus on the development of the information system.

In contemporary organisms, information flows from DNA to RNA to protein. This nucleic acid-based information system depends mostly on enzymatic proteins for replication, transcription, and translation of the nucleic acids. However, the specificity of enzymatic proteins depends on their amino acid sequences, which are determined by the sequences of nucleotides in nucleic acids. Thus, proteins depend on nucleic acids for their structure, and nucleic acids depend on proteins to catalyze their activities. How could one have appeared before the other? Scientists hypothesize the information system developed in stages.

The prevalent model for the development of the information system is the **RNA world model.** The RNA world model states that the first genes *and* enzymes were RNA molecules. That is, *ribozymes*—RNA molecules capable of catalyzing biochemical reactions—may have functioned both as informational molecules and as catalysts in protocells, without requiring protein enzymes for catalytic reactions (ribozymes are discussed in Section 4.6). Thus, a self-catalyzed RNA world may have been the first step in the development of an information system. (See *Unanswered Questions* in Chapter 4 for more about the RNA world model.)

Ribozymes may have originally developed by the chance assembly of RNA nucleotides taking part in oxidative and other metabolic reactions in protocells (RNA nucleotides such as ATP, NAD, and coenzyme A form important parts of many metabolic pathways, including glycolysis, respiration, and photosynthesis; see Chapters 8 and 9). The RNA molecules then developed the capacity to replicate themselves and other RNA molecules. That is, these RNA molecules acted both as templates—like mRNA—and as catalysts—like ribosomal RNA (see Section 15.4). Then ribozymes could replicate ribozymes, with no need for protein enzymes. Such self-replicating systems may have provided the basis of an RNA-based informational system, and founded the RNA world. *Insights from the Molecular Revolution* describes an experiment in which ribozymes that can replicate RNA were generated in a test tube.

In the RNA world, DNA would have developed as a subsequent step. At first, DNA nucleotides may have been produced by random removal of an oxygen atom from the ribose subunits of the RNA nucleotides. At some point, the DNA nucleotides paired with the RNA informational molecules, and were assembled into complementary copies of the RNA sequences. Some modern day viruses carry out this RNA-to-DNA reaction using the enzyme reverse transcriptase (see Section 18.1). Once the DNA copies were made, selection may have favored DNA as the informational storage molecule because it has greater chemical stability and can be assembled into much longer coding sequences than RNA can. RNA was left to function at intermediate steps between the stored information in DNA and protein synthesis, as it still does today.

As the RNA-based information system evolved, some RNAs may have acted as tRNA-like molecules, linking to amino acids and pairing with the RNA informational molecules. These associations could have led to the assembly of polypeptides with an ordered sequence of amino acids—the development of an RNA genetic code. When DNA took over information storage from RNA, the DNA would have picked up the code information that could then be transferred back to RNA by transcription.

Modern analysis of the ribosome, the organelle responsible for translation of mRNA (see Section 15.4) has shown that the enzymatic activity that catalyzes the formation of a peptide bond between amino acids is a function of one of the RNA molecules of the ribosome. This finding supports the proposal that, in addition to replicating themselves, RNA molecules also generated the first proteins.

Toward the Evolution of Life in the Lab: The construction of protocell-like vesicles containing an active ribozyme

Life is characterized by membrane-bound cells that grow and divide, and in which enzymatic reactions take place in a controlled and sequestered environment. We have learned in this chapter so far that living cells may have developed from protocells. And the discovery of ribozymes led to the proposal that an RNA world was the first step in the development of a molecular information system that could store, replicate, and translate the information required for protein synthesis. Constructing a simple protocell in the lab that contains an active ribozyme would provide a system with which to explore the possible steps for the origin and early evolution of life. That is, the simplest cellular system capable of evolution requires a self-replicating informational molecule, and a means to compartmentalize that molecule.

Research Goal

Construct stable protocell-like vesicles capable of growth, and that contain an active ribozyme.

Experiments

Jack Szostak and his research team at the Howard Hughes Medical Institute and Harvard Medical School set out to construct model protocell vesicles. Many chemicals are capable of forming simple vesicles, but the key requirement here is that the vesicle membrane must be stable and capable of growth under conditions that favor ribozyme activity. For example, fatty acids form vesicles that can grow and divide, but ribozymes cannot function in them because they need magnesium ions (Mg^{2+}) for activity, and divalent cations such as Mg^{2+} cause the fatty acids to precipitate.

Results

The researchers found that a mixture of particular, chemically simple amphiphiles (molecules with both hydrophilic and lipophilic properties) form vesicles with the desired protocell-like properties. That is, these vesicles are stable and grow, but, importantly, remain intact in the presence of Mg^{2+}. The vesicles are also permeable to Mg^{2+}, as shown by an experiment in which a ribozyme included in the vesicles became active and self-cleaved when Mg^{2+} was added to the solution.

Conclusion

The researchers successfully constructed simple vesicles containing active ribozymes. They concluded that the stability of the vesicles, and their ability to grow and allow the diffusion into them of Mg^{2+}, are "critical for building model protocells in the laboratory and may have been important for early cellular evolution."

THINK LIKE A SCIENTIST Why was the observation that a ribozyme could become activated within the protocell-like vesicles important?

Source: I. A. Chen, K. Salehi-Ashtiani, and J. W. Szostak. 2005. RNA catalysis in model protocell vesicles. *Journal of the American Chemical Society* 127:13213–13219.

Of course, we have no way of knowing exactly how life originated. Sifting through the various models and theories, we can perhaps agree that there were some basic steps: (1) the abiotic (nonliving) synthesis of organic molecules such as amino acids; (2) the assembly of complex organic molecules from simple molecules, including protein or RNA or both; and (3) the aggregation of complex organic molecules (likely including those of the information system) inside membrane-bound protocells. Once the information system fully developed in the protocells, and it could replicate, and the protocells could divide, they became true living cells. The advent of living cells marked the beginning of biological evolution, which depends on cells that can reproduce and pass on information to their descendants.

Prokaryotic Cells Were the First Living Cells

The change to biological evolution set the stage for the appearance of all the features of cellular life. One of these features was a nuclear region that contained the DNA of the coding system and the mechanisms replicating the DNA and transcribing it into RNA. Another feature was a cytoplasmic region containing ribosomes and the enzymes required to translate RNA information into sequences of amino acids in proteins. The cytoplasm also contained an oxidative system supplying chemical energy for protein synthesis and assembly of other required molecules. A mechanism of cell division also evolved, allowing replicated DNA to be distributed equally between daughter cells. All these systems were enclosed by a membrane controlling the flow of molecules and ions in and out of the cell. The stages leading to this level may have taken more than a billion years, occupying the period from Earth's formation 4.6 billion years ago to about 3.5 billion years ago.

There is geological evidence of different kinds for early life:

- **Isotope ratios determined by radiometric dating.** Radiometric dating is a technique used to date a rock and is based on the decay of isotopes in the rock (see Section 23.1). Each isotope of an element has a specific decay rate. However, if rock is subjected to biological activity that uses one isotope preferentially over another, then the ratio of the two isotopes will differ from that in inert rock from the same time. Thus, an altered isotope ratio in rock or mineral samples can be interpreted as evidence of biological activity. The earliest rock samples showing a significant alteration of an isotope ratio, interpreted to involve preferential use of $^{12}CO_2$ rather than $^{13}CO_2$ (as is seen in present-day bacteria), date to about 3.7 billion years ago. This may mark the earliest evidence of biochemical reactions by living cells which, by any present theory, would be prokaryotes.
- **Stromatolites.** Fossil stromatolites are layers of carbonate or silicate rock that resemble present-day stromatolites **(Figure 25.4A).** Geologists think that the fossils formed as layers of phototrophic prokaryotes grew and died, and their remaining forms were filled in by calcium carbonate or silica. ("Phototrophic" refers to an organism that obtains energy from light.) The earliest fossil stromatolites that are accepted by ge-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ologists date to about 3.4 billion years ago in the oldest rocks of the Archaean eon. However, the fossil rock is too deformed to allow details of cell structure to be analyzed, and some researchers question whether they are of biological origin.

- **Biosignatures. Biosignatures** are particular organic molecules in sedimentary rocks that could only have been formed by cellular activity. There are limited examples of biosignature molecules. One is a steroidlike molecule that is found only in the membrane lipids of cyanobacteria, and in no other organism known today. That particular biosignature molecule has been found in rock dated to 2.5 billion years ago, providing evidence for the presence of cyanobacteria by the end of the Archaean eon. Cyanobacteria are photosynthetic organisms. Since photosynthesis is a complex metabolic process, more primitive prokaryotes must have developed at an earlier time.
- **Microfossils.** A **microfossil** is the remains of a cell that has decayed and been filled in by calcium carbonate or silica **(Figure 25.4B).** (Section 23.1 discusses the fossil record and its use in providing information about life in the past.) The earliest microfossils are of filamentous and single-celled prokaryotes, and they date to about 2.0 billion years ago. Those microfossils are considered the most convincing geological evidence of early life. Microfossils from around 1.5 billion years ago include some with larger cells that resemble cells of present-day eukaryotic protists (see Chapter 27).

In sum, prokaryotes probably appeared first about 3.5 billion years ago and eukaryotes first appeared about 1.5 billion years ago, or perhaps earlier.

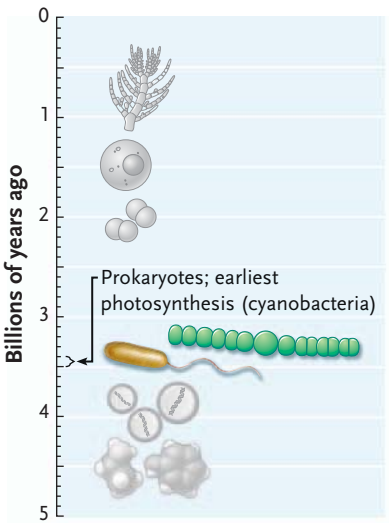
Subsequent Events Increased the Oxidizing Nature of the Atmosphere

According to Richard E. Dickerson of University of California, Los Angeles, and others, the earliest form of photosynthesis evolved about 3.5 billion years ago in the early prokaryotes. This form of photosynthesis probably used electron donors such as hydrogen sulfide (H_2S) that do not release oxygen. However, at some point, an enzymatic system evolved that could use the most abundant molecule of the environment, water (H_2O), as the electron donor for photosynthesis. This reaction split water into protons, electrons, and oxygen, which was released into the atmosphere.

The oxygen released by the water-splitting reaction accumulated in the atmosphere and set the stage for the development of electron transfer systems using oxygen as the final electron acceptor. These transfer systems arose when some cells developed cytochromes that could deliver low-energy electrons to oxygen (see Section 8.4). These cells were able to tap the greatest possible amount of energy from the electrons before releasing them from electron transfer, making the cells highly successful in their environment.

The first water-splitting photosynthesizers confirmed by fossil evidence are the cyanobacteria. As you learned earlier, convincing evidence from biosignatures indicates cyanobacteria were present 2.5 billion years ago. Present-day stromatolites predominantly contain cyanobacteria but, as stated earlier, the types of prokaryotes in fossil stromatolites cannot be identified with any certainty. If the stromatolites do contain cyanobacteria, that would date early water-splitting photosynthesis to about 3.4 billion years ago.

The photosynthesizing activity of cyanobacteria produced a gradual rise in the amount of oxygen in early Earth's atmosphere. That rising oxygen concentration likely killed off many prokaryotic groups to which oxygen is lethal. Around 2 billion years ago, the concentration of oxygen began to increase more rapidly. This abrupt change may correlate with the evolution of eukaryotic cells containing chloroplasts.



These major events established the preconditions for the evolution of eukaryotic cells. The next section traces this evolution, which was pivotal to the later evolution of large-scale multicellularity and the plants, animals, and the other organisms of the domain Eukarya.

FIGURE 25.4 Geological evidence for early life.

STUDY BREAK 25.2

Several mechanisms have been proposed for the assembly of organic molecules into protocells. Why is the model involving a lipid bilayer membrane a particularly attractive one?

THINK OUTSIDE THE BOOK

Individually or collaboratively investigate banded iron formations and outline the following in your investigation: (1) what they are; and (2) how researchers consider that they provide evidence for the presence of particular oxygen-producing organisms on early Earth.

25.3 The Origins of Eukaryotic Cells

Present-day eukaryotic cells have several interrelated characteristics that distinguish them from prokaryotes: (1) the separation of DNA and cytoplasm by a nuclear envelope; (2) the presence in the cytoplasm of membrane-bound compartments with specialized metabolic and synthetic functions—mitochondria, chloroplasts, the endoplasmic reticulum (ER), and the Golgi complex, among others; and (3) highly specialized motor (contractile) proteins that move cells and internal cell parts. In this section we discuss how eukaryotes most probably evolved from associations of prokaryotes. As you read, note that there are more good theories for the origin of eukaryotes than there are good data.

The Endosymbiotic Theory Proposes That Mitochondria and Chloroplasts Evolved from Ingested Prokaryotes

The **endosymbiotic theory,** put forward by Lynn Margulis at the University of Massachusetts, Amherst, proposes that the membranous organelles of eukaryotic cells, the mitochondria and chloroplasts, may each have originated from mutualistic (mutually advantageous) relationships between two prokaryotic cells **(Figure 25.5).** The theory proposes that the following events occurred:

1. **Generation of endosymbionts.** Mitochondria began to develop when photosynthetic and nonphotosynthetic prokaryotes coexisted in an oxygen-rich atmosphere. The nonphotosynthetic prokaryotes fed themselves by ingesting organic molecules from their environment. These prokaryotes included both anaerobes, which are unable to use oxygen as the final acceptor for electron transfer, and aerobes, which are fully capable of using oxygen. Only the aerobes could fully exploit the energy stored in organic molecules, but predatory anaerobes could capture that energy by eating aerobic cells. These anaerobic prokaryotes had become efficient predators, and lived by ingesting other cells. Among the ingested cells were some aerobic prokaryotes; instead of being digested, some of them persisted in the cytoplasm of the predators and continued to respire aerobically in their new location. They had become **endosymbionts,** organisms that live symbiotically within a host cell. The cytoplasm of the host anaerobe, formerly limited to the use of organic molecules as final electron acceptors, was now home to an aerobe capable of carrying out the much more efficient transfer of electrons to oxygen. From an evolutionary

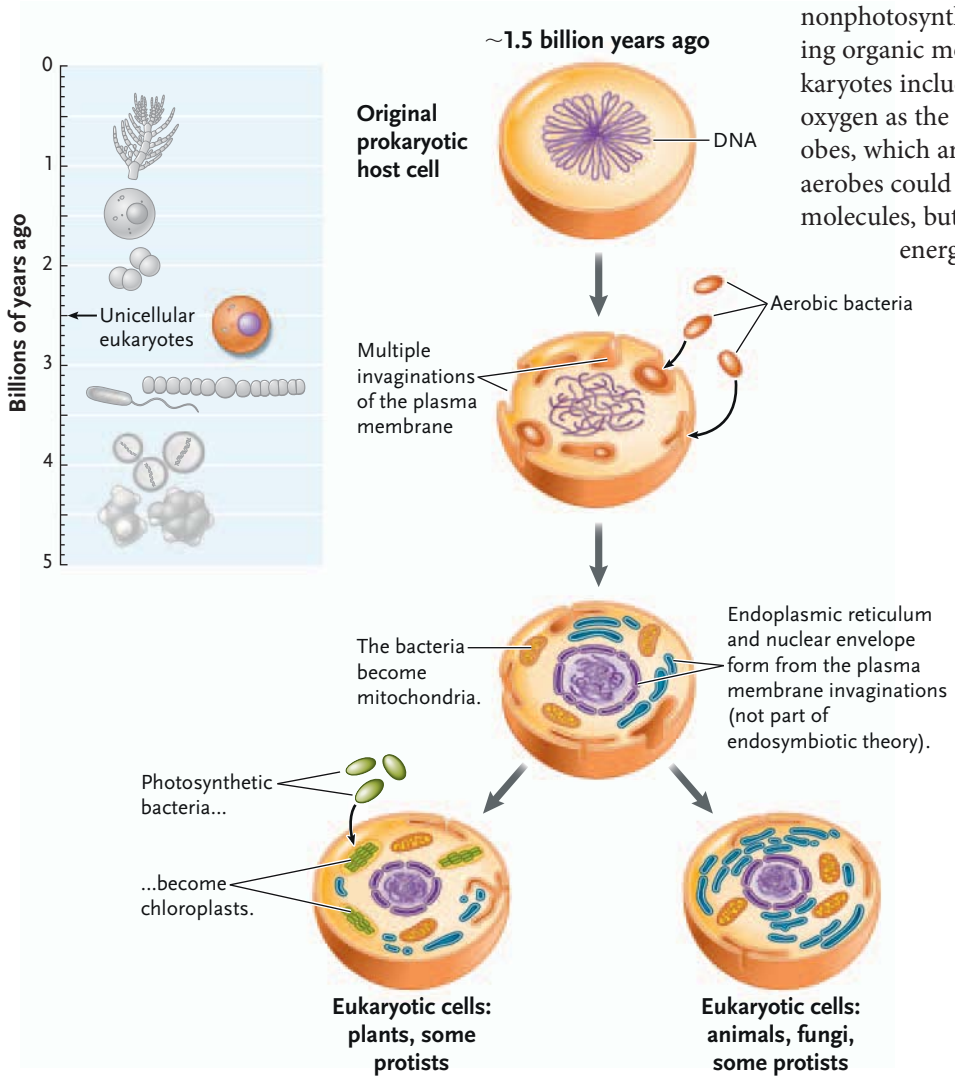

FIGURE 25.5 The endosymbiotic theory. The mitochondrion is thought to have originated from an aerobic prokaryote that lived as an endosymbiont within an anaerobic prokaryote. The chloroplast is thought to have originated from a photosynthetic prokaryote that became an endosymbiont within an aerobic cell that had mitochondria.

perspective, cells that had engulfed respiring bacterial cells capable of cellular respiration would have been at a considerable advantage compared to other cells, so natural selection would have favored their persistence. They could ingest simple carbohydrates from their environment and metabolize them as a source of energy.

2. **Formation of the nucleus and other membranous structures.** As a part of the transition to a true eukaryotic cell, the cell also evolved to acquire other membranous structures, the major ones being the nuclear envelope, the endoplasmic reticulum (ER), and the Golgi complex. Endocytosis, the process of infolding of the plasma membrane (see Figure 5.15), is thought to be responsible for the evolution of these structures. Researchers think that, in cell lines leading from prokaryotes to eukaryotes, pockets of the plasma membrane formed during endocytosis may have extended inward and surrounded the nuclear region. Some of these membranes fused around the DNA, forming the nuclear envelope and, hence, the nucleus. The remaining membranes formed vesicles in the cytoplasm that gave rise to the ER and the Golgi complex **(Figure 25.6).**
3. **Transfer of many functions from endosymbiont to the host cell.** Next, many functions duplicated in the aerobic endosymbiont were taken over by the host cell. As part of this transfer of function, most of the genes of the aerobe moved to the cell nucleus and became integrated into the host cell's DNA. At the same time, the host anaerobe became dependent for its survival on the respiratory capacity of the symbiotic aerobe. The ingested aerobe presumably benefited as well, because the host cell brought in large quantities of food molecules to be oxidized. This gradual process of mutual adaptation culminated in transformation of the cytoplasmic aerobe into a mitochondrion. The first eukaryotic cells had appeared, the ancestors of all modern-day eukaryotes.

The endosymbiotic theory also proposes that a similar mechanism led to the appearance of the membrane-bound **plastids** (the general term for chloroplasts and related organelles, both photosynthetic and nonphotosynthetic: see Section 5.4) some time after mitochondria evolved. A plastid originated when an aerobic cell that had a mitochondrion and were therefore capable of efficient cellular respiration, but was unable to carry out photosynthesis, ingested one or more photosynthetic prokaryotes resembling present-day cyanobacteria (see Figure 25.5). Cells that had engulfed photosynthetic prokaryotes were now capable of photosynthesis and no longer needed to ingest simple carbohydrates for energy. That is, the engulfed bacteria within them produced the carbon dioxide from carbon dioxide and water, with energy provided by sunlight. A photosynthetic prokaryote gradually changed into a plastid by evolutionary processes similar to those that produced a mitochondrion. A cell with both a plastid and a mitochondrion founded the cell lines that gave rise to the modern eukaryotic algae and plants.

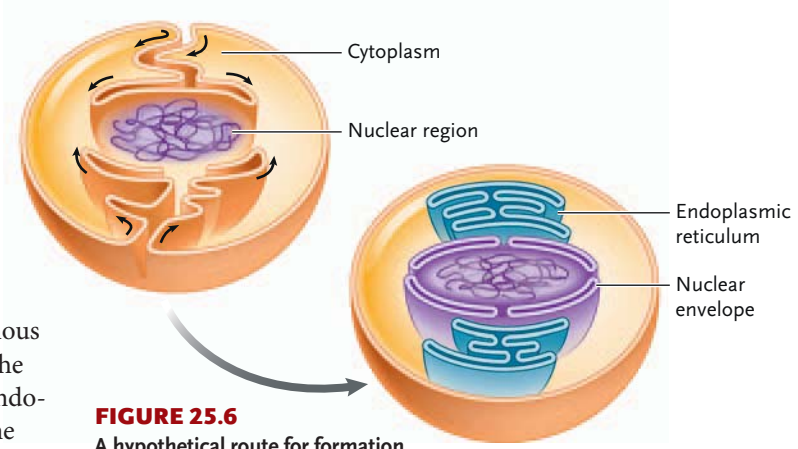

FIGURE 25.6
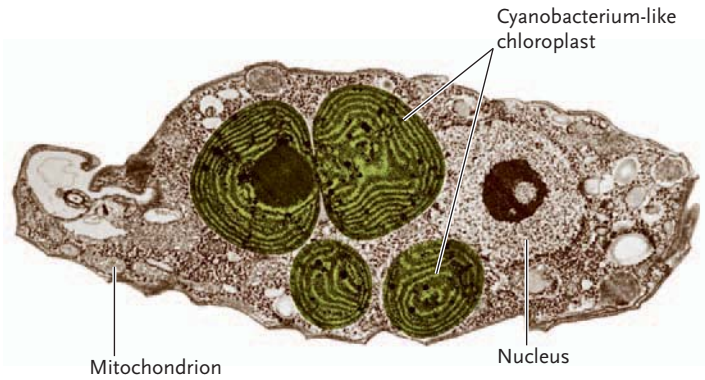
A hypothetical route for formation of the nuclear envelope and endoplasmic reticulum, through segments of the plasma membrane that were brought into the cytoplasm by endocytosis.
© Cengage Learning 2014



Several Lines of Evidence Support the Endosymbiotic Theory

A lot of evidence supports the endosymbiotic theory, including the following:

1. Mitochondria and plastids are similar in size to bacteria.
2. Both organelles divide by a process similar to binary fission (see Section 10.5).
3. Both organelles typically contain circular DNA molecules that closely resemble bacterial chromosomes.
4. The genomes of both organelles contain codes for ribosomes that resemble those found in bacteria rather than those found in eukaryotes. The rRNA components of the ribosomes are encoded by organelle genes.
5. Both organelles are surrounded by two or more membranes, the innermost of which has a chemical composition similar to that of a bacterial plasma membrane.
6. Chloroplasts resemble cyanobacteria in their internal structure, including the presence of particular chlorophylls and the existence of thylakoids. Moreover, DNA sequence analysis indicates that chloroplast DNA most closely resembles the DNA in modern cyanobacteria, with many of the same genes, supporting the conclusion that an ancient cyanobacterium was the ancestor of chloroplasts.

Another line of evidence supports a key assumption of the endosymbiont hypothesis by showing that engulfed cells or organelles can survive in the cytoplasm of the ingesting cell. Among animals, no less than 150 living genera, distributed among 11 phyla, include species that contain eukaryotic algae or cyanobacteria as residents in the cytoplasm of their cells. For example, larvae of the marine slug *Elysia* initially contain no chloroplasts, but after they begin feeding on algae, chloroplasts from the algal cells are taken up into the cells lining the gut. When the larvae develop into adult snails, the chloroplasts continue to carry out photosynthesis in their new location and produce carbohydrates that are used by the snails. Some of the

chloroplast proteins synthesized during this time are encoded by genes in the slug's nuclear genome. The uptake of functional chloroplasts has also been observed among the protists (see Chapter 27); **Figure 25.7** shows a protist with chloroplasts that closely resemble cyanobacteria.

How long did it take for evolutionary mechanisms to produce fully eukaryotic cells? The oldest known convincing microfossil eukaryotes are 1.5 billion years old. If prokaryotic cells first evolved some 3.5 billion years ago, it took up to 2 billion years for eukaryotic cells to evolve from prokaryotes (see Figure 25.1). If so, this long interval probably reflects the complexity of the adaptations leading from prokaryotic to eukaryotic cells. Of course, it is possible that eukaryotic cells evolved more quickly, and we have yet to find the supporting evidence.

Eukaryotic Cells May Have Evolved from a Common Ancestral Line Shared with Archaeans

The system of classification that has gained acceptance among biologists, and the one used in this book, groups all living organisms into three domains. One domain, Eukarya, contains the eukaryotes. The second domain, Bacteria, includes one of two groups of prokaryotes, the bacteria, which consists of both photosynthesizing and nonphotosynthesizing species. The third domain, Archaea, contains the other group of prokaryotes, the archaeans, many of which inhabit extreme environments, including highly saline environments and hot springs.

There is little question that the three domains originated from a common ancestral cell line. However, the events leading from this common ancestry to the three domains of life remain unclear. The most difficult questions surround the role of the archaeans in both bacterial and eukaryotic evolution.

Archaeans have some features that are typical of bacteria, including a circular DNA genome in a nucleoid region without a surrounding nuclear envelope, and no membrane-bound organelles in the cytoplasm. However, the archaeans also have some features that are typically eukaryotic, including the presence of introns (see Section 15.3) in some of their genes. The archaeans also have some characteristics that are unique to their domain, including features of gene and rRNA sequences, and features of cell wall and plasma membrane structure that are found nowhere else among living organisms. The characteristics shared by archaeans and eukaryotes suggest that their roots may lie in a common ancestral line that split off from the line leading to bacteria (see Figure 24.17). At some point, this ancestral line split into the lines leading to Domain Archaea and Domain Eukarya.

Multicellular Eukaryotes Probably Evolved in Colonies of Cells

The first eukaryotes were unicellular. They are the ancestors of the present-day diversity of unicellular eukaryotes. Multicellular eukaryotes evolved from unicellular eukaryotes and then diverged to produce multiple eukaryotic lineages. Molecular clock analysis indicates the first multicellular eukaryote likely arose between 800 and 1,000 million years ago, while the first fossil records (of small algae) are from 600 to 800 million years ago.

According to the prevalent theory, multicellular eukaryotes arose by the aggregation of cells of the same species into a colony. The ability to act in a coordinated way probably increased the capacity of colonies to adapt to changes in the environment. Subsequently, differentiation of cells into various specialized cell types with distinct functions produced organisms with a wider range of capabilities and adaptability. Cell differentiation in a colony would have required cell signals that affected gene expression. That is, because each cell in the colony has the same genome, the development of specific functions (phenotypes) would require intracellular signals that would change the program of gene regulation. (Gene regulation in eukaryotes is discussed in Section 16.4.) Over time, as genomes evolved, the division of function among cells led to the evolution of the tissues and organ systems of complex eukaryotes.

Multicellularity evolved several times in early eukaryotes, producing a number of lineages of algae as well as the ancestors of present day fungi, plants, and animals.

Life May Have Been the Inevitable Consequence of the Physical Conditions of the Primitive Earth

Some researchers maintain that the evolution of life on our planet was an inevitable outcome of the initial physical and chemical conditions established by Earth's origin, among them a reducing atmosphere (at least in some locations), a size that generates moderate gravitational forces, and a distance from the Sun that results in average surface temperatures between the freezing and boiling points of water. Given the same conditions and sufficient time, according to these scientists, it is inevitable that life has evolved or is evolving now on other planets in the universe.

The chapters that follow in this unit trace the course of evolution and its products after eukaryotic cells were added to the prokaryotes already living on Earth. Among prokaryotes, evolution established two major groups, the bacteria and ar-

chaea; among eukaryotes, further evolution established the protists, fungi, plants, and animals. The survey of life's diversity begins in the next chapter with a description of present-day bacteria and archaeans.

STUDY BREAK 25.3

What are the key points of the theory of endosymbiont origins for mitochondria and chloroplasts?

UNANSWERED QUESTIONS

What was the first polymer of life?

As discussed in this chapter, many researchers favor RNA for this role. This is because it both self-replicates and can catalyze chemical reactions, and is neatly connected with the contemporary life based on nucleic acids and proteins. There are, however, several problems with this hypothesis. One of them is that synthesis of RNA and its building blocks, nucleotides, is quite difficult under primordial conditions. To circumvent this difficulty, several researchers proposed that other genetic polymers that are simpler to synthesize might have preceded RNA. For example, Albert Eschenmoser from the Swiss Federal Institute of Technology (ETH) in Zurich replaced the difficult-to-synthesize ribose portion of nucleotides by the six-membered sugar pyranose. These polymers are stable and form a double helix. Most recently, Philipp Holliger and his group at the MRC Laboratory of Molecular Biology, Cambridge, U.K. showed that genetic information can be transferred between DNA and its analogs containing different sugars, xeno-nucleic acids. Another proposal is that the initial complement of nucleic acid bases was different than A, U, G, and C. This proposal is motivated by the poor stability of cytosine in water. Although we have no evidence that polymers alternative to contemporary nucleic acids were present on the early Earth, it is important to realize that such a possibility exists and might be used by life elsewhere.

The protein-first hypothesis is currently less popular, even though these polymers are excellent catalysts of chemical reactions, and their building blocks, amino acids, existed on prebiotic Earth and are found in relatively large quantities in meteorites. This is because there is no known mechanism for proteins to self-replicate. Some researchers speculate that a limited replication of proteins is possible. An alternative hypothesis is that replication of individual polymers was not necessary at the origin of life and, instead, the reproduction of protein functions in a population was initially sufficient. Currently, neither view has sufficient experimental support, but as we learn more about the structure and functions of small proteins major surprises might be in store.

THINK LIKE A SCIENTIST If RNA molecules were the first molecules capable of catalyzing biochemical reactions, why were they replaced by proteins?

Andrew Pohorille

Andrew Pohorille heads the NASA Center for Computational Astrobiology and Fundamental Biology at NASA's Ames Research Center. He is also professor of Chemistry and Pharmaceutical Chemistry at the University of California, San Francisco. For his work on the origin of life he was awarded the 2002 NASA Exceptional Scientific Achievement Medal.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

25.1 The Formation of Molecules Necessary for Life

- Living cells are characterized by a boundary membrane, one or more nucleic acid coding molecules in a nuclear region, a system for using the coded information to make proteins, and a metabolic system providing energy for those activities.
- Oparin and Haldane independently hypothesized that life arose *de novo* under the conditions they thought prevailed on the primitive Earth, including a reducing atmosphere that lacked oxygen. Reduction reactions, fueled by natural energy acting on the primitive atmosphere, produced organic molecules. Random aggregations of these molecules were able to carry out primitive reactions which were characteristic of life and that gradually became more complex until life appeared. Chemistry simulation experiments support the hypothesis that organic molecules would form under these conditions (Figure 25.2).
- Present thinking is that early Earth's atmosphere was not reducing, but in fact was neutral (neither reducing nor oxidizing). This has caused skepticism about Oparin and Haldane's hypothesis. One new theory proposes that life developed near hydrothermal vents in the sea floor.

Animation: Milestones in the history of life

Animation: Miller's reaction chamber experiment

25.2 The Origin of Cells

- Organic molecules produced in early Earth's environment by chance formed aggregates that became membrane-bound in protocells, primitive cell-like structures with some of the properties of life. Protocells may have been the precursors of cells (Figure 25.3).
- Next, living cells may have developed from protocells by the development of several critical components, in particular a system based on nucleic acids that could store and pass on the information required to make proteins.
- Subsequently, fully cellular life evolved, with a nuclear region containing DNA and the mechanisms for copying its information into RNA messages; a cytoplasmic region containing systems for utilizing energy and systems for translating RNA messages into proteins; a membrane separating the cell from its surroundings; and a reproductive system duplicating the informational molecules and dividing them among daughter cells.
- The first living cells were prokaryotes. Eventually, some early cells developed the capacity to carry out photosynthesis using water as an electron donor; the oxygen produced as a by-product accumulated and the oxidizing character of Earth's atmosphere increased. From this time on organic molecules produced in the environment were quickly broken down by oxidation, and life could arise only from preexisting life, as in today's world.

25.3 The Origins of Eukaryotic Cells

- According to the endosymbiotic theory, mitochondria evolved from ingested prokaryotes that were capable of using oxygen as final electron acceptors; chloroplasts evolved from ingested cyanobacteria (Figure 25.5).
- Eukaryotic structures such as the ER, Golgi complex, and nuclear envelope appeared through infoldings of the plasma membrane as a part of endocytosis (Figure 25.6).
- Multicellular eukaryotes probably evolved by differentiation of cells of the same species that had aggregated into colonies. Multicellularity evolved several times, producing lineages of several algae and ancestors of fungi, plants, and animals.

Animation: Eukaryotic evolution (formerly "endosymbiont theory")

UNDERSTAND & APPLY

Test Your Knowledge

1. Earth was formed ___ years ago, whereas the oldest known living cell formed about ___ years ago.
   a. 400×10^3; 3.6×10^6.
   b. 4.6×10^9; 1.0×10^9.
   c. 3.8×10^9; 4.6×10^7.
   d. 4.6×10^9; 3.5×10^9.
   e. 2.0×10^9; 600×10^6.
2. Which of the following is *not* a characteristic of all living organisms?
   a. They replicate genetic information and convert the information into proteins.
   b. They pass genetic information between generations.
   c. They have an internal metabolic system that provides energy for biological activity.
   d. They use external energy to drive internal reactions that require energy.
   e. They use mitochondria for synthesis of ATP.
3. Evidence for the appearance of the following is separated by the greatest amount of time:
   a. nonlife: prokaryotes.
   b. photosynthetic prokaryotes: first eukaryotes.
   c. nonphotosynthetic bacteria: photosynthetic bacteria.
   d. unicellular eukaryotes: multicellular eukaryotes.
   e. first prokaryotic cells: first eukaryotic cells.
4. According to the Oparin–Haldane hypothesis, the atmosphere when life began was believed to be composed primarily of the following substances that contain the maximum number of electrons:
   a. H_2O, N_2, and CO_2.
   b. H_2, H_2O, NH_3, and CH_4.
   c. H_2O, N_2, O_2, and CO_2.
   d. O_2 and no H_2.
   e. H_2 only.
5. The Miller–Urey experiment:
   a. was based on the understanding that the atmosphere was oxidizing.
   b. was able to synthesize amino acids and macromolecules from reduced gases.
   c. did not require much energy or a continuous energy source to keep synthesizing.
   d. did not require water to produce organic molecules.
   e. used free oxygen as a reactant.
6. An unknown organism was found in a park. It was unicellular, had no nuclear membrane around its DNA, and contained no mitochondria and no chloroplasts. It is most likely a:
   a. eukaryote.
   b. vertebrate or plant.
   c. bacteria or archaean.
   d. plant or fungi.
   e. virus.
7. Hydrothermal vents are theorized as sources for the origin of life because:
   a. the temperature of the water around them supports most life.
   b. most organic molecules undergo dehydration synthesis at high temperatures.
   c. the amino acids degrade in the colder water soon after synthesis.
   d. water is needed by living things.
   e. reducing conditions and abundant chemicals exist.
8. For the transition of protocells to living cells, which of the following probably had to occur?
   a. DNA had to code for cell membranes.
   b. Proteins had to be aggregated by RNA.
   c. Ribozymes had to adsorb onto clays.
   d. H_2O, which is essential for the chemistry of all biological systems, had to become available to cells via metabolism and dehydration synthesis.
   e. Informational molecules, such as ribozymes, had to evolve.
9. As part of the evolution of eukaryotic cell, endocytosis, the process of infolding of the plasma membrane, led to the formation of:
   a. chromosomes.
   b. the cell wall.
   c. ribosomes.
   d. the nuclear envelope.
   e. microtubules.
10. Which of the following is *not* part of the evidence supporting the endosymbiotic theory? Both mitochondria and plastids:
    a. are each the size of many bacterial cells.
    b. have inner membranes with a chemical composition similar to that of a bacterial plasma membrane.
    c. have ribosomes that are similar to bacterial ribosomes.
    d. contain circular DNA.
    e. have DNA similar to nuclear DNA.

Discuss the Concepts

1. What evidence supports the idea that life originated through inanimate chemical processes?
2. Explain, in terms of hydrophilic and hydrophobic interactions, how protocells might have formed in water from aggregations of lipids, proteins, and nucleic acids.
3. What conditions would likely be necessary on a planet located elsewhere in the universe for life to originate in a way similar to that which occurred on Earth?
4. Most scientists agree that life on Earth can arise only from preexisting life, but also that life could have originated spontaneously on the primordial Earth. Can you reconcile these seemingly contradictory statements?

Design an Experiment

Suppose you discover a hot spring-fed pool on a remote mountain that has never before been explored by humans. In the pool you find a cellular life form that appears to be prokaryotic. What experiments would you do to distinguish between the alternative hypotheses that this organism evolved on Earth from ancestral prokaryotes, or is descended from a life form that arrived at that location in a meteorite?

Interpret the Data

Studies of ancient rocks and fossils can provide insight into many of the events in Earth's history, including changes in its atmosphere that have taken place over geologic time. The **Figure** shows how asteroid impacts and the composition of the atmosphere have changed over time. Use this figure and information in the chapter to answer the following questions.

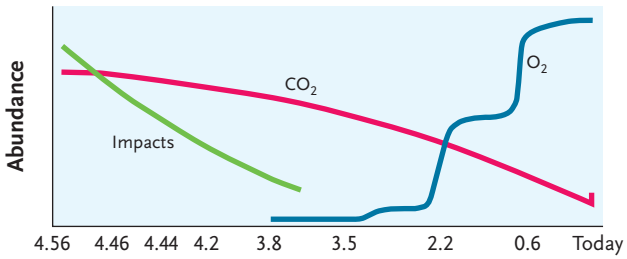

FIGURE **Changes over geologic time in asteroid impacts (green), atmospheric carbon dioxide concentration (pink), and oxygen concentration (blue).**

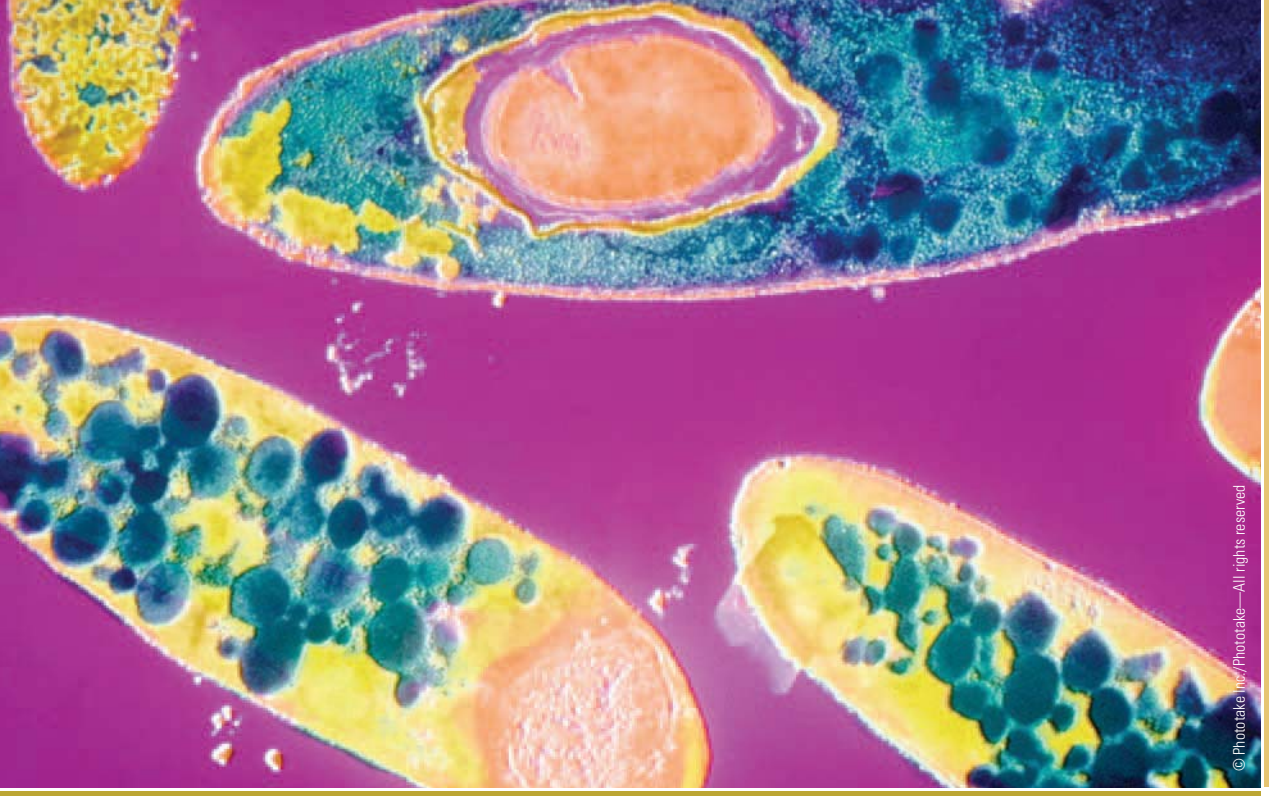

© Cengage Learning 2014

1. Which occurred first, a decline in asteroid impacts or a rise in the atmospheric level of oxygen?
2. How do modern levels of carbon dioxide and oxygen compare to those at the time when the first cells arose?
3. Which is now more abundant, oxygen or carbon dioxide?

Apply Evolutionary Thinking

In the evolution unit, you learned how changes in the environment can foster evolutionary changes in biological systems. How have changing biological systems influenced the evolution of changes in Earth's physical environment?

STUDY OUTLINE

26.1 Prokaryotic Structure and Function
26.2 The Domain Bacteria
26.3 The Domain Archaea

Prokaryotes: Bacteria and Archaea

Why it matters . . . You wait in line at a fast-food restaurant, eagerly anticipating your hamburger. In the back of your mind you may worry because, not too many years ago, people were sickened, and a few even died, because their fast-food hamburgers were contaminated by a pathogenic strain of the bacterium *Escherichia coli,* the normally harmless bacteria that inhabit our intestinal tract. Since then, fast-food restaurants have cooked their hamburgers well beyond the point required to kill any lurking pathogenic *E. coli* or other pathogenic species of bacteria.

The bacterium *E. coli* is a prokaryote, an organism lacking a true nucleus. Prokaryotes, the topic of this chapter, are the smallest organisms in the world **(Figure 26.1).** Few species are more than 1 to 2 μm long; from 500 to 1,000 of them would fit side by side across the dot above this letter "i."

Prokaryotes are small, but their total collective mass (their *biomass*) on Earth may be greater than that of all plant life. They colonize every niche on Earth that supports life, meaning essentially everywhere. Huge numbers of bacteria inhabit surfaces and cavities of the human body, including the skin, the mouth and nasal passages, the large intestine, and the vagina. Collectively, bacteria in and on the human body outnumber the body's own cells by about tenfold.

On the basis of molecular phylogenetics analyses, biologists classify prokaryotes into two of the three domains of life, the **Archaea** and the **Bacteria** (see Section 24.7 and Figure 24.16). The third domain, the **Eukarya,** includes all eukaryotes. Bacteria are the prokaryotic organisms most familiar to us, including many types responsible for diseases of humans and other animals and many other types found in a wide variety of ecosystems. Many members of the domain Archaea (*arkhaios* = ancient) live under conditions so extreme, including high salinity, acidity, or temperature, that their environments cannot be tolerated by other organ-

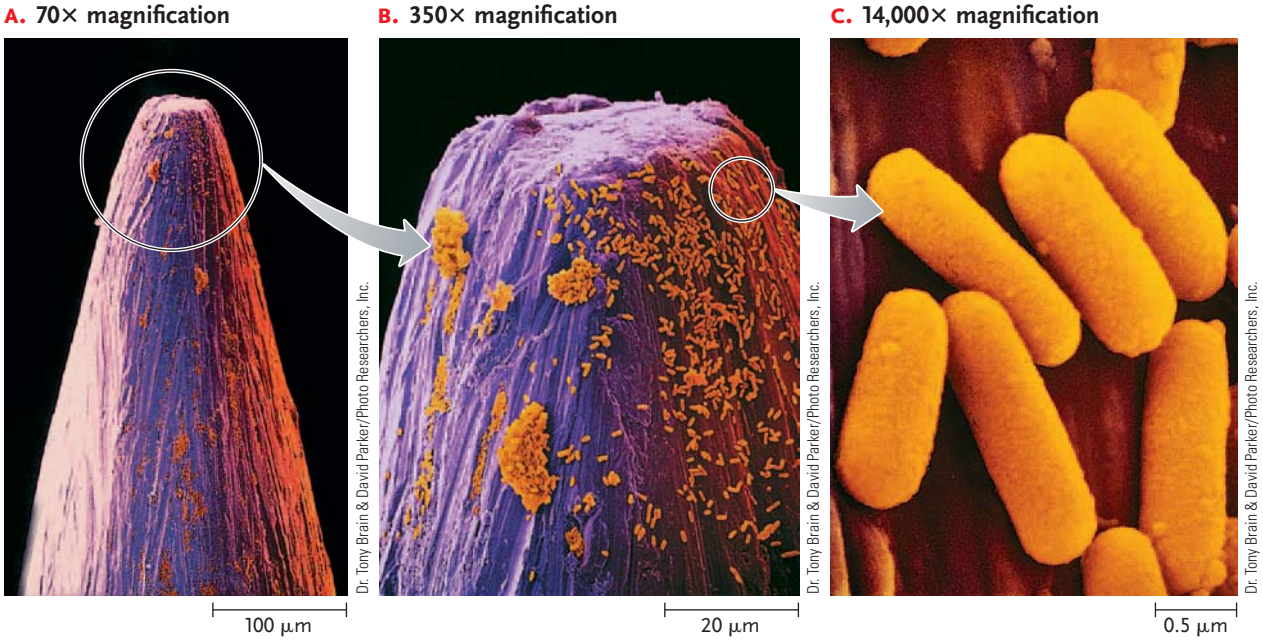

FIGURE 26.1 ***Bacillus*** **bacteria on the point of a pin.**

isms, including bacteria. In general, archaeans are less well studied, and therefore less well understood compared to bacteria.

As a group, prokaryotes have a wide range of metabolic capabilities. Their metabolic activities are crucial for maintenance of the biosphere. In particular, prokaryotes are the key players in the life-sustaining recycling of the elements carbon, nitrogen, and oxygen. For example, prokaryotes (along with other organisms) break down organic material in dead plants and animals, releasing carbon dioxide that is used for plant growth. In addition, prokaryotes are necessary to make nitrogen available to most forms of life. And a significant amount of the oxygen in the atmosphere originates from bacterial photosynthesis. An illustration of prokaryotes' importance is Biosphere 2, an attempt by scientists to build a completely closed ecosystem in Arizona. The attempt failed, in part because the researchers did not have a complete enough understanding of the activities of the microorganisms in the soil. Through respiration by soil microorganisms, the oxygen level in the Biosphere structure decreased to lower-than-expected levels and the ecosystem could no longer sustain itself. This small-scale example illustrates the essential role of prokaryotes in enabling life of all forms to exist.

Prokaryotes also have specific impacts on the lives of humans. Among other things, they are important for the production of certain foods; they carry out chemical reactions that are of importance in industry; they are used for the production of pharmaceutical products; they cause diseases; and they are used for bioremediation of polluted sites.

In Chapter 25 you learned how prokaryotic cells likely were produced from protocells. Evolution has generated the diversity of prokaryotes on Earth today. In this chapter you will learn about the structure and function of prokaryotes, and about the diverse organisms in the evolutionary branches of Bacteria and Archaea.

26.1 Prokaryotic Structure and Function

Prokaryotes show great diversity in their ability to colonize areas that can sustain life. Their cells are small and, while prokaryotes show a greater structural diversity than eukaryotes, prokaryotic cells are not as complex in organization as eukaryotic cells. For instance, although prokaryotes do not have a membrane-bound nucleus or organelles, their DNA and some proteins are localized in particular places. They vary in how their cell membrane is protected, and some species have specialized surface structures that protect them from their environment or that enable them to move actively. Prokaryotes also show great diversity in the ways they obtain energy and in their metabolic activities.

The diversity of prokaryotes has arisen through rapid adaptation to their environments as a result of evolution by natural selection. Genetic variability in prokaryotic populations, the basis for this rapid adaptation, derives largely from mutation and to a lesser degree from the transfer of genes between organisms by horizontal gene transfer, that is, by transformation, transduction, and conjugation (see Chapter 17). Since prokaryotes have much shorter generation times than eukaryotes and smaller genomes (roughly 1,000 times smaller than an average eukaryote), prokaryotes have roughly 1,000 times more mutations per gene, per unit time, per individual, than do eukaryotes. Furthermore, prokaryotes typically have much larger population sizes than eukaryotes, which contributes to their

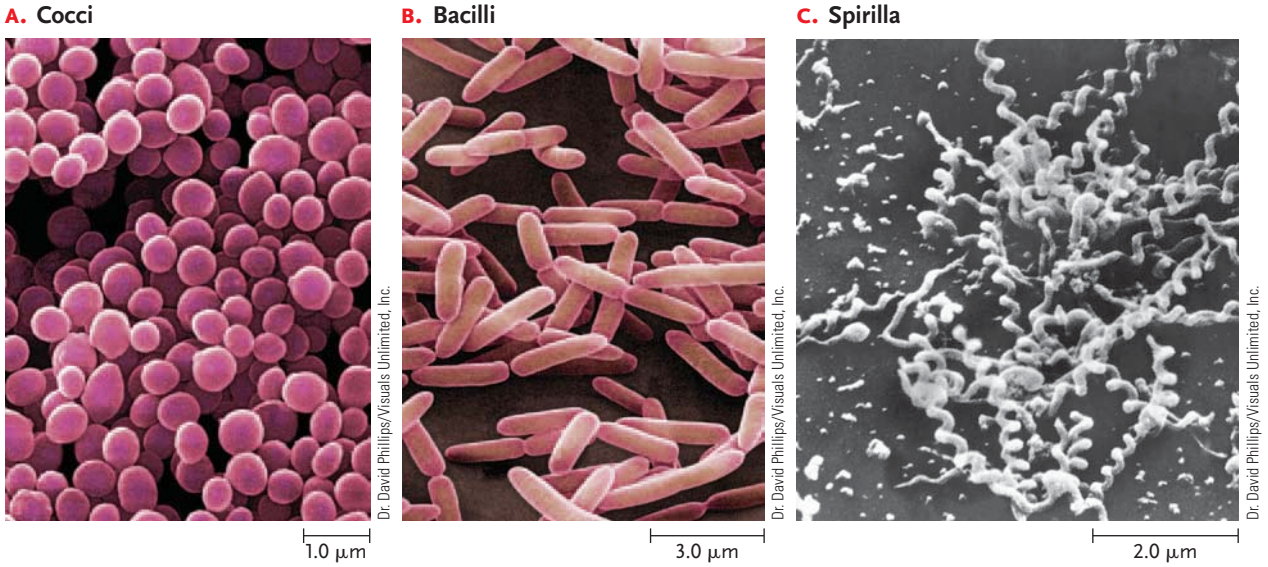

FIGURE 26.2 Common shapes among prokaryotes. (A) Scanning electron microscope (SEM) image of cocci of *Micrococcus* bacteria; **(B)** SEM image of bacilli of *Salmonella* bacteria; **(C)** SEM image of spirilla of *Spiroplasma* bacteria.

greater genetic variability. In short, prokaryotes have an enormous capacity to adapt, and this has been the key to their evolutionary success.

Prokaryotes Are Different in Structure and Organization from Eukaryotic Cells

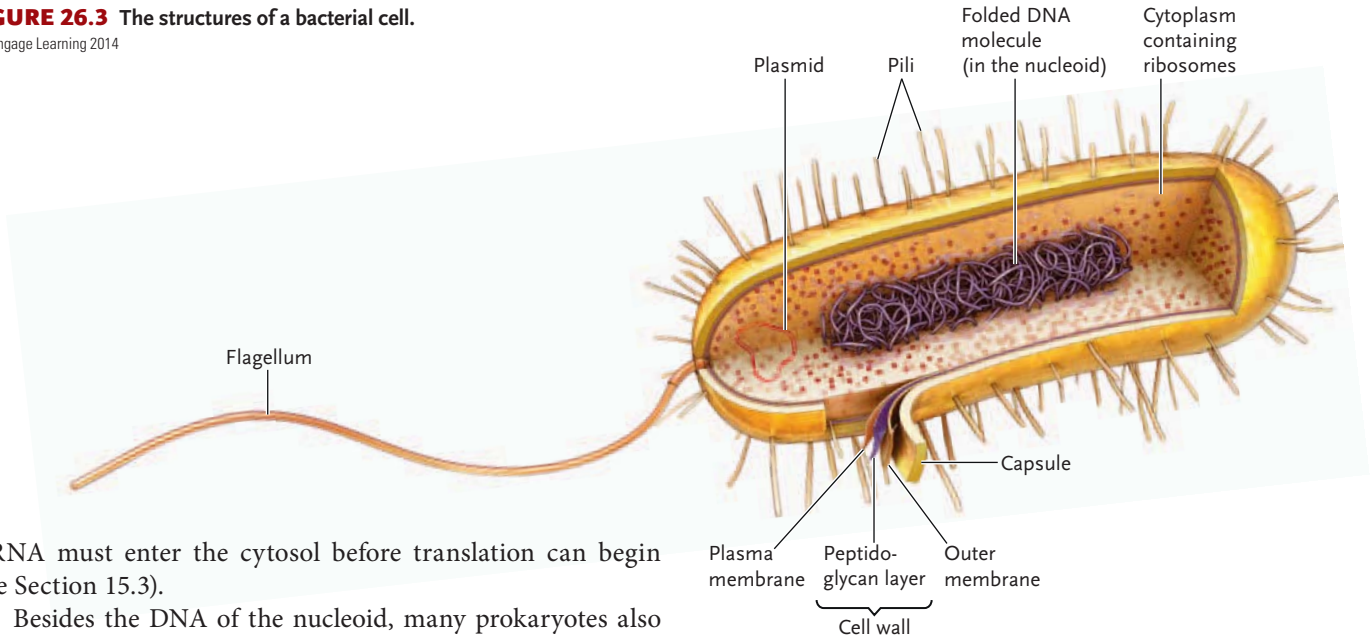
Like eukaryotic cells, prokaryotic cells are bounded by a plasma membrane. Prokaryotic cells also have a cell wall, which provides reinforcement and protection. Within the cell, the genetic material of prokaryotes is localized to a nonmembrane enclosed area of the cell, rather than being in a membrane-bound nucleus as in eukaryotes. Many prokaryotic species contain few if any internal membranes; they lack, therefore, the membrane-bound organelles characteristic of eukaryotic cells, including mitochondria, endoplasmic reticulum, Golgi complex, and chloroplasts. With few exceptions, the reactions carried out by these organelles in eukaryotes are distributed between the cytoplasmic solution and the plasma membrane in prokaryotes.

As you learned in Chapter 5, both prokaryotic and eukaryotic cells have cytoskeletons. Prokaryotic cytoskeletons play important roles in creating and maintaining the proper shape of cells, in cell division and, in certain prokaryotes, in determining polarity of the cells.

Although prokaryotic cells appear relatively simple according to this description, their simplicity is deceptive. Most can use a variety of substances as energy and carbon sources, and they can synthesize almost all of their required organic molecules from simple inorganic raw materials. In many respects, prokaryotes are more biochemically versatile than eukaryotes.

The following specifics of prokaryotic structure illustrate some of the diversity seen in this group of organisms.

SHAPE Three shapes are common among prokaryotes: spheres, rods, and spirals **(Figure 26.2).** The spherical prokaryotes are **cocci** (singular, *coccus*) (*kokkos* = berry). Cylindrical or rod-shaped prokaryotes are **bacilli** (singular, *bacillus*) (*bacillus* = small staff or rod). The spiral prokaryotes are the **spirilla** (singular, *spirillum*) (*speira* = coil, twist, wreath), which are twisted helically like a corkscrew, and **vibrios** (*vibrare* = to move quickly to and fro), which are curved and commalike. Among the prokaryotes of all structural types are some that live singly and others that link into chains or aggregates of cells.



INTERNAL STRUCTURES The genome of most prokaryotes consists of a single, circular DNA molecule called the *prokaryotic chromosome.* A few bacterial species, for example the causative agent of Lyme disease *(Borrelia burgdorferi),* have a linear chromosome. Genome sequencing projects have shown that the range of genome sizes among bacteria and archaeans is about 20-fold, with the smallest genome of any organism that can be cultured in the laboratory, that of *Mycoplasma genitalium,* being about 580,000 bp.

In all prokaryotes, the chromosome is packed into a central area of the cell called the **nucleoid.** The nucleoid has no nucleolus, and it has no boundary membranes equivalent to the nuclear envelope of eukaryotes (**Figure 26.3;** and see Sections 5.2 and 5.3). The arrangement of the genetic material in prokaryotes permits the translation of mRNA transcripts of protein-coding genes to begin while transcription is in progress. This is possible because the mRNA is immediately accessible to ribosomes, the cellular structures upon which translation takes place. Simultaneous transcription and translation is not possible in eukaryotes because the ribosomes are in the cytosol and the DNA is in the nucleus. Transcription and mRNA processing must be completed in the nucleus, and the

FIGURE 26.3 The structures of a bacterial cell.

© Cengage Learning 2014

mRNA must enter the cytosol before translation can begin (see Section 15.3).

Besides the DNA of the nucleoid, many prokaryotes also contain small circles of DNA called **plasmids,** which are distributed in the cytoplasm. The plasmids, which often contain genes with functions that supplement those in the nucleoid, contain a replication origin that allows them to replicate along with the nucleoid DNA and be passed on during cell division (see Section 14.5).

Prokaryotic ribosomes are smaller than eukaryotic ribosomes and contain fewer proteins and RNA molecules. Archaeal ribosomes resemble those of bacteria in size, but differ in structure. Scientists have demonstrated that, with some differences in detail, bacterial ribosomes carry out protein synthesis by the same mechanisms as those of eukaryotes (see Section 15.4). Interestingly, protein synthesis in archaeans is a combination of bacterial and eukaryotic processes, with some unique archaeal features. As a result, antibiotics that stop bacterial infections by targeting ribosome activity do not stop protein synthesis of archaeans.

Some prokaryotes are capable of photosynthesis. Photosynthetic bacteria and archaeans have complex layers of intercellular membranes formed by invaginations of the plasma membrane on which photosynthesis takes place. Those membranous structures correspond to those that carry out photosynthesis in plants, but they are organized differently.

The cytoplasm of many prokaryotes also contains storage granules holding glycogen, lipids, phosphates, or other materials. The stored material is used as an energy reserve or a source of building blocks for synthetic reactions.

PROKARYOTIC CELL WALLS The plasma membrane of prokaryotes must withstand both high intracellular osmotic pressures and the action of natural chemicals in the environment that have detergent properties. Most prokaryotes have one or more layers of materials coating the plasma membrane to form a cell wall that provides the necessary protection, although the structure of the wall is quite different in bacteria and archaeans.

Bacteria typically are surrounded by a cell wall. The primary structural molecule of bacterial cell walls is **peptidoglycan,** a polymer formed from a polysaccharide backbone tied together by short polypeptides. (Polysaccharides are described in Section 3.2.) Peptidoglycan varies in chemical structure among different bacterial species.

Differences in bacterial cell wall composition are of clinical importance. In 1882, Hans Christian Gram, a Danish physician, developed a staining method to distinguish two types of bacteria in body fluids, each of which could cause pneumonia. In this **Gram stain technique,** an investigator treats bacteria with the dye crystal violet and then with iodine, which fixes the dye to the cell wall. Next the bacteria are washed with alcohol, and then treated with a second stain, either fuchsin or safranin. Bacteria that appear purple after these steps have retained the crystal violet stain; they are **Gram-positive.** Bacteria that appear pink after these steps have lost the crystal violet stain in the alcohol wash and are stained pink with the second dye; they are **Gram-negative.** (Gram-positive cells also react with the second dye, but the stain does not affect the color imparted by the crystal violet.)

The staining difference reflects differences in the cell walls of the bacteria **(Figure 26.4).** The cell wall of typical Gram-positive bacteria consists of a thick peptidoglycan layer (see Figure 26.4A). In contrast, the cell wall of typical Gram-negative bacteria consists of a thin layer of peptidoglycan (see Figure 26.4B). Outside of the thin cell wall is an additional boundary membrane, called the **outer membrane,** which covers the peptidoglycan layer. The outer membrane contains **lipopolysaccharides,** assembled from lipid and polysaccharide subunits found nowhere else in nature. The outer membrane protects Gram-negative bacteria from potentially damaging substances in their environment. For example, the outer membrane of *E. coli* protects it from the detergent effects of bile re-

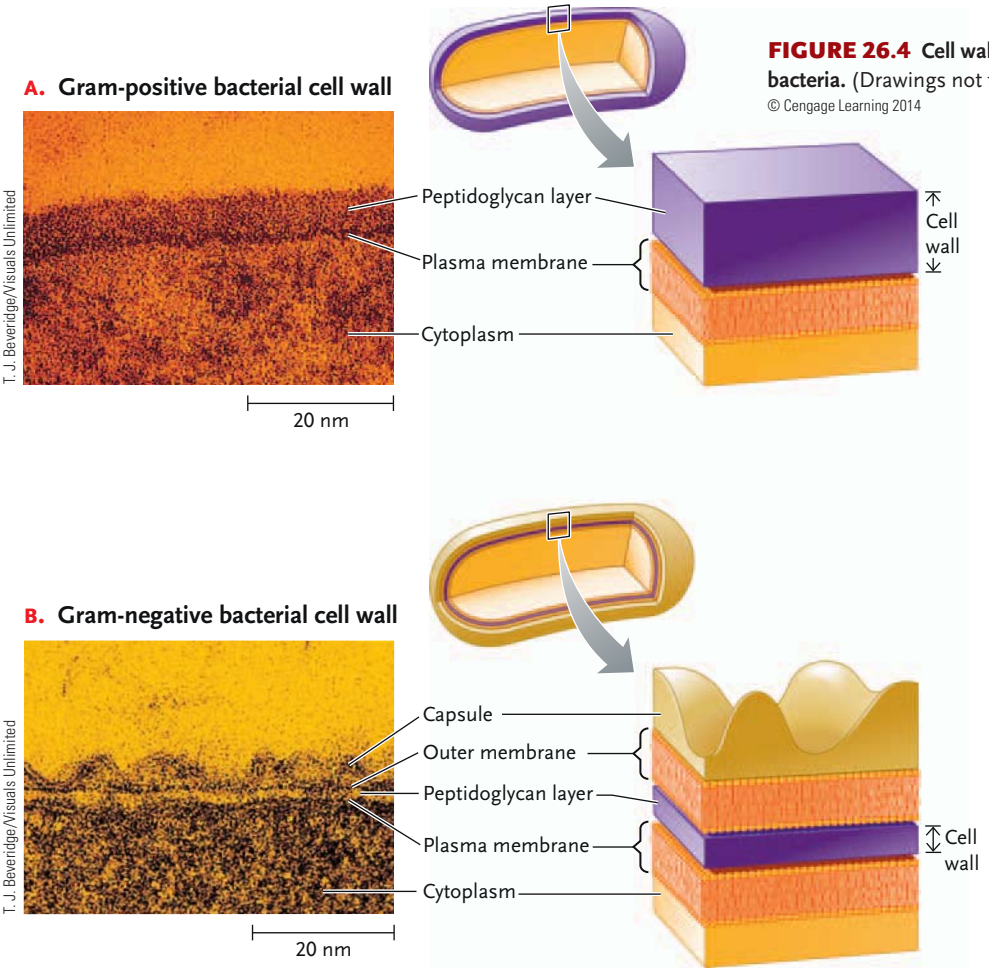

FIGURE 26.4 **Cell wall structure in Gram-positive and Gram-negative bacteria.** (Drawings not to scale.)

© Cengage Learning 2014

leased into the intestinal tract, which otherwise would lyse ("break open") the bacterium and kill it.

Rapidly distinguishing between Gram-positive and Gram-negative bacteria is important for determining the first line of treatment for bacterial-caused human diseases. Most pathogenic bacteria are Gram-negative species; their outer membrane protects them against the body's defense systems and blocks the entry of drugs such as antibiotics. For example, the antibiotic penicillin blocks new bacterial cell wall formation by inhibiting peptidoglycan crosslinking. The weakened cell wall soon leads to the death of the bacterium. Penicillin is effective against Gram-positive pathogens, but it is less effective against Gram-negative pathogens because their outer membrane inhibits entry of the antibiotic.

The walls of many Gram-positive and Gram-negative bacteria are coated with an external layer of polysaccharides called the **glycocalyx,** a slime coat typically composed of polysaccharides. When the glycocalyx is diffuse and loosely associated with the cells, it is a **slime layer;** when it is gelatinous and more firmly attached to the cells, it is a **capsule (Figure 26.5).** Depending on the species, the capsule ranges from a layer that is thinner than the cell wall to many times thicker than the entire cell. The glycocalyx helps protect cells from physical damage and desiccation, and to the effects of some antibiotics, and may enable a cell to attach to a surface.

In many bacteria, the capsule prevents bacterial viruses and molecules such as enzymes, antibiotics, and antibodies from reaching the cell surface. In many pathogenic bacteria, the presence or absence of the protective capsule differentiates virulent ("infective") from nonvirulent ("noninfective") forms. For example, normal *Streptococcus pneumoniae* bacteria are capsulated and are virulent, causing severe pneumonia in humans and other mammals. Mutant *S. pneumoniae* without capsules are nonvirulent and can easily be eliminated by the body's immune system if they are injected into mice or other animals (see Section 14.1).

Archaeans differ from bacteria by having some unique plasma membrane and cell wall characteristics. The lipid molecules in archaean plasma membranes have a chemical bond between the hydrocarbon chains and glycerol that is unlike that found in the plasma membranes of all other organisms. The difference is significant because the exceptional linkage is more resistant to disruption, making the plasma membranes of archaeans more tolerant of the extreme environmental conditions in which many of these organisms live.

The cell walls of some archaeans are assembled from molecules related to the peptidoglycans, but that have different molecular components and bonding structure. Others have walls assembled from proteins or polysaccharides instead of peptido-

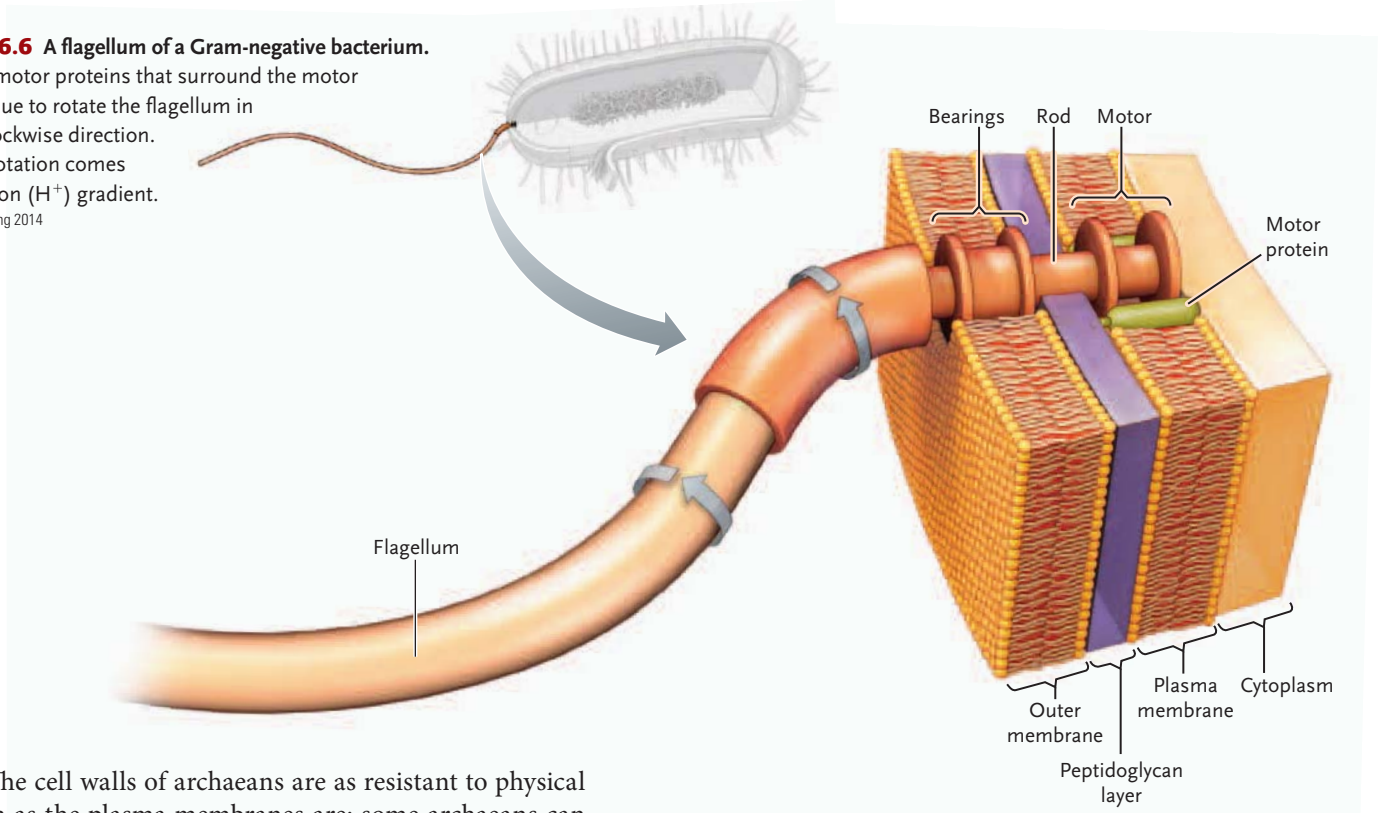

FIGURE 26.6 **A flagellum of a Gram-negative bacterium.** The ring of motor proteins that surround the motor provide torque to rotate the flagellum in a counterclockwise direction. Energy for rotation comes from a proton (H^+) gradient.

© Cengage Learning 2014

glycans. The cell walls of archaeans are as resistant to physical disruption as the plasma membranes are; some archaeans can be boiled in strong detergents without disruption. Different archaeans stain as either Gram-positive or Gram-negative.

FLAGELLA AND PILI Many bacteria and archaeans can move actively through liquids and across wet surfaces. The most common mechanism for movement involves the action of **flagella** (singular, *flagellum*) (*flagellum* = whip) extending from the cell wall **(Figure 26.6).** These flagella are much smaller and simpler than the flagella of eukaryotic cells and contain no microtubules (eukaryotic flagella are discussed in Section 5.3).

A bacterial flagellum consists of a helical fiber of protein that rotates in a socket in the cell wall and plasma membrane, much like the propeller of a boat. The rotation, produced by what is essentially a tiny electric motor, pushes the cell through liquid. The motor is powered by a proton gradient, which creates an electrical repulsion that makes the flagellum rotate. In some bacteria, flagella group together in bundles that rotate to propel the cell.

Archaeal flagella are analogous, not homologous, to bacterial flagella. That is, they carry out the same function, but they differ in their structure and mechanisms of action. The genes for the two types of flagellar systems are also different.

Some bacteria and archaeans have rigid, hairlike shafts of protein called **pili** (singular, *pilus*) extending from their cell walls **(Figure 26.7).** Among bacteria, pili are characteristic primarily of Gram-negative bacteria; relatively few Gram-positive bacteria produce these structures. Recognition proteins at the tips of pili allow bacterial cells to adhere to other cells. One type, called *sex pili,* allows bacterial cells to adhere to each other as a prelude to conjugation, a joining of two cells that leads to transfer of genetic material from one to the other (see Section 17.1). Other types help bacteria to bind to animal cells. For example, *Neisseria gonorrhoeae,* the Gram-negative bacterium that causes gonorrhea, has pili that allow it to attach to cells of the throat, eye, urogenital tract, or rectum in humans.

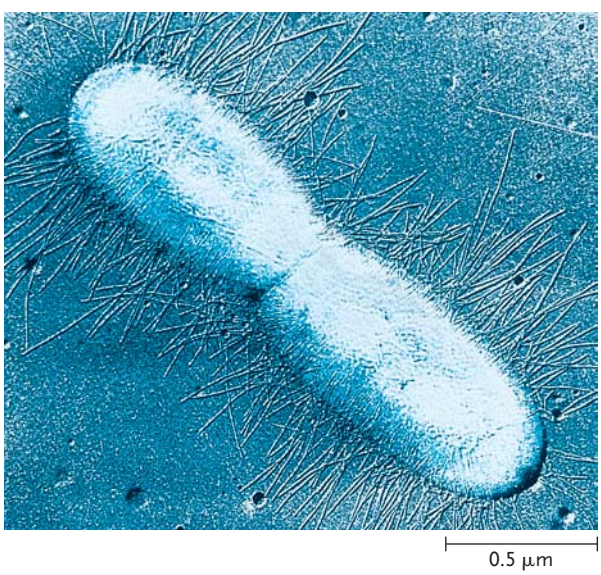

FIGURE 26.7 **Pili extending from the surface of a dividing *E. coli* bacterium.**

Prokaryotes Have the Greatest Metabolic Diversity of All Living Organisms

All organisms take in carbon and energy in some form, but prokaryotes show the greatest diversity in their modes of securing these resources **(Figure 26.8).** Prokaryotes are classified on the

*Inorganic molecules for chemoautotrophs and organic molecules for chemoheterotrophs.

FIGURE 26.8 Modes of nutrition among Bacteria and Archaea. All four modes of nutrition occur in the Bacteria, with chemoheterotrophs as the most common type. Among the Archaea, chemoautotrophs are most common, while other archaeans are chemoheterotrophs.

© Cengage Learning 2014

basis of the source of carbon atoms they use. Some prokaryotes are **autotrophs** (*auto* = self; *trophe* = nourishment), meaning that they, like plants, obtain carbon from CO_2 (which is considered to be an inorganic molecule). Others are **heterotrophs,** meaning that they, like humans and other animals, obtain carbon from organic molecules. Prokaryotic heterotrophs obtain carbon from the organic molecules of living hosts, or from organic molecules in the products, wastes, or remains of dead organisms.

Prokaryotes are also classified according to the source of the energy they use to drive biological activities. **Chemotrophs** (*chemo* = chemical; *trophe* = nourishment) obtain energy by oxidizing inorganic or organic substances, while **phototrophs** obtain energy from light. Combining carbon source and energy gives us the following four types (see Figure 26.8):

1. **Chemoautotrophs:** Prokaryotic chemoautotrophs obtain energy by oxidizing inorganic substances such as hydrogen, iron, sulfur, ammonia, nitrites, and nitrates and use CO_2 as their carbon source. They use the electrons they remove in the oxidations to make organic molecules by reducing CO_2 or to provide the energy for ATP synthesis (using an electron transfer system embedded in the plasma membrane). Chemoautotrophy occurs widely among prokaryotes, including many bacteria and most archaeans, but is not found among eukaryotes.
2. **Chemoheterotrophs:** Prokaryotic chemoheterotrophs oxidize organic molecules as their energy source and obtain carbon in organic form. They include most of the bacteria that cause disease in humans, domestic animals, and plants and many bacteria that are responsible for decomposing matter. They are the largest prokaryotic group in terms of numbers of known species.
3. **Photoautotrophs:** Photoautotrophs are photosynthetic organisms that use light as their energy source and CO_2 as their carbon source. They include several groups of bacteria, for example, the *cyanobacteria,* as well as plants and many protists. The cyanobacteria use water (H_2O) as their source of electrons for reducing CO_2. Some other types of phototrophic bacteria use sulfur or sulfur compounds.
4. **Photoheterotrophs:** Photoheterotrophs use light as their ultimate energy source and preexisting organic carbon molecules as reducing agents, but they cannot use CO_2. Photoheterotrophs are limited to three subgroups of *proteobacteria.*

Prokaryotes Differ in Whether Oxygen Can Be Used in Their Metabolism

Prokaryotes also differ in how their metabolic systems function with respect to oxygen (see Chapter 8). **Aerobes** require oxygen for cellular respiration (in other words, oxygen is the final electron acceptor for that process). **Obligate aerobes** cannot grow without oxygen. **Anaerobes** do not require oxygen to live. **Obligate anaerobes** are poisoned by oxygen, and survive either by fermentation, in which organic molecules are the final electron acceptors (see Section 8.5), or by a form of respiration in which inorganic molecules such as nitrate ions (NO_3^-) or sulfate ions (SO_4^{2-}) are used as final electron acceptors. **Facultative anaerobes** use O_2 when it is present, but under anaerobic conditions, they live by fermentation.

Prokaryotes Fix and Metabolize Nitrogen

Nitrogen is a component of amino acids and nucleotides and, hence, is of vital importance for the cell. Prokaryotes are able to metabolize nitrogen in many forms. For example, a number of bacteria and archaeans are able to reduce atmospheric nitrogen (N_2, the major component of Earth's atmosphere) to ammonia (NH_3), a process called **nitrogen fixation.** The ammonia is ionized quickly to ammonium (NH_4^+), which the cell then uses in biosynthetic pathways to produce nitrogen-containing molecules such as amino acids and nucleic acids. Nitrogen fixation is an exclusively prokaryotic process and is the only means of replenishing the nitrogen sources used by most microorganisms and by all plants and animals. In other words, all organisms use nitrogen that is fixed by bacteria. Examples of nitrogen-fixing bacteria are some of the cyanobacteria and *Azotobacter* species, which are free-living, and *Rhizobium* species, which are in symbiotic relationships with plants (see Chapter 35).

Not all bacteria convert fixed nitrogen directly into organic molecules. Some bacteria carry out **nitrification,** the conversion of ammonium (NH_4^+) to nitrate (NO_3^-). This is carried out in two steps by two types of *nitrifying bacteria.* One type of nitrifying bacterium (for example, *Nitrosomonas* species) converts ammonium to nitrite (NO_2^-), while the other (for example, *Nitrobacter* species) converts nitrite to nitrate. Because of

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

this specialization, both types of nitrifying bacteria are usually present in soils and water, with some converting ammonium to nitrite and others using that nitrite to produce nitrate. The nitrate can be used by plants and fungi to incorporate nitrogen into organic molecules. Animals obtain nitrogen in organic form by eating other organisms.

In sum, nitrification makes nitrogen available to many other organisms, including plants and animals and bacteria that cannot metabolize ammonia. You will learn more about nitrogen metabolism in connection with the nitrogen cycle (see Chapter 53). The metabolic versatility of the prokaryotes is one factor that accounts for their abundance and persistence on the planet; another factor is their impressive reproductive capacity.

Prokaryotes Pass Genes to Progeny by Binary Fission or, Rarely, from Cell to Cell by Horizontal Gene Transfer

In prokaryotes, reproduction occurs by binary fission in which a parent cell divides into two daughter cells that are exact genetic copies of the parent (see Figure 10.17). In this process, genetic material moves from generation to generation, that is, by descent.

Conjugation, in which two parent cells join or "mate," occurs in some bacterial and archaeal species. Conjugation depends on genes carried by a plasmid that replicates separately from the prokaryotic chromosome. Usually only the plasmid is passed on during conjugation, but in some bacteria, the plasmid integrates into the chromosome of the host so that host genes transfer from one parent (donor) to the other (recipient). Genetic recombination then occurs. The recombinant cell divides to produce daughter cells that differ in genetic information from either parent. The movement of genetic material between organisms by means other than descent, as is the case with conjugation, is **horizontal gene transfer.** Horizontal gene transfer by conjugation between bacterial cells is described in Section 17.1.

A small number of bacteria can produce an **endospore,** so-called because it develops *within* the cell **(Figure 26.9).** The endospore, which typically develops when environmental conditions become unfavorable, is a dormant cell containing the bacterial genome and some of the cytoplasm. It is inactive metabolically and highly resistant to heat, desiccation, and attack by enzymes or other chemical agents. In the first step of endospore formation, binary fission cuts the parent cell into two parts of unequal size. The larger cell then envelops the smaller one (which contains the genome) and surrounds it with a tough, chemically resistant protein coat; the smaller cell develops into the endospore. Rupture of the larger cell releases the endospore to the environment. If environmental conditions become favorable for growth, the spore germinates: it becomes permeable, water enters the cell, its surface coat breaks, and the cell is released in a metabolically active form.

No one is certain how long endospores can survive. There are claims that endospores survive for thousands to millions of years, but the data are controversial. They certainly can survive a very long time.

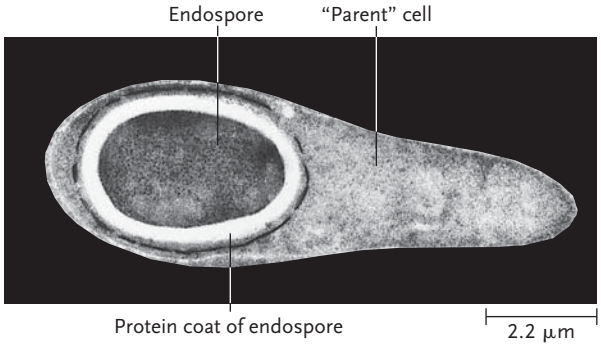

FIGURE 26.9 **A developing endospore within a cell of the bacterium *Clostridium tetani*, a dangerous pathogen that causes tetanus.**

In Nature, Bacteria May Live in Multicellular Associations

Researchers grow prokaryotes as individuals in liquid cultures or as isolated colonies on solid media. The results from studies using pure cultures have been crucial in developing an understanding of, among many other things, the nature of the genetic material, DNA replication, gene expression, and gene regulation. But, in nature, bacteria typically are not in pure cultures. Instead, there are mixed populations of bacterial species, perhaps also with archaeal and eukaryotic microbial species. Thus, information from pure cultures in the laboratory may not apply to populations of the same species in nature.

In addition, while prokaryotes are unicellular organisms, in nature prokaryotes may form *multicellular associations,* either of the same or mixed species. Those multicellular associations may function essentially as single cells do, or they may undergo some differentiation so that cells within the association carry out different functions. For example, the photoautotrophic cyanobacteria may live singly or form multicellular associations of various kinds, including filaments, sheets, or balls of cells. In the case of the cyanobacterium *Anabaena spiroides,* the cells associate into filaments in which cells differentiate into three different types: vegetative cells, *heterocysts,* and spores (see Figure 26.16B). Photosynthesis occurs only in the vegetative cells. Nitrogen starvation induces heterocysts to form. These cells lose their ability to perform photosynthesis and specialize in nitrogen fixation. Organic acids leak from the heterocysts and attract heterotrophic bacteria, which consume the oxygen surrounding the cell, thereby creating the anaerobic conditions necessary for nitrogen fixation. The third cell type, the spore, is a resting stage that can withstand adverse environmental conditions and then germinate to produce a new filament.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Another type of prokaryotic multicellular association is a **biofilm,** which consists of complex aggregation of microorganisms (either one or multiple species) attached, in most cases, to a surface. For instance, biofilms may be found on lake surfaces, on rocks in freshwater or marine environments (making the rocks slippery), surrounding plant roots and root hairs, and on animal tissues such as the intestinal mucosa and teeth (human dental plaque is a biofilm).

Biofilms may be beneficial or detrimental to humans. On the beneficial side, for example, biofilms on solid supports are used in sewage treatment plants for processing organic matter before the water is discharged. For example, biofilms adhere to many kinds of surgical equipment and supplies, including catheters and synthetic implants such as pacemakers and artificial joints. When pathogenic bacteria are involved, biofilms can cause infections which are difficult to treat, because pathogenic bacteria in a biofilm are up to 1,000 times more resistant to antibiotics than are the same bacteria in pure liquid cultures. Other examples of medical conditions resulting from the activities of biofilms include middle-ear infections, bacterial endocarditis (an infection of the heart's inner lining or the heart valves), and Legionnaire's disease (an acute respiratory infection caused by breathing in pieces of biofilms containing the pathogenic bacterium *Legionella*).

As already stated, biofilms can involve a single species, or multiple species of microorganism. They can form on a variety of organic and inorganic surfaces, and they can assume many different forms and carry out many different functions for different species. Biofilm formation may be induced by environmental signals that vary depending on the species, including temperature, pH, oxygen level, and the presence of particular amino acids.

Figure 26.10 illustrates a common pattern in the formation of many types of biofilms. The numbers in the following list correspond to the steps in the figure.

1. The species-specific environmental signal induces marked changes in the pattern of gene expression compared to that of free bacteria. In effect, the prokaryote becomes a significantly different organism. This observation is especially important in the case of pathogenic bacteria, since most research on the control of those bacteria is done with liquid cultures. (*Insights from the Molecular Revolution* presents the results of a study showing the gene expression changes in a gum-disease-causing bacterial pathogen.) The challenge is to devise new treatment strategies for biofilm-caused diseases.
2. The genetically reprogrammed bacteria attach to a surface, for example by pili or lipopolysaccharides, and secrete molecules that cause other free bacteria to attach and form a monolayer.
3. The bacteria attaching to the surface begin communicating with one another by sending and receiving chemical signals in a process called **quorum sensing.** The chemical signaling molecules are synthesized and secreted continuously by individual cells, but it is only when the population of cells reaches a certain level (a "quorum") that the concentration of the signal is high enough to be sensed. Recognition of the signal triggers more genetic changes that cause the bacteria to bind more strongly to the surface and to each other, producing small colonies.
4. The bacteria produce an extracellular matrix of polysaccharide polymers and entrapped organic and inorganic materials. The matrix enables the biofilm to mature, leading to complex three-dimensional forms in which channels supply the bacteria with nutrients for growth. Maturation of the biofilm may also involve trapping other microorganisms, including other bacterial species, algae, fungi, and/or protists, thereby producing diverse microbial communities.

Much remains to be learned about how bacteria form a biofilm, how the change in gene expression during the transition is regulated, and how they interact within the biofilm. Particularly for pathogenic bacteria, having the knowledge of genetic changes will be important for informing scientists about treating a biofilm-associated infection.

Gums the Word: Gene expression changes in an oral cavity pathogen associated with transition from free-living to biofilm

Gingivitis, a nondestructive periodontal disease, is inflammation of the gums. The gums are part of the periodontal tissue; that is, the tissue that supports the teeth. Commonly gingivitis develops due to plaque—bacterial biofilms—on the surfaces of teeth. Untreated, gingivitis can progress to periodontitis, which is a destructive periodontal disease affecting tooth-supporting tissues **(Figure)**. Without treatment, periodontitis can result in loosening and then loss of teeth.

Periodontitis is the leading cause of tooth loss in industrial nations, and one of the most frequently occurring infectious diseases in humans. *Porphyromonas gingivalis* is a Gram-negative pathogenic bacterium that is present in dental plaque. It is strongly implicated in the onset of periodontitis and the destructive progression of that disease. However, little is known about the physiology of *P. gingivalis* or about gene regulatory changes that occur in the biofilm that could relate to pathogenicity.

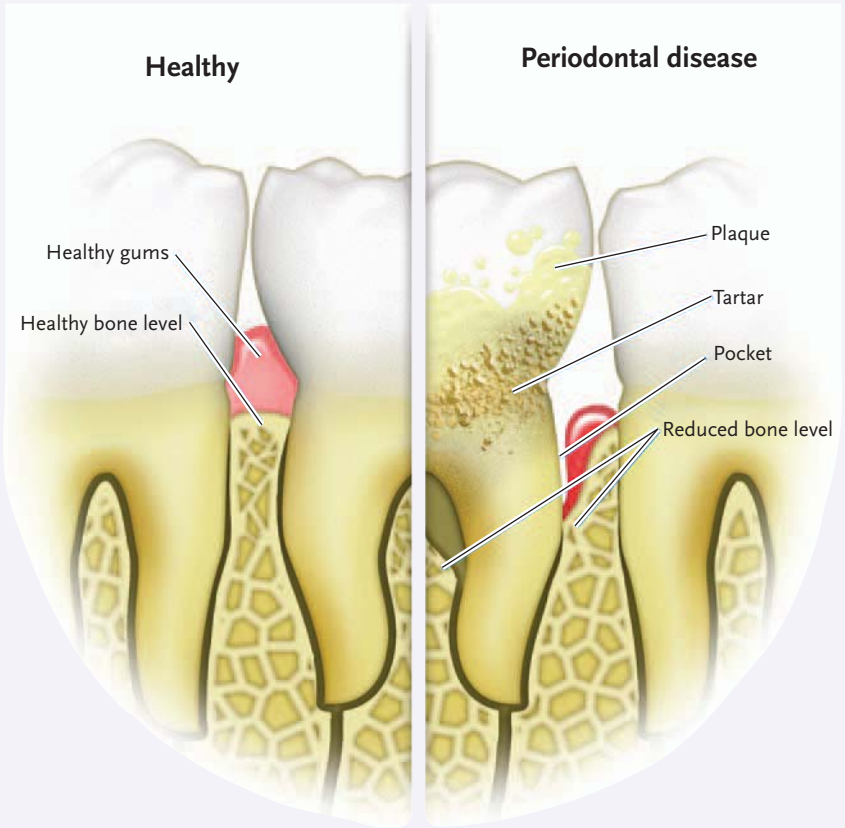
Research Question

How does gene expression differ in *P. gingivalis* in free-living cells versus cells in a biofilm?

Experiment

Eric Reynolds and his colleagues at Melbourne Dental School, The University of Melbourne, and Monash University in Australia answered this question using a genomics-based approach. That is, as was discussed in Section 18.3 and Figure 19.8, DNA microarray analysis can be used to compare, at the whole genome level, which genes are active under different conditions as well as determining the relative amount of expression. For their experiments, the researchers grew *P. gingivalis* in culture in fermenters to maintain anaerobic conditions. In one culture the bacterium was grown in a planktonic state (a culture of single cells), and in a second culture it was grown as a biofilm. Cells were harvested from each culture, RNA was extracted from the cells and from the mRNAs present, cDNA copies were made, incorporating a green fluorescent label for the cDNA derived from one culture and a red fluorescent label for the cDNA derived from the other culture. The labeled cDNAs were then mixed and added to a DNA microarray (DNA chip) containing DNA spots corresponding to all known genes of *P. gingivalis.* Hybridization of a cDNA to a spot was detected by laser analysis; the fluorescence indicated whether a particular cDNA hybridized and, therefore, whether the gene corresponding to that cDNA was active. More specifically, the results showed whether some genes were active only in free-living cells, only in biofilm cells, or active in both. For the latter, the relative amount of expression was quantified by the green and red fluorescence levels in the spot.

Results



The researchers found that 377 genes of the genome (18% of the total number of genes) were differentially expressed when the bacterium is grown as a biofilm. Of those genes, 191 were up-regulated, meaning they were expressed more in the biofilm compared with the planktonic cells, and the other 186 were down-regulated. Among those up-regulated were genes involved in transport (including signal transduction pathways), and among those down-regulated were genes involved in cell membrane synthesis, DNA replication, and energy production.

Conclusion

Taken together, the gene expression results suggest that the bacterium transitions to a decreased rate of cell replication and, hence of rate of growth, when it becomes a biofilm. The researchers argue that the changes in gene expression are involved in the adaptive response of the bacterium to growth in the biofilm state. How the changes in gene expression relate to the pathogenicity of *P. gingivalis* when it is growing in a biofilm is presently unknown. One caveat to consider here is that the experiments were done in pure cultures of the bacterium, whereas in the mouth exhibiting gingivitis, *P. gingivalis* is present in a biofilm with other microorganisms.

THINK LIKE A SCIENTIST Outline in a general way the molecular events that must occur for *P. gingivalis* to make the transition from planktonic to biofilm growth.

STUDY BREAK 26.1

1. What distinguishes a prokaryotic cell from a eukaryotic cell?
2. What is the difference between a chemoheterotroph and a photoautotroph?
3. What is the difference between an obligate anaerobe and a facultative anaerobe?
4. What is the difference between nitrogen fixation and nitrification? Why are nitrogen-fixing prokaryotes important?
5. What is a biofilm? Give an example of a biofilm that is beneficial to humans and one that is harmful.

THINK OUTSIDE THE BOOK

On your own or collaboratively, research a study in which genomic experiments have shown marked changes in gene expression pattern when a bacterium forms a biofilm. Outline how the experiment was done, and summarize the results of the experiments.

An abbreviated and simplified phylogenetic tree of prokaryotes.
© Cengage Learning 2014

26.2 The Domain Bacteria

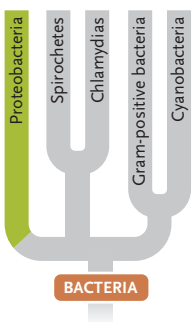

Figure 26.11 presents a simplified phylogenetic tree of the domains Bacteria and Archaea (the Eukarya is the third domain of life). This tree is a model based on molecular phylogenetics analysis of DNA sequences of a number of prokaryotes, including hundreds of complete genome sequences. (Molecular phylogenetics is discussed in Chapter 24.) It shows five major evolutionary groups; complete trees show several more groups. As more sequence data become available, undoubtedly the details of the tree in terms of the species represented will be refined and altered.

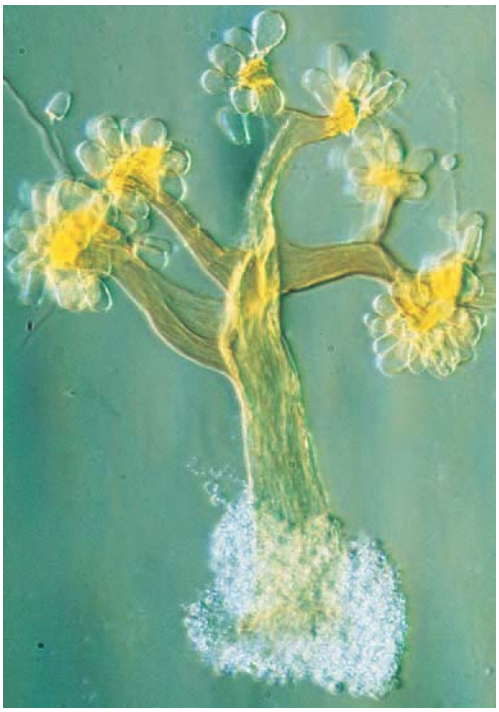
Note that phylogenetic tree construction in prokaryotes is complicated by the phenomenon of horizontal gene transfer. That is, phylogenetic tree construction involves using molecular sequence comparisons to hypothesize how observed variations in genes may be explained in terms of evolutionary lineages. An important assumption in such analysis is vertical inheritance, namely that genes are passed from parents to offspring. However, much more so for prokaryotes than for eukaryotes, evolution of genes also involves horizontal gene transfer (see Section 26.1). For scientists trying to reconstruct the phylogenetic history of a group of organisms on the basis of gene sequences, horizontal gene transfer muddies the waters significantly. That is, suppose a gene moved from ancient bacterium A to unrelated ancient bacterium B on a plasmid, and then subsequently moved to bacterium B's chromosome. Based on studying the sequences of the gene in present-day descendants, an investigator might conclude that the two bacterial species are closely related, whereas genome level studies could show them to be distantly related. The bottom line is that creating one Tree of Life that depicts the evolution of all life forms accurately and completely likely is not possible and, especially relevant to the prokaryotes, we may never understand completely how the earliest prokaryotes and eukaryotes evolved.

We discuss the major groups of the domain Bacteria in this section and of the domain Archaea in the next section.

The Five Major Evolutionary Groups of Bacteria Have Diverse Properties

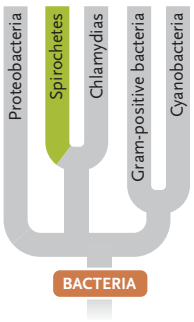
In this section we discuss the five major evolutionary groups of bacteria shown in Figure 26.11—the proteobacteria, the spirochetes, the chlamydias, the Gram-positive bacteria, and the cyanobacteria.



PROTEOBACTERIA The *proteobacteria* are a highly diverse group of Gram-negative bacteria that consist of at least 384 genera and 1,300 species. They exhibit a range of metabolic capabilities, including chemoautotrophy, chemoheterotrophy, and photoautotrophy. Some are aerobes, whereas others are anaerobes. Based on comparisons of rRNA sequences, the proteobacteria are divided into five subgroups, the Alphaproteobacteria, the Betaproteobacteria, the Gammaproteobacteria, the Deltaproteobacteria, and the Epsilonproteobacteria.

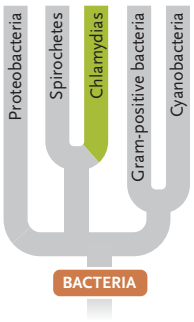
- **Alphaproteobacteria.** The alphaproteobacteria show considerable metabolic diversity. This subgroup includes many species that form symbiotic relationships with plants and animals, as well as some pathogens. For example, *Rhizobium* (see Figure 25.5) and *Agrobacterium* species infect the roots of leguminous plants to form nodules in which nitrogen fixation

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.



occurs. *Agrobacterium* infection has been developed as a method for producing transgenic plants (see Section 18.2). *Acetobacter* species convert ethanol into acetic acid, the acid component of vinegar. By law, only microbially produced vinegar can be sold in the U.S. *Rickettsia* species are obligate intracellular parasites of mammalian cells. Rocky Mountain Spotted Fever is produced as a result of a tick-borne infection involving *Rickettsia*. Mitochondria are thought to have evolved from endosymbiotic aerobic alphaproteobacteria. (The endosymbiotic theory for mitochondrion and chloroplast evolution is described in Section 25.3.)

- **Betaproteobacteria.** Betaproteobacteria are also metabolically diverse, and they include a number of important pathogens. For example, *Nitrosomonas* species are chemoautotrophs that carry out nitrification (see Section 26.1). *Bordetella pertussis* causes whooping cough in children, *Neisseria gonorrhoeae* causes the sexually transmissible disease gonorrhea, and *Neisseria meningitidis* causes meningococcal meningitis, an infection of the meninges (membranes that cover the brain and spinal cord).
- **Gammaproteobacteria.** The gammaproteobacteria are the largest subgroups of the proteobacteria. This subgroup is well known for facultative anaerobes that inhabit mammalian colons, such as *Escherichia coli* (see Figure 26.7). The subgroup also contains some important pathogens such as *Salmonella enterica typhi* (causes typhoid fever) (see Figure 26.2B), *Vibrio cholerae* (causes cholera), *Legionella* (causes legionellosis, one form of which is Legionnaire's disease), *Shigella dysenteriae* (causes dysentery), and *Haemophilus influenzae* (causes ear infections and meningitis, but not influenzae). Some gammaproteobacteria are photosynthetic; typically they are anaerobic bacteria that use photosynthesis to produce carbohydrates using chlorophyll, but do not produce oxygen.
- **Deltaproteobacteria.** The deltaproteobacteria include a group of anaerobes that are involved in the cyclic interchanges of sulfur-containing compounds in the biosphere. Other species have complex life cycles that include multicellular developmental forms. The best-studied examples are the slime-secreting myxobacteria ("slime bacteria"). Myxobacteria glide actively over the slime, typically traveling in swarms of cells that stay together using an intercellular signaling system. Enzymes secreted by the swarms digest "prey"—other bacteria, primarily—that become stuck in the slime. When environmental conditions become unfavorable, as when soil nutrients or water are depleted, myxobacteria form a *fruiting body* **(Figure 26.12),** which contains clusters of spores. When the fruiting body bursts, the spores disperse and form new colonies.
- **Epsilonproteobacteria.** This subgroup consists of a small group of bacteria that inhabit the animal digestive tract. The epsilonproteobacteria includes *Campylobacter* and *Helicobacter* species, some of which are pathogenic. *C. jejuni* is a major cause of food-borne intestinal disease, and *H. pyloris* is the most common form of peptic ulcers **(Figure 26.13).**



Hans Reichenbach, Gesellschaft for Biotechnologische Forschung, Braunsweig, Germany

FIGURE 26.12 The fruiting body of *Chondromyces crocatus*, a myxobacterium, a member of the Deltaproteobacteria subgroup of the Proteobacteria. Cells of this species collect together to form the fruiting body.

SPIROCHETES The spirochetes are Gram-negative bacteria with helically spiraled bodies and an unusual form of movement in which their flagella, which are embedded in the region between the outer membrane and the cell membrane, cause the entire cell to twist in a corkscrew pattern. Some spirochetes are pathogenic to humans. For example, *Treponema pallidum* causes syphilis, and *Borrelia burgdorferi* causes Lyme disease. Beneficial spirochetes in termite intestines aid in the digestion of plant fiber.

CHLAMYDIAS The chlamydias are structurally unusual among bacteria because, although they are Gram-negative and have cell walls with a membrane outside of them, they lack peptidoglycan. All the known chlamydias are obligate intracellular parasites, meaning that they can only reproduce within other cells. Chlamydias cause various diseases in animals. For example, *Chlamydia trachomatis* **(Figure 26.14)** is responsible for chlamydia, one of the most common sexually transmitted infections of the urinary and reproductive tracts of humans.

Demonstration of the Bacterial Cause of Peptic Ulcers

Question: Do bacteria cause gastric and duodenal ulcers?

Experiment: A gastric ulcer (also called a peptic ulcer) is an erosion of the mucosal layer of the stomach that can potentially penetrate into the deeper layers of the stomach wall. Pepsin and HCl in the stomach irritate the exposed stomach wall, causing extreme pain. Similar ulcers, called duodenal ulcers, can form in the duodenum. In 1982, physicians "knew" that gastric ulcers were caused by excessive amounts of stomach acid that was caused by stress, smoking, personality issues, or susceptibility genes. They treated an ulcer with various kinds of antacids or drugs to inhibit acid production in the stomach. Typically the ulcer symptoms returned after treatment was stopped. Prior to that time, various researchers had observed the presence of spiral or curved bacteria in biopsies taken from the majority of patients with gastric and duodenal ulcers. The bacteria were considered either to be contamin ants or not related to ulcer formation.

In 1982, Barry Marshall and J. Robin Warren of Royal Perth Hospital, Perth, Western Australia, tested the hypothesis that bacteria caused peptic ulcers. They took biopsies of peptic ulcers and duodenal ulcers and assayed for the presence of bacteria by Gram staining and culturing on Petri plates.

Results: The results of the biopsies, published in 1984, are shown in the **Table**.

Association of Bacteria with Biopsy Samples

Biopsy Appearance	Total Samples	Number (%) Associated with Bacteria
Gastric ulcer	22	18 (77%)
Duodenal ulcer	13	13 (100%)
Total	35	31 (89%)

The researchers' results showed that almost all cases of gastric or duodenal ulcers were associated with bacteria. The bacteria had a curved appearance, but the species was unknown at the time. It is now known to be the epsilonproteobacterium *Helicobacter pylori*.

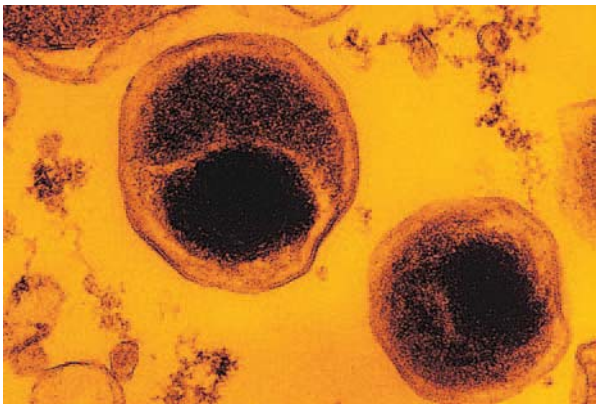
Helicobacter pylori

Yutaka Tsutsumi, M.D. Professor Department of Pathology Fujita Health University School of Medicine

Marshall and Warren's results were met with a great deal of skepticism, and most physicians were not persuaded that gastric and duodenal ulcers were bacterial diseases. How could it be shown that *H. pylori* can cause gastric and duodenal ulcers? The accepted way to prove that a bacterium is a pathogen is to fulfill Koch's postulates, a set of four conditions proposed in the nineteenth century by Robert Koch. The postulates are as follows:

1. The bacteria must be present in every case of the disease.
2. The bacteria must be isolated from the infected host and grown in pure culture.
3. The specific disease must be induced when a pure culture of the bacteria is introduced into a healthy host.
4. The bacteria must be isolated from the now experimentally infected host.

Postulates 3 and 4 had not been fulfilled in the study. Attempts to use piglets to fulfill them failed. Therefore, in a bold and highly unusual move, Marshall decided to try to fulfill postulates 3 and 4 himself. He drank 200 mL of an *H. pylori* suspension, then fasted the rest of the day. On the fifth to eighth day after drinking the bacteria, Marshall began feeling very nauseated to the point of vomiting. On the tenth day, a colleague performed a biopsy, the analysis of which showed the presence of *H. pylori* cells. *Helicobacter pylori* was proven to be a pathogen.



Conclusion: Marshall and Warren's experiments had shown that *Helicobacter pylori* can cause gastric and duodenal ulcers. This bacterium probably accounts for more than 80% of cases of such ulcers in humans in the United States. In *H. pylori*-caused ulcers, the effective treatment is an antimicrobial agent such as an antibiotic. Marshall and Warren received a Nobel Prize in 2005 "for their discovery of the bacterium *Helicobacter pylori* and its role in gastritis and peptic ulcer disease."

THINK LIKE A SCIENTIST Marshall developed a bacterial infection after drinking a solution of *Helicobacter*. Speculate on the origin of *Helicobacter* in patients who developed gastric or duodenal ulcers and were positive for the bacterium.

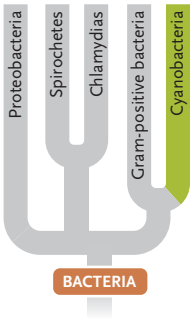
David M. Phillips/Visuals Unlimited

FIGURE 26.14 Cells of *Chlamydia trachomatis* inside a human cell. This bacterium is a major cause of infectious eye and genital diseases in humans.



GRAM-POSITIVE BACTERIA The large group of Gram-positive bacteria contains many species that live primarily as chemoheterotrophs. One species, *Bacillus subtilis* (see Figure 26.1), is studied by biochemists and geneticists almost as extensively as is *E. coli.* A number of Gram-positive bacteria are pathogenic to humans, including *Bacillus anthracis,* which causes anthrax; *Staphylococcus aureus,* which causes a range of illnesses including pimples, abscesses, toxic shock syndrome, pneumonia, meningitis and sepsis (an infection state involving a whole-body inflammation; commonly referred to as blood poisoning); and *Streptococcus pyogenes* **(Figure 26.15),** which is a cause of streptococcal pharyngitis ("strep throat"), scarlet fever, and rheumatic fever. Some Gram-positive bacteria are beneficial; *Lactobacillus* species, for example, carry out the lactic acid fermentation used in the production of pickles, sauerkraut, yogurt, and some other fermented foods. One unusual group of bacteria, the mycoplasmas, is classified in the group Gram-positive bacteria by molecular studies even though they lack a cell wall and, therefore, they react negatively to the Gram stain. Some species are pathogenic to humans; *Mycoplasma pneumonia,* for instance, causes a form of pneumonia.

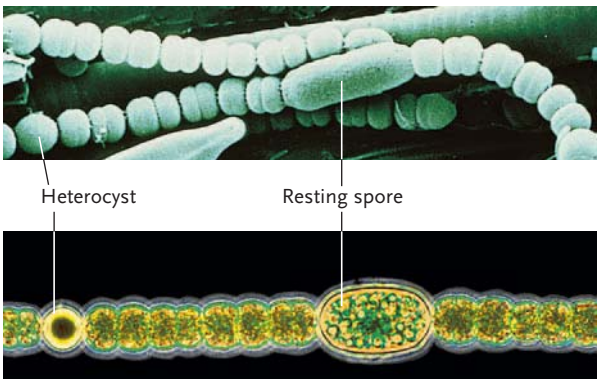
FIGURE 26.15 *Streptococcus* bacteria, a genus of Gram-positive bacteria, forming a long chain of cells, which is typical of the many species in this genus.

CYANOBACTERIA The cyanobacteria **(Figure 26.16)** are Gram-negative photoautotrophs that have a blue-green color and carry out photosynthesis using the same pathways as eukaryotic algae and plants, and use the same chlorophyll that plants have as their primary photosynthetic pigment. They release oxygen as a by-product of photosynthesis.



The direct ancestors of present-day cyanobacteria were the first organisms to use the water-splitting reactions of photosynthesis. As such, they were critical to the appearance of abundant oxygen in the atmosphere, which allowed the evolutionary development of aerobic organisms (see Section 25.2). Chloroplasts probably evolved from early cyanobacteria that were incorporated into the cytoplasm of primitive eukaryotes, which eventually gave rise to the algae and higher plants (see Section 25.3). Besides releasing oxygen, present-day cyanobacteria help fix nitrogen into organic compounds in aquatic habitats and also in lichens that involve a cyanobacterium and a filamentous fungus living together symbiotically (see Chapter 30). (Most lichens involve a green alga and a filamentous fungus.)

Bacteria Cause Diseases by Several Mechanisms

As you have just learned, some bacteria are pathogenic. Pathogenic bacteria vary in the ways they cause diseases. A number of bacterial lineages produce **exotoxins,** toxic proteins that are secreted from the bacterium or are released from the cell when it lyses, and interfere with the biochemical processes of body cells in various ways. For example, the exotoxin of the Gram-positive bacterium *Clostridium botulinum* is found as a contaminant in poorly preserved foods, and causes *botulism.* The botulism exotoxin is one of the most poisonous substances known: a few nanograms of the toxin can cause illness, and a few hundred grams could kill every human on Earth. It acts by interfering with the transmission of nerve impulses. The muscle paralysis produced by the exotoxin can be fatal if the muscles that control breathing are affected. The botulinum exotoxin, under the brand name Botox, is used in low doses for the cosmetic removal of wrinkles, in the treatment of migraine headaches, and of some other medical conditions.

Some other bacteria cause disease through **endotoxins.** Endotoxins are lipopolysaccharides released from the outer membrane surrounding the cell walls when the bacterium dies and lyses. Endotoxins are natural components of the outer membrane of all Gram-negative bacteria, which include the gammaproteobacteria *E. coli, Salmonella* species, and *Shigella* species. The lipopolysaccharides cause disease by overstimulating the host's immune system, often triggering inflammation (see Chapter 45). Endotoxin release has different effects, depending on the bacterial species and the site of infection, and include typhoid or other fevers, diarrhea, and, in severe cases, organ failure and death. For example, *Salmonella enterica typhi,* the cause of typhoid fever, enter the human intestines and penetrate the intestinal wall, eventually ending up in the lymph nodes. There they multiply, and some of the cells die and lyse, releasing endotoxins into the bloodstream. This both triggers the host's immune response and causes sepsis. Without treatment, the condition can progress to multiple organ system failure and, eventually, death.

Some bacteria release **exoenzymes,** enzymatic proteins that digest plasma membranes and cause cells of the infected host to rupture and die. Exoenzymes may also digest extracellular materials such as collagen, causing connective tissue diseases. Some exoenzymes attack red or white blood cells, leading to anemias, impairment of the immune response, or interference with blood clotting. Among the bacteria that release exoenzymes are particular species of the Gram-positive genera, *Streptococcus* (see Figure 26.15), *Staphylococcus,* and *Clostridium* (see Figure 26.9). Necrotizing fasciitis (flesh-eating disease), the spectacularly destructive and rapid degeneration of subcutaneous tissues in the skin, is caused by an exoenzyme released by *Streptococcus pyogenes, Staphylococcus aureus,* and some other bacteria.

Some of the ill effects of bacteria have little to do with exotoxins, endotoxins, or exoenzymes, but are caused purely by the body's responses to infection. The severe pneumonia caused by *Streptococcus pneumoniae,* for example, results from massive accumulation of fluid and white blood cells in the lungs in response to the infection. The white blood cells have little effect on the bacteria, however, because of the bacterial cell's protective capsule. As the fluid, white blood cells, and bacteria continue to accumulate, they block air passages in the lungs and severely impair breathing.

Pathogenic Bacteria Commonly Develop Resistance to Antibiotics

Antibiotics are routinely used to treat bacterial infections. These substances, produced as defensive molecules by some bacteria and fungi, or by chemical synthesis, kill or inhibit the growth of other microbial species. For example, streptomycins, produced by soil bacteria, block protein synthesis in their target cells. Penicillins, which are produced by fungi, prevent formation of covalent bonds that hold bacterial cell walls together, weakening the wall and causing the cells to rupture.

Many pathogenic bacteria develop resistance to antibiotics through mutations that allow them to break down the drugs or otherwise counteract their effects (see *Why It Matters,* Chapter 21). Resistance is also acquired by horizontal gene transfer when resistance genes on plasmids transfer between bacteria by conjugation, or when DNA is brought into pathogens by other pathways such as transformation and transduction (see Section 17.1). Taking antibiotics routinely in mild doses, or failing to complete a prescribed dosage, contribute to the development of resistance by selecting strains that can survive in the presence of the drug. Overprescription of antibiotics for colds and other virus-caused diseases does not affect the virus, but can result in resistance among bacteria present in the body. Antibacterial agents that may result in resistance are also commonly included in such commercial products as soaps, detergents, and deodorants. Resistance is a form of evolutionary adaptation; antibiotics alter the bacterium's environment, conferring a reproductive advantage on those strains best adapted to the altered conditions.

The development of resistant strains has made tuberculosis, cholera, typhoid fever, gonorrhea, "staph," and other diseases caused by bacteria difficult to treat with antibiotics. For example, as recently as 1988, drug-resistant strains of the Gram-positive bacterium *Streptococcus pneumoniae,* which causes pneumonia, meningitis, and middle-ear infections, were practically unheard of in the United States. Now, resistant strains of *S. pneumoniae* are common and increasingly difficult to treat with antibiotics.

In this section, you have seen that bacteria thrive in nearly every habitat on Earth, including the human body. However, some members of the second prokaryotic domain, the Archaea, the subject of the next section, live in habitats that are too forbidding even for the Bacteria.

STUDY BREAK 26.2

1. **What is an exotoxin, an endotoxin, and an exoenzyme, and how do they differ with respect to how they cause disease?**
2. **By what mechanisms can pathogenic bacteria develop resistance to antibiotics?**

THINK OUTSIDE THE BOOK

Individually or collaboratively, research the Internet to identify an example of a phylogenetic tree for bacteria that does not have a traditional treelike form. What does the alternate tree form say about the evolution of the group?

26.3 The Domain Archaea

The first-studied archaeans were found in extreme environments, such as hot springs, hydrothermal vents on the ocean floor, and salt lakes **(Figure 26.17).** For that reason, these prokaryotes were called *extremophiles* ("extreme lovers"). Subsequently archaeans have also been found living in normal environments; like bacteria, these are *mesophiles.*

Many archaeans are chemoautotrophs that obtain energy by oxidizing inorganic substances, while others are chemoheterotrophs that oxidize organic molecules. Recent research has identified some archaeans as possible human pathogens, for example a species associated with tooth infections.

Research has shown that archaeans have some eukaryotic features, some bacterial features, and some features that are unique to the group (also discussed in Section 25.3). **Table 26.1** compares the characteristics of Bacteria, Archaea, and Eukarya.

Molecular Studies Reveal Five Evolutionary Branches in the Archaea

Based on differences between the rRNA coding sequences in their genomes, the domain Archaea is divided into five groups (see Figure 26.11). Two major groups, the **Euryarchaeota** and

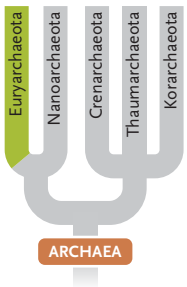

TABLE 26.1 Characteristics of the Bacteria, Archaea, and Eukarya

Characteristic	Bacteria	Archaea	Eukarya
DNA arrangement	Single, circular in most, but some linear and/or multiple	Single, circular	Multiple linear molecules
Chromosomal proteins	Prokaryotic histonelike proteins	Five eukaryotic histones	Five eukaryotic histones
Genes arranged in operons	Yes	Yes	No
Nuclear envelope	No	No	Yes
Mitochondria	No	No	Yes
Chloroplasts	No	No	Yes
Peptidoglycans in cell wall	Present	Present but modified, or absent	Absent
Membrane lipids	Unbranched; linked by ester linkages	Branched; linked by ether linkages	Unbranched; linked by ester linkages
RNA polymerase	One type	Multiple types	Multiple types
Ribosomal proteins	Prokaryotic	Some prokaryotic, some eukaryotic	Eukaryotic
First amino acid placed in proteins	Formylmethionine	Methionine	Methionine
Aminoacyl–tRNA synthetases	Prokaryotic	Eukaryotic	Eukaryotic
Cell division proteins	Prokaryotic	Prokaryotic	Eukaryotic
Proteins of energy metabolism	Prokaryotic	Prokaryotic	Eukaryotic
Sensitivity to chloramphenicol and streptomycin	Yes	No	No

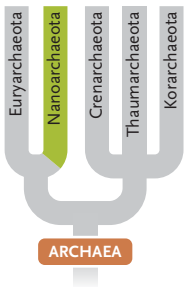
the **Crenarchaeota,** contain many species of archaeans that have been cultured and examined in the laboratory. Each of the other three groups, the **Nanoarchaeota,** the **Thaumarchaeota,** and the **Korarchaeota,** is represented by one to a few living species, with others in the group recognized by related rRNA coding sequences in DNA from environmental samples.

EURYARCHAEOTA The Euryarchaeota are found in different extreme environments. They include methanogens, which produce methane; extreme halophiles, which live in high concentrations of salt; and some extreme thermophiles, which live under high-temperature conditions.

Methanogens ("methane generators") live in reducing environments **(Figure 26.18),** and represent about one-half of all known species of archaeans. All known methanogens, for example *Methanococcus* and *Methanobacterium* species, belong to the Euryarchaeota. Methanogens are obligate anaerobes, meaning they are killed by oxygen. They are found in the anoxic ("oxygen-lacking") sediments of, for instance, swamps and marshes, as well as in more moderate environments, such as the rumen of cattle and sheep; the large intestine of dogs and humans; and the hindguts of insects such as termites and cockroaches. Methanogens generate energy by converting at least ten different substrates such as carbon dioxide and hydrogen gas, methanol, or acetate into methane gas (CH_4), which is released into the atmosphere.



Halophiles are salt-loving organisms. Extreme halophilic Archaea live in highly saline (salty) environments such as the Great Salt Lake or the Dead Sea, and on foods preserved by salting. Moreover, they *require* a minimum NaCl concentration of about 1.5 M (about 9% solution) to live, and they can live in a fully saturated solution (5.5 M, or 32%). All known extreme halophilic Archaea belong to the Euryarchaeota. Most are aerobic chemoheterotrophs; they obtain energy from sugars, alcohols, and amino acids using pathways similar to those of bacteria. Examples are *Halobacterium* and *Natrosobacterium* species.

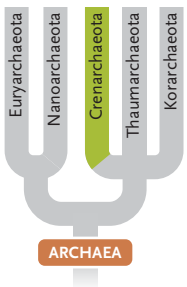


FIGURE 26.18 A colony of cells of the methanogenic archaean *Methanosarcina,* which live in the sulfurous, waterlogged soils of marshes and swamps.

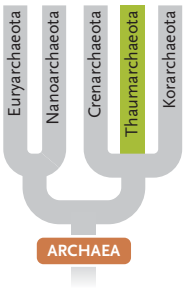
Extreme thermophiles live in extremely hot environments. Archaeans of this type live in thermal areas such as ocean-floor hydrothermal vents and hot springs such as those in Yellowstone National Park. Their optimal temperature range for growth is 70° to 95°C, approaching the boiling point of water. By comparison, no eukaryotic organism is known to live at a temperature higher than 60°C. Some extreme thermophiles, such as *Pyrophilus* species and *Thermoplasma* species, are members of the Euryarchaeota. Some of them, such as *Pyrophilus* species, are obligate anaerobes, while others, such as *Thermoplasma* species, are facultative anaerobes that grow on a variety of organic compounds.

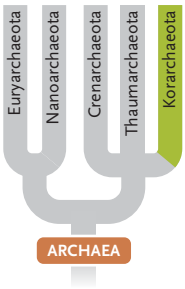
Two extreme thermophiles in this group have proved to be valuable for research. Recall that the polymerase chain reaction (PCR) uses a thermostable DNA polymerase (see Section 18.1). Two commercially available thermostable DNA polymerases for PCR are Vent DNA Polymerase, derived from *Thermococcus litoralis,* and Pfu DNA polymerase, derived from *Pyrococcus furiosus.*

NANOARCHAEOTA The group Nanoarchaeota consists of only one known living species, *Nanoarchaeum equitas;* other members are represented only by sequences detected in environmental samples. This extreme thermophile was discovered in a hydrothermal vent off the coast of Iceland. Analysis of its genome shows that it lacks genes for several metabolic pathways, including those for most nucleotides, amino acids, and lipids. It survives by being a symbiont of a thermophilic member of the Crenarchaeota.



CRENARCHAEOTA The group Crenarchaeota contains most of the extreme thermophiles. Their optimal temperature range of 75° to 105°C is higher than that of the Euryarchaeota. Most are unable to grow at temperatures below 70°C. The most thermophilic member of the group, *Pyrolobus,* grows optimally at 106°C, but dies below 90°C. *Pyrolobus* species lives in ocean-floor hydrothermal vents where the pressure makes it possible to have temperatures above 100°C, the boiling point of water on Earth's surface.

Also within this group are **psychrophiles** ("cold loving"), organisms that grow optimally in cold temperatures in the range of −10 to −20°C. These organisms are found mostly in the Antarctic and Arctic oceans, which are frozen most of the year, and in the intense cold of ocean depths.



Mesophilic members of the Crenarchaeota comprise a large part of plankton in cool, marine waters where they are food sources for other marine organisms. As yet, no individual species of these archaeans has been isolated and characterized.

Crenarchaeota archaeans exhibit a wide range of metabolism with regard to oxygen, and include obligate anaerobes, facultative anaerobes, and aerobes.

THAUMARCHAEOTA The Thaumarchaeota are a newly designated group of the Archaea consisting, at present, of four living species; other members are represented by sequences found in environmental samples. All living representatives are mesophilic, chemoautotrophic ammonia oxidizers. The establishing archaean for this group is *Cenarchaeum symbiosum*.

KORARCHAEOTA The group Korarchaeota consists of one living species, *Candidatus Korarcheum cryptofilum;* other members are represented in sequences in environmental samples. The living member is a thermophile; it was isolated from Obsidian Pool at Yellowstone National Park (a similar pool is shown in Figure 26.17B). The Korarchaeota diverged very early in the evolution of the Archaea.

From the highly varied prokaryotes, we now turn to eukaryotes, a group which does not equal the metabolic diversity or the conquest of extreme environments we have seen in the Bacteria and Archaea, but which does display new levels of physiological and behavioral complexity. The next six chapters discuss the eukaryotic kingdoms of protists, plants, fungi, and animals.

STUDY BREAK 26.3

1. What distinguishes members of the Archaea from members of the Bacteria and Eukarya?
2. How does a methanogen obtain its energy? In which group or groups of Archaea are methanogens found?
3. Where do extreme halophilic archaeans live? How do they obtain energy? In which group or groups of Archaea are the extreme halophiles found?
4. What are extreme thermophiles and psychrophiles?

UNANSWERED QUESTIONS

As you learned in this chapter, archaeans are morphologically similar to bacteria, yet they have a number of features that are more related to eukaryotes than to bacteria. More specifically, the DNA replication and transcription machineries of archaeans are related to those of eukaryotes and distinct from those found in bacteria. Also, recent work has revealed that, in some archaeans, aspects of cell division have close parallels in human cells but not in bacteria.

How is chromosome replication accomplished in species of the archaean genus *Sulfolobus*?

Analysis of the available genome sequences of archaeans show that the machinery that archaea use to replicate their DNA is, like the transcription machinery, related to that of eukaryotes and distinct from the bacterial apparatus. Recall from Chapter 14 that bacteria have a single replication origin per chromosome, whereas eukaryotes have many replication origins per chromosome. Some archaeans replicate their chromosomes from a single origin, but a number of species have multiple replication origins per chromosome. For example, species in the *Sulfolobus* genus (hyperthermophiles of the Crenarchaeota group of the domain Archaea) have three replication origins in their single chromosome. All three of these origins are used in every cell in every cell cycle, indicating that there is a sophisticated control system that ensures that each origin is used once, and only once, per cell division cycle. The nature of this control system is currently unknown.

The function of a replication origin is to recruit proteins to unwind double-stranded DNA, which exposes single-stranded DNA for use as templates. The single-stranded regions produced at an origin are extended by a DNA helicase (see Section 14.3), which, in archaeans, is called the MCM helicase. This archaean helicase has been the subject of intense structural and biochemical study, and much is now known about its form and function. However, the way in which it is recruited to replication origins remains poorly understood. Finally, with three replication origins being used in every cell for every cell division cycle, a total of six replication forks are simultaneously used for DNA replication (two from each origin). How these replication forks are resolved when they collide on the circular chromosome to produce two copies of the archaeal chromosome is currently not known.

How does cell division take place in the archaean *Sulfobolus*?

Once replication is complete, *Sulfolobus* keeps two replicated chromosomes paired for a time prior to their segregation at cell division. Until recently, the cell division machinery used by *Sulfolobus* and relatives in the Crenarchaeota was unknown. Nearly all bacteria, members of other archaeal groups, and eukaryotes have proteins belonging to the tubulin and actin families of cytoskeletal proteins, which play integral roles in cell division. However, *Sulfolobus* and its relatives lack these proteins yet they divide by binary fission. Recent work has established that cell division in *Sulfolobus* uses the so-called ESCRT machinery. Remarkably, the ESCRT proteins are conserved throughout the Eukarya, where they play roles in a wide variety of membrane processes. Cell biological and genetic studies have revealed that the ESCRT system plays a key role in *Sulfolobus* cell division, hinting at the ancestral role of this conserved machinery. Many questions remain unanswered, including: how are the *Sulfolobus* chromosomes segregated prior to cell division, and how is the site of cell division defined? With recent advances in the genetic manipulation of archaeans, researchers anticipate that these questions and others will be readily addressed.

THINK LIKE A SCIENTIST The ability to replicate DNA is fundamental to the propagation of all life on the planet. Yet it is apparent that bacteria use a different machinery to replicate their DNA than that employed by archaeans and eukaryotes. How can two distinct machineries for such a fundamentally important process have evolved?

Stephen D. Bell

Rachel Y. Samson

Stephen D. Bell and **Rachel Y. Samson** work at the Sir William Dunn School of Pathology, Oxford University. Steve is the Professor of Microbiology and his research group is focused on investigating transcription, DNA replication and cell division in the archaeal domain of life. Rachel joined Steve's group in 2007 and is researching the molecular and genetic basis of archaeal cell division. REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

26.1 Prokaryotic Structure and Function

- Three shapes are common in prokaryotes: spherical, rodlike, and spiral (Figure 26.2).
- Prokaryotic genomes typically consist of a single, circular DNA molecule packaged into the nucleoid. Many prokaryotic species also contain plasmids, which replicate independently of the main DNA (Figure 26.3).
- Gram-positive bacteria have a cell wall consisting of a thick peptidoglycan layer. Gram-negative bacteria have a thin peptidoglycan layer. The thin cell wall is surrounded by an outer membrane (Figure 26.4).
- A polysaccharide capsule, or slime layer, surrounds many bacteria. This sticky, slimy layer both protects the bacteria and helps them adhere to surfaces (Figure 26.5).
- Some prokaryotes have flagella, corkscrew-shaped protein fibers that rotate like propellers, and pili, protein shafts that help bacterial cells adhere to each other or to eukaryotic cells (Figure 26.7).
- Prokaryotes show great diversity in their modes of obtaining energy and carbon. Chemoautotrophs obtain energy by oxidizing inorganic substrates and use carbon dioxide as their carbon source. Chemoheterotrophs obtain both energy and carbon from organic molecules. Photoautotrophs are photosynthetic organisms that use light as a source of energy and carbon dioxide as their carbon source. Photoheterotrophs use light as a source of energy and obtain their carbon from organic molecules (Figure 26.8).
- Some prokaryotes are capable of nitrogen fixation, the conversion of atmospheric nitrogen to ammonia; others are responsible for nitrification, the two-step conversion of ammonium to nitrate.
- Prokaryotes normally reproduce by binary fission. Some prokaryotes are capable of conjugation, in which part of the DNA of one cell is transferred to another cell.
- In nature, prokaryotes may live in multicellular associations either of the same or mixed species. The associations may function as single cells do, or differentiate to produce cells with different functions. Examples are filaments of cyanobacteria, and biofilms, complex aggregations of microorganisms on a surface (Figure 26.10). Biofilms have both detrimental and beneficial consequences; they can harm human health, but they also can be effective in, for example, bioremediation.

Animation: Gram staining

Animation: Metabolic diversity of prokaryotes

Animation: Typical prokaryotic cell

26.2 The Domain Bacteria

- Bacteria are divided into several evolutionary branches (Figure 26.11).
- The proteobacteria are a highly diverse group of Gram-negative bacteria that exhibit a range of metabolic capabilities, including chemoautotrophy, chemoheterotropy, and photoautotrophy. Some are aerobic, others are anaerobes. Five subgroups of proteobacteria are recognized. Free-living proteobacteria include *Escherichia coli,* species that fix nitrogen, and the spore-forming myxobacteria (Figure 26.12).
- The chlamydias are Gram-negative, intracellular parasites that cause various diseases in animals. They have cell walls with an outer membrane, but they lack peptidoglycans (Figure 26.14).
- The spirochetes are spiral-shaped bacteria that are propelled by twisting movements produced by the rotation of flagella.
- The Gram-positive bacteria are primarily chemoheterotrophs and include many pathogenic species (Figure 26.15).
- The cyanobacteria are Gram-negative photoautotrophs that carry out photosynthesis and release oxygen as a by-product (Figure 26.16).
- Bacteria cause disease through exotoxins, endotoxins, and exoenzymes.
- Pathogenic bacteria may develop resistance to antibiotics through mutation of their own genes, or by acquiring resistance genes or plasmids from other bacteria.

26.3 The Domain Archaea

- Members of the domain Archaea have some features that are like those of bacteria, other features that are like those of eukaryotes, and some other features that are uniquely archaean (Table 26.1).
- The archaean plasma membrane contains unusual lipid molecules. The cell walls of archaeans consist of distinct molecules similar to peptidoglycans, or of protein or polysaccharide molecules.
- The Archaea are classified into five groups: the Euryarchaeota, which include the methanogens, the extreme halophiles, and some extreme thermophiles; the Nanoarchaeota, the only living member of which is an extreme thermophile; the Crenarchaeota, which contain most of the archaean extreme thermophiles, as well as psychrophiles and mesophiles; the Thaumarchaeota, all of which are mesophilic chemoautotrophs; and the Korarchaeota, the only living member of which is a thermophile.

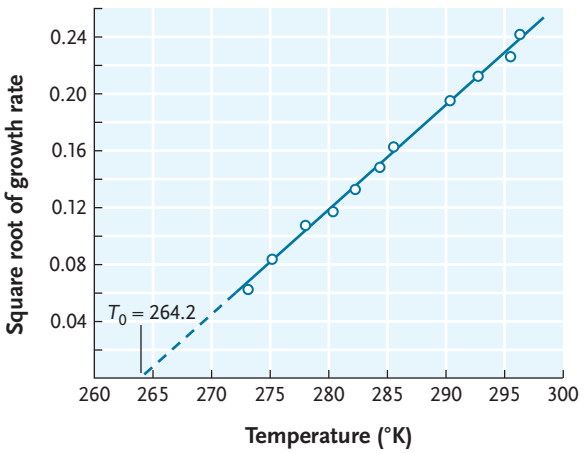
UNDERSTAND & APPLY

Test Your Knowledge

1. A urologist identifies cells in a man's urethra as bacterial. Which of the following descriptions applies to the cells?
   a. They have sex pili, which give them motility.
   b. They have flagella, which allow them to remain in one position in the urethral tube.
   c. They are covered by a capsule, which enables them to multiply quickly.
   d. They are covered by pili, which keep them attached to the urethral walls.
   e. They contain a peptidoglycan cell wall, which gives them buoyancy to float in the fluids of the urethra.
2. A bacterium that uses nitrites as its only energy source was found in a deep salt mine. It is a:
   a. chemoautotroph.
   b. parasite.
   c. photoautotroph.
   d. heterotroph.
   e. photoheterotroph.
3. The ___ are all oxygen-producing photoautotrophs.
   a. spirochetes
   b. chlamydias
   c. cyanobacteria
   d. Gram-positive bacteria
   e. proteobacteria
4. At the health center, a fecal sample was taken from a feverish student. Organisms with corkscrew-like flagella and no endomembranes but with cell walls that lack peptidoglycan were isolated as the cause for the illness. These organisms probably belong to the group:
   a. chlamydias.
   b. spirochetes.
   c. Euryarchaeota.
   d. Cyanobacteria.
   e. Archaea.
5. Which of the following is *not* a property of an endospore?
   a. resistant to boiling—must be autoclaved to be killed
   b. metabolically inactive
   c. can potentially survive millions of years
   d. provides a method to preserve bacterial DNA under harsh conditions
   e. is the portion of the bacterial cell that undergoes conjugation
6. Bacterial cells are generally thought to act independently. An exception to this is bacterial cells involved in:
   a. biofilms.
   b. photosynthesis.
   c. peptidoglycan layering.
   d. toxin release.
   e. facultative anaerobic metabolism.
7. Penicillin, an antibiotic, inhibits the formation of cross-links between sugar groups in peptidoglycan. Bacteria treated with penicillin should be:
   a. aerobic.
   b. anaerobic.
   c. Gram-negative.
   d. Gram-positive.
   e. flagellated.
8. The best choice when using/prescribing antibiotics is to:
   a. increase the dosage when the original amount does not work.
   b. determine the kind of bacterium causing the problem.
   c. stop taking the antibiotic when you feel better but the prescription has not run out.
   d. ask the doctor to prescribe a drug as a precaution for an infection you do not have.
   e. choose soaps that are labeled "antibacterial."
9. Archaeans have:
   a. proteins of energy metabolism like bacteria, cell division proteins like bacteria, and mitochondria like eukaryotes.
   b. multiple types of RNA polymerases like eukaryotes, chromosomes like bacteria, and formylmethionine as the first amino acid placed in proteins.
   c. operons like bacteria, multiple types of RNA polymerases like eukaryotes, and cell division proteins like bacteria.
   d. no sensitivity to streptomycin, histones like eukaryotes, and no operons.
   e. histones like eukaryotes, a single type of RNA polymerase like bacteria, and operons like bacteria.
10. Methanogens, obligate anaerobes that generate methane, are:
    a. members of the Proteobacteria.
    b. members of the Cyanobacteria.
    c. members of the Spirochetes.
    d. members of the Euryarchaeota.
    e. members of the Korarchaeota.

Discuss the Concepts



1. The digestive tract of newborn chicks is free of bacteria until, for example, they eat food that has been exposed to the feces of adult chickens. The ingested bacteria establishes a population in the digestive tract that is beneficial for the digestion of food. However, if *Salmonella* are present in the adult feces, this bacterium, which can be pathogenic for humans who ingest it, may become established in the digestive tracts of the chicks. To eliminate the possibility that *Salmonella* might become established, should farmers feed newborn chicks a mixture of harmless known bacteria from a lab culture, or a mixture of unknown fecal bacteria from healthy adult chickens? Design an experiment to answer this question.
2. Investigators in Australia found that mats of pond scum formed by the bacterium *Botyrococcus braunii* decayed into a substance resembling crude oil when the ponds dried up. Formulate a hypothesis explaining how this process may have contributed to Earth's oil deposits.

Design an Experiment

You receive a sample of an unidentified prokaryote. Design an experiment to see if it is a bacterium or an archaean.

Interpret the Data

The proteobacteria in the genus *Pseudomonas* are important spoilers of food. The rate at which food spoils is dependent upon temperature. The data in the **Figure** show the relationship between the square root of the growth rate (how fast the population is growing per day; unitless) and the temperature of the culture.

D. A. Ratkowsky et al. 1982. Relationship between temperature and growth rate of bacterial cultures. *Journal of Bacteriology* 149:1–5. Journal of bacteriology by American Society for Microbiology; Society of American Bacteriologists. STUDY OUTLINE

27.1 What Is a Protist?

27.2 The Protist Groups

Protists

Why it matters . . . Go for a swim just about anywhere in the natural world and you will share the water with multitudes of diverse organisms called protists. Like their most ancient ancestors, almost all of these eukaryotic species are aquatic. Structurally, single-celled protists are the simplest of all eukaryotes. Although most are microscopic in size, many have had or have a significant impact on the world. For example, the protist *Phytophthora infestans,* a water mold also referred to as a downy mildew, infects valuable crop plants such as potatoes. Potatoes were one of the main food staples in Europe in the nineteenth century, and *P. infestans* caused a lot of damage to potato crops in many countries. In Ireland, for instance, the growing seasons between 1845 and 1860 were cool and damp. Year after year, *P. infestans* spores spread along thin films of water on the plants. Late blight, a rotting of plant parts, became epidemic. In this so-called Irish potato famine, an estimated one million people starved to death or died of typhoid fever (a secondary effect), and another million people fled to other countries.

Today, related species threaten forests in the United States, Europe, and Australia. For example, when conditions favored its growth, *Phytophthora ramorum* started an epidemic of sudden oak death in California, during which tens of thousands of oak trees died. As the common name suggests, infected trees die rapidly. The first sign of infection is a dark red-to-black sap oozing from the bark surface. The pathogen has now jumped to madrones, redwoods, and certain other trees and shrubs. Cascading ecological changes resulting from tree death caused by this pathogen will reduce sources of food and shelter for forest species.

In this chapter, we describe several lineages of protists, a diverse array of eukaryotic organisms that are clearly not a monophyletic group. Also known as *protoctists,* protists are the products of the varied early branching of eukaryotic evolution. They are abundant on Earth and play key ecological, economic, and medical roles in the world's biological communities.

27.1 What Is a Protist?

Protists are easily the most varied of all Earth's creatures. **Figure 27.1** shows a number of protists, illustrating their great diversity. Protists include both microscopic single-celled and large multicellular organisms. They may inhabit aquatic environments, moist soils, or the bodies of animals and other organisms, and they may live as predators, photosynthesizers, parasites, or decomposers. The extreme diversity of the group has made the protists difficult to classify.

Protists Are Eukaryotes Other Than Fungi, Land Plants, and Animals

The one reasonable certainty about protist classification is that they are not prokaryotes, fungi, plants, or animals. Because protists are eukaryotes, the boundary between them and prokaryotes is clear and obvious. Unlike prokaryotes, protists have a true nucleus, with multiple, linear chromosomes and cytoplasmic organelles, including mitochondria (in most but not all species), endoplasmic reticulum, Golgi complex, and chloroplasts (in some species). They reproduce asexually by mitosis or sexually by meiosis and union of sperm and egg cells, rather than by binary fission as do prokaryotes.

Figure 27.2 shows the phylogenetic relationships between protists and other eukaryotes. This tree represents a consensus based on molecular data, including phylogenomics analysis, which compares sequences of whole genomes, or large segments of genomes. The tree shows the most ancient bifurcation of eukaryotes into the **Unikonta (unikonts),** eukaryotes with a single flagellum, and **Bikonta (bikonts),** eukaryotes with two flagella. Further evolution produced several categories of eukaryotes. As you can see in Figure 27.2, all eukaryotic organisms except animals, land plants, and fungi—three groups that arose from protist ancestors—are protists. Although some protists have features that resemble those of the fungi, land plants, or animals, several characteristics are distinctive. For instance, cell wall components in protists differ from those of the fungi (molds and yeasts). In contrast to land plants, protists lack highly differentiated structures equivalent to true roots, stems, and leaves; they also lack the protective structures that encase developing embryos in plants. Protists are distinguished from animals by their lack of highly differentiated structures such as limbs and a heart, and by the absence of features such as nerve cells, complex developmental stages, and an internal digestive tract. Protists also lack collagen, the characteristic extracellular support protein of animals.

The classification scheme for protists has been challenging to devise because of the diversity of these organisms. Changes and refinements are likely as more sequence data are accumulated. What is unequivocally clear, though, is that the protists are a polyphyletic assemblage of eukaryotic organisms. As Figure 27.2 shows, many protists are no more closely related to each other than they are to the fungi, plants, or animals.

For simplicity, we will refer to these organisms as protists in this book, with the understanding that it is a collection of largely unrelated organisms placed together for convenience. We will refer to the major evolutionary clusterings as groups (see Figure 27.2).

You may have heard two broad terms historically associated with large assemblages of protists, *protozoa* ("first animal") (also called *protozoans*) and *algae*. Neither of these assemblages corresponds to a taxonomic group of protists, however. Protozoa is a name for a diverse assemblage of hetero-

trophic protists, formerly considered to be animals, that are mobile and feed either by ingesting prey or absorbing organic molecules, whereas algae is a name for several sets of photosynthetic protists. The term "algae" will be used in this chapter in association with specific taxonomic groups of protists.

Protist Diversity Is Reflected in Their Metabolism, Reproduction, Structure, and Habitat

As you might expect from the broad range of organisms included, protists are highly diverse in metabolism, reproduction, structure, and habitat.

METABOLISM Almost all protists are aerobic organisms that live either as heterotrophs—by obtaining their organic molecules from other organisms—or as autotrophs—by producing organic molecules for themselves by photosynthesis. Among the heterotrophs, some protists obtain organic molecules by directly ingesting part or all of other organisms and digesting them internally. Others absorb organic molecules from their environment. A few protists can live as either heterotrophs or autotrophs.

REPRODUCTION Reproduction may be asexual by mitosis or sexual by meiotic cell division and formation of gametes. In protists that reproduce by both mitosis and meiosis, the two modes of cell division are combined into a life cycle that is highly distinctive among the different protist groups.

STRUCTURE Many protists live as single cells or as **colonies** in which individual cells show little or no differentiation and are potentially independent. Within colonies, individuals use cell signaling to cooperate on tasks such as feeding or movement. Some protists are large multicellular organisms, in which cells are differentiated and completely interdependent. For example, seaweeds are multicellular marine protists that include the largest and most differentiated organisms of the group; their structures include a holdfast to secure the organism to rocks, leaflike

fronds, and, in some cases, an air bladder for flotation. The giant kelp of coastal waters rival forest trees in size.

Some single-celled and colonial protists have complex intracellular structures, some found nowhere else among living organisms **(Figure 27.3).** For example, many freshwater protists have a mechanism that maintains water balance in and out of the cell to prevent lysis. Excess water entering cells by osmosis (see Section 6.3) is handled using a specialized cytoplasmic organelle, the **contractile vacuole.** The contractile vacuole gradually fills with water; when it reaches maximum size it moves to the plasma membrane and forcibly contracts, expelling the water to the outside through a pore in the membrane. Many protists also have **food vacuoles** that digest prey or other organic material engulfed by the cells. Enzymes secreted into the food vacuoles digest the organic molecules; any remaining undigested matter is expelled to the outside by a mechanism similar to the expulsion of water by contractile vacuoles.

The cells of some protists are supported by an external cell wall, or by an internal or external shell built up from organic or mineral matter; in some, the shell takes on highly elaborate forms. Other protists have a **pellicle,** a layer of supportive protein fibers located inside the cell, just under the plasma membrane, which provides strength and flexibility instead of a cell wall (see Figure 27.5).

Almost all protists have structures that provide motility at some time during their life cycle. Some move by amoeboid motion, in which the cell extends one or more lobes of cytoplasm called **pseudopodia** ("false feet"; see Figure 27.19). The rest of the cytoplasm and the nucleus then flow into a pseudopodium, completing the movement. Other protists move by the beating of flagella or cilia (see Section 5.3; cilia are essentially the same as flagella, except that cilia are often shorter and occur in greater numbers on a cell). In some protists, cilia are arranged in complex patterns, with an equally complex network of microtubules and other cytoskeletal fibers supporting the cilia under the plasma membrane. Among the protists are the most complex single cells known because of the wide variety of cytoplasmic structures they have.

HABITAT Protists live in aqueous habitats, including aquatic or moist terrestrial locations such as oceans, freshwater lakes, ponds, streams, and moist soils, and within host organisms. In bodies of water, small photosynthetic protists collectively make up the **phytoplankton** (*phytos* = plant; *planktos* = drifting), the abundant organisms that capture the energy of sunlight in nearly all aquatic habitats. These photosynthetic protists provide organic substances and oxygen for heterotrophic bacteria and protists and for the small crustaceans and animal larvae that are the primary constituents of **zooplankton** (*zoe* = life, usually meaning animal life); although protists are not animals, biologists often include them among the zooplankton. The phytoplankton and the larger multicellular protists forming seaweeds collectively account for about half of the total organic matter produced by photosynthesis.

In the moist soils of terrestrial environments, protists play important roles among the detritus feeders that recycle matter from organic back to inorganic form. In their roles in phytoplankton, zooplankton, and as detritus feeders, protists are enormously important in the world ecosystem.

Protists that live in host organisms are parasites, obtaining nutrients from the host. Indeed, many of the parasites that have significant effects on human health are protists, causing diseases such as malaria, sleeping sickness, and giardiasis.

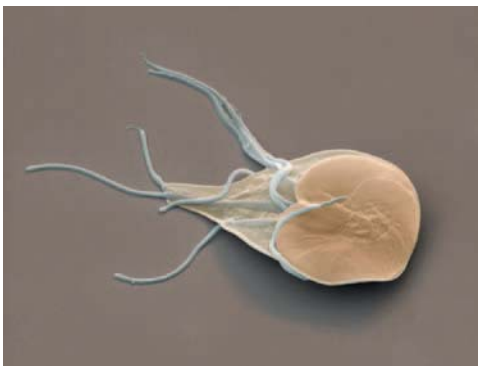
27.2 The Protist Groups

This section considers the biological features of each of the groups of protists in Figure 27.2.

The Excavates Include Protists with Unique Flagella and Protists with Modified Mitochondria



All members of the **Excavata** are single-celled animal parasites that have greatly reduced mitochondria, or organelles derived from mitochondria, and move by means of flagella; most have a scooped out (excavated) feeding apparatus on the ventral surface of the cell. Due to the lack of functional mitochondria, excavates are incapable of aerobic respiration and are limited to glycolysis as an ATP source. However, the nuclei of excavates contain genes derived from mitochondria, meaning that the ancestors of these protists probably had mitochondria. The changes in their mitochondria may have occurred as an adaptation to the parasitic way of life, in which oxygen is in short supply. Two major subgroups of the Excavata are the **Metamonada** and **Euglenozoa.**

METAMONADA **Metamonads** consist of the Diplomonadida and Parabasala. *Diplomonad* cells have two nuclei and move by means of multiple freely beating flagella. In addition to lacking mitochondria, they also lack a clearly defined endoplasmic reticulum and Golgi complex. The best-known representative of the group, *Giardia lamblia* **(Figure 27.4A),** infects the mammalian intestinal tract, inducing severe diarrhea and abdominal cramps. *Giardia* is spread by water that is contaminated with feces, in which resistant cysts of the protist can be present in large numbers.

Parabasalids also have freely beating flagella and, in addition, they have a sort of fin called an **undulating membrane,** formed by a flagellum buried in a fold of the cytoplasm. The buried flagellum allows parabasalids to move through thick and viscous fluids. Among the Parabasala are the trichomonads, including *Trichomonas vaginalis* **(Figure 27.4B),** which is responsible for infections of the urinary and reproductive tracts in both men and women. The infective trichomonad is passed from person to person primarily, but not exclusively, by sexual intercourse. It lives in the vagina in women and in the urethra of both sexes. The infection is usually symptomless in men, but in women *T. vaginalis* can cause severe inflammation and irritation of the vagina and vulva. It is easily cured by drugs.

EUGLENOZOA **Euglenozoans** include about 1,800 species, almost all single-celled, highly motile cells that swim by means of flagella. Their mitochondria are characterized by disc-shaped cristae (inner mitochondrial membranes). While most are photosynthetic, some are facultative heterotrophs; some can even alternate between photosynthesis and life as a heterotroph. The two major subgroups of the Euglenozoa are the *euglenids* and the *kinetoplastids.*

Euglenids. **Euglenids** are free-living protists with anterior flagella. The best-known species is *Euglena gracilis* **(Figure 27.5).** With the exception of a few marine species, the euglenids inhabit freshwater ponds, streams, and lakes. Most are autotrophs that carry out photosynthesis by the same mechanisms as plants, using the same photosynthetic pigments, including chlorophylls *a* and *b* and β-carotene. Many of the photosynthetic euglenids, including *E. gracilis,* can also live as heterotrophs by absorbing organic molecules through the plasma membrane. Some euglenids lack chloroplasts and live entirely as heterotrophs.

E. gracilis and other euglenids have a profusion of cytoplasmic organelles, including a contractile vacuole and, in photosynthetic species, chloroplasts (see Figure 27.5). Instead of an external cell wall, the euglenids have a spirally grooved pellicle formed from transparent, protein-rich material. Most of the photosynthetic euglenids, including *E. gracilis,* have an *eyespot*

containing carotenoid pigment granules in association with a light-sensitive structure. The eyespot is part of a sensory mechanism that stimulates cells to swim toward moderately bright light or away from intensely bright light so that the organism is positioned in light conditions for optimal photosynthetic activity. The cells swim by whiplike movements of flagella that extend from a pocketlike depression at one end of the cell. Most have two flagella, one rudimentary and short, the other long.

Kinetoplastids. Kinetoplastids are a group of nonphotosynthetic, heterotrophic cells that live as animal parasites **(Figure 27.6).** Their name reflects the structure of the single mitochondrion their cells, which contains a large DNA–protein deposit called a *kinetoplast.* Most kinetoplastids have two flagella, which are used for movement. In some cases, as in Figure 27.6, one of the flagella is attached to the side of the cell, forming an undulating membrane that is often used to enable the organism to glide along or attach to surfaces.

The kinetoplastids include the trypanosomes, responsible for several diseases afflicting millions of humans in tropical regions. *Trypanosoma brucei* (see Figure 27.6) causes African sleeping sickness, transmitted from one host to another by bites of the tsetse fly. Early symptoms include fever, headaches, rashes, and anemia. Untreated, the disease damages the central nervous system, leading to a sleeplike coma and eventual death. The disease has proved difficult to control because the same trypanosome infects wild mammals, providing an inexhaustible reservoir for the parasite. Other trypanosomes, also transmitted by insects, cause Chagas disease, which can lead to severe brain and heart damage, and leishmaniasis, which can produce disfiguring skin sores and ulcers.

The Chromalveolates Are a Heterogeneous Group of Protists with a Range of Forms and Life Styles

The **Chromalveolata** consists of the **Alveolata** and the **Stramenopila.**

ALVEOLATA The **alveolates** are so called because they have small, flattened, membrane-bound vesicles called *alveoli* (*alvus* = belly) in a layer just under the plasma membrane. The alveolates include two motile, primarily free-living groups, the **Ciliophora** and **Dinoflagellata,** and a nonmotile, parasitic group, the **Apicomplexa.**

Ciliophora. Ciliophora—the **ciliates**—include nearly 10,000 known species of primarily single-celled but highly complex heterotrophic organisms that swim by means of cilia (see Figures 27.1B and 27.3). Essentially any sample of pond water or bottom mud contains a wealth of these creatures.

The organisms in the Ciliophora have many highly developed organelles, including a mouthlike gullet lined with cilia;

structures that exude mucins, toxins, or other defensive and offensive materials from the cell surface; contractile vacuoles; and complex systems of food vacuoles. A pellicle reinforces cell shape. A complex cytoskeletal network of microtubules and other fibers anchors the cilia just below the pellicle and coordinates the ciliary beating. The cilia can stop and reverse their beating in synchrony, allowing ciliates to stop, back up, and turn if they encounter negative stimuli.

The ciliates are the only eukaryotes that have two types of nuclei in each cell: one or more small nuclei called *micronuclei,* and a single larger *macronucleus* (see Figure 27.3). A **micronucleus** is a diploid nucleus that contains a complete complement of genes. It functions primarily in cellular reproduction, which may be asexual or sexual.

The number of micronuclei present depends on the species. The **macronucleus** develops from a micronucleus, but loses all genes except those required for basic "housekeeping" functions of the cell and for ribosomal RNAs. These DNA sequences are duplicated many times, greatly increasing its capacity to transcribe the mRNAs needed for these functions, and the rRNAs needed to make ribosomes.

In asexual reproduction by mitosis, both types of nuclei replicate their DNA, divide, and are passed on to daughter cells. **Figure 27.7** illustrates sexual reproduction of *Paramecium,* which is initiated when two cells **conjugate** and a cytoplasmic bridge forms between the cells.

John Walsh/SPL/Photo Researchers, Inc.

Ciliates abound in freshwater and marine habitats, where they feed on bacteria, other protists, and each other. *Paramecium* is a typical member of the group (see Figure 27.3). Its rows of cilia drive it through its watery habitat, rotating the cell on its long axis while it moves forward, or backs and turns. The cilia also sweep water laden with prey and food particles into the gullet, where food vacuoles form. The ciliate digests food in the vacuoles and eliminates indigestible material through an anal pore. Contractile vacuoles with elaborate, raylike extensions remove excess water from the cytoplasm and expel it to the outside. When ciliates are under attack or otherwise stressed, surface organelles called **trichocysts** discharge dartlike protein threads.

Some ciliates live individually whereas others are colonial. Certain ciliates are animal parasites; others live and reproduce in their hosts as mutually beneficial symbionts. A compartment of the stomach of cattle and other grazing animals contains large numbers of symbiotic ciliates that digest the cellulose in their host's plant diet. The animals then digest the excess ciliates.

One ciliate, *Balantidium coli,* is a human intestinal parasite that causes diarrhea, with stools typically containing blood and pus. It is acquired when humans eat food contaminated by the feces of animals infected by *Balantidium,* particularly pigs.

Dinoflagellata. Dinoflagellata—dinoflagellates—consists of over 4,000 known species, most of which are single-celled organisms in marine phytoplankton. They live as heterotrophs or autotrophs; many can carry out both modes of nutrition. Some contain algae as symbionts. Typically, they have a shell formed from cellulose plates **(Figure 27.8).** The beating of flagella, which fit into grooves in the plates, makes dinoflagellates spin like a top, hence their name (*dinos* = spinning).

The cytoplasmic structures of dinoflagellates include mitochondria, chloroplasts in photosynthetic species, and other internal membrane systems characteristic of eukaryotes. The photosynthetic dinoflagellates contain chlorophylls *a* and *c* along with accessory pigments that make them golden-brown or brown; algal symbionts give some a green, blue, or red color.

Their abundance in phytoplankton makes dinoflagellates a major primary producer of ocean ecosystems. Some species live as symbionts in the tissues of other marine organisms such as jellyfish, sea anemones, corals, and mollusks. For example, dinoflagellates in coral use the coral's carbon dioxide and nitrogenous waste, while supplying 90% of the coral's nutrition. The vast numbers of dinoflagellates living as photosynthetic symbionts in tropical coral reefs allow the reefs to reach massive size; without the dinoflagellates, many coral species would die.

FIGURE 27.8 ***Karenia brevis,*** **a toxin-producing dinoflagellate.**

Dr. David Phillips/Visuals Unlimited, Inc.

Some dinoflagellates are **bioluminescent**—they glow or release a flash of light, particularly when disturbed. The production of light depends on the enzyme *luciferase* and its substrate *luciferin,* which is similar to the system that produces light in fireflies. Dinoflagellate fluorescence can make the sea glow in the wake of a boat at night, and coat nocturnal surfers and swimmers with a ghostly light.

At times dinoflagellate populations grow to such large numbers that they color the seas red, orange, or brown. The resulting **red tides** are common in spring and summer months along the warmer coasts of the world, including all the U.S. coasts. Some red-tide dinoflagellates (see Figure 27.8) produce a toxin that interferes with nerve function in the animals that ingest these protists. Fish that feed on plankton, and birds that feed on the fish, may be killed in huge numbers by the toxin. Dinoflagellate toxin does not noticeably affect clams, oysters, and other mollusks, but it becomes concentrated in their tissues. Eating the tainted mollusks can cause respiratory failure and death in humans and other animals. The toxin is especially deadly for mammals because it paralyzes the diaphragm and other muscles required for breathing.

Apicomplexa. Apicomplexa—apicomplexans—are all nonmotile parasites of animals. They absorb nutrients through their plasma membranes rather than by engulfing food particles, and they lack food vacuoles. They get their name from the *apical complex,* a special grouping of fibrils, microtubules, and organelles at one end of the cell that functions in attachment and invasion of host cells.

Typically, apicomplexan life cycles involve both asexual and sexual reproduction. All the apicomplexans, which includes almost 4,000 known species, produce infective sporelike stages called *sporozoites.* The sporozoites reproduce asexually in cells they infect, eventually bursting them, which releases the progeny to infect new cells. At some point they generate specialized cells that form gametes; fusion of gametes produces resistant cells known as *cysts.* Usually, a host is infected by ingesting cysts, which divide to produce sporozoites. This basic life cycle pattern varies considerably among the apicomplexans, and many of these organisms use more than one host species for different stages of their life cycle.

One apicomplexan genus, *Plasmodium,* is responsible for malaria, one of the most widespread and debilitating diseases of humans. The disease is transmitted by the bite of mosquitoes of the genus *Anopheles.* Although the disease is now rare in the United States, *Anopheles* mosquitoes are common enough to spread malaria if *Plasmodium* is introduced by travelers from other countries. The infective cycle of *Plasmodium,* described in *Focus on Applied Research,* is representative of the complex life cycles of apicomplexans.

Another organism in this group, *Toxoplasma,* has a sexual phase of its life cycle in cats and asexual phases in humans, cattle, pigs, and other animals. Cysts of the parasite in the feces of infected cats are spread in household and garden dust. Humans ingesting or inhaling the cysts develop toxoplasmosis, a

Malaria and the *Plasmodium* Life Cycle

Malaria is uncommon in the United States, but it is a major epidemic in many other parts of the world. From 300 million to 500 million people get malaria each year in tropical regions, including Africa, India, Southeast Asia, the Middle East, Oceania, and Central and South America. Of these, about 2 million die each year, which is twice as many deaths as from AIDS, worldwide. It is particularly deadly for children younger than six years old.

Four different species of *Plasmodium* cause malaria. In the life cycle of the parasites **(Figure),** sporozoites develop in a female *Anopheles* mosquito, which transmits them by its bite to human or bird hosts. The infecting parasites divide repeatedly in their hosts, initially in liver cells and then in red blood cells. Their growth causes red blood cells to rupture in regular cycles every 48 or 72 hours. The ruptured red blood cells clog vessels and release the parasite's metabolic wastes, causing cycles of chills and fever.

The victim's immune system is ineffective because, during most of the infective cycle, the parasite is inside body cells and thus "hidden" from antibodies. Further, *Plasmodium* regularly changes its surface molecules, continually producing new forms that are not recognized by antibodies developed against a previous form. In this way, the parasite keeps one step ahead of the immune system, often making malarial infections essentially permanent.

Travelers in countries with high rates of malaria are advised to use antimalarial drugs such as chloroquine, quinine, or quinidine as a preventative. However, many *Plasmodium* strains in Africa, India, and Southeast Asia have developed resistance to the drugs. Vaccines have proved difficult to develop; because vaccines work by inducing the production of antibodies that recognize surface groups on the parasites, they are defeated by the same mechanisms the parasite uses inside the body to keep one step ahead of the immune reaction.

While in a malarial region, travelers should avoid exposure to mosquitoes by remaining indoors from dusk until dawn and sleeping inside mosquito nets treated with insect repellent. When out of doors, travelers should wear clothes that expose as little skin as possible and are thick enough to prevent mosquitoes from biting through the cloth. An insect repellent containing DEET should be spread on any skin that is exposed.

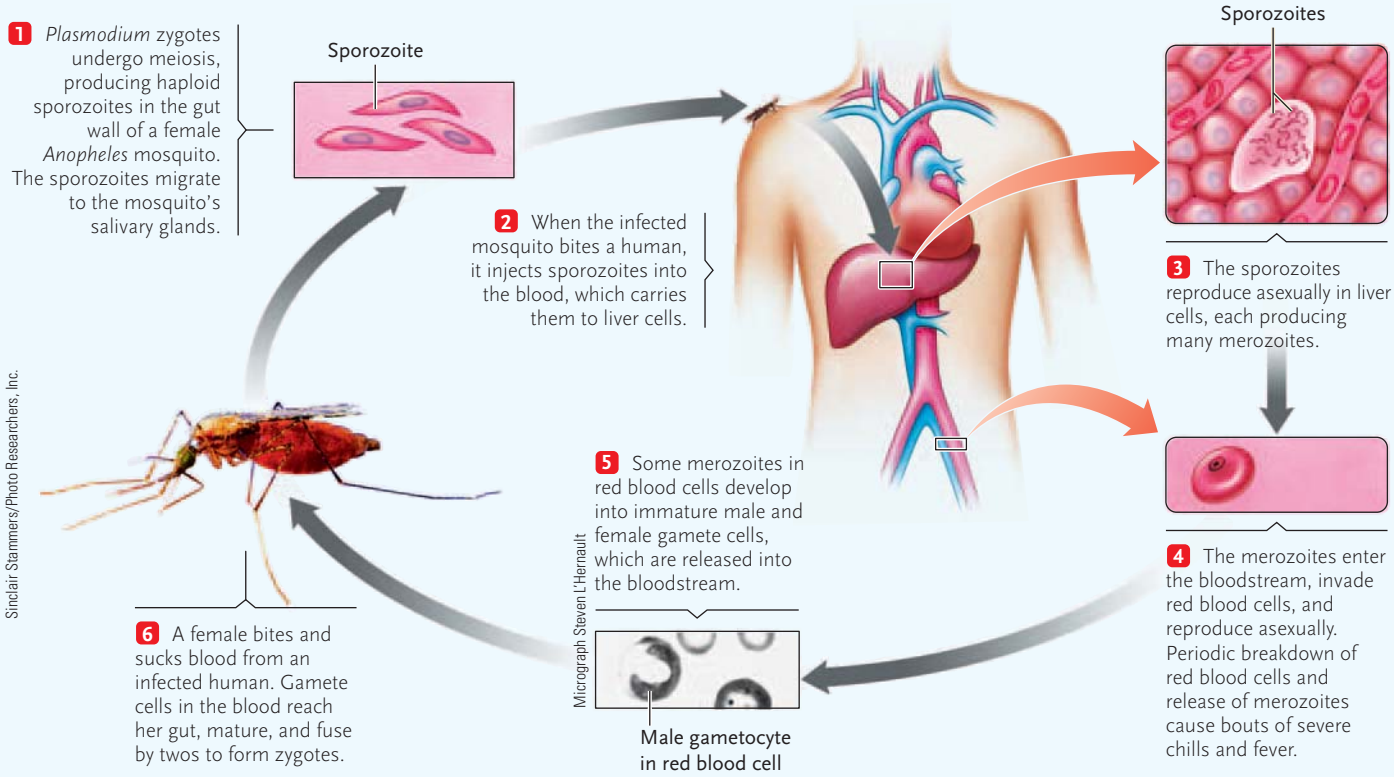

FIGURE Life cycle of a *Plasmodium* species that causes malaria.

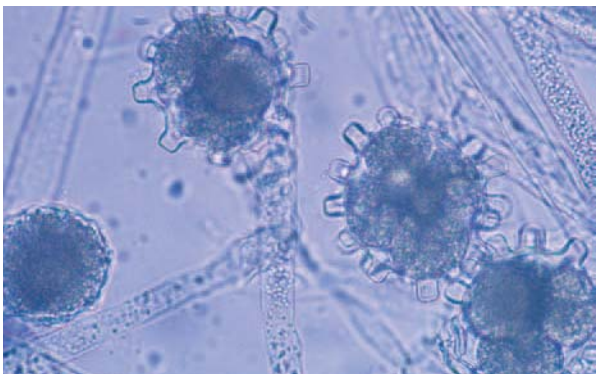
© Cengage Learning 2014

disease that is usually mild in adults but can cause severe brain damage or even death to a fetus.



STRAMENOPILA **Stramenopila**—**stramenopiles**—have two different flagella: one with hollow tripartite projections that give the flagellum a "hairy" appearance and a second one that is plain. The flagella occur only on reproductive cells such as eggs and sperm, except in the golden algae, in which cells are flagellated in all stages. The Stramenopila includes the **Oomycota** (water molds, white rusts, and mildews—formerly classified as fungi), **Bacillariophyta** (diatoms), **Chrysophyta** (golden algae), and **Phaeophyta** (brown algae).

Oomycota. Oomycota—water molds, white rusts, and **downy mildews**—are funguslike stramenopiles that lack chloroplasts and live as heterotrophs **(Figure 27.9).** Like fungi, they secrete enzymes that digest the complex molecules of surrounding dead or alive organic matter into simpler substances small enough to be absorbed into their cells. The water molds live almost exclusively in freshwater lakes and streams or moist terrestrial habitats. Most water molds are key decomposers of both aquatic and moist terrestrial habitats. Dead animal or plant material immersed in water commonly becomes coated with cottony water molds. Other water molds parasitize living aquatic animals, such as the mold growing on the fish shown in Figure 27.9B. The white rusts and downy mildews are parasites of land plants (see *Why It Matters*). Oomycota may reproduce asexually or sexually.

Like fungi, many Oomycota grow as microscopic, nonmotile filaments called **hyphae** (singular, *hypha*), which form a network called a **mycelium** (see Figure 27.9A). Other features, however, set the Oomycota apart from the fungi; chief among them are differences in nucleotide sequence, which clearly indicate close evolutionary relationships to the stramenopiles rather than to the fungi. Further, nuclei in hyphae are diploid in the Oomycota, rather than haploid as in the fungi, and reproductive cells are flagellated and motile; fungi have no motile stages. Finally, the cell walls of most Oomycota contain cellulose (see Figure 3.9C), whereas fungal cell walls contain a different polysaccharide, chitin (see Figure 3.9D).

At times it has nearly destroyed vineyards in Europe and North America.

Bacillariophyta. Bacillariophyta—diatoms—are single-celled organisms that are covered by a glassy silica shell, which is intricately formed and beautiful in many species. The two halves of the shell fit together like the top and bottom of a candy box **(Figure 27.10).** Substances move to and from the plasma membrane through elaborately patterned perforations in the shell. Although flagella are present only in gametes, many diatoms move by an unusual mechanism in which a secretion released through grooves in the shell propels them in a gliding motion.

Diatoms are autotrophs that carry out photosynthesis by pathways similar to those of plants. The primary photosynthetic organisms of marine plankton, diatoms fix more carbon into organic material than any other planktonic organism. They are also abundant in freshwater habitats as both phytoplankton and bottom-dwelling species. Although most diatoms are free living, some are symbionts inside other marine protists. One diatom, *Pseudo-nitzschia,* produces a toxic amino acid that can accumulate in shellfish. The amino acid, which acts as a nerve poison, causes amnesic shellfish poisoning when ingested by humans; the poisoning can be fatal.

Asexual reproduction in diatoms occurs by mitosis followed by a form of cytoplasmic division in which each daughter cell receives either the top or bottom half of the parent shell. The daughter cell then secretes the missing half, which becomes the smaller, inside shell of the box. The daughter cell receiving the larger top half grows to the same size as the parent shell, but the cell receiving the smaller bottom half is limited to the size of this shell. As asexual divisions continue, the cells receiving bottom halves become progressively smaller. Very small diatoms may switch to a sexual mode of reproduction in which they enter meiosis and

FIGURE 27.11 **Experimental Research**

The Evolutionary History of Diatoms as Revealed by Genome Analysis

Question: What do diatom genomes reveal about their evolutionary history?

Experiment: Diatoms are members of the chromalveolates. There are two major classes of diatoms, the radially symmetrical centrics and the bilaterally symmetric pennates. The earliest fossil centrics date to 180 million years ago, whereas the earliest fossil pennates date to 90 million years ago. Researchers have long been interested in how the two types of diatoms have evolved and diverged.

The genome sequence of a pennate diatom, *Phaeodactylum tricornutum,* was reported in 2008, and the genome sequence of a centric diatom, *Thalassiosira pseudonana,* was reported in 2004. Researchers involved in the 2008 report compared the genome sequences of the two diatoms, and compared the diatom genome sequences with the genome sequences of three metazoans, two plants, three green algae, one red alga, two fungi, and ten other chromalveolates.

Results: The table below presents the results of the genome sequence comparisons. In the table, three types of genes are distinguished:

- *Core genes:* Genes found in all of the eukaryotic groups with which the diatom sequences were compared.
- *Diatom-specific genes:* Genes found in both diatoms, but not in the other organisms.
- *Unique genes:* Genes found only in one or other of the two diatoms.

	Diatom species	
	P. tricornutum	*T. pseudonana*
Genome size (Mb[1])	27.4	32.4
Number of genes	10,402	11,776
Core genes	3,523	4,332
Diatom-specific genes	1,328	1,407
Unique genes	4,366	3,912

[1] Mb = 1 megabase = 10^6 base pairs

Notably, the results show that the two diatoms have only about 57% of their genes in common, illustrating a high degree of divergence since the split to the two diatom lineages.

The researchers made some other observations from the genome sequence comparisons:

- 171 of their chloroplast genes are of red algal origin; 108 of these genes are shared by the two species.
- 587 genes are of prokaryotic origin; 56% of these genes are found in both diatoms. These genes are presumed to have been obtained by horizontal gene transfer, the movement of genetic material between organisms other than by descent (see Sections 17.1 and 26.1). These genes represent more than 5% of the total genes of these diatoms, an unusually high percentage for a eukaryote. Most of the genes can be traced to proteobacteria, cyanobacteria, and various archaea. This observation is interpreted to mean that there has been a long-term association between diatoms and bacteria that has led to the transfer of useful genes.
- The diatom-specific genes are evolving faster than other genes in these diatoms or in eukaryotes in general. Although the exact reason for this fact is unknown, it is thought that it may correlate with the extensive diversification of diatoms.

Conclusion: Analysis of the two diatom genome sequences has provided insights into the evolutionary history of diatoms. The analysis provides interesting comparisons with other eukaryotic organisms, and supports the hypothesis that chromalveolates evolved from symbiosis between a photosynthetic red alga and a heterotrophic host (a concept discussed further later in the chapter). The evidence for the extent of horizontal gene transfer, and for the increased rate of evolution of diatom-specific genes, may help explain the high degree of diversity of diatoms and their adaptations for their life in the oceans.

THINK LIKE A SCIENTIST What would you do to obtain a better understanding of the evolutionary history of diatoms?

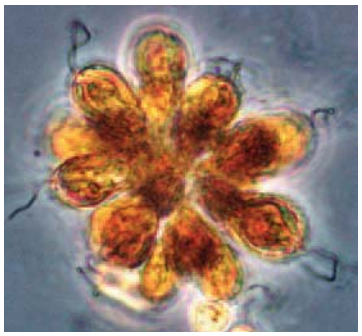
produce flagellated gametes that lose their shells and fuse in pairs to form a zygote. The zygote grows to normal size before secreting a completely new shell with full-size top and bottom halves.

The shells of diatoms are common in fossil deposits. In fact, more diatoms are known as fossils than as living species—some 35,000 extinct species have been described as compared with 7,000 living species. For about 180 million years, the shells of diatoms have been accumulating into thick layers of sediment at the bottom of lakes and seas. Since diatoms store food as oil, fossil diatoms may be a source of oil in many oil deposits. **Figure 27.11** presents the results of genome analysis experiments that provide some insights into the evolution of diatoms.



Grinding the fossilized shells into a fine powder produces *diatomaceous earth,* which is used in abrasives and filters, as an insulating material, and as a pesticide. Diatomaceous earth kills crawling insects by abrading their exoskeleton, causing them to dehydrate and die. Insect larvae are killed in the same way. Insects also die when they eat the powder but larger animals, including humans, are unaffected by it.

Chrysophyta. Chrysophyta—golden algae—mostly are colonial forms in which each cell of the colony bears a pair of flagella **(Figure 27.12A).** The golden algae have glassy shells, but in the form of plates or scales rather than in the candy-box form of the diatoms.

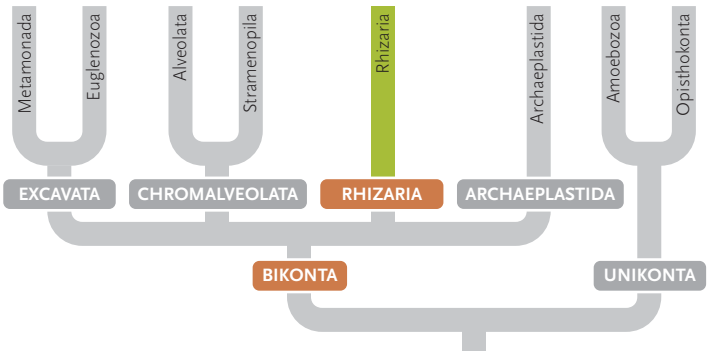
Nearly all chrysophytes are autotrophs and carry out photosynthesis using pathways similar to those of plants. Their color is due to a brownish carotenoid pigment, fucoxanthin, which masks the green color of the chlorophylls. Golden algae are important in freshwater habitats and in "nanoplankton," a community of marine phytoplankton composed of huge numbers of extremely small cells. During the spring and fall, "blooms" of golden algae can give a fishy taste and brownish color to the water.

Phaeophyta. Phaeophyta—brown algae (*phaios* = brown)—are photosynthetic autotrophs that range from microscopic forms to giant kelps that reach lengths of 50 m or more (Figure 27.1C and **Figure 27.12B and C**). Their color is also due to fucoxanthin. Their cell walls contain cellulose and a mucilaginous polysaccharide, alginic acid.



Nearly all of the 1,500 known phaeophyte species inhabit temperate or cool coastal marine waters. The kelps form vast underwater forests; fragments of these algae litter the beaches in coastal regions where they grow. Great masses of another brown alga, *Sargassum,* float in an area of the mid-Atlantic Ocean called the Sargasso Sea, which covers millions of square kilometers between the Azores and the Bahamas.

Kelps are the largest and most complex of all protists. Their tissues are differentiated into leaflike *blades,* stalklike *stipes,* and rootlike *holdfasts* that anchor them to the bottom. Hollow, gas-filled bladders give buoyancy to the stipes and blades and help keep them upright. The stalks of some kelps contain tubelike vessels, similar to the vascular elements of plants, which distribute dissolved sugars and other products of photosynthesis rapidly throughout the body of the alga.

Typically, life cycles among the brown algae are complex and in many species consist of alternating haploid and diploid generations **(Figure 27.13).** The large structures recognized as kelps and other brown seaweeds are diploid **sporophytes,** so called because they give rise to haploid spores by meiosis. The spores germinate and divide by mitosis to form a small, independent, haploid **gametophyte** generation, which gives rise to haploid gametes. Variations occur in smaller brown algae, including some life cycles in which the sporophytes and gametophytes are the same size and some in which the gametophyte is larger than the sporophyte.

The alginic acid in brown algal cell walls, called **algin** when extracted, is an essentially tasteless and nontoxic substance used to thicken such diverse products as ice cream, pudding, salad dressing, jellybeans, cosmetics, paper, and floor polish. Brown algae are also harvested as food crops and as fertilizers.

The Rhizarians Consist of Amoebas with Filamentous Pseudopods

Amoeba is a descriptive term for a single-celled protist that moves by means of temporary cellular projections called pseudopods. Several major groups of protists contain amoebas, which are similar in form but are not all closely related. The amoebas of the **Rhizaria** produce stiff, filamentous pseudopodia, and many produce hard outer shells, also called *tests.* We consider here two heterotrophic groups of rhizarian amoebas, the **Radiolaria** and the **Foraminifera,** and a third, photosynthesizing group, the **Chlorarachniophyta.**

RADIOLARIA **Radiolaria—radiolarians**—are marine protists that are distinguished by axopods, slender, raylike strands of cytoplasm supported internally by long bundles of microtubules. They engulf prey organisms that stick to the axopods and digest them in food vacuoles.

Radiolarians secrete a glassy internal skeleton from which the axopods project **(Figure 27.14A and B).** Just outside the skeleton, the cytoplasm is crowded with frothy vacuoles and lipid droplets, which provide buoyancy. The skeletons of dead radiolarians sink to the bottom of the ocean and become part of the sediment. Over time, they harden into sedimentary rocks that form an important part of the geological record.

FORAMINIFERA: FORAMS **Foraminifera—forams**—are also marine protists. Their shells consist of organic matter reinforced by calcium carbonate **(Figure 27.14C and D).** Most foram shells are chambered, spiral structures that, although microscopic, resemble those of mollusks. Forams are identified and classified primarily by the form of the shell; about 250,000 species are known. Some species are planktonic, but they are most abundant on sandy bottoms and attached to rocks along coasts. Their

name comes from the perforations in their shells (*foramen* = little hole), through which extend long, slender strands of cytoplasm supported internally by a network of needlelike spines. The forams engulf prey that adhere to the strands and conduct them through the holes in the shell into the central cytoplasm, where they are digested in food vacuoles. Some forams have algal symbionts that carry out photosynthesis, allowing them to live as both heterotrophs and autotrophs.

Marine sediments typically are packed with the shells of dead forams. The sediments may be hundreds of feet thick; the White Cliffs of Dover in England are composed primarily of the shells of ancient forams. Most of the world's deposits of limestone and marble contain foram shells; the great pyramids and many other monuments of ancient Egypt are built from blocks cut from fossil foram deposits. Because distinct species lived during different geological periods, they are widely used to establish the age of sedimentary rocks containing their shells.

CHLORARACHNIOPHYTA **Chlorarachniophyta—chlorarachniophytes**—are green, photosynthetic amoebas that also engulf food. They contain chlorophylls *a* and *b,* but they are phylogenetically distinct from other chlorophyll *b*-containing eukaryotes. Many filamentous pseudopodia extend from the cell surface.

The Archaeplastids Include the Red and Green Algae, and Land Plants

The **Archaeplastida** consist of the **Rhodophyta** (red algae) and **Chlorophyta** (green algae), which are protists, and the land plants (the *viridaeplantae,* or "true plants"), which comprise the kingdom Plantae. These three groups are descended from the first eukaryote that acquired a chloroplast from an endosymbiotic cyanobacterium (see Section 25.3 and later in this chapter), and they are all photosynthesizers. Here we describe the red and green algae; land plants are discussed in Chapters 28 and 29.

RHODOPHYTA: THE RED ALGAE Nearly all the 4,000 known species of red algae, which are also known as the Rhodophyta (*rhodon* = rose), are small marine seaweeds **(Figure 27.15).** Fewer than 200 species are found in freshwater lakes and streams or in soils. Most red algae grow attached to sandy or rocky substrates, but a few occur as plankton. Although most are free-living autotrophs, some are parasites that attach to other algae or plants.

Red algae are typically multicellular organisms, with plantlike bodies that are composed of interwoven filaments. The base of the body is differentiated into a holdfast, which anchors it to the bottom or other solid substrate, and into stalks with leaflike plates. Their cell walls contain cellulose and mucilaginous pectins that give them a slippery texture. In some species, the walls are hardened with stonelike deposits of calcium carbonate. Many of the red algae with stony cell walls resemble corals and occur with corals in reefs and banks.

Although most red algae are reddish in color, some are greenish purple or black. The color differences are produced by accessory pigments, mainly *phycobilins,* which absorb green wavelengths of light and reflect red ones, thereby masking the green color of their chlorophylls. The phycobilins are unusual photosynthetic pigments with structures similar to the ring structure of hemoglobin. The accessory pigments of some red algae make them highly efficient in absorbing the shorter wavelengths of light that penetrate to the ocean depths, allowing them to grow at deeper levels than any other algae. Some red algae live at depths to 260 m if the water is clear enough to transmit light to these levels.

Red algae have complex reproductive cycles involving alternation between diploid sporophytes and haploid gameto-

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

phytes. No flagellated cells occur in the red algae; instead, gametes are released into the water to be brought together by random collisions in currents.

Extracts containing the mucilaginous pectins of red algal cell walls are widely used in industry and science. Extracted **agar** is used as a moisture-preserving, inert agent in cosmetics and baked goods, as a setting agent for jellies and desserts, and as a solidifying agent for culture medium in the laboratory. **Carrageenan,** extracted from the red alga *Eucheuma,* is used to thicken and stabilize paints, dairy products such as pudding and ice cream, and many other creams and emulsions.

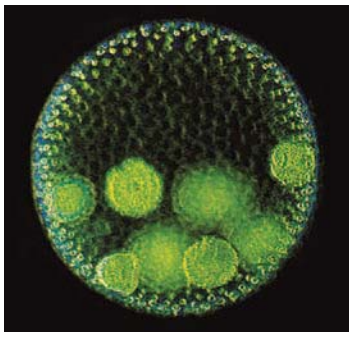
Some red algae are harvested as food in Japan and China. *Porphyra,* one of these harvested algae, is used in sushi bars as the *nori* wrapped around fish and rice.

CHLOROPHYTA: THE GREEN ALGAE Chlorophyta (*chloros* = green)—green algae—are autotrophs that carry out photosynthesis using the same pigments as plants. They include single-celled, colonial, and multicellular species (**Figure 27.16;** see also Figure 27.1D). Most green algae are microscopic, but some range upward to the size of small seaweeds. Although the multicellular green algae have bodies that are filamentous, tubular, or leaflike, they have relatively little cellular differentiation as compared with the brown algae. However, the most complex green algae, such as the sea lettuce *Ulva* (see Figure 27.16C), have tissues differentiated into a leaflike body and a holdfast.

With at least 16,000 species, green algae show more diversity than any other algal group. Most live in freshwater aquatic habitats, but some are marine, or live on rocks and soil surfaces, on tree bark, or even on snow. The green, slimy mat that grows profusely in stagnant pools and ponds, for example, consists of filaments of a green alga. A few species live as symbionts in other protists or in fungi and animals. Lichens (see Figure 30.15) are the primary example of a symbiotic relationship between green algae and fungi. Many animal phyla, including some marine snails and sea anemones, contain green algal chloroplasts, or entire green algae, as symbionts in their cells.

Life cycles among the green algae are as diverse as their body forms. Many can reproduce either sexually or asexually, and some alternate between haploid and diploid generations. Gametes in different species may be morphologically identical flagellated cells, or cells that have differentiated into a flagellated sperm cell and a nonmotile egg cell. Most common is a life cycle with a multicellular haploid phase and a single-celled diploid phase **(Figure 27.17).**

Among all the algae, the nucleic acid sequences of green algae are most closely related to those of land plants. In addition, as we have noted, green algae use the same photosynthetic pigments as plants, including chlorophylls *a* and *b,* and have the same complement of carotenoid accessory pigments. In some green algae, the thylakoid membranes within chloroplasts are arranged into stacks resembling the grana of plant chloroplasts (see Section 5.4). As storage reserves, green algae contain starches of the same types as plants, and the cell walls of some green algal species contain cellulose, pectins, and other polysaccharides like those of plants. On the basis of these similarities, many biologists propose that some ancient green alga gave rise to the evolutionary ancestors of modern-day plants.



What green alga might have been the ancestor of modern land plants? Many biologists consider a group known as the **charophytes** to be most similar to the algal ancestors of land plants. These organisms, including *Spirogyra* **(Figure 27.18),** *Nitella,* and *Coleochaete,* live in freshwater ponds and lakes. Their ribosomal RNA and chloroplast DNA sequences are more closely related to plant sequences than those of any other green alga. Further, the new cell wall separating daughter cells in charophytes is formed through development of a cell plate, by a mechanism closely similar to that of plants (see Section 10.2). The body form is distinctly plantlike, with a stemlike axis on which whorls of leaflike blades occur at intervals.

FIGURE 27.18 **The charophyte *Spirogyra*, representative of a group of green algae that may have given rise to the plant kingdom.**

The **Unikonta—unikonts**—include amoebas with unsupported pseudopods, protists closely related to animals or fungi, and animals and fungi themselves. The unikonts consist of the **Amoebozoa** and the **Opisthokonta.**

AMOEBOZOA The **Amoebozoa** include most of the amoebas (others are in the Opisthokonta and the Rhizaria) as well as the cellular and plasmodial slime molds. All members of this group use pseudopods for locomotion and feeding for all or part of their life cycles.

Amoebas. Amoebas of the Amoebozoa are single-celled organisms that are abundant in marine and freshwater environments and in the soil. They use pseudopods for locomotion and

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

feeding. The pseudopods extend and retract at any point on their body surface and are unsupported by any internal cellular organization. This type of pseudopod—called a *lobose* ("lobe-like") *pseudopod*—distinguishes these amoebas from those in the Rhizaria, which have stiff, supported pseudopods. As a result of their pseudopod activity, and the ability to flatten or round up, these amoebas have no fixed body shape. A number of species are parasites, but most species feed on bacteria, other protists, and bits of organic matter. The ingested matter is enclosed in food vacuoles and digested by enzymes secreted into the vacuoles. Any undigested matter is expelled to the outside by fusion of the vacuole with the plasma membrane. Their reproduction is entirely asexual, through mitotic divisions.

The most-studied amoeba of the amoebozoans is *Amoeba proteus* **(Figure 27.19).** Its natural habitat is in freshwater ponds and streams. Another member, *Acanthamoeba,* which lives in the soil, is widely used as a source of actin and myosin for scientific studies of amoeboid motion and cytoplasmic streaming.

The parasitic amoebas include some 45 species that infect the human digestive tract, one in the mouth and the rest in the intestine. One of the intestinal parasites, *Entamoeba histolytica,* causes amoebic dysentery. Cysts of this amoeba contaminate water supplies and soil in regions with inadequate sewage treatment. When ingested, a cyst breaks open to release an amoeba that feeds and divides rapidly in the digestive tract. Enzymes released by the amoebas destroy cells lining the intestine, producing the ulcerations, painful cramps, and debilitating diarrhea characteristic of the disease. Amoebic dysentery afflicts millions of people worldwide; in less-developed countries, it is a leading cause of death among infants and small children. Other parasitic amoebas cause less severe digestive upsets.

Slime Molds. Slime molds are heterotrophic protists that, at some stage of their life cycle, exist as individuals that move by amoeboid motion but the remainder of the time exist in more complex forms. They live on moist, rotting plant material such as decaying leaves and bark. The cells engulf particles of dead organic matter, and also bacteria, yeasts, and other microorganisms, and digest them internally. At one stage of their life cycles, they differentiate into a funguslike, stalked structure called a **fruiting body,** which forms spores by either asexual or sexual reproduction. Some species are brightly colored in hues of yellow, green, red, orange, brown, violet, or blue. The two major evolutionary lineages of slime molds, the *cellular slime molds* and the *plasmodial slime molds,* differ in cellular organization.

Michael Abbey/Visuals Unlimited, Inc.

FIGURE 27.19 ***Amoeba proteus*** **of the Amoebozoa, perhaps the most familiar protist.**

Cellular slime molds exist primarily as individual cells, either separately or as a coordinated mass. Among the 70 or so species of cellular slime molds, *Dictyostelium discoideum* is best known. **Figure 27.20** shows asexual reproduction (steps 1–5) and sexual reproduction (steps 6–7) in *D. discoideum.*

Plasmodial slime molds exist primarily as a large composite mass, the **plasmodium,** in which individual nuclei are suspended in a common cytoplasm that is surrounded by a single plasma membrane. (Do not confuse this with *Plasmodium,* the genus of apicomplexans that causes malaria.) There are about 500 known species of plasmodial slime molds. The main phase of the life cycle, the plasmodium (see Figure 27.1A), flows and feeds as a single huge amoeba—a single cell that contains thousands to millions or even billions of diploid nuclei surrounded by a single plasma membrane. Typically, a plasmodium, which may range in size from a few centimeters to more than a meter in diameter, moves in thick, branching strands connected by thin sheets. The movements occur by cytoplasmic streaming, driven by actin microfilaments and myosin (see Section 5.3).

At some point, often in response to unfavorable environmental conditions, fruiting bodies form at sites on the plasmodium. At the tips of the fruiting bodies, nuclei become enclosed in separate cells, each surrounded by its own plasma membrane and cell wall. Depending on the species, either chitin or cellulose may reinforce the walls. These cells undergo meiosis, forming haploid, resistant spores that are released from the fruiting bodies and carried about by water or wind. If they reach a favorable environment, the spores germinate to form flagellated or unflagellated gametes, depending on the species, that fuse to form a diploid zygote. The zygote nucleus then divides repeatedly without an accompanying division of the cytoplasm, forming many diploid nuclei suspended in the common cytoplasm of a new plasmodium.

Both the cellular and plasmodial slime molds, particularly *Dictyostelium* (cellular) and *Physarum* (plasmodial; see Figure 27.1A), have been of great interest to scientists because of their ability to differentiate into fruiting bodies with stalks and spore-bearing structures. This differentiation is much simpler than the complex developmental pathways of other eukaryotes, providing a unique opportunity to study cell differentiation at its most fundamental level. One such study, examining the role of cAMP (cyclic AMP) in differentiation, is described in *Insights from the Molecular Revolution.*

OPISTHOKONTA The opisthokonts (*opisthen* = behind or posterior) are a broad group of eukaryotes that includes the protist groups, the choanoflagellates and the nucleariids. If present at some stage of the life cycle, the single flagellum is located at the posterior.

Choanoflagellata (*choanos* = collar)—**choanoflagellates**—are named for a collar of closely packed microvilli that surrounds the single flagellum by which these protists move and take in food **(Figure 27.21).** The collar resembles an upside-down lampshade. There are about 150 species of choanoflagellates. They live in fresh and marine waters. Some species are mobile, with the flagellum pushing the cells along, as is the case with animal sperm, in contrast to most flagellates, which are pulled by their flagella. Most choanoflagellates, though, are *sessile;* that is, attached via a stalk to a surface. A number of species are colonial with a cluster of cells on a single stalk.

Choanoflagellates have the same basic structure as choanocytes (collar cells) of sponges, and they are similar to collared cells that act as excretory organs in organisms such as flatworms and rotifers. These morphological similarities, as well as molecular sequence comparison data, indicate that an ancestor of a present-day choanoflagellate is likely to have been the ancestor of animals.

Nucleariidae—**nucleariids**—are heterotrophic, predominantly spherical amoebae with radiating, fine pseudopods that are not supported by microtubules. Molecular sequence data show that nucleariids are more closely related to fungi than to animals (see Chapter 30).

Getting the Slime Mold Act Together: What molecules regulate development of *Dictyostelium*?

Development of differentiated structures can be followed at its simplest level in slime molds. In the cellular slime mold *Dictyostelium discoideum,* the aggregation of individual cells leading to differentiation begins when unfavorable living conditions induce some cells to secrete cyclic AMP (cAMP). Other *Dictyostelium* cells move toward the regions of highest cAMP concentration and aggregate into the slug stage. Further pulses of cAMP trigger differentiation into a stalk and spores.

The extracellular cAMP binds a cell surface G-protein–coupled receptor, activating it. This leads to activation of adenylyl cyclase within the cell, which generates cAMP. This intracellular cAMP activates a cAMP-dependent protein kinase (PKA; see Section 7.4). The PKA, which is active only when cAMP is present, adds phosphate groups to target proteins in the cells. The target proteins, activated or deactivated by addition of the phosphate groups, trigger cellular developmental processes that lead to slug formation and differentiation of the stalk and spores.

Research Question

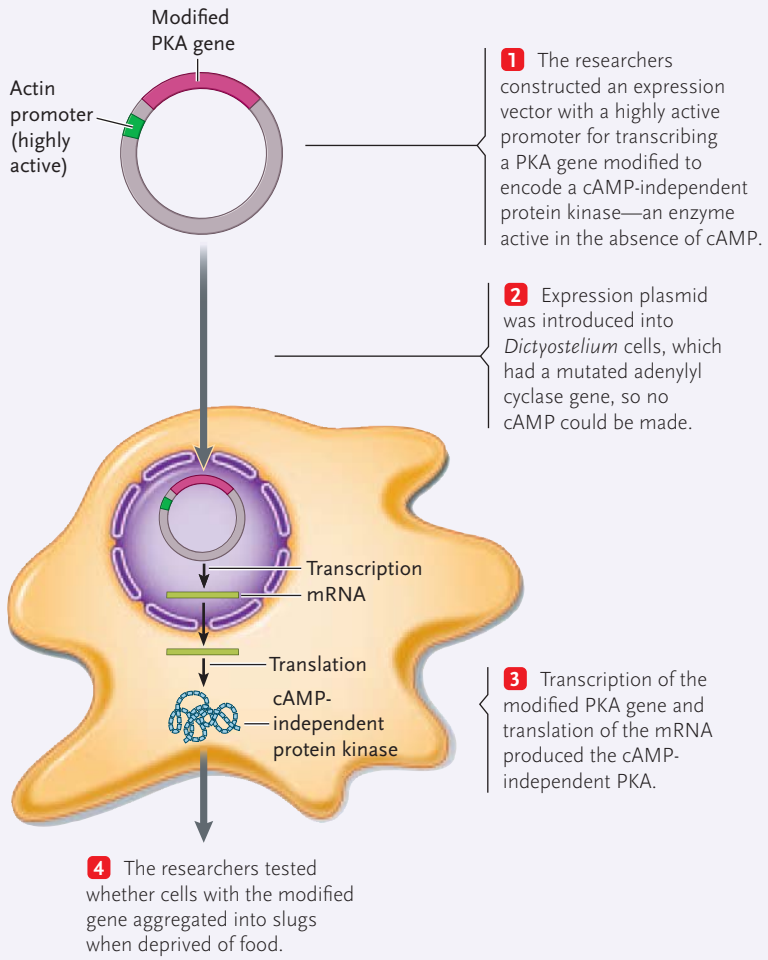
Which is more important to the process of development in *Dictyostelium,* cAMP or PKA?

Experiments

Adam Kuspa and his graduate student Bin Wang at Baylor College of Medicine, Houston, Texas, set out to answer this question. Their experimental approach is shown in the **Figure.**

Results

The researchers found that the cAMP-deficient cells with the modified PKA gene aggregated into slugs when the cultures were deprived of food (in this case, bacteria). The slugs then differentiated normally into fruiting bodies. No cAMP could be detected in the cells.



Conclusions

The results indicated that activated PKA by itself can trigger all the steps in the developmental pathway from individual cells to slugs. Thus the requirement for cAMP in normal slime mold development is primarily or exclusively to stimulate the PKA. And because development can proceed with active PKA alone, this protein kinase is probably more central to the growth and differentiation processes of the slime mold than is cAMP.

These results are of significance because both cAMP and cAMP-dependent protein kinases are also active in animal development and intercellular signaling, including that of humans and other mammals.

THINK LIKE A SCIENTIST In triggering the developmental response described, extracellular cAMP acts as a signal molecule that, by binding to and activating a G-protein–coupled receptor in the plasma membrane, triggers the production of the intracellular cAMP molecules which activate the protein kinase. Review Chapter 7 and outline the molecular steps involved in this sequence of events.

In Several Protist Groups, Plastids Evolved from Endosymbionts

We have encountered chloroplasts in a number of eukaryotic organisms in this chapter: red algae, green algae, land plants, euglenids, dinoflagellates, stramenopiles, and chlorarachniophytes. How did these chloroplasts evolve?

In Section 25.3 we discussed the endosymbiotic theory for the origin of eukaryotes. In brief, an anaerobic prokaryote ingested an aerobic prokaryote, which survived as an endosymbi-

ont (see Figure 25.5). Over many generations, the endosymbiont became an organelle, the mitochondrion, which was incapable of free living, and the result was a true eukaryotic cell. Cells of animals, fungi, and some protists derive from this ancestral eukaryote. The addition of plastids (the general term for chloroplasts and related organelles) through further endosymbiotic events produced the cells of all photosynthetic eukaryotes, including land plants, algae, and some other protists.

Figure 27.22 presents a model for the origin of plastids in eukaryotes through two major endosymbiosis events. First, in a single **primary endosymbiosis** event perhaps 600 million years ago, a eukaryotic cell engulfed a photosynthetic cyanobacterium (a photosynthetic prokaryote, remember). In some such cells, the cyanobacterium was not digested, but instead formed a symbiotic relationship with the engulfing host cell—it became an endosymbiont. Over time the symbiont lost genes no longer required for independent existence, and most of the remaining genes migrated from the prokaryotic genome to the host's nuclear genome. The symbiont had become an organelle—a chloroplast. All plastids subsequently evolved from this original chlo-

roplast. Evidence for the single origin of plastids comes from a variety of sequence comparisons, including recent sequencing of the genomes of key protists: a red alga and a diatom.

The first photosynthesizing eukaryote was essentially an ancestral single-celled alga. The chloroplasts of the Archaeplastida—the red algae, green algae, and land plants—result from evolutionary divergence of this organism. Their chloroplasts, which originate from primary endosymbiosis, have two membranes, one from the plasma membrane of the engulfing eukaryote and the other from the plasma membrane of the cyanobacterium.

At least three **secondary endosymbiosis** events led to the plastids in other protists (see Figure 27.22). In each case, a nonphotosynthetic eukaryote engulfed a photosynthetic eukaryote, and new evolutionary lineages were produced. In one of these events, a red alga ancestor was engulfed and became an endosymbiont. In models accepted by a number of scientists, the transfer of functions that occurred over evolutionary time led to the chloroplasts of the stramenopiles, ciliates, and dinoflagellates. And from the same photosynthetic ancestor, loss of chloroplast functions occurred in the lineage of the Apicomplexa, which have a remnant plastid. In an independent event, a nonphotosynthetic eukaryote engulfed a green alga ancestor. Subsequent evolution in this case produced the euglenids. In a different event, a similar endosymbiosis involving a green alga led to the chlorarachniophytes. In these protists, the chloroplast is contained still within the remnants of the original symbiont cell, with a vestige of the original nucleus (the nucleomorph) also present.

Note that secondary endosymbiosis has produced plastids with additional membranes acquired from the new host, or series of hosts. For example, euglenids have plastids with three membranes, while chlorarachniophytes have plastids with four membranes (see Figure 27.22). Sequencing the genomes of the chlorarachniophyte's nucleus, chloroplast, and vestigial nucleus is providing interesting information about the early endosymbiosis event that generated these organisms.

In sum, the protists are a highly diverse and ecologically important group of organisms. Their complex evolutionary relationships, which have long been the subject of contention, are now being revised as new information is discovered, including more complete genome sequences. A deeper understanding of protists is also contributing to a better understanding of their recent descendants, the fungi, plants, and animals. We turn to these descendants in the next four chapters, beginning with the fungi.

STUDY BREAK 27.2

1. **What is the evidence that the Excavates, which lack mitochondria, derive from ancestors that had mitochondria rather than from ancestors that were in lineages that never contained mitochondria?**
2. **In primary endosymbiosis, a nonphotosynthetic eukaryotic cell engulfed a photosynthetic cyanobacterium. How many membranes surround the chloroplast that evolved?**

UNANSWERED QUESTIONS

What was the first eukaryote?

Since prokaryotes precede eukaryotes in the fossil record, we assume that eukaryotes arose after prokaryotes. The first eukaryote would have been some sort of protist—a single-celled organism with a nucleus and some rudimentary organelles, perhaps even a half-tamed mitochondrion. One approach to identifying which of the surviving protists is the most ancient has been to infer evolutionary trees from gene sequence data. To determine the earliest branching eukaryote, these trees need to include the prokaryotes. But herein lies the problem—prokaryotes are very distant, evolutionarily speaking, from even the simplest eukaryotes, and the mathematical models used to construct evolutionary trees are not yet up to the job. Initially, these models suggested that some protist parasites, like the excavates *Giardia* and *Trichomonas,* might be the most ancient eukaryotes, and this idea fit nicely with the fact that these protists lacked mitochondria. Indeed, for a time it was thought that the excavates might actually have diverged from the eukaryotic branch of life before the establishment of mitochondria. However, we know now that *Giardia* and *Trichomonas* did have mitochondria initially. The latest research shows that they even have a tiny relic of the mitochondrion, though exactly what it does in these oxygen-shunning parasites remains to be figured out. Thus, trees depicting *Giardia* and *Trichomonas* at the base of the great expansion of eukaryotic life must be viewed with some caution—these protists might be the surviving representatives of the earliest cells with a nucleus, but they might not be. We simply need better methods for identifying just what the first eukaryotes were like.

How many times did plastids arise by endosymbiosis?

For many years researchers thought that the green algae, plants, and red algae were the only organisms to have primary endosymbiosis-derived plastids. However, a second, independent primary endosymbiosis has been recently discovered in which a shelled amoeba has captured and partially domesticated a cyanobacterium. This organism, known as *Paulinella,* is a vital window into the process by which autotrophic eukaryotes first arose some 600 million years ago. *Paulinella* has tamed the cyanobacterium sufficiently to have it divide and segregate in coordination with host cell division, but the endosymbiont is still very much a cyanobacterium and has undergone little of the modification and streamlining we see in the red or green algal plastids.

After a primary endosymbiosis was established, the second chapter in plastid acquisition could take place. Secondary endosymbiosis involves a eukaryotic host engulfing and retaining a eukaryotic alga. Essentially, secondary endosymbiosis can convert a heterotrophic organism into an autotroph by hijacking a photosynthetic cell and putting it to work as a solar-powered food factory. Secondary endosymbiosis results in plastids with three or four membranes, and we know that it occurred at least three times—once for the euglenids, once for the chlorarachniophytes, and once for the chromalveolates (a grouping of stramenopiles and alveolates). We can even tell what kind of endosymbiont was involved by the biochemistry and genetic makeup of the plastid: a green alga for euglenids and chlorarachniophytes, and a red alga for chromalveolates. The number of secondary endosymbioses is hotly debated, largely

because not all protistologists support the existence of chromalveolates. Some contend that there were multiple, independent enslavements of different red algae to produce the dinoflagellates, stramenopiles, and apicomplexans. Understanding these events is crucial to confirming or refuting the proposed chromalveolate "supergroup."

A nice example of secondary endosymbiosis-in-action was recently discovered by Japanese scientists who found a flagellate, *Hatena,* with a green algal endosymbiont. *Hatena* has not yet assumed control of endosymbiont division and has to get new symbionts each time it divides, so it appears to be at a very early stage in establishing a relationship. We also want to know how secondary endosymbioses proceed because they have been a major driver in eukaryotic evolution. The stramenopiles, for instance, are the most important ocean phytoplankton and are key to ocean productivity and global carbon cycling. Knowing exactly how they got to be autotrophs in the first place is fundamental to understanding the world we live in.

THINK LIKE A SCIENTIST

1. What does the research examining the history of the earliest eukaryotes and endosymbioses reveal about evolution and the process of science?
2. Given that parasitic species are often considered to have free-living ancestors, and therefore are more evolutionarily recent than a closely related free-living form, is it possible that prokaryotes evolved from a single-celled eukaryote?

Geoff McFadden is a professor of botany at the University of Melbourne. He studies the early evolution of eukaryotes, especially the origin and evolution of plastids and mitochondria. You can learn more about McFadden's research by visiting http://homepage.mac.com/fad1/McFaddenLab.html.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

27.1 What Is a Protist?

- Protists are eukaryotes that differ from fungi in having motile stages in their life cycles and distinct cell wall molecules. Unlike plants, they lack true roots, stems, and leaves. Unlike animals, protists lack collagen, nerve cells, and an internal digestive tract, and they lack complex developmental stages (Figures 27.1 and 27.2).
- Protists are aerobic organisms that live as autotrophs or heterotrophs, or by a combination of both nutritional modes. Some are parasites or symbionts living in or among the cells of other organisms.
- Protists live in aquatic or moist terrestrial habitats, or as parasites within animals as single-celled, colonial, or multicellular organisms, and range in size from microscopic to some of Earth's largest organisms.
- Reproduction may be asexual by mitotic cell divisions, or sexual by meiosis and union of gametes in fertilization.
- Many protists have specialized cell structures including contractile vacuoles, food vacuoles, eyespots, and a pellicle, cell wall, or shell. Most are able to move by means of flagella, cilia, or pseudopodia (Figure 27.3).

27.2 The Protist Groups

- The most ancient bifurcation separates eukaryotes into the Unikonta and Bikonta. Protist groups are found in both the unikonts and bikonts (Figure 27.2).
- The Excavata includes the Metamonada, protists with unique flagella, and the Euglenozoa, protists with modified mitochondria.
- Metamonads consist of diplomonads and parabasalids, which have flagellated, single cells that lack mitochondria (Figure 27.4).
- Euglenozoans are almost all single-celled, autotrophic or heterotrophic (some are both), motile protists that swim using flagella. The free-living, photosynthetic forms—the euglenids—typically have complex cytoplasmic structures, including eyespots. The parasitic, nonphotosynthetic forms—the kinetoplastids—have characteristic mitochondrial structures (Figures 27.5 and 27.6).
- The Chromalveolata, protists with heterogeneous forms and life styles, includes the Alveolata and the Stramenopila.
- The alveolates include the ciliates, dinoflagellates, and apicomplexans. The ciliates swim using cilia and have complex cytoplasmic structures and two types of nuclei, the micronucleus and macronucleus. The dinoflagellates swim using flagella and are primarily marine organisms; some are photosynthetic. The apicomplexans are nonmotile parasites of animals (Figures 27.7 and 27.8).
- The stramenopiles include the funguslike groups, the Bacillariophyta (diatoms), Chrysophyta (golden algae), and Phaeophyta (brown algae). For most stramenopiles, flagella occur only on reproductive cells. Many Oomycota grow as masses of microscopic hyphal filaments and secrete enzymes that digest organic matter in their surroundings. Diatoms are single-celled organisms covered by a glassy silica shell; golden algae are colonial forms; brown algae are primarily multicellular marine forms that include large seaweeds with extensive cell differentiation (Figures 27.9–27.13).
- Rhizaria, amoebas with filamentous pseudopods supported by internal cellular structures, include the Radiolaria, the Foraminifera, and the Chlorarachniophyta. Many rhizarians produce hard outer shells.
- Radiolaria (radiolarians) are primarily marine organisms that secrete a glassy internal skeleton. They feed by engulfing prey that adhere to their axopods. Foraminifera (forams) are marine, single-celled organisms that form chambered, spiral shells containing calcium. They engulf prey that adhere to the strands of cytoplasm extending from their shells. Chlorarachniophytes engulf food using their pseudopodia (Figure 27.14).
- The Archaeplastida include the Rhodophyta (red algae) and Chlorophyta (green algae), as well as the land plants.
- Red algae are typically multicellular, primarily photosynthetic organisms of marine environments, with plantlike bodies composed of interwoven filaments. They have complex life cycles including alternation of generations, with no flagellated cells at any stage (Figure 27.15).
- Green algae are single-celled, colonial, and multicellular species that live primarily in freshwater habitats and carry out photosynthesis by mechanisms similar to those of plants; all produce flagellated gametes (Figures 27.16–27.18).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The Unikonta includes the Amoebozoa, protists with unsupported pseudopods, and Opisthokonta, protists closely related to animals and fungi, and animals and fungi themselves.
- Amoebozoans include most amoebas and two heterotrophic slime molds, cellular (which move as individual cells) and plasmodial (which move as large masses of nuclei sharing a common cytoplasm). The amoebas in this group are heterotrophs abundant in marine and freshwater environments and in the soil. They move by extending pseudopodia (Figures 27.19 and 27.20).
- The opisthokonts are a broad group of eukaryotes that includes the choanoflagellates and the nucleariids. Choanoflagellates are characterized by a collar of microvilli surrounding a single flagellum. An ancestor of a present-day choanoflagellate is considered likely to have been the ancestor of animals (Figure 27.21). Nucleariids are spherical amoeba with fine pseudopods. They are more closely related to fungi than to animals.
- Several groups of protists, as well as land plants, contain chloroplasts. Present-day chloroplasts and other plastids result from endosymbiosis events that took place millions of years ago: in a primary endosymbiosis event, a eukaryotic cell engulfed a cyanobacterium, which became an endosymbiont. Over time, the symbiont became an organelle, the chloroplast. This first photosynthesizing organism was a green alga. Evolutionary divergence produced the red algae, green algae, and land plants. By secondary endosymbiosis, in which a nonphotosynthetic eukaryote engulfed a photosynthetic eukaryote, the various photosynthetic protists were produced (Figure 27.22).

UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following is a characteristic of protists that is also found in at least one other group?
   a. division by binary fission
   b. multicellular structures
   c. complex developmental stages
   d. peptidoglycan cell walls
   e. organelles and reproduction by meiosis/mitosis
2. Which of the following is *not* found among the protist groups?
   a. life cycles
   b. contractile vacuoles
   c. pellicles
   d. collagen
   e. pseudopodia
3. A member of this group can cause urinary infections and be spread by sexual intercourse. The group is characterized by a flagellum buried in a fold of the cytoplasm that allows the organisms to move through thick and viscous fluids of humans. The group is:
   a. Ciliophora.
   b. Apicomplexa.
   c. Amoebozoa.
   d. Parabasala.
   e. Diplomonadida.
4. When *Paramecium* conjugate:
   a. cytoplasmic division produces four daughter cells, each having two micronuclei and two macronuclei.
   b. one haploid micronucleus in each cell remains intact; the other three degenerate. The micronucleus of each cell divides once, producing two nuclei, and each cell exchanges one nucleus with the other cell. In each partner the two micronuclei fuse, forming a diploid zygote micronucleus in each cell.
   c. the micronucleus of each of the disengaged partners divides meiotically. Macronuclei divide again in each cell, and the original micronucleus breaks down. Each cell has two haploid micronuclei; one of the macronuclei develops into a micronucleus.
   d. the mating cells join together at opposite sites of their oral depression.
   e. the micronucleus in each cell undergoes mitosis. When mitosis is complete, there are four diploid macronuclei; the micronucleus then breaks down.
5. The group Diplomonadida is characterized by:
   a. a mouthlike gullet and hairlike surface. *Paramecium* is an example.
   b. flagella and a lack of mitochondria. *Giardia* is an example.
   c. nonmotility, parasitism, and sporelike infective stages. *Toxoplasma* is an example.
   d. switching between autotrophic and heterotrophic lifestyles. *Euglena* is an example.
   e. large protein deposits and movement by two flagella, which are part of an undulating membrane. *Trypanosoma* is an example.
6. The greatest contributors to protist fossil deposits, and probable source of oil in many oil deposits, are:
   a. Oomycota.
   b. Chrysophyta.
   c. Bacillariophyta.
   d. Sporophyta.
   e. Alveolata.
7. The group with the distinguishing characteristic of gas-filled bladders and a cell wall composed of alginic acid, which is used by humans to thicken such diverse products as ice cream and floor polish, is:
   a. Chrysophyta.
   b. Phaeophyta.
   c. Oomycota.
   d. Bacillariophyta.
   e. none of the preceding.
8. *Plasmodium* is transmitted to humans by the bite of a mosquito *(Anopheles).* Its life cycle is characterized by spores, gametes, and cysts that can "hide" in human cells. This infective protist belongs to the group:
   a. Apicomplexa.
   b. Archaeplastida.
   c. Dinoflagellata.
   d. Oomycota.
   e. Ciliophora.
9. Tripping on a rotten log, a hunter notices a mass resembling mucus that appears to be moving slowly toward what appear to be brightly colored fruiting bodies. The organisms in the mass are:
   a. amoebas in the group Rhizaria.
   b. slime molds.
   c. red algae.
   d. green algae.
   e. charophytes.

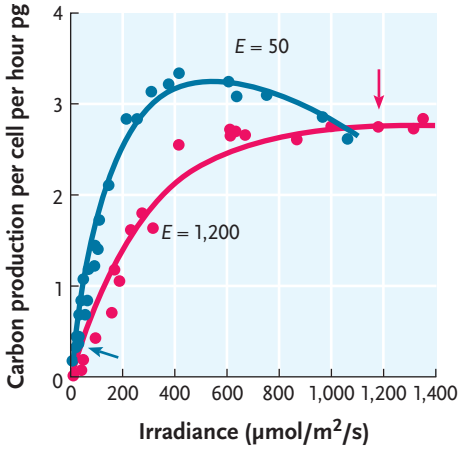
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

10. Endosymbioses that lead to the evolution of euglenoids and, separately, the evolution of chlorarachniophytes were the result of the combining of:
    a. two ancestral nonphotosynthetic prokaryotes.
    b. two ancestral photosynthetic prokaryotes.
    c. a nonphotosynthetic eukaryote with a photosynthetic eukaryote.
    d. a photosynthetic prokaryote with a nonphotosynthetic eukaryote.
    e. mitochondria with an already established plastid.

Discuss the Concepts



1. You decide to vacation in a developing country where sanitation practices and standards of personal hygiene are inadequate. Considering the information about protists covered in this chapter, would you consider it safe to drink water in that country? What treatments could make the water safe to drink? What kinds of foods might be best avoided? What kinds of preparation might make foods safe to eat?
2. The overreproduction of dinoflagellates, which produces red tides, is sometimes caused by fertilizer runoff into coastal waters. The red tides kill countless aquatic species, birds, and other wildlife. Would you consider drastic cutbacks in the use of fertilizers as a means to lessen the red tides? Why?

Design an Experiment

Design an experiment to demonstrate whether the flagellated protist *Euglena* is phototropic, that is, is attracted to and moves toward light. Also propose a follow-up experiment (on the assumption of a positive result) to determine the wavelength range and light intensity range sufficient to cause phototropic movement.

Interpret the Data

Marine diatoms are a crucial part of marine productivity because they are food for many organisms. Their productivity is dependent on how well they photosynthesize. The **Figure** shows the response of photosynthesis in the marine diatom *Skeletonema costatum* to light.

T. Anning et al. 2000. Photoacclimation in the marine diatom *Skeletonema costatum. Limnology and Oceanography* 45(8):1807–1817. Reprinted by permission of the Association for the Sciences of Limnology and Oceanography.

Photosynthesis is expressed on the *y* axis as carbon production in picograms (pg) per cell per hour, and light is expressed on the *x* axis as the number of photons of irradiance that can activate photosynthesis (0 mmol/m^2/s would be complete darkness, and 2,000 mmol/m^2/s would be full sunlight at midday). The blue symbols show a cell culture grown for five days at 50 mmol/m^2/s of irradiance (the treatment irradiance), with an arrow showing the level of photosynthetic production at the end of this period. The red symbols show a different population of cells from the same culture grown for five days at 1,200 mmol/m^2/s of irradiance (the treatment irradiance), with an arrow showing the level of photosynthetic production. Both cultures were then exposed to all of the possible irradiance conditions for 30-minute periods.

1. In each light treatment, at what irradiance was the photosynthetic rate maximized? Was this the same rate as the treatment irradiance? Why or why not?
2. The response of photosynthesis to irradiance at low irradiance is linear. The rate of this linear increase is the same as the organism's photosynthesis efficiency with respect to light. Which treatment has higher photosynthesis efficiency?

Source: T. Anning et al. 2000. Photoacclimation in the marine diatom *Skeletonema costatum. Limnology and Oceanography* 45(8):1807–1817.

Apply Evolutionary Thinking

Use the Internet to research why studies of a molecular sensor, receptor tyrosine kinase (see Section 7.3), supports the hypothesis that a choanoflagellate type of protist is the ancestor of animals. Summarize your findings.

Ferns, familiar representatives of the ancient seedless plant lineage Pteridophyta.

28

Seedless Plants

STUDY OUTLINE

28.1 The Transition to Life on Land
28.2 Bryophytes: Nonvascular Land Plants
28.3 Seedless Vascular Plants

Why it matters . . . Ages ago, along the edges of the ancient supercontinent Laurentia, the only sound was the rhythmic crash of waves breaking in the distance. There were no birds or other animals, no plants with leaves rustling in the breeze. In the preceding eons, oxygen-producing photosynthetic cells had come into being and had gradually changed Earth's atmosphere. Solar radiation had converted much of the oxygen into a dense ozone layer—a shield against lethal doses of ultraviolet radiation, which had kept early organisms below the water's surface. Now, they could populate the land.

Cyanobacteria may have been the first to adapt to intertidal zones and then to spread into the freshwater environment of shallow, coastal streams. Later, green algae and fungi made the same journey. Some 700 to 800 mya (million years ago), green algae living near the edge of a pond or stream became the ancestors of modern plants. From molecular and morphological evidence we know that a series of adaptive shifts in certain freshwater green algae gave rise to the clade we recognize as the **Kingdom Plantae.** Today the plant kingdom—sometimes called the Viridiplantae, or "green plants"—encompasses at least 260,000 living species, organized in this textbook into 10 phyla. The vast majority of these extant species are plants in which embryos develop protected inside a seed during the reproductive part of the life cycle. Chapter 29 focuses on such seed plants, including the flowering plants and conifers that dominate natural land ecosystems.

The first land plants lacked seeds, however, and their lineages persist today in the seedless groups we survey in this chapter, including mosses, horsetails, and ferns **(Figure 28.1).** As seedless plants arose, a variety of adaptive changes were crucial for the transition to a fully terrestrial life. Eons of natural selection provided solutions to problems such as avoiding desiccation, physically supporting the plant body in air, obtaining nutrients from soil, and reproducing sexually in environments where water would not be available for dispersal of eggs and sperm. With time, plants

evolved features that not only addressed these problems but also provided access to nearly every land environment. Those ecological opportunities opened the way for the dramatic radiation of plant species—and of animal species that eventually came to include our own.

All plants are multicellular. Most also are autotrophs, the primary producers that carry out photosynthesis, using solar energy, carbon dioxide, water, and dissolved minerals to manufacture their own food. Together with photosynthetic bacteria and "protists," plant tissues provide the nutritional foundation for nearly all communities of life.

28.1 The Transition to Life on Land

Land plants and green algae share several fundamental traits: they have cellulose in their cell walls, they store energy captured during photosynthesis as starch, and their light-absorbing pigments include both chlorophyll *a* and chlorophyll *b*. Like some other green algae described in Chapter 27, the lineage from which land plants evolved were adapted to freshwater habitats such as ponds and stream edges, and probably had invaded land by about 450 mya. There is widespread agreement that these algae belonged to the phylum Charophyta. Comparison of 129 gene sequences from 40 plant taxa points to the charophyte order Zygnematales as the sister clade—the closest relatives—of land plants. Modern representatives of this clade include filamentous green algae in the genus *Spirogyra* **(Figure 28.2).** A key next step in exploring this proposed relationship will be gathering more information on charophyte genomes, including one or more full genome sequences.

The fossil record is sketchy in pinpointing when the first truly terrestrial plants appeared. One reason for the dearth of information is that the earliest land plants lacked hard parts (such as wood) that fossilize well. A British and Arab research team working in the Middle East found fossilized tissue and spores from what appears to be a land plant in rocks dated to about 475 mya. If the remains indeed are from a plant, they represent the earliest known plant fossils. Even in more recent deposits, the most common finds of possible plant parts are microscopic bits and pieces. Obvious leaves, stems, roots, and reproductive parts seldom occur together, or if they do, it can be difficult to determine if the fossilized bits all belong to the same individual. Whole plants are extremely rare. Adding to the challenge, more than a few chemical and structural adaptations to life on land arose independently in several plant lineages. Consequently, a fossil may have some but not all the features of modern land plants, making it difficult to determine whether a given specimen was actually terrestrial, aquatic, or a transitional form. Despite these problems, plant scientists have been able to gain insight into a variety of innovations and overall trends in plant evolution.

Early Biochemical and Structural Adaptations Enhanced Plant Survival on Land

Because land environments pose very different challenges than aquatic environments, evolution in land plants produced a range of adaptations essential to survival on dry land. For instance, unlike algae in their aquatic habitats, plants living—and reproducing—on land had to have protection against drying out. The earliest land plants may have benefited from an inherited ability to make **sporopollenin,** a resistant polymer that surrounds the zygotes of modern charophytes. In land plants, capsules called **sporangia** ("spore chamber"; singular, *sporangium*) produce reproductive spores, and sporopollenin is a major component of the thick sporangium wall that protects spores from drying and other damage. Other reproductive adaptations in plants included multicellular chambers that protect developing gametes,

and a dependent, multicellular embryo that is sheltered inside tissues of a parent plant. Botanists use the term **embryophyte** (*phyton* = plant) as a synonym for land plants because all land plants produce a protected embryo during their reproductive cycle.

Some of the first land plants also evolved an outer waxy layer called a **cuticle,** which slows water loss, helping to prevent desiccation **(Figure 28.3A).** Another adaptation in most land plant lineages was the presence of **stomata** (singular, *stoma; stoma* = mouth), tiny openings in the cuticle-covered surfaces **(Figure 28.3B).** A stoma is formed by a pair of cells that can change shape and so open up or close a space between them, and stomata became the main route for plants to take up carbon dioxide and control water loss by evaporation. The next unit describes stomata more fully.

If you had been a botanist about 470 million years ago, you would have noted two general categories of land plants. One included **nonvascular plants**—for historical reasons also called **bryophytes**—which lacked well-developed internal tubes for transporting water and organic compounds such as sugars. Mosses are in this category. As far as we know, nonvascular plants are not monophyletic; that is, the various phyla described shortly do not share a recent ancestor. In fact, they are extremely diverse. The other general category encompassed **vascular plants,** more closely related lineages in which specialized transport tissues had arisen. One of these tissues, called **xylem,** contained stacked water-conducting cells called *tracheids,* which is why vascular plants collectively are also known as **tracheophytes.** Another vascular tissue, called **phloem,** is an adaptation for transporting sugars and other metabolic products.

In addition to vascular tissue, another adaptation that roughly correlated with the divergence of nonvascular and vascular plants was the capacity to synthesize **lignin,** a tough, rather inert polymer that strengthens the secondary walls of certain types of plant cells and thus helps vascular plants to grow taller and stay erect on land, giving photosynthetic tissues better access to sunlight. Vascular plants also have **apical meristems,** regions of unspecialized dividing cells near the tips of shoots and roots. Meristem tissue is the foundation for a vascular plant's extensively branching stem parts. Chapter 33 describes in detail how descendants of such unspecialized cells differentiate and form all mature plant tissues. As you'll read shortly, although mosses are classified as nonvascular, they have apical meristems and some other adaptive similarities to vascular plants.

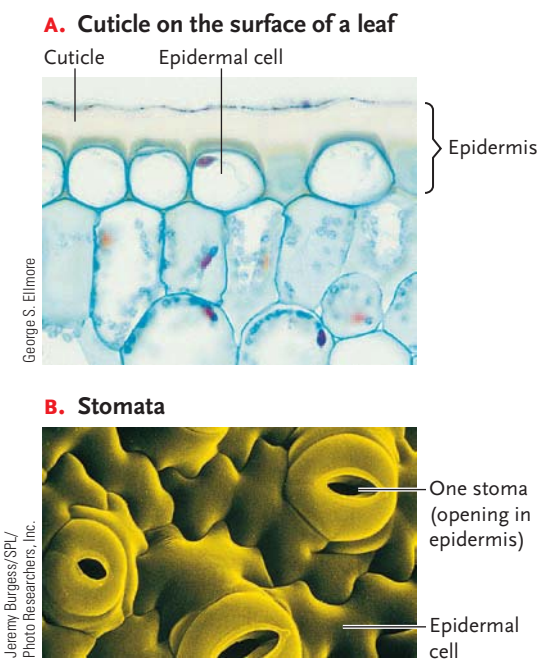

FIGURE 28.3 Land plant adaptations for limiting water loss. (A) A waxy cuticle, which covers the epidermis of land plants and helps reduce water loss. **(B)** Surface view of stomata in the epidermis (surface layer of cells) of a leaf. Stomata allow carbon dioxide to enter plant tissues and oxygen to leave while controlling loss of water.

Vascular Tissue Was an Adaptation for Transporting Substances within a Large Plant Body

The Latin *vas* means duct, and vascular plants have specialized tissues made up of cells arranged in lignified, tubelike structures that branch throughout the plant body, conducting water and solutes. As you've just read, the vascular tissue called xylem distributes water—including dissolved mineral ions—through plant parts. The other vascular tissue, phloem, distributes sugars manufactured during photosynthesis. Chapter 34 explains how tracheids and other specialized cells of xylem and phloem perform these key internal transport functions.

Most of the plants you are familiar with—flowering plants, conifers, ferns—are vascular plants. Supported by cells with lignin and serviced by a well-developed vascular system, the body of a plant can grow large. Extreme examples are the giant redwood trees of the northern California coast, some of which are more than 300 feet tall. By contrast, nonvascular plants lack lignified cells, and have very simple internal transport systems, or none at all. This is why modern nonvascular plants generally are small.

Shoot and Root Systems Were Adaptations for Support and Nutrition

A nonvascular plant has no true stems, structures that are fundamental adaptations for support of an erect plant body. In vascular plants, the evolution of sturdy stems became the basis of a large, aerial *shoot system.* This adaptive shift was correlated with the capacity to synthesize lignin.

The first unquestioned fossils of a vascular plant are specimens in the extinct genus *Cooksonia.* As **Figure 28.4A** shows, this plant had leafless "naked" stems with simple, forked branches of equal size. Sporangia formed at the branch tips and simple xylem wove through the stems. Other species formerly lumped into the genus *Cooksonia* were early vascular plants

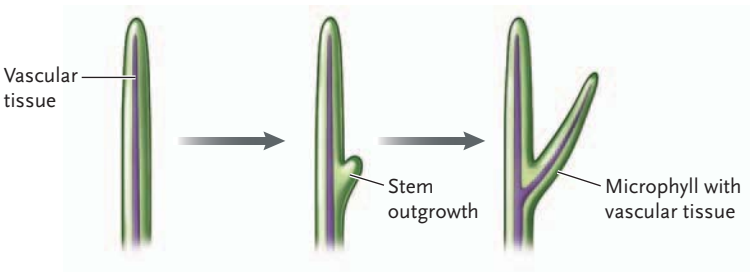

FIGURE 28.4 **Fossils from early vascular plants. (A)** *Cooksonia,* which dates to about 420 mya. *Cooksonia* stems lacked leaves and were probably less than 3 cm long. The cup-shaped structures at the top of the stems produced reproductive spores. **(B)** Cross section of the stem of a rhyniophyte, *Rhynia gwynne-vaughnii,* about 3 mm in diameter. This fossil was embedded in chert approximately 400 mya. Still visible in it are traces of the transport tissues xylem and phloem, along with other specialized tissues.

called *rhyniophytes* (because numerous specimens are from rock outcrops near Rhynie, Scotland). *Cooksonia* and rhyniophyte fossils all date to about 425 mya and show similar features, including vascular tissue **(Figure 28.4B).** Most likely none of these species had roots, which are organs specialized to anchor a vascular plant and take up water and minerals. Instead these ancestral forms probably were supported physically by a **rhizome**—a horizontal, modified stem that can penetrate a substrate and anchor the plant. Cells called *rhizoids,* which can help anchor a plant and take up water, may have extended into the soil.

UPRIGHT GROWTH: LIGNIFIED SHOOT SYSTEMS Above ground, the simple stems of early land plants gradually became more specialized, evolving into the **shoot systems** we see in all living vascular plants. Shoot systems have stems and leaves that arise from apical meristems and that absorb light energy from the sun and carbon dioxide from the air. Lignin became incorporated in the water-conducting tracheids of xylem. Its added mechanical strength in these and other types of cells provided vascular plants with adaptive advantages. For instance, a strong, internal scaffold composed of tracheids could support upright, branching stems bearing leaves and other photosynthetic structures—and so help increase the surface area for intercepting sunlight. Also, reproductive structures such as sporangia borne on aerial stems might serve as platforms for more efficient launching of spores from the parent plant.

ENHANCED PHOTOSYNTHESIS: LEAVES WITH STOMATA AND VEINS Structures we think of as "leaves" arose several times during plant evolution. Leaves are modifications of stems and fall into two general categories. *Microphylls* are narrow and have a single strand of vascular tissue, or **vein.** *Megaphylls* are broad leaves with multiple veins. **Figure 28.5** illustrates the basic steps of possible evolutionary pathways for these leaf forms. Among the lycophytes (see Section 28.3), microphyll-like parts may have evolved as flaplike outgrowths of the plant's main vertical stem (see Figure 28.5A). Club mosses, the most common living lycophytes, still have this type of leaf. In contrast, megaphylls are thought to have arisen from modi-

A. Development of microphylls as an offshoot of the main vertical axis

B. Development of megaphylls in a branching pattern

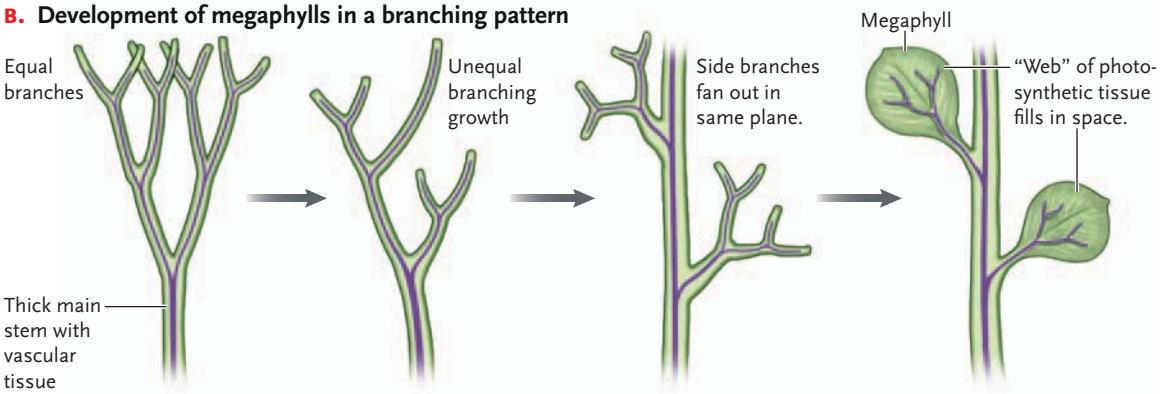

FIGURE 28.5 **Evolution of leaves. (A)** One type of early leaflike structure, the microphyll, may have evolved as an offshoot of the plant's main vertical axis. Each leaf contained a single vein (transport vessel). The seedless vascular plants known as lycophytes (club mosses) still have this type of leaf. **(B)** In other seedless vascular plants, the form of leaf called a megaphyll could have arisen in a series of steps that began when the main stem evolved a branching growth pattern. In this scenario, small side branches then fanned out and photosynthetic tissue filled the space between them, becoming the leaf blade. With time the small branches became modified into veins. Ferns, horsetails, gymnosperms, and angiosperms all have this type of leaf.

fied branches, and by the late Paleozoic era (about 350 mya), they were appearing in several plant groups. Figure 28.5B shows a simplified scenario for this adaptive shift: a slender stem branches into two roughly equal sections in a recurring pattern (called dichotomous branching). As slender branched sections are overtopped by more robust ones, the sections flatten out and a web of tissue having cells with chloroplasts then fills in the gap between branches. Over evolutionary time the tissue gains stomata, which provide access to carbon dioxide for photosynthesis, and a simple network of veins that transport water.

There is a strong correlation between the density of venation in a plant's leaves and the plant's capacity for photosynthesis—and, ultimately, for producing energy for growth. Timothy Brodribb and Taylor Feild, plant physiologists who compared the leaves of more than 500 living and extinct flowering plants, documented a dramatic increase in the number of leaf veins over the course of angiosperm evolution. They discovered that by about 100 mya, leaves of later evolving flowering plant species had up to 10 times more veins than leaves of more ancient species. Brodribb and Feild calculated that even a tripling in the number of veins would have increased the capacity of photosynthesis by 100%. Their findings suggest strongly that the evolution of large leaves with numerous stomata and a dense system of veins was a major factor in the remarkable proliferation of flowering plants that has occurred over the past 150 million years.

SUPPORT AND NUTRITION: ROOTS As upright growth emerged as a basic feature of vascular plants, it required a means of anchoring aerial parts in the soil, as well as effective strategies for obtaining water and soil nutrients. The evolution of **roots**—anchoring organs that also absorb water and nutrients—fulfilled these requirements. Frustratingly, fossils of early vascular plants are not very helpful in this regard and we are left with more questions than answers. Exactly when roots appeared is uncertain, and it is quite possible that the feature arose independently in various groups. At some point, ancestral vascular plants did come to have roots, and ultimately vascular plants developed whole specialized **root systems,** which generally consist of underground, cylindrical absorptive structures with a large surface area that favors the rapid uptake of soil water and dissolved minerals.

In the Plant Life Cycle, the Diploid Phase Became Dominant

As early plants moved into drier habitats, their life cycles also were modified considerably. You may recall that in sexually reproducing organisms, meiosis in diploid cells produces haploid (*n*) reproductive cells (see Chapter 11). These cells may be gametes—sperm or eggs—or they may be **spores,** which can give rise to a new haploid individual asexually, without mating.

All sexually reproducing organisms form both diploid and haploid cells, but what happens after each cell type forms varies greatly. In sexually reproducing animals, for example, a multicellular body develops only when diploid cells divide by mitosis. Haploid cells do not divide but become gametes. In plants, by contrast, mitosis occurs in both diploid and haploid cells, so plants essentially have two multicellular phases, one diploid and one haploid. This phenomenon, found in all plants, is called **alternation of generations (Figure 28.6).** The diploid generation produces haploid spores and is called a **sporophyte** ("spore producer"). The haploid generation produces gametes and is called a **gametophyte** ("gamete producer").

Some green algae show alternation of generations, but most are entirely haploid organisms. They produce many swimming gametes, and their zygotes do not develop a multicellular diploid phase. The first land plants had long-lived haploid gametophytes and short-lived diploid sporophytes. The bryophytes we consider later in this chapter still show this life cycle pattern. As plant adaptations to terrestrial life accumulated, the haploid gametophyte phase became physically smaller and less complex and had a shorter life span, while just the opposite occurred with the diploid sporophyte phase. Accordingly, in mosses and other bryophytes—all nonvascular plants—the sporophyte is a little larger and longer-lived than in green algae, and in vascular plants the sporophyte clearly is larger and more complex and lives much longer than the gametophyte **(Figure 28.7).** When you look at a pine tree, for example, you see a large, long-lived sporophyte.

The sporophyte generation begins after fertilization, when the resulting zygote grows mitotically into a multicellular, diploid organism. Its body will eventually develop sporangia, which produce spores.

The haploid phase of the plant life cycle begins in the sporangia. There, meiosis produces haploid spores. The spores divide by mitosis and give rise to multicellular haploid gametophytes. A gametophyte's function is to produce, nourish, and protect the forthcoming generation. These functions were linked to major changes in gametophyte structure as different groups of land plants evolved.

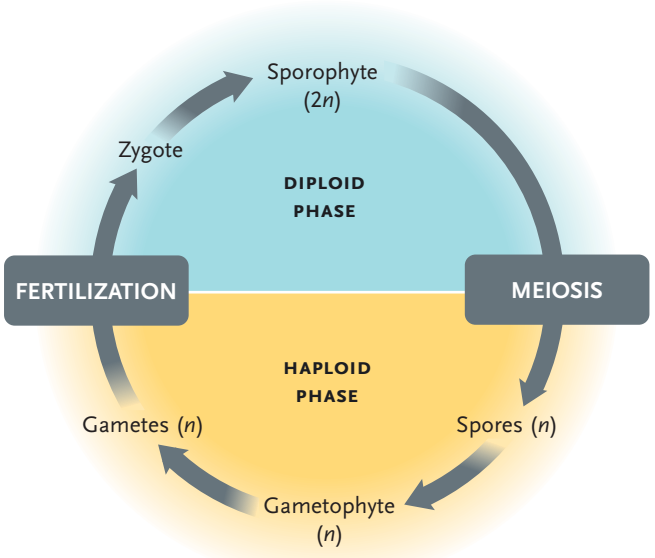

FIGURE 28.6 Overview of the alternation of generations, the basic pattern of the plant life cycle. The relative dominance of haploid and diploid phases is different for different plant groups (compare with Figure 28.7).

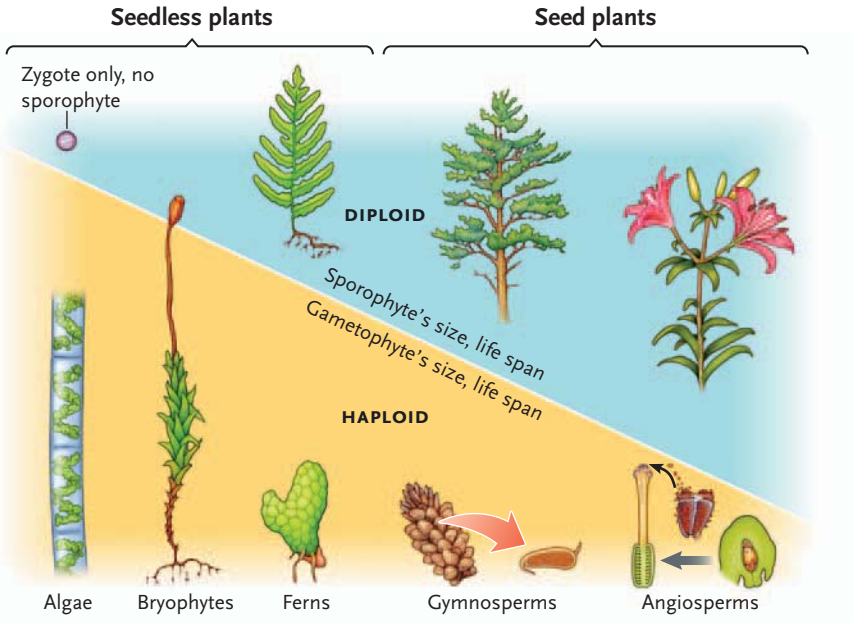

FIGURE 28.7 **Evolutionary trend from dominance of the gametophyte (haploid) generation to dominance of the sporophyte (diploid) generation, represented here by existing species ranging from a charophyte alga *(Spirogyra)* to a flowering plant.** This trend developed as early plants were colonizing habitats on land. In general, the sporophytes of vascular plants are larger and more complex than those of bryophytes, and their gametophytes are reduced in size and complexity. In this diagram ferns represent seedless vascular plants.

© Cengage Learning 2014

Some Vascular Plants Evolved Separate Male and Female Gametophytes

During sexual reproduction in plants, meiosis produces spores. When a plant makes only one type of spore, it is said to be **homosporous** ("same spore"). A gametophyte that develops from such a spore is bisexual—it can produce both sperm and eggs.

The sperm have flagella and are motile, for they have to swim through liquid water in order to encounter female gametes. Other vascular plants, including gymnosperms and angiosperms, are **heterosporous.** They produce two types of spores in two different types of sporangia, and those spores develop into small, sexually different gametophytes. The smaller spore type develops into a male gametophyte—a *pollen grain.* The larger one develops into a female gametophyte, in which eggs form and fertilization occurs.

So many new fossils appear in Devonian rocks that paleobotanists (who study fossil plants) have thus far been unable to determine which fossil lineages gave rise to modern plant phyla. Regardless, as each major lineage came into being, its characteristic adaptations included modifications of existing structures and functions (**Figure 28.8** and **Table 28.1**). The next sections fill out this general picture with respect to the seedless plants. We begin with bryophytes, nonvascular seedless plants that most clearly resemble the plant kingdom's algal ancestors.

TABLE 28.1 Trends in Plant Evolution

Traits derived from algal ancestor: cell walls with cellulose, energy stored in starch, two forms of chlorophyll (*a* and *b*); possibly, sporopollenin in spore wall.

Bryophytes	Ferns and Their Relatives	Gymnosperms	Angiosperms	Functions in Land Plants
Cuticle →	→	→	→	Protection against water loss, pathogens
Stomata →	→	→	→	Regulation of water loss and gas exchange (CO_2 in, O_2 out)

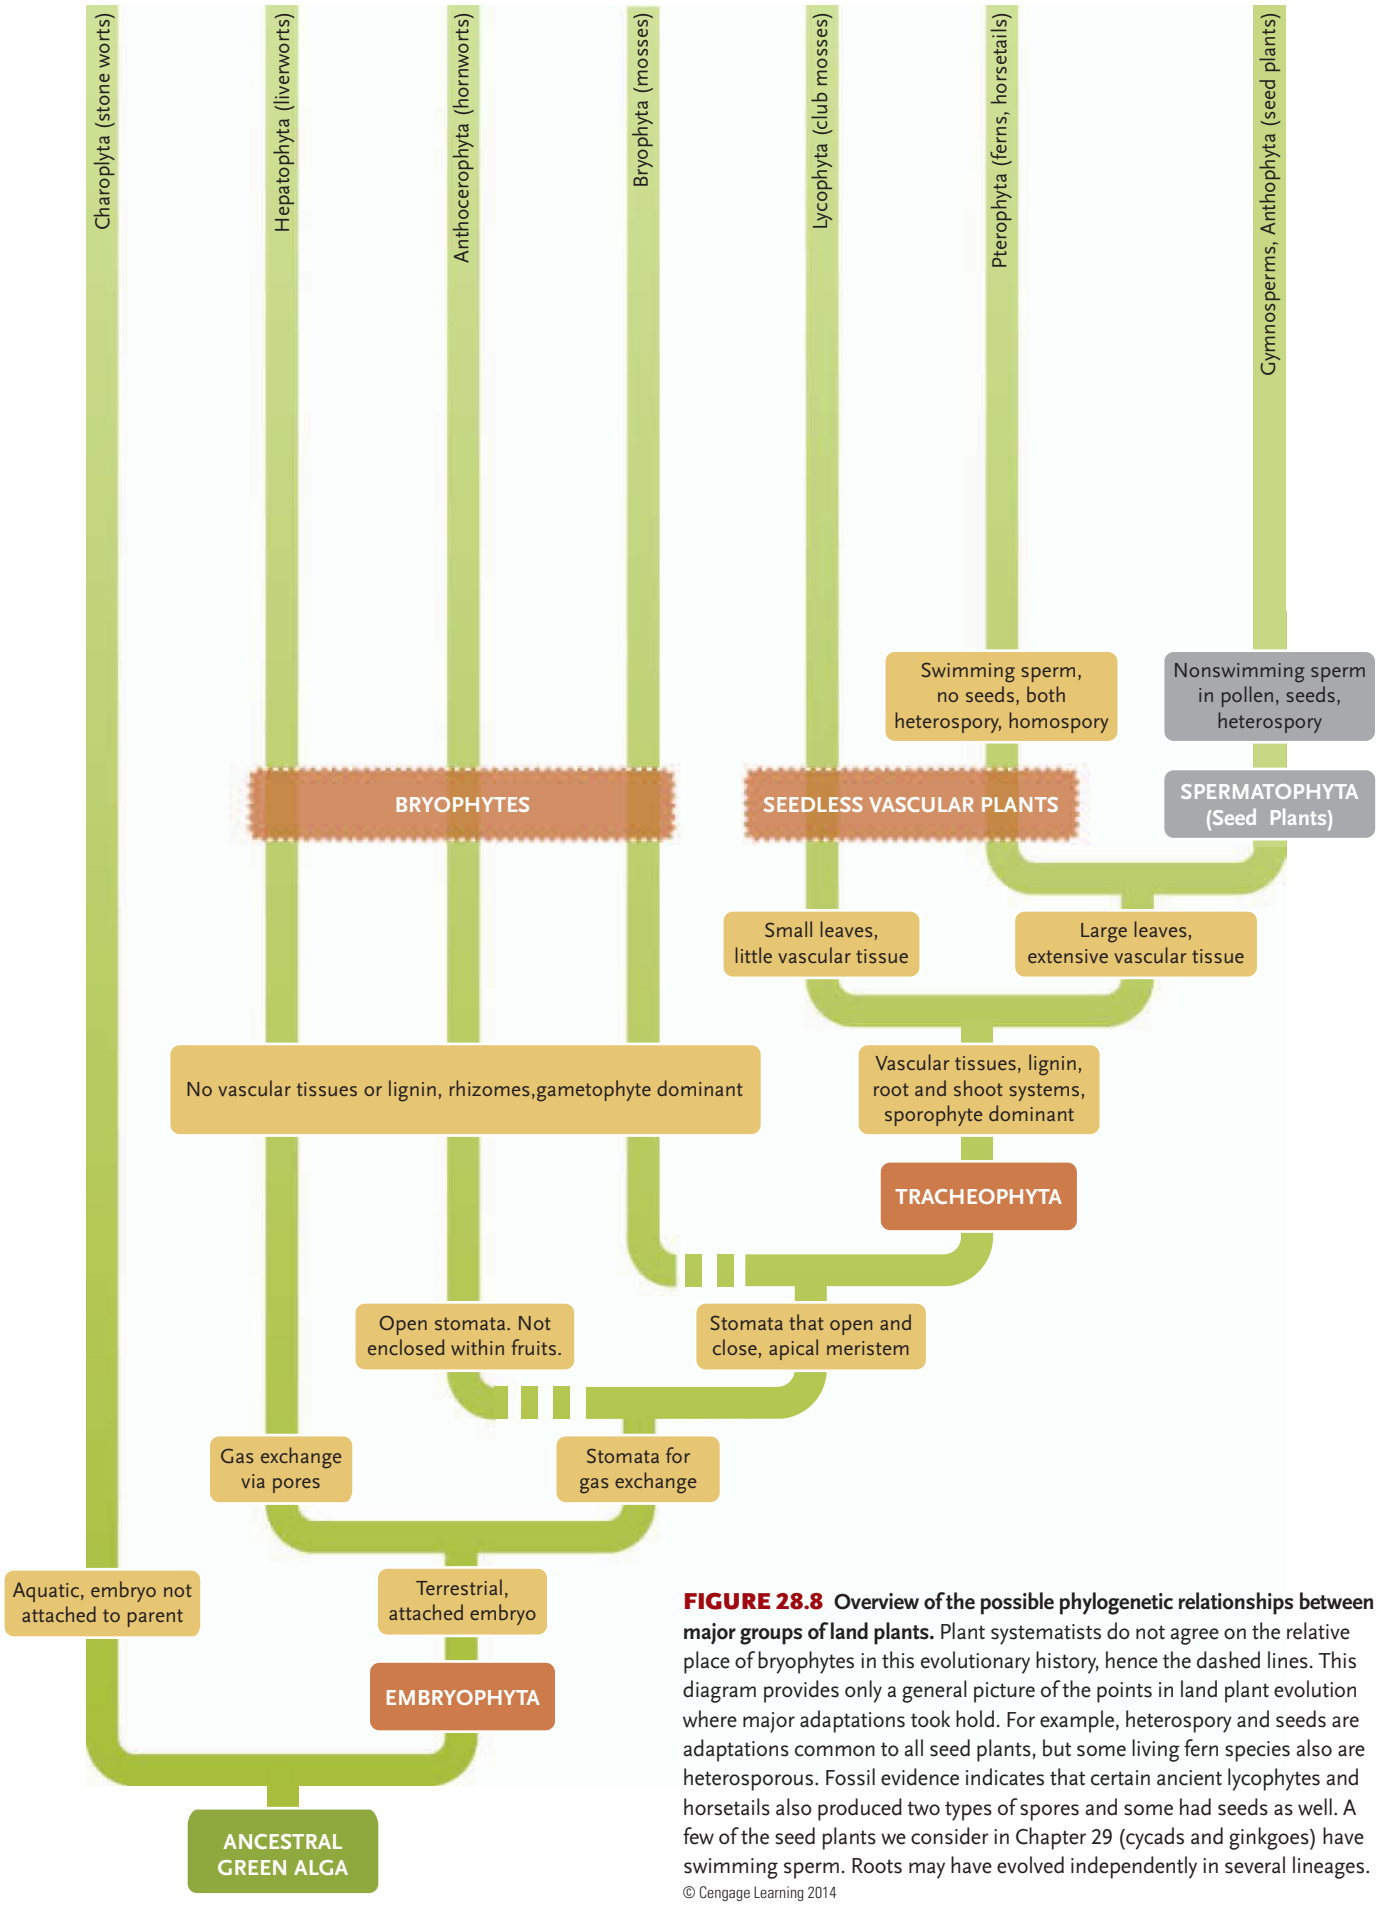

FIGURE 28.8 Overview of the possible phylogenetic relationships between major groups of land plants. Plant systematists do not agree on the relative place of bryophytes in this evolutionary history, hence the dashed lines. This diagram provides only a general picture of the points in land plant evolution where major adaptations took hold. For example, heterospory and seeds are adaptations common to all seed plants, but some living fern species also are heterosporous. Fossil evidence indicates that certain ancient lycophytes and horsetails also produced two types of spores and some had seeds as well. A few of the seed plants we consider in Chapter 29 (cycads and ginkgoes) have swimming sperm. Roots may have evolved independently in several lineages.

STUDY BREAK 28.1

1. **How did plant adaptations such as a root system, a shoot system, and a vascular system collectively influence the transition to terrestrial life?**
2. **Describe the difference between homospory and heterospory, and explain how heterospory paved the way for other reproductive adaptations in land plants.**

THINK OUTSIDE THE BOOK

In 2009 researchers studying seaweeds off the coast of California reported discovering a species of red alga with lignin in its tissues. The project's lead scientist was Patrick Martone, now at the University of British Columbia. Use the Internet to learn more about Martone's work. Why was the discovery of lignin in a red alga so surprising, and what are its potential evolutionary implications?

28.2 Bryophytes: Nonvascular Land Plants

The bryophytes (*bryon* = moss)—liverworts, hornworts, and mosses—have a combination of traits that allow them to bridge aquatic and land environments. Bryophytes lack a well-developed system for conducting water, and while some can withstand desiccation, it is not surprising that they commonly grow on wet sites along creek banks or on rocks just above running water; in bogs, swamps, or the dense shade of damp forests; and on moist tree trunks or rooftops. Some species are **epiphytes** (*ep* = upon)—they grow independently (that is, not as a parasite) on another organism or some other moist place, ranging from the splash zone just above high tide on rocky shores to edges of snowbanks.

In general, bryophytes are strikingly algalike. They produce flagellated sperm that must swim through water to reach eggs, and they do not have a complex vascular system (although some have a primitive type of conducting tissue). Bryophytes do have parts that are rootlike, stemlike, and leaflike. However, the "roots" are rhizoids, and bryophyte "stems" and "leaves" did not evolve from the same structures as vascular plant stems and leaves did. (That is, stems and leaves are not homologous in the two groups.) Also, as already mentioned, bryophyte tissues do not contain lignified cells. The absence of this strengthening material and the lack of internal pipelines for efficient nutrient transport partly account for bryophytes' small size—typically less than 20 cm long—and for their tendency to grow sprawled along surfaces instead of upright.

Notwithstanding these limitations, bryophytes are clearly adapted to land. Along with their leaflike, stemlike, and fibrous, rootlike organs, sporophytes of some species have a water-conserving cuticle and stomata. Like most plants, bryophytes also have both sexual and asexual reproductive modes. And as is true of all plants, the life cycle has both gametophyte (n) and sporophyte ($2n$) phases, though the sporophyte is tiny and lives only a short time. **Figure 28.9** shows the green, leafy gametophyte of a moss plant, with miniscule diploid sporophytes attached to it by slender stalks. Bryophyte gametophytes produce gametes sheltered within a layer of protective cells called a **gametangium** (plural, *gametangia*). The gametangia in which bryophyte eggs form are flask-shaped structures called **archegonia** (*archi* = first, *gonos* = seed). Flagellated sperm form in rounded gametangia called **antheridia** (*antheros* = flowerlike). The sperm swim through a film of water on the plant to the archegonia and fertilize eggs. Each fertilized egg gives rise to a diploid embryo sporophyte, which stays attached to the gametophyte, produces spores—and the cycle repeats.

Despite their similarities to more complex plants, bryophytes are unique in several ways. Unlike in vascular species, the gametophyte is much larger than the sporophyte and obtains its nutrition independently of the sporophyte body. In fact, the comparatively tiny sporophyte remains attached to the gametophyte and depends on the gametophyte for much of its nutrition.

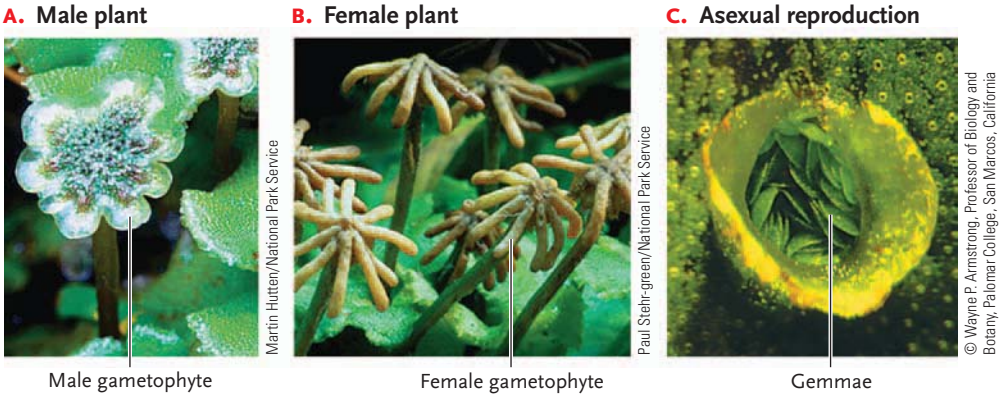

FIGURE 28.10 The bryophyte *Marchantia*, the only liverwort to produce (A) male and (B) female gametophytes on separate plants. *Marchantia* also reproduces asexually by way of **(C)** gemmae, multicellular vegetative bodies that develop in tiny cups on the plant body. Gemmae can grow into new plants when splashing raindrops transport them to suitable sites.

The position of bryophytes in plant evolution is still an open question. The basic bryophyte body plan may be similar to the ancestral condition from which higher plants evolved. In another view, bryophytes are a side shoot of evolution, completely separate from the path that led to vascular plants. The fossil record does not help much in resolving the issue. Although the 475-million-year-old spores noted earlier resemble modern liverwort spores, the first undisputed bryophyte fossils appear in late-Devonian rocks 350 mya, after vascular plants were already on the scene.

Despite questions raised by recent fossil finds, most current molecular, biochemical, cellular, and morphological evidence supports the view that bryophytes are not a monophyletic group. Instead, the various bryophytes evolved as separate lineages, in parallel with vascular plants. The relationships are far from resolved, however. For example, molecular evidence can be interpreted to mean that liverworts diverged early on from the lineage that led to all other land plants, with hornworts diverging later and mosses later still. Until new discoveries and interpretive work clarify this picture, the classification scheme in this chapter places liverworts, hornworts, and mosses in separate phyla. Our survey of nonvascular plants begins with the liverworts and hornworts, the simplest of the group, and concludes with mosses—plants that not only are more familiar to most of us, but whose structure and physiology more closely resemble that of vascular plants.

Liverworts May Have Been the First Land Plants

Liverworts make up the phylum Hepatophyta, and early herbalists thought that these small plants were shaped like the lobes of the human liver (*hepat* = liver; *wort* = herb). The resemblance might be vague to modern eyes: many of the 6,000 species of liverworts consist of a flat, branching, ribbonlike plate of tissue closely pressed against damp soil. This simple body, called a *thallus* (plural, *thalli*) is the gametophyte generation. Threadlike rhizoids anchor the gametophytes to their substrate. About two-thirds of liverwort species have leaflike structures, and some have stemlike parts. None have stomata, the openings that regulate gas exchange in most other land plants, although some species do have pores that open and close. Mitochondrial gene sequence data show that liverworts lack a few features (three introns) that are present in other bryophytes and in vascular plants. This finding has bolstered the hypothesis that liverworts were probably the first land plants.

In species of the liverwort genus *Marchantia* **(Figure 28.10),** male and female gametophytes are separate plants. Male plants produce antheridia and female plants produce archegonia on specialized stalked organs (see Figure 28.10A, B). The sperm released from an antheridium must swim through surface water to encounter an egg inside an archegonium of a female gametophyte. After fertilization, a small, diploid sporophyte develops inside the archegonium, matures there, and produces haploid spores by meiosis. During meiosis, *Marchantia* sex chromosomes segregate, so some spores have the male genotype and others the female genotype. As in other liverworts, the spores develop inside jacketed sporangia that split open to release the spores. A spore that is carried by air currents to a suitable location germinates and gives rise to a haploid gametophyte, which is either male or female. *Marchantia* also can reproduce asexually by way of **gemmae** (*gem* = bud), small cell masses that form in cuplike growths on a thallus (see Figure 28.10C). Gemmae can grow into new thalli when rainwater splashes them out of the cups and onto an appropriately moist substrate.

Hornworts Have Both Plantlike and Algalike Features

About 100 species of hornworts make up the phylum **Anthocerophyta.** Simple stomata, which are permanently open, appear in this group. Like some liverworts, a hornwort gametophyte has a flat thallus, but the sporangium of the sporophyte phase is long and pointed, like a horn **(Figure 28.11).** The sporangia split into two or three ribbonlike sections when they release spores. Sexual reproduction occurs in basically the same way as in liverworts: free-swimming sperm fertilize eggs, which give rise to the sporophytes. Hornworts sometimes reproduce asexually by fragmentation as pieces of a thallus break off, form rhizoids, and develop into new individuals. Many hornwort species have cell features in common with green algae, including the presence in each cell of a single large chloroplast that contains protein bodies called pyrenoids. No other group of land plants has this feature, and some biologists have speculated that the

distinction of "first land plant" should be assigned not to liverworts but to hornworts instead.

Mosses Most Closely Resemble Vascular Plants

Chances are that you have seen, touched, or sat on at least several of the approximately 10,000 species of mosses, and the use of the name **Bryophyta** for this phylum underscores the fact that mosses are the best-known bryophytes. They also are structurally and functionally most similar to the vascular plants we will consider in following sections. Their spores, produced by the tens of millions in sporangia, give rise to threadlike, haploid gametophytes that grow into the familiar moss plants, which often form tufts or carpets of vegetation on the surface of rocks, soil, or bark.

The moss life cycle, diagrammed in **Figure 28.12,** begins when a haploid (*n*) spore lands on a wet soil surface. After the

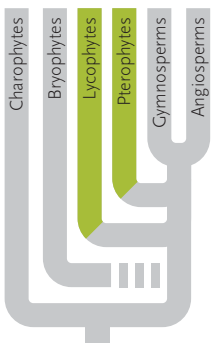
spore germinates, it elongates and branches into a filamentous web of tissue called a **protonema** ("first thread"), which can become dense enough to color the surface of soil, rocks, or bark visibly green. After several weeks of growth, the budlike cell masses on a protonema develop into leafy, green gametophytes anchored by rhizoids. A single protonema can be extremely prolific, producing bud after bud—and in this way giving rise to a dense clone of genetically identical gametophytes. Leafy mosses also may reproduce asexually by gemmae produced at the surface of rhizoids as well as on aboveground parts.

When a leafy moss is sexually mature, gametangia develop on its gametophytes and gametes form in them. In some moss genera, plants are unisexual and produce male *or* female gametangia—antheridia at the tips of male gametophytes and archegonia at the tips of female gametophytes. In other genera, plants are bisexual and produce both antheridia and archegonia. Propelled by a pair of flagella, sperm released from antheridia swim through a film of dew or rainwater and down a channel in the neck of the archegonium, attracted by a gradient of a chemical secreted by each egg. Fertilization produces the new sporophyte generation inside the archegonium, in the form of diploid zygotes that develop into small, mature sporophytes, each consisting of a sporangium on a stalk. Moss sporophytes may eventually develop chloroplasts and nourish themselves by photosynthesis, but initially they depend on the gametophytes for food. And even after a moss sporophyte begins photosynthesis, it still must obtain water, carbohydrates, and some other nutrients from the gametophyte.

Certain moss gametophytes are structurally complex, with features somewhat similar to those of higher plants. For example, mosses have stomata that open and close, and some species have a central strand of primitive conducting tissue. One kind of this tissue is made up of elongated, thin-walled, dead and empty cells that conduct water. These specialized cells, called hydroids, have oblique end walls that sometimes are partly dissolved or perforated with pores. Experiments with dyes show that water moves through them, as it does in similar xylemlike arrangements in vascular plants (see Chapters 33 and 34). In a few mosses, the water-conducting cells are surrounded by sugar-conducting tissue resembling the phloem of vascular plants.



Mosses and other bryophytes are important both ecologically and economically. As colonizers of bare land, their small bodies trap particles of organic and inorganic matter, helping to build soil on bare rock and stabilizing soil surfaces with a biological crust in harsh places like coastal dunes, inland deserts, and embankments created by road construction. Some hornworts harbor mutualistic nitrogen-fixing cyanobacteria, and so increase the amount of nitrogen available to other plants. In arctic tundras, bryophytes constitute as much as half the biomass, and they are crucial components of the food web that supports animals in that ecosystem. People have long used *Sphagnum* and other absorbent "peat" mosses (which typically grow in bogs) for everything from diapering babies and filtering whiskey to increasing the water-holding capacity of garden soil. Peat moss also is used as a fuel; each day the Rhode generating station in Ireland, one of several in that nation, burns 2,000 metric tons of peat to produce electricity.

In the next section we turn to the vascular plants, which have specialized tissues that can transport water, minerals, and sugars. Without the capacity to move these substances efficiently throughout the plant body, large sporophytes could not have evolved on land. Unlike bryophytes, modern vascular plants are monophyletic—all groups are probably descended from a common ancestor.

2. **How do specific aspects of a moss plant's anatomy resemble those of vascular plants?**

28.3 Seedless Vascular Plants

The first vascular plants, which did not "package" their embryos inside protective seeds, were the dominant plants on Earth for almost 200 million years, until seed plants became abundant. The fossil record shows that seedless vascular plants were well established by the late Silurian, some 427 mya, and they flourished until the end of the Carboniferous, about 250 mya. Some living seedless vascular plants have certain bryophyte-like traits, whereas others have some characteristics of seed plants. On one hand, like bryophytes, seedless vascular plants reproduce sexually by releasing spores, and they have swimming sperm that require free water to reach eggs. On the other hand, as in seed plants, the sporophyte of a seedless vascular plant separates from the gametophyte at a certain point in its development and has well-developed vascular tissues (xylem and phloem). Also, the sporophyte is the larger, longer-lived stage of the life cycle and the gametophytes are very small. Some gametophytes even lack chlorophyll. **Table 28.2** summarizes these characteristics and gives an overview of seedless vascular plant features.

Seedless vascular plants once encompassed a huge number of diverse species of trees, shrubs, and herbs. In the late Paleozoic era, they were Earth's dominant vegetation. Their remains formed most of the vast coal deposits that literally fueled the Industrial Revolution and continue to be major global energy sources. Some lineages have endured to the present, but collectively these survivors total fewer than 14,000 species. The taxonomic relationships between various lines are still under active investigation, and comparisons of gene sequences from the genomes in plastids, cell nuclei, and sometimes mitochondria are revealing previously unsuspected links between some of them. In this book we assign seedless vascular plants to two phyla, the

TABLE 28.2 Seedless Plant Phyla and Major Characteristics

Phylum	Common Name	Number of Species*	Common General Characteristics
Bryophytes: Nonvascular plants. Gametophyte dominant, free water required for fertilization, cuticle and stomata present in some.			
Hepatophyta	Liverworts	6,000	Leafy or simple flattened thallus with pores, rhizoids; spores in capsules; cuticle. Moist, humid habitats.
Anthocerophyta	Hornworts	100	Simple flattened thallus, rhizoids; stomata; hornlike sporangia. Moist, humid habitats.
Bryophyta	Mosses	10,000	Feathery or cushiony thallus, some have hydroids; spores in capsules. Moist, humid habitats; colonizes bare rock, soil, or bark.
Seedless vascular plants: Sporophyte dominant, swimming sperm, free water required for fertilization, cuticle and stomata present in all.			
Lycophyta	Club mosses	1,000	Simple leaves, true roots; most species have sporangia on sporophylls. Mostly wet or shady habitats.
Pterophyta	Ferns, whisk ferns, horsetails	13,000	*Ferns:* Finely divided leaves, woody stems in tree ferns; sporangia in sori. Habitats from wet to arid. *Whisk ferns:* Branching stem from rhizomes; sporangia on stem scales. Tropical to subtropical habitats. *Horsetails:* Hollow photosynthetic stem, scalelike leaves with silica in cell walls, sporangia in strobili. Swamps, disturbed habitats.

*Numbers of species are approximate.

Lycophyta (club mosses and their close relatives) and the Pterophyta (ferns, whisk ferns, and horsetails).

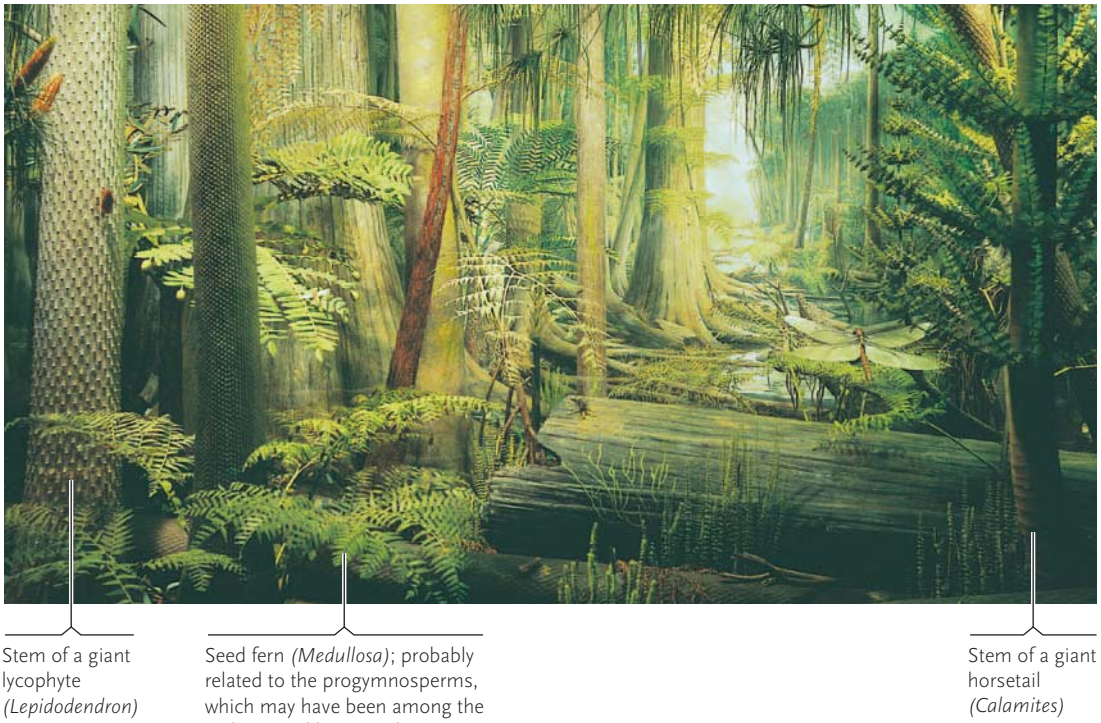
Early Seedless Vascular Plants Flourished in Moist Environments

The extinct plant genus *Cooksonia* (see Figure 28.4) probably was one of the earliest ancestors of modern seedless vascular plants. It and similar plants dominated the mudflats and swamps of the Devonian period (408–360 mya). Like other members of its extinct phylum (Rhyniophyta), *Cooksonia* species were small, rootless, and leafless, but their simple stems had a central core of xylem, an arrangement seen in many existing vascular plants. Although this and other now-extinct phyla came and went, ancestral forms of both modern phyla of seedless vascular plants appeared. In botanical terms, the earliest seedless vascular plants were "herbs"—that is, they did not have woody, lignified tissue. By the start of the ensuing Carboniferous period, however, the small, herbaceous Devonian plants had given rise to larger shrubby species and to trees—long-lived plants with a single main stem containing woody tissue. Other features of some of these early trees may have included bark, roots, leaves, and even seeds.

Carboniferous forests were lush, swampy places dominated by members of the phylum **Lycophyta,** a group in which roots evolved—an innovation that provided both firm anchoring in the soil and enhanced access to soil water and nutrients. One example is *Lepidodendron,* which had broad, straplike leaves and sporangia near the ends of the branches **(Figure 28.13A).** It also had xylem and several other types of tissues that are typical of all modern vascular plants, although probably not in the same proportions as seen today.

Carboniferous forests also were home to representatives of the phylum **Pterophyta,** including ferns such as *Medullosa* and giant horsetails such as *Calamites*—huge treelike plants that could have a trunk 30 cm in diameter. The strong, upright stems were attached to a system of rhizomes. Ferns populated the forest understory. Some early seed plants were present as well, including now-extinct fernlike plants, called seed ferns, which bore seeds at the tips of leaves **(Figure 28.13B).**

When leaves, branches, and old trees in swampy Carboniferous landscapes fell to the ground, they became buried in anaerobic sediments. Over geologic time, these buried remains were compressed and fossilized, and today they form much of the world's coal reserves. This is why coal is called a "fossil fuel," and the Carboniferous period is called the Coal Age. Characterized by a humid climate over much of the planet, and by the dominance of seedless vascular plants, the Carboniferous period continued for 150 million years, ending when climate patterns changed during the Paleozoic era (550–250 mya).



Most modern seedless vascular plants are ferns, and like their ancestors they are confined largely to wet or humid environments because they require external water for reproduction. Except for whisk ferns, their gametophytes do not rely on vascular tissues for water transport, and male gametes swim through water to reach eggs. In the wild, the few vascular seedless plants that are adapted to dry environments such as deserts can reproduce sexually only when seasonal rains make surface water available.

Modern Lycophytes Are Small and Have Simple Vascular Tissues

Unlike their ancient relatives, the most familiar of the 1,000 or so living species of lycophytes are small, ground-hugging species. They include spike mosses, quillworts, and the club mosses shown in **Figure 28.14A**—members of genera such as *Lycopodium* that grow on forest floors. A club moss sporophyte has stems and roots that contain a small amount of the vascular tissue xylem. Near the tips of stems are small, green microphyll-type leaves called **sporophylls,** with a single sporangium tucked at the base of each one. A cluster of sporophylls forms a conical **strobilus** (plural, *strobili*). In some species the sporangia release haploid spores produced by meiosis **(Figure 28.14B).** If a spore germinates (sometimes several years after it is released), it forms a free-living gametophyte that differs markedly from the sporophyte. Ranging in size from nearly invisible to several centimeters, the gametophyte easily becomes buried under decomposing plant litter. There rhizoids attach it to a substrate. It cannot photosynthesize, and instead obtains nutrients by way of mycorrhizae, a symbiotic interaction in which a plant's rhizoids or roots associate with a particular fungus. Although many lycophyte species are homosporous—gametophytes are bisexual and produce both eggs and sperm—some are heterosporous. Regardless, as with ancestral lycophytes, the sperm require water in which they can swim to the eggs. After fertilization, the life cycle comes full circle as the zygote develops into a diploid embryo that grows into a sporophyte.

Ferns, Whisk Ferns, Horsetails, and Their Relatives Make Up the Diverse Phylum Pterophyta

Second only to the flowering plants, the phylum Pterophyta (*pteron* = wing) contains a large and diverse group of vascular plants—the 13,000 or so species of ferns, whisk ferns, and horsetails. Most ferns, including some that are popular houseplants, are native to tropical and temperate regions. Some floating species are less than 1 cm across, while some tropical "tree ferns" grow to 25 m tall. Other species are adapted to life in arctic and alpine tundras, salty mangrove swamps, and semi-arid deserts.

COMPLEX ANATOMICAL FEATURES IN FERNS The familiar plant body of a fern is the sporophyte phase **(Figure 28.15).** It produces an aboveground clump of fern leaves, called fronds. Often finely divided and featherlike, and containing multiple strands of vascular tissue, fronds are an example of large, macrophyll-type leaves, a trait ferns share with seed plants. A typical frond has a well-developed epidermis with chloroplasts in the epidermal cells and stomata on the lower surface. Young fronds are tightly coiled, and as they emerge above the soil these "fiddleheads" (so named because they resemble the scroll of a violin) unroll and expand. Some people enjoy collecting and eating the unfurled fiddleheads of edible (noncarcinogenic) species.

Except for tropical tree ferns, the stems of most ferns are underground rhizomes. The stem's vascular system is organized into a complex, interconnecting network of bundles, each having a core of xylem surrounded by phloem. Roots descend along the length of the rhizomes. Remarkably, a rhizome can live for centuries, growing at its tip and extending outward horizontally through the soil, sometimes over a considerable area. In most ferns, the fronds arise from nodes positioned along the rhizome. A **node** is the point on a stem where one or more leaves are attached.

In most fern species, the sporophyte produces sporangia on the lower surface or margin of some leaves. Often, several sporangia are clustered into a rust-colored **sorus** (plural, *sori*). Sori may be exposed or they may be protected with a flap of tissue. Each sporangium is a delicate case, shaped rather like an old-fashioned pocket watch and covered by a layer of epidermal cells. In the layer, a row of thick-walled cells called the **annulus** ("ring") nearly encircles the sporangium.

Inside the sporangium, haploid spores arise by meiosis. Meanwhile, the sporangium slowly dries, and in the process

the annulus contracts. Eventually the force of the contracting annulus rips open the sporangium, which snaps back on itself, flinging out the mature spores. In this way fern spores can be dispersed up to 2 m away from the parent plant. Wind may carry them much farther: on board the *Beagle,* Charles Darwin collected fern spores hundreds of miles from shore.

A germinating spore develops into a gametophyte, which is typically a small, heart-shaped plant anchored to the soil by rhizoids. Both antheridia and archegonia are present on the lower surface of each gametophyte, where moisture is trapped. Inside an antheridium is a globular packet of haploid cells, each of which develops into a helical sperm cell with many flagella. When water is present, the antheridium bursts, releasing the sperm. If mature archegonia are nearby, the sperm swim toward them, drawn by a chemical attractant that diffuses from the neck of the archegonium, which is open when free water is present.

After a sperm fertilizes an egg, the diploid zygote begins dividing and developing into an embryo, which at this stage obtains nutrients from the gametophyte. In a short time, however, the embryo develops into a young sporophyte that is larger than the gametophyte and has its own green leaf and a root system. The sporophyte now is nutritionally independent, and the parent gametophyte degenerates and dies.

FEATURES OF EARLY VASCULAR PLANTS IN WHISK FERNS

The whisk ferns and their relatives are represented by two genera, *Psilotum* (pronounced si-LOW-tum) and *Tmesipteris* (may-SIP-ter-is), with only about 10 species in all. These rather uncommon plants grow in tropical and subtropical regions, often as epiphytes. In the United States the range for *Psilotum* species **(Figure 28.16)** includes Hawaii, Gulf Coast states such as Florida and Louisiana, and parts of the West.

Whisk fern sporophytes are up to 60 cm tall and resemble the extinct *Cooksonia.* Like those early vascular plants, they lack roots and leaves. Instead, small scales adorn an upright branching stem that ascends from a horizontal rhizome system anchored by rhizoids. The rhizoids have mycorrhizal fungi associated with them, which provide enhanced access to some nutrients.

A whisk fern's stem is structurally and functionally multifaceted. Its epidermal cells carry out photosynthesis, whereas its core has the transport tissues xylem and phloem and other anatomical features of more complex vascular plants. Sporangia rest atop some of the stem scales. Inside them, meiotic divisions of specialized cells produce haploid spores.

HORSETAILS, REMNANTS OF AN ANCIENT PAST

Only fifteen horsetail species in a single genus, *Equisetum,* have survived to the present **(Figure 28.17).** Unlike towering ancestors such as *Calamites,* most modern horsetails grow less than a meter high, in moist soil along streams and in disturbed habitats, such as roadsides and beds of railroad tracks. Their sporophytes typically have underground rhizomes along with roots that anchor the rhizome to the soil. Whorls of scalelike leaves are arranged around a photosynthetic stem that is stiff and gritty from the silica that horsetails accumulate in their tissues. They came to be known popularly as "scouring rushes" because American pioneers used them to scrub out pots and pans.

Equisetum sporangia are borne in strobili on highly specialized stem structures quite different from the sporophylls of club mosses. Each stalked spore-bearing structure in a strobilus resembles an umbrella and is attached at right angles to a main axis. Haploid spores develop in sporangia attached near the edge of the "umbrella's" underside, and air currents disperse them.

blickwinkel/Alamy

The Powerful Genetic Toolkit for Studying Plant Evolution

Unlike most other eukaryotes, plants have three distinct sets of genes—in the cell nucleus, in mitochondria, and in chloroplasts. Chloroplast DNA, or cpDNA, has been especially useful for evolutionary studies, particularly the chloroplast *rbcL* gene. Mutations of the gene have occurred slowly, at about one-fourth to one-fifth the rate of genes in the nucleus. As a result, the DNA sequences of *rbcL* genes of different species diverge less than those of most other plant genes. Further, there are no introns—noncoding sequences—interrupting the coding sequence of the *rbcL* gene. Researchers can compare *rbcL* DNA from different species base by base, with no need to subtract introns. At the same time, the *rbcL* genes of different species are different enough to allow researchers to assemble evolutionary trees based on the degree of sequence variation.

Research Question

What were the major branch points in plant evolution?

Experiments

Studies using cpDNA have helped fuel several fundamental shifts in our understanding of branch points in plant evolution. For example, together with gene sequence data from nuclear DNA, analysis of *rbcL* genes provided evidence that charophyte green algae were the evolutionary forerunners of land plants. Similarly, in the late 1990s an international research team led by Yin-Long Qiu at the University of Massachusetts at Amherst correlated the loss of introns from two mitochondrial genes with the hypothesis that the first land plants were liverworts. Qiu and his colleagues carried out a genetic survey of more than 350 land plants representing all major lineages. They discovered that the noncoding sequences were present in all other bryophytes and all major lines of vascular plants, but were absent in liverworts, green algae, and all other eukaryotes. Analysis of *rbcL* sequences in various plant groups support the findings. Data from cpDNA and mtDNA analyses also underlie the hypothesis that, as land plants evolved, the ancient relatives of club mosses (lycophytes) were the forerunners of other vascular plants. Clearly, these varied molecular tools, and cpDNA in particular, are helping plant scientists explore evolutionary relationships across the whole spectrum of the Kingdom Plantae.

Conclusions

The evidence from cpDNA and mtDNA analysis points to liverworts as the first land plants, and ancient relatives of club mosses as the forerunners of other vascular plants.

THINK LIKE A SCIENTIST Suppose a paleobotanist came across an intact fossil of a small, previously unknown lycophyte having rather well developed vascular tissue. Might this discovery significantly alter our understanding of early vascular plant evolution?

Source: Y.-L. Qiu et al. 1998. The gain of three mitochondrial introns identifies liverworts as the earliest land plants. *Nature* 394:671–674.

They must germinate within a few days to produce gametophytes, which are free-living plants about the size of a small pea.

STUDY BREAK 28.3

1. Compare and contrast the lycophyte and bryophyte life cycles with respect to the sizes and longevity of gametophyte and sporophyte phases.
2. In ferns, whisk ferns, and horsetails, what kinds of structures fulfill the roles of roots and leaves?
3. How does the life cycle of a horsetail differ from that of a fern?

THINK OUTSIDE THE BOOK

Seed ferns, an extinct group mentioned briefly in this section, are assigned to the extinct phylum Pteridospermophyta. They were nearly wiped out by the Permian–Triassic mass extinction event that occurred about 251 mya and became extinct soon thereafter. Seed-bearing conifers living at the time fared better, and conifers were the dominant land plants for at least another 100 million years. Using Internet or library resources, develop a plausible explanation for why the seed fern and conifer lineages had such differing evolutionary fates.

UNANSWERED QUESTIONS

Why is the homosporous lifestyle correlated with unusually large numbers of chromosomes?

My laboratory at the University of Arizona is interested in how plant genomes evolve, and, in particular, how changes in chromosome number and organization occur. In the plant kingdom, and in fact across all eukaryotes, homosporous ferns and lycophytes have the largest numbers of chromosomes: on average $n = 57.05$. How this strikingly large average chromosome number correlates with reproductive strategies in homosporous lycophytes and ferns has long been a mystery to plant evolutionary biologists. In general, chromosome numbers may increase due to dysploidy—a change in the number of single chromosomes without a change in the overall number of genes—or by polyploidy (duplication of a whole genome). Decades of research have uncovered only rare examples of dysploidy in plants, but polyploidy is much more common. This observation has fueled hypotheses about why high chromosome numbers are correlated with homospory.

One possible explanation is that the capacity of a single spore to produce both sperm and egg may support higher rates of polyploidy. During polyploidy, the new zygote with duplicated chromosomes is nearly always reproductively isolated from its parental, diploid relatives. This means that for polyploid lineages to survive and establish clades with higher numbers of chromosomes, they must be able to reproduce. If a polyploid individual arises and is the only one of its kind, then the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

reproductive assurance of having homosporous gametophytes will aid in the new line's initial survival. In contrast, a heterosporous plant would need to have a megaspore and a microspore near each other for reproduction, instead of just a single spore.

Alternatively, it may be that having more chromosomes relieves potential deleterious effects of the extreme inbreeding possible in homosporous ferns and lycophytes. Assuming that the overall number of genes remains similar, a greater number of chromosomes will increase independent assortment and thus effectively increase the recombination rate. Whether increased polyploidy, selection for increased independent assortment, or some combination of both is driving the evolution of high chromosome numbers in homosporous lycophytes and ferns remains an open question. New genomic tools are being applied to study the genomes of these groups to give us new insights into how the diversity of plant lifestyles has influenced the diversity of plant genomes.

THINK LIKE A SCIENTIST How would you expect changes in chromosome number to influence recombination and independent assortment? How are changes in chromosome number achieved without creating problems during meiosis? Would you expect all chromosomes to be equally likely to be duplicated or lost?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

28.1 The Transition to Life on Land

- Plants are thought to have evolved from green algae between 425 and 490 million years ago (Figure 28.2).
- Key adaptations in early land plants include an outer cuticle that helps prevent desiccation, tissues containing lignified cells, spores protected by a wall containing sporopollenin, multicellular chambers that protect developing gametes, and an embryo sheltered inside a parent plant (Figure 28.3).
- Land plant evolution also included the development of vascular tissues, root systems, and shoot systems, including stems containing lignified cells and leaves having stomata; a shift from dominance by a long-lived, larger haploid gametophyte to dominance of a long-lived, larger diploid sporophyte; and a shift from homospory to heterospory with separate male and female gametophytes (Figures 28.5–28.8).

  Animation: The importance of alternation of generations

  Animation: Evolutionary tree for plants

28.2 Bryophytes: Nonvascular Land Plants

- Existing nonvascular land plants, or bryophytes, include the liverworts (Hepatophyta), hornworts (Anthocerophyta), and mosses (Bryophyta). Liverworts may have been the first land plants.
- Bryophytes release spores and produce flagellated sperm that swim through free water to reach eggs. They lack a vascular system; true roots, stems, and leaves; and lignified tissue. A larger, dominant gametophyte (n) phase alternates with a small, fleeting sporophyte ($2n$) phase (Figures 28.9–28.12).

  Animation: Fern life cycle

  Animation: Marchantia, a liverwort

  Animation: Moss life cycle

28.3 Seedless Vascular Plants

- Existing seedless vascular land plants include the lycophytes (club mosses), whisk ferns, horsetails, and ferns. They release spores and have swimming sperm, but have well-developed vascular tissues. The sporophyte is the larger, longer-lived stage of the life cycle and develops independently of the small gametophyte.
- Club mosses (Lycophyta) have sporangia clustered at the bases of specialized leaves called sporophylls. Clusters of sporophylls form a strobilus ("cone"). Haploid spores germinate to form small gametophytes. The life cycle is similar in ferns, whisk ferns, and horsetails (Pterophyta) (Figures 28.13–28.17).
- Ferns are the most diverse group of seedless vascular plants. Most species do not have aboveground stems, only leaves that arise from nodes along an underground rhizome. Fern leaves typically have well-developed stomata, and the vascular system consists of bundles, each with xylem surrounded by phloem. Sporangia on sporophylls ("fronds") release spores that develop into gametophytes. Sexual reproduction produces a much larger, long-lived sporophyte.

UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following is *not* an evolutionary trend among plants?
   a. developing vascular tissues
   b. becoming seedless
   c. having a dominant diploid generation
   d. producing nonmotile gametes
   e. producing two types of spores
2. As plants made the evolutionary transition to a terrestrial existence, they benefited from adaptations that:
   a. increased the motility of their gametes on dry land.
   b. flattened the plant body to expose it to the sun.
   c. reduced the number and distribution of roots to prevent drying.
   d. provided mechanisms for gaining access to nutrients in soil.
   e. allowed stems and leaves to absorb water from the atmosphere.

3. Which of the following is *not* generally thought to be accurate with respect to the evolution of leaves?
   a. Leaves arose more than once during land-plant evolution.
   b. Microphylls may have arisen as modifications of the main vertical stem.
   c. Macrophylls may have come about as modifications of stem branches.
   d. The evolution of higher-density leaf venation correlates with increased capacity for photosynthesis.
   e. Only macrophyll-type leaves, which have stomata and a network of veins, are observed in extant plant species.
4. Which is the correct matching of phylum and plant group?
   a. Hepatophyta: liverworts
   b. Anthocerophyta: mosses
   c. Bryophyta: horsetails
   d. Lycophyta: ferns
   e. Pterophyta: hornworts
5. A homeowner noticed moss growing between bricks on his patio. Closer examination revealed tiny brown stalks with cuplike tops emerging from green leaflets. These brown structures were:
   a. the sporophyte generation.
   b. the gametophyte generation.
   c. elongated haploid reproductive cells.
   d. archegonia.
   e. antheridia.
6. In addition to having simple vascular tissue, seedless vascular plants differ from all bryophytes in that:
   a. they do not require free water for fertilization.
   b. the sporophyte generation is dominant.
   c. most do not require a moist, humid, or shaded habitat.
   d. the group is much more diverse, with many more species overall.
   e. most have a feathery or flattened thallus.
7. Which feature(s) do ferns share with all other land plants?
   a. sporophyte and gametophyte life cycle stages
   b. gametophytes supported by a thallus
   c. dispersal of spores from a sorus
   d. asexual reproduction by way of gemmae
   e. water uptake by means of rhizoids
8. In comparing bryophytes and seedless vascular plants, which of the following statements is not accurate?
   a. In general, bryophyte traits more closely resemble those of algae.
   b. We only see true leaves, stems, and roots in seedless vascular plants.
   c. Both groups have lignified cells in some body parts.
   d. Bryophytes lack complex conducting tissues (xylem and phloem).
   e. Seedless vascular plants have sexual and asexual reproductive modes, but in bryophytes only asexual reproduction has been observed.
9. Based solely on numbers of species, the most successful seedless plants today are:
   a. horsetails.
   b. ferns.
   c. liverworts.
   d. mosses.
   e. club mosses.
10. Which of the following is/are true with respect to seedless vascular plants?
   a. Ferns are the most numerous species in this group.
   b. Lycophyte species grow the largest of all modern seedless vascular plants.
   c. Seedless vascular plants, including trees, shrubs, and herbaceous ("nonwoody") species dominated Earth's terrestrial environments for nearly 200 million years.
   d. The strobilus, where spore-producing parts sporangia are located, is a reproductive adaptation found in all seedless vascular plants.
   e. In the fern life cycle, the young sporophyte is dependent on the gametophyte, but quickly develops into an independent, larger plant with its own root system and leaves where photosynthesis occurs.

Discuss the Concepts

1. Working in the field, you discover a fossil of a previously undescribed plant species. The specimen is small and may not be complete; the bits you have do not include any floral parts. What sorts of observations would you need in order to classify the fossil as a seedless vascular plant with reasonable accuracy? What evidence would you need in order to distinguish between a fossil lycopod and a fern?
2. Compare the size, anatomical complexity, and degree of independence of a moss gametophyte and a fern gametophyte. Which one is the most protected from the external environment? Which trends in plant evolution does your work on this question bring to mind?

Design an Experiment

A moss species that you study occurs in lush abundance in the moist, shaded forest floor in a grove of coast redwoods *(Sequoia sempervirens)* in Northern California. When one of the massive old trees abruptly topples over, there is a dramatic increase in the amount of light and air movement in a sizable patch of the moss' habitat. This is a rare opportunity for you to study the effects on the moss of a sudden shift in the environmental conditions in which it grows. Devise an experimental plan to guide your research, including hypotheses about one or more ways the change may affect the species' growth and/or life cycle.

Interpret the Data

Green plants, green algae, red algae, and microscopic freshwater algae called glaucophytes are all primary photosynthetic eukaryotes—they have plastids, including chloroplasts that carry out photosynthesis. Biologists have long accepted the hypothesis that plastids arose by way of endosymbiosis of a cyanobacterium during the evolution of lineages leading to primary photosynthetic eukaryotes (see Sections 25.3 and 27.2). Until recently, however, there was no unequivocal molecular evidence to support this assumption. If the assumption is correct, then a phylogenetic tree based on molecular data should support the prediction that all primary photosynthetic eukaryotes are descended from a common ancestor. Naiara Rodríguez-Ezpeleta at the University of Montreal led a team that tested this prediction. They already knew that proteins associated with plastids in cyanobacteria and photosynthetic eukaryotes share some amino acid sequences. In the experiment of interest here, they sequenced the amino acids in 143 proteins encoded by nuclear genes of species representing all the primary photosynthetic groups. They used a computerized statistical method called bootstrapping to analyze the large number of different data sets from the selected species. Basically, bootstrapping produced a series of phylogenetic trees based on comparisons of the amino acid sequences in the target proteins from each species. It then compared the trees to see where overlaps occurred, and generated a summary tree like the one in **Figure A.**

1. Does Figure A support or contradict the hypothesis that a single endosymbiosis event correlated with the evolution of organisms containing plastids?
2. Do the data support the prediction that glaucophytes and green plants are sister groups—that is, that they are more closely related to each other than to other groups in the phylogeny?

Source: N. Rodriguez-Ezpeleta et al. 2005. Monophyly of primary photosynthetic eukaryotes: green plants, red algae, and glaucophytes. *Current Biology* 15:1325–1330.

Apply Evolutionary Thinking

One proposed bryophyte phylogeny considers hornworts and vascular plants (such as lycophytes and ferns) to be sister clades (see Figure A). Among other factors, a shared morphological feature supports this hypothesis: hornwort and vascular plant sporophytes both show indeterminate growth—once a sporophyte develops, it grows for the remainder of the plant's life. Indeterminate growth has not been observed in other bryophyte lineages. Can you think of a different evolutionary explanation for the growth pattern shared by hornworts and vascular plants?

Why it matters . . . Chances are, *Gossypium hirsutum* is one of the few truly indispensable plants in your life. This angiosperm, commonly called upland or Mexican cotton, produces the most widely used plant fiber in the world. While questions remain about where and when *Gossypium* species arose, archeological finds in places as distant as Peru, Pakistan, and Egypt show that humans have been using cotton in diverse ways for thousands of years. Today *G. hirsutum* accounts for about 90% of commercially grown cotton worldwide; its fibers are raw materials in a vast gamut of items ranging from jeans, T-shirts, and virtually every other sort of clothing, to bandages, rugs, bedding, and upholstery. Botanically the fibers are long, cellulose-rich "hairs" that develop from the protective coat around a cotton plant's seeds **(Figure 29.1).** The subset of cotton fibers called "lint" can be spun into strong thread.

FIGURE 29.1 **Some representative seed plants. TABLE 29.1 Seed Plant Phyla and Major Characteristics

Phylum	Common Name	Number of Species*	Common General Characteristics
Gymnosperms: Vascular plants with "naked" seeds. Nonmotile sperm arise from male gametophytes in pollen grains.			
Cycadophyta	Cycads	185	Shrubby or treelike with palmlike leaves, pithy stems; male and female strobili on separate plants. Widely distributed in warm climates.
Ginkgophyta	Ginkgo	1	Woody-stemmed tree, deciduous fan-shaped leaves. Male, female structures on separate plants. Temperate areas of China.
Gnetophyta	Gnetophytes	70	Shrubs or woody vines; one has strappy leaves. Male and female strobili on separate plants. Limited to deserts, tropics.
Coniferophyta	Conifers	550	Mostly evergreen, woody trees and shrubs with needlelike or scalelike leaves; male and female cones usually on same plant.
Angiosperms (Anthophyta): Woody or herbaceous plants with flowers, and seeds protected inside fruits; nearly all land habitats, some aquatic.			
Major groups: Magnoliids, Monocots, Eudicots			
Magnoliids	Magnolias, laurels, avocado, black peppers, and others	8,000+	Pollen grains have a single groove; some species with three of more cotyledons.
Monocots	Grasses, palms, lilies, orchids, and others	60,000+	Pollen grains have a single groove; one cotyledon. Parallel-veined leaves common.
Eudicots	Most fruit trees, roses, cabbages, melons, beans, potatoes, and others	200,000+	Pollen grains have three grooves. Most species have two cotyledons; net-veined leaves common.

*Numbers of species are approximate.

Cotton is just one example of the extraordinary benefits human societies gain from seed plants. It's easy to tick off many more, starting with wood, paper, and crucial food crops like rice, corn, and wheat. Beyond meeting human needs, seed plants are the main sources of nutrients and other materials essential to the functioning of nearly all land ecosystems. Technically seed plants are spermatophytes ("seed plant"), and seed plants as a whole belong to a grouping called the Spermatophyta. They are subdivided into gymnosperms—conifers and their relatives—and angiosperms, the flowering plants (Table 29.1). In this chapter we begin our survey of seed plants with the gymnosperms, the first to appear on the evolutionary stage.

29.1 Gymnosperms: The "Naked Seed" Plants

Gymnosperms are the conifers and their relatives. The earliest fossils identifiable as gymnosperms are found in Devonian rocks dating to about 390 mya (million years ago). By the Carboniferous (360–300 mya), when ferns and other seedless plants were dominant, many lines of gymnosperms had also arisen, and the first true conifers appeared. These radiated during the Permian period (300–250 mya), and the Mesozoic era that followed, 251 to 65 mya, was the age not only of the dinosaurs but of the gymnosperms as well.

The evolution of gymnosperms involved sweeping changes in plant structures related to reproduction. As a prelude to our survey of modern gymnosperms, we begin by considering some of these innovations, which opened new adaptive options for land plants.

Major Adaptations in Growth and Reproduction Occurred as Gymnosperms Evolved

Early gymnosperm evolution was marked by several innovations, all of which facilitated the radiation of gymnosperms into various land environments. These changes included increasing size and major reproductive adaptations—the ovule, pollen and pollination, and the seed. These adaptations helped spark the diversification of plants in the Devonian period, 416 to 359 mya. Although the fossil record is sketchy, it provides glimpses of the order and types of changes that accompanied this shift.

A NEW MERISTEM FOR SECONDARY GROWTH By about 390 mya, in the mid Devonian, a group called *progymnosperms* had evolved from seedless vascular plants. Progymnosperms did not have seeds, but they did have megaphyll-type leaves (with branching veins; refer to Figure 28.5). Some also had woody

© Cengage Learning 2014

trunks more than a meter in diameter. Such girth was the result of a new adaptation, a lateral meristem that produced *secondary growth*—the development of woody layers of xylem and phloem that takes place once the initial, primary plant body forms and makes roots and stems sturdier by increasing their diameter. (Chapter 33 discusses secondary growth in detail.) **Figure 29.2** shows an artist's rendering of the progymnosperm *Archaeopteris,* a small tree with a tapering trunk that was common over parts of Europe and North America and is thought to have reached a height of about 6 m.

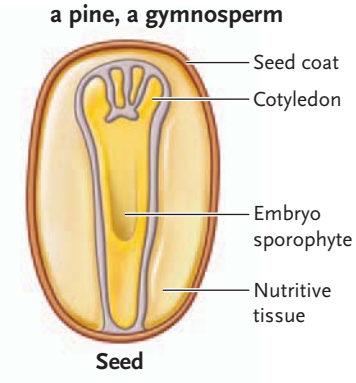
OVULES, POLLEN, AND SEEDS The word *gymnosperm* is derived from the Greek *gymnos,* meaning naked, and *sperma,* meaning seed. Although progymnosperms were seedless, fossil evidence suggests that seed-bearing gymnosperm lineages probably arose from them. For example, fossils reveal that species in the progymnosperm group that included *Archaeopteris* were heterosporous: they produced two types of spores (megaspores and microspores) that were released from structurally different sporangia. Some progymnosperm fossils indicate that megaspores were retained instead of released, and were surrounded by a layer of tissue called an *integument*—an arrangement that has been interpreted as the foundation for an ovule that would develop into the gymnosperm seed. Fossils dating to the late Devonian confirm the existence of (at least) two seed-bearing gymnosperm groups: early conifers, and a now-extinct lineage of small, woody, treelike species called *seed ferns,* so named because they had leaves resembling fern fronds.

Other changes, perhaps happening simultaneously, resulted in the evolution of pollen grains from microspores. As described next, pollen grains have hard walls and fossilize relatively well. Some amazingly well-preserved specimens reveal that as the Devonian period came to a close, several different types of gymnosperm pollen grains existed.

POLLEN AND OVULES: SHELTER FOR SPORES Unlike bryophytes and seedless vascular plants, gymnosperm sporophytes do not disperse their spores. The sporophyte produces haploid spores by meiosis, but it retains these spores inside reproductive structures where they give rise to multicellular haploid gametophytes. A **pollen grain** is a male gametophyte, which produces sperm. Each pollen grain is produced from a microspore that typically has walls reinforced with the polymer sporopollenin. All but a few gymnosperms have nonmotile sperm. Usually, two of these nonswimming cells develop inside each pollen grain—very different from the flagellated, swimming sperm of algae and seedless plants.

An **ovule** is a structure in a sporophyte in which a female gametophyte develops, complete with an egg. Physically connected to the sporophyte and surrounded by the ovule's protective layers, a female gametophyte no longer faces the same risks of predation or environmental assault that can threaten a free-living gametophyte.

Pollination is the transfer of pollen to female reproductive parts via air currents or on the bodies of animal pollinators. Pollen and pollination were enormously important adaptations for gymnosperms, because the shift to nonswimming sperm along with a means for delivering them to female gametes meant that reproduction no longer required liquid water. The only gymnosperms that have retained swimming sperm are the cycads and ginkgoes described shortly, which have relatively few living species and are restricted to a smattering of native habitats.



SEEDS: PROTECTING AND NOURISHING PLANT EMBRYOS A **seed** is the structure that forms when an ovule matures after a pollen grain reaches it and a sperm fertilizes the egg. It consists of three basic parts: (1) the embryo sporophyte; (2) tissues around it containing carbohydrates, proteins, and lipids that nourish the embryo until it becomes established as a plantlet with leaves and roots; and (3) a tough, protective outer seed coat **(Figure 29.3).** This complex structure makes seeds ideal packages for sheltering an embryo from drought, cold, or other adverse conditions. As a result, seed-making plants enjoy a tremendous survival advantage over species that simply release spores to the environment. Encased in a seed, the embryo also can be transported far from its parent, as when ocean currents carry coconut seeds ("coconuts" protected in large, buoyant fruits) hundreds of kilometers across the sea. As discussed in Chapter 36, some plant embryos housed in seeds can remain dormant for months or years before environmental conditions finally stimulate them to germinate and grow.

Modern Gymnosperms Include Conifers and a Few Other Groups

Today there are about 800 gymnosperm species, including the largest and oldest living land plants. Giant sequoias *(Sequoiadendron giganteum)* may grow to more than 80 m, and coast redwoods *(Sequoia sempervirens)* to more than 112 m. Both are native to Cali-

fornia. Tree-ring analysis revealed that one specimen of another California native, the bristlecone pine *(Pinus aristata),* has survived almost 5,000 years, making it the world's oldest known continuously standing tree. The sporophytes of nearly all gymnosperms are sizable trees or shrubs, although a few are woody vines. The most widespread and familiar gymnosperms are the conifers (Coniferophyta). Others are the cycads (Cycadophyta), ginkgoes (Ginkgophyta), and gnetophytes (Gnetophyta).

Economically, gymnosperms, particularly conifers, are vital to human societies. They are sources of lumber, paper pulp, turpentine, and resins, among other products. They also have huge ecological importance. Their habitats range from tropical forests to deserts, but gymnosperms are most dominant in the cool-temperate zones of the northern and southern hemispheres. They flourish in poor soils where flowering plants do not compete as well. In North America, for example, conifer forests cover more than one-third of the continent's landmass—although in some areas, logging has significantly reduced the once-lush forest cover. Our survey of living gymnosperms begins, however, with the cycads, ginkgoes, and gnetophytes—the latter two groups remnants of lineages that have all but vanished from the modern scene.

Carlton Ray/Science Photo Library/Photo Researchers, Inc.

FIGURE 29.4 The cycad *Encephalartos.* Note the large, terminal female cone and fernlike leaves.

Cycads Are Restricted to Warmer Climates

During the Mesozoic era (251–65 mya), the **Cycadophyta** (*kykas* = palm), or cycads, flourished along with the dinosaurs. This lineage probably arose from ancient seed ferns. About 185 species have survived to the present, confined to the tropics and subtropics.

At first glance, you might mistake a cycad for a small palm tree **(Figure 29.4).** Some cycads have massive, cone-shaped strobili (clusters of sporophylls) that bear either pollen or ovules. Air currents or beetles transfer pollen from male plants to the developing gametophyte on female plants. Poisonous alkaloids that may help deter insect predators occur in various cycad tissues. In tropical Asia, some people consume cycad seeds and flour made from cycad trunks, but only after the toxic compounds have been rinsed away. Much in demand from fanciers of unusual plants, cycads in some countries are uprooted and sold in what amounts to a black-market trade—greatly diminishing their numbers in the wild.

Ginkgoes Are Limited to a Single Living Species

The phylum **Ginkgophyta** may also have arisen from seed ferns, though evidence supporting this hypothesis is debated. The phylum has one living species, the ginkgo (maiden-hair) tree *(Ginkgo biloba),* which grows wild today only in warm-temperate forests of central China. Ginkgo trees are large, diffusely branching trees with characteristic fan-shaped leaves **(Figure 29.5)** that turn a brilliant yellow in autumn. Nursery-propagated male trees often are planted in cities because they are resistant to insects, disease, and air pollutants. The female trees are equally pollution-resistant, but their fleshy seeds synthesize butyric acid, which has a notoriously foul odor.

Gnetophytes Include Simple Seed Plants with Intriguing Features

The phylum Gnetophyta contains three genera—*Gnetum, Ephedra,* and *Welwitschia*—that together include about 70 species. Moist, tropical regions are home to about 30 species of *Gnetum,* which includes both trees and leathery leafed vines (lianas). About 35 species of *Ephedra* grow in desert regions of the world **(Figure 29.6A–B).**

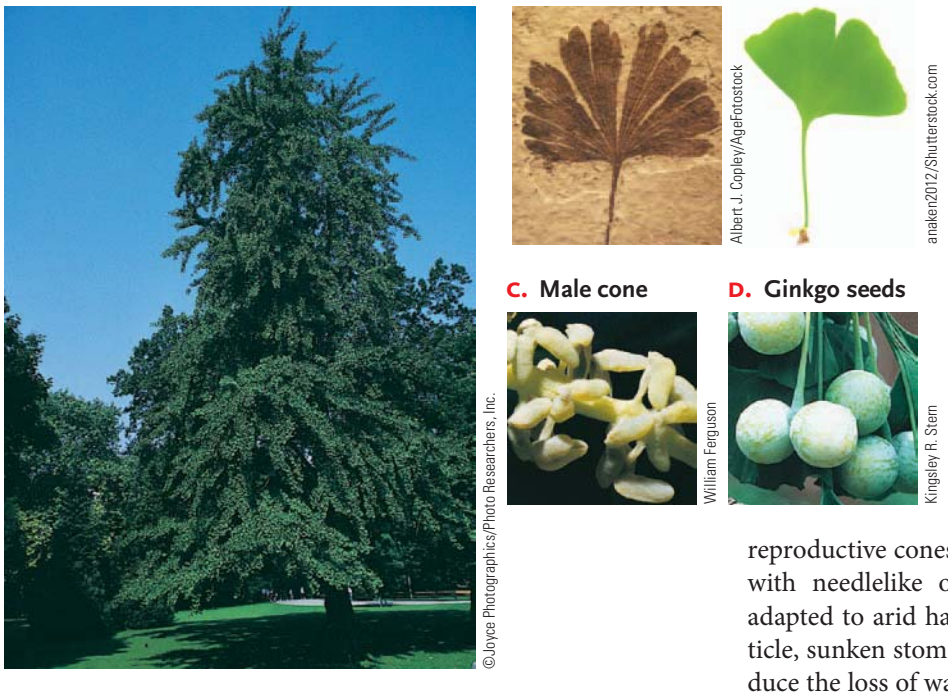

FIGURE 29.5 ***Ginkgo biloba.*** **(A)** A ginkgo tree. **(B)** Fossilized ginkgo leaf compared with a leaf from a living tree. The fossil formed at the Cretaceous–Tertiary boundary. Even though 65 million years have passed, the leaf structure has not changed much. **(C)** Pollen-bearing cones and **(D)** fleshy-coated seeds of the *Ginkgo*.

Of all the gymnosperms, *Welwitschia* strikes many people as the most bizarre. It grows in the hot deserts of southern and western Africa. The bulk of the plant is a deep-reaching taproot, with the only exposed part a woody disk-shaped stem that bears cone-shaped strobili and leaves. The plant never produces more than two strap-shaped leaves, which split lengthwise repeatedly as the plant grows older, producing a rather scraggly pile **(Figure 29.6C).**

Although gnetophytes are structurally and functionally simpler than most other seed plants, recent studies of sexual reproduction mechanisms in *Gnetum* and *Ephedra* species uncovered a two-step process of fertilization—which is a hallmark of angiosperms, the most advanced seed plants. This discovery raised some provocative evolutionary questions, even leading some investigators to propose that ancient gnetophytes may have given rise to flowering plants. This hypothesis has since been contradicted by molecular findings, such as those arrived at by a research team at the Academia Sinica in Taiwan (China). When the team compared 65 nuclear rRNA sequences from ferns, gymnosperms, and angiosperms, their analysis supported the hypothesis that cycads and ginkgoes represent the earliest gymnosperm lineage, with a divergent lineage of gnetophytes and conifers arising later. The team found no molecular evidence for a link between the Gnetophyta and angiosperms. The cladogram in **Figure 29.7** shows these proposed evolutionary relationships.

Conifers Are the Most Common Gymnosperms

About 80% of all living gymnosperm species belong to the phylum **Coniferophyta,** or conifers ("cone-bearers"). Conifer sporophytes are longer-lived, and anatomically and morphologically more complex, than any plant sporophyte we have discussed so far. For example, each year most of the 550 conifer species produce a new layer of woody secondary tissue (which you can see illustrated in Figures 33.24 and 33.26); in some species, such as the sequoias and Douglas fir *(Pseudotsuga menziesii),* the girth of mature trees can easily exceed 6 m, and some individuals measure more than 15 m in diameter. Conifers also form woody reproductive cones, and most species are woody trees or shrubs with needlelike or scalelike leaves, which are anatomically adapted to arid habitats. For instance, needles have a thick cuticle, sunken stomata, and a fibrous epidermis, all traits that reduce the loss of water vapor.

Most conifers are evergreens. That is, although they shed old leaves, often in autumn, they retain enough leaves so that they still look "green," unlike deciduous species like maples,

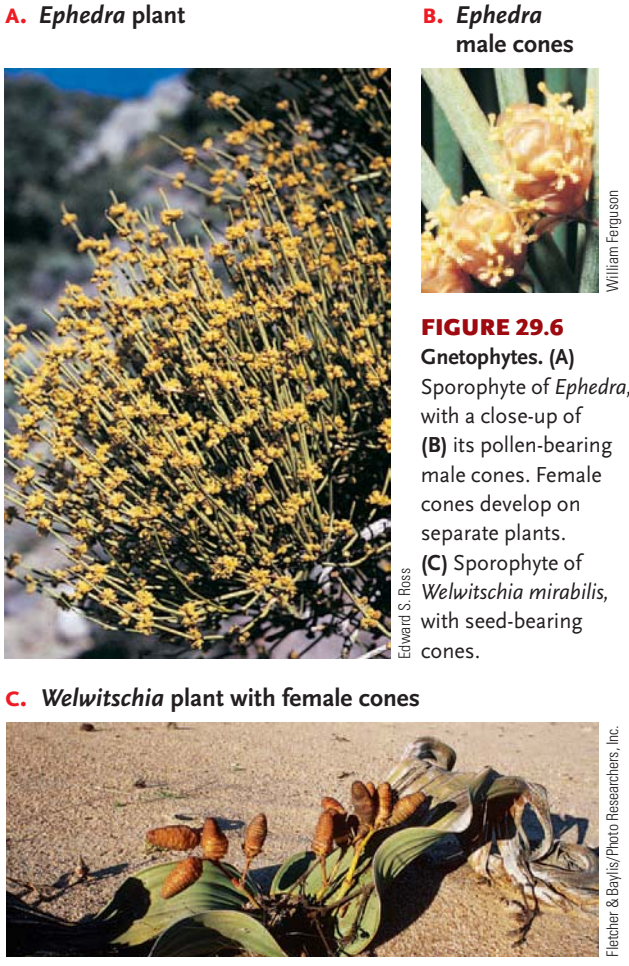

FIGURE 29.6 **Gnetophytes. (A)** Sporophyte of *Ephedra,* with a close-up of **(B)** its pollen-bearing male cones. Female cones develop on separate plants. **(C)** Sporophyte of *Welwitschia mirabilis,* with seed-bearing cones.

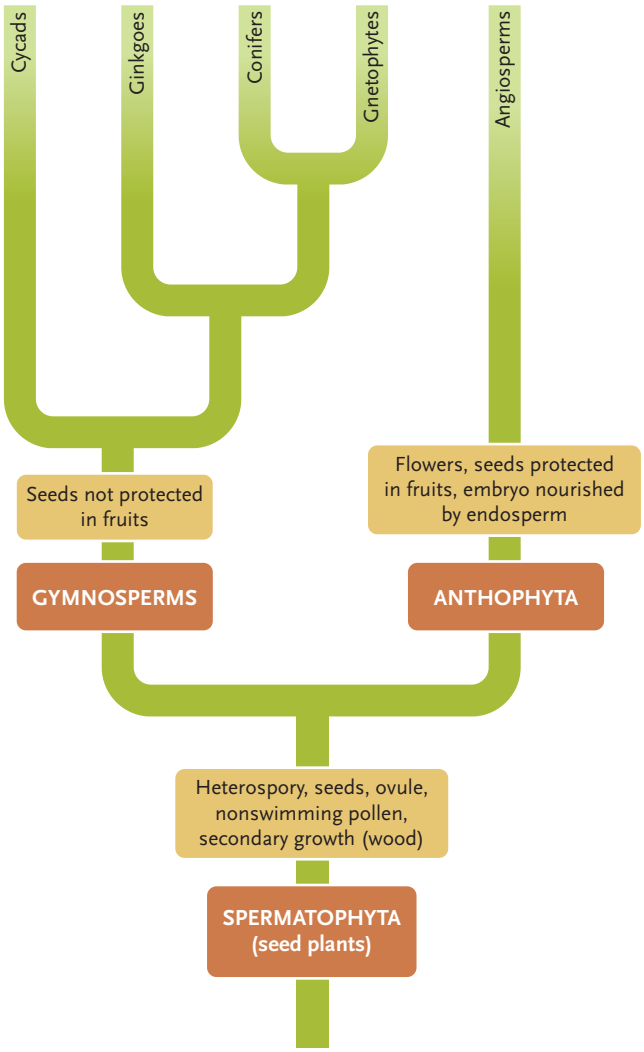

FIGURE 29.7 Overview of the possible phylogenetic relationships between the lineages of seed plants. This diagram provides only a general picture of the points in seed plant evolution where major adaptations took hold. For example, heterospory and seeds are shown as adaptations common to all seed plants, but some living fern species also are heterosporous. Fossil evidence indicates that certain ancient lycophytes and horsetails also produce two types of spores and some had seeds as well. Cycads and ginkgoes are unlike other gymnosperms in that they have swimming sperm.

© Cengage Learning 2014

which shed *all* their leaves as winter approaches. Familiar conifer examples are the pines, spruces, firs, hemlocks, junipers, cypresses, and redwoods. Conifers produce pollen in clusters of small strobili and ovules in larger, woody ones. Both types of strobili are often referred to as cones. Seeds develop on the shelf-like scales of the female cones.

Pines and many other gymnosperms produce resins, a mix of organic compounds that are by-products of metabolism. Resin accumulates and flows in long resin ducts through the wood, inhibiting the activity of wood-boring insects and certain microbes. Pine resin extracts are the raw material of turpentine and (minus the volatile terpenes) the sticky rosin used to treat violin bows.

We know a great deal about the pine life cycle **(Figure 29.8),** so it is a convenient model for gymnosperm life cycles. All but 1 of the 93 pine species are trees (*Pinus mugo,* native to high elevations in Europe, is a shrub). The male cones (strobili) are relatively small and delicate, only about 1 cm long, and are borne on the lower branches. Each one consists of many small scales, which are specialized leaves (called sporophylls) attached to the cone's axis in a spiral. Two sporangia, called *microsporangia,* develop on the underside of each scale. Inside the microsporangia, spore "mother cells" called microsporocytes undergo meiosis and give rise to haploid **microspores.** Each microspore then undergoes mitosis to develop into a winged pollen grain—an immature male gametophyte. At this stage the pollen grain consists of four cells, two that will degenerate and two that will function later in reproduction.

Young female cones develop higher in the tree, at the tips of upper branches. The cone scales bear ovules. Inside each ovule is a spore mother cell called a megasporocyte. Unlike microsporocytes, the megasporocyte in an ovule undergoes meiosis only when conditions are right. It then produces four haploid spores called **megaspores.** Only one megaspore survives, however, and it develops slowly, becoming a mature female gametophyte only when pollination is underway. In a pine, the process takes well over a year. The mature female gametophyte is a small oval mass of cells with several archegonia at one end, each containing an egg.

Each spring, air currents lift vast numbers of pollen grains off male cones—by some estimates, a single pine may spew billions. The extravagant numbers ensure that at least some pollen grains will land on female cones. The process is not as random as it might seem: studies have shown that the contours of female cones create air currents that can favor the "delivery" of pollen grains near the cone scales. After pollination, the pollen grain develops into a *pollen tube* that grows toward the female spore mother cell. As it does, sperm form in the tube and stimulate maturation of the female gametophyte and the production of eggs. When a pollen tube reaches an egg, the stage is set for fertilization, the formation of a zygote, and early development of the plant embryo. Often, fertilization occurs months to a year after pollination. Once an embryo forms, a pine seed—which, recall, includes the embryo, female gametophyte tissue, and seed coat—eventually is shed from the cone. The seed coat protects the embryo from drying out, and the female gametophyte tissue serves as its food reserve. This tissue makes up the bulk of a "pine nut."

STUDY BREAK 29.1

1. **What are the four major reproductive adaptations that evolved in gymnosperms?**
2. **What are the basic parts of a seed, and how is each one adaptive?**
3. **Describe some features that make conifers structurally more complex than other gymnosperms.**

THINK OUTSIDE THE BOOK

Seed ferns are assigned to the extinct phylum Pteridospermophyta. They were nearly wiped out by the Permian–Triassic mass extinction event that occurred about 251 mya and became extinct soon thereafter. Seed-bearing conifers living at the time fared better, and conifers were the dominant land plants for at least another 100 million years. Using Internet or library resources, develop a plausible explanation for why the seed fern and conifer lineages had such differing evolutionary fates.

29.2 Angiosperms: Flowering Plants

Of all plant phyla, the flowering plants, or angiosperms, are the most widespread today. At least 260,000 species are known (**Figure 29.9** shows a few examples), and researchers regularly discover new ones in previously unexplored regions of the tropics. The word angiosperm means "enclosed seed." It refers to the fact that a modified leaf called a **carpel** surrounds and protects the ovules and later, the seeds of angiosperms. Carpels are parts of flowers, reproductive structures that are a key defining feature of angiosperms. Another defining angiosperm feature is the fruit, which surrounds the angiosperm embryo and aids seed dispersal.

In addition to having flowers and fruits, angiosperms are the most ecologically diverse plants on Earth, growing on dry land and in wetlands, in fresh water and the seas. They range in size from tiny duckweeds about 1 mm long to towering *Eucalyptus* trees more than 100 m tall. Most are free-living photosynthesizers. Others lack chloroplasts and obtain nutrients through associations with fungi.

The Fossil Record Reveals Little about the Origin of Flowering Plants

The evolutionary origin of angiosperms has confounded plant biologists for well over a hundred years. Charles Darwin famously called it the "abominable mystery," because flowering plants seem to appear suddenly in the fossil record, without a fossil sequence that clearly links them to any other plant groups. The oldest well-documented fossil specimens date back about 125 million years to the early Cretaceous. Discovered in China, these remarkable fossils show complex and strikingly modern-looking plants that have leaves, stems, fruits, and seeds **(Figure 29.10).** Two species have been unearthed and have been assigned to the genus *Archaefructus,* representing a newly discovered, extinct angiosperm group.

The fossil record has yet to reveal obvious transitional organisms connecting either seedless vascular plants or gymnosperms to flowering plants.

As with gymnosperms, attempts to reconstruct the earliest flowering plant lineages from morphological, developmental, and biochemical characteristics have produced conflicting classifications and family trees. Some paleobotanists hypothesize

that flowering plants arose in the Jurassic period (200–145 mya); others propose they arose earlier, in the Triassic (250–200 mya) from now-extinct gymnosperms or from seed ferns.

As the Mesozoic era ended and the modern Cenozoic era began, great extinctions occurred within both plant and animal kingdoms. Gymnosperms declined, and dinosaurs disappeared. Flowering plants, mammals, and social insects flourished, radiating into new environments. Today we live in what has been called "the age of flowering plants."

Angiosperms Are Subdivided into Several Clades, Including Monocots, Eudicots, and Various Basal Angiosperms

Angiosperms are assigned to the phylum **Anthophyta,** a name that derives from the Greek *anthos,* meaning flower. The great majority of angiosperms are classified either as monocots or eudicots. **Monocots** are distinguished by the morphology of their embryos, which have a single seed leaf called a cotyledon ("cup-like hollow"). **Eudicots** ("true dicots"), which generally have two cotyledons, are set apart from other angiosperms by the structure of their pollen grains, which have three grooves **(Figure 29.11).** By contrast, the pollen of monocots and all other seed plants (including more than 8,500 species once lumped with eudicots under the term "dicots") have only a single groove. Paleobotanists use this clear structural difference not only to help establish the general type of plant that produced fossil pollen, but also what types of plants were present in fossil deposits of a particular age or geographic location.

Although most angiosperms can fairly easily be categorized as either monocots or eudicots, figuring out the appropriate classification for other angiosperms is an ongoing challenge and an extremely active area of plant research. Genetic and phylogenetic studies are playing a pivotal role in this arena. For example, in 2007, Robert K. Jansen at the University of Texas in Austin and 15 colleagues in the United States and Germany published an ambitious phylogenetic study of 76,583 nucleotide positions in 81 plastid genes from the genomes of 64 plant species. Three species of gymnosperms (a pine, a ginkgo, and a cycad) served as the outgroup. The researchers used their data to generate alternative phylogenetic hypotheses that they evaluated along with six previously published ones, using approaches (such as parsimony) outlined in Chapter 24. Their statistical analysis provided the strongest support for a phylogenetic tree summarized in **Figure 29.12.** In addition to eudicots and monocots, this

proposed tree encompasses five clades of **basal angiosperms** thought to represent the earliest branches of the flowering plant lineage **(Figure 29.13).** The **magnoliids** includes magnolias (see Figure 29.13A), laurels, and avocados. The **Chloranthales** includes plants that are the sources of spices such as peppercorns, nutmeg, and cinnamon. **Austrobaileyales** includes star anise and its close relatives (see Figure 29.13B), while water lilies are in the **Nymphaeales** (see Figure 29.13C). The Jansen group's work and several other analyses have identified the shrub *Amborella trichopoda* (see Figure 29.13D) as the closest living relative of the first flowering plants—hence *Amborella's* divergence near the base of the phylogenetic tree **(Figure 29.14).** *Amborella* is found only in cloud forests of the South Pacific island of New Caledonia. Morphological differences also help make it the current leading candidate for "most ancient" living basal angiosperm. *Amborella's* small white flowers and vascular system are structurally simpler than those of other angiosperms, and its female gametophyte differs as well.

Figure 29.15A gives some idea of the variety of living monocots, which include grasses, palms, lilies, and orchids. The world's major crop plants (wheat, corn, rice, rye, sugarcane, and barley) are domesticated grasses, and all are monocots. There are at least 60,000 species of monocots, including 10,000 grasses and 20,000 orchids. Eudicots are even more diverse, with nearly 200,000 species **(Figure 29.15B).** They include flowering shrubs and trees, most nonwoody (herbaceous) plants, and cacti. **Figure 29.16** shows the life cycle of a monocot, a lily. The life cycle of a typical eudicot is described in detail in the next unit, which focuses on the structure and function of flowering plants.

Many Factors, Including Developmental Plasticity, Contributed to the Adaptive Success of Angiosperms

Throughout the panorama of land plant evolution, no group can match angiosperms in terms of one fundamental attribute: their *developmental plasticity.* No other plant group even comes close to equaling the sheer numbers of angiosperm species and the astonishing diversity of the sizes, shapes, habitats, growth habits, and nutrition modes of flowering plants. Whatever changes resulted in the evolution of the angiosperm lineage from one rooted in a gymnosperm heritage, they must have included a capacity to undergo (and survive) genetic changes that created new options for growth, development, and functioning. Here we consider just a small subset of basic shifts that helped distinguish angiosperms from gymnosperms.

MORE EFFICIENT TRANSPORT OF WATER AND NUTRIENTS

Where gymnosperms have only one type of water-conducting cell (tracheids), angiosperms have an additional, more specialized type (called vessel elements). As a result, an angiosperm's xylem vessels move water more rapidly from roots to shoot parts. Also, modifications in angiosperm phloem tissue allow it to more efficiently transport sugars produced in photosynthesis through the plant body.

ENHANCED NUTRITION AND PHYSICAL PROTECTION FOR EMBRYOS

Other changes in angiosperms made it more likely that reproduction would succeed. For example, a two-step *double fertilization* process in the seeds of flowering plants gives rise to both an embryo and a unique nutritive tissue (called endosperm) that nourishes the embryonic sporophyte. The ovule containing a female gametophyte is enclosed within an **ovary,** which develops from a carpel and shelters the ovule against desiccation and against attack by herbivores or pathogens. In turn, ovaries develop into the fruits that house angiosperm seeds. As noted earlier, a fruit not only protects seeds, but helps disperse them—for instance, when an animal eats a fruit, seeds may pass through the animal's gut none the worse for the journey and be released in a new location in the animal's feces. Above all, angiosperms have flowers, the unique reproductive organs that you will read much more about in the next unit.

COEVOLUTION WITH ANIMAL POLLINATORS

The evolutionary success of angiosperms correlates not only with the adaptations just described, but also with efficient mechanisms of transferring pollen to female reproductive parts. While a conifer depends on air currents to disperse its pollen, angiosperms coevolved with pollinators—insects, bats, birds, and other animals that withdraw pollen from male floral structures (often while

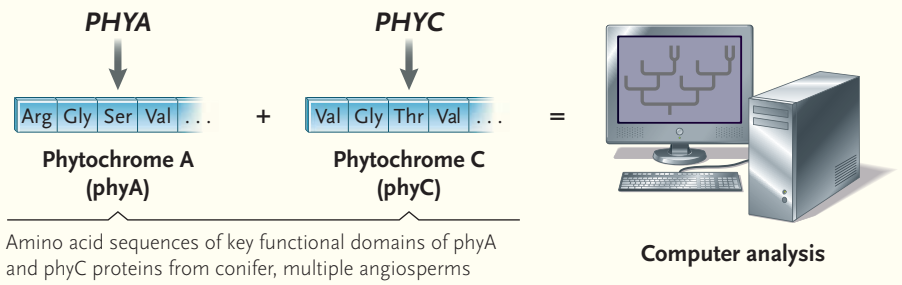
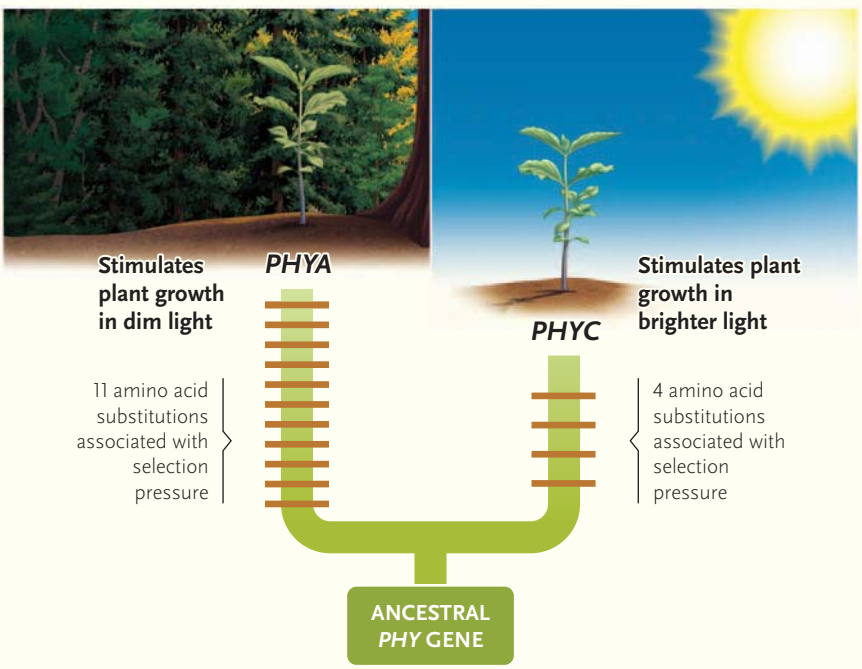
FIGURE 29.14 **Experimental Research**



Analyzing Phytochromes to Explore Angiosperm Evolution

Question: Did adaptive changes in light-sensitive pigments play a role in the early evolution of flowering plants?



Experiment: Many paleobotanists consider that the first angiosperms arose in the understory of moist land habitats dominated by large Mesozoic gymnosperms and ferns—a habitat not too unlike that where *Amborella* lives today. In this shaded environment, young plants that could gain a roothold despite the lack of bright light might have a distinct survival advantage. To investigate the possibility that strong selection pressure favoring adaptation to dim light played a part in angiosperm evolution, researchers looked at the genes coding for pigment proteins called *phytochromes* that allow plants to detect light of red and far-red wavelengths—wavelengths that predominate in dim light.

An activated phytochrome launches a signaling pathway that may stimulate or inhibit some aspect of plant growth. In seed plants, a small family of *PHY* genes encodes five main phytochromes, A through E, each with a distinct function. The nucleotide sequences of two of the genes, *PHYA* and *PHYC,* are about 50% identical. Plant scientists hypothesize that duplication of an ancestral *PHY* gene occurred before angiosperms arose. *PHYA* and *PHYC* evidently are the descendants of this duplicated ancestral gene. *PHYC* is sensitive to relatively bright light but apparently doesn't respond to dim light and *PHYA* is highly sensitive to dim light and is inactivated by bright light.

To investigate the hypothesis that strong selection pressure drove the divergence of these two genes in ancestral angiosperms, researchers obtained amino acid sequence data for key functional domains of the phytochrome proteins encoded by *PHYA* and *PHYC* in 45 plant species. Most species in the sample were angiosperms; several conifers represented the presumed ancestral gene. Analysis of the data focused both on the number of substitutions in the targeted phytochrome amino acid sequences, as well as on the biochemical effects of the substitutions. Among other information, the analysis produced a phylogenetic tree that displayed genetic divergences as branch points.

Results: In the tree branch leading from the presumed ancestral *PHY* gene to *PHYA,* 32 amino acid substitutions occurred. Of these, 11 could be best interpreted as shifts associated with selection pressure. In the branch leading to *PHYC,* only seven substitutions occurred; four were best interpreted as associated with selection pressure.

Conclusion: These findings support the hypothesis that diverging molecular characteristics of *PHYA* and *PHYC* correlated with diverging functional features of the phytochromes the genes encode. Evidently, *PHYA* evolved under strong selection pressure. The availability of phytochrome phyA may have allowed early angiosperm seedlings to grow in mostly dim light conditions—an adaptive change that may have fostered the establishment of angiosperms in the shade of Mesozoic forests.

obtaining nectar) and inadvertently transfer it to female reproductive parts. **Coevolution** occurs when two or more species interact closely in the same ecological setting. A heritable change in one species affects selection pressure operating between them, and the other species evolves as well. Over time, plants that came to have distinctive flowers, scents, and sugary nectar coevolved with animals that could take advantage of the rich food source.

In general, a flower's reproductive parts are positioned so that visiting pollinators will brush against them. In addition, many floral features correlate with specific pollinators. For example, reproductive parts may be located above nectar-filled floral tubes the same length as the feeding structure of a preferred pollinator. Nectar-sipping bats **(Figure 29.17A)** and moths forage by night. They pollinate intensely sweet-smelling flowers with white or pale petals that are more visible than colored petals in the dark. Long, thin mouthparts of moths and butterflies reach nectar in narrow floral tubes or flora spurs. The Madagascar hawkmoth uncoils a mouthpart the same length—an astonishing 22 cm—as a narrow floral spur of an orchid it pollinates, *Angraecum sesquipedale* **(Figure 29.17B).** Red and yellow flowers attract birds **(Figure 29.17C),** which have good daytime vision but a poor sense of smell. Hence bird-pollinated plants do not squander metabolic resources to make fragrances. By contrast, flowers of species that are pollinated by beetles or flies may smell like rotten meat, dung, or decaying matter. Daisies and other fragrant flowers with distinctive patterns, shapes, and red or orange components attract butterflies, which forage by day.

Bees see ultraviolet light and visit flowers with sweet odors and parts that appear to humans as yellow, blue, or purple **(Figure 29.17D).** Produced by pigments that absorb ultraviolet light, the colors form patterns called "nectar guides" that attract bees—which may pick up or "drop off" pollen during the visit. Here, as in our other examples, flowers contribute to the reproductive success of plants that bear them.

STUDY BREAK 29.2

1. How has the relative lack of fossils of early angiosperms affected our understanding of this group?
2. Describe two basic features that distinguish monocots from eudicots, and give some examples of species in each clade.
3. List at least three adaptations that have contributed to the evolutionary success of angiosperms as a group.

29.3 Frontiers of Plant Genome Research

Today some of the most exciting research in all of biology involves studies exploring links between genetic changes and key evolutionary transitions in plant form and functioning. A case in point is research on the gene *LFY,* which encodes the regulatory protein LEAFY (Chapter 16 discusses regulatory proteins in detail). The LEAFY protein typically controls expression of several genes by binding to the genes' control sequences. All land plants carry the *LFY* gene, but its effects on phenotype vary markedly in different plant groups. In mosses, which arose almost 400 million years ago, the LEAFY protein regulates growth throughout the plant. In ferns and gymnosperms, which arose later, LEAFY controls growth in a subset of tissues. In angiosperms, LEAFY regulates gene expression only in the particular type of meristem tissue that gives rise to flowers (a topic of Chapter 36). Curious about the evolutionary shift from a general to a specific effect, Alexis Maizel and his team at the Max Planck Institute for Developmental Biology in Germany compared *LFY* sequences and their corresponding proteins in 14 species, including a moss, ferns, gymnosperms, and the angiosperms *Arabidopsis* (thale cress) and snapdragon. Remarkably, they discovered that the evolutionary honing of the effects of the LEAFY protein correlated with only a handful of changes in the base sequence of the *LFY* gene. Each change affected how—or if—the LEAFY protein regulated the expression of a given gene. Over time, LEAFY took on its highly specific, crucial role in angiosperms, helping to direct the developmental events that produce flowers.

As more and more whole plant genomes are sequenced, plant scientists are able to analyze and compare the resulting data in revealing ways. One area of basic interest is the relationship between large-scale shifts in genomes and the evolution of fundamental characteristics of major lineages. *Insights from the Molecular Revolution* describes an example: the comparison of the genomes of a tree species, black cottonwood *(Populus trichocarpa)* and the small weed and model research organism thale cress *(Arabidopsis thaliana).*

Many plant genome-sequencing efforts—such as the one now underway to obtain the full genome sequence of *Amborella*—have a corollary goal of developing improved sequencing methods that will advance future opportunities for research. Sequencing of the genomes of globally important agricultural plants—including wheat *(Triticum),* tomato *(Solanum)* corn *(Zea mays),* rice *(Oryza sativa),* and soybeans *(Glycine max)*—is already providing plant geneticists with major new insights into traits such as growth regulation, disease and pest resistance, and tolerance to drought.

Jump Starting Studies on Plant Genome Evolution

Research Question

Can comparing genome sequences provide clues to the evolution of contrasting adaptations in woody and nonwoody plants?

Experiments

The black cottonwood (*Populus trichocarpa,* **Figure**) is a fast-growing tree native to western North America used widely in the manufacture of high-grade paper, plywood, and other products. It also has a relatively small nuclear genome of about 45,550 protein-coding genes located on 19 chromosomes. These and other characteristics made *P. trichocarpa* the species of choice for an international effort to obtain the first complete gene sequence of a tree. Led by tree geneticist Gerald A. Tuskan of Oak Ridge National Laboratory, 34 researchers worked to sequence the *P. trichocarpa* genome and then compare it to that of the nonwoody plant *Arabidopsis thaliana* (thale cress)—the only other complete eudicot genome sequence then available.

iStockphoto.com/Kevin Davidson

FIGURE Black cottonwood, ***Populus trichocarpa.***

The sequencing used DNA from a single female genotype and employed a whole-genome shotgun approach. In this method, a genome is broken into random, overlapping fragments. After the nucleotide sequence of each fragment is determined, a computer assembles the sequences. In this project, subsequent gene mapping produced a draft sequence for the whole genome with genes assigned to specific chromosomes.

The study produced some provocative findings. For example, genetic events that can have major adaptive significance—such as large-scale chromosome rearrangements and nucleotide substitutions—have occurred much more slowly in *P. trichocarpa* than in *A. thaliana.* Said another way, the "molecular clock" described in Section 24.6 ticks more slowly in *P. trichocarpa.* About 110 mya, a duplication event in *P. trichocarpa* apparently coincided with the divergence of the *P. trichocarpa* and *A. thaliana* lineages from a common ancestor. Then, roughly 45 million years later, about 8,000 pairs of *P. tricocarpa* genes descended from the previous duplication were duplicated again. Tuskan and his colleagues hypothesized that this duplication event had a major impact, affecting more than 90% of the genome. Another key finding was that, while both *P. trichocarpa* and *A. thaliana* have genes that influence disease resistance and membrane transporters, in *P. trichocarpa* evolution has resulted in more multiple-gene families for such traits. The transporters include those that function in hormonal responses governing processes such as the development of vascular tissues that transport water and nutrients. Genes governing wood development (secondary growth) are present in *P. trichocarpa* but not in *A. thaliana.*

Conclusions

Comparing the draft *P. trichocarpa* genome sequence with that of *A. thaliana* pointed to a wide array of opportunities for studying how plant gene families arise and how genomes may become reorganized in the course of evolution. The research also provides a broader basis for investigating the genetics of disease resistance, development of vascular tissues, and the formation of wood.

THINK LIKE A SCIENTIST This study focused in part on comparing and contrasting genes for particular traits in two species with very different life histories—a tree and a tiny herbaceous plant. What other factors could be explored to learn more about the differences the study revealed?

© Cengage Learning 2014

To date, more than 30 plant genomes have been partially or fully sequenced. In addition to the species already noted, these genomes range from cucumber, potato, and cannabis (marijuana) to cultivated apple, orange, and cacao (the source of chocolate). As the genes of many more plant species are sequenced and correlated with evidence from comparative morphology and the fossil record, we can expect a steady stream of new insights about the adaptations and evolutionary journey of all major plant lineages. It will probably not be long before we have a much deeper understanding of the evolutionary paths by which leaves, flowers, efficient vascular systems and many other plant characteristics have come into being.

In Chapter 30 a very different group of organisms, the fungi, takes center stage. Although many fungal species seem superficially plantlike, biologists today are avidly exploring evolutionary links between fungi and animals.

STUDY BREAK 29.3

1. **How do studies of the plant regulatory protein LEAFY help elucidate changing gene functions during plant evolution?**
2. **Briefly explain some benefits to be gained from having the entire sequences of numerous plant genomes.**

UNANSWERED QUESTIONS

What is the role of gene duplication in the evolution of plant diversity?

What is the genetic basis of the origin of new and complex structures, such as the flower, during the course of evolution? One important factor is gene duplication, thought to be one of the driving forces behind the increase in organismal complexity that we see with evolution. When a plant gene is duplicated, initially there are two identical copies with identical functions (called "redundancy"); often over time one of the copies either is eliminated or becomes nonfunctional, so that the original condition of one gene is restored. But sometimes, through the process of mutation and sequence divergence, the two copies take on different functions. They may divide the functions of the original single gene between them ("subfunctionalization"), or one of the copies may take on entirely new functions, leaving the other copy to perform the original function ("neofunctionalization"). It is this last possibility—the origin of new gene functions after duplication—that is thought to provide the raw material for the origin of new plant structures such as the flower.

Like all gymnosperms, the ancestors of angiosperms produced separate cones with male and female reproductive structures, whereas flowers produce both male and female reproductive organs surrounded by a novel structure unique to flowers, the sterile perianth (sepals and petals). What genetic changes occurred in proto-angiosperms that allowed for the development of the complex bisexual flower and the perianth? Of course we cannot look at the genomes of the extinct angiosperm ancestors, however, by comparing the genomes of extant gymnosperms and angiosperms we can identify key flower development genes that are found only in angiosperms. In *Arabidopsis thaliana, APETALA1 (AP1)* and *SEPALLATA (SEP)* genes are required for proper flower formation. If *AP1* genes are eliminated, the plants will not form flowers. If *SEP* genes are eliminated, the plants form structures similar to flowers but with all the floral organs replaced by tiny leaves. *AP1* and *SEP* genes are found only in flowering plants; combined with the observation that these genes are required to form flowers, this suggests that they may have played a role in the evolution of the flower.

AP1 and *SEP* genes appear to have arisen by way of two duplications from a third gene group *(AGL6)* that is found in both gymnosperms and angiosperms. Along with the B- and C-function genes of the ABC model, these genes belong to the MADS-box family of transcription factors, members of which play key roles throughout plant development. Repeated duplication during the course of plant evolution has led to an increase in the number of these regulatory genes from one in algae to over 100 in *Arabidopsis;* the proliferation of these key developmental regulators may be one of the driving forces behind the increase in complexity from algae to angiosperms, and is quite likely to have played a role in the origin of the flower. Thus, duplications in these genes led to the origin in gymnosperms of the B- and C-function genes, which in gymnosperms appear to play a role in specifying reproductive organ identity that is carried into the angiosperms. In contrast, later duplications, coinciding with the origin of the angiosperms, led to the establishment of the *AP1* and *SEP* gene lineages. These angiosperm-specific genes are required for flower formation, and may have been critical, in particular, in the origin of the flower-specific perianth.

THINK LIKE A SCIENTIST If the A function of the ABC model is not found in any species outside the mustard family, explain how the "BCE" model can still account for the formation of four different types of floral organs.

Amy Litt

Amy Litt is Director of Plant Genomics and Cullman Curator at the New York Botanical Garden, where she also earned her Ph.D. Her main interests lie in the evolution of plant form and how changes in gene function during the course of plant evolution have produced novel plant forms and functions—particularly new flower and fruit morphologies. REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

29.1 Gymnosperms: The "Naked Seed" Plants

- Gymnosperms (conifers and their relatives), together with angiosperms (flowering plants), are the seed-bearing vascular plants. During the Mesozoic era (248–65 mya), gymnosperms were the dominant land plants (Figures 29.1–29.3).
- Major reproductive adaptations in gymnosperms include pollination, the ovule, and the seed. Gymnosperm seeds mainly protect, nourish, and help disperse embryonic sporophytes (Figures 29.4–29.7).
- Gymnosperm phyla include cycads, ginkgos, and gnetophytes, but conifers are the dominant living group and the conifer life cycle is well understood. An ovule is a sporangium in which a large spore gives rise to a female gametophyte, which is attached to and protected by the sporophyte. Male gametophytes arise from a smaller spore type. Pollination and fertilization do not require water. Fertilization occurs with the ovule and ultimately results in a seed. Pollination takes place via air currents or animal pollinators (Figures 29.8 and 29.9).

Animation: Eudicot seed development

Animation: Pine life cycle

29.2 Angiosperms: Flowering Plants

- Angiosperms (Anthophyta) have dominated the land for more than 100 million years and currently are the most diverse plant group. The two main angiosperm clades are monocots and eudicots. Clades of basal angiosperms are represented by: magnolias and their relatives (magnoliids); peppercorns and their relatives (Chloranthales); the star anise group (Austrobaileyales), water lilies (Nymphaeales), and *Amborella,* a single species thought to be the most basal living angiosperm (Figures 29.10–29.14).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Angiosperms have the most efficient plant vascular system (xylem and phloem). Reproductive adaptations include a protective ovary around the ovule, endosperm, fruits that aid seed dispersal, the complex organs called flowers, and the coevolution of flower characteristics with the structural and/or physiological characteristics of animal pollinators (Figures 29.15–29.18).

Animation: Eudicot life cycle

Animation: Eudicots and monocots

29.3 Frontiers of Plant Genome Research

- Sequencing and analysis of plant genomes has begun to yield important insights into plant evolution.
- Genome analysis also is increasingly being used in studies of the genetic basis of important agricultural traits, such as disease resistance and drought tolerance.

UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following was *not* a gymnosperm reproductive innovation?
   a. seeds
   b. pollen grains
   c. the ovule
   d. embryonic cotyledons
   e. rudimentary "proto flowers" at the tips of cones
2. Gymnosperm evolution is also notable for which of the following adaptive feature or features?
   a. pollination by means of water
   b. secondary growth by way of a lateral meristem
   c. no major increase in body size over ancestral seedless plants
   d. liberation of free microspores as part of the life cycle
   e. a seasonal loss of all leaves
3. In which modern gymnosperm groups do we see swimming sperm, an ancient reproductive trait?
   a. Ginkgoes and cycads
   b. Conifers and ginkgoes
   c. Gnetophytes and cycads
   d. Conifers and cycads
   e. Gnetophytes and gingkoes
4. The gymnosperm group distinguished by having the greater part of its bulk underground is:
   a. Coniferophyta.
   b. Ginkophyta.
   c. Cycadophyta.
   d. Gnetophyta.
5. Angiosperms and gymnosperms share which of the following reproductive characteristic(s)?
   a. pollination
   b. ovules protected within an ovary
   c. megaspores and microspores produced by meiosis
   d. seeds
   e. a dominant sporophyte generation
6. Which of the following are defining reproductive features of angiosperms?
   a. flowers
   b. seeds protected by a seed coat
   c. sperm transfer by way of a growing pollen tube
   d. development of fruit
   e. development of embryo-nourishing tissue within seeds
7. The angiosperm clade distinguished by having pollen with three grooves is:
   a. monocots.
   b. magnoliids.
   c. the star anise group.
   d. *Amborella.*
   e. eudicots.
8. Which is *not* true of eudicots?
   a. Many species produce grains humans use for food.
   b. The group includes a large number of flowering shrubs.
   c. Most nonwoody plants are eudicots.
   d. There are probably at least three times as many eudicots as monocots.
   e. Eudicots generally have more seed leaves than monocots do.
9. Developmental plasticity evidently has been a hallmark of angiosperm evolution. Which of the following is *not* an example of this?
   a. diversity of growth habits and habitats
   b. larger size than most gymnosperms
   c. unparalleled numbers of species
   d. more diverse shapes of the plant body
   e. wide range of nutrition modes
10. Adaptations that correlate with the adaptive success of angiosperms include:
    a. more rapid water and nutrient transport.
    b. protection of the ovule inside an ovary.
    c. seed dispersal by way of fruits.
    d. coevolution with animals that pollinate flowers.
    e. nourishment of developing embryos by tissues of the female gametophyte.

Discuss the Concepts

1. Suggest adjustments in the angiosperm life cycle that would better suit plants to some future world where environments were generally hotter and more arid. Do the same for a colder and wetter environment.
2. Working in the field, you discover a fossil of a previously undescribed plant species. The specimen is small and may not be complete; the parts you have do not include any floral organs. What sorts of observations would you need in order to classify the fossil as a vascular seed plant with reasonable accuracy? What evidence would you need in order to distinguish between a fossil monocot and eudicot?
3. Modern humans emerged about 100,000 years ago. How accurate is it to state that our species has lived in the Age of Wood? Explain.
4. Compare the size, anatomical complexity, and degree of independence of a Douglas fir female gametophyte and a dogwood female gametophyte. Which one is the most protected from the external environment? Which trend(s) in plant evolution does your work on this question bring to mind?

Design an Experiment

You are studying mechanisms that control the development of flowers, and your research to date has focused on eudicots. A colleague has suggested that you broaden your analysis to include representative basal angiosperms. Outline the rationale for this expanded approach and indicate which additional species or group(s) you plan to include. Discuss the type(s) of data you plan to gather and why you feel the information will make your study more complete.

Interpret the Data

In an inversion, a chromosome segment breaks and then reattaches to the chromosome with the order of genes reversed (see Section 13.3). Inversions disrupt recombination during meiosis, and can have evolutionary consequences. Some plant scientists have proposed a "local adaptation" mechanism in which reproductive isolation—the hallmark of speciation—arises after an inversion yields one or more altered phenotypes that confer a selective advantage in the local environment. There was not much real-world support for this hypothesis until a field study conducted by Duke University researchers David B. Lowery and John H. Willis documented local adaptation and reproductive isolation in populations of the yellow monkeyflower, *Mimulus guttatus*. In this species, which is native to a large swath of western North America, there are two distinct ecotypes. Annuals (AN) complete the life cycle in a single growing season and live in inland habitats where soil moisture is scarce in summer. Perennials (PE) survive for at least two growing seasons and live where soil is moist year-round. Lowery and Willis identified a chromosomal inversion that closely tracked this life history difference. They also found evidence that the inversion contributes to several reproductive isolating barriers, including the time frame for flowering (which is when pollination and fertilization occur). In the experiments, AN and PE plants were grown in test plots in both habitats. In addition, to help ensure that findings reflected the influence of the inversion, Lowery and Willis used laboratory breeding techniques to obtain seedlings having the AN or PE arrangement of genes in a variety of genetic backgrounds. The Key indicates colors associated with each set of test plants. **Figure A** graphs the cumulative proportion of *M. guttatus* plants surviving to flower at the inland growing site. **Figure B** graphs the cumulative proportion of plants that survived at the coastal field site. **Figure C** graphs the cumulative proportion of plants that survived at the inland field site.

Mushroom-forming fungi of the genus *Mycena*, which are commonly found on decaying wood.

30

STUDY OUTLINE

30.1 General Characteristics of Fungi
30.2 Major Groups of Fungi
30.3 Fungal Associations

Fungi

Why it matters . . . In most natural environments, decay is everywhere—rotting leaves, moldering branches, perhaps the disintegrating carcass of an insect or a small mammal. Gradually, this organic matter is broken down and its elements are recycled in a long-term process that has a huge impact on terrestrial ecosystems. For example, each year the cycling of nutrients returns at least 85 billion tons of carbon, in the form of carbon dioxide, to the atmosphere. Chief among the recyclers are the curious and, to many eyes, beautiful organisms of the **Kingdom Fungi**—about 70,000 described species of molds, mushroom-forming fungi, yeasts, and their relatives **(Figure 30.1),** and an estimated 1.5 million more that are yet to be described.

Fungi are eukaryotes, most are multicellular, and all are heterotrophs, obtaining their nutrients by breaking down organic molecules that other organisms have synthesized. Molecular evidence suggests that fungi were present on land at least 500 million years ago, and possibly much earlier. In the course of the intervening millennia, evolution equipped fungi with a remarkable ability to break down organic matter, ranging from living and dead organisms and organic wastes to your groceries, clothing, paper and wood, even photographic film. Along with heterotrophic bacteria, they have become Earth's premier decomposers.

Fungi collectively also are a major cause of plant diseases, and a host of species causes disease in humans and other animals. Some even produce carcinogenic toxins. On the other hand, 90% of plants obtain needed minerals by way of a symbiotic relationship with a fungus. Humans have harnessed the metabolic activities of certain fungi to obtain substances ranging from cheeses and wine to therapeutic drugs such as penicillin and the immunosuppressant cyclosporin. And, as you know from previous chapters, species such as the yeast *Saccharomyces cerevisiae* and the mold *Neurospora crassa* are pivotal model organisms in studies of DNA structure and function, and *S. cerevisiae* has also been important in the development of genetic engineering methods.

FIGURE 30.1 Examples of fungi that hint at the rich diversity within the Kingdom Fungi.

Despite their profound impact on ecosystems and other life forms, most people are acquainted with fungi mainly as edible treats or the invisible but annoying causes of skin infections like athlete's foot. This chapter introduces mycology, the study of fungi (*mykes* = mushroom, *logia* = study). We begin with general characteristics of this kingdom and then discuss its major groups.

30.1 General Characteristics of Fungi

We begin our survey of fungi by examining how fungi differ from other forms of life, how fungi obtain nutrients, and the adaptations for reproduction and growth that enable fungi to spread far and wide through the environment.

Fungi May Be Single-Celled or Multicellular

Two basic body forms, single-celled and multicellular, emerged as the lineages of fungi evolved. A single-celled form is called a **yeast.** A cottony mesh of threadlike filaments makes up multicellular fungi. Some fungal species alternate between yeast and multicellular forms at different stages of the life cycle. Regardless, a rigid wall usually surrounds the plasma membrane of fungal cells. Generally the polysaccharide **chitin** provides this rigidity, the same function it serves in the external skeletons of insects and other arthropods.

A multicellular fungus exploits food sources by way of its slender filaments, which branch repeatedly as they grow over or into organic matter. Each filament is a **hypha** (*hyphe* = web) (plural, *hyphae*), and the combined mass of hyphae is called a **mycelium** (plural, *mycelia*) **(Figure 30.2A).** Hyphae generally are tubular. In most multicellular fungi, cross walls called *septa* (*saeptum* = partition, or fence) (singular, *septum*) divide hyphae into cell-like compartments that contain organelles. In a relatively few multicellular species, nuclei in growing hyphae divide without cytokinesis, so no septa develop and organelles share a common cytoplasm **(Figure 30.2B).** Such fungi are said to be **coenocytic,** which means "contained in a shared vessel."

Depending on the species, hyphal cells may have more than one nucleus, and septa have pores that permit nuclei and other organelles to move between hyphal cells. These passages also allow cytoplasm to extend from one hyphal cell to the next, throughout the whole mycelium. By a mechanism called **cytoplasmic streaming,** cytoplasm can flow through the hyphae, carrying nutrients from food-absorbing parts of the fungus to reproductive structures or other nonabsorptive parts. While mycologists commonly consider fungi with cell-like compartments to be "multicellular," they do so with the understanding that the term has a special meaning for these organisms.

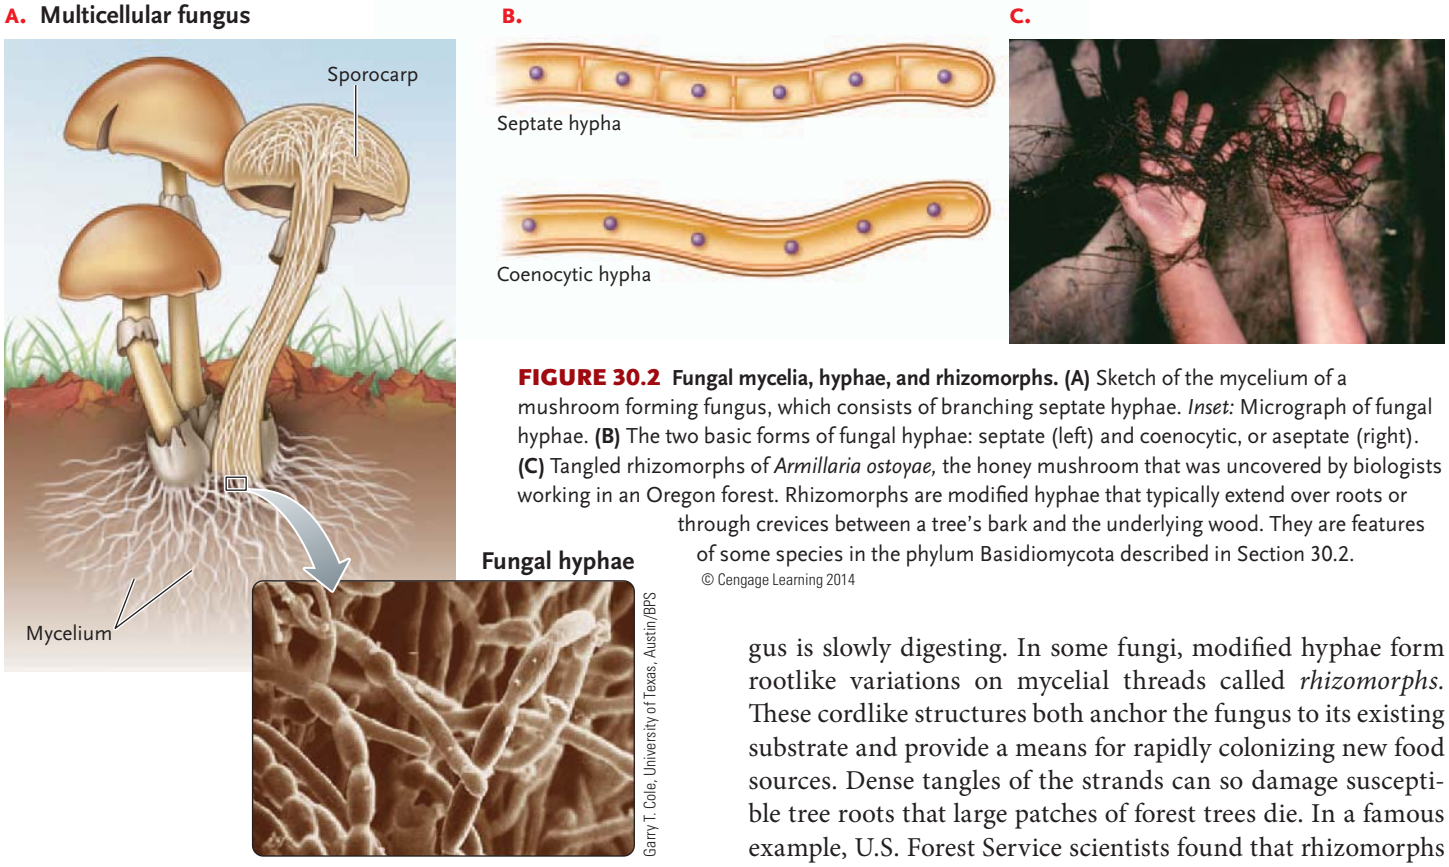

FIGURE 30.2 **Fungal mycelia, hyphae, and rhizomorphs. (A)** Sketch of the mycelium of a mushroom forming fungus, which consists of branching septate hyphae. *Inset:* Micrograph of fungal hyphae. **(B)** The two basic forms of fungal hyphae: septate (left) and coenocytic, or aseptate (right). **(C)** Tangled rhizomorphs of *Armillaria ostoyae,* the honey mushroom that was uncovered by biologists working in an Oregon forest. Rhizomorphs are modified hyphae that typically extend over roots or through crevices between a tree's bark and the underlying wood. They are features of some species in the phylum Basidiomycota described in Section 30.2.

© Cengage Learning 2014

A multicellular fungus grows larger as its hyphae elongate and branch. Each hypha elongates at its tip as new wall polymers (delivered by vesicles) are incorporated and additional organelles and cytoplasm are synthesized. As the new hyphae elongate and branch, an extensive mycelium can form quickly. Each forming branch fills with cytoplasm that includes new nuclei produced by mitosis. Although the rapid branching of hyphae is what allows multicellular fungi to grow aggressively—sometimes increasing in mass many times over within a few days—researchers have only recently gained the tools to explore the mechanisms that underlie this phenomenon. Studies spurred by the sequencing of the genome of *Neurospora crassa* suggest that multiple steps involving a variety of genes and their interacting protein products determine where and when a new branch arises. Given that the rapid growth of fungal mycelia has such a tremendous impact in ecosystems and in the progression of fungal disease in plants and animals, this topic is a significant area of mycological research.

Beyond their role in nutrient transport, aggregations of hyphae are the structural foundation for all other parts that arise as a multicellular fungus develops. For example, in many fungi a subset of hyphae interweave tightly, becoming prominent reproductive structures sometimes called *sporocarps* (see Figure 30.2A). Grocery store mushrooms are examples. But while a mushroom or some analogous structure may be the most conspicuous part of a given fungus, it usually represents only a small fraction of the organism's total mass. The rest, often invisible to the unaided eye, penetrates the food source the fungus is slowly digesting. In some fungi, modified hyphae form rootlike variations on mycelial threads called *rhizomorphs.* These cordlike structures both anchor the fungus to its existing substrate and provide a means for rapidly colonizing new food sources. Dense tangles of the strands can so damage susceptible tree roots that large patches of forest trees die. In a famous example, U.S. Forest Service scientists found that rhizomorphs of a single individual of the parasitic honey mushroom *Armillaria ostoyae* **(Figure 30.2C)** cover an area of about 880 hectares (roughly 1,665 football fields) in an eastern Oregon forest. By one estimate, the mass of tangled strands extends an average of 1 m deep and nearly 6,000 m across, making the fungus perhaps one of the largest organisms on Earth.

Fungi Obtain Nutrients by Extracellular Digestion and Absorption

Some major selection pressures have shaped the adaptations by which fungi obtain nutrients. As heterotrophs, fungi must secure nutrients by breaking down organic substances formed by other organisms. Nearly all fungi are terrestrial, but unlike other land-dwelling heterotrophs (such as animals), fungi do not move about in their environment. They also lack mouths or appendages for seizing and handling food items. Instead, fungi have a very different suite of adaptations for obtaining nutrients.

Experiments have shown that most species of fungi can synthesize nearly all their required nutrients from a few raw materials, including water, some minerals and vitamins (especially B vitamins), and a sugar or some other organic carbon source. For many species, carbohydrates in dead organic matter are the carbon sources, and fungi with this mode of nutrition are called *saprobes* (*sapros* = rotten). Other fungi are parasites, which extract carbohydrates from tissues of a living host, harming it in the process. Most fungi that parasitize living plants produce hyphal branches called **haustoria** (*haustor* = drinker), which penetrate the walls of a host plant's cells and channel nu-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

trients back to the fungal body. Parasitic fungi include those responsible for many devastating plant diseases, such as wheat rust and Dutch elm disease. Still other fungi are nourished by plants with which they have a mutually beneficial symbiotic association, a topic we return to later in this chapter.

Regardless of their nutritional mode, all fungi gain the raw materials to build and maintain their cells by absorption from the environment. Fungi can absorb many small molecules directly, and they gain access to other nutrients through extracellular digestion. In this process, a fungus synthesizes digestive enzymes and packages them in secretory vesicles via the pathway described in Section 15.4. When released to the outside, the enzymes digest nearby organic matter, breaking down larger molecules into absorbable fragments. Fungal species differ in the particular digestive enzymes they synthesize, so a substrate that is a suitable food source for one species may be unavailable to another. Although there are exceptions, in nature fungi typically thrive only in moist environments where they can directly absorb water, dissolved ions, simple sugars, amino acids, and other small molecules. When some of a mycelium's hyphal filaments contact a food source, growth is channeled toward it.

Various parts of a hypha absorb nutrients. Small atoms and molecules pass readily through the tips, and then transport mechanisms move them through the underlying plasma membrane. Large organic molecules, such as the carbohydrate cellulose (see Section 3.2), *cannot* directly enter any part of a fungus. To feed on such substances, a fungus must secrete hydrolytic enzymes that break down the large molecules into smaller, absorbable subunits. Depending on the size of the subunit, further digestion may occur inside fungal cells.

As described earlier, fungal adaptations for extracellular digestion make them masters of the decay so vital to terrestrial ecosystems. For instance, in a single autumn, one elm tree can shed 400 pounds of withered leaves; and in a tropical forest, a year's worth of debris may total 60 tons per acre. Without the metabolic activities of saprobic fungi and other decomposers such as bacteria, natural communities would rapidly become buried in their own detritus. As fungi digest dead tissues of other organisms, they also make a major contribution to the recycling of chemical elements from those tissues, including key nutrients such as nitrogen and phosphorus. But the prime example of this recycling virtuosity involves carbon. The respiring cells of fungi and other decomposers give off carbon dioxide, liberating carbon that would otherwise remain locked in the tissues of dead organisms. Each year this activity recycles a vast amount of carbon to plants, the primary producers of nearly all ecosystems on Earth.

All Fungi Reproduce by Way of Spores, but Other Aspects of Reproduction Vary

Biologists have observed striking reproductive variations in fungi, differences that are part of what makes them fascinating to study. As you will learn in the next section, fungi have traditionally been classified on the basis of their reproductive characteristics, although today evidence from molecular analysis also plays a prominent role.

Overall, most fungi can reproduce both sexually and asexually. Although no single diagram can depict all the variations, **Figure 30.3** gives an overview of the life cycle stages that mycologists have observed in several groups of fungi. The figure illustrates three general points. First, as you can see in step 1, genetically different **mating types** exist in many species of fungi (in the figure example, there are two mating types, denoted + and −). Second, the life cycle of multicellular fungi typically involves a haploid (*n*) stage (step 1 is the end point of this stage), a diploid (2*n*) stage (step 5), and between them a dikaryotic ("two nuclei") stage in which the fungus forms hyphae (and a mycelium) that have two haploid nuclei, making them $n + n$—neither strictly haploid *nor* diploid (step 3). Depending on the type of fungus, this stage may be long lasting or brief, and it is described more fully later in this section. Third, all fungi, whether they are multicellular or in a single-celled (yeast) form, can reproduce via **fungal spores.** The spores are microscopic, and in all but one group they are nonmotile (not propelled by flagella). Each spore is a walled single cell or multicellular structure that is dispersed from the parent body, often via wind or water. The spores of single-celled fungi form inside the parent cell, then escape when the cell wall bursts. In multicellular fungi, spores arise in or on specialized hyphal structures and may develop thick walls that help them withstand cold temperatures or drying out after they are released.

Reproductive spores represent a crucial fungal adaptation. Most fungi are opportunists, obtaining energy by exploiting unpredictable food sources in the environment. Spores can go dormant for long periods, then germinate and grow when environmental conditions become favorable. Being lightweight, fungal spores are easily disseminated by air or water—increasing the potential for finding suitable substrates. And releasing vast numbers of spores, as some fungi do, improves odds that at least a few spores will germinate and produce a new individual.

In nature generally, opportunistic organisms are adapted to rapidly take advantage of new food sources. Fungi that can quickly degrade simple sugars and starches often are among the first decomposers to exploit a new source of food. Competition for such resources is stiff, but once fungal spores encounter potential food and favorable conditions, they can quickly develop into new individuals that simultaneously feed and rapidly make more spores.

Many opportunistic fungi develop rapidly and reproduce before the food source is depleted. A common trade-off for speed, however, is small, even microscopic, body size. Larger species of fungi are often adapted to exploit food sources such as cellulose and lignin (a complex polymer in the walls of many plant cells), which their predecessors may have lacked the enzymatic machinery to digest efficiently. Some of these fungi may produce huge mycelia (and reproductive sporocarps such as mushrooms) by extracting nutrients from dead trees that contain enough organic material to sustain an extended period of growth.

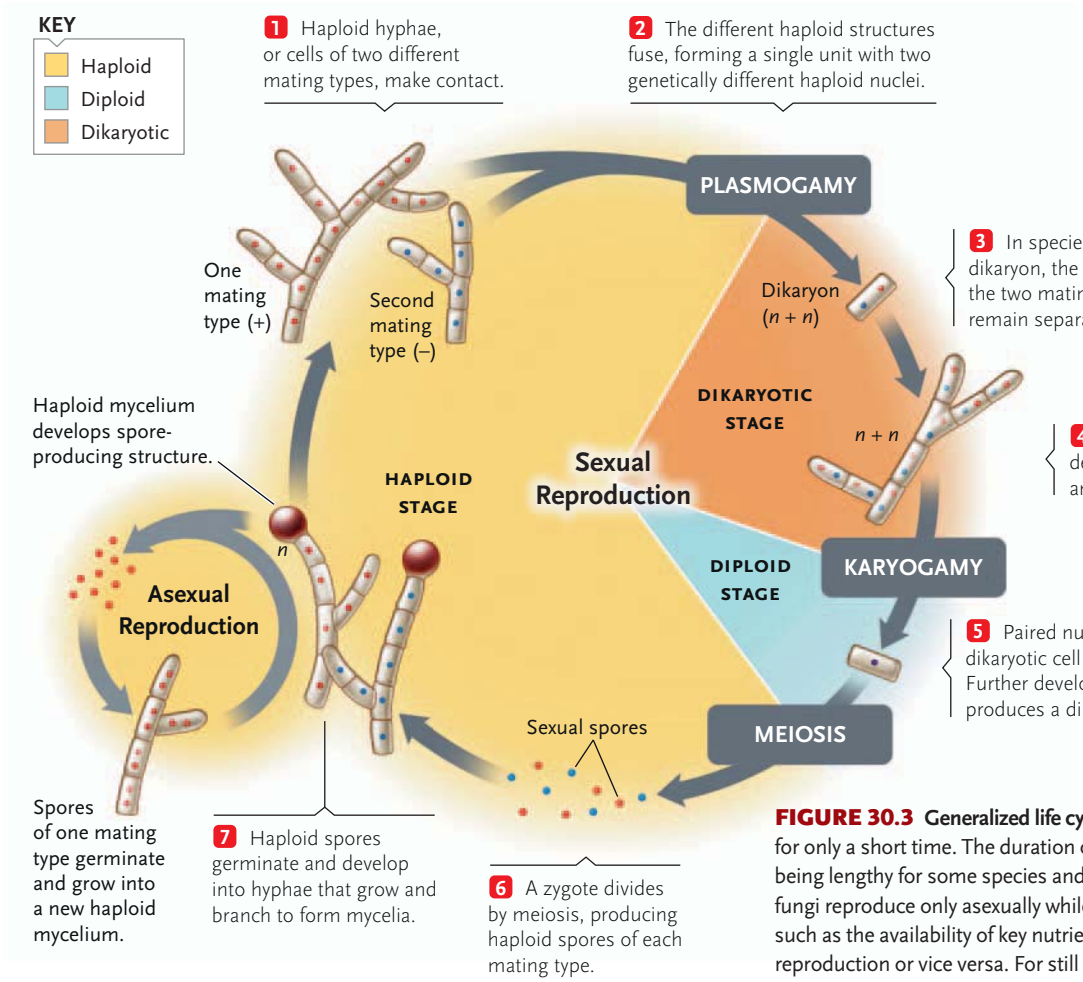

FIGURE 30.3 Generalized life cycle for many fungi. Most fungi are diploid for only a short time. The duration of the dikaryon stage varies considerably, being lengthy for some species and extremely brief in others. Some types of fungi reproduce only asexually while in others shifts in environmental factors, such as the availability of key nutrients, can trigger a shift from asexual to sexual reproduction or vice versa. For still others sexual reproduction is the norm.

© Cengage Learning 2014

FEATURES OF ASEXUAL REPRODUCTION IN FUNGI When a fungus produces spores asexually (see Figure 30.3), it may disperse billions of them into the environment. Some fungi (including many yeasts) also can reproduce asexually by budding or fission, or, in multicellular types, when fragments of hyphae break away from the mycelium and grow into separate individuals. In still others, the fungus produces hyphal fragments *or* asexual spores, depending on environmental factors. Asexual reproductive strategies all result in new individuals that are essentially clones of the parent fungus. They can be viewed as adaptations for reproductive efficiency, because the alternative—sexual reproduction—requires the presence of a suitable partner and generally involves several more steps.

The asexual stage of many multicellular fungi—including the pale gray fuzz you might see on berries or bread—is often called a **mold.** The term can be confusing if you are trying to keep track of taxonomic groupings. For example, the water molds and slime molds described in Chapter 27 are protists, although they were grouped with fungi until additional research revealed their true evolutionary standing. The mold visible on an overripe raspberry is actually a fungal mycelium with aerial structures bearing sacs of haploid spores at their tips.

FEATURES OF SEXUAL REPRODUCTION IN FUNGI Although asexual reproduction is the norm, quite a few fungi shift to sexual reproduction when environmental conditions (such as a lack of nitrogen) or other influences dictate. Recall from Chapter 11 that in sexual reproduction two haploid cells unite, and in most species fertilization—the fusion of two gamete nuclei to form a diploid zygote nucleus—soon follows. In fungi, however, the partners in sexual union can be two hyphae, two gametes, or other types of cells; the particular combination depends on the species involved. And in sharp contrast to most other life forms, many days, months, or even years may pass between the time fertilization gets underway and when it is completed.

During the initial sexual stage, called *plasmogamy* (*plasma* = a formed thing, *gamos* = marriage), the cytoplasms of two genetically different partners fuse. The resulting new cell, a **dikaryon** ("two nuclei"), contains two haploid nuclei, one from each parent. A dikaryon itself is not haploid (the condition of having one set of chromosomes) because it contains two nuclei. But neither is it diploid, because the nuclei are not fused. So, to be precise, we say that a dikaryon has an $n + n$ nuclear condition.

For example, one form of plasmogamy occurs when hyphal cells of two different mating types fuse. The uniting hyphae belong to mycelia of different individuals of the same species that

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

happen to grow near one another. The fusion of different mating types ensures genetic diversity in new individuals.

Once a dikaryon forms, when the next stage will begin depends on the type of fungus, as described in the next section. Sooner or later, however, a second phase of fertilization unfolds: the nuclei in the dikaryotic cell fuse to make a 2*n* zygote nucleus. This process is **karyogamy** ("nuclear union"). In fungi that form mushrooms, it occurs in the tips of hyphae that end on the underside of a mushroom cap (see Figure 30.1). In animals, a zygote is the first cell of a new individual, but in the world of fungi the zygote has a different fate. After it forms, meiosis converts the zygote nucleus into four haploid (*n*) nuclei. Those nuclei commonly are packaged into haploid "sexual spores" that vary genetically from each parent. Then the spores are released to the environment.

To sum up, in most fungi asexual and sexual spores are haploid, and both can germinate into haploid individuals. However, asexual spores are genetically identical products of asexual reproduction, while sexual spores are genetically varied products of sexual reproduction. We turn now to current ideas on the evolutionary history of fungi, and a survey of the major taxonomic groups in this kingdom.

STUDY BREAK 30.1

1. What features distinguish the two basic fungal body forms?
2. What is a fungal spore, and how does it function in reproduction?
3. Fungi reproduce sexually or asexually, but for many species the life cycle includes an unusual stage not seen in other organisms. What is this genetic condition, and what is its role in the life cycle?

THINK OUTSIDE THE BOOK

Section 19.2 introduced computer-based methods of genome sequence determination and annotation. Complete genome sequences are now available for several species of fungi. Using the Internet or other resources, find out which sequences are available and describe potential research or benefits scientists are hoping to realize from this knowledge.

30.2 Major Groups of Fungi

The evolutionary origins and lineages of fungi have been obscure ever since the first mycologists began mulling over the characteristics of this group. With the advent of molecular techniques, these topics have become extremely active and exciting areas of biological research that may shed light on fundamental events in the evolution of all eukaryotes. Not surprisingly when so much new information is coming to light, mycologists hold a wide range of views on how different groups arose and may be related. Even so, there is wide agreement on three phyla of fungi, known formally as the Glomeromycota, Ascomycota, and Basidiomycota **(Figure 30.4).** A fourth traditional phylum, a small but diverse array of fungi called the Zygomycota, probably is not monophyletic, and considerable research is underway to sort out the evolutionary relationships among the lineages typically included in the group. Molecular studies suggest that some members of a fifth traditional phylum, the Chytridiomycota, also should more properly be reclassified into two other, separate phyla. All chytrids share certain features, however, and here we consider them as a unit.

In a sixth group, termed *conidial* fungi, asexual reproduction produces spores called conidia ("dust"). "Conidial" is not a true taxonomic classification, however. Rather, it serves as a holding station for fungal species that have not yet been assigned to one of the five phyla because no sexual reproductive phase has been observed. This is another instance in which the name for a fungal group can be confusing, because numerous species belonging to the Zygomycota, Ascomycota, and Basidiomycota also form conidia as part of their asexual reproductive cycle.

Finally, we will briefly consider a particularly odd group of single-celled parasites called **microsporidia.** Based on genetic studies, some researchers suspect they may have arisen from a zygomycete ancestor. Other mycologists have proposed that microsporidia make up yet another phylum within the Kingdom Fungi.

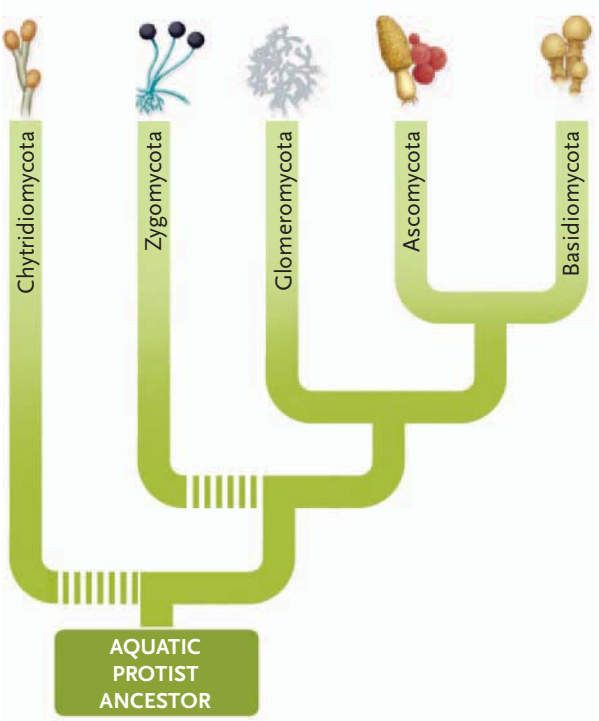

FIGURE 30.4 A phylogeny of fungi. This scheme represents a widely accepted view of the general relationships between major groups of fungi, but it may well be revised as new molecular findings provide more information. The dashed lines indicate that within two traditional groups, the chytrids and zygomycetes, lines of descent of some subgroups are not well understood and the phyla are probably not monophyletic.

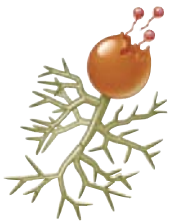
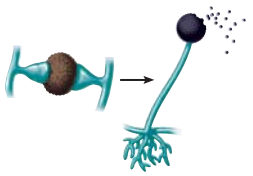
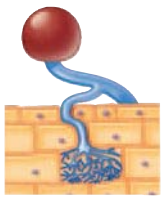
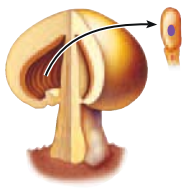
Fungi Arose from an Amoeba-like Flagellated Protist

For many years fungi were classified as plants, partly because many species seem to have a plantlike appearance. Recent comparisons of RNA and DNA sequences, and the discovery of chitin in fungal cells, all indicate that fungi and animals are more closely related to each other than they are to most other eukaryotes (see *Insights from the Molecular Revolution*). Phylogenetic studies, including extensive gene sequence analysis, suggest that the lineages of both fungi and animals arose from single-celled, flagellated protists in the clade Opisthokonta (Section 27.2). One such protist, a single-celled choanoflagellate, evidently gave rise to the lineage of animals, while molecular data show that fungi are more closely related to **nucleariids,** single-celled amoebas belonging to a different line of opisthokont protists Among other implications, these findings suggest that multicellular forms of animals and fungi evolved independently.









In general, soft-bodied organisms do not fossilize well, so the fossil record of possible early fungi is sparse. Although traces of what may be fossil fungi exist in rock formations nearly 1 billion years old, the oldest fossils that we can confidently assign to the Kingdom Fungi appear in strata laid down about 500 million years ago.

Once They Appeared, Fungi Radiated into Several Major Lineages

Most likely, the first fungi were aquatic, like their protist ancestors. When other kinds of organisms began to colonize land, they may well have brought fungi along with them. For example, researchers have discovered what appear to be mycorrhizae—symbiotic associations of a fungus and a plant—in fossils of some of the earliest known land plants (see Chapter 28). The final section of this chapter examines the nature of mycorrhizae more fully.

Over time, fungi diverged into the strikingly diverse groups that we consider in the rest of this section **(Table 30.1).** As the lineages diversified, different adaptations associated with reproduction arose. For this reason, mycologists traditionally assigned fungi to phyla according to the type of structure that houses the final stages of sexual reproduction and releases sexual spores. These features can still be useful indicators of the phylogenetic standing of a fungus, although now the powerful tools of molecular analysis are bringing many revisions to our understanding of the evolutionary journey of fungi. Our survey begins with chytrids, which probably most closely resemble the fungal kingdom's flagellated protist ancestors.

TABLE 30.1 Summary of Fungal Phyla

Phylum	Body Type	Key Feature	
Chytridiomycota and other chytrids	One to several cells	Motile spores propelled by flagella; usually asexual	
Zygomycota (zygomycetes)	Hyphal	Sexual stage in which a resistant zygospore forms for later germination	
Glomeromycota (glomeromycetes)	Hyphal	Hyphae associated with plant roots, forming arbuscular mycorrhizae	
Ascomycota (ascomycetes)	Hyphal	Sexual spores produced in sacs called asci	
Basidiomycota (basidiomycetes)	Hyphal	Sexual spores (basidiospores) form in basidia of a prominent fruiting body (basidiocarp)

Chytrids Produce Motile Spores That Have Flagella

There are about a thousand species of chytrids, most assigned to the phylum Chytridiomycota. Chytrids are the only fungi that produce motile spores, propelled by flagella. Nearly all chytrids are microscopic **(Figure 30.5A),** and mycologists have recently begun paying significant attention to them, in part because their characteristics strongly suggest that the lineages in this group arose near the beginning of fungal evolution. Research interest is also keen because the chytrid *Batrachochytrium dendrobatidis* is responsible for a disease epidemic that has wiped out an estimated two-thirds of the species of harlequin frogs *(Atelopus)* of the American tropics **(Figure 30.5B and C).** The epidemic has correlated with the rising average temperature in the frogs' habitats, an increase credited to global warming. The warmer environment provides optimal growing temperatures for the chytrid pathogen.

Most chytrids are aquatic, although a few live as saprobes in soil, feeding on decaying organic matter; as parasites on plants and some animals, or even as symbiotic partners in the gut of cattle and some other herbivores. Wherever a chytrid

There Was Probably a Fungus among Us

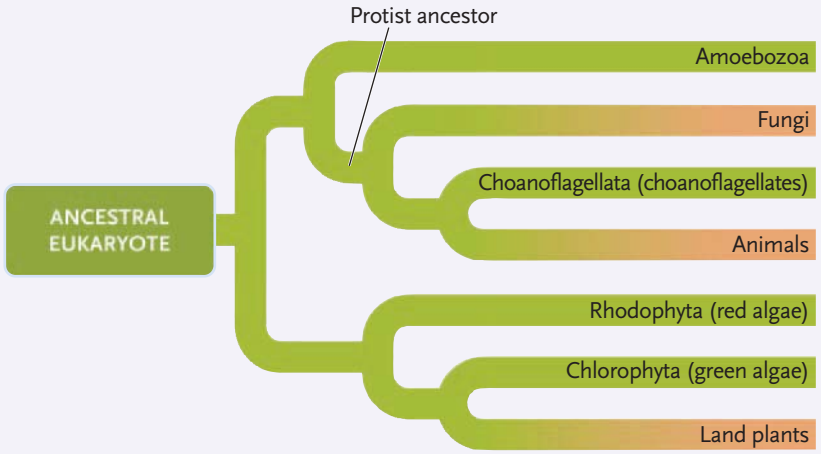
What is the taxonomic relationship between the fungi and other eukaryotes? The relationships of the fungi to protists, plants, and animals are buried so far back in evolutionary history that they have proved difficult to reconstruct.

Research Question

At the Kingdom level, which other organisms are the closest relatives of fungi?

Experiment

Relying on morphological comparisons, taxonomists classified fungi as most closely related to protists or plants until an investigation of ribosomal RNA (rRNA) sequences forced significant revision of this hypothesis.



Patricia O. Wainwright, Gregory Hinkle, Mitchell L. Sogin, and Shawn K. Stickel of Rutgers University and the Marine Biology Laboratory, Woods Hole, carried out the analysis by comparing sequences of 18S rRNA, an rRNA molecule that forms part of the small ribosomal subunit in eukaryotes (see Section 15.4). The investigators compared the 18S rRNA sequences of fungi to the 18S rRNA molecules of certain sponges, ctenophores, and cnidarians, of plants, and of several protists, including protozoans and algae. They used a computer program that sorts the rRNA sequences into related groups under the assumption that species with the greatest similarities in 18S rRNA sequence are most closely related. Analyses of the sequence information in several different combinations yielded the same family tree each time **(Figure).**

Conclusion

The family tree placed animals as the branch most closely related to fungi and indicates that the two groups probably share a common protist ancestor not shared with algae or plants. Other investigators have cited similarities in biochemical pathways in fungi and animals, such as pathways that make the amino acid hydroxyproline, the protein ferritin (which combines with iron atoms), and the polysaccharide chitin, which is a primary constituent of both fungal cell walls and arthropod exoskeletons. As described in the main text, subsequent molecular studies have further refined our understanding of the early origins of both fungi and animals.

THINK LIKE A SCIENTIST This study compared the 18S rRNA sequence across widely different groups of organisms. In terms of molecular analysis, what is a logical next step in seeking new data that may support the research findings?

lives, reproduction requires at least a film of water through which the spores can swim.

A chytrid's entire life cycle may unfold within a few days. For most species, asexual reproduction occupies much of this brief span. Although individuals initially exist as a vegetative (nonreproductive) phase, the fungus soon shifts into a reproductive mode. Flagella-bearing spores are released and each swims until it comes to rest on a substrate and a tough cyst forms around it. Under proper conditions, it will soon germinate and launch the life cycle anew.

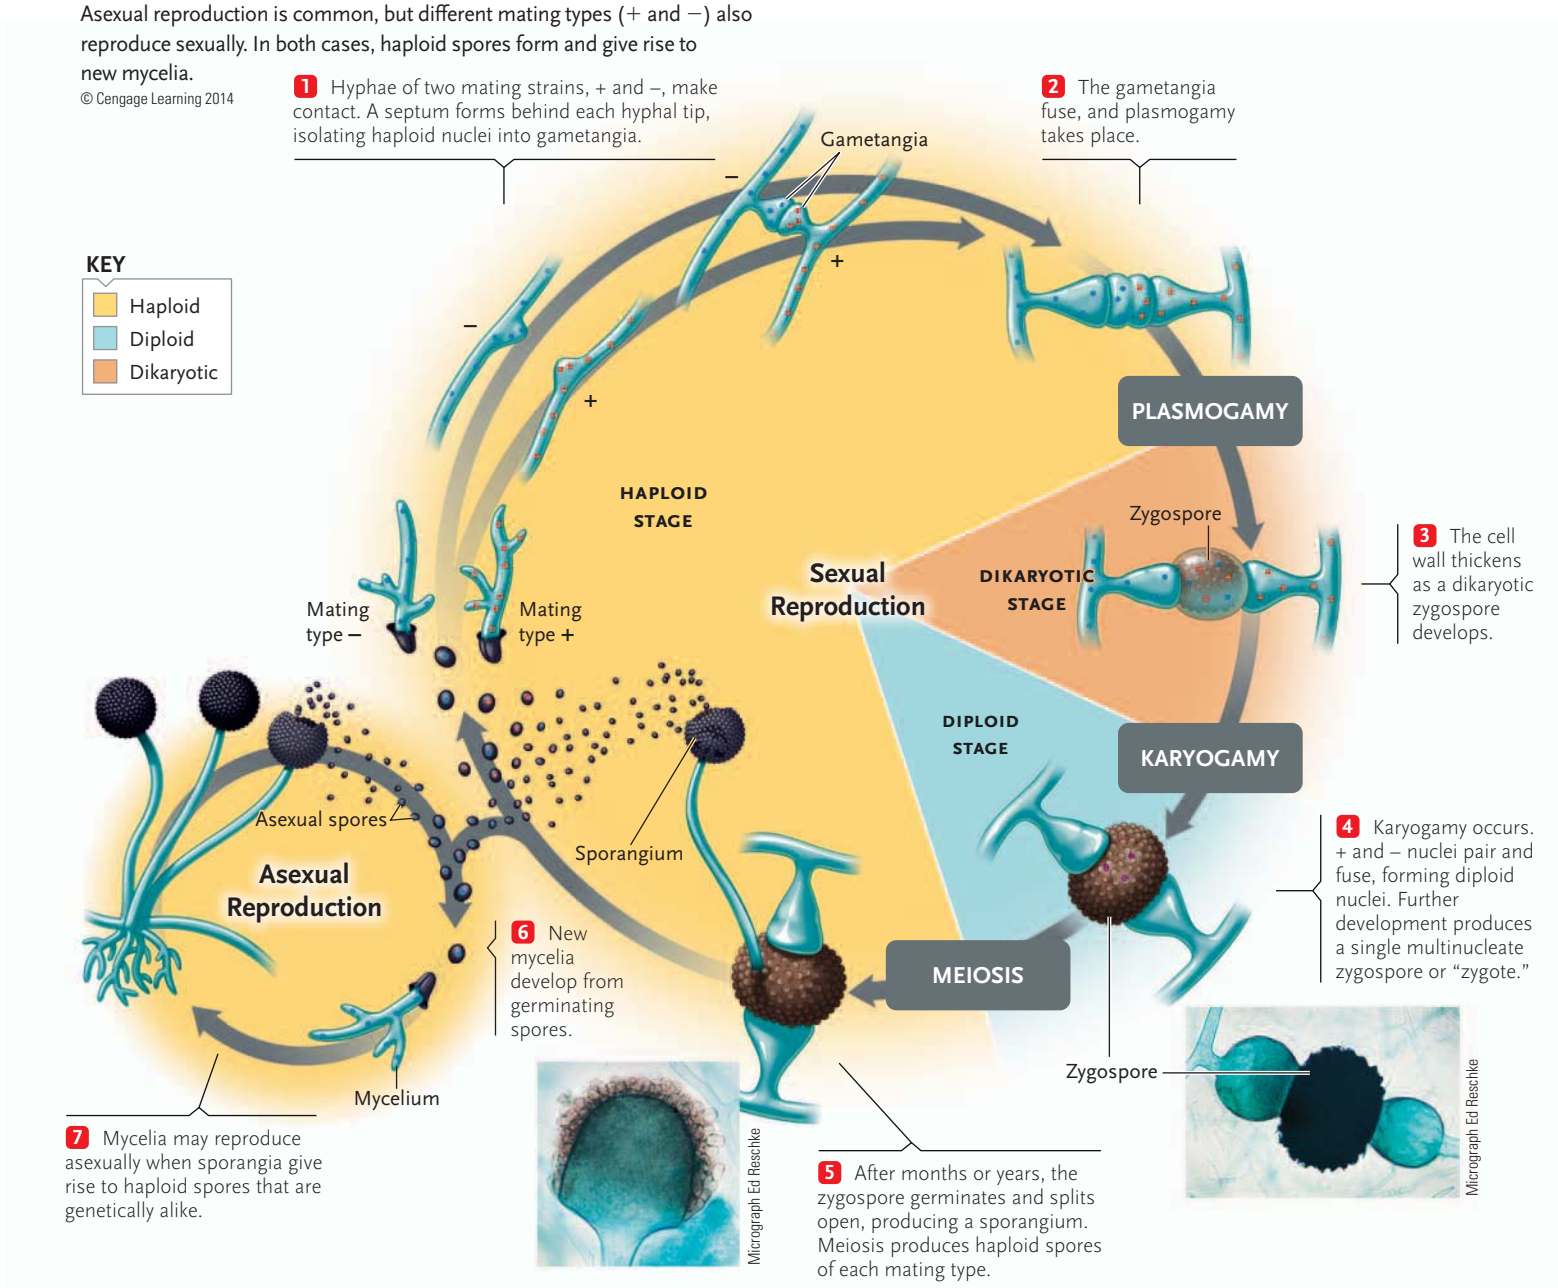
A few chytrids reproduce sexually. Mycologists have observed a remarkable variety of sexual modes, but in all of them spores of different mating types unite. Karyogamy directly follows plasmogamy to produce a $2n$ zygote. This cell may form a mycelium that produces sporangia, or it may directly give rise to either asexual or sexual spores.



Zygomycetes Form Zygospores for Sexual Reproduction

Fewer than a thousand species are assigned to the phylum Zygomycota—fungi that reproduce sexually by way of structures called *zygospores* **(Figure 30.6).** What zygomycetes lack in numbers, however, they make up for in impact on other organisms. Many zygomycetes are saprobes that live in soil, feeding on plant detritus. There, their metabolic activities release mineral nutrients in forms that plant roots can take up. Some zygomycetes are parasites of insects (and even other fungi), and some wreak havoc on human food supplies, spoiling stored grains, bread, fruits, and vegetables such as sweet potatoes. Others, however, have become major partners in commercial enterprises, where they are used in manufacturing products that range from industrial pigments to pharmaceuticals.

Most zygomycetes have aseptate hyphae, unlike the other multicellular fungi. Mycelia of many zygomycetes may occur in either a + or − mating type (Figure 30.6, step 1), and the nuclei of the two mating types are equivalent to gametes. Each strain secretes steroidlike hormones that can stimulate the development of sexual structures in the complementary strain and cause sexual hyphae to grow toward each other. When +

FIGURE 30.6 **Life cycle of the bread mold *Rhizopus stolonifer*, a zygomycete.** Asexual reproduction is common, but different mating types (+ and −) also reproduce sexually. In both cases, haploid spores form and give rise to new mycelia.

and − hyphae come into close proximity, a septum forms behind the tip of each hypha, producing a terminal **gametangium** that contains haploid nuclei. When the gametangia of the two strains touch, cellular enzymes digest the wall between them, yielding a single large, thin-walled cell that contains many nuclei from both parents (steps 2 and 3). In other words, plasmogamy has occurred, and this new cell is a dikaryon. Gradually an inner wall forms, thickens, and hardens. This structure, with the multinucleate cell inside it, is a **zygospore,** and gives this fungal group its scientific name. It becomes dormant and can stay dormant for months or years.

Karyogamy follows plasmogamy and eventually the diploid zygospore breaks dormancy. Then, meiosis produces a stalked sporangium (step 5). The sporangium contains haploid spores of each mating type, which are released to the outside. When a spore later germinates, it produces either a + or a − mycelium, and the sexual cycle can continue.

Like other fungi, however, zygomycetes usually reproduce asexually, as shown at the lower left in Figure 30.6. When a haploid spore lands on a favorable substrate, it germinates and gives rise to a branching mycelium. Some of the hyphae grow upward, and saclike, thin-walled sporangia form at the tips of these aerial hyphae. Inside the sporangia the asexual cycle comes full circle as new haploid spores arise through mitosis and are released.

The black bread mold, *Rhizopus stolonifer,* may produce so many charcoal-colored sporangia **(Figure 30.7A)** that moldy bread looks black. *R. stolonifer* spores are lightweight, dry, and readily wafted away by air currents. In fact, winds have dispersed them just about everywhere on Earth, including the Arctic. Another zygomycete, *Pilobolus* **(Figure 30.7B),** spews its sporangia away from the dung in which it grows. A grazing animal may eat a sporangium on a blade of grass; the spores then pass through the animal's gut unharmed and begin the life cycle again in a new dung pile.

Zygomycetes that have aseptate hyphae are structurally simpler than the species in most other fungal groups. Although septa wall off the reproductive structures, in effect the branching mycelium of each fungus is a single, huge, multinucleate cell—the same body structure as found in some algae and certain protists. Because such zygomycetes have numerous nuclei in a common cytoplasm, these fungi are examples of coenocytic species which means "contained in a shared vessel." By contrast, in other fungal groups septa at least partially divide the hyphae into individual cells, which typically contain two or more nuclei.

Presumably, having hyphae that lack septa confers some selective advantages. One benefit may be that without septa to impede the flow, nutrients can move freely from the absorptive hyphal tips to other hyphae where reproductive parts develop.

In zygomycetes, aggregations of "cooperating" hyphae may form body structures specialized for certain functions. However, such structures are more common in the three groups of more complex fungi that we consider next.

FIGURE 30.7 Two of the numerous strategies for spore dispersal by zygomycetes. (A) The sporangia of *Rhizopus stolonifer,* shown here on a slice of bread, release powdery spores that are easily dispersed by air currents. **(B)** In *Pilobolus,* the spores are contained in a sporangium (the dark sac) at the end of a stalked structure. When incoming rays of sunlight strike a light-sensitive portion of the stalk, turgor pressure (pressure against a cell wall due to the movement of water into the cell) inside a vacuole in the swollen portion becomes so great that the entire sporangium may be ejected outward as far as 2 m—a remarkable feat, given that the stalk is only 5 to 10 mm tall.

Glomeromycetes Form Asexual Spores, at the Ends of Hyphae

The 160 known members of the phylum Glomeromycota are all specialized to form the associations called mycorrhizae with plant roots. It would be hard to overestimate their ecological impact, for Glomeromycota collectively make up roughly half of the fungi in soil and form mycorrhizae with an estimated 80% to 90% of all land plants. Virtually all glomeromycetes reproduce asexually, by way of spores that form at the tips of hyphae. The hyphae also secrete enzymes that allow them to enter plant roots, where their tips branch into treelike clusters. As described in the next section, the clusters, called arbuscules, nourish the fungus by taking up sugars from the plant and in return supply the plant roots with dissolved minerals from the surrounding soil.

Ascomycetes, the Sac Fungi, Produce Sexual Spores in Saclike Asci

The phylum Ascomycota includes more than 30,000 species that produce reproductive structures called *asci* **(Figure 30.8).** A few ascomycetes prey on agricultural insect pests and thus have potential for use as "biological pesticides." Many more are destructive plant pathogens, including *Venturia inaequalis,* the fungus responsible for apple scab, and *Ophiostoma ulmi,* which causes

Dutch elm disease. Ascomycete pathogens on humans range from those that cause nuisance infections like athlete's foot and ringworm, to those that are potentially lethal. *Claviceps purpurea,* a parasite on rye and other grains, causes ergotism, a disease marked by vomiting, hallucinations, convulsions, and, in severe cases, gangrene and even death. Species of *Aspergillus* grow in damp grain or peanuts; over time their metabolic wastes, known as aflatoxins, can cause cancer in people who eat the poisoned food. By contrast, certain species of *Penicillium* **(Figure 30.9A)** are the source of the penicillin family of antibiotics, while others produce the aroma and distinctive flavors of Camembert and Roquefort cheeses. Gourmet delicacies such as truffles *(Tuber melanosporum)* and the succulent true morel *Morchella esculenta* come from ascomycetes as well. The orange bread mold *Neurospora crassa* has been important in genetic research, including the elucidation of the one gene–one enzyme hypothesis (see Section 15.1). A few ascomycetes even show trapping behavior, ensnaring small worms that they then digest **(Figure 30.9B).**

Although yeasts and filamentous fungi with a yeast stage in the life cycle occur in all fungal groups except chytrids and glomeromycetes, many of the best-known yeasts are ascomycetes. *Candida albicans* **(Figure 30.10)** commonly infects mucous membranes, especially of the mouth (where it causes a disorder called thrush) and the vagina. *Saccharomyces cerevisiae,* which

FIGURE 30.9 Other ascomycete representatives. (A) *Eupenicillium.* Notice the rows of conidia (asexual spores) atop the structures that produce them. **(B)** Hyphae of *Arthrobotrys dactyloides,* a trapping ascomycete, form nooselike rings. When the fungus is stimulated by the presence of a prey organism, rapid changes in ion concentrations draw water into the hypha by osmosis. The increased turgor pressure shrinks the "hole" in the noose and captures this nematode. The hypha then releases digestive enzymes that break down the worm's tissues.

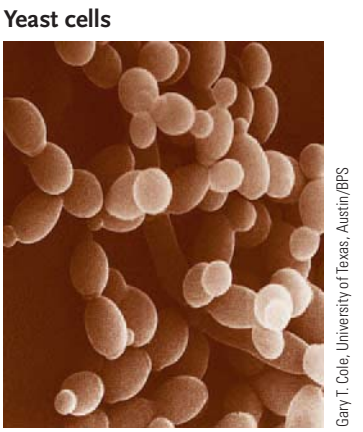

FIGURE 30.10 *Candida albicans*, cause of yeast infections of the mouth and vagina.

produces the ethanol in alcoholic beverages and the carbon dioxide that leavens bread, has also been a model organism for genetic research. By one estimate, it has been the subject of more genetic experiments than any other eukaryotic microorganism. Yeasts commonly reproduce asexually by fission or budding from the parent cell, but many also can reproduce sexually after the fusion of two cells of different mating types (analogous to the mating types described earlier). Many ascomycete yeasts are found naturally in the nectar of flowers and on fruits and leaves. At least 1,500 species have been described, and mycologists suspect that thousands more are yet to be identified.

Tens of thousands of ascomycetes, however, are not yeasts. They are multicellular, with tissues built up from septate hyphae. Although septa do slow the flow of nutrients (which, recall, can cross septa through pores), they also confer advantages. For example, septa present barriers to the loss of cytoplasm if a hypha is torn or punctured, whereas in an aseptate zygomycete, fluid pressure may force out a significant amount of cytoplasm before a breach can be sealed by congealing cytoplasm. In ways that are not well understood, septa can also limit the damage from toxins that are secreted by competing fungi.

As with zygomycetes, certain hyphae in ascomycetes are specialized for asexual reproduction. Many ascomycetes produce asexual spores called *conidia* (*konis* = dust) (singular, *conidium*). In some of these species, the conidia form in chains that elongate from modified hyphal branches called **conidiophores.** In other ascomycetes, the conidia pinch off from the hyphae in a series of "bubbles," a bit like a string of detachable beads. Either way, an ascomycete can form and release spores much more quickly than a zygomycete can. Each newly formed conidium contains a haploid nucleus and some

of the parent hypha's cytoplasm. Conidia and conidiophores of some ascomycete species are visible as the white powdery mildew that attacks grapes, roses, grasses, and the leaves of squash plants.

Ascomycetes can also reproduce sexually and are commonly termed *sac fungi* because most of the events that generate haploid sexual spores occur in saclike cells called *asci* (*askos* = leather bag) (singular, *ascus*). In *Neurospora crassa* and other complex ascomycetes, reproductive bodies called **ascocarps** bear or contain the asci. Some ascocarps resemble globes, others flasks or open dishes. In *N. crassa,* an ascocarp begins to develop when a conidium from a hypha of one mating type fuses with a hypha of the opposite mating type. **Figure 30.11,** step 1). Plasmogamy then takes place, with the details differing from species to species. During plasmogamy, the fused sexual structures give rise to dikaryotic hyphae. Asci form at the hyphal tips. Inside them, karyogamy takes place, producing a diploid zygote nucleus. It divides by meiosis, producing four haploid nuclei. In yeasts and some other ascomycetes, cell division stops at this point, but in *N. crassa* and in many other species, a round of mitosis ensues and results in eight nuclei. Regardless, the nuclei, other organelles, and a portion of cytoplasm then are incorporated into ascospores that may germinate on a suitable substrate and continue the life cycle.

Basidiomycetes, the Club Fungi, Form Sexual Spores in Club-Shaped Basidia

The 30,000 or so species of fungi in the phylum Basidiomycota include the mushroom-forming species, shelf fungi, coral fungi, bird's nest fungi, stinkhorns, smuts, rusts, and puffballs **(Figure 30.12).** Basidiomycetes are known commonly as club fungi because their spore-producing cells, called *basidia* (*basis* = base or foundation), usually are club shaped. Some species have enzymes for digesting cellulose and lignin and are important decomposers of woody plant debris. A surprising number of basidiomycetes, including the prized edible oyster mushrooms *(Pleurotus ostreatus),* also can trap and consume bacteria and small animals such as nematodes by secreting paralyzing toxins or gluey substances that immobilize the prey. This adaptation gives the fungus access to a rich source of molecular nitrogen, an essential nutrient that is often scarce in terrestrial habitats.

Many basidiomycetes take part in vital mutualistic associations with the roots of forest trees, as discussed later in this chapter. Others, the rusts and smuts, are parasites that cause serious diseases in wheat, rice, and other plants.

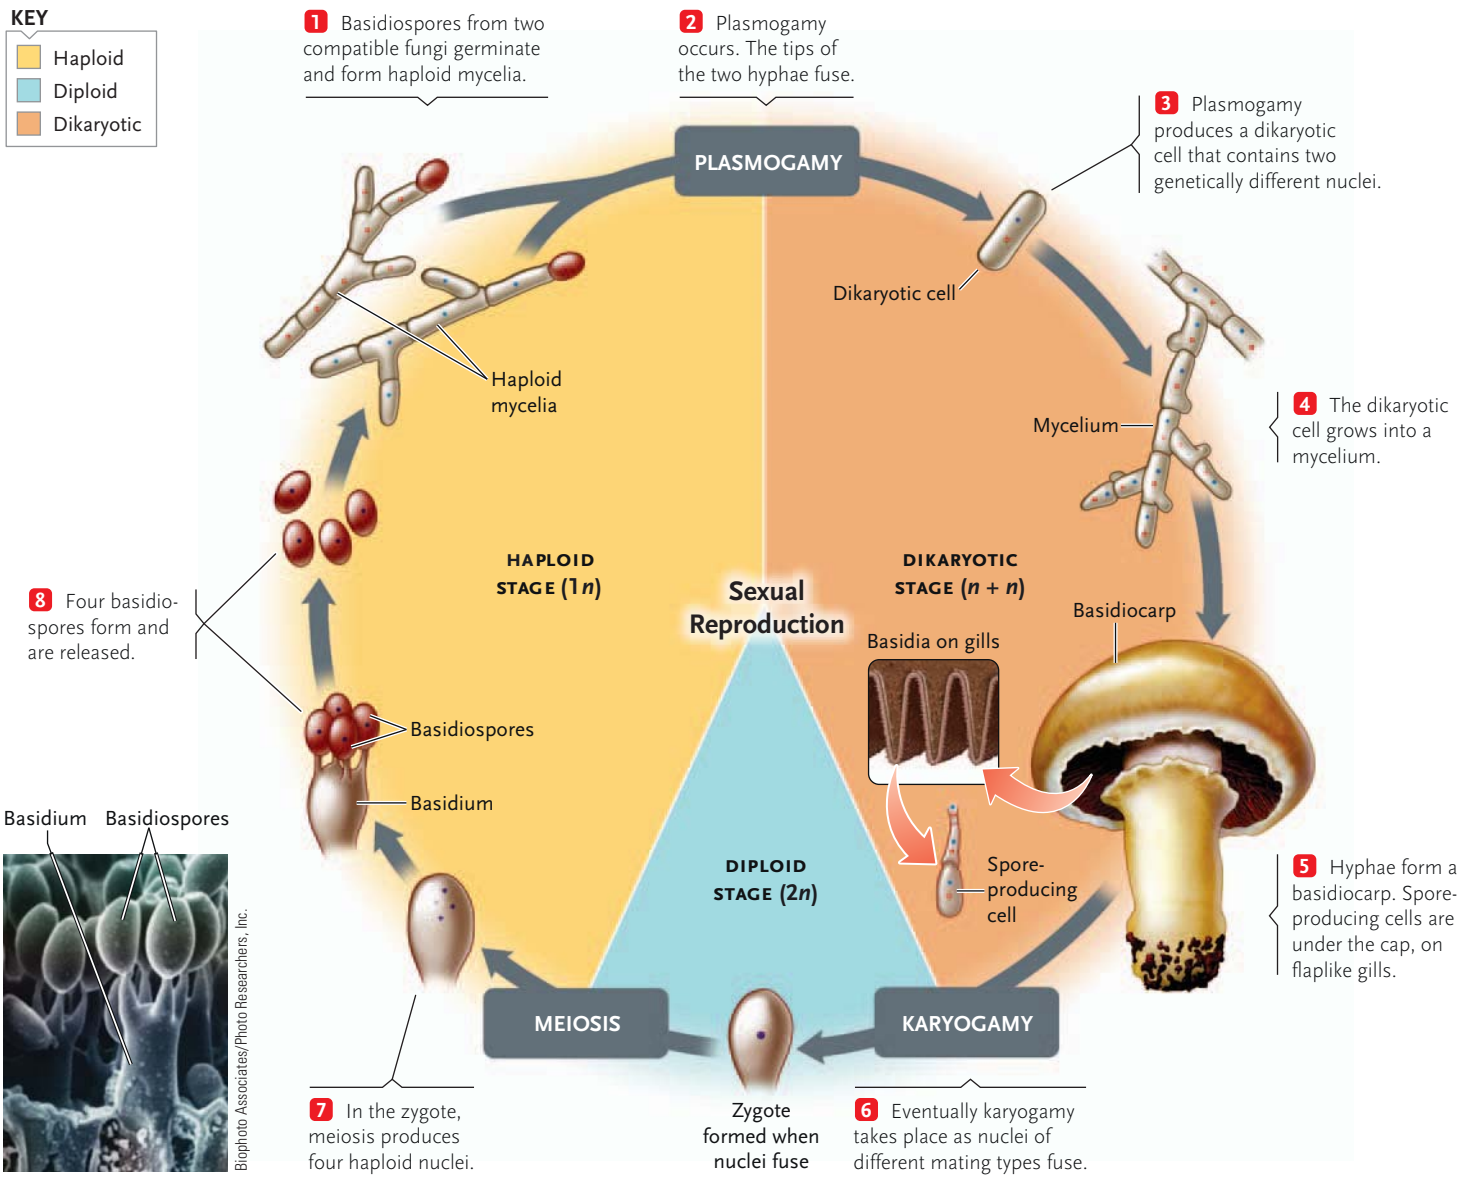
religious rituals of ancient societies in Central America, Russia, and India. (Less pleasant side effects can include powerful nausea.) Other species of this genus, including the death cap mushroom *Amanita phalloides,* produce deadly toxins. In eukaryotic cells, the *A. phalloides* toxin, a short peptide called α-amanitin, halts the transcription of protein-coding genes by RNA polymerase II (see Section 15.2), thereby inhibiting protein synthesis. Ingesting as little as 5 mg of the toxin can trigger violent vomiting and diarrhea within 8 to 24 hours. Later, kidney and liver cells start to degenerate; without intensive medical care, death can follow within a few days.



In a few basidiomycetes, reproduction is usually asexual, by budding or shedding a fragment of a hypha. One is *Cryptococcus neoformans,* which causes a form of meningitis in humans. In general, however, basidiomycetes do reproduce sexually, producing large numbers of haploid sexual spores. **Figure 30.13** shows the life cycle of a typical basidiomycete.

Basidia typically develop on a **basidiocarp,** which is the reproductive body of the fungus. A basidiocarp consists of tight clusters of hyphae; the feeding mycelium is buried in the soil or decaying wood. The shelflike bracket fungi on trees are basidiocarps, and about 10,000 species of club fungi produce the basidiocarps we call mushrooms. Each is a short-lived reproductive body consisting of a stalk and a cap. Basidia develop on sheetlike "gills" on the underside of the cap. The basidia undergo meiosis to produce microscopic, haploid **basidiospores** (Figure 30.13, inset) that disperse throughout the environment.

When a basidiospore lands on a suitable food source, it germinates and gives rise to a haploid mycelium. Compatible mating types growing near each other may undergo plasmog-

FIGURE 30.13 Generalized life cycle of the basidiomycete *Agaricus arvensis*, a close relative of the common button mushroom sold in grocery stores. amy. The resulting mycelium is dikaryotic, its cells containing one nucleus from each mating type. The dikaryotic stage of a basidiomycete is the feeding mycelium, which can grow for years—a major departure from an ascomycete's short-lived dikaryotic stage. Accordingly, a basidiomycete has many more opportunities for producing sexual spores, and the mycelium can give rise to reproductive bodies many times.

After an extensive mycelium develops, and when environmental conditions such as moisture are favorable, basidiocarps grow from the mycelium and develop basidia. At first, each basidium in the mushroom or other reproductive body is dikaryotic, but then the two nuclei undergo karyogamy, fusing to form a diploid zygote nucleus. The zygote exists only briefly; meiosis soon produces haploid basidiospores, which are wafted away from the basidium by air currents. Basidia can produce huge numbers of spores—for many species, estimates run as high as 100 million spores *per hour* during reproductive periods, day after day.

Squirrels and many other small animals may eat mushrooms almost as soon as they appear, but in some species the underlying mycelium can live for many years. As such a mycelium grows, specialized mechanisms during cell division maintain the dikaryotic condition and the paired nuclei in each hyphal cell.

Conidial Fungi Are Species for Which No Sexual Phase Is Known

As noted earlier, fungi generally are classified on the basis of their structures for sexual reproduction. When a sexual phase is absent or has not yet been detected, the fungal species is lumped into a convenience grouping, the conidial fungi (recall that conidia are asexual spores). Other historical names for this grouping are "imperfect fungi" and deuteromycetes.

When researchers discover a sexual phase for a conidial fungus, or when molecular studies establish a clear relationship to a sexual species, the conidial fungus is reassigned to the appropriate phylum. Thus far, some have been classified as basidiomycetes, but most conidial fungi have turned out to be ascomycetes.

Microsporidia Are Single-Celled Sporelike Parasites

There are more than 1,200 species of the single-celled parasites called **microsporidia.** They are known to infect insects including honeybees and grasshoppers, and vertebrates including fish and humans—especially individuals with compromised immune systems. Microsporidia are rather mysterious organisms. Physically they resemble spores **(Figure 30.14),** but they lack mitochondria and have other puzzling characteristics. Molecular studies suggest that they are related to zygomycetes, and some researchers have proposed that the group may have lost many typical fungal features as it evolved a highly specialized parasitic lifestyle.

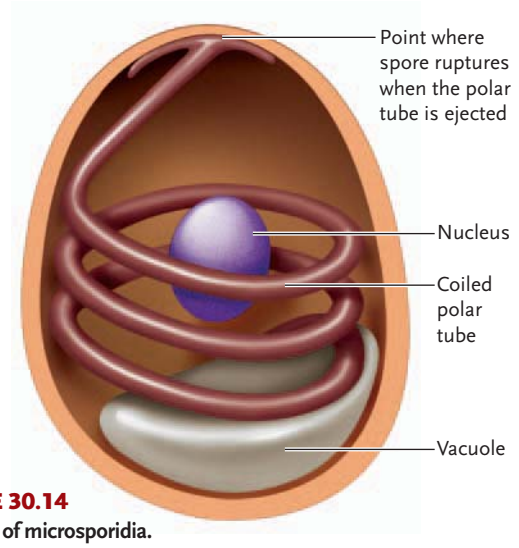

FIGURE 30.14
Structure of microsporidia.
When a spore germinates, its vacuole expands and forces the coiled "polar tube" outward and into a nearby, soon-to-be host cell. The nucleus and cytoplasm of the parasite enter the host through the tube, launching developmental steps that lead to the development of more microsporidia inside the host.

STUDY BREAK 30.2

1. **Name the major phyla and phylum-level categories of the Kingdom Fungi and describe the reproductive adaptations that distinguish each one.**
2. **In terms of structure, which are the simplest fungal groups? The most complex?**
3. **Describe some ways, positive or negative, that members of each fungal phylum interact with other life forms.**

THINK OUTSIDE THE BOOK

Humans are biologically attractive hosts for a wide range of fungi that colonize epidermal tissues—skin, hair, and nails. These fungal species, often described medically as dermatophytes, are categorized as anthrophilic, zoophilic, and geophilic species. Investigate this topic and make a list of the skin disorders associated with each type, as well as common sources of infection. What basic nutrition source do all dermatophytes share?

30.3 Fungal Associations

Many fungi are partners in mutually beneficial interactions with plants and other photosynthesizers, with insects, and even with mammals—associations that play major roles in the functioning of ecosystems. A **symbiosis** is a state such as parasitism or mutualism in which two or more species live together in close association. Chapter 54 discusses general features of symbiotic associations more fully; here we are interested in some examples of the symbioses fungi form with photosynthetic partners—cyanobacteria, green algae, and plants.

Lichens as Monitors of Air Pollution's Biological Damage

Lichens have become reliable pollution-monitoring devices all over the world—in some cases, replacing costly electronic monitoring stations. Different species are vulnerable to specific pollutants. For example, *Ramalina* lichens are damaged by nitrate and fluoride salts. Elevated levels of sulfur dioxide (a major component of acid rain) cause old man's beard *(Usnea trichodea)* to shrivel and die, but strongly promote the growth of a crusty European lichen, *Lecanora conizaeoides.* The sensitivity of yellow *Evernia* lichens to SO_2 enabled the scientist who discovered its damage at remote Isle Royale in Michigan to point the finger northward to coal-burning furnaces at Thunder Bay, Canada. Conversely, healthy lichens on damaged trees of Germany's Black Forest lifted suspicion from French coal-burning power plants and allowed investigators to identify the true source of the tree damage: nitrogen oxides from automobile exhausts. The result was Germany's first auto emission standards, which went into effect in the 1990s.

Usnea (old man's beard), a pendent (hanging) lichen.

A Lichen Is an Association between a Fungus and a Photosynthetic Partner

Thousands of ascomycetes and a few basidiomycetes form the kind of symbiosis called a lichen. Technically, a **lichen** is a single vegetative body that results from an association between a fungus and a photosynthetic partner. The fungal partner in a lichen, called the **mycobiont,** usually makes up about 90% of the whole. The other 10% is the photosynthetic partner, called the **photobiont.** Only about 100 photosynthetic species serve as photobionts. Most frequently, these are green algae of the genus *Trebouxia* or cyanobacteria of the genus *Nostoc.*

Lichens often live in harsh, dry microenvironments, including on bare rock and wind-whipped tree trunks. Yet lichens have vital ecological roles and important human uses. Lichens secrete acid that eats away at rock, breaking it down and facilitating the development of new soil. Some paleobiologists (who study ancient life forms) have suggested that lichens may have been some of the earliest land organisms, covering bare rocks during the Ordovician period (roughly 500 million–425 million years ago). In this scenario, millennia of decaying lichens would have created the first soils in which the earliest land plants could grow. Today, lichens continue to enhance the survival of other life forms. For instance, in arctic tundra, where plants are scarce, reindeer and musk oxen can survive by eating lichens. Insects and some other invertebrates also consume lichens, and they are nest-building materials for many birds and small mammals. People have derived dyes from lichens; they are even a component of garam masala, an ingredient in Indian cuisine. Some environmental chemists monitor air pollution by observing lichens, most of which cannot grow in heavily polluted air (see *Focus on Applied Research*).

Because lichens are composite organisms, it may seem odd to talk of lichen "species." Biologists do give lichens binomial names, however, based on the characteristics of the mycobiont. More than 13,500 lichens are recognized, each one a unique combination of a particular species of fungus and one or more species of photobiont. The relationship often begins when a fungal mycelium contacts a free-living cyanobacterium, algal cell, or both. The fungus parasitizes the photosynthetic host cell, sometimes killing it. If the host cell can survive, however, it multiplies in association with the fungal hyphae. The result is a tough, pliable body called a **thallus,** which can take a variety of forms **(Figure 30.15A).** Short, specialized hyphae penetrate photobiont cells of the thallus, which become the fungus's sole source of nutrients. Often, the mycobiont of a lichen absorbs up to 80% of the carbohydrates the photobiont produces.

Benefits for the photobiont are less clear-cut, in part because the drain on nutrients hampers its growth and reproduction. In one view, many and possibly most lichens are parasitic symbioses in which the photobiont does not receive equal benefit. On the other hand, it is relatively rare to find a lichen's photobiont species living independently in the same conditions under which the lichen survives. Studies have also revealed that at least some green algae do clearly benefit from the relationship. Such algae are sensitive to desiccation and intense ultraviolet radiation. Sheltered by a lichen's fungal tissues, a green alga can thrive in locales where alone it would perish.

As you might expect with such a communal life form, reproduction has its quirky aspects. In lichens that involve an ascomycete, the fungus produces ascospores that are dispersed by the wind. The spores germinate to form hyphae that may colonize new photosynthetic cells and so establish new symbioses. A lichen itself can also reproduce in at least two ways. In some types, a section of the thallus detaches and grows into a new lichen. In about one-third of lichens, specialized regions of the thallus give rise asexually to reproductive cell clusters called **soredia** (*soros* = heap) (singular, *soredium*). Each cluster includes both algal and hyphal cells **(Figure 30.15B).** As the lichen grows, the soredia detach and are dispersed by water, wind, or passing animals.

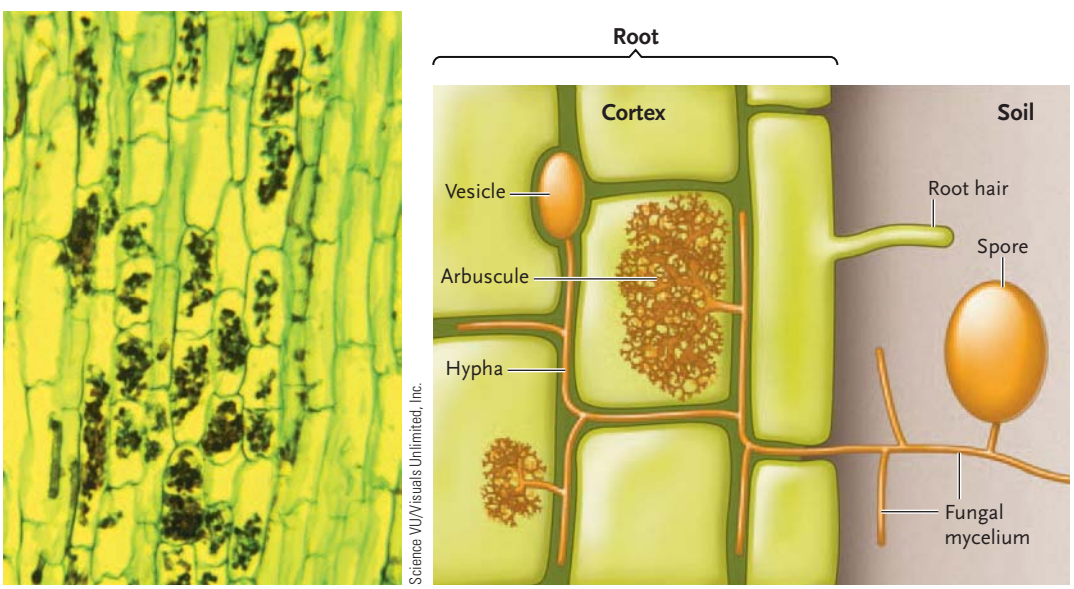
Mycorrhizae Are Symbiotic Associations of Fungi and Plant Roots

A **mycorrhiza** ("fungus root") is a mutualistic symbiosis in which fungal hyphae associate intimately with plant roots. Mycorrhizae greatly enhance the plant's ability to extract various nutrients, especially phosphorus and nitrogen, from soil (see Chapter 35).

In **endomycorrhizae,** the fungal hyphae penetrate the walls of root cells. This kind of association occurs on the roots of nearly all flowering plants, and in most cases a glomeromycete is the fungal partner. The branched hyphae of endomycorrhizae are called arbuscules **(Figure 30.16),** and glomeromycetes are sometimes referred to as arbuscular mycorrhizal fungi.



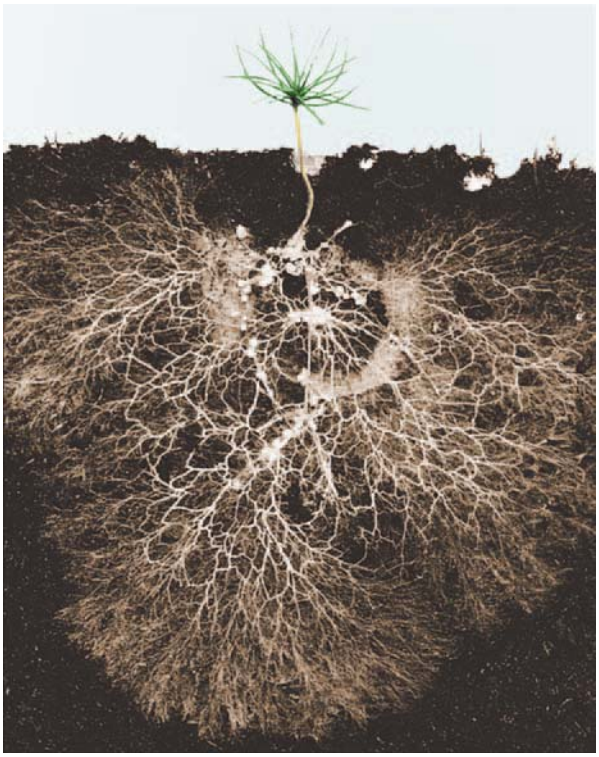


FIGURE 30.16 **Endomycorrhizae. (A)** In this instance, the roots of leeks are growing in association with the glomeromycete *Glomus versiforme* (longitudinal section). Notice the arbuscules that have formed as the fungal hyphae branched after entering the leek root **(B).**

FIGURE 30.17 **Ectomycorrhizae. (A)** Seedling of pine, *Pinus contorta*, longitudinal section. Notice the extent of the mycorrhiza compared with the above-ground portion of the seedling, which is only about 4 cm tall. **(B)** Mycorrhiza of a hemlock tree.

Basidiomycetes are the usual fungal partners in **ectomycorrhizae (Figure 30.17),** in which hyphal tips grow between and around the young roots of trees and shrubs but never enter the root cells. Ectomycorrhizal associations with trees—often several of them—are common. For instance, the extensive root system of a mature pine may be studded with ectomycorrhizae involving dozens of fungal species. The musky-flavored truffles *(Tuber melanosporum)* prized by gourmets are ascomycetes that form ectomycorrhizal associations with oak trees (genus *Quercus*).

Orchids are partners in a unique mycorrhizal relationship. The fungal partner, usually a basidiomycete, lives inside the orchid's tissues and provides the plant with a variety of nutrients.

F. B. Reeves

FIGURE 30.18 **Effect of mycorrhizal fungi on plant growth.** The six-month-old juniper seedlings on the left were grown in sterilized low-phosphorus soil inoculated with a mycorrhizal fungus. The seedlings on the right were grown under the same conditions but without the fungus.

In fact, seeds of wild orchids germinate, and seedlings survive, only when such mycorrhizae are present.

In general, mycorrhizae represent a "win-win" situation for the partners. The fungal hyphae absorb carbohydrates made by the plant, along with some amino acids and perhaps growth factors as well. The growing plant in turn absorbs mineral ions made accessible to it by the fungus. Collectively, the fungal hyphae have a huge surface area for absorbing mineral ions from a large volume of the surrounding soil. Dissolved mineral ions accumulate in the hyphae when they are plentiful in the soil and are released to the plant when they are scarce. This service is a survival boon to a great many plants, especially species that cannot readily absorb mineral ions, particularly phosphorus **(Figure 30.18).** For plants that inhabit soils poor in mineral ions, such as in tropical rain forests, mycorrhizal associations are crucial for survival. Likewise, in temperate forests, species of spruce, oak, pine, and some other trees die unless mycorrhizal fungi are present. Plants that live in dry habitats often rely on specialized mycorrhizal hyphae that serve as conduits for water into the root. Like lichens, mycorrhizae are highly vulnerable to damage from pollutants, especially acid rain.

Mycorrhizae have a long evolutionary history. Fossils show that endomycorrhizae were common among ancient land plants, and some biologists have speculated they might have been key for enhancing the transport of water and minerals to the plants. In that scenario, endomycorrhizae may have played a crucial role in allowing plants to make the transition to life on land.

STUDY BREAK 30.3

1. **Explain what a lichen is and how each partner contributes to the whole.**
2. **Describe the biological and ecological roles of mycorrhizae.**
3. **How do endomycorrhizae and ectomycorrhizae differ?**

UNANSWERED QUESTIONS

Do different fungal species respond differently to environmental changes?

Ecologists Shigeo Yachi and Michel Loreau formulated the "biological insurance" hypothesis, which predicts that ecosystem functions will be maintained more reliably in natural communities having species that perform the same general ecological function (such as serving as decomposers) but that differ in their responses to environmental changes. When environmental conditions shift in such communities, a species that fills the same ecological role as another but is better suited to the new conditions can then "take over" for a species better adapted to the former conditions. Changes in the makeup of fungal communities resulting from climate change or other ecological perturbations could have important consequences for ecosystem functions such as the availability of soil nutrients, storage of carbon in organic material, and plant growth. For instance, experiments in which fungi were exposed to above-normal concentrations of nitrogen have demonstrated pronounced shifts in the composition of communities of mycorrhizal and saprobic fungi. Studies of CO_2 effects have shown changes in fungal community composition when the fungi were exposed to elevated CO_2 treatments, although several longer-term studies indicate that these differences wane over time. Gaining a better understanding of the mechanisms underlying these patterns and linking changes in community composition to changes in how ecosystems function are important directions for further research.

THINK LIKE A SCIENTIST Ectomycorrhizal fungal communities often exhibit high local diversity, where the root systems of single trees may contain dozens—and a single-host forest stand may contain hundreds—of different fungal symbionts. What factors might allow multiple species of fungi to coexist on a single tree? What factors might favor the dominance of one symbiont over another? How might a better understanding of these phenomena be beneficial to conservation planning?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

30.1 General Characteristics of Fungi

- Fungi are key decomposers contributing to the recycling of carbon and some other nutrients. They occur as single-celled yeasts or multicellular filamentous organisms.
- The fungal mycelium consists of filamentous hyphae that grow throughout the substrate the fungus feeds on (Figure 30.2). A wall containing chitin surrounds the plasma membrane, and in most species septa partition the hyphae into cell-like compartments.
- Pores in septa permit cytoplasm and organelles to move between hyphal cells. Aggregations of hyphae form all other tissues and organs of a multicellular fungus.
- Fungi gain nutrients by extracellular digestion and absorption. Saprobic species feed on nonliving organic matter. Parasitic types obtain nutrients from tissues of living organisms. Many fungi are partners in symbiotic relationships with plants.
- All fungi may reproduce via spores generated either asexually or sexually (Figure 30.3). Some types also may reproduce asexually by budding or fragmentation of the parent body.
- Sexual reproduction usually has two stages. First, in plasmogamy, the cytoplasms of two haploid cells fuse to become a dikaryon containing a haploid nucleus from each parent. Later, in karyogamy, the nuclei fuse and form a diploid zygote. Meiosis then generates haploid spores.

30.2 Major Groups of Fungi

- The main phyla of fungi are the Chytridiomycota (which have motile spores), Zygomycota (zygospore-forming fungi), Glomeromycota, Ascomycota (sac fungi), and Basidiomycota (club fungi) (Figure 30.4). The phyla traditionally have been distinguished mainly by the structures of sexual reproduction. When a sexual phase cannot be detected or is absent from the life cycle, the specimen is assigned to an informal grouping, the conidial fungi.
- Chytrids usually are microscopic. They are the only fungi that produce motile, flagellated spores. Many are parasites (Figure 30.5).
- Zygomycetes have aseptate hyphae and are coenocytic, with many nuclei in a common cytoplasm. They sometimes reproduce sexually by way of hyphae that occur in 1 and 2 mating types; haploid nuclei in the hyphae function as gametes. Further development produces the zygospore, which may become dormant.
- When the zygospore of a zygomycete breaks dormancy, it produces a stalked sporangium containing haploid spores of each mating type, which are released (Figures 30.6 and 30.7).
- Glomeromycetes form a distinct type of endomycorrhizae in association with plant roots. They reproduce asexually, by way of spores that form at the tips of hyphae.
- Most ascomycetes are multicellular (Figure 30.9). In asexual reproduction, chains of haploid asexual spores called conidia elongate or pinch off from the tips of conidiophores (modified aerial hyphae; Figure 30.10).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- In sexual reproduction of ascomycetes, haploid sexual spores called ascospores arise in saclike cells called asci. In the most complex species, reproductive bodies called ascocarps bear or contain the asci. Ascospores can give rise to a new haploid mycelium (Figures 30.8 and 30.11).
- Most basidiomycete species reproduce only sexually. Club-shaped basidia develop on a basidiocarp and bear sexual spores on their surface. When dispersed, these basidiospores may germinate and give rise to a haploid mycelium (Figure 30.13).
- Microsporidia are single-celled sporelike parasites of arthropods, fish, and humans (Figure 30.14).

Animation: Rhizopus

Animation: How a Fungus Makes a Living

30.3 Fungal Associations

- Many ascomycetes and a few basidiomycetes enter into symbioses with cyanobacteria or green algae to produce the communal life form called a lichen, which has a tough, pliable body called a thallus. The algal cells supply the lichen's carbohydrates, most of which are absorbed by the fungus.
- In some lichens a section of the thallus may detach and grow into a new individual. In others, specialized regions of the thallus give rise asexually to reproductive soredia that include both algal and hyphal cells (Figure 30.15).
- In the symbiosis called a mycorrhiza, fungal hyphae make mineral ions and sometimes water available to the roots of a plant partner. The fungus in turn absorbs carbohydrates, amino acids, and possibly other growth-enhancing substances from the plant (Figures 30.16–30.18).
- In endomycorrhizae, the fungal hyphae (usually of a glomeromycete) penetrate the cells of the root. With ectomycorrhizae, hyphae form a netlike structure that surrounds the cortical cells of young roots but hyphae do not enter root cells; the usual fungal partner is a basidiomycete.

UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following statements does *not* reflect current understanding of phylogenetic relationships and features among fungi?
   a. Lineages leading to fungi diverged from those leading to plants about 1 billion years ago.
   b. Chytrids are probably a paraphyletic grouping and may most closely resemble the earliest fungi.
   c. There are four broadly accepted fungal phyla, the Zygomycota, Glomeromycota, Ascomycota, and Basidiomycota.
   d. As fungal lineages diversified, each evolved distinctive reproductive adaptations.
   e. Conidial fungi do not belong to a recognized fungal phylum.
2. Which of the following events is/are a necessary part of a typical asexual cycle in fungal reproduction?
   a. formation of a dikaryon
   b. hyphae developing into a mycelium
   c. formation of a diploid zygote
   d. plasmogamy, which occurs when hyphae fuse at their tips
   e. production and release of large numbers of spores
3. A trait common to all fungi is:
   a. reproduction via spores.
   b. parasitism.
   c. septate hyphae.
   d. a dikaryotic phase inside a zygospore.
   e. plasmogamy after an antheridium and ascogonium come into contact.
4. The chief characteristic used to classify fungi into the major fungal phyla is:
   a. nutritional dependence on nonliving organic matter.
   b. recycling of nutrients in terrestrial ecosystems.
   c. adaptations for obtaining water.
   d. features of reproduction.
   e. cell wall metabolism.
5. At lunch George ate a mushroom, some truffles, a little Camembert cheese, and a bit of moldy bread. Which of the following groups was *not* represented in the meal?
   a. Basidiomycota
   b. Ascomycota
   c. conidial fungi
   d. chytrids
   e. Zygomycota
6. Which of the following fungal reproductive structures are diploid?
   a. basidiocarps
   b. ascospores
   c. conidia
   d. gametangia
   e. zygospores
7. A mushroom is:
   a. the food-absorbing region of an ascomycete.
   b. the food-absorbing region of a basidiomycete.
   c. a reproductive structure formed only by basidiomycetes.
   d. a specialized form of mycelium not constructed of hyphae.
   e. a collection of saclike cells called asci.
8. A zygomycete is characterized by:
   a. usually, aseptate hyphae.
   b. mostly sexual reproduction.
   c. absence of + and − mating types.
   d. the tendency to form mycorrhizal associations with plant roots.
   e. a life cycle in which karyogamy does not occur.
9. Which of the following statements apply/applies to lichens?
   a. It is a fungus that breaks down rock to provide nutrients for an alga.
   b. It colonizes bare rocks and slowly degrades them to small particles.
   c. It spends part of the life cycle as a mycobiont and part as a fungus.
   d. It is an association between a basidiomycete and an ascomycete.
   e. It is an association between a photobiont and a fungus.
10. In a college greenhouse, a new employee observes fuzzy mycorrhizae in the roots of all the plants. Destroying no part of the plants, she carefully removes the mycorrhizae. The most immediate result of this "cleaning" is that the plants cannot:
    a. carry out photosynthesis.
    b. absorb water through their roots.
    c. transport water up their stems.
    d. extract as much nitrogen from soil.
    e. store carbohydrates in their roots.

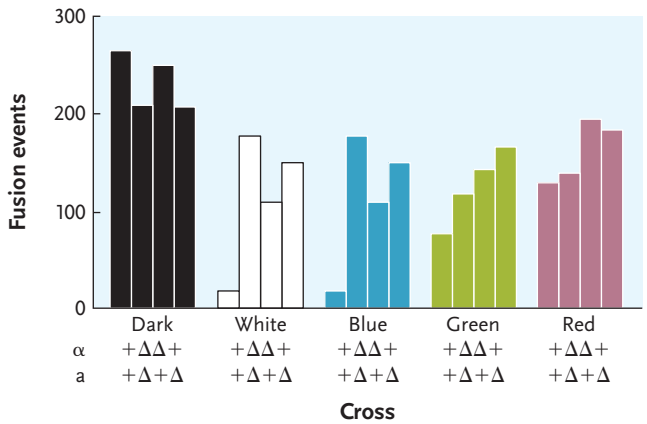
Discuss the Concepts

1. A mycologist wants to classify a specimen that appears to be a new species of fungus. To begin the classification process, what kinds of information on body structures and/or functions must the researcher obtain in order to assign the fungus to one of the major fungal groups?
2. In a natural setting—a pile of horse manure in a field, for example—the sequence in which various fungi appear illustrates ecological succession, which is the replacement of one species by another in a community (see Chapter 52). The first fungi to appear are the most efficient opportunists, for they can form and disperse spores most rapidly. In what order would you expect representatives from each division of fungi to appear on the manure pile? Why?
3. As the text noted, conifers, orchids, and some other types of plants cannot grow properly if their roots do not form associations with fungi, which provide the plant with minerals such as phosphate and in return receive carbohydrates and other nutrients synthesized by the plant. In some instances, however, the plant receives proportionately more nutrients than the fungus does. Even so, biologists still consider this to be a mycorrhizal association. Explain why you agree or disagree.
4. Humans are fundamentally diploid organisms. Explain how this state of affairs compares with the fungal life cycle, then compare the two general life cycles in light of the two groups' overall reproductive strategies.

Design an Experiment

Experiments on the orange bread mold *Neurospora crassa,* an ascomycete, were pivotal in elucidating the concept that each gene encodes a single enzyme. As *N. crassa* ascospores arise through meiosis and then mitosis in an ascus, each ascospore occupies a particular position in the final string of eight spores the ascus contains:



© Cengage Learning 2014

This quirk of ascospore development was extremely useful to early geneticists, because it vastly simplified the task of figuring out which alleles ended up in particular ascospores following meiosis. Recalling genetics topics discussed in Chapter 11, why was the analysis easier?

Interpret the Data

The fungus *Cryptococcus neoformans,* a basidiomycete yeast, is a dangerous pathogen in humans who have a weakened immune system, such as HIV/AIDS patients. The disease it causes, cryptococcosis, produces severe symptoms ranging from a pneumonia-like illness to encephalitis. *C. neoformans* thrives in dark places such as soil, dung, and caves, and light inhibits its sexual reproduction by preventing the development of a dikaryon stage. The recent sequencing of its genome has spurred efforts to identify genes that control this inhibition. Alexander Idnurm and Joseph Heitman of Duke University Medical Center performed a series of experiments using wild-type and mutant *C. neoformans* specimens. As described in Section 30.2, a dikaryon develops when haploid hyphae of two mating types fuse, forming the $n + n$ structure. In the wild *C. neoformans* has two mating types, denoted α and **a.** In both, the normal gene BWC encodes the light-based inhibition response; there is no inhibition in strains having the mutant *bwc1.* In one series of experiments, Idnurm and Heitman tested how efficiently fusion events occurred in crosses between matings of wild-type parental hyphae (denoted +) and mutant hyphae (denoted by Δ) that were exposed to different light wavelengths. Colored bars in the **Figure** indicate the color (wavelength) of the light stimulus; black denotes darkness, and red denotes dim light at the red/far-red end of the visible spectrum. Green and blue represent wavelengths toward the other end of the visible spectrum. To interpret this graph, you must read the mating combinations vertically.

A. Idnurm and J. Heitman. 2005. Light controls growth and development via a conserved pathway in the fungal kingdom. *PLoS Biology* 3:e95.

1. In the dark, did matings in which both partners were either wild-type or mutant forms produce a different response to the varying light stimuli than crosses of a wild-type and a mutant?
2. Within the other categories of light stimuli, how did the makeup of the different mating pairs correlate with the response?

Source: A. Idnurm and J. Heitman. 2005. Light controls growth and development via a conserved pathway in the fungal kingdom. *PLoS Biology* 3:e95.

Apply Evolutionary Thinking

The hypothesis that fungi are more closely related to animals than to plants is supported by studies of fungus genomes. For instance, scientists have documented striking similarities in the structure of many fungal and human genes—similarities that may be especially important in medicine. One mycologist, John Taylor of the University of California, Berkeley, suggests that a close biochemical relationship between fungi and animals may explain why fungal infections are typically so resistant to treatment, and why it has proven rather difficult to develop drugs that kill fungi without damaging their human or other animal hosts. Dozens of fungal genomes have been sequenced, including those of several medically important species. If you are a researcher working to develop new antifungal drugs, how could you make use of this growing genetic understanding? Using Internet resources, can you find examples of antifungal drugs that exploit biochemical differences between animals and fungi?

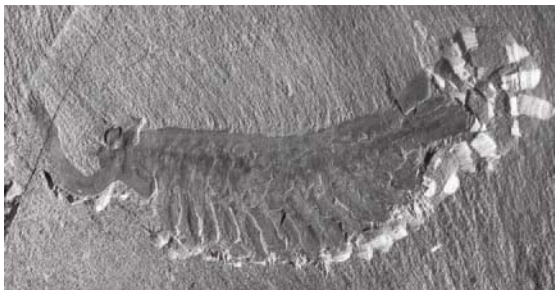
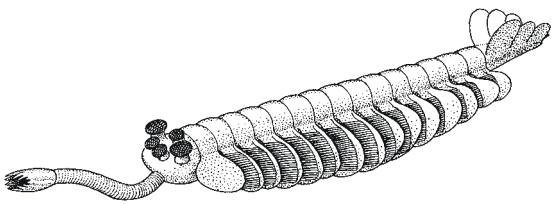
Animal Phylogeny, Acoelomates, and Protostomes



Why it matters . . . In 1909, a lucky fossil hunter named Charles Walcott tripped over a rock on a mountain path in British Columbia, Canada. Under the force of his hammer, the rock split apart, revealing the discovery of a lifetime. As Walcott and other workers examined rocks at this locality, they soon found fossils of more than 120 species of previously unknown animals from the Cambrian period. These creatures had lived on the muddy sediments of a shallow ocean basin; about 530 million years ago, an underwater avalanche buried them in a rain of silt that was eventually compacted into finely stratified shale. Over millions of years, the shale was uplifted by tectonic activity and incorporated into the mountains of western Canada. It is now known as the Burgess Shale formation.

Some animals in the Burgess Shale were truly bizarre **(Figure 31.1).** For example, *Opabinia* was about as long as a tube of lipstick; it had five eyes on its head and a grasping organ that it may have used to capture prey. No living animals even remotely resemble *Opabinia*. The smaller *Hallucigenia* sported seven pairs of large spines on one side and seven pairs of soft organs on the other. Recent research suggests that *Hallucigenia* may belong in the phylum Onychophora, described in Section 31.7. Nevertheless, most species of the Burgess Shale left no descendants that are still alive today. Thus, this remarkable assemblage of fossils provides a glimpse of some evolutionary novelties that—whether through the action of natural selection or just plain bad luck—were ultimately unsuccessful.



Other animal lineages have shown much greater longevity. Zoologists have described nearly 2 million living species in the kingdom **Animalia.** The familiar **vertebrates,** animals with a back-

© Cengage Learning 2014

bone, encompass only a small fraction (about 47,000) of that total. The overwhelming majority of animals fall within the descriptive grouping of **invertebrates,** animals without a backbone.

The remarkable evolutionary diversification of animals resulted from their ability to consume other organisms as food and, for most groups, their ability to move from one place to another. Today, animals are important consumers in nearly every environment on Earth. Their diversification has been accompanied by the evolution of specialized tissues and organ systems as well as complex behaviors.

In this chapter, we introduce the general characteristics of animals and a phylogenetic hypothesis about their evolutionary history and classification. We also survey some of the major invertebrate phyla; a *phylum* is an ancient monophyletic lineage with a distinctive body plan. In Chapter 32 we examine the deuterostome clade, which includes the vertebrates and their nearest invertebrate relatives.

31.1 What Is an Animal?

Biologists recognize the Kingdom Animalia as a monophyletic group that is easily distinguished from the other kingdoms.

All Animals Share Certain Structural and Behavioral Characteristics

Animals are eukaryotic, multicellular organisms. Their cells lack cell walls, a trait that differentiates them from plants and fungi. Because the individual cells of most animals are similar in size, very large animals like elephants have many more cells than small ones like fleas. In large animals, most cells are far from the body surface, but specialized tissues and organ systems deliver nutrients and oxygen to them and carry wastes away.

All animals are **heterotrophs:** they eat other organisms to acquire energy and nutrients. Food is ingested (eaten), then digested (broken down), and its breakdown products are absorbed by specialized tissues. Animals use oxygen to metabolize the food they eat through the biochemical pathways of aerobic respiration, and most store excess energy as glycogen, oil, or fat.

All animals are **motile**—able to move from place to place—at some time in their lives. They travel through the environment to find food or shelter and to interact with other animals. Most familiar animals are motile as adults. However, in some species, such as mussels and barnacles, only the larval stages are motile; they eventually settle down as **sessile** (unable to move from one place to another) adults. The advantages of motility have fostered the evolution of locomotor structures, including fins, legs, and wings that are powered by muscles, which are specialized contractile tissues that move individual body parts. Most animals also have sensory and nervous systems that allow them to receive, process, and respond to information about the environment through which they are traveling.

Animals reproduce either asexually or sexually; in some groups they switch from one mode to the other. Sexually reproducing species produce short-lived, haploid **gametes** (eggs and sperm), which fuse to form diploid **zygotes** (fertilized eggs). Animal life cycles generally include a period of development during which mitosis transforms the zygote into a multicelled **embryo;** an embryo develops into a reproductively immature juvenile or a free-living **larva,** which becomes a reproductively mature adult. Larvae often differ markedly from adults and may occupy different habitats and consume different foods.

Animals Probably Arose from a Colonial Choanoflagellate Ancestor

An overwhelming body of morphological and molecular evidence indicates that all animal phyla had a common ancestor. For example, all animals share similarities in their cell-to-cell junctions and the molecules in their extracellular matrices (see Section 5.5) as well as similarities in the structure of their ribosomal RNAs.

In 1874 the German embryologist Ernst Haeckel proposed that the common ancestor of all animals was a colonial, hollow, ball-shaped organism with unspecialized flagellated cells. According to his hypothesis, its cells became specialized for particular functions, and a developmental reorganization produced a double-layered, sac-within-a-sac body plan **(Figure 31.2).** As you will see in Chapter 50, the embryonic development of many living animals roughly parallels this hypothetical evolutionary transformation.

Most biologists now agree that the common ancestor of all animals was probably a colonial, flagellated protist that lived at least 700 million years ago, during the Precambrian era. It may have resembled the minute, sessile choanoflagellates that live in both freshwater and marine habitats today (see Figure 27.21). Several lines of morphological and molecular evidence support this hypothesis. First, living choanoflagellates are almost identical in structure to the "collar cells" of sponges, the most ancient living clade of animals; similar cells have also been discovered in other distantly related animal phyla, such as flatworms and echinoderms. Second, DNA sequence data suggest that choanoflagellates and animals are sister clades. Moreover, researchers have identified several genes for cell adhesion and cell signaling that are present in both choanoflagellates and animals.

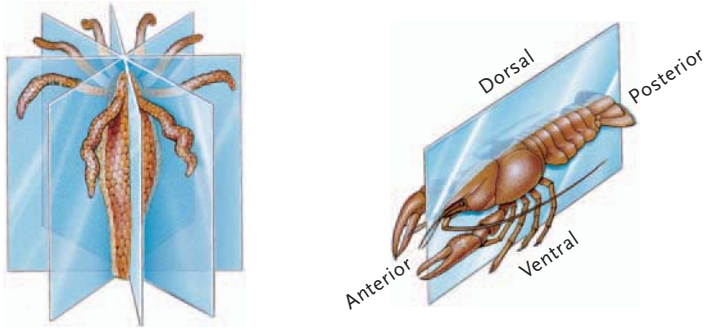
31.2 Key Innovations in Animal Evolution

Once established, the animal lineage diversified quickly into an amazing array of body plans. Before the development of molecular sequencing techniques, biologists identified several key morphological innovations that they used to develop hypotheses about the evolutionary relationships of the major animal groups.

Tissues and Tissue Layers Appeared Early in Animal Evolution

The presence or absence of **tissues**—groups of cells that share a common structure and function—divides the animal kingdom into two distinct branches. One branch, the sponges, or Parazoa (*para* = alongside, *zoon* = animal), lacks tissues. All other animals, collectively grouped in the Eumetazoa (*eu* = true, *meta* = in common with), have tissues.

During the development of eumetazoans, embryonic tissues form as either two or three concentric **primary cell layers** (described further in Chapter 50). The innermost layer, the **endoderm** (generally illustrated in yellow), eventually develops into the lining of the gut (digestive system) and, in some animals, respiratory organs. The outermost layer, the **ectoderm** (generally illustrated in blue), forms the external body surface and nervous system. Between the two, the **mesoderm** (generally illustrated in red) forms the muscles of the body wall and most other structures between the gut and the body surface. Some animals have a **diploblastic** body plan that includes only two layers, endoderm and ectoderm. However, most animals are **triploblastic,** having all three primary cell layers.



Most Animals Exhibit Either Radial or Bilateral Symmetry

The most obvious feature of an animal's body plan is its shape **(Figure 31.3).** Most animals are **symmetrical;** in other words, their bodies can be divided by a plane into mirror-image halves. The rare exceptions include most sponges, which have irregular shapes and are therefore **asymmetrical.**

Eumetazoans exhibit one of two body symmetry patterns. The Radiata includes two phyla, Cnidaria (hydras, jellyfishes, and sea anemones) and Ctenophora (comb jellies), which have **radial symmetry.** Their body parts are arranged regularly around a central axis, like the spokes on a wheel. Thus, any cut down the long axis of a hydra divides it into matching halves. Radially symmetrical animals are usually sessile or slow moving and receive sensory input from all directions.

All other eumetazoan phyla fall within the Bilateria, animals that have **bilateral symmetry.** In other words, only a cut along the midline from head to tail divides them

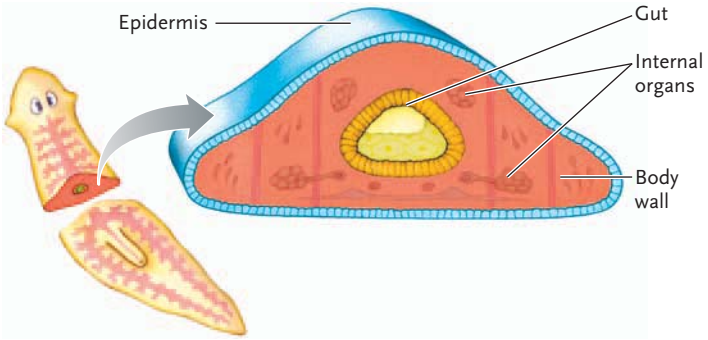
Radial symmetry Bilateral symmetry

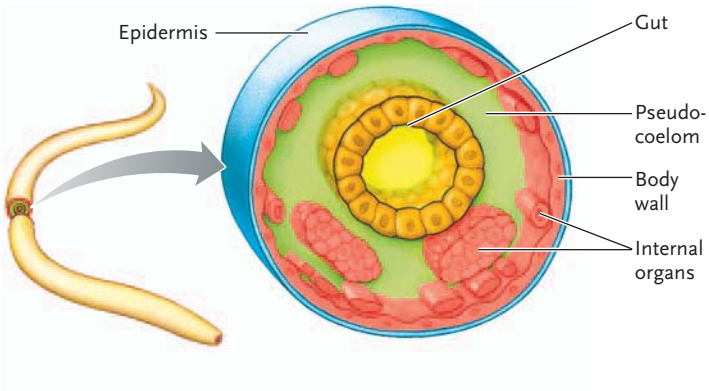
FIGURE 31.3 **Patterns of body symmetry.** Most animals have either radial or bilateral symmetry.

© Cengage Learning 2014



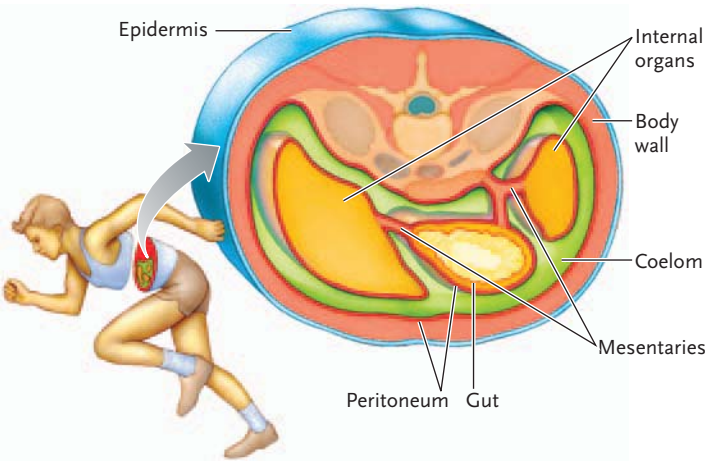
into left and right sides that are essentially mirror images of each other. Bilaterally symmetrical animals also have **anterior** ("front") and **posterior** ("back") ends as well as **dorsal** ("upper") and **ventral** ("lower") surfaces. As these animals move through the environment, the anterior end encounters food, shelter, or enemies first. Thus, in bilaterally symmetrical animals, natural selection also favored **cephalization,** the development of an anterior head where sensory organs and nervous-system tissue are concentrated.

Many Animals Have Body Cavities That Surround Their Internal Organs



The body plans of many bilaterally symmetrical animals include a body cavity that separates the gut from the muscles of the body wall **(Figure 31.4). Acoelomate** animals (*a* = not, *koilomat* = hollow), such as flatworms (phylum Platyhelminthes), lack such a cavity; a continuous mass of tissue, derived largely from mesoderm, packs the region between the gut and the body wall (see Figure 31.4A). **Pseudocoelomate** animals (*pseudo* = false), including the roundworms (phylum Nematoda) and wheel animals (phylum Rotifera), have a **pseudocoelom,** a fluid- or organ-filled space between the gut and the muscles of the body wall, that is partially lined by tissues derived from mesoderm (see Figure 31.4B). Internal organs lie within the pseudocoelom and are bathed by its fluid. **Coelomate** animals have a **coelom,** a fluid-filled body cavity, also between the gut and body wall, that is completely lined by the **peritoneum,** a thin tissue derived from mesoderm (see Figure 31.4C). Membranous extensions of the inner and outer layers of the peritoneum, the **mesenteries,** surround the internal organs and suspend them within the coelom.

Biologists describe the body plan of pseudocoelomate and coelomate animals as a "tube within a tube"; the digestive system forms the inner tube, the body wall forms the outer tube, and the body cavity lies between them. The body cavity separates internal organs from the body wall, allowing the organs to function independently of whole-body movements. The fluid within the cavity also protects delicate organs from mechanical damage. And, because the volume of the body cavity is fixed, the incompressible fluid within it serves as a **hydrostatic skeleton,** which provides support. In some animals muscle contractions can shift the fluid, changing the animals' shape and allowing them to move from place to place (see Section 43.2).



A. In acoelomate animals, no body cavity separates the gut and body wall.

B. In pseudocoelomate animals, the pseudocoelom forms between the gut (a derivative of endoderm) and the body wall (a derivative of mesoderm).

C. In coelomate animals, the coelom is completely lined by peritoneum (a derivative of mesoderm).

Developmental Patterns Mark a Major Divergence in Animal Ancestry

Embryological and molecular evidence suggests that bilaterally symmetrical animals are divided into two clades: the protostomes, which includes most phyla of invertebrates, and the deuterostomes, which includes the vertebrates and their nearest invertebrate relatives. Protostomes and deuterostomes differ in several developmental characteristics **(Figure 31.5).**

Shortly after fertilization, an egg undergoes a series of mitotic divisions called **cleavage** (see Section 50.2). The first two cell divisions divide a zygote as you might slice an apple, cutting it into four wedges from top to bottom. In many protostomes, subsequent cell divisions produce daughter cells that lie *between* the pairs of cells below them; this pattern is called **spiral cleavage** (left side of Figure 31.5A). In deuterostomes, by contrast, subsequent cell divisions produce a mass of cells that are stacked directly above and below one another; this pattern is called **radial cleavage** (right side of Figure 31.5A).

Protostomes and deuterostomes often differ in the timing of important developmental events. During cleavage, certain genes are activated at specific times, determining a cell's developmental path and ultimate fate. Many protostomes undergo **determinate cleavage:** each cell's developmental path is determined as the cell is produced. Thus, one cell isolated from a two- or four-cell protostome embryo cannot develop into a functional embryo or larva. By contrast, many deuterostomes have **indeterminate cleavage:** the developmental fates of cells are determined later. A cell isolated from a four-cell deuterostome embryo will develop into a functional, although smaller than usual, embryo or larva. Like other deuterostomes, humans have indeterminate cleavage; thus, the two cells produced by the first cleavage division sometime separate and develop into identical twins.

As development proceeds after cleavage, some cells migrate to the inside of the embryo through the **blastopore,** an opening on its surface. These cells become the endoderm, which forms the **archenteron,** the developing gut (see Figure 31.5B). Later in development, a second opening at the opposite end of the embryo transforms the pouchlike archenteron into a digestive tube (see Figure 31.5C).

In protostomes (*protos* = first, *stoma* = mouth), the blastopore develops into the mouth, and the second opening forms the anus. In some deuterostomes (*deuteros* = second), the blastopore develops into the anus, and the second opening becomes the mouth.

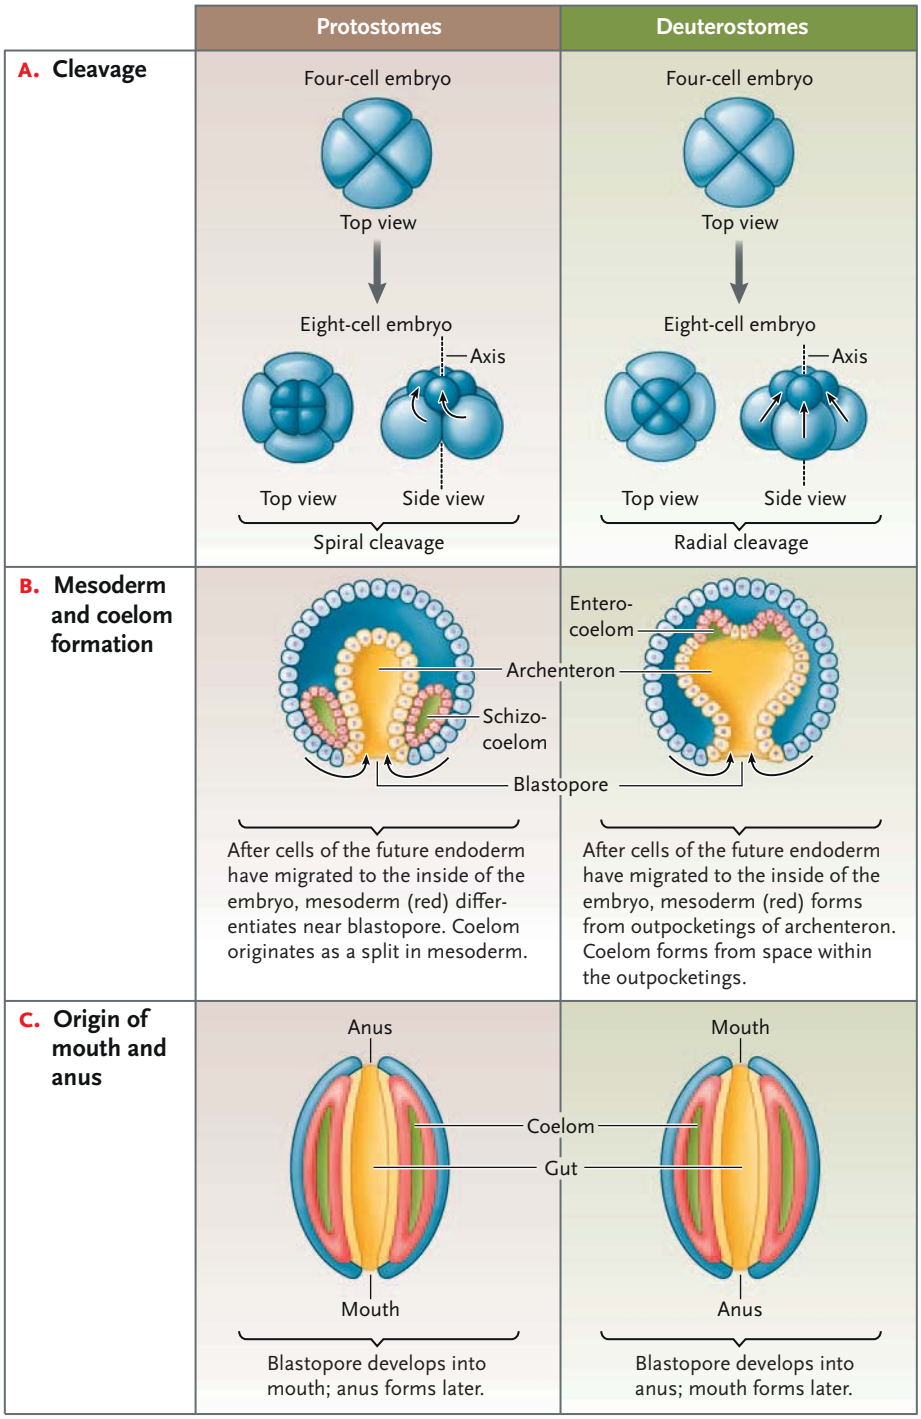

FIGURE 31.5 Protostomes and deuterostomes. The two clades of coelomate animals differ in **(A)** cleavage patterns, **(B)** the origin of mesoderm and the coelom, and **(C)** the origin of the mouth and the anus.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Protostomes and deuterostomes also differ in the origin of mesoderm and the coelom (see Figure 31.5B). In most protostomes, mesoderm originates from a few specific cells near the blastopore. As the mesoderm grows and develops, it splits into inner and outer layers. The space between the layers is called a **schizocoelom** (*skhizein* = split). In deuterostomes, mesoderm often forms from outpocketings of the archenteron. The space pinched off from the archenteron by the outpocketing mesoderm is called an **enterocoelom** (*enteron* = intestine).

Several other characteristics also differ in adult protostomes and deuterostomes. For example, the central nervous system of protostomes is generally positioned on the ventral side of the body, and their brain surrounds the anterior section of the digestive tract. By contrast, the nervous system and brain of deuterostomes lie on the dorsal side of the body.

Segmentation Divides the Bodies of Some Animals into Repeating Units

Some phyla in both the protostome and deuterostome clades exhibit varying degrees of **segmentation,** the production of body parts as repeating units. During development, segmentation first arises in the mesoderm, the middle tissue layer that produces most of the body's bulk. In humans and other vertebrates, we see evidence of segmentation in the vertebral column ("backbone"), ribs, and associated muscles, such as the "six-pack abs" that sit-ups accentuate. In some animals, segmentation is also reflected in structures derived from the endoderm and ectoderm. For example, the ringlike pattern on an earthworm or a caterpillar matches the underlying segments.

Segmentation provides several advantages. In markedly segmented animals, such as earthworms and their relatives, each segment may include a complete set of important organs, including respiratory surfaces and parts of the nervous, circulatory, and excretory systems. Thus, a segmented animal may survive damage to the organs in one segment, because those in other segments perform the same functions. Segmentation also improves control over movement, especially in wormlike animals. Each segment has its own set of muscles, which can act independently of those in other segments. Thus, an earthworm can move its anterior end to the left while it swings its posterior end to the right. Similarly, the segmented backbone and body wall musculature of vertebrates allow greater flexibility of movement than would unsegmented structures.

31.3 An Overview of Animal Phylogeny and Classification

For many years, biologists used the morphological innovations and embryological patterns described earlier to trace the phylogenetic history of animals. These efforts were sometimes hampered by the difficulty of identifying homologous structures in different phyla and by morphological data that led to contradictory interpretations. More recently, researchers have used molecular sequence data to reanalyze animal relationships. Although biologists now recognize nearly 40 animal phyla, in this chapter we focus on 14 phyla, many of which include substantial numbers of species, that represent a diversity of body forms and ways of life **(Table 31.1).** In Chapter 32, we consider three deuterostomes phyla, which represent a distinct clade within the animals.

TABLE 31.1 Classification of the Animal Phyla Described in This Book

Major Clade	Phylum	Known Diversity (Approximate Number of Living Species Described)
Parazoa	Porifera	9,000
Eumetazoa		
Radiata	Cnidaria	9,000
Bilateria	Ctenophora	150
Protostomia		
Lophotrochozoa	Ectoprocta	5,000
	Brachiopoda	300
	Phoronida	20
	Platyheminthes	20,000
	Rotifera	1,800
	Nemertea	1,100
	Mollusca	100,000
	Annelida	16,000
Ecdysozoa	Nematoda	25,000
	Onychophora	100
	Arthropoda	1,150,000
Deuterostomia	Echinodermata	6,000
	Hemichordata	100
	Chordata	65,000

Molecular Phylogenetics Has Refined Our Understanding of Animal Phylogeny

Molecular phylogenies of animal relationships have usually been based on the nucleotide sequences in small subunit ribosomal RNA and mitochondrial DNA (see Chapter 15). Recent analyses of *Hox* gene sequences provide similar results. (*Hox* genes are described in Sections 16.4 and 23.6.) Because these studies have focused on only a few dozen genes, rather than entire genomes, the phylogenetic tree based on molecular sequence data **(Figure 31.6)** will likely be refined as researchers accumulate additional data on other parts of the genome.

The phylogenetic tree in Figure 31.6 includes all of the major clades that biologists had defined using morphological innovations and embryological characters. For example, molecular data confirm the distinctions between the Parazoa and the Eumetazoa and between the Radiata and the Bilateria. They also confirm the separation of the deuterostome phyla from all others within the Bilateria.

However, the molecular phylogeny groups many other phyla—including the acoelomate animals, pseudocoelomate animals, protostomes, and a few others—into one taxon, the

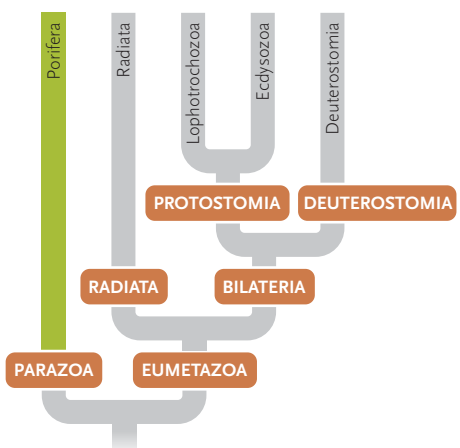
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Protostomia. This group is, in turn, subdivided into two major clades, the Lophotrochozoa and the Ecdysozoa, which were not previously recognized. The name Lophotrochozoa (*lophos* = crest, *trochos* = wheel) refers to both the lophophore, a feeding structure found in three phyla (illustrated in Figure 31.15), and the trochophore, a type of larva found in annelids and mollusks (illustrated in Figure 31.23). The name Ecdysozoa (*ekdysis* = a stripping or casting off) refers to the cuticle or external skeleton that species within this group secrete and periodically molt (or "cast off") when they experience a growth spurt or begin a different stage of the life cycle (illustrated in Figure 31.34); the molting process is called **ecdysis.**

The Molecular Phylogeny Reveals Some Surprising Patterns in the Evolution of Key Morphological Innovations

Phylogenetic trees contain explicit hypotheses about evolutionary change, and the molecular phylogeny has forced biologists to reevaluate the evolution of several important morphological innovations. For example, traditional phylogenies based on morphology and embryology usually inferred that the absence of a body cavity, the acoelomate condition, was an ancestral state and that the presence of a body cavity, the pseudocoelomate or coelomate condition, was derived. But the molecular tree provides a very different view. Because most protostome phyla have a schizocoelom, the molecular phylogeny suggests that this trait evolved in the common ancestor of all protostomes. If that hypothesis is correct, then the acoelomate condition of flatworms (phylum Platyhelminthes) represents the evolutionary *loss* of the schizocoelom, *not* an ancestral condition. Similarly, the molecular phylogeny hypothesizes that the pseudocoelom evolved independently in rotifers (Lophotrochozoa, phylum Rotifera) and in roundworms (Ecdysozoa, phylum Nematoda). Thus, according to the molecular phylogeny, the pseudocoelomate condition of these organisms is the product of convergent evolution.



Phylogenies based on embryological and morphological characters also suggested that the segmented body plan of several protostome phyla was inherited from a segmented common ancestor and that segmentation arose independently in chordates by convergent evolution. The molecular phylogeny in Figure 31.6, by contrast, suggests that segmentation evolved independently in *three* clades—segmented worms (Lophotrochozoa, phylum Annelida), arthropods and velvet worms (Ecdysozoa, phyla Arthropoda and Onychophora), and chordates (Deuterostomia, phylum Chordata)—rather than in just two. However, in 2010, Nicolas Dray of the Centre Génétique Moléculaire du CNRS, and colleagues from other European research institutes, demonstrated that the development of segmentation in one species of annelid requires expression of the Hedgehog signaling pathway, which also plays a prominent role in the development of segmentation in arthropods. Thus, the genetic basis of segmentation may have originated in the common ancestor of annelids and arthropods. If this conclusion is correct, it is consistent with the traditional view that segmentation was present in the common ancestor of all protostomes. Further research should confirm or refute this hypothesis and reveal more about the evolutionary history of this key morphological innovation in animals.

Despite these surprising findings about morphological evolution, biologists embrace the hypothesis provided by molecular sequence studies. In the future, new data will undoubtedly foster fascinating discussions, heated disputes, and revisions of the phylogeny. As a student, you may be understandably frustrated by the lack of consensus among experts and an ever-changing phylogeny for animals. But these disagreements highlight the uniqueness of science as a way of knowing the natural world through the process of collecting evidence and rigorously challenging accepted hypotheses. The phylogenetic tree based on molecular sequence data is truly revolutionary, and the dust has yet to settle on the disagreements that new analyses provoke.

31.4 Animals without Tissues: Parazoa

Parazoa is the basal animal clade that is the sister group to Eumetazoa. It includes just one group of animals, the sponges, phylum Porifera (meaning "pore bearers").

Sponges lack true tissues: during development, their cells do not form the complex layers typical of other phyla. Mature sponges are sessile, and their shapes are less fixed than those of other animals, because mobile cells allow them to change shape in response to local conditions **(Figure 31.7).** Sponges have been abundant since the Cambrian, especially in shallow coastal areas. Most of the 9,000 living species are marine and range in size from 1 cm to 2 m at maturity.

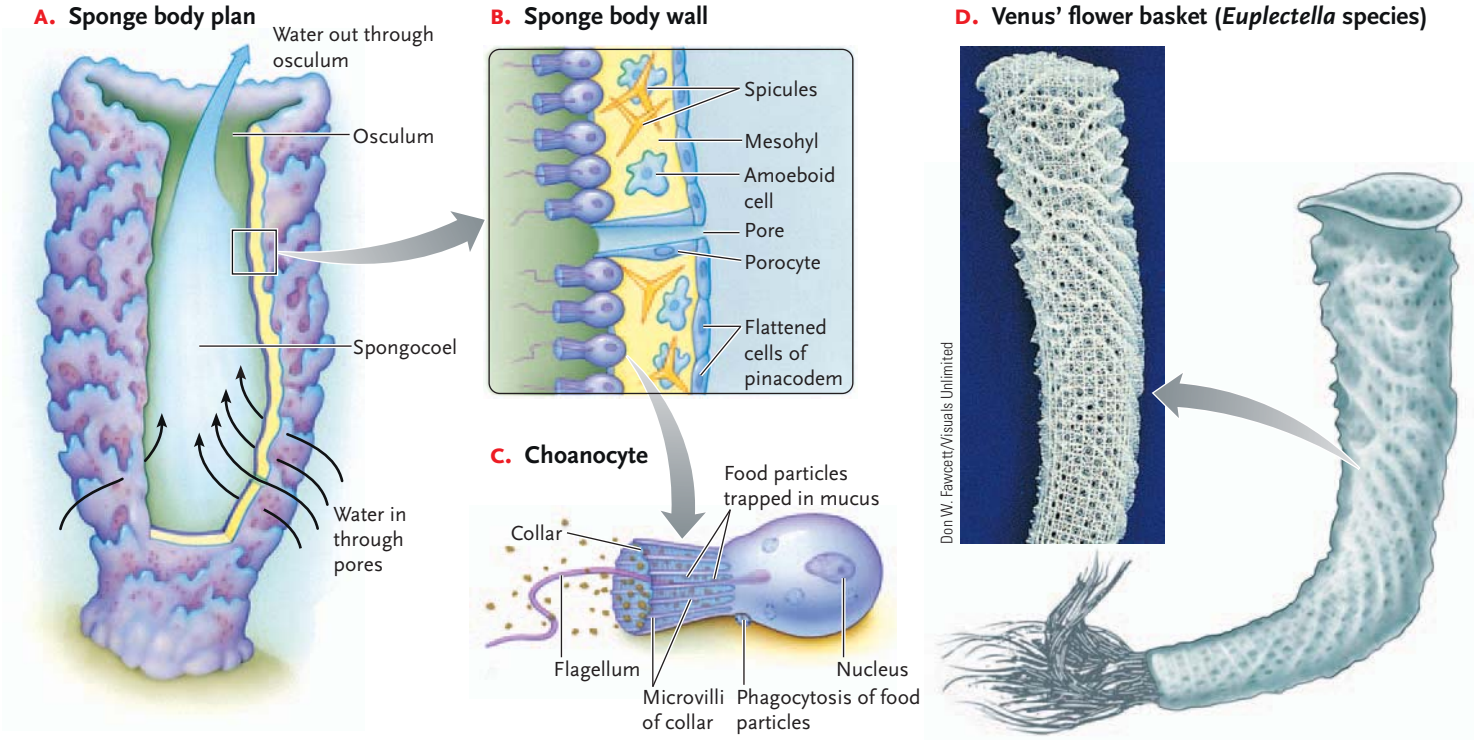
©WATKINS, BRUCE/Animals Animals

FIGURE 31.7 Asymmetry in sponges. Sponges, such as this *Haliclona* species from the Philippines, often have an asymmetrical shape.



Sponges have simple body plans **(Figure 31.8).** Flattened cells form an outer layer, the **pinacoderm.** The inner surface of saclike sponges is lined by collar cells, **choanocytes,** each equipped with a beating flagellum and a surrounding "collar" of modified microvilli. Amoeboid cells wander through the gelatinous **mesohyl** between the two layers; they secrete a supporting skeleton of a fibrous protein and *spicules,* small needlelike structures of calcium carbonate or silica (see Figure 31.8D). The natural sponges that are used for bathing and washing are the fibrous remains of the bath sponge (*Spongia* species), which lacks mineralized parts.

A sponge's body is an elaborate system for filtering food particles from the surrounding water. Water flows through pores in the pinacoderm into a central chamber, the **spongocoel,** and then out of the sponge through one or more openings called **oscula** (singular, *osculum*). The beating flagellae of the choanocytes maintain a constant flow of water, and contractile pore cells *(porocytes)* adjust the flow rate. Even a small sponge may filter as much as 20 liters of water per day. The choanocytes capture suspended particles and microorganisms from the water and pass this food to mobile amoeboid cells, which carry nutrients to cells of the pinacoderm.

Most sponges are **hermaphroditic:** individuals produce both sperm and eggs. Sperm are released into the spongocoel and then out into the environment through oscula; eggs remain in the mesohyl, where sperm from other sponges, drawn in with water, fertilize them. Zygotes develop into flagellated larvae that are expelled to fend for themselves. Surviving larvae attach to substrates and undergo **metamorphosis** (a reorganization of form) into sessile adults. Some sponges also reproduce asexually; small fragments break off an adult and grow into new sponges. Many species also produce *gemmules,* clusters of cells with a resistant covering that allows them to survive unfavorable conditions; gemmules germinate into new sponges when conditions improve.

FIGURE 31.8 The body plan of sponges. Most sponges have **(A)** simple body plans and **(B)** relatively few cell types. **(C)** Beating flagella on the choanocytes create a flow of water through incurrent pores, into the spongocoel, and out through the osculum. **(D)** Venus' flower basket, a marine sponge, has spicules of silica fused into a rigid framework.

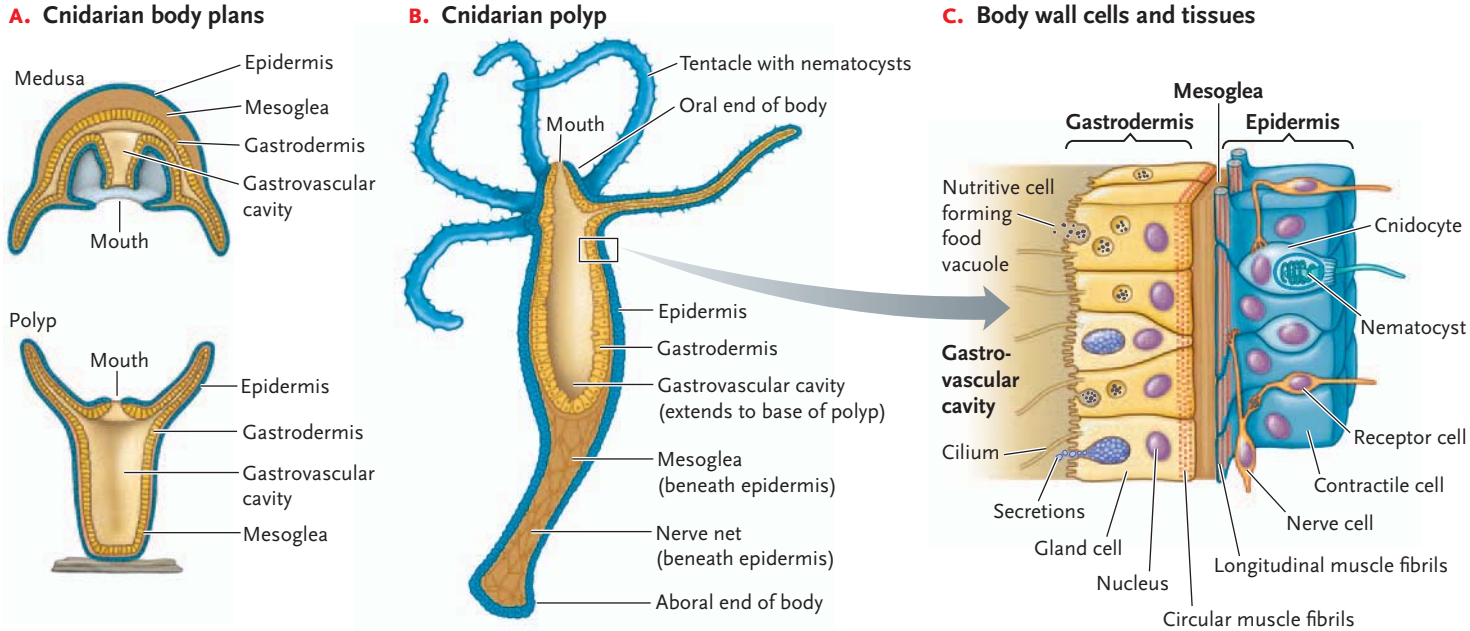
31.5 Eumetazoans with Radial Symmetry

Unlike sponges, eumetazoans have true tissues, which develop from distinct layers in the embryo. Working together, the cells of a tissue perform complex functions beyond the capacity of individual cells. For example, nerve tissue transmits information rapidly through an animal's body, and epithelial tissue forms barriers that surround the body and line body cavities. In this section, we describe eumetazoans with radial symmetry. This symmetry enables them to sense stimuli from all directions, an effective adaptation for life in open water.

Two phyla of soft-bodied organisms, Cnidaria and Ctenophora, have radial symmetry and tissues, but they lack organ systems and a coelom. Species in both phyla possess a **gastrovascular cavity** that serves both digestive and circulatory functions. It has a single opening, the mouth. Gas exchange and excretion occur by diffusion because no cell is far from a body surface.

The radiate phyla have a diploblastic body plan with only two tissue layers, the inner *gastrodermis* (an endoderm derivative) and the outer *epidermis* (an ectoderm derivative). Most species also possess a gelatinous *mesoglea* (*mesos* = middle, *glia* = glue) between the two layers. The mesoglea contains widely dispersed amoeboid cells.



Cnidarians Use Nematocysts to Stun or Kill Prey

Nearly all of the 9,000 species in the phylum Cnidaria (*knide* = stinging nettle, a plant with irritating surface hairs) live in the sea **(Figure 31.9).** Their body plan is organized around a saclike gastrovascular cavity; the mouth is ringed with tentacles, which push food into it. Cnidarians may be vase-shaped, upward-pointing **polyps** or bell-shaped, downward-pointing **medusae** (see Figure 31.9A). Most polyps attach to a substrate at the *aboral* (opposite the mouth) end; medusae are unattached and float.

Cnidarians are the simplest animals that exhibit a division of labor among specialized tissues (see Figure 31.9B and C). (Sponges have specialized cells, but no tissues.) The gastrodermis includes gland cells and phagocytic nutritive cells, both of which contain circular muscle fibrils. Gland cells secrete enzymes into the gastrovascular cavity for the extracellular digestion of food, which is then engulfed by nutritive cells and exposed to intracellular digestion. The epidermis includes nerve

FIGURE 31.9 The cnidarian body plan. (A) Cnidarians exist as either polyps or medusae. **(B)** The body of both forms is organized around a gastrovascular cavity, which extends all the way to the aboral end of the animal. **(C)** The two tissue layers in the body wall, the gastrodermis and the epidermis, include a variety of cell types.

cells, sensory cells, contractile cells, and cells specialized for prey capture. A layer of acellular mesoglea separates the gastrodermis from the epidermis.

Cnidarians prey on crustaceans, fishes, and other animals. The epidermis includes unique cells, **cnidocytes,** each armed with a stinging **nematocyst (Figure 31.10).** The nematocyst is an encapsulated, coiled thread that is fired at prey or predators, sometimes releasing a toxin through its tip. Discharge of nematocysts may be triggered by touch, vibrations, or chemical stimuli. The toxin can paralyze small prey by disrupting nerve cell membranes. The painful stings of some jellyfishes and corals result from the discharge of nematocysts.

Cnidarians engage in directed movements by contracting muscle fibrils in cells of the epidermis and gastrodermis. In medusae, the mesogleal jelly serves as a deformable skeleton against which contractile cells act. Rapid contractions narrow the bell, forcing out jets of water that propel the animal. Polyps use their water-filled gastrovascular cavity as a hydrostatic skeleton. When some cells contract, fluid within the chamber is shunted about, changing the body's shape and moving it in a particular direction.

The **nerve net,** which threads through both tissue layers, coordinates responses to stimuli, but it has no central control organ or brain. Impulses initiated by sensory cells are transmitted in all directions from the site of stimulation.

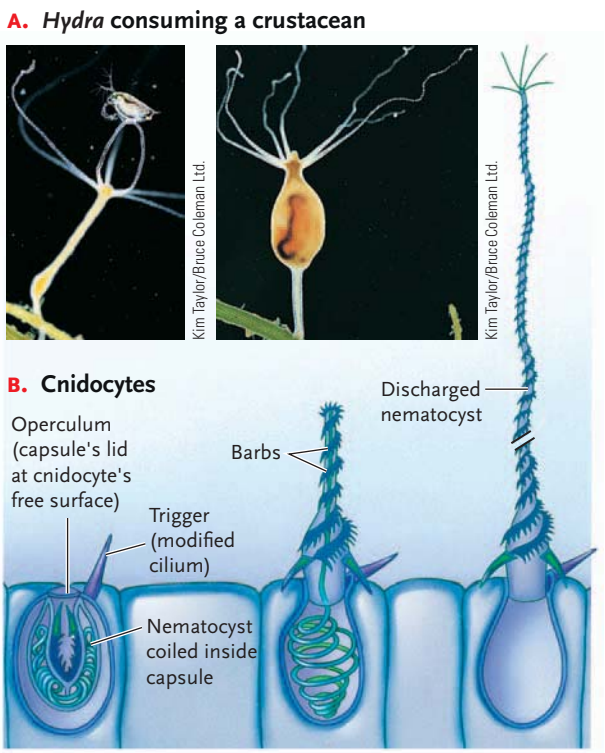

FIGURE 31.10 **Predation by cnidarians. (A)** A polyp of a freshwater *Hydra* captures a small crustacean with its tentacles and swallows it whole. **(B)** Cnidocytes, special cells on the tentacles, encapsulate nematocysts, which are discharged at prey.

Many cnidarians exist in only the polyp or the medusa form, but some have a life cycle that alternates between them **(Figure 31.11).** In the latter type, the polyp often produces new individuals asexually from buds that break free of the parent (see Figure 49.2). The medusa is often the sexual stage, producing sperm and eggs, which are released into the water. The four clades of Cnidaria differ in the form that predominates in the life cycle.

HYDROZOA Most of the species in the Hydrozoa have both polyp and medusa stages in their life cycles (see Figure 31.11). The polyps form sessile colonies that develop asexually from one individual. A colony can include thousands of polyps, which may be specialized for feeding, defense, or reproduction. They share food through their connected gastrovascular cavities.

Unlike most hydrozoans, freshwater species of *Hydra* (see Figure 31.10A) live as solitary polyps that attach temporarily to rocks, twigs, and leaves. Under favorable conditions, hydras reproduce by budding. Under adverse conditions, they produce eggs and sperm; the zygotes, which are encapsulated in a protective coating, develop and grow when conditions improve.

SCYPHOZOA The medusa stage predominates in the Scyphozoa **(Figure 31.12A),** which are commonly known as jellies or jellyfishes. Scyphozoans range from 2 cm to more than 2 m in diameter. Nerve cells near the margin of the bell control their tentacles and coordinate the rhythmic activity of contractile cells, which move the animal. Specialized sensory cells are clustered at the edge of the bell: **statocysts** sense gravity and **ocelli** are sensitive to light. Scyphozoan medusae are either male or female; they release gametes into the water where fertilization takes place.

CUBOZOA The 20 known species of box jellyfish, the Cubozoa **(Figure 31.12B),** exist primarily as cube-shaped medusas only a few centimeters tall; the largest species grows to 25 cm in height. Nematocyst-rich tentacles grow in clusters from the four corners of the boxlike medusa, and groups of light receptors and image-forming eyes occur on the four sides of the bell. Unlike the true jellyfish, cubozoans are active swimmers. They feed on small fishes and invertebrates, immobilizing their prey with one of the deadliest toxins produced by animals. Cubozoans live in tropical and subtropical coastal waters, where they sometimes pose a serious threat to swimmers.

ANTHOZOA The Anthozoa includes corals and sea anemones **(Figure 31.13).** Anthozoans exist only as polyps, and often reproduce by budding or fission; most also reproduce sexually. Corals are always sessile and usually colonial. Most species build calcium carbonate skeletons, which sometimes grow together to form gigantic underwater reefs. The energy needs of many corals are partly fulfilled by the photosynthetic activity of symbiotic protists that live within the corals' cells. For this reason, corals

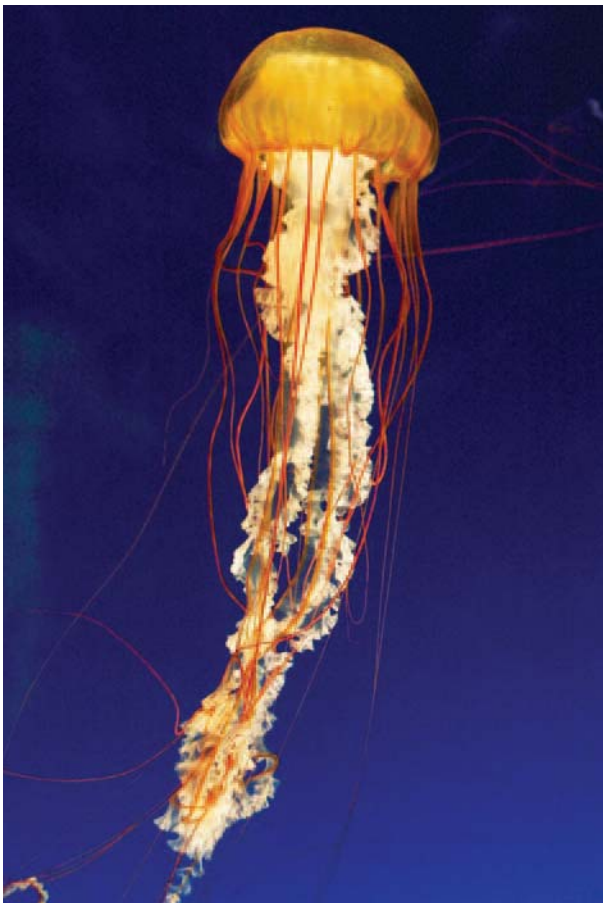
are restricted to shallow water where sunlight can penetrate. Sea anemones are soft-bodied, solitary polyps, ranging from 1 cm to 10 cm in diameter. Many species occupy shallow coastal waters. Most species are essentially sessile, but some move by crawling slowly or by using their gastrovascular cavity as a hydrostatic skeleton.

Ctenophores Use Tentacles to Feed on Microscopic Plankton

Like the cnidarians, the 150 species of comb jellies in the phylum Ctenophora (*ktenos* = comb, *-phoros* = bearing) have radial symmetry, mesoglea, and feeding tentacles. However, they differ from cnidarians in significant ways: they lack nematocysts; they expel some waste through anal pores opposite the mouth; and certain tissues appear to be of mesodermal origin. These transparent, and often luminescent, animals range in size from a few millimeters to a few meters **(Figure 31.14).** They live primarily in coastal regions of the oceans.



Ctenophores move by beating cilia arranged on eight longitudinal plates that resemble combs. They are the largest animals to use cilia for locomotion, but they are feeble swimmers. Nerve cells connected to the cilia coordinate the animals' movements, and a gravity-sensing statocyst helps them maintain an upright position. They capture microscopic plankton with their two tentacles, which have specialized cells that discharge sticky filaments; food particles are ingested as the food-laden tentacles are drawn across the mouth. Ctenophores are hermaphroditic, producing gametes in cells that line the gastrovascular cavity. Eggs and sperm are expelled through the mouth or from special pores, and fertilization occurs in the open water.

STUDY BREAK 31.5

1. How do cnidarians capture, consume, and digest their prey?
2. Which group of cnidarians has only a polyp stage in its life cycle?
3. What do ctenophores eat, and how do they collect their food?

FIGURE 31.15 Lophophorate animals. Although the lophophorate animals differ markedly in appearance, they all use a lophophore—the feathery structures in the photos—to acquire food.

31.6 Lophotrochozoan Protostomes

The remaining organisms described in this chapter fall within the group Bilateria: they have bilateral symmetry and triploblastic development (that is, their embryological development includes three tissue layers). Bilaterians also have organ systems, structures that include two or more tissue types that perform specific functions. Most of them also possess a coelom or pseudocoelom. With bilateral symmetry and sensory organs concentrated at the anterior end of the body, most bilaterians engage in highly directed, often rapid movements in pursuit of food, mates, or to escape danger. And their complex organ systems accomplish tasks more efficiently than simple tissues. For example, animals that have a tubular digestive system surrounded by a space (the coelom or pseudocoelom) use muscular contractions of the digestive system to move ingested food past specialized epithelia that break it down and absorb the breakdown products.

Molecular analyses group eight of the most diverse phyla into the monophyletic Lophotrochozoa, one of the two main protostome clades (see Figure 31.6).

The Lophophorate Phyla Share a Distinctive Feeding Structure

Three small groups of aquatic, coelomate animals—the phyla Ectoprocta, Brachiopoda, and Phoronida—possess a **lophophore,** a circular or U-shaped fold with one or two rows of hollow, ciliated tentacles surrounding the mouth **(Figure 31.15).** Molecular sequence data as well as the lophophore suggest that these phyla share a common ancestry.

The lophophore, which looks like a crown of tentacles at the anterior end of the animal, serves as a site for gas exchange and waste elimination as well as for food capture. Most lophophorates are sessile suspension-feeders as adults: movement of cilia on the tentacles brings food-laden water toward the lophophore, the tentacles capture small organisms and debris, and the cilia transport them to the mouth. The lophophorates have a complete digestive system, which is U-shaped in most species, with the anus lying outside the ring of tentacles.

PHYLUM ECTOPROCTA The Ectoprocta (sometimes called Bryozoa) are tiny colonial animals that mainly occupy marine habitats (see Figure 31.15A). They secrete a hard covering over their soft bodies and feed by extending the lophophore through a hole. Each colony, which may include more than a million individuals, is produced asexually by a single animal. Ectoprocta colonies are permanently attached to solid substrates, where they form encrusting mats, bushy upright growths, or jellylike blobs. Nearly 5,000 living species are known.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

PHYLUM BRACHIOPODA The Brachiopoda, or lampshells, have two calcified shells that develop on the animal's dorsal and ventral sides (see Figure 31.15B). Most species attach to substrates with a stalk that protrudes through one of the shells. The lophophore is held within the two shells, and the animal feeds by opening its shell and drawing water over its tentacles. Although only 300 species of brachiopods live today, more than 30,000 extinct species are known from the fossil record, mostly from Paleozoic seas.

PHYLUM PHORONIDA The 20 or so species of phoronid worms vary in length from a few millimeters to 25 cm (see Figure 31.15C). They usually build tubes in soft ocean sediments or on hard substrates, and feed by protruding the lophophore from the top of the tube. The animal can withdraw into the tube when disturbed. Phoronida reproduce both sexually and by budding.

Flatworms Have Digestive, Excretory, Nervous, and Reproductive Systems, but Lack a Coelom

The 20,000 flatworm species in the phylum Platyhelminthes (*platys* = flat; *helminth-* = worm) live in aquatic and moist terrestrial habitats. Like cnidarians, flatworms can swim or float in water, but they are also able to crawl over surfaces. They range from less than 1 mm to more than 60 cm in length, but most are just a few millimeters thick. Free-living species eat live prey or decomposing carcasses, whereas parasitic species consume the tissues of living hosts.

Like the radiate phyla, flatworms are acoelomate, but they have a complex structural organization that reflects their triploblastic construction **(Figure 31.16).** Endoderm derivatives line the gastrovascular (digestive) cavity with cells specialized for the chemical breakdown and absorption of ingested food. Mesoderm, the middle tissue layer, produces muscles and reproductive organs. Ectoderm produces a ciliated epidermis, the nervous system, and the *flame cell system.* Flame cells function in osmoregulation; they regulate the concentrations of salts and water within body fluids, allowing free-living flatworms to live in freshwater habitats. Flatworms do not have circulatory or respiratory systems, but, because all cells of their dorsoventrally (top-to-bottom) flattened bodies are near an interior or exterior surface, diffusion supplies them with nutrients and oxygen.

The flatworm nervous system includes two or more longitudinal ventral nerve cords interconnected by numerous smaller nerve fibers, like rungs on a ladder. An anterior **ganglion,** a concentration of nervous system tissue that serves as a primitive brain, integrates their behavior. Most free-living species have *ocelli,* or eye spots, that distinguish light from dark and tiny chemoreceptor organs that sense chemical cues.

The phylum Platyhelminthes includes four clades, defined largely by their anatomical adaptations to free-living or parasitic habits.

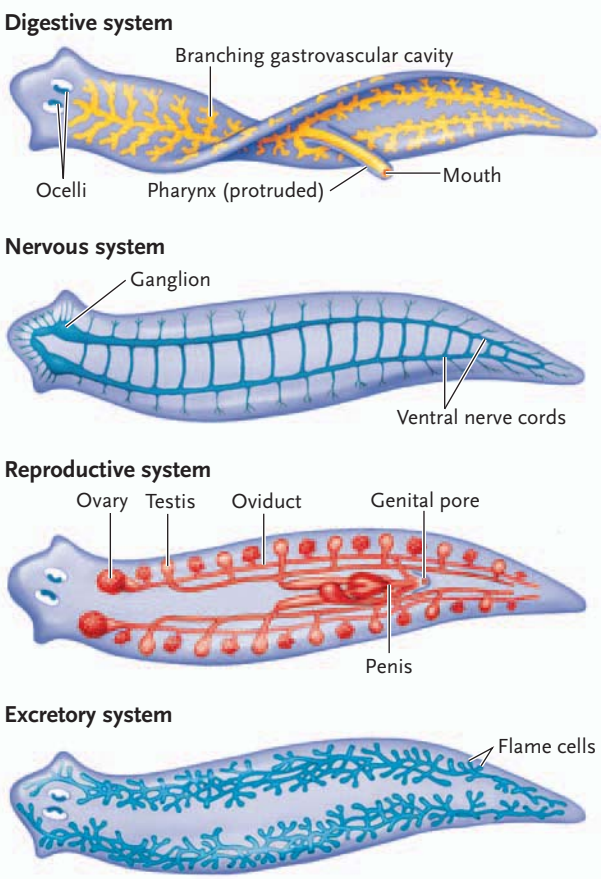

FIGURE 31.16 Flatworms. Species in the phylum Platyhelminthes, exemplified by a freshwater planarian, have well-developed digestive, excretory, nervous, and reproductive systems. Because flatworms are acoelomate, their organ systems are embedded in a solid mass of tissue between the gut and the epidermis.

TURBELLARIA Most free-living flatworms (Turbellaria) live in the sea **(Figure 31.17),** but the familiar planarians and a few others live in fresh water or on land. Turbellarians swim by undulating the body wall musculature, or they crawl across surfaces by using muscles and cilia to glide on mucous trails produced by the ventral epidermis.

E. R. Degginger/Photo Researchers, Inc.

FIGURE 31.18 Trematoda. The hermaphroditic Chinese liver fluke *(Opisthorchis sinensis)* uses a well-developed reproductive system to produce thousands of eggs.

The gastrovascular cavity in free-living flatworms is similar to that of cnidarians. Food is ingested and wastes are eliminated through a single opening, the mouth, located on the ventral surface. Food passes from the mouth to a muscular **pharynx** that leads to the digestive cavity (see Figure 31.16). Chemicals secreted into the saclike cavity digest the food into particles; then cells throughout the gastrovascular surface engulf the particles and subject them to intracellular digestion. In some species, the digestive cavity is highly branched, increasing the surface area for digestion and absorption.

Nearly all turbellarians are hermaphroditic, with complex reproductive systems (see Figure 31.16). When they mate, each partner functions simultaneously as a male and a female. Many free-living species also reproduce asexually by separating their anterior half from their posterior half. Both halves subsequently regenerate the missing parts.

TREMATODA AND MONOGENOIDEA Flukes (Trematoda and Monogenoidea) are parasites that obtain nutrients from tissues of a living host **(Figure 31.18).** Most adult trematodes are **endoparasites,** living in the gut, liver, lungs, bladder, or blood vessels of vertebrates. Monogenes are **ectoparasites,** attaching to the gills or skin of aquatic vertebrates. Flukes are structurally specialized for a parasitic existence. They use suckers or hooks to attach to hosts, and a tough outer covering protects them from chemical attack. They produce numerous eggs that can readily infect new hosts. Monogene flukes usually have simple life cycles with a single host species. Trematodes, by contrast, have complex life cycles and multiple hosts. Humans suffer potentially fatal infections by many flukes, as discussed in *Focus on Applied Research.*

CESTODA Tapeworms (Cestoda) develop, grow, and reproduce within the intestines of vertebrates **(Figure 31.19).** Through evolution, they have lost their mouths and digestive systems and absorb nutrients directly through their body wall. Tapeworms have a specialized structure, the *scolex,* with hooks and suckers that attach to the host's intestine; like the flukes, they also have a protective covering resistant to digestive enzymes.

Most of a tapeworm's body, which may be up to 20 m long, consists of a series of segmental structures, *proglottids,* that contain little more than male and female reproductive systems. New proglottids are generated near the scolex; older proglottids, each carrying as many as 80,000 fertilized eggs, break off from the tapeworm's posterior end, and leave the host's body in feces. Tapeworms are important parasites on humans, pets, and livestock.

Rotifers Are Tiny Pseudocoelomates with a Jawlike Feeding Apparatus

Most of the 1,800 species in the phylum Rotifera (*rota* = wheel; *ferre* = to carry) live in fresh water **(Figure 31.20).** All are microscopic—about the size of a ciliate protist—but they have well-developed digestive, reproductive, excretory, and nervous systems as well as a pseudocoelom. In some habitats, rotifers make up a large part of the zooplankton, tiny animals that float in open water.

Rotifers use coordinated movements of cilia, arranged in a wheel-like *corona* around the head, to propel themselves in the environment. Cilia also bring food-laden water to their mouths. Ingested microorganisms are conveyed to the *mastax,* a toothed grinding organ, and then passed to the stomach and intestine. Rotifers have a **complete digestive tract:** food enters through the mouth, and undigested waste is voided through the anus.

The life history patterns of some rotifers are adapted to the ever-changing environments in small bodies of water. During

Breaking the Life Cycles of Parasitic Worms

Many parasitic flatworms (phylum Platyhelminthes) and roundworms (phylum Nematoda) call the human body home, frequently causing disfiguring or life-threatening infections. The effort to control or eliminate these infections often begins when parasitologists or public health researchers study the worms' life cycles and ecology. This approach is successful because the worms often have more than one host: humans may be the *primary host,* harboring the sexually mature stage of the parasites' life cycles, but other animals serve as *intermediate hosts* to the larval stages. If researchers can learn the details of a parasite's life cycle, they can identify ways to cut it short before the parasite infects a human host.

Roughly 200 million people, most of them in sub-Saharan Africa or in Asia, suffer from *schistosomiasis,* a disease caused by several species of flatworms called blood flukes (Trematoda). Japanese blood flukes *(Schistosoma japonicum)* mature and mate in blood vessels of the human intestine **(Figure 1).** Sharp spines on their eggs rupture the blood vessels, releasing the eggs into the lumen of the gut, from which they are passed with feces. When the infected human waste enters standing fresh water, the eggs hatch into ciliated larvae, which burrow into some aquatic snail species. The larvae feed on the snail's tissues and reproduce asexually. Their offspring leave the snail and, when they contact human skin, bore inward to a blood vessel. They eventually reach the intestine, where they complete their complex life cycle and produce fertilized eggs.

Infected humans mount an immune response against flukes, but it is always a losing battle. Severe infections cause coughs, rashes, pain, and eventually diarrhea, anemia, and permanent damage to the intestines, liver, spleen, bladder, and kidneys. Death often results. Drug therapy can reduce the symptoms and limit the spread of these parasites, but schistosomiasis is most common in countries where people have limited access to medical care. Research has demonstrated that the disease can be controlled by proper sanitation and the elimination of the snails that serve as intermediate hosts.

The nematodes called filarial worms (*Wuchereria* and *Brugia*) cause another debilitating infection. These large roundworms (up to 10 cm long) live in the human lymphatic system, where they obstruct the normal flow of lymphatic fluid to the bloodstream. Female worms release first-stage larvae, which are acquired by mosquitoes, the intermediate host, when they feed on human blood. The larvae develop into second-stage larvae in mosquitoes, and when a mosquito bites another human, it may transmit those larvae to a new host. If victims experience severe filarial worm infection, their lymphatic vessels can be so obstructed that surrounding tissues swell grotesquely, a condition known as *elephantiasis* **(Figure 2).** Public health programs that reduce or eliminate mosquito populations lower the incidence of this disease.

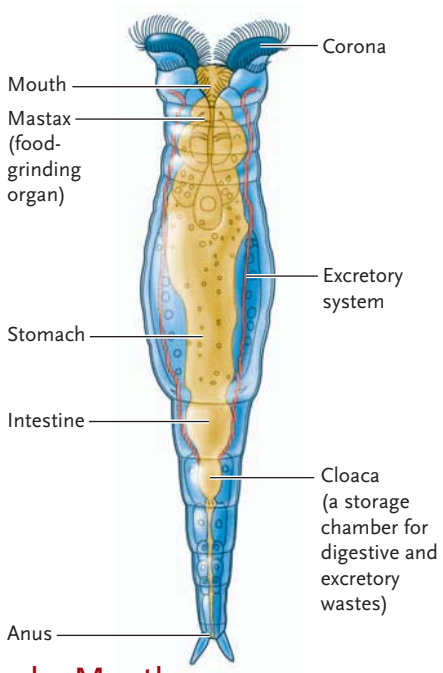
most months, rotifer populations include only females that reproduce by **parthenogenesis,** a form of asexual reproduction in which unfertilized eggs develop into diploid females (see Section 49.1). When environmental conditions deteriorate, females produce eggs that develop into haploid males. The males fertilize haploid eggs to produce diploid female zygotes. The fertilized eggs have durable shells and food reserves to survive drying or freezing.



Ribbon Worms Use a Proboscis to Capture Food

The 1,100 species of ribbon worms or proboscis worms (phylum Nemertea) vary from less than 1 cm to 30 m in length **(Figure 31.21).** Most species are marine, but a few occupy moist, terrestrial habitats. Although the often brightly colored ribbon worms superficially resemble free-living flatworms, their body

plans are more complex. First, they possess both a mouth and an anus; thus, they have a complete digestive tract. Second, nemerteans have a circulatory system in which fluid flows through **circulatory vessels** that carry nutrients and oxygen to tissues and remove wastes (see Section 44.1). Finally, they have a muscular, mucus-covered proboscis, a tube that can be everted (turned inside out) through the mouth or a separate pore to capture prey. The proboscis is housed within a chamber, the *rhynchocoel,* which is unique to this phylum.

Mollusks Have a Muscular Foot and a Mantle That Secretes a Shell or Aids in Locomotion

Most of the 100,000 species in the phylum Mollusca (*mollis* = soft)—including clams, snails, octopuses, and their relatives—are marine. However, many clams and snails occupy freshwater habitats, and some snails live on land. Mollusks vary in length from clams less than 1 mm to the giant squids, which can exceed 18 m.

In mollusks, the body is divided into three regions: the visceral mass, the foot, and the head **(Figure 31.22).** The **visceral mass** contains digestive, excretory, and reproductive systems and the heart. The muscular **foot** often provides the major means of locomotion. In more active groups, the **head** is well-defined and carries sensory organs and a brain. The mouth often includes a toothed **radula,** which scrapes food into small particles or drills through the shells of prey. Many mollusks are covered by a protective shell of calcium carbonate secreted by the **mantle,** which comprises one or two folds of the body wall that often enclose the visceral mass. The mantle also defines a space, the *mantle cavity.* In aquatic species, the mantle cavity houses the *gills,* delicate respiratory structures with enormous surface area. In most mollusks, cilia on the mantle and gills generate a steady flow of water into the mantle cavity.

The large size of mollusks requires a circulatory system to maintain cells that are far from the body surface. Most mollusks have an **open circulatory system** in which **hemolymph,** a bloodlike fluid, leaves the circulatory vessels and bathes tissues directly (see Figure 44.3A). Hemolymph pools in spaces called *sinuses,* and then drains into vessels that carry it back to the heart.

The sexes are usually separate, although many snails are hermaphroditic. Fertilization may be internal or external. The

zygotes of marine species often develop into free-swimming, ciliated *trochophore* larvae **(Figure 31.23),** typical of both this phylum and the phylum Annelida, which we describe next. In some mollusks, the trochophore develops into a second larval stage, called a *veliger,* before metamorphosing into an adult. Some snails as well as octopuses and squids have direct development: embryos develop into miniature replicas of the adults.

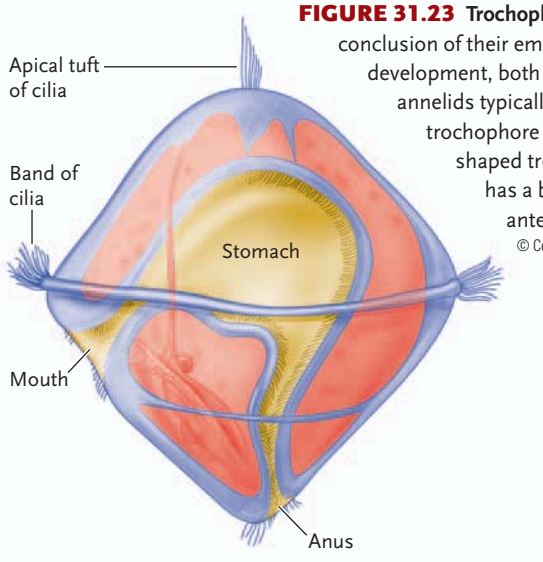

FIGURE 31.23 **Trochophore larva.** At the conclusion of their embryological development, both mollusks and annelids typically pass through a trochophore stage. The top-shaped trochophore larva has a band of cilia just anterior to its mouth.

© Cengage Learning 2014

Mollusca includes eight clades. Here we examine the four that are most commonly encountered.

POLYPLACOPHORA The chitons (Polyplacophora: *poly* = many; *plax* = flat surface) are sedentary mollusks that graze on algae along rocky marine coasts. The oval, bilaterally symmetrical body has a dorsal shell divided into eight plates that allow it to conform to irregularly shaped surfaces **(Figure 31.24).** When a chiton is disturbed or exposed to strong wave action, the muscles of its broad foot maintain a tenacious grip, and the mantle's edge functions like a suction cup to hold fast to the substrate.

GASTROPODA Snails and slugs (Gastropoda: *gaster* = belly; *podos* = foot) are the largest molluscan group, numbering 40,000 species **(Figure 31.25).** Aquatic species use gills to acquire oxygen, but in terrestrial species a modified mantle cavity functions as an air-breathing lung. Gastropods feed on algae, vascular plants, or animal prey. Some are scavengers, and a few are parasites.

The visceral mass of most snails is housed in a coiled or cone-shaped shell that is balanced above the rest of the body, much as you balance a backpack full of books (see Figure 31.25A and B). Most shelled snails undergo **torsion,** a curious realignment of body parts that is independent of shell coiling. Muscle contractions and differential growth twist the visceral mass and mantle 180° relative to the head–foot. This rearrangement moves the mantle cavity forward so that the head can be withdrawn into the shell in times of danger. It also brings the gills, anus, and excretory openings above the head—a potentially messy configuration, were it not for cilia that sweep away wastes.

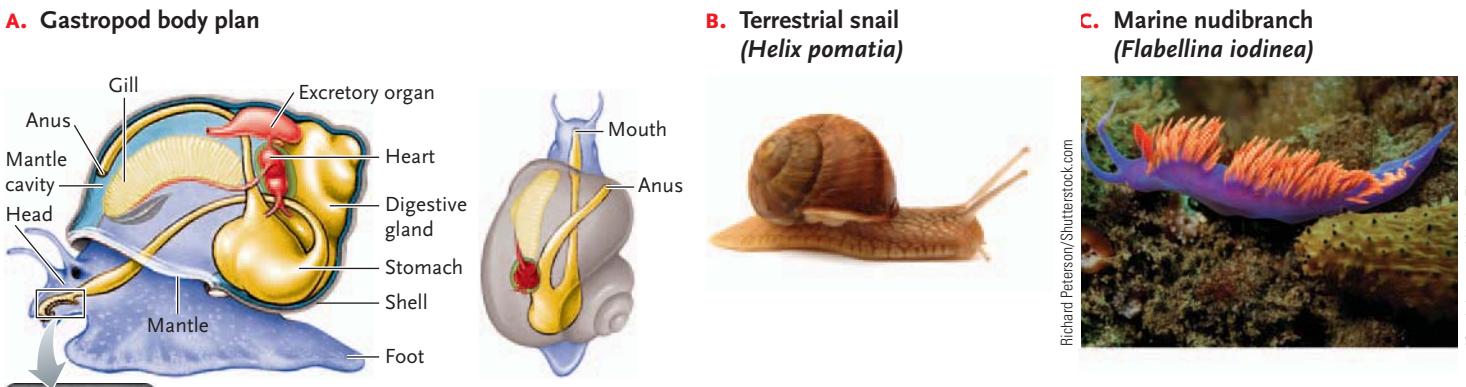

FIGURE 31.25 **Gastropoda. (A)** Most gastropods have a coiled shell that houses the visceral mass. A developmental process called torsion causes the digestive and excretory systems to eliminate wastes into the mantle cavity, near the animal's head. **(B)** The edible snail is a terrestrial gastropod. **(C)** Nudibranchs, like this Spanish shawl nudibranch, are shell-less marine snails.

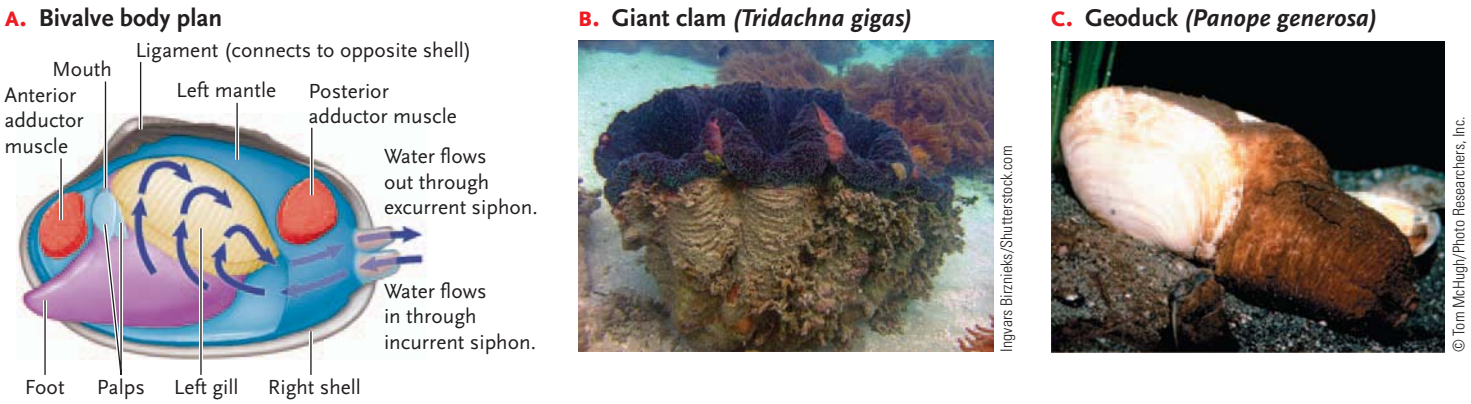
© Cengage Learning 2014

Some gastropods, including terrestrial slugs and colorful nudibranchs (sea slugs), are shell-less, a condition that leaves them vulnerable to predators (see Figure 31.25C). Some nudibranchs consume cnidarians and then transfer undischarged nematocysts to projections on their dorsal surface, where these "borrowed" stinging capsules provide protection.

The nervous and sensory systems of gastropods are well developed. Tentacles on the head include chemical and touch receptors; the eyes detect changes in light intensity but don't form images.

BIVALVIA The clams, scallops, oysters, and mussels (Bivalvia: *bi* = two; *valva* = folding door) are restricted to aquatic habitats. They are enclosed within a pair of shells, hinged together dorsally by an elastic ligament **(Figure 31.26).** Contraction of one or two **adductor muscles** closes the shell by pulling the two sides together; when the muscles relax, the elastic ligament opens the shell by pulling them apart (see Figure 31.26A). Although some bivalves are tiny, giant clams of the South Pacific can be more than 1 m across and weigh 225 kg (see Figure 31.26B).



Adult mussels and oysters are sessile and permanently attached to hard substrates, but many clams are mobile and use their muscular foot to burrow in sand or mud. Some bivalves, such as young scallops, swim by rhythmically clapping their valves ("shells") together, forcing a current of water out of the mantle cavity. The "scallops" that we eat are the scallops' well-developed adductor muscles.

Bivalves have a reduced head, and they lack a radula. Part of the mantle forms two tubes called *siphons* (see Figure 31.26C). Beating of cilia on the gills and mantle carries water into the mantle cavity through the incurrent siphon and out through the excurrent siphon. Incurrent water carries dissolved oxygen and food particles to the gills, where oxygen is absorbed. Mucus strands on the gills trap the food, which is then transported by cilia to *palps,* where final sorting takes place; edible tidbits are carried to the mouth. The excurrent water carries away metabolic wastes and feces.

Despite their sedentary existence, bivalves have moderately well-developed nervous systems; sensory organs that detect chemicals, touch, and light; and statocysts to sense their orientation. When they encounter pollutants, many bivalves stop pumping water and close their shells. When confronted by a predator, some burrow into sediments or swim away.

FIGURE 31.26 **Bivalvia. (A)** Bivalves are enclosed in a hinged two-part shell. Part of the mantle forms a pair of water-transporting siphons. **(B)** Giant clams in the South Pacific *(Tridachna gigas)* sometimes weigh hundreds of kilograms. **(C)** The geoduck is a clam with enormous muscular siphons.

© Cengage Learning 2014

CEPHALOPODA The octopuses, squids, and nautiluses (Cephalopoda: *kephale* = head) are active marine predators, including the fastest and most intelligent invertebrates **(Figure 31.27).** They vary in length from a few centimeters to 18 m. Giant squids, the largest invertebrates known, may be the source of "sea monster" stories.

The cephalopod body has a fused head and foot (see Figure 31.27D). The head comprises the mouth and eyes. The ancestral "foot" forms a set of arms and tentacles, equipped with suction pads, adhesive structures, or hooks. Cephalopods use these structures to capture prey and a pair of beaklike jaws to bite or crush it. Venomous secretions often speed the captive's death. Some species use their radula to drill through the shells of other mollusks.

Cephalopods have a highly modified shell. Octopuses have no remnant of a shell at all. In squids and cuttlefishes, it is reduced to a stiff internal support. Only the chambered nautilus and its relatives retain an external shell.

Squids are the most mobile cephalopods, moving rapidly by a kind of jet propulsion. When muscles in the mantle relax, water is drawn into the mantle cavity. When they contract, a jet of water is squeezed out through a funnel-shaped excurrent siphon. By manipulating the position of the mantle and siphon, the animal can control the rate and direction of its locomotion. When threatened, a squid can make a speedy escape. Many species simultaneously release a dark fluid, commonly called "ink," that obscures their direction of movement. Being highly active, cephalopods need lots of oxygen, and they alone among the mollusks have a **closed circulatory system:** hemolymph is confined within the walls of hearts and blood vessels, providing increased pressure to the vascular fluid. Moreover, accessory hearts speed the flow of hemolymph through the gills, enhancing the uptake of oxygen and the release of carbon dioxide.

Compared with other mollusks, cephalopods have large and complex brains. Giant nerve fibers connect the brain with the muscles of the mantle, enabling quick responses to food or danger. Their image-forming eyes are similar to those of vertebrates. Cephalopods are also highly intelligent. Octopuses, for example, learn to recognize objects with distinctive shapes or colors, and they can be trained to approach or avoid them.

Cephalopods have separate sexes and elaborate courtship rituals. Males store sperm within the mantle cavity and use a specialized tentacle to transfer packets of sperm into the female's mantle cavity, where fertilization occurs. Fertilized eggs, wrapped in a protective jelly, are attached to objects in the environment. The young hatch with an adult body form.

Annelids Exhibit a Serial Division of the Body Wall and Some Organ Systems

The 16,000 species of segmented worms (phylum Annelida: *anellus* = little ring) occupy marine, freshwater, and moist terrestrial habitats. Terrestrial annelids eat organic debris; aquatic species consume algae, microscopic organisms, detritus, or other animals. They range from a few millimeters to several meters in length.

The annelid body is highly segmented: the body wall muscles and some organs—including respiratory surfaces, parts of the nervous, circulatory, and excretory systems, and the coelom itself—are divided into similar repeating units **(Figure 31.28).** Body segments are separated by transverse partitions called **septa.** The digestive system and major blood vessels are not segmented and run the length of the animal.

The body wall muscles of annelids have both circular and longitudinal layers (see Figure 31.28). Alternate contractions of these muscle groups allow annelids to make directed movements, using the pressure of the fluid in the coelom as a hydrostatic skeleton. All annelids except leeches also have chitin-reinforced bristles, called **setae** (sometimes written *chaetae*), which protrude outward from the body wall. Setae anchor the worm against the substrate, providing traction.

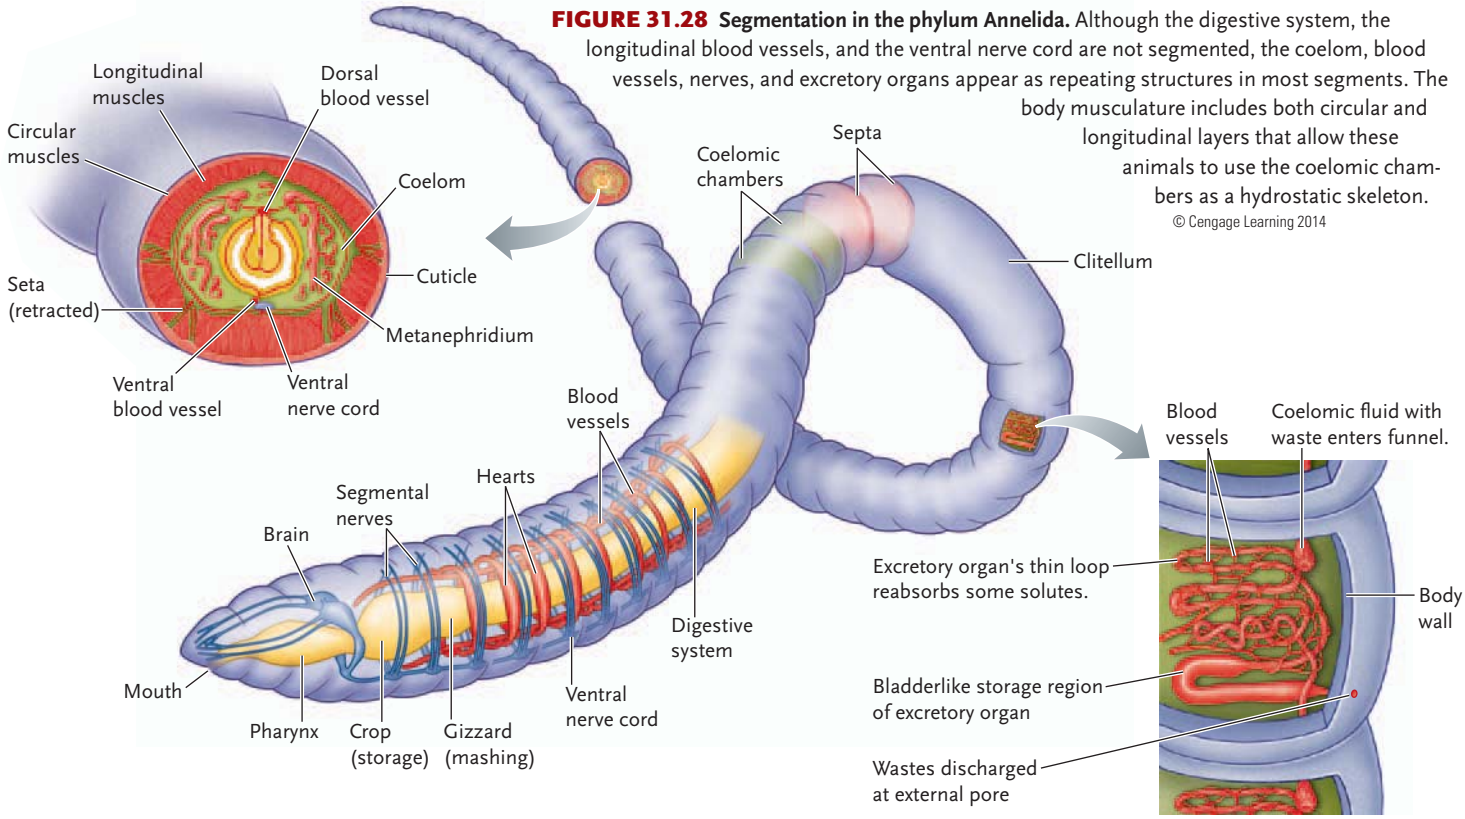

FIGURE 31.28 Segmentation in the phylum Annelida. Although the digestive system, the longitudinal blood vessels, and the ventral nerve cord are not segmented, the coelom, blood vessels, nerves, and excretory organs appear as repeating structures in most segments. The body musculature includes both circular and longitudinal layers that allow these animals to use the coelomic chambers as a hydrostatic skeleton.

© Cengage Learning 2014

Annelids have a complete digestive system and a closed circulatory system. However, they lack a discrete respiratory system; oxygen and carbon dioxide diffuse through the skin. The excretory system is composed of pairs of **metanephridia** that usually occur in all body segments posterior to the head. The nervous system is highly developed, with ganglia (local control centers) in every segment, a simple brain in the head, and sensory organs that detect chemicals, moisture, light, and touch.

Most freshwater and terrestrial annelids are hermaphroditic, and worms exchange sperm when they mate. Newly hatched worms have an adult morphology. Some terrestrial annelids also reproduce asexually by fragmenting and regenerating missing parts. Marine annelids usually have separate sexes, and release gametes into the sea for fertilization. The zygotes develop into trochophore larvae that add segments, gradually assuming an adult form.

Annelida includes three clades, each of which is largely restricted to one environment.

POLYCHAETA The bristle worms (Polychaeta: *chaite* = bristles or hair) are primarily marine **(Figure 31.29).** Many live under rocks or in tubes constructed from mucus, calcium carbonate secretions, grains of sand, or small shell fragments. Their setae project from well-developed **parapodia** (singular, *parapodium* = closely resembling a foot), fleshy lateral extensions of the body wall used for locomotion and gas exchange. In more mobile species, sense organs are concentrated on a well-developed head.

Crawling or swimming polychaetes are often predatory; they use sharp jaws in a protrusible muscular pharynx to grab small invertebrate prey. Other species graze on algae or scavenge organic matter. A few tube dwellers draw food-laden water into the tube by beating their parapodia; most others collect food by extending feathery, ciliated, mucus-coated tentacles.

OLIGOCHAETA Most oligochaete worms (Oligochaeta: *oligos* = few) are terrestrial **(Figure 31.30),** but they are restricted to moist habitats because they quickly dehydrate in dry air or soil. They range in length from a few millimeters to more than 3 m. Terrestrial oligochaetes, the earthworms, are nocturnal, spending their days in burrows that they excavate. Aquatic species live in mud or detritus at the bottom of lakes, rivers, and estuaries.

Earthworms are scavengers on decomposing organic matter. In his book *The Formation of Vegetable Mould through the Action of Worms,* Darwin noted that earthworms can ingest their own weight in soil every day. He calculated that a typical population of 16,000 worms per hectare (10,000 sq m) consumes more than 20 tons of soil in a year. This impressive activity aerates soil and makes nutrients available to plants by mixing the subsoil with the topsoil. Earthworms have complex organ systems (see Figure 31.28), and they sense light and touch at both ends of the body. In addition, they have moisture receptors, an important adaptation in organisms that must stay damp to allow gas exchange across the skin.

HIRUDINEA The leeches (Hirudinea: *hirudo* = leech) are mostly freshwater parasites. They have dorsoventrally flattened, tapered bodies with a sucker at each end. Although the body wall is segmented, the coelom is reduced and not partitioned by septa.

FIGURE 31.29 **Polychaeta.** **(A)** The tube-dwelling fan worm has mucus-covered tentacles that trap small food particles. **(B)** Some polychaetes actively seek food; when they encounter a suitable tidbit, they evert their pharynx, exposing sharp jaws that grab the prey and pull it into the digestive system. **(C)** Many marine polychaetes have numerous setae, which they use for locomotion.
© Cengage Learning 2014

Many leeches are ectoparasites of vertebrates, but some attack small invertebrate prey.

Parasitic leeches feed on the blood of their hosts. Most attach to the host with the posterior sucker, and then use their sharp jaws to make a small, often painless, triangular incision. A sucking apparatus draws blood from the prey, while a special secretion, *hirudin,* maintains the flow by preventing the host's blood from coagulating. Leeches have a highly branched gut that allows them to consume huge blood meals **(Figure 31.31).** For centuries, doctors used medicinal leeches *(Hirudo medicinalis)* to "bleed" patients; today, surgeons use them to drain excess fluid from tissues after reconstructive surgery, reducing swelling until the patient's blood vessels regenerate and resume this function.

31.7 Ecdysozoan Protostomes

The three phyla in the protostome group Ecdysozoa all have an external covering that they shed periodically. The outer covering protects these animals from harsh environmental conditions, and it helps parasitic species resist host defenses. Although many of these animals live in either aquatic or moist terrestrial habitats, a tough exoskeleton allows one group, the insects, to thrive on dry land and in the air.

Nematodes Are Unsegmented Worms Covered by a Flexible Cuticle

Roundworms (phylum Nematoda: *nema* = thread) are perhaps the most abundant animals on Earth. A cupful of rich soil, a dead earthworm, or a rotting fruit may contain thousands of them. Although 25,000 species have been described, experts estimate that more than half a million exist. Many nematodes are almost microscopically small, but some species are a meter or more long. They occupy nearly every freshwater, marine, and terrestrial habitat on Earth, consuming detritus, microorganisms, plants, or animals.

©2006 Alistair Dove/Image Quest Marine

FIGURE 31.32 Phylum Nematoda. Some roundworms, like these *Anguillicola crassus* in the swim bladder of an eel, are parasites of plants or animals. Others are important consumers of dead organisms in most ecosystems.

The roundworm body is cylindrical and usually tapered at both ends **(Figure 31.32).** None of the cells have cilia or flagella. Roundworms are covered in a tough but flexible, water-resistant **cuticle,** which must be molted periodically; the cuticle is replaced by the underlying epidermis as the worm grows. The cuticle prevents the animal from dehydrating in dry environments, and, in parasitic species, it resists attack by acids and enzymes in a host's digestive system. Beneath the cuticle and epidermis, a layer of longitudinal muscles extends the length of the body. Alternating contractions of these muscles on a nematode's dorsal and ventral sides push against the substrate and propel the worm forward, usually with a thrashing motion.

The adults of one soil-dwelling species, *Caenorhabditis elegans,* are transparent and contain fewer than 1,000 cells. As *Focus on Model Research Organisms* explains, biologists have studied this worm inside and out.

Nematodes reproduce sexually, and the sexes are separate in most species. In some, internal fertilization produces many thousands of fertile eggs per day. The eggs of many species can remain dormant if environmental conditions are unsuitable.

Because of their great numbers, nematodes have enormous ecological, agricultural, and medical significance. Free-living species are responsible for decomposition and nutrient recycling in many habitats. Parasitic nematodes attack the roots of plants, causing tremendous crop damage. Some species parasitize animals, including humans. Although some, like pinworms *(Enterobius),* are more of a nuisance than a danger, others, like trichinas or filarial worms, can cause serious disease, disfigurement, or even death (see *Focus on Applied Research* on page 686). More than 1 billion people worldwide suffer from debilitating and life-threatening nematode infections.

Velvet Worms Have Segmented Bodies and Numerous Unjointed Legs

The 100 or so living species of velvet worms (phylum Onychophora: *onyx* = claw) live under stones, logs, and forest litter in the tropics and in moist temperate habitats in the southern hemisphere. They range in size from 15 mm to 15 cm and feed on small invertebrates.

Onychophorans have a flexible cuticle, segmented bodies, and numerous pairs of unjointed legs **(Figure 31.33).** Like the annelids, they have pairs of excretory organs in most segments. But unlike annelids, they have an open circulatory system, a specialized respiratory system, relatively large brains, jaws, and tiny claws on their feet. Many produce live young, which, in some species, are nourished within a uterus. Fossil evidence indicates that the onychophoran body plan has not changed much over the last 500 million years.

Caenorhabditis elegans

Researchers studying the tiny, free-living nematode *Caenorhabditis elegans* have made many recent advances in molecular genetics, animal development, and neurobiology. It is so popular as a model research organism that most workers simply refer to it as "the worm."

Several attributes make *C. elegans* a model research organism. It has an adult size of about 1 mm and thrives on cultures of *E. coli* or other bacteria; thus, thousands can be raised in a culture dish. It is hermaphroditic and often self-fertilizing, which allows researchers to maintain pure genetic strains. It completes its life cycle from egg to reproductive adult within 3 days at room temperature. Furthermore, stock cultures can be kept alive indefinitely by freezing them in liquid nitrogen or in an ultra-cold freezer set to minus 80°C. Researchers can therefore store new mutants for later research without having to clean, feed, and maintain active cultures.

Best of all, the worm is anatomically simple **(Figure);** an adult contains just 959 cells (excluding the gonads). Having a fixed cell number is relatively uncommon among animals, and developmental biologists have made good use of this trait. The eggs, juveniles, and adults of the worm are completely transparent, and researchers can observe cell divisions and cell movements in living animals with straightforward microscopy techniques. There is no need to kill, fix, and stain specimens for study. And virtually every cell in the worm's body is accessible for manipulation by laser microsurgery, microinjection, and similar approaches.

Arthropods Are Segmented Animals with a Hard Exoskeleton and Jointed Appendages

The 1.15 million known species of arthropods (phylum Arthropoda: *arthron* = joint) include more than half the animal species on Earth—and only a fraction of the living arthropods have been described. This huge clade includes insects, spiders, crustaceans, millipedes, centipedes, the extinct trilobites, and their relatives.

Arthropods have a segmented body encased in a rigid **exoskeleton.** This external covering is made of chitin, a mix of polysaccharide fibers glued together with glycoproteins, as well as waxes and lipids that block the passage of water. In some marine groups, such as crabs and lobsters, it is hardened with calcium carbonate. The exoskeleton probably first evolved in marine species, providing protection against predators. In terrestrial habitats, it provides support against gravity and protection from dehydration, which contributes to the success of insects in even the driest places on Earth. The exoskeleton is especially thin and flexible at the joints between body segments and in the appendages. Contractions of muscles attached to the inside of the exoskeleton move individual body parts like levers, allowing highly coordinated movements and patterns of locomotion that are more precise than those in soft-bodied animals with hydrostatic skeletons.

Although the exoskeleton has obvious advantages, it is nonexpandable and therefore could limit growth of the animal. But, like other Ecdysozoa, arthropods grow and periodically develop a soft, new exoskeleton beneath the old one, which they shed in the complex process of ecdysis **(Figure 31.34).** After shedding the old exoskeleton, aquatic species swell with water and terrestrial species swell with air before the new one hardens. They are especially vulnerable to predators at these times. "Soft-shelled" crabs, prized as food in many countries, are crabs that have recently molted.

As arthropods evolved, body segments became fused in various ways, reducing the overall number of segments. Each region of the body, along with its highly modified paired appendages, is specialized, but the structure and function vary

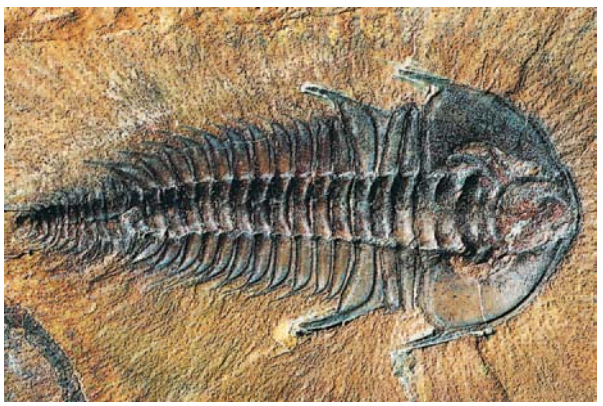
Mitsuhiko Imamori/Minden Pictures

FIGURE 31.34 Ecdysis in insects. Like all other arthropods, this cicada *(Graptopsaltria nigrofuscata)* sheds its old exoskeleton as it grows and when it undergoes metamorphosis into a winged adult.

greatly among groups. In insects (see Figure 31.43), which have three body regions, the **head** includes a brain, sensory structures, and some sort of feeding apparatus. The segments of the **thorax** bear walking legs and, in some insects, wings. The **abdomen** includes much of the digestive system and sometimes part of the reproductive system.

The coelom of arthropods is greatly reduced, but another cavity, the *hemocoel,* is filled with bloodlike hemolymph. The heart pumps the hemolymph through an open circulatory system, bathing tissues directly.

Arthropods are active animals and require substantial quantities of oxygen. Different groups have distinctive mechanisms for gas exchange, because oxygen cannot cross the impermeable exoskeleton. Marine and freshwater species, like crabs and lobsters, rely on diffusion across gills. The terrestrial groups—insects and spiders—have developed unique and specialized respiratory systems.



High levels of activity also require intricate sensory structures. Many arthropods are equipped with a highly organized central nervous system, touch receptors, chemical sensors, **compound eyes** that include multiple image-forming units, and in some, hearing organs.

Arthropod systematics is an active area of research, and scientists are currently using molecular, morphological, and developmental data to reexamine relationships within this immense group. As *Insights from the Molecular Revolution* explains, hypotheses about the phylogeny and classification of arthropods are in a state of flux. Some researchers even argue for splitting them into four or more phyla. We follow the traditional definition of five *subphyla,* partly because this classification adequately reflects arthropod diversity and partly because no alternative hypothesis has been widely adopted by experts.

SUBPHYLUM TRILOBITA The trilobites (subphylum Trilobita: *tri* = three, *lobos* = lobe), now extinct, were among the most numerous animals in shallow Paleozoic seas. They disappeared in the Permian mass extinction, but the cause of their demise is unknown. Most trilobites were ovoid, dorsoventrally flattened, and heavily armored, with two deep longitudinal grooves that divided the body into the one median and two lateral lobes for which the group is named **(Figure 31.35).** Their segmented bodies were organized into three body regions: the head, which included a pair of sensory **antennae** (chemosensory organs) and two compound eyes, and a thorax and an abdomen, both of which bore pairs of walking legs.

The position of trilobites in the fossil record indicates that they were among the earliest arthropods. Thus, biologists are confident that their three body regions and numerous unspecialized appendages—one pair per segment—represent ancestral traits within the phylum. As you will learn as you read about the other four subphyla, the subsequent evolution of the different arthropod groups included dramatic remodeling of the major body regions as well as modifications of the ancestral, unspecialized paired appendages into highly specialized structures that perform different functions.

SUBPHYLUM CHELICERATA In spiders, ticks, mites, scorpions, and horseshoe crabs (subphylum Chelicerata: *chela* = claw, *keras* = horn), the first pair of appendages, the **chelicerae,** are fanglike structures used for biting prey. The second pair of appendages, the *pedipalps,* serve as grasping organs, sensory organs, or walking legs. All chelicerates have two major body regions, the **cephalothorax** (a fused head and thorax) and the abdomen. The group originated in shallow Paleozoic seas, but most living species are terrestrial. They vary in length from less than a millimeter to 20 cm; all are predators or parasites.

Dr. Chip Clark

Unscrambling the Arthropods: Morphological versus molecular characteristics?

For years, biologists disagreed about the evolutionary relationships among the major clades of arthropods. Some researchers grouped hexapods and myriapods together (**Figure,** *Traditional tree*) because they share certain morphological characteristics, which may indicate a common ancestry: unbranched appendages, a tracheal system for gas exchange, Malpighian tubules for excretion, and one pair of antennae. However, other researchers noted that hexapods and crustaceans shared a different set of important morphological characters: jawlike mandibles on the fourth head segment, similar compound eyes, comparable development of the nervous system, and similarities in the structure of thoracic appendages.

Research Question

Given the variety of morphological characteristics that hexapods share with myriapods and those that they share with crustaceans, what are the evolutionary relationships among these major clades of arthropods?

Experiment

A molecular study by Jeffry L. Boore and his colleagues at the University of Michigan lends support to the hypothesis that hexapods may indeed be more closely related to crustaceans than to myriapods. Boore and his coworkers compared the arrangement of genes in the mitochondrial DNA of representative arthropod species. Mitochondrial DNA (mtDNA) was chosen for study because it has been subject to many random rearrangements during the evolutionary history of the arthropods, producing wide variations in the order and placement of the 36 or 37 genes typically present. As long as the rearrangements do not disrupt gene function, they appear to have little or no effect on fitness; therefore, they may not be affected by natural selection. As Boore and his colleagues noted, the large number of possible rearrangements of the mtDNA genes makes it unlikely that the same gene order would appear by chance in any two groups; thus, groups with the same arrangement are likely to share a common ancestor in which the rearrangement first appeared.

The investigators sequenced the mtDNA of a chelicerate, two crustaceans, and a myriapod (listed in the figure caption). They also sequenced the mtDNA of a mollusk and an annelid, animals that are only distantly related to arthropods, to provide outgroup comparisons. They compared these sequences with those in 14 other invertebrates, including four hexapods and one crustacean, already obtained by other workers.

Results

The locations of two genes encoding leucine-carrying tRNAs provide the strongest clue to the evolutionary relationships of these organisms. These genes are positioned next to each other in the mtDNA of the chelicerate, the mollusk, and the annelid. This arrangement appears to reflect the ancestral gene order present in the common ancestor of annelids, mollusks, and arthropods. However, in the hexapods and the crustaceans studied, one of the leucine tRNA genes is located at a different position, between two genes coding for electron transfer proteins. Moreover, this rearrangement does not appear in the myriapod examined. It is extremely unlikely that the same translocation of the leucine tRNA gene occurred independently in hexapods and crustaceans. Instead, this gene rearrangement probably occurred in an ancestor shared by hexapods and crustaceans after this ancestor diverged from the lineage that includes the chelicerates and myriapods.

Conclusion

The shared gene arrangement in insects and crustaceans and the absence of a matching arrangement in myriapods suggests that hexapods and crustaceans are closely related, and that hexapods and myriapods are not, in spite of their morphological similarities (see **Figure,** *New tree*). Other investigators, who compared the sequences of ribosomal RNA genes in a variety of arthropod species, reached the same conclusions independently.

THINK LIKE A SCIENTIST If we were able to sequence the DNA of a trilobite, do you think that the locations of the two genes encoding leucine-carrying tRNAs would more closely match the locations of these genes in the mtDNA of chelicerates or of crustaceans?

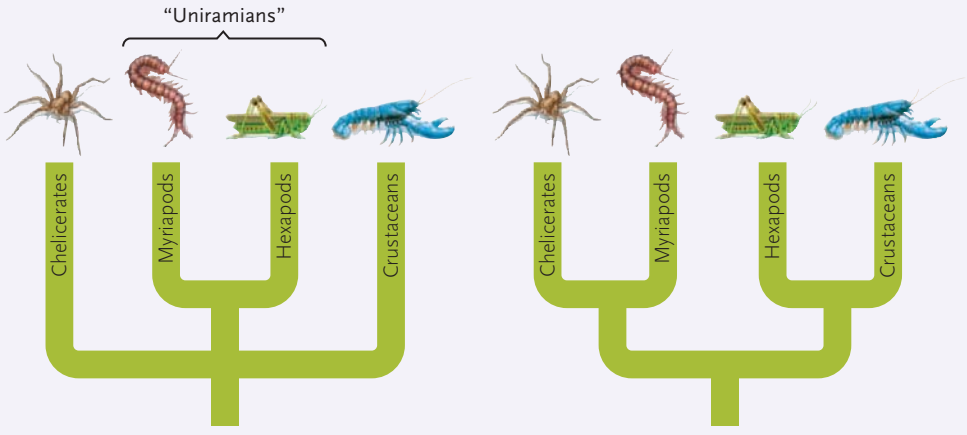

FIGURE The traditional phylogenetic tree for arthropods (left) differs from that suggested by the research described in this box. The DNA sequences used to construct the new phylogenetic tree (right) were obtained from the chelicerate *Limulus,* the myriapod *Thyrophygus,* the hexapod *Drosophila,* and the crustaceans *Daphnia* and *Homarus.*

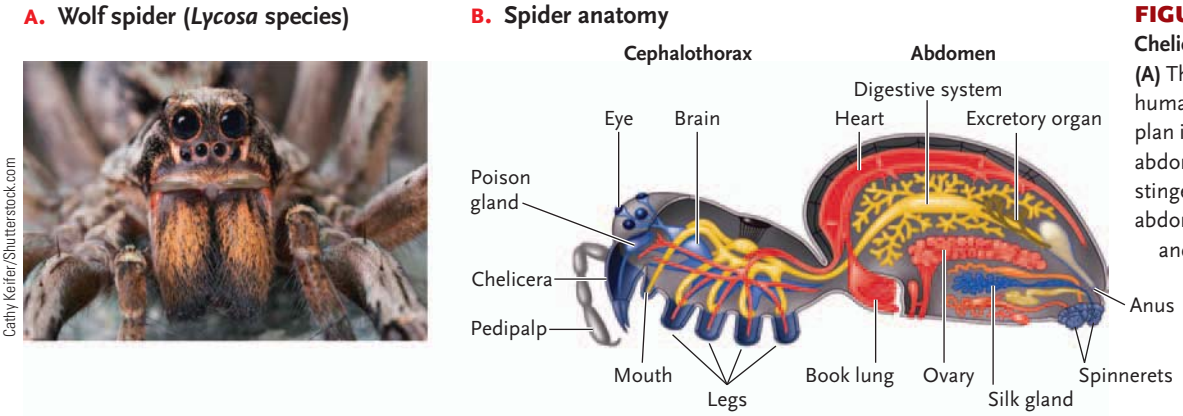

FIGURE 31.36 **Subphylum Chelicerata, subgroup Arachnida.** **(A)** The wolf spider is harmless to humans. **(B)** The arachnid body plan includes a cephalothorax and abdomen. **(C)** Scorpions have a stinger at the tip of the segmented abdomen. Many protect their eggs and young. **(D)** House dust mites, shown in a scanning electron micrograph, feed on microscopic debris.
© Cengage Learning 2014

The spiders, scorpions, mites, and ticks (Arachnida) represent the vast majority of chelicerates **(Figure 31.36).** Arachnids have four pairs of walking legs on the cephalothorax and highly modified chelicerae and pedipalps. In some spiders, males use their pedipalps to transfer packets of sperm to females. Scorpions use them to shred food and to grasp one another during courtship. Many predatory arachnids have excellent vision, provided by simple eyes on the cephalothorax. Scorpions and some spiders also have unique pocketlike respiratory organs, called **book lungs,** which are derived from abdominal appendages.

Spiders, like most other arachnids, subsist on a liquid diet. They use their chelicerae to inject paralyzing poisons and digestive enzymes into prey and then suck up the partly digested tissues. Many spiders are economically important predators, helping to control insect pests. Only a few are a threat to humans. The toxin of a black widow *(Latrodectus mactans)* causes paralysis, and the toxin of the brown recluse *(Loxosceles reclusa)* destroys tissues around the site of the bite.

Although many spiders hunt actively, others capture prey on silken threads secreted by **spinnerets,** which are modified abdominal appendages. Some species weave the threads into complex, netlike webs. The silk is secreted as a liquid, but quickly hardens on contact with air. Spiders also use silk to make nests, to protect their egg masses, as a safety line when moving through the environment, and to wrap prey for later consumption.

Most mites are tiny, but they have a big impact. Some are serious agricultural pests that feed on the sap of plants. Others cause mange (patchy hair loss) or painful and itchy welts on animals. House dust mites cause allergic reactions in many people. Ticks, which are generally larger than mites, are blood-feeding ectoparasites that often transmit pathogens, such as the bacteria that cause Rocky Mountain spotted fever and Lyme disease.

The subphylum Chelicerata also includes five species of horseshoe crabs (Merostomata), an ancient lineage with a morphology that has not changed much over its 350-million-year history **(Figure 31.37).** Horseshoe crabs are carnivorous bottom feeders in shallow coastal waters. Beneath their characteristic shell, they have one pair of chelicerae, a pair of pedipalps, four pairs of walking legs, and a set of paperlike gills that are derived from ancestral walking legs.

SUBPHYLUM CRUSTACEA The shrimps, lobsters, crabs, and their relatives (subphylum Crustacea: *crusta* = crust or hard shell) represent a lineage that emerged more than 500 million years ago. They are abundant in marine and freshwater habitats. A few species, such as sowbugs and pillbugs, live in moist, sheltered terrestrial environments. In many crustaceans two, or even all three, of the arthropod body regions—head, thorax, and abdomen—are fused; a fused cephalothorax and a separate abdomen is an especially common pattern. The edible "tail" of a lobster, shrimp, or crayfish is actually a highly muscularized abdomen. In some, the exoskeleton includes a

carapace, a protective covering that extends backward from the head. Crustaceans vary in size from water fleas less than 1 mm long to lobsters that can grow to 60 cm in length and weigh as much as 20 kg.

Crustaceans generally have five characteristic pairs of appendages on the head **(Figure 31.38).** Most have two pairs of sensory antennae and three pairs of mouthparts. The latter include one pair of *mandibles,* which move laterally to bite and chew, and two pairs of *maxillae,* which hold and manipulate food. Numerous paired appendages posterior to the mouthparts vary among groups.

Most crustaceans are active animals that exhibit complex patterns of movement. Their activities are coordinated by elaborate sensory and nervous systems, including chemical and touch receptors in the antennae, compound eyes, statocysts on the head, and sensory hairs embedded in the exoskeleton throughout the body. The nervous system is similar to that of annelids, but the ganglia are larger and more complex, allowing a finer level of motor control. High levels of activity require substantial amounts of oxygen, and larger species have complex, feathery gills tucked beneath the carapace. Activity also produces abundant metabolic wastes that are excreted by diffusion across the gills or, in larger species, by glands located in the head.

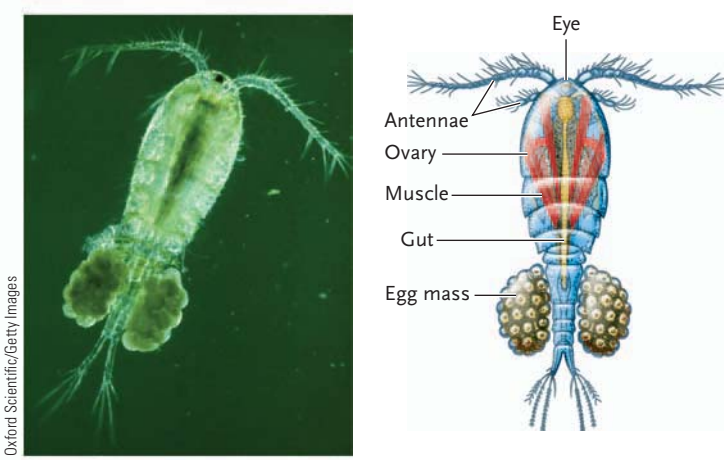
The sexes are typically separate, and courtship rituals are often complex. Eggs are usually brooded on the surface of the female's body or beneath the carapace. Many have free-swimming larvae that, after undergoing a series of molts, gradually assume an adult form.

The subphylum includes so many different body plans that it is usually divided into six major groups with numerous subgroups. The crabs, lobsters, and shrimps (Decapoda, meaning "10 feet," which is a subgroup of the Malacostraca) number more than 10,000 species. The vast majority of decapods are marine, but a few shrimps, crabs, and crayfishes occupy freshwater habitats. Some crabs also live in moist terrestrial habitats, where they scavenge dead vegetation, clearing the forest floor of debris.

All decapods exhibit extreme specialization of their appendages. In the American lobster, for example, each of the 19 pairs of appendages is different (see Figure 31.38C). Behind the antennae, mandibles, and maxillae, the thoracic segments have three pairs of *maxillipeds,* which shred food and pass it up to the mouth, a pair of large *chelipeds* (pinching claws), and four pairs of walking legs. The abdominal appendages include a pair specialized for sperm transfer (in males only), *swimmerets* for locomotion and for brooding eggs, and *uropods,* a pair of appendages that, combined with the *telson,* the tip of the abdomen, form a fan-shaped tail. If any appendage is damaged, the animal can autotomize ("drop") it and begin growing a new one before its next molt.

Representatives of several crustacean groups—fairy shrimps, amphipods, water fleas, krill, ostracods, and copepods **(Figure 31.39)**—live as plankton in the upper waters of oceans and lakes. Most are only a few millimeters long, but are present in huge numbers. They feed on microscopic algae or detritus and are themselves food for larger invertebrates, fishes, and some suspension-feeding marine mammals like the baleen whales. Planktonic crustaceans are among the most abundant animals on Earth.

Adult barnacles (Cirripedia, meaning "hairy footed," a subgroup of the Maxillopoda) are sessile, marine crustaceans that



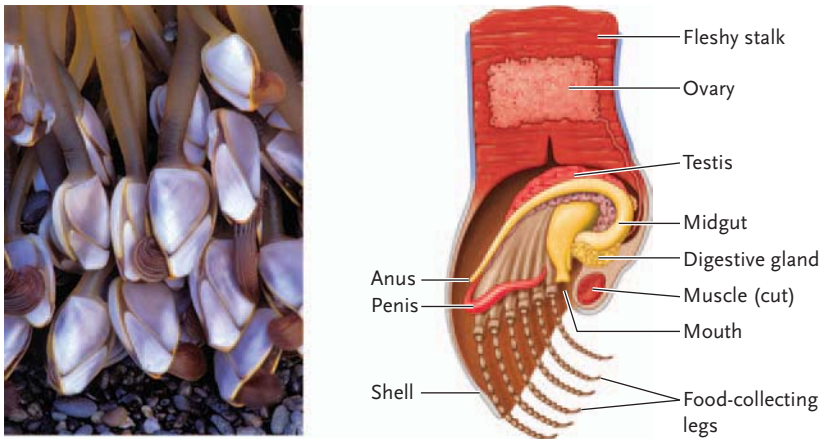


FIGURE 31.39 **Copepods.** Tiny crustaceans, like these copepods (*Cyclops* species), occur by the billions in freshwater and marine plankton.

live within a strong, calcified cup-shaped shell **(Figure 30.40).** Their free-swimming larvae attach permanently to substrates—rocks, wooden pilings, the hulls of ships, the shells of mollusks, even the skin of whales—and secrete the shell, which is actually a modified exoskeleton. To feed, barnacles open the shell and extend six pairs of feathery legs. The beating legs capture microscopic plankton and transfer it the mouth. Unlike most crustaceans, barnacles are hermaphroditic.

SUBPHYLUM MYRIAPODA The centipedes (Chilopoda) and millipedes (Diplopoda) are classified together in the subphylum Myriapoda (*myrias* = ten thousand, *pod-* = feet). Myriapods have two body regions, a head and a segmented trunk **(Figure 31.41).** The head bears one pair of antennae, and the trunk bears one (centipedes) or two (millipedes) pairs of walking legs on most of its many segments. Myriapods are terrestrial, and many species live under rocks or dead leaves. Centipedes are fast and voracious predators, using powerful toxins to kill their prey; they generally feed on invertebrates, but some eat small vertebrates. The bite of some species is harmful to humans. Although most species are less than 10 cm long, some grow to 25 cm. The millipedes are slow but powerful herbivores or scavengers. The largest species attain a length of nearly 30 cm. Although they lack a poisonous bite, they curl into a ball and exude noxious liquids when disturbed.

SUBPHYLUM HEXAPODA In terms of sheer numbers, diversity, and the range of habitats they occupy, the 1,000,000 or more species of insects and their closest relatives (subphylum Hexapoda, *hexapoda* = six feet) are the most successful animals on Earth. They were among the first animals to colonize terrestrial habitats, where most species still live. The oldest insect fossils date from the Devonian, 380 million years ago. Insects have one pair of antennae on the head, a pair of mandibles for feeding, and unbranched appendages. Insects are generally small, ranging from 0.1 mm to 30 cm in length. The lineage is divided into about 30 subgroups **(Figure 31.42).** The insect body plan always includes a head, thorax, and abdomen **(Figure 31.43).** The head is equipped with multiple mouthparts, a pair of compound eyes, and one pair of sensory antennae. The thorax has three pairs of walking legs and often one or two pairs of wings. Insects are the only invertebrates capable of flight. Their wings, which are made of lightweight but durable sheets of chitin and sclerotin, arise embryonically from the body wall; unlike the wings of birds and bats, insect wings are not derived from ancestral appendages.

Studies in evolutionary developmental biology have begun to unravel the genetic changes that fostered certain aspects of the insect body plan. For example, the *Distal-less* gene (*Dll* for short) is a highly conserved tool-kit gene (see Section 23.6) that triggers the development of appendages in all sorts of animals—the legs of chickens, the fins of fishes, the parapodia of polychaete worms, and the diverse appendages of arthropods. All arthropods also have a gene called *Ultrabithorax* (*Ubx* for short). It is one of the *Hox* genes that control the overall body plans of animals. In insects, the *Ubx* gene contains a unique mutation, not found in other arthropods, that causes the protein for which it codes to repress *Dll,* thereby preventing the forma-

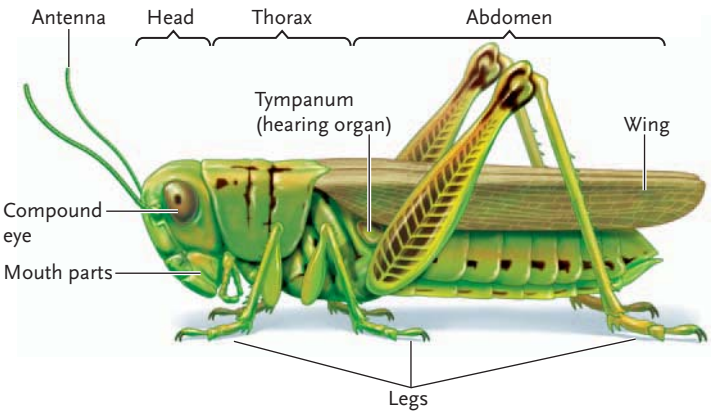
H. Like many other ant species, fire ants (Hymenoptera, *Solenopsis invicta*) live in large cooperative colonies. Fire ants—named for their painful sting—were introduced into southeastern North America, where they are now serious pests.

FIGURE 31.42 **Insect diversity.** Insects are grouped into about 30 clades, 8 of which are illustrated here.



tion of appendages wherever *Ubx* is expressed. And because insects express *Ubx* in their abdomen, they do not grow abdominal appendages. All other arthropods, which have the ancestral, nonrepressing form of the *Ubx* gene, have appendages in the posterior region of their body. Thus, one mutation in a *Hox*-family gene has fostered the evolution of a highly distinctive morphological trait in insects—having legs on the thorax, but not on the abdomen.

Insects exchange gases through a specialized **tracheal system,** a branching network of tubes that carry oxygen from small openings in the exoskeleton to tissues throughout the body (see Figure 46.5). Insects excrete nitrogenous wastes through specialized **Malpighian tubules** that transport wastes to the digestive system for disposal with feces (see Figure 48.6). Both of these organ systems are unique among animals. Insect sensory systems are diverse and complex. Besides image-forming compound eyes (see Figure 41.10), many insects have light-sensing ocelli on their heads. Many also have hairs, sensitive to touch, on their antennae, legs, and other regions of the body. Chemical receptors are particularly common on the legs, allowing the identification of food. And many groups of insects have hearing or-

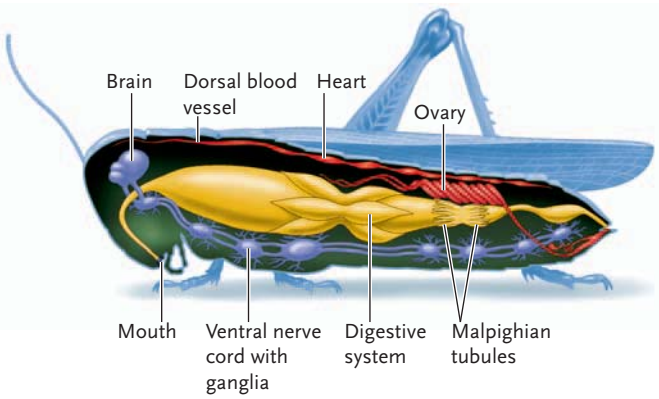


FIGURE 31.43 **The insect body plan.** Insects have distinct head, thorax, and abdomen. Of all the internal organ systems, only the dorsal blood vessel, ventral nerve cord, and some muscles are strongly segmented.

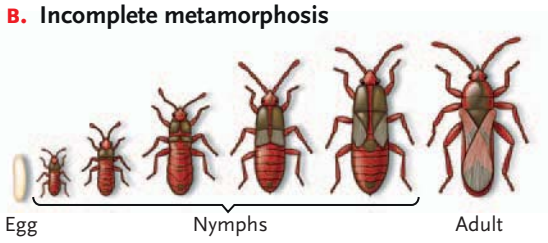
gans to detect predators and potential mates. The familiar chirping of crickets, for example, is a mating call emitted by males that may repel other males and attract females.

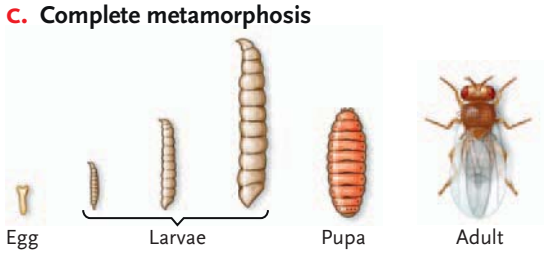
As a group, insects feed in every conceivable way and on most other organisms. Species that eat plants, such as grasshoppers, have a pair of rigid mandibles, which chew food before it is ingested. Behind the mandibles is a pair of maxillae, which may also aid in food acquisition. Insects also have inflexible upper and lower lips, the *labrum* and *labium,* respectively. A tongue-like structure, just dorsal to the labium in chewing insects, houses the openings of the salivary glands. But evolution has modified this ancestral mandibulate pattern in numerous ways **(Figure 31.44).** In houseflies, the mouthparts are adapted for sopping up liquid food. In butterflies and moths, the mouthparts include a long proboscis to drink nectar. And in some biting flies, like mosquitoes and blackflies, the mouthparts have evolved into piercing structures.

After it hatches from an egg, an insect passes through a series of developmental stages called *instars.* Several hormones control development and ecdysis, which marks the passage from one instar to the next. Insects exhibit one of three basic patterns of postembryonic development **(Figure 31.45).** Primitive, wingless species simply grow and shed their exoskeleton without undergoing major changes in morphology. Other species undergo **incomplete metamorphosis;** they hatch from the egg as a *nymph,* which lacks functional wings. In many species, such as grasshoppers (Orthoptera), the nymphs resemble the adults. In other insects, such as dragonflies (Odonata), the aquatic nymphs are morphologically very different from the adults.



Most insects undergo **complete metamorphosis:** the larva that hatches from the egg differs greatly from the adult. Larvae and adults often occupy different habitats and consume different food. The larvae (caterpillars, grubs, or maggots) are often worm-shaped, with chewing mouthparts. They grow and molt several times, retaining their larval morphology. Before they transform into sexually mature adults, they spend a period of time as a sessile **pupa.** During this stage, the larval tissues are drastically reorganized. The adult that emerges is so different from the larva that it is often hard to believe that they are of the same species. Moths, butterflies, beetles, and flies are examples of insects with complete metamorphosis. Their larval stages specialize in feeding and growth, whereas the adults are adapted for dispersal and reproduction. In some species, the adults never feed, relying on the energy stores accumulated during the larval stage.

A. No metamorphosis



Some wingless insects, like silverfish (Thysanura), do not undergo a dramatic change in form as they grow.

B. Incomplete metamorphosis

Other insects, such as true bugs (Hemiptera), have incomplete metamorphosis; they develop from nymphs into adults with relatively minor changes in form.

C. Complete metamorphosis

Fruit flies (Diptera) and many other insects have complete metamorphosis; they undergo a total reorganization of their internal and external anatomy when they pass through the pupal stage of the life cycle.

The 240-million-year history of insects has been characterized by innovations in morphology, life cycle patterns, locomotion, feeding, and habitat use. Their well-developed nervous systems govern exceptionally complex patterns of behavior, including parental care, a habit that reaches its zenith in the colonial social insects, the ants, bees, and wasps (see Chapter 56). The factors that contribute to the insects' success also make them our most aggressive competitors. They destroy vegetable crops, stored food, wool, paper, and timber. They feed on blood from humans and domesticated animals, sometimes transmitting disease-causing pathogens as they do so. Nevertheless, insects are essential members of terrestrial ecological communities. Many species pollinate flowering plants, including important crops. Many others attack or parasitize species that are harmful to human activities. And most insects are a primary source of food for other animals. Some even make useful products like honey, beeswax, and silk.

In the next chapter we consider the lineage of deuterostomes, which includes the vertebrates and their closest invertebrate relatives.

STUDY BREAK 31.7

1. **What part of a parasitic nematode's anatomy protects it from the digestive enzymes of its host?**
2. **If an arthropod's rigid exoskeleton cannot be expanded, how does the animal grow?**
3. **How do the number of body regions and the appendages on the head differ among the four subphyla of living arthropods?**
4. **How do the life stages differ between insects that have incomplete metamorphosis and those that have complete metamorphosis?**

UNANSWERED QUESTIONS

What are the evolutionary relationships among the invertebrate clades?

If we step back from our vertebrate and terrestrial biases, invertebrates are the dominant form of life on Earth. Many students of natural history are overwhelmed by the sheer numbers of organisms that one encounters, particularly in the aquatic environment, and the challenge of categorizing them taxonomically. Sorting them out in terms of their ecological roles is equally daunting. The problem we face is that invertebrates do it all—they are predators, herbivores, parasites, detritivores, and the primary symbiotic organisms on Earth. This adaptability of form and function is a fascinating hallmark of the animal way of life, but it poses a legion of questions, many still unanswered. Recent advances in genetic technology have advanced our understanding, but there is much left to do.

In the past two decades, our ability to compare genetic information from various invertebrate groups has led to a remarkable reshuffling of the long-established categories used to classify these organisms. The first categories to be eliminated were groups based on superficial phenotypic resemblances, such as the "pseudocoelomates," which had plagued student understanding of diversity. Today, we have a much deeper knowledge of the evolutionary relationships of these organisms. Perhaps the most exciting discovery is that much of the diversity we see is not the product of slow changes in protein-coding gene sequences, but rather the result of variations in the timing and location of the expression of genes that affect development. Evo-devo, the melding of evolutionary and developmental biology—mostly made possible by intensive studies of two model invertebrates, *Caenorhabditis elegans* and *Drosophila melanogaster*—has revealed that changes in the expression of relatively simple sets of genes have brought about the myriad forms of life we see among the invertebrates. As systematists incorporate these new discoveries in their analyses, our understanding of the evolutionary relationships among the invertebrates will surely change.

What is the genetic basis of the diversity of form and function observed among invertebrates?

Because of advances in genetics research, we are on the cusp of being able to answer some fundamental questions. How does an animal's body develop either radial or bilateral symmetry? How does an organism develop a head with a concentration of nervous system tissue, and how do all the exquisite sensory systems associated with a big brain develop? From where do the respiratory pigments, which increase the capacity of the hemolymph or blood to carry oxygen, increasing an organism's capacity for activity, arise? How does the immune system develop, and what genetic change fosters the quantum leap from a nonspecific defense system to one that responds specifically to foreign invaders? More practically, are there genetic switches that we can manipulate? Can we make blood-feeding invertebrates, such as mosquitoes, or parasitic species, like tapeworms or filarial worms, innocuous? Is it possible to use genetic engineering to reduce the ability of the mosquito *Anopheles gambiae* (the "deadliest organism on Earth") to transmit malaria? Will it be possible to forestall or reverse the global decline of coral reefs, one of the richest habitats on Earth?

The answers to these and many more basic and applied questions lie within a deep knowledge and understanding of the invertebrates and the roles they play on our planet. If one looks at invertebrates as dynamic systems, as rich sources of clues to life on Earth, the questions they pose easily provide a lifetime of investigation and reward.

THINK LIKE A SCIENTIST

1. Based on your reading of this chapter, provide two examples of how recent genetic comparisons of invertebrates have confirmed groupings based on morphology and embryology.
2. Based on the content of this chapter, which genes would you study if you wanted to learn about the genetic basis of diversity among invertebrates?

William S. Irby

William S. Irby is an associate professor in the Department of Biology at Georgia Southern University in Statesboro. His research focuses on the ecology and evolution of blood-feeding behavior in mosquitoes. To learn more about Irby's work, go to http://www.bio.georgiasouthern.edu/amain/fac-list.html.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

31.1 What Is an Animal?

- Animals are eukaryotic, multicellular, heterotrophs that are motile at some time in their lives.
- Animals probably arose from a colonial flagellated ancestor during the Precambrian era (Figure 31.2).

31.2 Key Innovations in Animal Evolution

- All animals except sponges have tissues, which are organized into either two or three tissue layers.
- Although some animals exhibit radial symmetry, most exhibit bilateral symmetry (Figure 31.3).
- Acoelomate animals have no body cavity. Pseudocoelomate animals have a body cavity between the derivatives of endoderm and mesoderm. Coelomate animals have a body cavity that is entirely lined by derivatives of mesoderm (Figure 31.4).
- Two lineages of bilaterally symmetrical animals differ in developmental patterns (Figure 31.5). Most protostomes exhibit spiral, determinate cleavage, and their coelom forms from a split in a solid mass of mesoderm. Most deuterostomes have radial, indeterminate cleavage, and the coelom usually forms within outpocketings of the primitive gut.
- Four animal phyla exhibit segmentation.

Animation: Types of body cavities

Animation: Directional terms and planes of symmetry

Animation: Developmental differences between protostomes and deuterostomes

31.3 An Overview of Animal Phylogeny and Classification

- Analyses of molecular sequence data have refined our view of animal evolutionary history (Figure 31.6). The molecular phylogeny recognizes some major clades that had been identified on the basis of morphological and embryological characters. Sponges are grouped in the Parazoa. All other clades are grouped in the Eumetazoa. Among the Eumetazoa, the Radiata includes animals with two tissue layers and radial symmetry, and the Bilateria includes animals with three tissue layers and bilateral symmetry.
- Bilateria is further subdivided into Protostomia and Deuterostomia. The new phylogeny divides the Protostomia into the Lophotrochozoa and the Ecdysozoa.
- The molecular phylogeny suggests that ancestral protostomes had a coelom and that segmentation arose more than once.

31.4 Animals without Tissues: Parazoa

- Sponges (phylum Porifera) are asymmetrical animals with limited integration of cells in their bodies (Figure 31.7).
- The body of many sponges is a water-filtering system (Figure 31.8). Flagellated choanocytes draw water into the body and capture particulate food.

Animation: Body plan of a sponge

31.5 Eumetazoans with Radial Symmetry

- The two major radiate phyla, Cnidaria and Ctenophora, have two well-developed tissue layers with a gelatinous mesoglea between them (Figure 31.9). Members of both phyla lack organ systems. All are aquatic.
- Cnidarians capture prey with tentacles and stinging nematocysts (Figures 31.10, 31.12, and 31.13). Their life cycles may include polyps, medusae, or both (Figure 31.11).
- Ctenophores use long tentacles to capture particulate food and use rows of cilia for locomotion (Figure 31.14).

Animation: Cnidarian body plans

Animation: Nematocyst action

Animation: Cnidarian life cycle

31.6 Lophotrochozoan Protostomes

- The taxon Lophotrochozoa includes eight phyla.
- Three small phyla (Ectoprocta, Brachiopoda, and Phoronida) use a lophophore to feed on particulate matter (Figure 31.15).
- Free-living flatworm species (phylum Platyhelminthes) have well-developed digestive, excretory, reproductive, and nervous systems (Figures 31.16 and 31.17). Parasitic species attach to their animal hosts with suckers or hooks (Figures 31.18 and 31.19).
- The rotifers (phylum Rotifera) are tiny and abundant inhabitants of freshwater and marine ecosystems (Figure 31.20). Movements of cilia in the corona control their locomotion and bring food to their mouths.
- The ribbon worms (phylum Nemertea) are elongate and often colorful animals with a proboscis housed in a rhynchocoel (Figure 31.21).
- Mollusks (phylum Mollusca) have fleshy bodies that are often enclosed in a hard shell. The molluscan body plan includes a head, a foot, the visceral mass, and a mantle (Figures 31.22 and 31.24–31.27).
- Segmented worms (phylum Annelida) generally exhibit segmentation of the coelom and of the muscular, circulatory, excretory, respiratory, and nervous systems. They use the coelom as a hydrostatic skeleton for locomotion (Figures 31.28–31.31).

Animation: Clam body plan

Animation: Cuttlefish body plan

Animation: Earthworm body plan

Animation: Insect development

Animation: Insect head parts

Animation: Molluscan classes

Animation: Planarian organ systems

Animation: Roundworm body plan

Animation: Tapeworm life cycle

31.7 Ecdysozoan Protostomes

- The taxon Ecdysozoa includes three phyla that periodically shed their cuticle or exoskeleton.
- Roundworms (phylum Nematoda) feed on decaying organic matter or parasitize plants or animals (Figure 31.32). They move by alternately contracting longitudinal muscles on the dorsal and ventral sides of the body wall.

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The velvet worms (phylum Onychophora) have segmented bodies and unjointed legs (Figure 31.33). Some species bear live young, which develop in a uterus.
- The segmented bodies of the arthropods (phylum Arthropoda) have specialized appendages for feeding, locomotion, or reproduction. Arthropods shed their exoskeleton as they grow or enter a new stage of the life cycle (Figure 31.34). They have an open circulatory system, a complex nervous system, and, in some groups, highly specialized respiratory and excretory systems.
- Arthropods are divided into five subphyla. The extinct trilobites (subphylum Trilobita), with three-lobed bodies and relatively undifferentiated appendages, were abundant in Paleozoic seas (Figure 31.35). Chelicerates have a cephalothorax and abdomen; appendages on the head serve as pincers or fangs and pedipalps (Figures 31.36 and 31.37). Crustaceans have a carapace that covers the cephalothorax as well as highly modified appendages, including antennae and mandibles (Figures 31.38–31.40). Myriapods have a head and an elongate, segmented trunk (Figure 31.41). Hexapods have three body regions, three pairs of walking legs on the thorax, and three pairs of feeding appendages on the head (Figures 31.42–31.44). Insects exhibit three patterns of postembryonic development (Figure 31.45).

UNDERSTAND & APPLY

Test Your Knowledge

1. Which of the following characteristics is *not* typical of most animals?
   a. heterotrophic
   b. sessile
   c. bilaterally symmetrical
   d. multicellular
   e. motile at some stage of life cycle
2. A body cavity that separates the digestive system from the body wall but is *not* completely lined with mesoderm is called a:
   a. schizocoelom.
   b. mesentery.
   c. peritoneum.
   d. pseudocoelom.
   e. hydrostatic skeleton.
3. Protostomes and deuterostomes typically differ in:
   a. their patterns of body symmetry.
   b. the number of germ layers during development.
   c. their cleavage patterns.
   d. the size of their sperm.
   e. the size of their digestive systems.
4. The nematocysts of cnidarians are used primarily for:
   a. capturing prey.
   b. detecting light and dark.
   c. courtship.
   d. sensing chemicals.
   e. gas exchange.
5. Which organ system is absent in flatworms (phylum Platyhelminthes)?
   a. nervous system
   b. reproductive system
   c. circulatory system
   d. digestive system
   e. excretory system
6. Which part of a mollusk secretes the shell?
   a. visceral mass
   b. radula
   c. trochophore
   d. head–foot
   e. mantle
7. What is the major morphological innovation seen in annelid worms?
   a. a complete digestive system
   b. image-forming eyes
   c. a respiratory system
   d. an open circulatory system
   e. body segmentation
8. Which phylum includes the most abundant animals in soil?
   a. Nematoda
   b. Rotifera
   c. Mollusca
   d. Annelida
   e. Brachiopoda
9. Which body region of an insect bears the walking legs?
   a. head
   b. carapace
   c. abdomen
   d. thorax
   e. trunk
10. Ecdysis refers to a process in which:
    a. bivalves use siphons to pass water across their gills.
    b. arthropods shed their old exoskeletons.
    c. cnidarians build skeletons of calcium carbonate.
    d. rotifers produce unfertilized eggs.
    e. squids escape from predators in a cloud of ink.

Discuss the Concepts

1. Many invertebrate species are hermaphroditic. What selective advantages might this characteristic offer? In what kinds of environments might it be most useful?
2. People who eat raw clams and oysters harvested from sewage-polluted waters often develop mild to severe gastrointestinal infections. These mollusks are suspension feeders. Develop a hypothesis about why people who eat them raw may be at risk.
3. On a voyage to the ocean bottom, a biologist discovers a worm that appears to be new to science. What characteristics of this animal should the biologist examine to determine whether or not she has discovered a previously undescribed phylum?
4. What are the relative advantages and disadvantages of radially symmetrical and bilaterally symmetrical body plans?

Design an Experiment

Design an experiment to test the hypothesis that the cuticle of parasitic nematodes protects them from the acids and enzymes present in the digestive systems of their hosts. Your design must include both experimental and control treatments.

Interpret the Data

A research team led by Andreas Michalsen of the Kliniken Essen, a hospital in Germany, compared the relative effectiveness of "leech therapy" and the topical application of diclofenac, an antiinflammatory drug, for the treatment of pain caused by osteoarthritis in the thumb. Leech saliva contains more than 30 biologically active compounds, including some with antiinflammatory effects. For the group receiving drug therapy, the patients applied the drug to their thumbs at least twice a day for up to 30 days. For the group receiving leech therapy, researchers applied two or three leeches to the affected joint and allowed them to feed until they were satiated; the average feeding time was 50 minutes. Patients in the leech therapy group received just one treatment. The researchers asked patients to score their pain (0 = no pain; 100 = severe pain) before treatment (day 0 in the **Figure**) and again one week, one month, and two months after treatment. The results are presented in the accompanying bar chart. Which treatment had the greater effect in reducing the pain of arthritis patients in this study? Did leech therapy have a prolonged effect?

Apply Evolutionary Thinking

Many insects have a larval stage that is morphologically different from the adult and that feeds on different foods. What selection pressures may have fostered the evolution of a life cycle with such distinctive life stages? Your answer should address the different biological activities that characterize each life cycle stage.

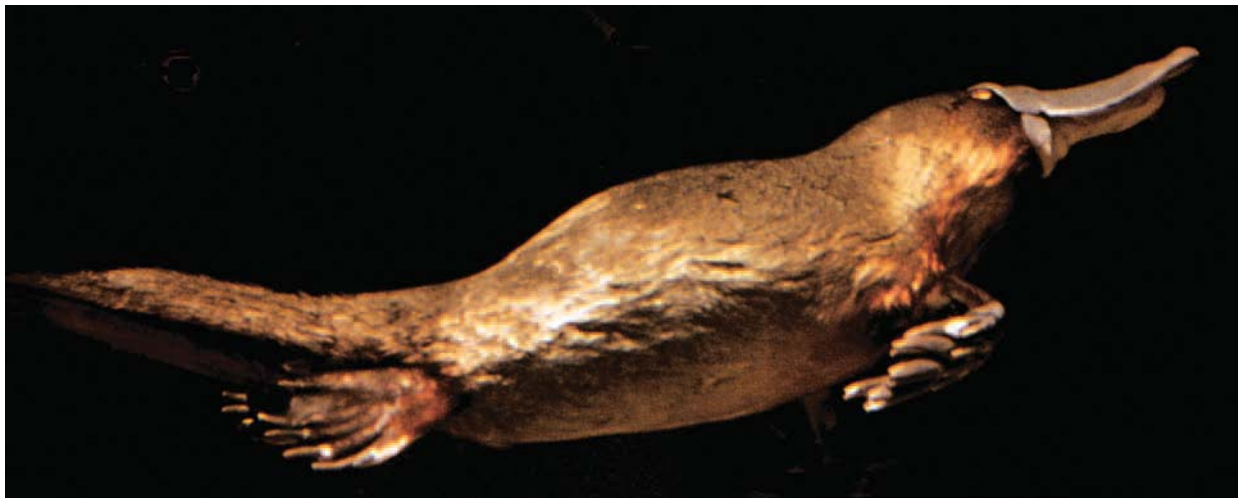
Deuterostomes: Vertebrates and Their Closest Relatives



Why it matters . . . In 1798, naturalists at the British Museum skeptically probed a curious specimen that had been sent from Australia. The furry creature—about the size of a housecat—had webbed front feet, a ducklike bill, and a flat, paddlelike tail **(Figure 32.1).** The scientists eagerly searched for evidence that a prankster had stitched together parts from wildly different animals, but they found no signs of trickery and soon accepted the duck-billed platypus *(Ornithorhynchus anatinus)* as a genuine zoological novelty.

Further study has revealed that the platypus is even stranger than those scientists could have imagined. Like other mammals, the platypus is covered with hair, and females produce milk that the offspring lick off the fur on their mother's belly. But like turtles and birds, a platypus has no teeth, and it reproduces by laying eggs instead of giving birth to its offspring. And like turtles, birds, lizards, snakes, and crocodilians, it has a cloaca, a multipurpose chamber through which it releases feces, urine, and eggs. Scientists had never before seen such a weird combination of traits, and they didn't quite know what to make of them.

Studies of the platypus under natural conditions have helped biologists make sense of its characteristics. The platypus inhabits streams and lagoons in Australia and Tasmania. It rests in streamside burrows during the day, but at night it slips into the water to hunt for invertebrates. Its dense fur keeps its body warm and dry under water, and its tail serves both as a rudder and as a storehouse for energy-rich fat. It uses its bill to scoop up food and the horny pads that line its jaws to grind up prey. While underwater, the platypus clamps shut its eyes, ears, and nostrils, relying on roughly 800,000 sensory receptors in its bill to detect the movements and weak electrical discharges of nearby prey.

The platypus, with its strange combination of characteristics, illustrates the remarkable diversity of adaptations that enable vertebrates—animals with backbones—to occupy nearly every

FIGURE 32.1 A puzzling animal. Because of its strange mixture of traits, the platypus *(Ornithorhynchus anatinus)* amazed the first European zoologists who saw it.

habitat on Earth. Despite the platypus's mixed characteristics, biologists eventually classified it as a member of the mammal lineage because, like all other mammals, it has hair on its body and produces milk to nourish its offspring. Today biologists know that it is one of just a few remaining survivors of an early lineage of egg-laying mammals.

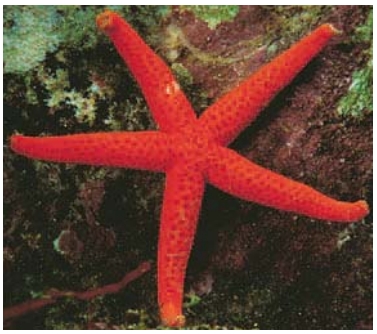
In this chapter, we survey the Deuterostomia, a monophyletic lineage of animals that dates to the Paleozoic. The deuterostomes are defined by features of early embryological development and molecular sequence data (see Chapter 31). There are three living phyla of deuterostomes; we briefly consider two phyla of invertebrate deuterostomes before focusing on the Phylum Chordata, which includes a few thousand species of invertebrates as well as many living species of vertebrates.

32.1 Invertebrate Deuterostomes

Deuterostome body plans have been so modified by evolution that a casual observer would not readily group the two phyla of invertebrate deuterostomes—Echinodermata and Hemichordata—together with the Phylum Chordata. However, embryological and molecular analyses agree that all three are indeed closely related.

Echinoderms Have Secondary Radial Symmetry and an Internal Skeleton

The phylum Echinodermata (*echinos* = spiny, *derma* = skin) includes roughly 6,000 species of sea stars, sea urchins, sea cucumbers, brittle stars, and sea lilies. These slow-moving or sessile, bottom-dwelling animals are important herbivores and predators in shallow coastal waters and the ocean depths. Although the phylum was diverse in the Paleozoic, only a remnant of that fauna remains. Living species vary in size from less than 1 cm to more than 50 cm in diameter.



Echinoderms develop from a bilaterally symmetrical, free-swimming larva. But as a larva develops, it assumes a secondary radial symmetry, often organized around five rays or "arms" **(Figure 32.2).** Many echinoderms have an *oral surface,* with the mouth facing the substrate, and an *aboral surface* facing in the opposite direction. Virtually all echinoderms have an internal skeleton made of calcium-stiffened *ossicles* that develop from mesoderm. In some groups, fused ossicles form a rigid container called a *test.* In most, spines or bumps project from the ossicles.

The internal anatomy of echinoderms is unique among animals **(Figure 32.3).** They have a well-defined coelom and a complete digestive system (see Figure 32.3A), but no excretory or respiratory systems, and most have only a minimal circulatory system. In many, gases are exchanged and metabolic wastes eliminated through projections of the epidermis and peritoneum near the base of the spines. Given their radial symmetry, there is no head or central brain; the nervous system is organized around nerve cords that encircle the mouth and branch into the rays. Sensory cells are abundant in the skin.

Echinoderms have a unique locomotor system, the *water vascular system,* which consists of fluid-filled canals (see Figure 32.3B). In a sea star, for example, water enters the system through the *madreporite,* a sievelike plate on the aboral surface. A short tube connects it to the *ring canal,* which surrounds the esophagus. The ring canal branches into five *radial canals* that extend into the arms. Each radial canal is connected to numerous *tube feet* that protrude through holes in the ossicles (see Figure 32.3C). Each tube foot has a mucus-covered, suckerlike tip and a small muscular bulb, the *ampulla,* which lies inside the body. When an ampulla contracts, fluid is forced into the tube foot, causing it to lengthen and attach to the substrate. The tube foot then contracts, pulling the animal along. As the tube foot

shortens, water flows back into the ampulla, and the tube foot releases its grip on the substrate. The tube foot can then take another step forward, reattaching to the substrate. Although each tube foot has limited strength, the coordinated action of hundreds or thousands of them is so strong that they can hold an echinoderm to a substrate even against strong wave action.

Echinoderms have separate sexes, and most reproduce by releasing gametes into the water. Radial cleavage is so clearly apparent in the transparent eggs of some sea urchins that they are commonly used for demonstrations of cleavage in introductory biology laboratories. A few echinoderms also reproduce asexually by splitting in half and regenerating the missing parts; some can regenerate body parts lost to predators.

Echinoderms are divided into six groups, one of which, the sea daisies (Concentricycloidea), was discovered only in 1986. These small, medusa-shaped animals occupy sunken, waterlogged wood in the deep sea. Here we describe the five other groups, which are more diverse and better known.

ASTEROIDEA Sea stars (Asteroidea, from *asteroeides* = starlike) live from rocky shorelines to depths of 10,000 m. The asteroid body plan consists of a central disk surrounded by 5 to 20 radiating "arms" (see Figure 32.2A), with the mouth centered on the oral surface. The ossicles of the endoskeleton are not fused, permitting flexibility of the arms and disk. Small pincers, **pedicellariae,** at the base of short spines remove debris that falls onto the animal's surface (see Figure 32.3C). Many sea stars feed on soft-bodied invertebrates and small fishes. Other species consume bivalve mollusks: after using their tube feet to pry apart the two shells, they evert their stomachs and secrete digestive enzymes onto the mollusk's flesh. Some sea stars are destructive predators of corals, endangering many reefs.

OPHIUROIDEA Brittle stars and basket stars (Ophiuroidea, from *ophioneos* = snakelike) occupy roughly the same range of habitats as sea stars. Their bodies have a well-defined central disk and slender, elongate arms that are sometimes branched (see Figure 32.2B). Ophiuroids can crawl fairly swiftly across substrates by moving their arms in coordinated fashion. As their common name implies, the arms are delicate and easily broken, an adaptation that allows them to escape from predators with only minor losses. Brittle stars feed on small prey, suspended plankton, or detritus that they extract from muddy deposits.

ECHINOIDEA Sea urchins and sand dollars (Echinoidea, *ekhinos* = porcupine) lack arms altogether (see Figure 32.2C). Their ossicles are fused into solid tests, which provide excellent protection but restrict flexibility. The test is spherical in sea urchins and flattened in sand dollars. Five rows of tube feet, used primarily for locomotion, emerge through pores in the test. Most echinoids have movable spines, some with poison glands that protect them from predators; a jab from certain tropical species can cause severe pain and inflammation to a careless swimmer. Echinoids graze on algae and other organisms that cling to marine surfaces. In the center of an urchin's oral surface is a five-part nipping jaw that is controlled by powerful muscles. Some species damage kelp beds, disrupting the habitat of young lobsters and other crustaceans.

HOLOTHUROIDEA Sea cucumbers (Holothuroidea, from *holothourion* = water polyp) are elongate animals that lie on their sides on the ocean bottom (see Figure 32.2D). Although they have five rows of tube feet, their endoskeleton is reduced to widely separated microscopic plates. The body, which is elongated along the oral–aboral axis, is soft and fleshy, with a tough, leathery covering. Modified tube feet form a ring of tentacles around the mouth, which points to the side or upward. Some species secrete a mucous net that traps plankton or other food particles. Other species extract food from bottom sediments. Many sea cucumbers exchange gases through an extensively branched *respiratory tree* that arises from the rectum, the part of the digestive system just inside the anus at the aboral end of the animal. A well-developed circulatory system distributes oxygen and nutrients to tissues throughout the body.

CRINOIDEA Sea lilies and feather stars (Crinoidea, from *krinon* = lily) are the surviving remnants of a fauna that was diverse and abundant 500 million years ago (see Figure 32.2E). Most species occupy marine waters of medium depth. The central disk and mouth point upward rather than toward the substrate. Between five and several hundred branched arms surround the disk; new arms are added as a crinoid grows larger. The branches of the arms are covered with tiny mucus-coated tube feet, which trap suspended microscopic organisms. The sessile sea lilies have the central disk attached to a flexible stalk that can reach a meter in length. Adult feather stars can swim or crawl weakly, attaching temporarily to substrates.

Acorn Worms Use A Pharynx with Branchial Slits to Acquire Food and Oxygen

The approximately 100 species of acorn worms (phylum Hemichordata, *hemi* = half, *chorda,* referring to the phylum Chordata) are sedentary marine animals that live in U-shaped tubes or burrows in coastal sand or mud. Their soft bodies, which range from 2 cm to 2 m in length, are organized into an anterior proboscis, a tentacled collar, and an elongate trunk **(Figure 32.4).** They use their muscular, mucus-coated proboscis to construct burrows and trap food particles. Acorn worms also have pairs of **branchial slits** (sometimes called *pharyngeal slits* or *gill slits*) in the pharynx, the part of the digestive system just posterior to the mouth. Beating cilia create a flow of water, which enters the pharynx through the mouth and exits through these openings. As water passes through, suspended food is trapped and shunted into the digestive system, and gases are exchanged across the partitions between the slits. This coupling of feeding and respiration reflects the evolutionary relationship between hemichordates and chordates, the phylum that we consider next.

STUDY BREAK 32.1

1. **What organ system is unique to echinoderms, and what is its function?**
2. **How does a perforated pharynx enable hemichordates to acquire food and oxygen from seawater?**

32.2 Overview of the Phylum Chordata

The phylum Chordata contains three subphyla: two lineages of invertebrates, Cephalochordata and Urochordata, and the diverse lineage of vertebrates, Vertebrata.

Key Morphological Innovations Distinguish Chordates from Other Deuterostome Phyla

Chordates are distinguished from other deuterostomes by a set of key morphological innovations: a *notochord, segmental muscles in the body wall and tail, a dorsal hollow nerve chord,* and a *perforated pharynx* **(Figure 32.5).** These structures foster higher levels of activity, unique modes of aquatic locomotion, and more efficient feeding and oxygen acquisition.

NOTOCHORD Early in chordate development, mesoderm that is dorsal to the developing digestive system forms a **notochord** (*noton* = the back; *chorda* = string). This flexible rod, constructed of fluid-filled cells surrounded by tough connective tissue, supports the embryo from head to tail. The notochord later forms the skeleton of invertebrate chordates. Body wall muscles are anchored to the notochord, and when these muscles contract, the notochord bends, but it does not shorten. As a result, the chordate body swings left and right during locomotion, propelling the animal forward; unlike annelids and other nonchordate invertebrates, the chordate body does not shorten when the animal is moving. Remnants of the notochord persist as gelatinous disks in the backbones of adult vertebrates.

SEGMENTAL BODY WALL AND TAIL MUSCLES Chordates evolved in water, and they swim by contracting segmentally arranged blocks of muscles in the body wall and tail. The chordate tail, which is posterior to the anus, provides much of the propulsion in aquatic species. Segmentation allows each muscle block to contract independently; waves of contractions pass down one side of the animal and then down the other, sweeping the body and tail back and forth in a smooth and continuous movement.

DORSAL HOLLOW NERVE CORD The central nervous system of chordates is a hollow nerve cord on the dorsal side of the animal (see Chapter 40). By contrast, most nonchordate invertebrates have solid nerve cords on the ventral side. In vertebrates, an anterior enlargement of the nerve cord forms the brain; in invertebrates, the anterior concentration of nervous system tissue is described as a *ganglion.*

PERFORATED PHARYNX Like the hemichordates described above, most chordates have outpocketings, perforations, or slits in the pharynx during some stage of the animal's life cycle. These paired openings originated as exit holes for water that carried particulate food into the mouth. Invertebrate chordates exchange gases with water as it passes by the walls of the pharynx, acquiring oxygen and eliminating carbon dioxide. Invertebrate chordates and fishes retain a perforated pharynx throughout their lives. In most air-breathing terrestrial vertebrates, the outpocketings or slits are present only during embryonic development and in larvae.

Invertebrate Chordates Are Small, Marine Suspension Feeders

Two subphyla of invertebrate chordates exhibit the basic chordate body plan in its simplest form.

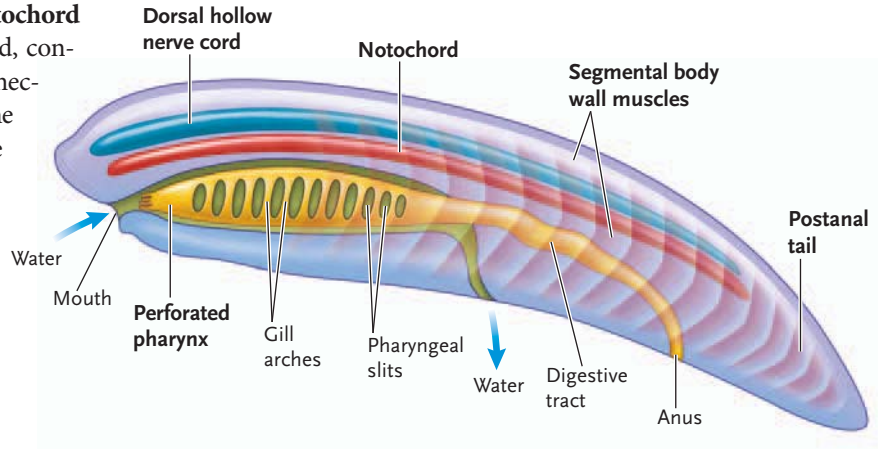

FIGURE 32.5 Diagnostic chordate characters. Chordates have a notochord; a muscular postanal tail; a segmental body wall and tail muscles; a dorsal, hollow nerve cord; and a perforated pharynx.

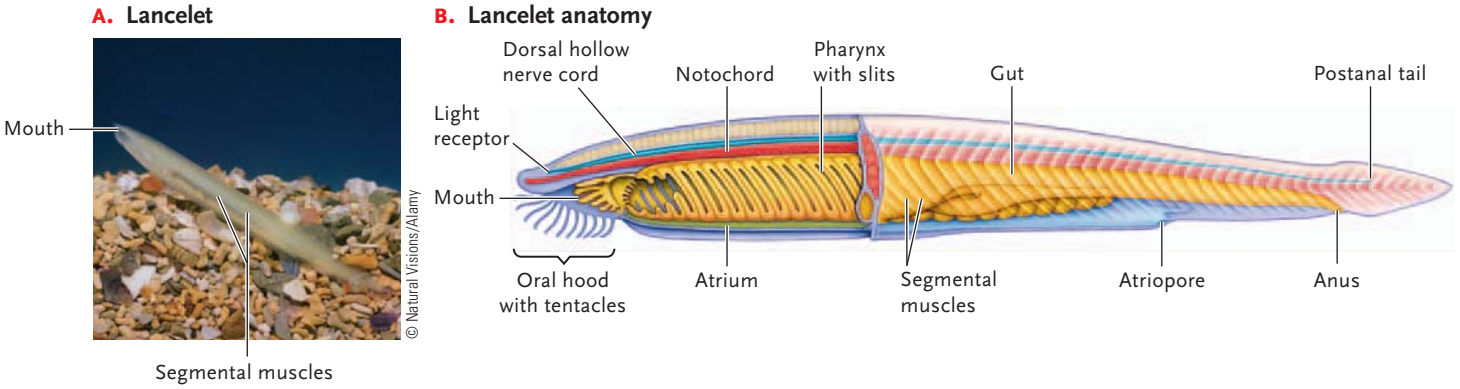

FIGURE 32.6 **Cephalochordates. (A)** The unpigmented skin of adult lancelets reveals their segmental body wall muscles. A cutaway view **(B)** illustrates their internal anatomy.
© Cengage Learning 2014

SUBPHYLUM CEPHALOCHORDATA The 28 lancelet species (subphylum Cephalochordata, *kephale* = head) occupy warm, shallow marine habitats where they lie mostly buried in sand **(Figure 32.6).** Although generally sedentary, they have well-developed body wall muscles and a prominent notochord. Most species are included in the genus *Branchiostoma* (formerly *Amphioxus*). Lancelet bodies, which are 5 to 10 cm long, are pointed at both ends like the double-edged surgical tools for which they are named. Adults have light receptors on the head as well as chemical sense organs on tentacles that grow from the **oral hood.** Lancelets use cilia to draw food-laden water through hundreds of pharyngeal slits; water flows into the atrium and is expelled through the **atriopore.** Most gas exchange occurs across the skin.

SUBPHYLUM UROCHORDATA The 2,500 species of tunicates, sometimes called sea squirts (subphylum Urochordata, from *oura* = tail), float in surface waters or attach to substrates in shallow marine habitats. The sessile adults of many species secrete a gelatinous or leathery "tunic" around their bodies and squirt water through a siphon when disturbed; adults grow to several centimeters **(Figure 32.7).** In the most common group of sea squirts (Ascidiacea), the swimming larvae possess the defining chordate features. Larvae eventually attach to substrates and transform into sessile adults. During metamorphosis, they lose most traces of the notochord, dorsal nerve cord, and tail, and their basketlike pharynx enlarges. In adults, beating cilia pull water into the pharynx through an **incurrent siphon.** A mucous net traps particulate food, which is carried, with the mucus, to the gut. Water passes through the pharyngeal slits, enters a chamber called the **atrium,** and is expelled—along with digestive wastes and carbon dioxide—through the **atrial siphon.** Oxygen is absorbed across the walls of the pharynx.

Vertebrates Possess Several Unique Tissues, Including Bone and Neural Crest

The most distinctive anatomical characteristic of the subphylum Vertebrata is an internal skeleton that provides structural support for muscles and protection for the nervous system and other organs. The skeleton—and the muscles attached to it—also enable most vertebrates to move rapidly through the environment. A vertebrate's skeleton is composed of many separate, bony elements. Indeed, vertebrates are the only animals

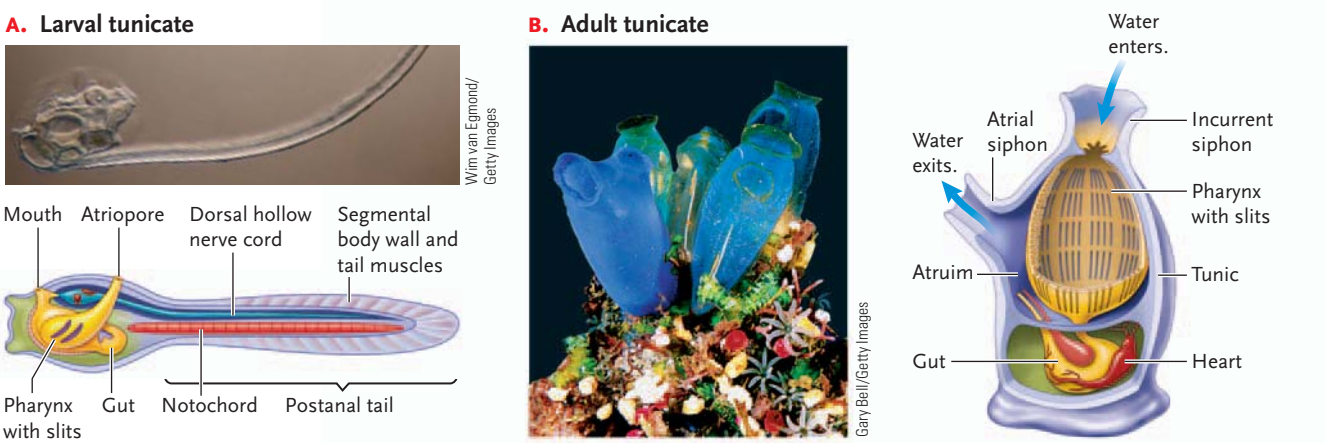

FIGURE 32.7 **Urochordates. (A)** A tadpolelike tunicate larva metamorphoses into **(B)** a sessile adult. After a larva attaches to a substrate at its anterior end, the tail, notochord, and most of the nervous system are recycled to form new tissues. Slits in the pharynx multiply, the mouth becomes the incurrent siphon, and the atriopore becomes the atrial siphon.

that have **bone,** a connective tissue in which living cells secrete the mineralized matrix that surrounds them (see Figure 38.4D). The **vertebral column,** made up of individual **vertebrae,** surrounds and protects the dorsal nerve cord, and a bony **cranium** surrounds the brain. The cranium, vertebral column, ribs, and sternum (breastbone) make up the **axial skeleton.** Most vertebrates also have a **pectoral girdle** anteriorly and a **pelvic girdle** posteriorly that attach bones in the fins or limbs to the axial skeleton. Bones of the two girdles and the appendages constitute the **appendicular skeleton.** One vertebrate lineage, Chondrichthyes, has lost its bone over evolutionary time; its skeleton is made of cartilage, a dense but flexible connective tissue that is often a developmental precursor of bone (see Section 38.2).

Vertebrates also possess a unique cell type, **neural crest,** which is distinct from endoderm, mesoderm, and ectoderm. Neural crest cells arise next to the developing nervous system, but later migrate throughout a vertebrate's body. They ultimately contribute to many uniquely vertebrate structures, including parts of the cranium, teeth, sensory organs, cranial nerves, and the medulla (that is, the interior part) of the adrenal glands.

Finally, the brains of vertebrates are much larger and more complex than those of invertebrate chordates. Moreover, the vertebrate brain is divided into three regions—the forebrain, midbrain, and hindbrain—each of which governs distinct nervous system functions (see Section 40.1).

2. **What structures distinguish vertebrates from invertebrate chordates?**

32.3 The Origin and Diversification of Vertebrates

Biologists use embryological, molecular, and fossil evidence to trace the origin of vertebrates and to chronicle their evolutionary diversification.

Vertebrates Probably Arose from an Invertebrate Chordate Ancestor through the Duplication of Genes That Regulate Development

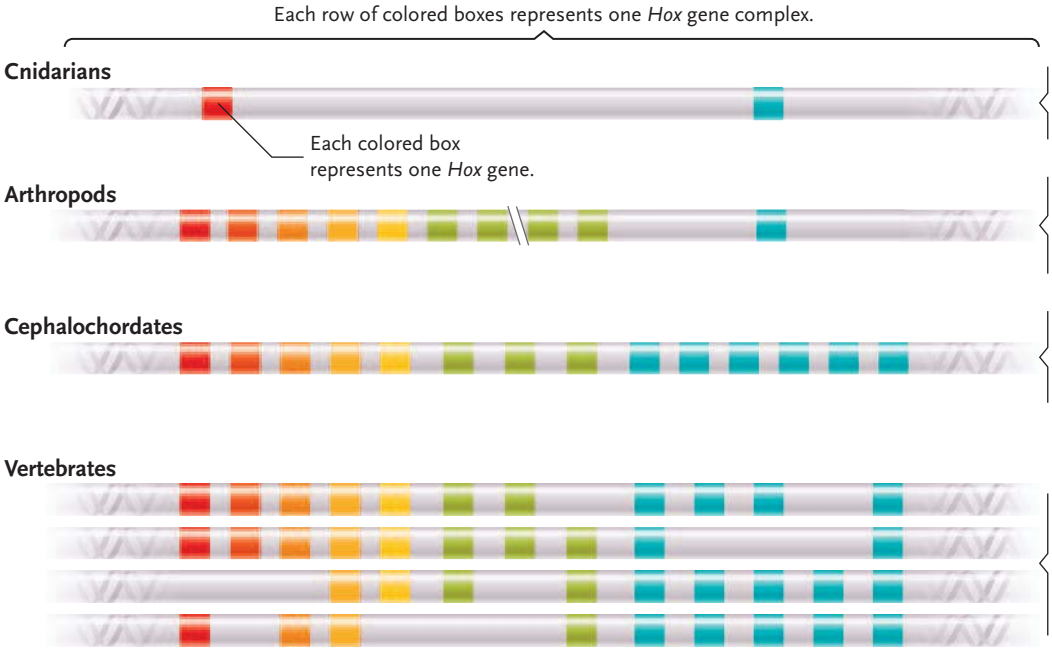
Recent genetic sequence studies suggest that vertebrates are more closely related to urochordates than to cephalochordates. Nevertheless, the fishlike form of adult lancelets probably better represents the anatomy of the earliest vertebrates than does the highly specialized morphology of adult tunicates. The evolution of vertebrates from an invertebrate chordate ancestor was marked by the emergence of neural crest, bone, and other typically vertebrate traits. What genetic changes were responsible for these remarkable developments? Biologists now hypothesize that an increase in the number of homeotic—structure determining—genes may have made the development of more complex anatomy possible. (Homeotic genes are described in Sections 16.4, 20.3, and 23.6.)

In animals, one group of homeotic genes, the *Hox* genes, influences the three-dimensional shape of the animal and the locations of important structures—such as eyes, wings, and legs—particularly along the head-to-tail axis of the body. *Hox* genes are arranged on the chromosomes in a particular order, forming what biologists call the *Hox* gene complex (see Section 23.6 and Chapter 36). Each gene in the complex governs the development of particular structures. Animal groups with the simplest structure, such as cnidarians, have two *Hox* genes. Those with more complex anatomy, such as insects, have 10. Chordates have as many as 13 or 14. Thus, lineages with many *Hox* genes generally have more complex anatomy than do those with fewer *Hox* genes.

Molecular analyses also reveal that the entire *Hox* gene complex was duplicated several times in the evolutionary history of vertebrates, producing multiple copies of all its genes **(Figure 32.8).** The cephalochordate *Branchiostoma* has just one *Hox* gene complex, but the most primitive living vertebrates, the jawless hagfishes described later, have two. All vertebrates that possess jaws, a derived characteristic, have at least four sets, and some fishes have as many as seven. Evolutionary developmental biologists hypothesize that after the wholesale duplication of *Hox* genes and other tool-kit genes, the original copies of these genes maintained their ancestral functions, but the duplicate copies assumed *new* functions, directing the development of novel structures, such as the vertebral column and jaws.

Early Vertebrates Diversified into Numerous Lineages with Distinctive Adaptations

The oldest known vertebrate fossils were discovered in the late 1990s, when scientists in China described several species from the early Cambrian period, about 550 million years ago. Both *Myllokunmingia* and *Haikouichthys* were fish-shaped animals about 3 cm long **(Figure 32.9).** In both species the brain was surrounded by a cranium, which, in these cases, was formed of fibrous connective tissue or cartilage. They also had segmented body-wall muscles and fairly well-developed fins, but neither shows any evidence of bone.



The early vertebrates gave rise to numerous descendants, which varied greatly in anatomy, physiology, and ecology. New feeding mechanisms and locomotor structures were often crucial to their success. Today, vertebrates occupy nearly every habitat and feed on virtually all other organ-

CLOSER LOOK

FIGURE 32.8 *Hox* genes and the evolution of vertebrates.

The *Hox* genes in different animal groups appear to be homologous, indicated here by their color and position in the complex.

A. Invertebrates with simple anatomy, such as cnidarians, have a single *Hox* gene complex that includes just a few *Hox* genes.

B. Invertebrates with more complicated anatomy, such as arthropods, have a single *Hox* gene complex, but with a larger number of *Hox* genes.

C. Invertebrate chordates, such as cephalochordates, also have a single *Hox* gene complex, but with even more *Hox* genes than are found in nonchordate invertebrates.

D. Vertebrates, such as the laboratory mouse, have numerous *Hox* genes, arranged in two to seven *Hox* gene complexes. The additional *Hox* gene complexes are products of wholesale duplications of the ancestral *Hox* gene complex.

SUMMARY Vertebrates have many more individual *Hox* genes than most invertebrates do because the entire *Hox* gene complex was duplicated in the vertebrate lineage. The additional copies of *Hox* genes probably evolved to specify the development of uniquely vertebrate characteristics, such as the cranium, vertebral column, and neural crest cells.

THINK LIKE A SCIENTIST Given the information available to you in this figure, what change in overall body plan accompanied the evolution of an increased number of *Hox* genes *within* the *Hox* gene complex.

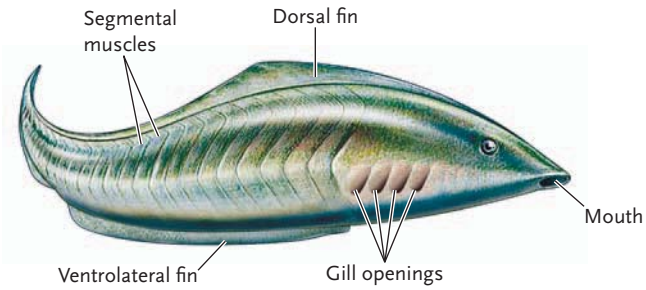

FIGURE 32.9 An early vertebrate. *Myllokunmingia,* one of the earliest vertebrates yet discovered, had no bones; it was about 3 cm long.

© Cengage Learning 2014

isms. Here we briefly introduce the major vertebrate lineages **(Figure 32.10).**

Although biologists use four key morphological innovations—a cranium, vertebrae, bone, and neural crest cells—to identify vertebrates, these structures did not arise all at once. Instead, they appeared somewhat independently of one another as new groups arose. Some researchers and textbooks present a phylogeny and classification that places the "vertebrates" (animals that have vertebrae) within a larger lineage called the "craniates" (animals that have a cranium). But only one small group, the hagfishes (Myxinoidea, described later), has a cranium but no vertebrae, and some recent molecular analyses do not support its separation from the other vertebrates. Thus, for the sake of simplicity, we describe organisms that possessed any of the four key innovations as "vertebrates."

Several groups of early jawless vertebrates are *described* as "agnathans" (*a* = not, *gnathos* = jaw), but they do not form a monophyletic group (that is, one that includes an ancestor and all of its descendants). Although most became extinct in the Paleozoic era, two ancient lineages, Myxinoidea and Petromyzontoidea, still live today. All other vertebrates possess moveable jaws; they are members of the monophyletic lineage **Gnathostomata** ("jawed mouth"). Some early clades of jawed fishes, the Acanthodii and Placodermi, are now extinct. But three lineages of jawed fishes are still abundant in aquatic

habitats: the Chondrichthyes, such as sharks and skates, have cartilaginous skeletons; the Actinopterygii and Sarcopterygii have bony skeletons. All jawless vertebrates and jawed fishes are restricted to aquatic habitats, and they use gills to extract oxygen from the water that surrounds them.

The Gnathostomata also includes the monophyletic lineage **Tetrapoda** (*tetra* = four, *pod* = foot); most tetrapods use four limbs for locomotion. Many tetrapods are semiterrestrial or terrestrial, although some, like sea turtles and porpoises, have secondarily returned to aquatic habitats. Adult tetrapods generally use air-breathing lungs for gas exchange. Within the Tetrapoda, one lineage, the amphibians, includes animals, such as frogs and salamanders, that typically need standing water to complete their life cycles. Another lineage, the **Amniota,** comprises animals with specialized eggs that can develop on land. Since their appearance, the amniotes diversified into lineages that include mammals, turtles, lizards, snakes, alligators, and birds. We consider the detailed evolutionary history of the amniotes in Section 32.7.

STUDY BREAK 32.3

1. How do the *Hox* genes of vertebrates differ from those of cephalochordates?
2. Which of the taxonomic groups Amniota, Gnathostomata, and Tetrapoda includes the largest number of species? Which includes the fewest?

32.4 "Agnathans": Hagfishes and Lampreys, Conodonts and Ostracoderms

The earliest vertebrates lacked jaws, but they had a muscular pharynx, which they used to suck edible tidbits into their mouths. Although they do not form a monophyletic group, we describe four groups of jawless vertebrates together because their ancestral jawless condition distinguishes them from the monophyletic Gnathostomata. The two living groups of agnathans as well as species that flourished in the Paleozoic vary greatly in size and shape as well as in the number of vertebrate characters they possess.

Hagfishes and Lampreys Are the Living Descendants of Ancient Agnathan Lineages

Two apparently separate lineages of jawless vertebrates, hagfishes (Myxinoidea) and lampreys (Petromyzontoidea), still live today. Both have skeletons composed entirely of cartilage. Although scientists have found no fossilized hagfishes or lampreys from the early Paleozoic era, the absence of both jaws and bone in these groups suggests that their lineages arose early in vertebrate history, before the evolution of bone. Hagfishes and lampreys have a well-developed notochord, but no true vertebrae or paired fins, and their skin has no scales. Individuals grow to a maximum length of about 1 m **(Figure 32.11).**

The axial skeleton of the 60 living species of hagfishes includes only a cranium and a notochord; it has no specialized structures surrounding the dorsal nerve cord. Some biologists

do not even include hagfishes among the Vertebrata, because they lack any sign of vertebrae. Hagfishes are marine scavengers that burrow in sediments on continental shelves. They feed on invertebrate prey and on dead or dying fishes. In response to predators, they secrete an immense quantity of sticky, noxious slime; when no longer threatened, a hagfish ties itself into a knot and wipes the slime from its body. Hagfish life cycles are simple and lack a larval stage.

The 40 or so living species of lampreys have traces of an axial skeleton. Their notochord is surrounded by dorsally pointing cartilages that partially cover the nerve cord; many biologists hypothesize that this arrangement reflects an early stage in the evolution of the vertebral column. Most lamprey species are parasitic as adults. They have a circular mouth surrounded by a sucking disk with which they attach to a fish or other vertebrate host; they feed on a host's body fluids after rasping through its skin. In most species, sexually mature adults migrate from the ocean or a lake to the headwaters of a stream, where they lay eggs and then die. Their suspension-feeding larvae, which resemble adult cephalochordates, burrow into mud and develop for as long as seven years before undergoing metamorphosis and migrating to the sea or a lake to live as parasitic adults.

Conodonts and Ostracoderms Were Early Jawless Vertebrates with Bony Structures

Mysterious bonelike fossils, most less than 1 mm long, have long been known in oceanic rocks dating from the early Paleozoic era through the early Mesozoic era. Called **conodont** ("cone tooth") elements, these abundant fossils were once described as the support structures of marine algae or the feeding structures of ancient invertebrates. However, recent analyses of their mineral composition reveal that they were made of dentine, a bonelike component of vertebrate teeth. In the 1980s and 1990s, several research teams discovered fossils of intact conodont animals with these elements in place.

Conodonts were elongate, soft-bodied animals; most were 3 to 10 cm long. They had a notochord, cranium, segmental body wall muscles, and large, moveable eyes **(Figure 32.12A).** The conodont elements at the front of the mouth were forward pointing, hook-shaped structures that apparently functioned to collect food; those in the pharynx were stouter, suitable for crushing small items that had been consumed. Paleontologists now classify conodonts as vertebrates—the earliest vertebrates with bonelike structures.

An assortment of jawless fishes, representing several evolutionary lineages and collectively described as **ostracoderms** (*ostrakon* = shell), was abundant from the Ordovician through the Devonian periods **(Figure 32.12B).** Like their invertebrate chordate ancestors, ostracoderms used their pharynx to extract small food particles from mud and water. However, the ostracoderms' muscular pharynx enabled them to *suck* mud and water into their mouths, providing a much stronger flow than the cilia-driven currents of invertebrate chordates. The greater flow rate allowed ostracoderms to collect food more rapidly. It also supported a larger body size: although most species were small, some ostracoderms reached a length of 2 m.

The skin of ostracoderms was heavily armored with bony plates and scales. Although some ostracoderms had paired lateral extensions of their armor, they could not move them the way living fishes move their paired fins. Ostracoderms lacked a true vertebral column, but some had rudimentary support structures surrounding the nerve cord. They also had other distinctly vertebrate-like characteristics. For example, imprints in the head shields of some species indicate that their brains had the three regions—forebrain, midbrain, and hindbrain—typical of all later vertebrates (see Section 40.1).

STUDY BREAK 32.4

1. **What characteristics of the living hagfishes and lampreys suggest that their lineages arose very early in vertebrate evolution?**
2. **What traits in conodonts and ostracoderms are derived relative to those in hagfishes and lampreys?**

A. Jaws evolved from gill arches in the pharynx of jawless fishes.

B. In early jawed fishes, the upper jaw was firmly attached to the cranium.

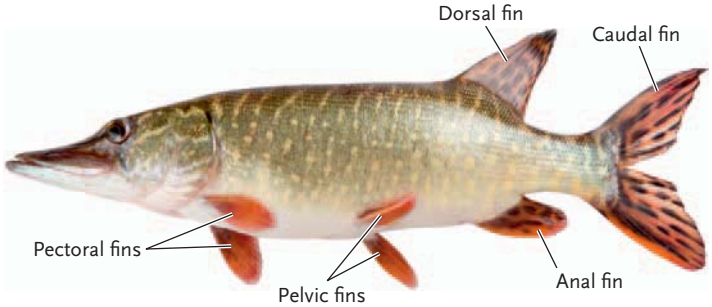
C. In later jawed fishes, the jaws were supported by the hyomandibular bones, which were derived from a second pair of gill arches.

32.5 Gnathostomata: The Evolution of Jaws

The first gnathostomes were jawed fishes. Key derived traits made their feeding and locomotion more efficient than those of their ancestors.

Jawed Fishes First Appeared in the Paleozoic Era

The renowned anatomist and paleontologist Alfred Sherwood Romer of Harvard University described the evolution of jaws as "perhaps the greatest of all advances in vertebrate history." Hinged jaws allow vertebrates to grasp, kill, shred, and crush large food items. Some living species also use their jaws for defense, for grooming, to construct nests, and to transport their young.



THE ORIGIN OF JAWS AND FINS Embryological evidence suggests that jaws evolved from paired **gill arches**—cartilaginous or bony supporting structures between the gill slits—in the pharynx of a jawless ancestor **(Figure 32.13).** One pair of ancestral gill arches formed bones in the upper and lower jaws, while a second pair was transformed into the hyomandibular bones that braced the jaws against the cranium. Nerves and muscles of the ancestral suspension-feeding pharynx control and move the jaws.

Innovative locomotor mechanisms have often appeared at roughly the same time as innovative feeding mechanisms in the vertebrate lineage; selection probably favored individuals that had the ability to pursue and capture a large range of animal prey as well as feed on them. Thus, many early jawed fishes also had fins. The earliest fins were folds of skin and moveable spines that stabilized locomotion and deterred predators. Moveable fins appeared independently in several lineages, and by the Devonian period, most fishes had unpaired (dorsal, anal, and caudal) and paired (pectoral and pelvic) fins **(Figure 32.14).**

EARLY JAWED FISHES In two early lineages of jawed fishes, spiny sharks and placoderms, the upper jaw was firmly attached to the cranium (see Figure 32.13B); their inflexible mouths simply snapped open and shut **(Figure 32.15).** Both groups also show evidence of an internal skeleton.

Spiny sharks (Acanthodii, *akantha* = thorn), which persisted from the late Ordovician through the Permian periods, were less than 20 cm long. Their small, light scales, streamlined bodies, well-developed eyes, large jaws, and numerous teeth suggest that they were fast swimmers and efficient predators. Most had a row of ventral spines and fins with internal skeletal support on each side of the body. Acanthodian anatomy suggests that they are closely related to the bony fishes living today.

Placoderms (Placodermi, *plax* = flat surface) appeared in the Silurian and diversified in the Devonian and Carboniferous

periods, but they left no direct descendants. Some, like *Dunkleosteus,* reached a length of 10 m. The anterior part of the placoderm body was covered by heavy bony plates and the posterior part by smaller, bony scales. Their jaws had sharp cutting edges, but not separate teeth, and their paired fins had internal skeletons and powerful muscles.

Chondrichthyes Includes Fishes with Cartilaginous Endoskeletons

The 850 living species in the Chondrichthyes (*khondros* = cartilage, *ikhthys* = fish) have skeletons composed entirely of cartilage, which is much lighter than bone. In most vertebrates, the internal skeleton is first formed of cartilage, but the cartilage is gradually replaced by bone during embryonic development (see Section 38.2). Apparently, some mutation or mutations eliminated the second, bone-forming step in this process when this lineage arose. Because all fishes that lived before the appearance of Chondrichthyes had either bony armor or bony endoskeletons, biologists conclude that the absence of bone in Chondrichthyes is a derived, not an ancestral, trait.

Most living chondrichthyans are grouped in the Elasmobranchii, which includes the skates, rays, and sharks; nearly all are marine predators **(Figure 32.16).** Skates and rays are dorsoventrally flattened (see Figure 32.16A). They swim by undulating their enlarged pectoral fins. Most are bottom dwellers that often lie partly buried in sand. They feed on hard-shelled invertebrates, which they crush with massive, flattened teeth. The largest species, the manta ray *(Manta birostris),* which measures 6 m across, feeds on plankton in the open ocean. Some rays have electric organs that stun prey with as much as 200 volts.

Sharks (see Figure 32.16B) are among the ocean's dominant predators. Flexible fins, lightweight skeletons, streamlined bodies, and the absence of heavy body armor allow most sharks to pursue prey rapidly. Their large livers contain copious amounts of oil, which is lighter than water, increasing their buoyancy. The great white shark *(Carcharodon carcharias)* is the largest predatory species, attaining a length of 10 m. The whale shark *(Rhincodon typus),* which grows to 18 m, is the largest fish known; it feeds on plankton.

Elasmobranchs—including sharks, skates, and rays—exhibit remarkable adaptations for acquiring and processing food. Their teeth develop in whorls under the fleshy parts of the mouth (Figure 32.16D). New teeth migrate forward as old, worn teeth break free. In many sharks, the upper jaw is loosely attached to the cranium, and it swings down during feeding. As the jaws open, the mouth spreads widely, sucking in large,

hard-to-digest chunks of prey, which are swallowed intact. Although the elasmobranch digestive system is short, it includes a corkscrew-shaped **spiral valve,** which slows the passage of material and increases the surface area available for digestion and absorption.

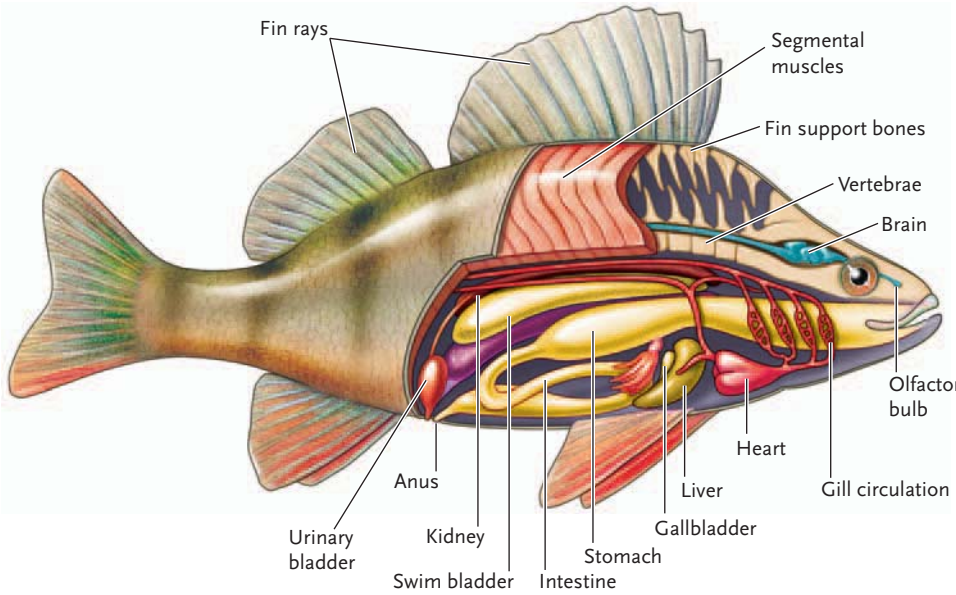
Elasmobranchs also have well-developed sensory systems. In addition to vision and olfaction, they use **electroreceptors** to detect weak electric currents produced by other animals. And their **lateral-line system,** a row of tiny sensors in canals along both sides of the body, detects vibrations in water (see Figure 41.5).

Chondrichthyans exhibit numerous reproductive specializations. Males have a pair of organs, the **claspers,** on the pelvic fins, which help transfer sperm into the female's reproductive tract. Fertilization occurs internally. In many species, females produce large, yolky eggs with tough, leathery shells (see Figure 32.16C). Others retain the eggs within the oviduct until the young hatch. A few species nourish young within a uterus.

The Actinopterygii and Sarcopterygii Are Fishes with Bony Endoskeletons

In terms of diversity and sheer numbers, the fishes with bony endoskeletons—a cranium, vertebral column with ribs, and bones supporting their moveable fins—are the most successful of all vertebrates. The endoskeleton provides lightweight support, particularly compared with the heavy bony armor of ostracoderms and placoderms, and enhances their locomotor efficiency. Fishes with bony endoskeletons first appeared in the Silurian period and rapidly diversified into two lineages. The ray-finned fishes (Actinopterygii, *aktis* = ray, *pteron* = wing) have fins that are supported by thin and flexible bony rays. The fleshy-finned fishes (Sarcopterygii, from *sarco* = flesh) have fins that are supported by muscles and an internal bony skeleton. Ray-finned fishes have always been more diverse, and they vastly outnumber the fleshy-finned fishes today. The 21,000 living species of bony fishes occupy nearly every aquatic habitat and represent more than 95% of living fish species. Adults range from 1 cm to more than 6 m in length.

Bony fishes have numerous adaptations that increase their swimming efficiency. In many modern ray-finned fishes, a gas-filled **swim bladder** serves as a hydrostatic organ that increases buoyancy (see Figure 32.18A). The swim bladder is derived from an ancestral air-breathing lung that allowed early actinopterygians to gulp air, supplementing their gill respiration in aquatic habitats where dissolved oxygen concentration was low. The scales of most bony fishes are small, smooth, and lightweight. And their bodies are covered with a protective coat of mucus, which retards bacterial growth and smoothes the flow of water.



ACTINOPTERYGII The most primitive living actinopterygians, sturgeons and paddlefishes, have mostly cartilaginous skeletons **(Figure 32.17A).** These large fishes live in rivers and lakes of the northern hemisphere. Sturgeons feed on detritus and invertebrates; paddlefish consume plankton. Gars and bowfins are remnants of a more recent radiation **(Figure 32.17B).** They occur only in the eastern half of North America, where they feed on fishes and other prey. Gars are protected from predators by a heavy coat of bony scales.

Teleosts, the latest radiation of Actinopterygii, are the most diverse, successful, and familiar bony fishes. Evolution has produced a wide range of body forms **(Figure 32.18).** Teleosts have an internal skeleton made almost entirely of bone. On either side of the head, a flap of the body wall, the **operculum,** covers a chamber that houses the gills. Sensory systems generally include large eyes, a lateral-line system, sound receptors, chemoreceptive nostrils, and taste buds. Variations in jaw structure allow different teleosts to consume plankton, seaweed, invertebrates, or other vertebrates.

Teleosts exhibit remarkable feeding and locomotor adaptations. When some teleosts open their mouths, bones at the front of the jaws swing forward to create a circular opening. Folds of skin extend backward, forming a tube through which they suck food (see Figure 32.18F). Many also have symmetrical caudal fins, posterior to the vertebral column, which provide power for locomotion. And their pectoral fins lie high on the sides of the body, providing fine control over swimming. Some species use their pectoral fins for acquiring food, for courtship, and for care of eggs and young. Some teleosts even use them for crawling on land or gliding in air.

Most marine species produce small eggs that hatch into planktonic larvae. Eggs of freshwater teleosts are generally larger and hatch into tiny versions of the adults. In freshwater species, parents often care for their eggs and young, fanning oxygen-rich water over them, removing fungal growths, and

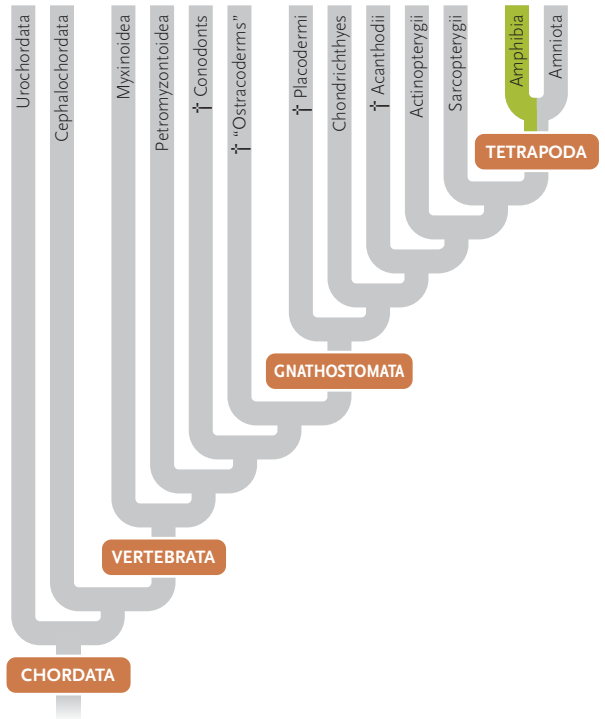
protecting them from predators. Some freshwater species, such as guppies, give birth to live young.

SARCOPTERYGII Two groups of fleshy-finned fishes (Sarcopterygii), the lobe-finned fishes and lungfishes, are now represented by only eight living species **(Figure 32.19).**



Although lobe-finned fishes were once thought to have been extinct for 65 million years, a living coelacanth *(Latimeria chalumnae)* was discovered in 1938 near the Comoros Islands, off the southeastern coast of Africa. We now know that a population of this meter-long fish lives at depths of 70 to 600 m, feeding on fishes and squid. Remarkably, a second population of coelacanths was discovered in 1998, when a specimen was found in an Indonesian fish market, 10,000 km east of the Comoros population. Based on analyses of its DNA, it is a distinct species *(Latimeria menadoensis).*

Lungfishes have changed relatively little over the last 200 million years. Six living species are distributed on southern continents. The Australian lungfishes, which live in rivers and pools, use their lungs to supplement gill respiration when dissolved oxygen concentration is low. The South American and African species, which live in swamps, use their lungs to collect oxygen during the annual dry season, which they spend encased in a mucus-lined burrow in the dry mud. When the rains begin, water fills the burrow and the fishes awaken from dormancy.

STUDY BREAK 32.5

1. What characteristics of sharks and rays make them more efficient predators than the acanthodians or placoderms?
2. How do the air bladder and fins of ray-finned bony fishes increase their locomotor abilities?
3. How do the lungs of lungfishes allow them to survive in stressful environments?

32.6 Tetrapoda: The Evolution of Limbs

The fossil record suggests that tetrapods arose from a group of fleshy-finned fishes, the *osteolepiforms,* in the late Devonian period, about 380 million years ago. Osteolepiforms and early tetrapods shared several derived characteristics: both had curious infoldings of their tooth surfaces, a trait with unknown function, and the shapes and positions of bones of the skulls and appendages were similar **(Figure 32.20).**

Key Adaptations Facilitated the Transition to Land

Fishes are not adapted to live on land, and the first tetrapods faced serious environmental challenges. First, because air is less dense than water, it provides less support for an animal's body. Second, animals exposed to air inevitably lose body water by evaporation. Third, the sensory systems of fishes, which work well under water, do not function well in air. However, swampy, late-Devonian habitats also offered distinct

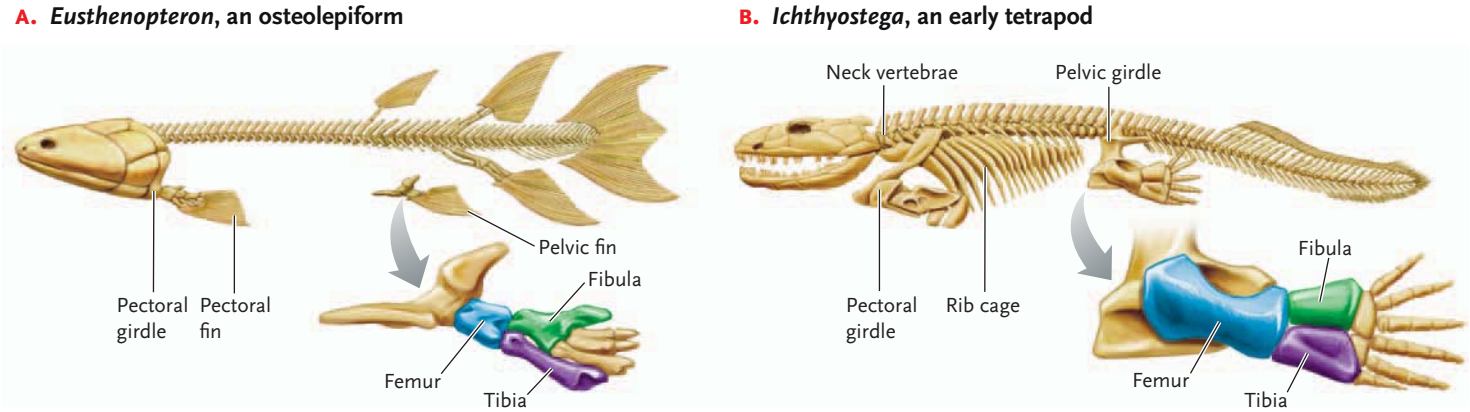

FIGURE 32.20 **Evolution of tetrapod limbs. (A)** The limb skeleton of osteolepiform fishes is homologous to that of **(B)** early tetrapods. Although *Ichthyostega* retained many fishlike characteristics, its pectoral girdle was completely freed from the cranium and it had a heavy rib cage. Fossils of its forefoot have not yet been discovered.

© Cengage Learning 2014

advantages. Land plants, soft-bodied invertebrates, and arthropods provided abundant food, oxygen was more readily available in air than in water, and predators did not yet live in these new habitats.

In some ways, osteolepiforms had characteristics that may have facilitated the transition to land (see Figure 32.20A). Most had strong, stout fins that enabled them to crawl on the muddy bottom of shallow pools, and their vertebral column included crescent-shaped bones that provided good support. They had nostrils leading to sensory pits that housed olfactory ("smell") receptors. And they almost certainly had lungs to augment gill respiration in the swampy, oxygen-poor waters where they lived.

The earliest tetrapod for which we have nearly complete skeletal data is the semiterrestrial, meter-long *Ichthyostega* (see Figure 32.20B), which lived about 365 million years ago. Compared with its fleshy-finned ancestors, *Ichthyostega* had a stronger vertebral column, sturdier girdles and appendages, a rib cage that protected its internal organs (including lungs), and a neck. In fishes the pectoral girdle is fused to the cranium; thus, fishes have no neck. But in *Ichthyostega,* several vertebrae separated the head from the body, allowing this early tetrapod to move its head to scan the environment and to capture food. However, *Ichthyostega* retained a fishlike lateral-line system, caudal fin, and scaly covering on its body.

Life on land also required changes in sensory systems. In fishes, for example, the body wall picks up sound vibrations and transfers them to sensory receptors directly. But sound waves are harder to detect in air. Early tetrapods developed a **tympanum,** a specialized membrane on either side of the head that is vibrated by airborne sounds. The tympanum connects to the **stapes,** a bone that is homologous to the hyomandibula, which had supported the jaws of fishes (see Figure 24.6). The stapes, in turn, transfers vibrations to the sensory cells of an inner ear.

Modern Amphibians Are Very Different from Their Paleozoic Ancestors

Most of the more than 6,000 species of living amphibians—including frogs, salamanders, and caecelians—are small, and their skeletons contain less bone than those of Paleozoic tetrapods like *Ichthyostega.* All living amphibians are carnivorous as adults, but the aquatic larvae of some species are herbivores.

Most living amphibians have a thin, scaleless skin, well supplied with blood vessels, that is a major site of gas exchange. Because gases must enter the body across a thin layer of water, the skin of most amphibians must remain moist, restricting them to aquatic or wet terrestrial habitats. Adults of some species also acquire oxygen through saclike lungs. The evolution of lungs was accompanied by modifications of the heart and circulatory system that increase the efficiency with which oxygen is delivered to body tissues (see Section 42.1).

The life cycles of many amphibians (*amphi* = of both kinds, *bios* = life) include both larval and adult stages. Eggs are laid and fertilized in water, where they hatch into larvae, such as the tadpoles of frogs, which eventually metamorphose into adults (see Figure 42.8). Although the larvae of many species are aquatic, adults may be aquatic, amphibious, or terrestrial. Some salamanders are paedomorphic; the larval stage attains sexual maturity without changing its form or moving to land. By contrast, some frogs and salamanders reproduce on land and skip the larval stage altogether. But even though they are terrestrial breeders, their eggs dry out quickly unless they are laid in moist places.

Modern amphibians are represented by three lineages **(Figure 32.21).** Populations of practically all amphibian species have declined rapidly in recent years, probably because of exposure to environmental pollutants and fungal infections (see Chapter 55).

ANURA The 6,400 species of frogs and toads have short, compact bodies, and adults lack tails. Their elongate hind legs and webbed feet allow them to hop on land or swim. A few species

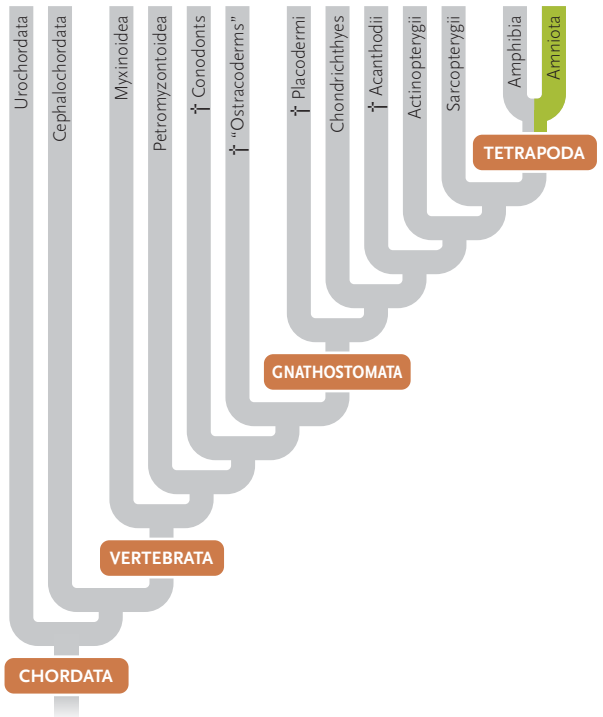
FIGURE 32.21 **Living amphibians. (A)** Frogs and toads have compact bodies and long hind legs; their larvae (inset), called tadpoles, are legless and rely on their tails for locomotion. **(B)** Salamanders and newts have an elongate body and four legs. **(C)** Caecelians are legless, burrowing amphibians.

are adapted to dry habitats, withstanding periods of drought by encasing themselves in mucous cocoons.



CAUDATA Most of the 580 species of salamanders and newts have an elongate, tailed body and four legs. They walk by alternately contracting muscles on either side of the body much the way fishes swim. Species in the most diverse group, the lungless salamanders, are fully terrestrial throughout their lives, using their skin and the lining of the throat for gas exchange.

GYMNOPHIONA The 170 species of caecelians (Gymnophiona, from *gymnos* = naked, *ophioneos* = snakelike) are legless burrowing amphibians with wormlike bodies. They occupy tropical habitats throughout the world. Unlike other modern amphibians, caecelians have small bony scales embedded in their skin. Fertilization is internal, and females give birth to live young.

STUDY BREAK 32.6

1. For the first tetrapods, what were the advantages and disadvantages of moving onto the land?
2. What parts of the life cycle in most modern amphibians are dependent on water or very moist habitats?

32.7 Amniota: The Evolution of Fully Terrestrial Vertebrates

The amniote lineage arose about 320 million years ago, during the Carboniferous period, when seed plants and insects, which served as excellent food resources, began to occupy higher ground. The lineage is named for the amnion, a fluid-filled sac that surrounds the embryo during development.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Key Adaptations Allow Amniotes to Live a Fully Terrestrial Life

Based on the abundance and diversity of their fossils, amniotes were extremely successful, quickly replacing many nonamniote species in terrestrial habitats. Although the fossil record includes abundant skeletons of early amniotes, it provides little direct information about their soft body parts and physiology. For amniotes living today, three key adaptations allow them to live in dry habitats, freeing them from a dependency on moist surroundings and standing water. First, they have a tough, dry skin. The skin cells are filled with keratin and lipids, substances that are relatively impermeable to water. Thus, amniotes do not dehydrate in air as quickly as amphibians do.

Second, many amniotes produce an **amniote egg,** which can survive and develop on dry land. The eggs of modern reptiles and birds have four specialized membranes and a hard or leathery shell **(Figure 32.22).** The membranes protect the developing embryo and facilitate gas exchange and excretion; the shell, which is perforated by microscopic pores, mediates the exchange of air and water between the egg and its environment. The egg also includes generous supplies of **yolk,** the embryo's main energy source, and **albumin,** a source of nutrients and water. Compared with those of amphibians, amniote eggs are large; and, as amniotes lack a larval stage, the young hatch as miniature versions of the adult. In contrast to reptiles and birds, the eggs of virtually all mammals lack a shell. Instead, mammalian embryos, which have the same four membranes associated with them, implant in the wall of the mother's uterus and receive nutrients and oxygen directly from her.

Third, many amniotes produce uric acid as a waste product of nitrogen metabolism (see Chapter 48). By contrast, fishes and amphibians produce ammonium ions or urea, toxic materials that require lots of water to flush them from body tissues. Because uric acid is less toxic than these other compounds, it can be excreted as a semisolid paste, which conserves body water.

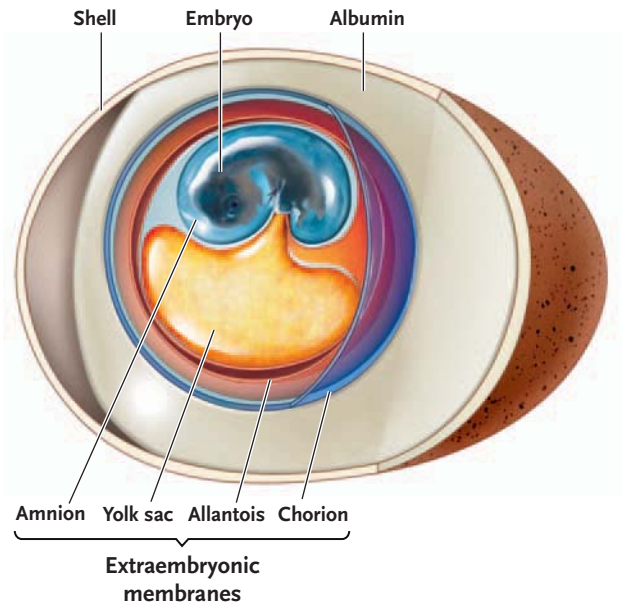

FIGURE 32.22 The amniote egg. A water-retaining egg with four specialized membranes (the amnion, allantois, chorion, and yolk sac) and a hard or leathery shell allowed amniotes and their descendants to reproduce in dry terrestrial environments.

The Fossil Records Suggests That Amniotes Diversified into Three Major Lineages

A traditional view, based largely on the morphology of extinct species, suggests that amniotes differentiated into three lineages during the Carboniferous and Permian periods: synapsids, anapsids, and diapsids **(Figure 32.23).** These three groups are distinguished by differences in the number of openings, called **temporal fenestrae** (*fenestra* = window), and the **bony temporal arches** that border them on the sides of the skull. In the animals that have them, temporal fenestrae provide space for large and powerful jaw muscles. We briefly describe the three traditionally recognized lineages and examine diversification within the diapsids before considering alternative views of amniote relationships.

SYNAPSIDA Nearly all researchers agree that **Synapsida** (*syn* = with; *apsis* = arch), a group of small terrestrial predators, was the earliest lineage to emerge from the ancestral amniotes. They had one temporal fenestra and one temporal arch on either side of the skull. Synapsids appeared late in the Permian period; mammals are their living descendants.

ANAPSIDA According to the traditional view, **Anapsida** ("no arch") was the second amniote lineage to arise; they lacked temporal fenestrae and temporal arches, a condition that scientists recognize as the ancestral amniote skull morphology. Traditionally, biologists hypothesized that turtles are the only living representatives of this lineage, because all extinct and living turtles lack temporal fenestrae and temporal arches.

DIAPSIDA Most Mesozoic amniotes belong to the third lineage, **Diapsida** ("two arches"); these animals had two temporal fenestrae and two temporal arches. Their living descendants include lizards and snakes, crocodilians, and birds. Morphological and genetic sequence data from living species confirm that the diapsids form a monophyletic lineage.

Diapsids Diversified Wildly during the Mesozoic Era

Fossil evidence and molecular sequence data from living species reveal that the early diapsids differentiated into two major lineages, the **Archosauromorpha** (*arkhon* = ruler, *sauros* = lizard, *morphe* = form) and the **Lepidosauromorpha** (*lepis* = scale), which differed in many skeletal characteristics.

The archosauromorphs (commonly called archosaurs), or "ruling reptiles," include crocodilians, pterosaurs, dinosaurs, and birds. Crocodilians, which first appeared during the Triassic period, have bony armor and a laterally flattened tail that propels

them through water. Pterosaurs, now extinct, were flying predators of the Jurassic and Cretaceous periods. Their wings were composed of thin sheets of skin attached to the sides of the body and supported by an elongate finger. Small pterosaurs may have been active fliers, but large ones, with wingspans as wide as 13 m, probably soared on air currents as vultures do today.

Two lineages of dinosaurs, "lizard-hipped" saurischians and "bird-hipped" ornithischians proliferated in the Triassic and Jurassic periods. As their names imply, they differed in the anatomy of their pelvic girdles.

The largely herbivorous ornithischian dinosaurs had enormous, stocky bodies. This lineage included the armored or plated dinosaurs (*Ankylosaurus* and *Stegosaurus*), the duck-billed dinosaurs *(Hadrosaurus),* horned dinosaurs *(Styracosaurus),* and some with remarkably thick skulls *(Pachycephalosaurus).* The ornithischians were most abundant in the Jurassic and Cretaceous periods.

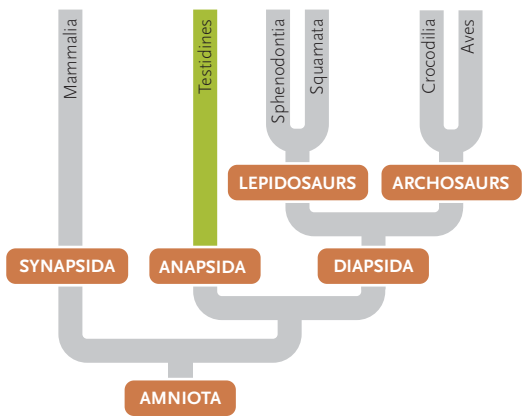
The saurischian lineage included bipedal carnivores and quadrupedal herbivores. Most carnivorous saurischians were swift runners. Their forelimbs, however, were often ridiculously short. *Tyrannosaurus,* which was 15 m long and stood 6 m high, is the most familiar carnivorous saurischian, but most species were much smaller. One group of small carnivorous saurischians was ancestral to birds. By the Cretaceous period, some herbivorous saurischians had also attained gigantic size, and many had long, flexible necks. For example, *Apatosaurus* (previously known as *Brontosaurus*) was 25 m long and may have weighed 50,000 kg.

The second major lineage of diapsids was the lepidosauromorphs (commonly called lepidosaurs), a diverse group that included both marine and terrestrial animals. Ichthyosaurs were porpoise-like animals with laterally flattened tails. They were so highly specialized for marine life that they could not venture onto land, even to reproduce. Instead, they gave birth to live young under water as porpoises and whales do today. Plesiosaurs were marine, fish-eating creatures that used long, paddle-shaped limbs to row through the water. A third important group within this lineage is the squamates, which includes the living lizards and snakes.

The Phylogenetic Position of Turtles Is a Subject of Ongoing Debate

Scientists have debated the evolutionary relationships among the amniotes for more than a century, and they still have not reached a consensus. The most persistent problem is how turtles fit into the amniote phylogenetic tree. The traditional hypothesis (described previously and pictured in Figure 32.23) regards turtles as the living descendants of an ancient anapsid lineage. According to this hypothesis, turtle skulls lack temporal fenestrae and arches because this lineage retained the ancestral anapsid skull condition.

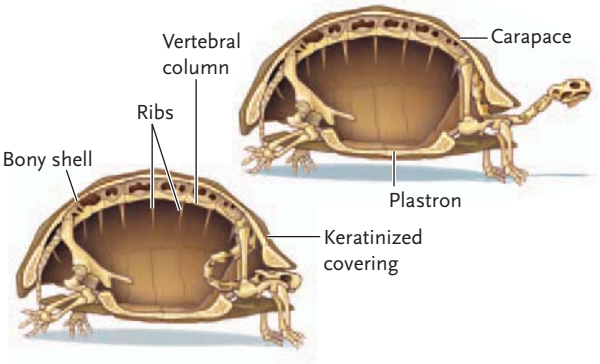
In the 1990s, however, researchers who conducted a detailed morphological analysis of some amniote groups suggested that turtles are closely related to lepidosaurs and therefore part of the diapsid lineage. Hoping to resolve the ongoing dispute about amniote relationships, biologists turned to molecular analyses. But molecular analyses have not produced a clear conclusion: although much molecular research suggests that turtles are diapsids, some studies indicate that they are closely related to archosaurs, whereas other studies indicate a close relationship to lepidosaurs. According to hypotheses that include turtles within the diapsids (that is, that they are closely related either to archosaurs *or* to lepidosaurs), a turtle ancestor must have had the two temporal fenestrae and two temporal arches that are characteristic of the diapsid lineage. If that was the case, the turtle lineage must have subsequently lost those characteristics and returned to what *appears to be* the ancestral anapsid condition. To confuse matters even further, other analyses that include data from the fossil record as well as morphological and genetic sequence data on living species provide as much support for the traditional hypothesis that turtles are part of the anapsid lineage as for the newer hypotheses that place turtles among the diapsids. Thus, although it is easy to recognize turtles when we see them, the details of their evolutionary history are not yet understood.



STUDY BREAK 32.7

1. How did the evolution of the amniote egg free amniotes from a dependence on standing water?
2. What groups of animals are included in each of the three traditionally defined amniote lineages?
3. Based on the evolutionary history of the diapsid amniotes, are crocodilians more closely related to lizards or to birds?

THINK OUTSIDE THE BOOK



Visit a local natural history museum or search the Internet to learn more about extinct diapsids, such as plesiosaurs, ichthyosaurs, pterosaurs, and non-avian dinosaurs. What types of habitats did they occupy, and what foods did they eat?

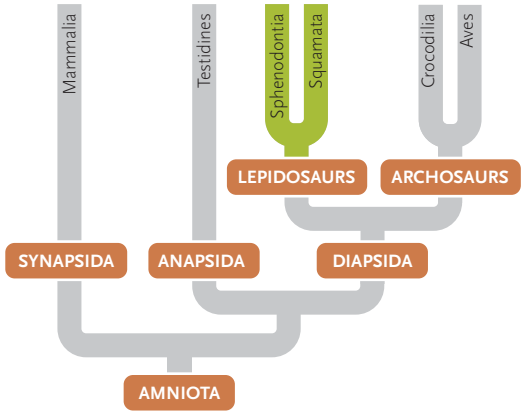
Turtles Have Bodies Encased in a Bony Shell



The turtle body plan, largely defined by a bony, boxlike shell, has changed little since the group first appeared during the Triassic period **(Figure 32.24).** The shell includes a dorsal **carapace** and a ventral **plastron.** A turtle's ribs are fused to the inside of the carapace, and, in contrast to other tetrapods, the pectoral and pelvic girdles lie *within* the ribcage. Large, keratinized scales cover the bony plates that form the shell.

The 250 living species of turtles occupy terrestrial, freshwater, and marine habitats. They range from 8 cm to 2 m in length. All species lack teeth, but they use a keratinized beak and powerful jaw muscles to feed on plants or animal prey. When threatened, most species retract into their shells. Many species are now highly endangered because adults are hunted for meat, their eggs are consumed by humans and other predators, and their young are collected for the pet trade.

STUDY BREAK 32.8

How does the overall structure of turtles distinguish them from other amniotes?

32.9 Living Lepidosaurs: Sphenodontids and Squamates

Two groups of lepidosaurs—Sphenodontida and Squamata—still live today. In addition to sharing certain skeletal characteristics, their bodies are encased in a dry, scaly skin.

Living Sphenodontids Are Remnants of a Diverse Mesozoic Lineage

The tuatara *(Sphenodon punctatus)* is one of two living representatives of the sphenodontids (*sphen* = wedge, *odont* = tooth), a diverse Mesozoic lineage **(Figure 32.25A).** These lizard-shaped animals survive on a few islands off the coast of New Zealand. Adults are about 60 cm long. They live in dense colonies, where males and females defend small territories using vocal and visual displays. They often share underground burrows with seabirds, feeding mainly on invertebrates and small vertebrates. They are primarily nocturnal and maintain low body temperatures during periods of activity.

Squamates—Lizards and Snakes—Are Covered by Overlapping, Keratinized Scales

The skin of lizards and snakes (Squamata, *squama* = scale) is composed of overlapping, keratinized scales that protect against dehydration. Squamates periodically shed their skin as they grow, much the way arthropods shed their exoskeletons (see Section 31.7). Most squamates regulate their body temperature behaviorally; they are active only when weather conditions are favorable, and they shuttle between sunny and shady places when they need to warm up or cool down (see Section 48.7).

Most of the 4,800 lizard species are less than 15 cm long **(Figure 32.25B).** However, the Komodo dragon *(Varanus komodoensis)* grows to nearly 3 m. Lizards occupy a wide range of habitats, but they are especially common in deserts and the tropics; one species *(Zootoca vivipara)* occurs within the Arctic Circle. Most lizards feed on insects, although some eat leaves or meat. The diverse tropical genus *Anolis* has be-

come a frequent subject of research, as described in *Focus on Model Research Organisms.*

The 2,900 species of snakes evolved from a lineage of lizards that lost their legs over evolutionary time (see Section 20.3). Streamlined bodies make snakes efficient burrowers or climbers **(Figure 32.25C).** Many subterranean species are only 10 or 15 cm long, but the giant constrictors may grow to 10 m. Unlike lizards, all snakes are predators that swallow prey whole. Snakes have thinner skull bones than their lizard ancestors did, and the bones are connected to each other by elastic ligaments that stretch remarkably, allowing some snakes to swallow food that is larger than their heads. Snakes also have well-developed sensory systems for detecting prey. The flicking tongue carries airborne molecules to sensory receptors in the roof of the mouth. Most snakes can detect vibrations on the ground, and some, like rattlesnakes, have heat-sensing organs (see Figure 41.22). Many snakes kill by constriction, which suffocates prey, and several groups produce toxins that immobilize, kill, and partially digest the prey before it is swallowed.

1. **In addition to losing their legs over evolutionary time, how do snakes differ from their lizard ancestors?**
2. **How do the diets of lizards and snakes differ?**

32.10 Living Archosaurs: Crocodilians and Birds

Two groups of archosaurs—Crocodilia and Aves—have survived since the Mesozoic era. Although they bear little resemblance to each other in their external morphology, similarities in their heart and respiratory structures as well as molecular sequence data confirm their close relationship.

Crocodilians Are Semiaquatic, Predatory Archosaurs

In addition to birds, the 21 living species of alligators and crocodiles (Crocodilia, from *crocodilus* = crocodile) are the remnants of a once-diverse archosaur lineage **(Figure 32.26).** The largest

Anolis Lizards of the Caribbean

The lizard genus *Anolis* has been a model system for studies in ecology and evolutionary biology since the 1960s, when Ernest E. Williams of Harvard University's Museum of Comparative Zoology first began studying it. With roughly 400 known species—and new ones being described all the time—*Anolis* is one of the most diverse vertebrate genera. Most anoles are less than 10 cm long, not including the tail, and many occur at high densities, making it easy to collect lots of data in a relatively short time. Male anoles defend territories, and their displays make them conspicuous even in dense forests.

Anolis species are widely distributed in South America and Central America, but nearly 40% occupy Caribbean islands. The number of species on an island is generally proportional to the island's size. Cuba, the largest island, has more than 50 species, whereas small islands have just one or two.

Studies by Williams and others suggest that the anoles on some large islands are the products of independent adaptive radiations. Eight of the 10 *Anolis* species now found on Puerto Rico probably evolved on that island from a common ancestor. Similarly, the seven *Anolis* species on Jamaica shared a common ancestor, which was different from the ancestor of the Puerto Rican species. The anole faunas on Cuba and Hispaniola are the products of several independent radiations on each island.

Williams discovered that these independent radiations had produced similar-looking species on different islands. He developed the concept of the *ecomorph,* a group of species that have similar morphological, behavioral, and ecological characteristics even though they are not closely related within the genus. Williams named the ecomorphs after the vegetation that they commonly used **(Figure).** For example, grass anoles are small, slender species that usually perch on low, thin vegetation. Trunk-ground anoles have chunky bodies and large heads, and they perch low on tree trunks, frequently jumping to the ground to feed. Although the grass anoles or the trunk-ground anoles on different islands are similar in many ways, they are not closely related to each other. Their resemblances are the products of convergent evolution.

Ecomorphs exist because evolutionary processes have accentuated the morphological differences among species that occupy different types of vegetation. Jon Losos of Harvard University has demonstrated that trunk-ground anoles, which have relatively long legs and tails, can run faster on wide surfaces and jump farther than species with relatively short legs. And in nature the trunk-ground anoles run and jump more frequently than the other ecomorphs do.

Different ecomorphs on an island use different parts of their habitats by choosing different perch sites (grass, tree trunks, rocks). When two or more species of the same ecomorph inhabit the same island, they occupy habitats with different temperature and shade conditions (see Figure). For example, in Puerto Rico, one species of trunk-ground anole *(Anolis gundlachi)* occupies cool, shady uplands; another *(Anolis cristatellus)* lives in warm, fairly open lowland habitats; and a third species *(Anolis cooki)* lives in desert habitats. Other species in Puerto Rico exhibit similar differences in their distributions. These differences in geographical distribution and habitat use presumably allow the different species to avoid competition with each other and gain access to the resources they need to survive and reproduce.

Evolutionary processes have also fostered physiological differences that reinforce the ecological separation established by the lizards' use of different habitats. For example, *A. cristatellus* maintains higher body temperatures than *A. gundlachi,* and neither is physiologically adapted to the environment of the other: *A. cristatellus* dies in the high altitude forests where *A. gundlachi* thrives, while *A. gundlachi* suffers heat stress at body temperatures that are typical for *A. cristatellus.*

Researchers throughout the Americas continue to explore the ecology and evolution of anoles. Some unravel their biogeography and systematic relationships; others focus on the ecology of populations and communities; still others study their social behavior or sensory physiology. With so many species distributed across hundreds of Caribbean islands, the lizard genus *Anolis* provides fertile ground for testing hypotheses about nearly every aspect of vertebrate biology.

species, the Australian saltwater crocodile *(Crocodylus porosus),* grows to 7 m. Crocodilians are aquatic predators that consume other vertebrates. Striking anatomical adaptations distinguish them from living lepidosaurs, including a four-chambered heart and a one-way flow of air through their lungs, characters that are homologous to those of birds.

American alligators *(Alligator mississippiensis)* exhibit strong maternal behavior, which also reflects their relationship to birds. Females guard their nests ferociously and help their young break out of their eggshells. The young stay close to the mother for about a year, feeding on scraps that fall from her mouth and living under her watchful protection.

Most alligator and crocodile species are highly endangered. Their habitats have been disrupted by human activities, and they have been hunted for meat and leather. Protection efforts have been extremely successful, however. American alligators, for example, have recovered from the brink of extinction.

Birds Have Key Adaptations That Reduce Body Weight and Power Flight

Birds (Aves) appeared in the Jurassic period as descendants of carnivorous, bipedal dinosaurs. Thus, they are full-fledged members of the archosaur lineage. Their evolutionary relationship to dinosaurs is evident in their skeletal anatomy, the scales on their legs and feet, and their posture when walking. However, powered flight gave birds access to new adaptive zones, setting the stage for their astounding evolutionary success **(Figure 32.27A).**

The skeletons of birds are both lightweight and strong **(Figure 32.27B).** For example, the endoskeleton of the frigate bird, which has a 1.5 m wingspan, weighs little more than 100 g, far less than its feathers. Most birds have hollow limb bones with small supporting struts that crisscross the internal cavities. Evolution has also reduced the number of separate bony elements in the wings, skull, and vertebral column (especially the tail), making the skeleton light and rigid. And all modern birds lack teeth, which are dense and heavy; they acquire food with a lightweight, keratinized bill. Many species have a long, flexible neck, which allows them to use their bills for feeding, grooming, nest-building, and social interactions.

The bones associated with flight are generally large. The forelimb and forefoot are elongate, forming the structural support for the wing. And most modern birds possess a **keeled sternum** (breastbone) to which massive flight muscles are attached **(Figure 32.27C).** Not all birds are strong fliers, however; ostriches and other bipedal runners have strong, muscular legs but small wings and flight muscles (see Figure 20.2).

Like the skeleton, soft internal organs are modified in ways that reduce weight. Most birds lack a urinary bladder; uric acid paste is eliminated with digestive wastes. Females have only one ovary and never carry more than one mature egg; eggs are laid as soon as they are shelled.

All birds also possess **feathers (Figure 32.27D),** sturdy, lightweight structures derived from scales in the skin of their ancestors. Each feather has numerous barbs and barbules with tiny hooks and grooves that maintain the feathers' structure, even during vigorous activity. Flight feathers on the wings provide lift, contour feathers streamline the surface of the body, and down feathers form an insulating cover close to the skin. Worn feathers are molted and replaced once or twice each year.

Other adaptations for flight allow birds to harness the energy needed to power their flight muscles. Their metabolic rates are eight to ten times higher than those of other comparably sized diapsids, and they process energy-rich food rapidly. A complex and efficient respiratory system (see Figure 46.7) and four-chambered heart (see Figure 44.5D) enable them to consume and distribute oxygen efficiently. As a consequence of high rates of metabolic heat production, birds maintain a high and constant body temperature (see Section 48.8).

Flying Birds Were Abundant by the Cretaceous Period

Although the earliest known bird, the pigeon-sized *Archaeopteryx,* had feathers, its skeleton was essentially that of a small dinosaur (see Figure 20.13). It had digits and claws on the forelimbs, teeth on its jaws, many bones in its wings and vertebral column, and only a poorly developed sternum. How could flight evolve in so unbirdlike an animal? Some biologists hypothesize that *Archaeopteryx* ran after prey, using its feathered wings like fly swatters. Larger wings would have provided extra lift when it jumped at prey, and gradual evolutionary modifications of the wing bones and muscles could have led to powered flight.

Crow-sized birds with full flight capability appeared by the early Cretaceous period. They had a keeled sternum and other modern skeletal features. The modern groups of wading birds and seabirds first appear in late Cretaceous rocks; fossils of other modern groups are found in slightly later deposits. Woodpeckers, perching birds, birds of prey, pigeons, swifts, the flightless ratites, penguins, and some other groups were all present by the end of the Oligocene; birds continued to diversify through the Miocene (see Table 23.1).

Modern Birds Vary in Morphology, Diet, Habits, and Patterns of Flight

The 9,000 living bird species show extraordinary ecological specializations, but they share the same overall body plan. Living birds are traditionally classified into nearly 30 groups **(Figure 32.28).** They vary in size from the bee hummingbird *(Mellisuga helenae)* of Cuba, which weighs little more than 1 g, to the ostrich *(Struthio camelus),* which can weigh as much as 150 kg.

The structure of the bill usually reflects a bird's diet. Seed and nut eaters, such as finches and parrots, have deep, stout bills that crack hard shells. Carnivorous hawks and carrion-eating vultures have sharp bills to rip flesh, and nectar-feeding hummingbirds have slender bills to reach into flowers. The bills of ducks are modified to extract particulate matter from water, and many perching birds have slender bills to feed on insects.

Birds also differ in the structure of their feet and wings. Predators have large, strong talons ("claws"), whereas ducks and other swimming birds have webbed feet that serve as paddles. Long-distance fliers like albatrosses have narrow wings; those that hover at flowers, such as hummingbirds, have wide ones. The wings of some species, like penguins, are so specialized for swimming that they are incapable of aerial flight.

All birds have well-developed sensory and nervous systems, and their brains are proportionately larger than those of other diapsids of comparable size. Large eyes provide sharp vision, and most species also have good hearing, which nocturnal hunters like owls use to locate prey. Some vultures and other

Bird diversity. Birds, the living feathered archosaurs, have diversified into lineages that are adapted to live in different habitats and feed on different foods.

A. The black-bowed albatross (Procellariiformes, *Thalassarche melanophrys*) has the long, thin wings typical of birds that fly great distances.

B. The saddle-billed stork (Ciconiiformes, *Ephippiorhynchus senegalensis*) searches for aquatic prey, which it captures with its long bill.

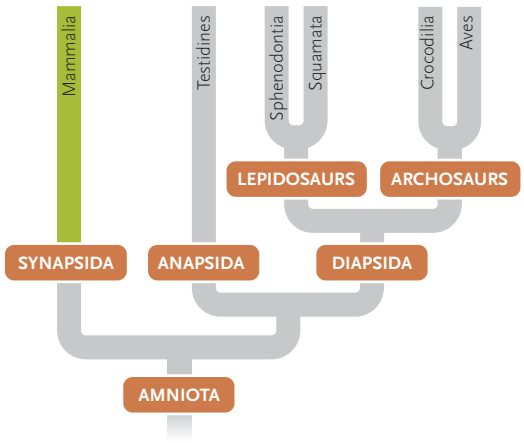
C. The bald eagle (Falconiformes, *Haliaeetus leucocephalus*) uses its sharp bill and talons to capture and tear apart prey.

D. A tawny frogmouth (Caprimulgiformes, *Podargus strigoides*) uses its wide mouth to capture flying insects.

E. A rufus hummingbird (Apodiformes, *Selasphorus rufus*) uses its long, thin bill to delve into flowers in search of nectar.

F. The black-capped chickadee (Passeriformes, *Poecile atricapillus*) uses its thin bill to probe for insects in dense vegetation.

species have a good sense of smell, which they use to find food. Migrating birds use polarized light, changes in air pressure, and Earth's magnetic field for orientation.



Most birds exhibit complex social behavior, including courtship, territoriality, and parental care. Many species communicate with vocalizations and visual displays to challenge other individuals or attract mates. Most raise their young in a nest, using body heat to incubate eggs. The nest may be a simple depression on a gravelly beach, a cup woven from twigs and grasses, or a feather-lined hole in a tree.

Many bird species embark on a semiannual, long-distance migration (see Section 56.3). The golden plover *(Pluvialis dominica),* for example, migrates 20,000 km twice each year. Migrations are a response to seasonal changes in climate. Birds travel toward the tropics as winter approaches; in spring, they return to high latitudes using seasonally available food sources.

32.11 Mammalia: Monotremes, Marsupials, and Placentals

The synapsid lineage, which includes the living mammals, was the first group of amniotes to diversify broadly on land. Indeed, during the late Paleozoic era, medium- to large-sized synapsids were the most abundant predators in terrestrial habitats. One particularly successful and persistent branch of the synapsid lineage, the *therapsids,* exhibited many mammal-like characteristics in their legs, skulls, jaws, and teeth. And by the end of the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Triassic period, the earliest mammals—most of them no bigger than a rat—had emerged from therapsid ancestors. Several mammalian lineages coexisted with dinosaurs and other diapsids throughout the Mesozoic, but paleontologists hypothesize that most Mesozoic mammals were active only at night to avoid predatory dinosaurs, which were active during the day. Two mammalian lineages, the egg-laying Prototheria (or monotremes) and the live-bearing Theria (marsupials and placentals), survived the mass extinction that eliminated most dinosaurs at the end of the Mesozoic. The Theria diversified into the mammalian groups that are most familiar today.

Mammals Exhibit Key Adaptations in Anatomy, Physiology, and Behavior

Four sets of key adaptations fostered the success of mammals.

HIGH METABOLIC RATE AND BODY TEMPERATURE Like birds, mammals have high metabolic rates that release enough energy from food to maintain high activity levels and enough heat to maintain high body temperatures (see Section 48.8). An outer covering of fur and a layer of subcutaneous fat help retain body heat. Using metabolic heat to stay warm requires lots of oxygen, and mammals have a muscular organ, the diaphragm, that fills their lungs with air (see Figure 46.8). Four-chambered hearts and complex circulatory systems deliver oxygen to active tissues (see Figure 44.5D).

SPECIALIZATIONS OF THE TEETH AND JAWS Mammals also have anatomical features that allow them to feed efficiently. Ancestrally, mammals have four types of teeth (see Figure 47.18): flattened **incisors** nip and cut food; pointed **canines** pierce and kill prey; and two sets of cheek teeth, **premolars** and **molars,** grind and crush food. Moreover, teeth in the upper and lower jaws occlude (that is, fit together) tightly as the mouth is closed; thus, mammals can use their large jaw muscles to chew food thoroughly. The occlusion of premolars and molars allows some mammals to feed on exceptionally tough plant material, such as grasses and twigs.

PARENTAL CARE Mammals provide substantial parental care to their young. In most species, young complete development within a female's uterus, deriving nourishment through the **placenta,** a specialized organ that mediates the delivery of oxygen and nutrients (see Section 49.2). Females also have **mammary glands,** specialized structures that produce energy-rich milk, a watery mixture of fats, sugars, proteins, vitamins, and minerals. This perfectly balanced diet is the sole source of nutrients for newborn offspring.

COMPLEX BRAINS Finally, mammals have larger brains than other tetrapods of equivalent body size; the difference lies primarily in the **cerebral cortex,** the part of the forebrain responsible for information processing and learning (see Figure 40.6). Most mammals have a keen sense of olfaction; as *Insights from the Molecular Revolution* explains, a huge variety of olfactory receptor proteins send information to the parts of the cerebral cortex that allow mammals to sense and interpret a wide variety of odors. Extensive postnatal care provides opportunities for offspring to learn from older individuals. Thus, mammalian behavior is strongly influenced by past experience as well as by genetically programmed instincts.

The Major Groups of Modern Mammals Differ in Their Reproductive Adaptations

Biologists recognize a primary distinction between two lineages of modern mammals: the egg-laying Prototheria (*protos* = first, *therion* = wild beast), or monotremes, and the live-bearing Theria. The Theria, in turn, diversified into two sublineages: the

FIGURE 32.30 Marsupials. An Eastern gray kangaroo *(Macropus giganteus)* carries her "joey" in her pouch.

Metatheria (*meta* = between), or marsupials, and the Eutheria (*eu* = true), or placentals, which also differ in their reproductive adaptations.

MONOTREMES The three living species of monotremes (Prototheria), which are limited to the Australian region, reproduce with a leathery-shelled egg **(Figure 32.29).** Newly hatched young lap up milk secreted by modified sweat glands on the mother's belly. The two species of echidnas, or spiny anteaters (*Tachyglossus aculeatus* and *Zaglossus bruijni*), feed on ants or termites. The duck-billed platypus *(Ornithorhynchus anatinus)* lives in burrows along riverbanks and feeds on aquatic invertebrates.

MARSUPIALS The 240 species of marsupials (Metatheria) have short gestation; the young are nourished through a placenta very briefly—sometimes only for 8 to 10 days—before birth. Newborns use their forelimbs to drag themselves across the mother's belly fur and enter her abdominal pouch, the **marsupium,** where they complete development attached to a teat. Marsupials are the dominant native mammals of Australia and a minor component of the South American fauna **(Figure 32.30);** only one marsupial species, the opossum *(Didelphis virginiana),* occurs in North America.

PLACENTALS The 4,000 species of placental mammals (Eutheria) are the dominant mammals today. They complete embryonic development in the mother's uterus, nourished through a placenta until they reach a fairly advanced stage of development. Some species, like humans, are helpless at birth, but others, such as horses, are quickly mobile.

Biologists divide eutherians into about 18 groups, traditionally identified as orders, only eight of which include more than 50 living species **(Figure 30.31).** Rodents (Rodentia) make up about 45% of eutherian species, and bats (Chiroptera) comprise another 22%. Our own group, Primates, is represented by fewer than 250 living species (less than 5% of all mammalian species), many of which are highly endangered.

Some eutherians have highly specialized locomotor structures. For example, whales and dolphins (Cetacea) are descended from terrestrial ancestors, but their appendages do not function on land; they are now restricted to aquatic habitats. By contrast, seals and walruses (Carnivora) feed underwater but rest and breed on land. Bats (Chiroptera) use wings for powered flight.

Although early mammals appear to have been insectivorous, the diets of modern eutherians are diverse. Odd-toed ungulates (*ungula* = hoof) like horses and rhinoceroses (Perissodactyla), even-toed ungulates like cows and camels (Artiodactyla), and rabbits and hares (Lagomorpha) feed on vegetation. Lions and wolves (Carnivora) consume other animals. Many hedgehogs, moles, and shrews (Lipotyphla) and bats eat insects, but some feed on flowers, fruit, and nectar. Many whales and dolphins prey on fishes and other animals, but some eat plankton. And some groups, including rodents and primates, feed opportunistically on both plant and animal matter.

1. **During the Mesozoic era, why were most mammals active only at night?**
2. **Which key adaptations in mammals allow them to be active under many types of environmental conditions?**
3. **On what basis are the three major groups of living mammals distinguished?**

32.12 Nonhuman Primates

We now focus our attention on Primates, the mammalian lineage that includes humans, apes, monkeys, and their close relatives. The first Primates appeared early in the Eocene epoch, about 55 million years ago, in forested habitats in North America, Europe, Asia, and North Africa.

Key Derived Traits Enabled Primates to Become Arboreal, Diurnal, and Highly Social

Several derived traits allow primates to be arboreal (to live in trees rather than on the ground). For example, most primates have a more erect posture than other mammals, and they have flexible hip and shoulder joints, which allow a variety of locomotor activities. They can grasp objects with their hands and feet, because they have nails, not claws, on their fingers and toes; their fingertips are well endowed with sensory nerves that enhance the sense of touch. Unlike other mammals, most primates have an opposable big toe, which can touch the tips of other digits and the sole of the foot; many species also have an opposable thumb.

Most primates are diurnal (active during daylight hours), and, unlike most mammals, they rely more on vision than on their sense of smell (see *Insights from the Molecular Revolution*). Thus, they generally have short snouts and small olfactory lobes of the brain. Most species have forward-facing eyes with overlapping fields of vision, providing excellent depth perception, which comes in handy when moving through trees. Many species have color vision.

Primate brains—especially the regions that integrate information—are large and complex. As a result, they have an exceptional capacity to learn. Most species live in social groups; thus, young primates, which mature slowly, can interact with and learn from their elders and peers during an extended period of parental care. Females give birth to only one or two young at a time, allowing them to devote substantial attention to each offspring.

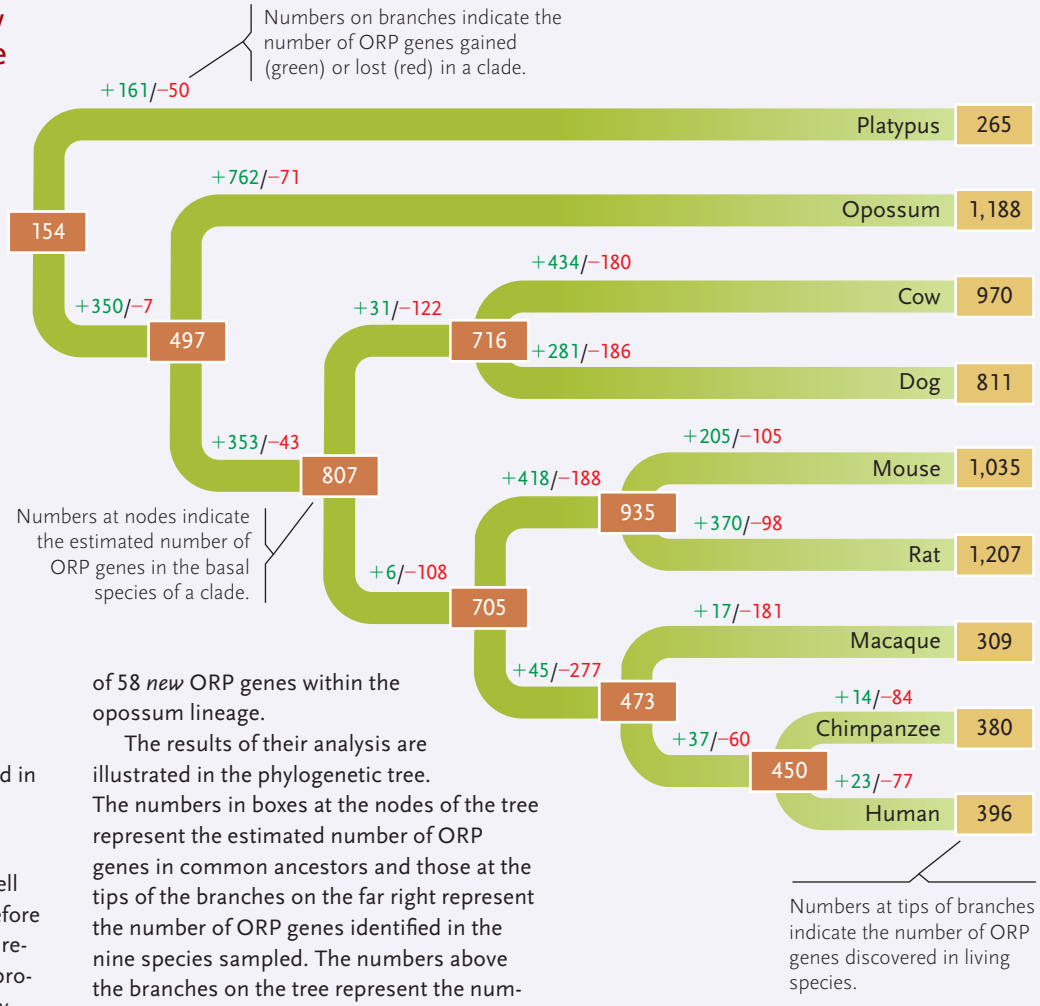
Building a Better Nose: How did the sense of smell evolve in mammals?

The sense of olfaction (that is, smell) in vertebrates is made possible by olfactory receptor proteins (ORPs) in specialized cells in their nasal sinuses (see Section 41.5). Humans express hundreds of different ORPs, each of which binds specific airborne molecules, thereby allowing us to detect the presence of many different molecules. Hundreds of different genes—all of which are members of one large multi-gene family of g-protein-coupled receptors (see Chapters 7 and 20)—code for hundreds of different ORPs. The vertebrate sense of smell evolves when new genes arise through gene duplication and when old genes are lost as mutations turn them into pseudogenes (see Section 19.4).



Research Question

What new olfactory receptor genes evolved in different groups of mammals?

Experiment

Mammals rely more on their sense of smell than do most other vertebrates. It is therefore reasonable to suppose that new olfactory receptor genes evolved in early mammals, producing their acute olfaction. To test this hypothesis, Yoshihito Niimura and coworkers searched a range of mammalian genomes for representatives of the multi-gene family coding for ORPs. Their work examined the genomes of one monotreme (platypus), one marsupial (opossum) and seven placentals (dog, cow, mouse, rat, macaque monkey, chimpanzee, and human).

The researchers made multiple pair-wise comparisons of the ORP gene sequences in the nine mammal species to construct phylogenetic trees of ORP genes; these phylogenetic trees illustrate which genes are more closely related to each other. By comparing the ORP gene phylogenetic trees with a phylogenetic tree for the nine mammal species, they were able to estimate how many new ORP genes had evolved in each mammalian lineage and how many ORP genes had been lost through mutation. For example, the opossum genome contains one family of 59 ORP genes that are more closely related to one another than they are to ORP genes in any of the other species. The most parsimonious explanation for this discovery is that a series of gene duplications led to the evolution of 58 *new* ORP genes within the opossum lineage.

The results of their analysis are illustrated in the phylogenetic tree. The numbers in boxes at the nodes of the tree represent the estimated number of ORP genes in common ancestors and those at the tips of the branches on the far right represent the number of ORP genes identified in the nine species sampled. The numbers above the branches on the tree represent the number of new ORP genes that evolved (in green) and the number of ORP genes lost to mutation (in red) within each lineage.

Many new ORP genes evolved in the lineage that was ancestral to both placental and marsupial mammals. After those clades diverged, new ORP genes continued to evolve in many lineages. The rodents (represented in the study by mouse and rat) experienced the evolution of a strikingly large number of new ORP genes. By contrast, the primates (represented in the study by macaque, chimpanzee, and human) experienced a net loss of ORP genes through mutation.

Conclusion

These findings reflect the relative importance of olfaction in different groups of mammals. The platypus is thought to rely less on olfaction than other mammals do, perhaps because they use electroreceptors in their bill to find food (see Section 41.7); this observation is consistent with the relatively few new ORP genes that evolved in that lineage. The evolution of nocturnal activity in early mammals is thought to have increased the need for olfactory information, an observation that is consistent with the evolution of many new ORP genes in the marsupial and placental lineages. In fact, of the 1,035 ORP genes in mice, at least 783 appeared after the emergence of mammals, suggesting that most of a mouse's ability to smell has been acquired during the past 200 million years. The numbers of ORP genes lost outpaced the numbers of ORP genes gained only among the primates, as members of that lineage began to rely increasingly on their sense of vision. A decreased reliance on olfaction is typical of all primates, including humans.

THINK LIKE A SCIENTIST Early primates were almost certainly arboreal, leaping or climbing from one branch to another in trees. How would this behavior favor the evolution of their increased reliance on vision and decreased reliance on olfaction?

FIGURE 32.31 Eutherian diversity. Among the traditionally defined orders of mammals, only eight include more than 50 living species. Seven of these clades are pictured here. The eighth clade, Primates, is described later in this chapter.

Living Primates Include Two Major Lineages

Primatologists recognize two lineages within the Primates **(Figure 32.32),** the Strepsirhini (*streptos* = twisted or turned, *rhinos* = nose) and the Haplorhini (*haplos* = single or simple).

STREPSIRHINI The 36 living species of Strepsirhini—lemurs, lorises, and galagos—possess many ancestral morphological traits, including moist, fleshy noses and eyes that are positioned somewhat laterally on their heads **(Figure 32.33).** Strepsirhines generally have short gestation periods and rapid maturation. Today, 22 lemur species survive on Madagascar, a large island off the east coast of Africa; they are ecologically diverse and range in size from 40 g to 7 kg. Some lemurs are arboreal, whereas others spend substantial time on the ground. The 12 species of lorises and galagos occupy tropical forest and subtropical woodlands in Africa, India, and Southeast Asia; they are all arboreal and nocturnal.

HAPLORHINI Most species in the Haplorhini—the familiar monkeys and apes—have many derived primate characteristics, including compact, dry noses, and forward-facing eyes.

However, five species of tarsiers, which are restricted to tropical forests on the islands of Southeast Asia, exhibit several ancestral traits: small body size (about 100 g), large eyes and ears, and two grooming claws on each foot **(Figure 32.34).** But they share the derived characteristics of dry noses and forward-facing eyes with the other haplorhines; DNA sequence data

link them to the monkeys and apes and not to the strepsirhines described earlier.

The 130 or so species of monkeys, 13 species of apes, and humans constitute the monophyletic haplorhine lineage **Anthropoidea,** which probably arose in Africa. Fossils of a diverse and abundant radiation of forest-dwelling anthropoids, dating from the late Eocene epoch, have been discovered in northern Egypt. Continental drift then established long-term geographical and evolutionary separation of anthropoids in the New World and Old World **(Figure 32.35).**

By the middle of the Oligocene epoch, about 30 million years ago, the ancestors of the New World monkeys had arrived in South America and begun to diversify there. They probably rafted across the Atlantic, which was narrower at that time, on trees or other storm debris. New World monkeys now live in Central and South America (see Figure 32.35A). They range in size from tiny marmosets and tamarins (350 g), to hefty howler monkeys (10 kg). Most are exclusively arboreal and diurnal. The larger species may hang below branches by their arms, and some use a prehensile (grasping) tail as a fifth limb.

Cagan Sekercioglu/Visuals Unlimited

FIGURE 32.33 **Strepsirhines.** The ring-tailed lemur *(Lemur catta)* of Madagascar has ancestral primate characteristics, such as a long snout and wet nose.

Anthropoids diversified most spectacularly in the Old World, however, eventually giving rise to two lineages—one ancestral to Old World monkeys and the other to apes and humans. Although many people assume that the apes are descended from Old World monkeys, the fossil record contradicts that impression. The earliest hominoid ("ape") fossils date to

the early Miocene, roughly 23 million years ago, but the oldest known Old World monkeys appeared several million years later.

Old World monkeys, which occupy habitats ranging from tropical rain forests to deserts in Africa and Asia, may grow as large as 35 kg (see Figure 30.35B). Many species are sexually dimorphic; in other words, males and females attain different adult sizes (see Section 21.3). Arboreal species use all four limbs for locomotion, but none has a prehensile tail. Some species, such as baboons, often walk or run on the ground.

Within the anthropoid lineage, the **Hominoidea** ("humanlike") is a monophyletic group that includes apes and humans. The climate of the early Miocene was wetter than it is today, and eastern Africa, where many early hominoid fossils are found, was covered with extensive forests. A shift to a cooler and drier climate in the middle Miocene, between 17 and 14 million years ago, converted dense forests into more open woodlands. Hominoids probably adopted a more terrestrial existence and shifted their diets to include leaves and hard foods. Miocene hominoids ranged in size from 4 kg to 80 kg. They occupied both forest and open woodland habitats; some may have been at least partially ground dwelling.

A. Spider monkey *(Ateles geoffroyi)*

B. Hamadryas baboon *(Papio hamadryas)*

Joseph Van Os/Getty Images Inc.

FIGURE 32.35 **New World and Old World monkeys. (A)** Many New World monkeys, such as the spider monkey, have prehensile tails, which they use as a fifth limb. Old World monkeys lack prehensile tails, and many, such as **(B)** the Hamadryas baboon, are largely terrestrial.

Although hominoids are closely related to Old World monkeys, several characteristics distinguish them. Apes lack a tail, and the great apes (orangutans, gorillas, chimpanzees, and bonobos) are much larger than monkeys. Moreover, the posterior region of the vertebral column is shorter and more stable in apes. Apes also show more complex behavior.

The gibbons and siamangs, which live in tropical forests in Southeast Asia, are the smallest of the apes, ranging in weight from 6 to 11 kg. With extremely long arms and strong shoulders, they hang below branches by their arms and swing themselves forward, a pattern of locomotion called **brachiation (Figure 32.36A).** The much larger orangutan *(Pongo pygmaeus),* now restricted to forested areas on the islands of Borneo and Sumatra, can grow to 90 kg. Orangutans use both hands and feet to climb trees; they sometimes venture onto the ground on all fours.

Gorillas *(Gorilla gorilla),* which are currently restricted to two large central African forests, are the largest of the living primates. Males can weigh 180 kg; females are about half that size. Because of their size, gorillas spend most of their time on the ground. They often use "knuckle-walking" locomotion, leaning forward and supporting part of their weight on the backs of their hands. Gorillas are almost exclusively vegetarian.

Chimpanzees *(Pan troglodytes)* are also forest dwellers, weighing up to 45 kg **(Figure 32.36B).** Like gorillas, they spend most of their waking hours on the ground; they often knuckle-

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

walk, but sometimes adopt a **bipedal** (two-legged) stance and swagger short distances. Groups of related males form loosely defined communities of up to 50 individuals, which may cooperate in hunts and foraging. Bonobos *(Pan paniscus),* sometimes called pygmy chimpanzees, are restricted to a small area in central Africa. Somewhat smaller than chimps, they have longer legs and smaller heads.

The Primates also includes humans *(Homo sapiens),* which occupy virtually all terrestrial habitats. Humans have adaptations that allow an upright posture and bipedal locomotion. They are ground-dwelling animals with extremely broad diets and complex social behavior.

STUDY BREAK 32.12

1. What characteristics of primates allow them to spend a great deal of time in trees?
2. What is the lowest taxonomic group that includes monkeys, apes, and humans? What is the lowest taxonomic group that includes only apes and humans?
3. Which ape species spend the most time on the ground?

32.13 The Evolution of Humans

Genetic analyses of living hominoid species indicate that African hominoids diverged into several lineages between 10 million and 5 million years ago; one lineage, the **hominins,** includes modern humans and our bipedal ancestors. (Until recently, biologists used the term "hominid" to describe humans and their bipedal ancestors, but that term now defines the group that includes humans, bipedal human ancestors, and the apes.)

Hominins First Walked Upright in East Africa about 6 Million Years Ago

Upright posture and bipedal locomotion are key adaptations that distinguish hominins from apes. Researchers infer these capabilities in early hominin fossils from the anatomy of the skull, spine, pelvis, knees, ankles, and feet **(Figure 32.37).** As a consequence of bipedal locomotion, the hands were no longer used for locomotor functions, allowing them to become specialized for other activities, such as tool use. Hominins also eventually developed larger brains.

Since the mid-1990s, paleontologists have uncovered an astounding array of fossils of hominin species that lived in East Africa and South Africa between 7 million and 1 million years ago **(Figure 32.38).** In 2000, researchers found 13 fossils of *Orrorin tugenensis* ("first man" in a local African language), a species that lived about 6 million years ago in East African forests. Shortly thereafter, researchers described the skull of an even older fossil, *Sahelanthropus tchadensis,* but because the pelvis and legs of this species are still unknown, scientists are unsure about its ability to walk bipedally. Indeed, the fossilized remains of most hominins are fragmentary.

In 1994, Tim White of the University of California, Berkeley and two Ethiopian colleagues made a spectacular discovery of early hominin fossils: they unearthed the remains of 36 individuals of *Ardipithecus ramidus* in the Awash Valley of central Ethiopia. The animals had lived in a closed-canopy woodland

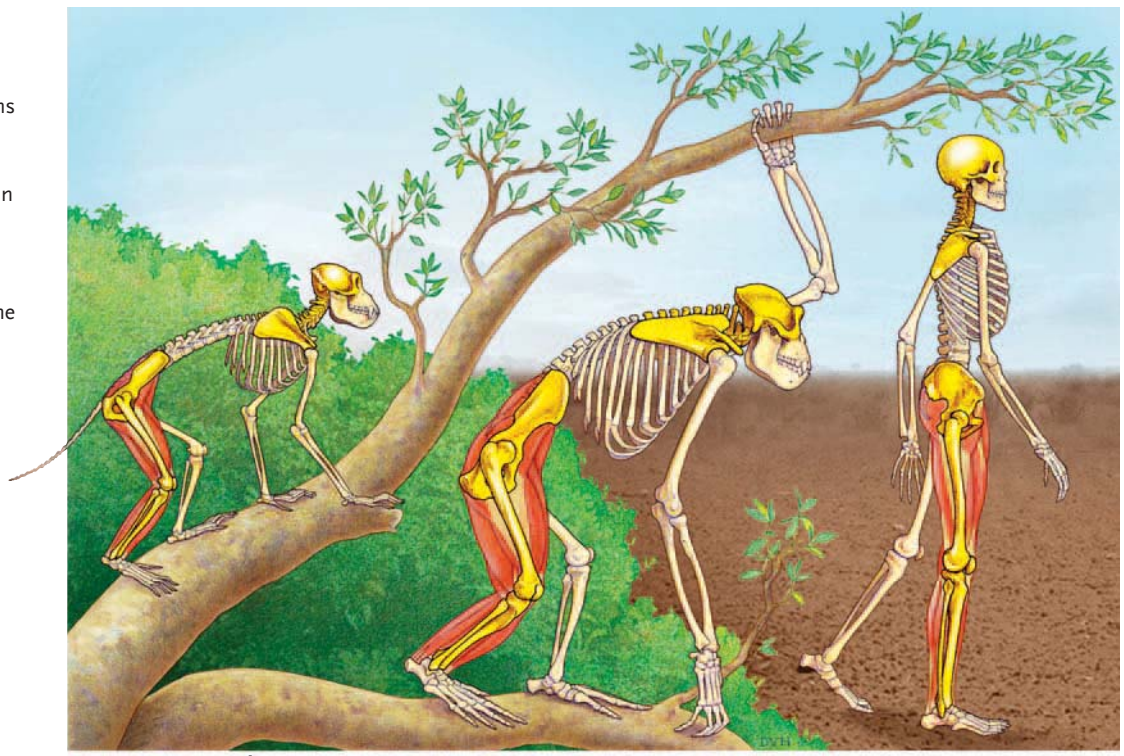

FIGURE 32.37 Adaptations for bipedal locomotion. Differences in the posture, skeleton, and muscles of monkeys, great apes, and humans illustrate the anatomical changes that accompanied upright, bipedal locomotion. Evolutionary changes in the spine, pelvis, hip, knee, ankle, and foot were accompanied by changes in the sizes of leg muscles and their points of attachment to the bones they move.

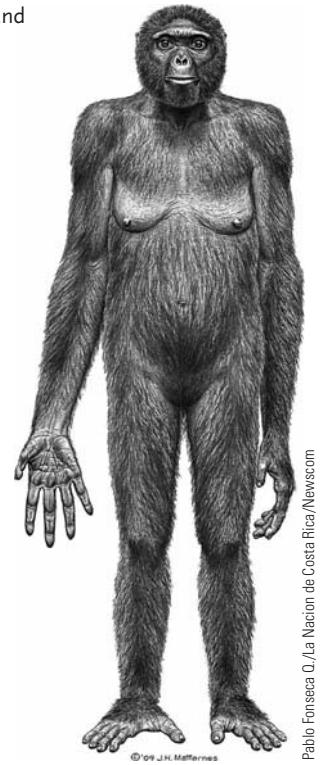
about 4.4 million years ago. The fossils were badly deformed and so fragile that they turned to dust in the researchers' hands. After the fossils were carefully excavated and transported to a laboratory at the National Museum of Ethiopia, an international and interdisciplinary team of 47 researchers labored for 15 years to analyze them. They published their findings in a series of 11 papers in *Science* magazine. The work was later hailed by the editors of *Science* as the "breakthrough of the year" in 2009.



Among the fossils that White's team uncovered, the researchers found 125 pieces of one female's skeleton, including bones from her arm and hand, pelvis, leg, ankle, and foot, lower jaw with teeth, and cranium **(Figure 32.39).** Nicknamed "Ardi," she had the body size and brain size of a modern chimpanzee; stood about 120 cm tall and weighed about 50 kg. Studies of Ardi's anatomy revealed that her face protruded less and her upper canine teeth were shorter and duller than those of modern chimpanzees. The upper parts of her pelvis are shorter and broader than those of living apes, and the anatomy of her hand suggests that she did not knuckle-walk as modern chimps and gorillas do. These observations suggest that she was able to walk bipedally on the ground, although perhaps not as well as later hominins. Nevertheless, Ardi's foot had an opposable big toe, and the bones of her fingers were long and curved; these characters suggest that she spent considerable time climbing trees, perhaps to escape predators, seek food, or build nests for sleeping. White and his team described Ardi as having an anatomy that was intermediate between that of chimps and later groups of hominins. Some researchers have taken issue with some of the interpretations that White's team published, partly because the fossils were in terrible condition when they were found and partly because, at the time of this writing, few other researchers have yet had the opportunity to study the fossils in detail.

Hominin fossils from 4.2 million to 1.2 million years ago are well known from many sites in East, Central, and South Africa. They are currently assigned to the genera *Australopithecus* (*australis* = southern, *pithekos* = ape) and *Paranthropus* (*para* = beside, and *anthropos* = human being). With their large faces, protruding jaws, and small skulls and brains, most of these hominins had an apelike appearance (see Figure 32.38). *Australopithecus anamensis,* which lived in East Africa around 4 million years ago, is the oldest known species. It had thick enamel covering on its teeth, a derived hominin characteristic; the structure of a fossilized leg bone suggests that it was bipedal.

Specimens of more than 60 individuals of *Australopithecus afarensis* have been found in northern Ethiopia, including about 40% of a female skeleton, named "Lucy" by its discover-

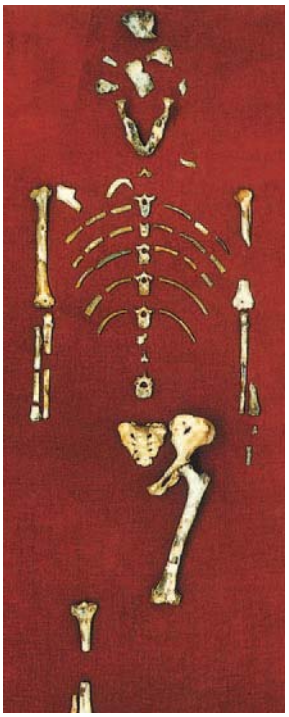
ers **(Figure 32.40).** *A. afarensis* lived 3.5 million to 3 million years ago, but it retained several ancestral characteristics. For example, it still had moderately large and pointed canine teeth, and a relatively small brain. Males and females were 150 cm and 120 cm tall, respectively. Skeletal analyses suggest that *A. afarensis* was fully bipedal, a conclusion supported by fossilized footprints preserved in a layer of volcanic ash.

Other species of *Australopithecus* and *Paranthropus* lived in East Africa or South Africa between 3.7 million and 1 million years ago. Adult males ranged from 40 to 50 kg in weight and from 130 to 150 cm in height; females were smaller. Most species had deep jaws and large molars. Several species had a crest of bone along the midline of the skull, providing a large surface for the attachment of jaw muscles. These anatomical features suggest that they fed on hard food, such as nuts, seeds, and other vegetable products.



One species, *Australopithecus africanus,* known only from South Africa, had small jaws and teeth, indicating that it probably consumed a softer diet. Yet another species, *Australopithecus sediba,* first described in 2010 from fossils discovered in a South African cave, had even more derived characteristics than *A. africanus:* smaller teeth, longer legs, and a more vertically oriented pelvis. Researchers believe that *A. sediba* may be a descendant of *A. africanus* and an ancestor of the genus that includes modern humans. The phylogenetic relationships of the species classified as *Australopithecus* and *Paranthropus*—and their exact relationships to later hominins—are not yet fully understood. But most scientists agree that *Australopithecus* was ancestral to humans, which are classified in the genus *Homo.*

Homo Habilis Was Probably the First Hominin to Manufacture Stone Tools

Pliocene fossils of the earliest humans, which may have included several species, are fragmentary. They are also widely distributed in space and time, complicating analyses of their relationships. For the sake of simplicity, we describe them as belonging to one species, *Homo habilis* ("handy man").

From 2.3 million to 1.7 million years ago, *H. habilis* occupied the woodlands and savannas of eastern and southern Africa, sharing these habitats with various species of *Paranthropus.* The two genera are easy to tell apart because the brains of *H. habilis* were at least 20% larger, and they had larger incisors and smaller molars than their hominin cousins. Their diet included hard-shelled nuts and seeds as well as soft fruits, tubers, leaves, and insects. They may also have hunted small prey or scavenged carcasses left by large predators.

Researchers have found numerous tools dating to the time of *H. habilis,* but they are not sure which species used them. Many of the hominin species alive at the time probably cracked marrowbones with rocks or scraped flesh from bones with sharp stones. Paleoanthropologist Louis Leakey was the first to discover evidence of tool *making* at East Africa's Olduvai Gorge, which cuts through a great sequence of sedimentary rock layers. The oldest tools at this site are crudely chipped pebbles, which were probably manufactured by *H. habilis.*

Homo Erectus Dispersed from Africa to Other Continents

Early in the Pleistocene epoch, about 1.8 million years ago, new species of humans appeared in East Africa. Most fossils are fragmentary. For convenience, we describe them all as *Homo erectus* ("upright man"), recognizing that they probably represent several species. One nearly complete skeleton suggests that *H. erectus* was taller than its ancestors, had a much larger brain, a thicker skull, and protruding brow ridges **(Figure 32.41).**

H. erectus made fairly sophisticated tools, including the hand axe (see Figure 32.41B), which they apparently used to cut food and other materials, to scrape meat from bones, and to dig for roots. *H. erectus* probably fed on both plants and animals; they may have hunted and scavenged animal prey. Archaeological data point to their use of fire to process food and to keep themselves warm.

The pressure of growing populations apparently forced groups of *H. erectus* to move out of Africa about 1.5 million years ago. They dispersed northward from East Africa into both northwestern Africa and Eurasia. Some moved eastward through Asia as far as the island of Java. Recent discoveries in Spain indicate that *H. erectus* also occupied parts of Western Europe.

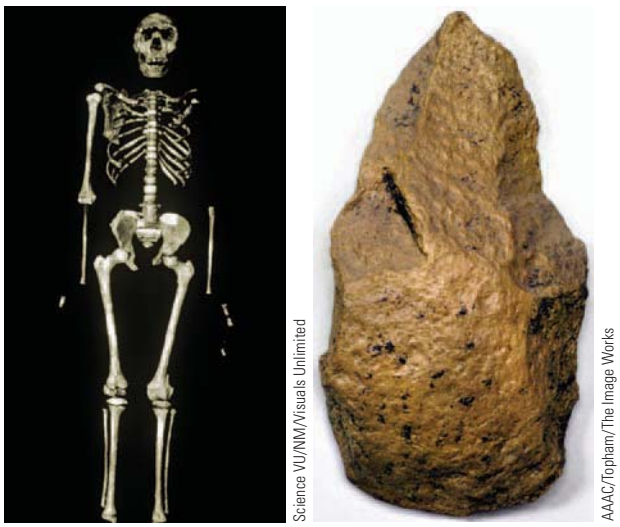

FIGURE 32.41 ***Homo erectus.*** **(A)** A nearly complete skeleton of *Homo erectus* was discovered in Kenya. **(B)** Hand axes are frequently found at *H. erectus* sites.

Modern Humans Are the Only Surviving Descendants of *Homo Erectus*

Judging from its geographical distribution, *Homo erectus* was successful in many environments. Fossils from Africa, Asia, and Europe indicate that it gave rise to several species that first appeared more than 400,000 years ago. These early descendants, described as archaic humans, generally had a larger brain, rounder skull, and smaller molars than *H. erectus.* Like *H. erectus* before them, archaic humans left Africa and established populations in the Middle East, Asia, and Europe.

Some time later, 200,000 to 100,000 years ago, modern humans, *Homo sapiens* ("wise man"), arose in Africa. These modern humans also migrated into Europe and Asia and may have eventually driven the archaic humans to extinction, perhaps through competition for resources rather than hostile interactions.

ARCHAIC HUMANS The Neanderthals *(Homo neanderthalensis),* who occupied Europe and western Asia from 150,000 to 28,000 years ago, are the best-known archaic humans. Compared with modern humans, they had a heavier build, more-pronounced brow ridges, and slightly larger brains (see Figure 32.38). Neanderthals were culturally and technologically sophisticated. They made complex tools, including wooden spears, stone axes, and flint scrapers and knives. At some sites they built shelters of stones, branches, and animal hides, and they routinely used fire. They were successful hunters and probably consumed nuts, berries, fishes, and bird eggs. Some groups buried their dead, and they may have used rudimentary speech.

Researchers once classified Neanderthals as a subspecies of *H. sapiens,* but most scientists now recognize them as a separate species. In 1997 two teams of researchers, Matthias Kring and Svante Pääbo of the University of Munich and Anne Stone and Mark Stoneking of Pennsylvania State University, independently analyzed short segments of mitochondrial DNA (mtDNA) extracted from the fossilized arm bone of a Neanderthal. Unlike nuclear DNA, which individuals inherit from both parents, only mothers pass mtDNA to offspring. It does not undergo genetic recombination (see Section 13.5), and it has a high mutation rate, making it useful for phylogenetic analyses. Many scientists believe that mutation rates in mtDNA are fairly constant, allowing this molecule to serve as a molecular clock (see Section 24.6). Comparing the Neanderthal sequence with mtDNA from 986 living humans, the researchers discovered three times more differences between the Neanderthals and modern humans than between pairs of modern humans in their sample. These results suggest that Neanderthals and modern humans are different species that diverged from a common ancestor 690,000 to 550,000 years ago—hundreds of thousands of years before modern humans appeared.

In 2003, researchers discovered eight skeletons of a tiny hominin, tentatively described as *Homo floresiensis,* in a cave on the Indonesian island Flores. Remarkably, these individuals stood just 1 m tall and are estimated to have weighed about 25 kg. The researchers who discovered these remains have hypothesized that

they represent a new archaic hominin species, a descendant of *H. erectus,* that lived in Southeast Asia until roughly 12,000 years ago. Some skeptics suggested that these individuals represent a population of modern humans who suffered from some genetic disease or condition that caused their small size. But subsequent analyses of their skeletal remains indicate that *H. floresiensis* branched off from *H. erectus* even earlier than *H. neanderthalensis.* Their diminutive stature may have resulted from selection for a reduction in size, a phenomenon observed in other island-dwelling mammals. Indeed, fossils of miniature elephants have been discovered nearby. The unresolved questions about this new archaic human include how and where it first evolved and how it may have interacted with modern humans who lived nearby.

MODERN HUMANS Modern humans *(Homo sapiens)* differ from Neanderthals and other archaic humans in having a slighter build, less-protruding brow ridges, and a more prominent chin. The earliest fossils of modern humans found in Africa and Asia are roughly 150,000 years old; those from the Middle East are 100,000 years old. Fossils from about 20,000 years ago are known from Western Europe, the most famous being those of the Cro-Magnon deposits in southern France. The widespread appearance of modern humans roughly coincided with the demise of Neanderthals in Western Europe and the Middle East 40,000 to 28,000 years ago. Although the two species apparently coexisted in some regions for thousands of years, until recently, we have had little concrete evidence about their interactions.

In May 2010, an international team of more than 50 scientists, led by Svante Pääbo, reported a draft sequence of the Neanderthal genome in the journal *Science.* The researchers collected genetic data from fossils of three Neanderthal females who had lived more than 38,000 years ago in what is now Croatia. They compared the Neanderthal DNA sequences to those of five living humans—one each from southern Africa, West Africa, China, Papua New Guinea, and France. Remarkably, the European and the Asians shared between 1% and 4% of their recently derived (that is, newly evolved) nuclear DNA sequences with Neanderthals. Subsequent research, published by another team of researchers in 2011, also found evidence of a small number of archaic human DNA sequences in some modern human populations in central Africa. These data suggest that modern humans interbred with archaic humans on several continents as recently as 35,000 years ago. Although the analyses are far from complete at the time of this writing, the genes that modern Europeans and Asians share with Neanderthals appear to be involved in cognitive development, skeletal development, and metabolism. Thus, there may well be a little Neanderthal in all of us, no matter where on Earth our recent ancestors lived.

Many researchers believe that all modern human populations are descended from an ancestral population that originated in Africa. DNA sequence data from modern humans confirm this hypothesis. In 1987, Rebecca Cann, Mark Stoneking, and Allan Wilson of the University of California, Berkeley, and their colleagues published an analysis of mtDNA sequences from more than 100 ethnically diverse humans on four continents. They found that contemporary African populations contain the greatest variation in mtDNA. One explanation for this observation is that neutral mutations have been accumulating in African populations longer than in others, marking the African populations as the oldest on Earth. They also found that all human populations contain at least one mtDNA sequence of African origin, suggesting an African ancestry for all modern humans. Cann and her colleagues named the ancestral population, which lived approximately 200,000 years ago, the "mitochondrial Eve."

Other researchers have examined genetic material that males inherit only from their fathers. In 1995, L. Simon Whitfield and his colleagues at Cambridge University published a study on an 18,000-base-pair sequence from the Y chromosome, which does not undergo recombination with the X chromosome. Because the sequence contains no genes, it should not be subject to natural selection. Thus, sequence variations should result only from random mutations, which can serve as a molecular clock. The researchers discovered only three sequence mutations among the five subjects examined—a surprising result, given that the sample included a European, a Melanesian, a South American, and two Africans. By contrast, a chimpanzee exhibited 207 differences from the human version of the sequence. Using a sophisticated statistical analysis, the Whitfield team calculated that the common ancestor of these five diverse humans, dubbed the "African Adam," lived between 37,000 and 49,000 years ago. The limited genetic diversity and relatively recent origin of a common ancestor clearly support the African origin of *H. sapiens.* Follow-up studies on the Y chromosomes of thousands of men from Africa, Europe, Asia, Australia, and the Americas have confirmed that all modern humans are the descendants of a single migration out of Africa.

Ever since Darwin first included humans in his analyses about the diversity of life, the study of human evolution has been a controversial subject. Some disputes arise because the fossil record for humans gives up its secrets slowly and in piecemeal fashion. Other disagreements result from the assumptions that researchers must make about the sizes and geographical ranges of ancient populations, the amount of gene flow they experienced, and how natural selection may have affected them. But intellectual disputes are routine in science, and they challenge researchers to refine their hypotheses and to test them in new ways. Questions about the details of human origins are at the center of one of the liveliest debates in evolutionary biology today; additional research will surely clarify the evolutionary history of our species.

STUDY BREAK 32.13

1. **What trait allows researchers to distinguish between apes and humans?**
2. **What evidence suggests that Neanderthals and modern humans represent two distinct species?**
3. **What evidence suggests that modern humans originated in Africa?**

UNANSWERED QUESTIONS

What causes the evolution of diversity?

In this chapter, you have read about the extensive diversity—in size, shape, color, structure, lifestyle, and habitats—of the vertebrate animals. Their mechanisms for maintaining themselves—including behaviors such as moving, feeding, reproducing, hiding, fighting, and sleeping—are equally varied. But nearly all vertebrates share some fundamental features. Recent research shows us that this generality is especially true of early development, but it is also apparent in many of the basic homeostatic mechanisms that vertebrates share—features of digestion and metabolism, respiration, and other characteristics regulated by the products of genetic networks and cascades. Biologists had long thought that once we understood the genetics of a variety of species, we would also understand the basis for their evolution and the maintenance of diversity. But now that biologists have sequenced a number of animal genomes, we have actually learned more about the genetic information that is shared by all animal species than we have learned about the genes that promote diversification. One of the great unanswered questions in biology, therefore, is how diversity arises and how it is maintained, given that so much genetic information is shared among even distantly related species. Equally important is why the same kinds of features evolved almost identically time after time in many unrelated lineages.

The ever-increasing body of genetic information is opening the "black box" of why there are so many species, and how they came to be. For example, we've long known that limbs evolved from fins, based on fossil evidence (which continues to accumulate, providing additional supportive evidence). But we haven't known what the *mechanisms* for forming a fin or a limb are, and how selection works to modify such structures. Now, with our knowledge of *Hox* and other tool-kit genes that control embryonic development, we understand how fins and limbs are formed. We can also experimentally manipulate development and perform selection experiments to test possible pathways of evolution—the "how they came to be."

Why do we see the recurrent, independent evolution of common themes?

A phenomenon that we often see, but don't yet fully understand, is why certain themes—such as body elongation, limblessness, and tooth modification—recur among distantly related vertebrates. The evolution of viviparity, live-bearing reproduction, is one such theme. In the vast majority of animals, reproduction occurs when a female lays her eggs in water and a male sprays sperm over them; typically both parents then abandon the fertilized eggs. But some species in many separate vertebrate lineages have evolved forms of viviparity. Cartilaginous and bony fishes exhibit diverse modes of embryonic nutrition, and in one group, the sea horses, it is the males that become pregnant. Amphibians also exhibit diverse patterns of viviparity: some have pregnant fathers and others have mothers that brood embryos in the skin of their backs, in their stomachs, or in their oviducts. And many squamate reptiles grow placentas similar to those of mammals. All mammals except monotremes are live-bearers with maternal nutrition. In fact, among the living vertebrate groups, birds are the only group that has not evolved the live-bearing habit. Can you think of some reasons why?

In some fishes, amphibians, and squamates, the mother supplies all the nutrition for the developing young through her investment in the egg; but in other species, females resorb their yolks and provide nutrients directly to offspring that are born as fully metamorphosed juveniles. Given that viviparity has evolved independently in approximately 200 vertebrate groups, it is not surprising that we see such a variety of reproductive patterns. Biologists are just beginning to understand the evolution of viviparity and to determine which patterns are shared among different evolutionary lineages and which are not. It appears that the hormonal basis for viviparity is similar in many groups, although the timing, the receptors involved, and the physiological responses vary. Researchers are now identifying candidate genes in the hope of unraveling the genetic networks that have fostered the different modes of viviparity. Ecological studies are revealing the interactions of potential selection regimes that influence reproductive modes. However, we still have much to learn about how genetics, development, physiology, and ecology interact in the evolution of diversity and common recurring themes.

THINK LIKE A SCIENTIST If viviparity has evolved multiple times in different vertebrate lineages, it must have been favored by natural selection. What might some of the benefits of viviparity be?

Marvalee H. Wake

Marvalee H. Wake is a professor in the Department of Integrative Biology and the graduate school at the University of California, Berkeley. She studies vertebrate evolutionary morphology, development, and reproductive biology, with the goal of understanding evolutionary patterns and processes. REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

32.1 Invertebrate Deuterostomes

- Echinoderms have secondary radial symmetry, a five-part body plan, and a unique water vascular system that is used in locomotion and feeding (Figures 32.2 and 32.3).
- Hemichordates collect oxygen and particulate food from seawater that enters the mouth and exits the pharynx through the branchial slits (Figure 32.4).

32.2 Overview of the Phylum Chordata

- Chordates share several derived characteristics: a notochord; postanal tail; segmentation of body wall and tail muscles; a dorsal,

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

hollow nerve cord; and a perforated pharynx at some stage of the life cycle (Figure 32.5).

- Two subphyla of invertebrate chordates use their perforated pharynx to collect particulate food (Figures 32.6 and 32.7).
- The subphylum Vertebrata includes animals with a bony endoskeleton, structures derived from neural crest cells, and a brain divided into three regions.

Animation: Chordate Innovations in the Animal Body Plan

Animation: Lancelet body plan

Animation: Tunicate body plan

Animation: Crocodile body plan

32.3 The Origin and Diversification of Vertebrates

- Vertebrates evolved from an invertebrate chordate ancestor, probably through duplication of the *Hox* gene complex (Figure 32.8).
- The earliest vertebrates were fish-shaped animals with only some vertebrate characteristics (Figure 32.9).
- Vertebrates diversified into numerous lineages (Figure 32.10). Gnathostomata includes all jawed vertebrates. Tetrapoda includes all lineages that ancestrally had four legs. Amniota includes groups descended from animals that produced an amniote egg.

Animation: Vertebrate evolution

32.4 "Agnathans": Hagfishes and Lampreys, Conodonts and Ostracoderms

- Living agnathans—hagfishes and lampreys—are jawless fishes that lack vertebrae and paired fins (Figure 32.11).
- Conodonts had bonelike elements in the pharynx. Ostracoderms were heavily armored, jawless fishes that sucked particulate food into their mouths (Figure 32.12).

32.5 Gnathostomata: The Evolution of Jaws

- Jaws arose through the evolutionary modification of gill arches, which supported the pharynx of ostracoderms (Figure 32.13). Fins arose at the same time (Figure 32.14).
- The first jawed fishes, Acanthodii and Placodermi, are now extinct (Figure 32.15). Chondrichthyans have a skeleton composed of cartilage (Figure 32.16). Actinopterygians and Sarcopterygians have a skeleton composed of bone. Actinopterygians have fins supported by bony rays (Figures 32.17 and 32.18). Sarcopterygians have fins supported by muscles and a bony endoskeleton (Figure 32.19).

Animation: Evolution of jaws

Animation: Cartilaginous fishes

Animation: Bony fish body plan

32.6 Tetrapoda: The Evolution of Limbs

- Tetrapods arose in the late Devonian (Figure 32.20). Key tetrapod adaptations include a strong vertebral column, girdles, limbs, and modified sensory systems.
- Modern amphibians are generally restricted to moist habitats. Their life cycles often include larval and adult stages. Caudata (salamanders) are elongate, tailed amphibians. Anura (frogs) have compact bodies, long legs, and no tails. Gymnophiona (caecelians) are legless burrowers (Figure 32.21).

Animation: Amniote egg

32.7 Amniota: The Evolution of Fully Terrestrial Vertebrates

- Key adaptations in amniotes, the first fully terrestrial vertebrates, included a water-resistant skin, amniote eggs (Figure 32.22), and the excretion of nitrogen wastes as uric acid.
- A traditional view suggests that early amniotes diversified into three lineages (anapsids, synapsids, and diapsids) distinguished by the number of temporal fenestrae and temporal arches on the skull (Figure 32.23).
- Diapsids split into two lineages: archosaurs and lepidosaurs.
- The phylogenetic position of turtles is the subject of disagreement.

32.8 Testudines: Turtles

- The turtle body plan includes a bony shell, with a dorsal carapace and ventral plastron (Figure 32.24).

Animation: Tortoise shell and skeleton

32.9 Living Lepidosaurs: Sphenodontids and Squamates

- Sphenodontids are remnants of a once-diverse lineage (Figure 32.25A).
- Squamates have skin composed of overlapping, keratinized scales (Figure 32.25B and C). Lizards consume a variety of foods, but all snakes are predators on other animals.

32.10 Living Archosaurs: Crocodilians and Birds

- Crocodilians are semiaquatic predators (Figure 32.26).
- Birds have adaptations that reduce their weight and generate power for flight (Figure 32.27).
- Modern birds exhibit adaptations of their bills, feet, wings, and behavior (Figure 32.28).

32.11 Mammalia: Monotremes, Marsupials, and Placentals

- Key adaptations of mammals include endothermy, which allows high levels of activity; modification of the teeth and jaws; extensive parental care of offspring; and large and complex brains.
- There are three major groups of mammals: the Prototheria, to which the monotremes belong, and two lineages of Theria, to which the marsupials and the placentals belong. The three groups differ in their reproductive patterns.
- Monotremes are restricted to Australia and New Guinea (Figure 32.29). Marsupials are abundant in Australia and occur in South America and North America (Figure 32.30). Most living mammals are placentals, occupying nearly all terrestrial and aquatic habitats (Figure 32.31).

32.12 Nonhuman Primates

- Key adaptations allow Primates to be arboreal and diurnal: upright posture and flexible limbs; good depth perception; and a large and complex brain.
- The Primates includes two major lineages (Figure 32.32). The Strepsirhini have many ancestral primate characteristics (Figure 32.33). The Haplorhini have many derived primate characteristics (Figures 32.34 and 32.35).
- Primates arose in forests about 55 mya (million years ago). The hominoid lineage, which includes apes and humans, arose in Africa about 23 mya (Figure 32.36).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

32.13 The Evolution of Humans

- Hominins, the lineage that includes humans, arose in Africa between 10 mya and 5 mya. Hominin anatomy permits bipedal locomotion (Figure 32.37). Over time, hominins developed larger brains and tool-making behavior. Several genera of hominins occupied sub-Saharan Africa for several million years (Figures 32.38–32.40).
- *Homo habilis* was the first hominin species to make stone tools. *Homo erectus,* which arose in East Africa about 1.8 mya, made sophisticated stone tools (Figure 32.41).
- The early descendants of *H. erectus* left Africa in waves, populating Asia and Europe. Neanderthals, the best known of these groups, became extinct about 30,000 years ago.
- Modern humans, *Homo sapiens,* arose approximately 150,000 years ago and migrated out of Africa, eventually replacing archaic humans in Europe and Asia.

UNDERSTAND & APPLY

Test Your Knowledge

1. Which phylum includes animals that have a water vascular system?
   a. Echinodermata
   b. Hemichordata
   c. Chordata
   d. Tetrapoda
   e. Amniota
2. Which of the following is *not* a characteristic of all chordates?
   a. notochord and postanal tail
   b. segmental body wall and tail muscles
   c. segmented nervous system
   d. dorsal hollow nerve cord
   e. perforated pharynx
3. Which group of vertebrates has adaptations that allow it to reproduce on land?
   a. agnathans
   b. tetrapods
   c. gnathostomes
   d. amniotes
   e. ichthyosaurs
4. Which group of fishes has the most living species today?
   a. sarcopterygians
   b. actinopterygians
   c. chondrichthyans
   d. acanthodians
   e. ostracoderms
5. Modern amphibians:
   a. closely resemble their Paleozoic ancestors.
   b. always occupy terrestrial habitats as adults.
   c. never occupy terrestrial habitats as adults.
   d. are generally larger than their Paleozoic ancestors.
   e. are generally smaller than their Paleozoic ancestors.
6. Which of the following key adaptations allows amniotes to occupy terrestrial habitats?
   a. the production of carbon dioxide as a metabolic waste product
   b. an unshelled egg that is protected by jellylike material
   c. a dry skin that is largely impermeable to water
   d. a lightweight skeleton with hollow bones
   e. feathers or fur that provide insulation against cold weather
7. Which of the following characteristics does *not* contribute to powered flight in birds?
   a. a lightweight skeleton
   b. efficient respiratory and circulatory systems
   c. enlarged forelimbs and a keeled sternum
   d. a high metabolic rate that releases energy from food rapidly
   e. scaly skin on the legs and feet
8. Which of the following characteristics did *not* contribute to the evolutionary success of mammals?
   a. extended parental care of young
   b. an erect posture and flexible hip and shoulder joints
   c. specializations of the teeth and jaws
   d. enlargement of the brain
   e. high metabolic rate and high body temperature
9. The Hominoidea is a monophyletic group that includes:
   a. apes and monkeys.
   b. apes only.
   c. humans and human ancestors.
   d. apes and humans.
   e. monkeys, apes, and humans.
10. Which of the following hominin species was the earliest?
    a. *Ardipithecus ramidus*
    b. *Australopithecus afarensis*
    c. *Homo habilis*
    d. *Homo erectus*
    e. *Homo neanderthalensis*

Discuss the Concepts

1. Most sharks and rays are predatory, but the largest species feed on plankton. Construct a hypothesis to explain this observation. How would you test your hypothesis?
2. When tetrapods first ventured onto the land, what new selection pressures did they face? What characteristics might have fostered the success of these animals as they made the transition from aquatic to terrestrial habitats?
3. Use a pair of binoculars to observe several species of birds that live in different types of environments, such as lakes and forests. How are their beaks and feet adapted to their habitats and food habits?
4. Imagine that you unearthed the complete fossilized remains of a mammal. How would you determine the food habits of this now extinct animal?
5. Many myths about human evolution are embraced by popular culture. Using the information you have learned about human evolution, argue against each of the following myths.
   a. Humans evolved from chimpanzees.
   b. Evolution occurred in a steady linear progression from primitive primate to anatomically modern humans.
   c. All human characteristics, such as bipedal locomotion and an enlarged brain, evolved simultaneously and at the same rate.

Design an Experiment

Walking along a rocky coast one day, you discover two small creatures—one lumpy and the other worm-shaped. What anatomical studies would you conduct to determine whether or not they are chordates? What genetic studies might provide supplementary evidence?

Interpret the Data

The phylogenetic tree for vertebrates depicted below was constructed from sequence data for two rRNA mitochondrial genes (12S and 16S). How do the results of this analysis compare with the traditional view of turtles as living representatives of an anapsid lineage?

R. Zardoya and A. Meyer. 1998. Complete mitochondrial genome suggests diapsid affinities of turtles. *Proceedings of the National Academy of Sciences, USA* 95:14226–14231. Copyright 1998 National Academy of Sciences, U.S.A.

Source: R. Zardoya and A. Meyer. 1998. Complete mitochondrial genome suggests diapsid affinities of turtles. *Proceedings of the National Academy of Sciences, USA* 95:14226–14231.

Apply Evolutionary Thinking

Birds and crocodiles are both descended from an ancestral archosaur. What shared anatomical and behavioral characteristics reflect this common ancestry? Explain why dinosaurs, which were also members of the archosaur lineage, may have shared these traits as well. Review Figure 32.23 before formulating your answer.

Basic parts of the shoot system of an apple tree *(Malus domestica)*, including leaves, stems, and vividly colored fruits.

STUDY OUTLINE

33.1 Plant Structure and Growth: An Overview
33.2 The Three Plant Tissue Systems
33.3 Primary Shoot Systems
33.4 Root Systems
33.5 Secondary Growth

The Plant Body

Why it matters . . . Fossil teeth discovered in the East African Rift Valley indicate that the early ancestors of humans likely consumed a variety of plant parts—hard-shelled nuts, dry seeds, soft fruits, and leaves. By about 11,000 years ago, agriculture got its start when humans began domesticating seed plants. Today crop plants such as wheat and rice provide the majority of calories humans consume. In fact, directly or indirectly, plant leaves, stems, roots, flowers, seeds, and fruits are the basic sources of food energy for nearly all of Earth's animal life **(Figure 33.1A).** Plants also provide the materials for building human dwellings, beaver lodges, and bird nests, not to mention raw materials for making paper, dozens of pharmaceuticals, and a host of essentials of modern life **(Figure 33.1B–D).**

As described in Chapter 28, plants that made the transition from aquatic to terrestrial life did so only as evolutionary adaptations in form and function helped solve problems posed by the terrestrial environment. These adaptations included a shoot system that helps support leaves and other body parts in air, a root system that anchors the plant in soil and provides access to soil nutrients and water, tissues for internal transport of nutrients and water, and specializations for preventing water loss.

This chapter launches this textbook's survey of the structure and functioning of plants—their morphology, anatomy, and physiology. *Morphology* refers to the shape and overall appearance of plant parts, such as leaves. *Anatomy* is the physical structure of plant parts, and plant *physiology* examines their function. Our focus throughout this unit is the plant phylum Anthophyta—angiosperms, or flowering plants. In terms of distribution and sheer numbers of species, angiosperms are the most successful plants on Earth.

33.1 Plant Structure and Growth: An Overview

Because plants are photosynthetic autotrophs, they require access to sunlight and the carbon dioxide in air, as well as the water available in soil. Many plants also require nutrients that are usually available only in soil, and their aboveground parts may need physical anchoring. Evolutionary responses to these challenges produced a plant body consisting of two connected but quite different structural elements—a photosynthetic *shoot system* extending upward into the air and a nonphotosynthetic *root system* extending down into the soil. Each system consists of various **organs**—body structures that contain two or more types of tissues and that have a definite form and function. Leaves, stems, and roots are examples of plant organs. A **tissue** is a group of cells and intercellular substances that function together in one or more specialized tasks. For example, a leaf consists of tissue called parenchyma that includes cells specialized for functions such as photosynthesis and gas exchange.

Various Structural and Developmental Features Distinguish Plant Cells and the Makeup of Certain Plant Tissues

All plant cells share certain features that were introduced in Chapter 5. For example, new plant cells develop a primary wall around the **protoplast,** the botanical term for the cell's cytoplasm, organelles, and plasma membrane. The primary wall is made up of cellulose fibers embedded in a matrix of hemicellulose and other branched carbohydrates (see Section 5.4). This combination helps make the wall rigid but flexible. The polysaccharide pectin also is abundant in the primary wall and in the middle lamella, the layer between the primary walls of adjacent cells that helps bind cells together in tissues. (Plant pectin is often used to congeal jams and jellies.) As a plant grows, the protoplast of many types of plant cells deposits additional cellulose and other materials inside the primary wall, forming a strong secondary wall (see Figure 5.26).

Certain vascular plant tissues contain cells that perform their functions only after they are dead and their protoplasts have disintegrated. As Chapter 36 discusses in more detail, in a plant embryo (unlike in an animal embryo), the position of a cell rather than its genetics determines its ultimate fate in the adult. Once the cell's location is established, specific genes become active as the cell *differentiates* (becomes specialized for a particular function). In the vascular tissue called xylem, water moves through cells that died as they differentiated and no longer contain protoplasts.

Vascular plants also contain lignified cells—that is, cells having walls incorporating the polymer lignin, which is inert and insoluble in water. This **lignification** anchors and stiffens the cellulose fibers in the walls of such cells, it protects the other wall components from physical or chemical damage, and it prevents water from penetrating the cell walls. Many biologists believe that the evolution of large vascular plants became possible when certain cells developed biochemical pathways leading to lignification and could therefore become organized into watertight conducting channels.

Water and minerals pass from one lignified cell to another across *pits,* narrow regions where the secondary wall is absent and the primary wall is thinner and more porous than elsewhere. Solutes such as amino acids and sugars, as well as other substances, move in the plasmodesmata linking living plant cells (see Figure 5.26).

Shoot and Root Systems Perform Different but Integrated Functions

A plant's **shoot system** is basically a series of modules—repeating components such as stems, leaves, and, in angiosperms, flowers **(Figure 33.2).** This modular organization correlates with physiological flexibility that is one of the most striking characteristics of plants. Unlike animals, plants have the genetic capacity to modify the development of organs as environmental conditions shift. In general, during the course of a plant's life cycle, embryonic shoots called *buds* give rise to leaves, flowers, or both, as different gene-guided developmental pathways unfold. Section 33.3 looks more closely at the growth of stems and leaves, and Chapter 36 describes the development of flowers and other reproductive structures.

Some or all of a plant's shoot system grows aboveground and is highly adapted for photosynthesis. Leaves are organs that greatly increase a plant's surface area and thus its exposure to light. Aboveground stems position leaves for maximum light exposure—an adaptation for maximizing photosynthesis—and in angiosperms they position flowers for pollination. As you will read shortly, some shoot system organs also store carbohydrates manufactured during photosynthesis.

They thread through ground tissues, which make up most of the plant body. Dermal tissues (epidermis, in this case) cover the surfaces of the root and shoot systems.

© Cengage Learning 2014

The **root system** usually grows below ground. It anchors the plant, and in most land plants provides structural support for a plant's upright parts. The root system also absorbs water and dissolved minerals from soil and stores carbohydrates. Adaptations in the structure and function of plant cells, organs, and tissues were an integral part of the evolution of both shoots and roots. For example, vascular tissues became specialized as pipelines that conduct water, minerals, and organic substances throughout the plant. The root hairs sketched in Figure 33.2 are surface cells specialized for absorbing water from soil.

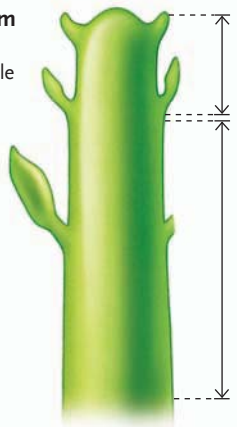
Shoot and Root Systems Contain Meristem Tissue with Key Roles in Growth of the Plant Body

As you know from experience, in animals growth slows dramatically or stops once the organism reaches a certain size. This pattern is called **determinate growth.** In contrast, most plant species have parts that can grow throughout the plant's life, a pattern called **indeterminate growth.** Certain plant organs such as leaves, flowers, and fruits exhibit determinate growth, but every plant's shoot and root system also includes clumps of self-perpetuating embryonic tissue called **meristems** (*merizein* = to divide) that produce new tissues more or less continuously while a plant is alive. (Chapter 36 provides a closer look at the role of meristems in early plant development.) A capacity for indeterminate growth gives plants a great deal of structural and functional flexibility—or what biologists often call *plasticity*—in their responses to changes in environmental factors such as light, temperature, water, and the supply of nutrients. This plasticity has major adaptive benefits for an organism that cannot move about, as most animals can. For example, if external factors change the direction of incoming light for photosynthesis, stems can "shift gears" and grow in that direction. Likewise, roots can grow outward toward water.

Meristems Are Responsible for Growth in Both Height and Girth

All vascular plants have a type of meristem that adds length to the plant body, and some also have a different type of meristem for increasing girth **(Figure 33.3).** An increase in length arises from **apical meristems,** clumps of self-perpetuating tissue at the tips of their buds, stems, and roots (see Figure 33.3A). Tissues that develop from apical meristems are called **primary tissues** and make up the **primary plant body.** Growth of the primary plant body is called **primary growth.**

Some species of plants—grasses and marigolds, for example—show only primary growth, which occurs at the tips of roots and shoots. Others, particularly plants such as trees that have a woody body, show **secondary growth,** which originates at self-perpetuating cylinders of tissue called **lateral meristems.** Secondary growth increases the girth (diameter) of older roots and stems (see Figure 33.3B). The tissues that develop from lateral meristems, called **secondary tissues,** make up the woody **secondary plant body** we see in trees and shrubs.



Primary and secondary growth can go on simultaneously in a single plant, with primary growth making shoot parts longer and secondary growth adding girth. Each spring, for example, primary growth increases the length of a maple tree's root and shoot tips, while secondary growth increases the diameter of its older woody parts. Plant hormones govern these growth processes and other key events that are described in Chapter 37.

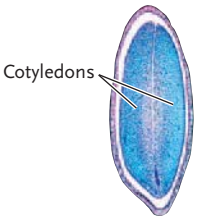
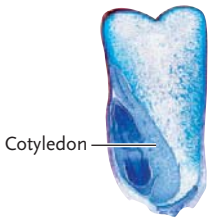
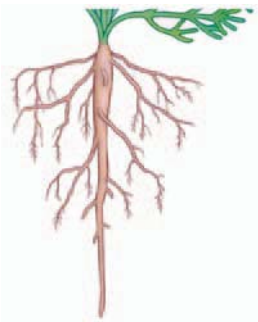
Monocots and Eudicots Are the Two General Structural Forms of Flowering Plants







As you know, evolutionary events resulted in two dominant groups, the monocot and eudicot lineages introduced in Chapter 28. Grasses and palms are examples of monocots. Eudicots include nearly all familiar angiosperm trees and shrubs, as well as many other types of plants. Although monocots and eudicots have similar types of tissues, their body structures typically differ in distinctive ways **(Table 33.1).** We say "typically" because botanists have discovered numerous exceptions to such a neat categorization scheme, including monocot species that have certain "eudicot" structural traits and vice versa. The possible adaptive significance of the various contrasting monocot and eudicot traits—such as parallel versus netted leaf veins—is an even trickier topic, subject to plenty of scholarly speculation but little convincing research. That said, the structural differences noted in Table 33.1 are widely observed in nature, and we will refer to them often as we discuss flowering plant morphology.

In Angiosperms, Different Overall Patterns of Growth Evolved and Correlate with Lifespan

Beyond the contrasting structural features that generally distinguish monocots and eudicots, evolution has generated differences in patterns of growth and reproduction we observe in flowering plants. A major distinction is that some angiosperm species have a body formed partly by secondary growth, and others do not. Secondary growth, which produces woody tissue, demands a substantial investment of energy and other resources. It correlates with a long life and, presumably, repeated opportunities for reproduction. Many eudicots (and all gymnosperms) have secondary growth. By contrast, most monocots and some eudicots show little or no secondary growth. They do not have

significant woody tissue and are termed *herbaceous* plants. Herbaceous species mature and reproduce quickly, with a relatively small investment of energy and other resources.

Annuals are herbaceous plants that develop a complete suite of mature organs and tissues and complete their life cycle in one growing season. With little or no secondary growth, annuals usually have only apical meristems. Examples are marigolds (a eudicot) and corn (a monocot). **Biennials** complete the life cycle in two growing seasons, with limited secondary growth in some species. Roots, stems, and leaves form in the first season, then the plant flowers, forms seeds, and dies in the second. Examples are carrots and celery (eudicots). **Perennials** grow and reproduce year after year. Many perennials, such as trees, shrubs, and some vines, have secondary tissues, although others, such as irises and daffodils, do not.

STUDY BREAK 33.1

1. **Compare and contrast the components and functions of a land plant's shoot and root systems.**
2. **Explain what meristem tissue is, and name and describe the roles of the basic types of meristems in forming the plant body.**

33.2 The Three Plant Tissue Systems

Meristems produce three tissue systems that provide the foundation for the various plant organs. The **ground tissue system,** which makes up most of the primary plant body, functions in metabolism, storage, and support. The **vascular tissue system** consists of interconnecting cells that form channels that transport water and nutrients throughout the plant. Vascular tissues are organized in bundles that are dispersed through the ground tissues. The **dermal tissue system** serves as a skinlike protective covering for the plant body. Figure 33.2 shows the general location of each system in the shoot and root.

Each tissue system includes several types of tissue, and each tissue is made up of cells with specializations for different functions **(Table 33.2).** *Simple* tissues have only one type of cell. *Complex* tissues have organized arrays of two or more types of cells. **Figure 33.4** will help you interpret micrographs of plant

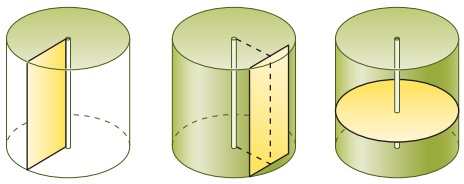

FIGURE 33.4 Terms that identify how tissue specimens are cut from a plant. Along the radius of a stem or root, longitudinal cuts give radial sections. Cuts at right angles to a root or stem radius give tangential sections. Cuts perpendicular to the long axis of a stem or root give transverse sections (cross sections).

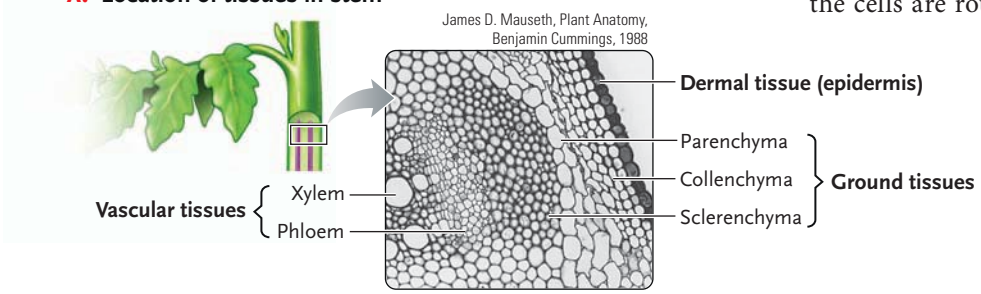
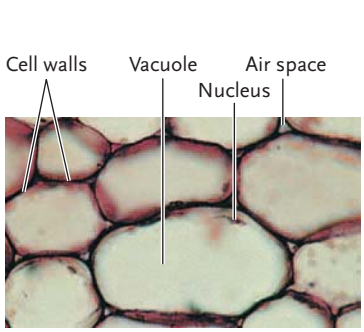
tissues, beginning with the tissues in a transverse section of a stem shown in **Figure 33.5A.**



Ground Tissues Are All Structurally Simple, but Differ in Important Ways



Plants have three types of ground tissue, each with a distinct structure and function—*parenchyma, collenchyma,* and *sclerenchyma* **(Figure 33.5B–D).** Each type is structurally simple, being composed mainly of one kind of cell. In a real sense, the cells in ground tissues are the "worker bees" of plants, carrying out photosynthesis, storing carbohydrates or water, providing mechanical support for the plant body, and performing other basic functions. Each kind of cell has a distinctive wall structure, and some also have variations in the protoplast.

PARENCHYMA: SOFT PRIMARY TISSUES Most of the soft, moist primary growth of roots, stems, leaves, flowers, and fruits is **parenchyma** (*para* = around, *khein* = fill in, or pour). Parenchyma cells can occur both as part of parenchyma tissue and as individual cells in other tissues.

Most parenchyma cells have only a thin primary wall (and no lignin), so they are pliable and permeable to water. Often the cells are round or many-sided, although they also can be

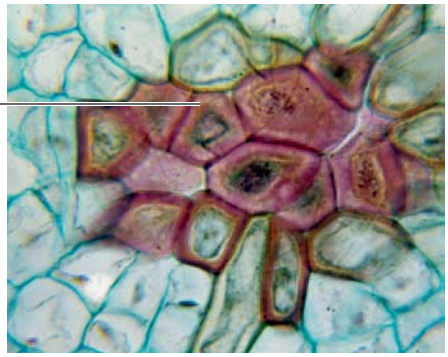
elongated like a sausage, as in Figure 33.5B. Sometimes there are air spaces between parenchyma cells, especially in leaves (see Figure 33.16).

On the whole, parenchyma cells are considered to be relatively unspecialized. Yet subsets of them do become differentiated for specialized roles. For example, photosynthesis occurs in parenchyma cells in which a large number of chloroplasts develop. The flesh of a potato tuber or an apple is mainly parenchyma specialized for carbohydrate storage. And in many plant species, some parenchyma cells are specialized for short-distance transport of solutes. These cells are common in tissues in which water and solutes must be rapidly moved from cell to cell—for example, in vascular tissues and in tissues that secrete nectar. Parenchyma cells usually remain alive and capable of dividing when they are mature. In fact, their mitotic divisions produce the new cells that often heal wounds in plant parts.



COLLENCHYMA: FLEXIBLE SUPPORT The ground tissue called **collenchyma** (see Figure 33.5C) helps support plant parts (*kolla* = glue). Collenchyma cells typically are elongated. Collectively they often form strands or a sheathlike cylinder under the dermal tissue of growing shoot regions and the stemlike *petiole* at the base of a leaf. The "strings" of celery include collenchyma. Like parenchyma cells, collenchyma cells remain alive and metabolically active as they mature.

Collenchyma is an especially important adaptation in parts such as elongating stems that require structural support as they grow. Each collenchyma cell develops only a primary wall built of layers of cellulose and pectin, but over time it thickens as the cell synthesizes these components. The result is a strong primary wall that can stretch as the cell elongates. This sturdy but physically flexible structure is an adaptation that ensures that collenchyma is not so rigid as to hamper the growth of plant parts it supports.

SCLERENCHYMA: RIGID SUPPORT AND PROTECTION Mature plant parts gain additional mechanical support and protection from **sclerenchyma** (*skleros* = hard). Most cells of this ground tissue develop thick secondary walls (see Figure 33.5D) that become heavily lignified. Once a sclerenchyma cell is encased in lignin, it dies because its protoplast can no longer take up nutrients or exchange gases with the environment. The walls remain, however, providing protection and support for the life of the plant.

There are two types of sclerenchyma cells, *sclereids* and *fibers*. **Sclereids** take a variety of shapes. Clumped, roughly cube-shaped sclereids give pears their slightly gritty texture **(Figure 33.6A).** Other sclereids form a thick protective coat around some kinds of seeds. Peach and cherry pits and the hard shells of coconuts, walnuts, and brazil nuts are examples. **Fibers (Figure 33.6B)** are elongated sclerenchyma cells that are sometimes compared to heavy rubber because they are somewhat pliable but resist stretching. Cotton fabric is woven from fibers that develop around the seeds of cotton plants *(Gossypium),* while linen cloth is made from fibers in the stems of flax plants. Tree bark gains a great deal of tensile strength from fibers that are incorporated in it. Fibers also occur in a plant's vascular tissues, the topic we turn to next.

Vascular Tissues Are Specialized for Conducting Fluids

Plant vascular tissues are complex tissues composed of specialized conducting cells, parenchyma cells, and fibers. *Xylem* and *phloem,* the two kinds of vascular tissues in flowering plants, are organized into bundles of interconnected cells that extend throughout the plant.

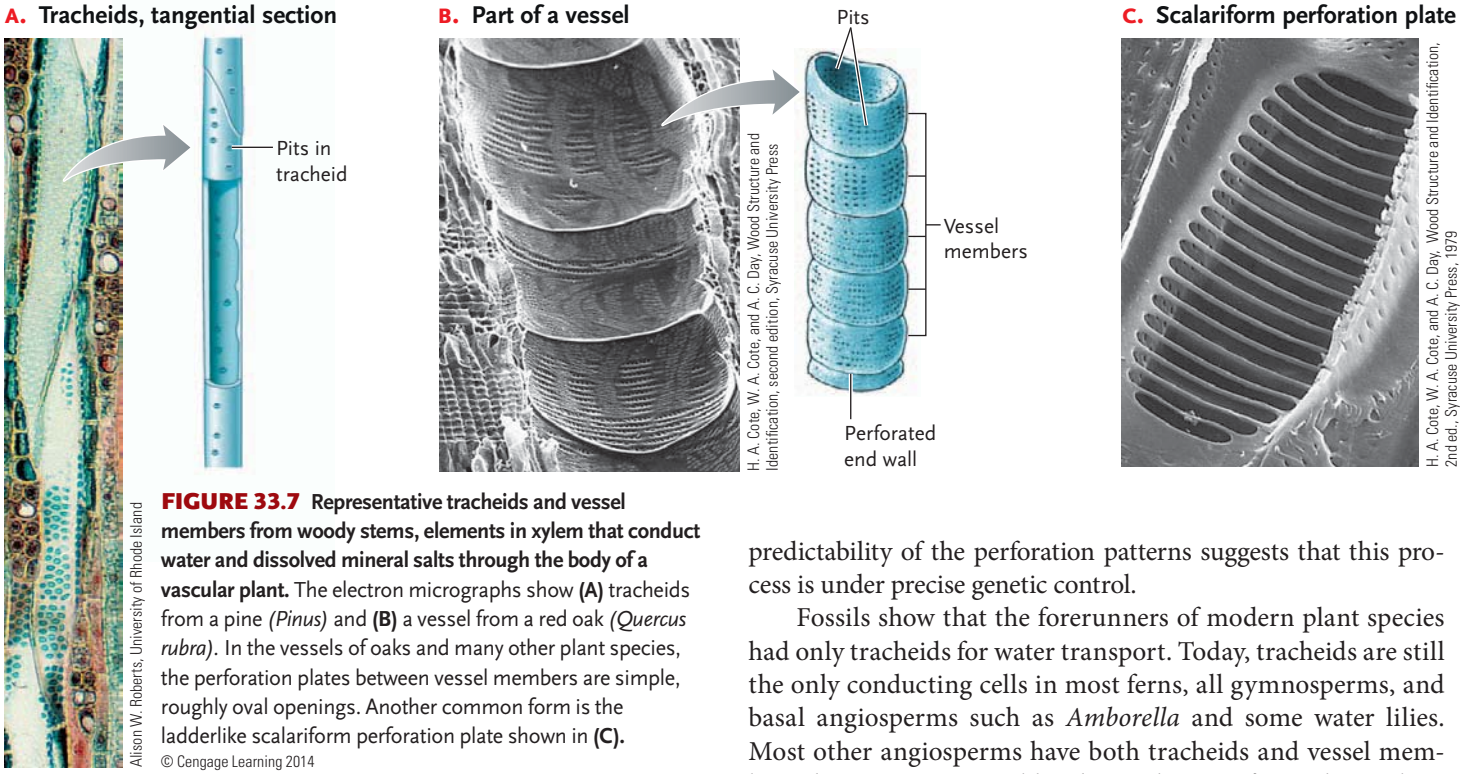

FIGURE 33.7 Representative tracheids and vessel members from woody stems, elements in xylem that conduct water and dissolved mineral salts through the body of a vascular plant. The electron micrographs show **(A)** tracheids from a pine *(Pinus)* and **(B)** a vessel from a red oak *(Quercus rubra)*. In the vessels of oaks and many other plant species, the perforation plates between vessel members are simple, roughly oval openings. Another common form is the ladderlike scalariform perforation plate shown in **(C).**

© Cengage Learning 2014

XYLEM: TRANSPORTING WATER AND MINERALS **Xylem** (*xylon* = wood) conducts water and minerals absorbed from the soil upward from a plant's roots to the shoot. This watery solution is pulled upward through the plant in a process that depends heavily on the physical properties of water, including the cohesion of water molecules. That process, called *transpiration,* is a key topic of Chapter 34. As you may recall from Chapter 28, xylem was a key adaptation in early land plants. Xylem contains two types of conducting cells: *tracheids,* which evolved first, and *vessel members,* which arose in most lineages of angiosperms. When both types of conducting cells reach maturity, they lay down secondary cell walls that are thickened and strengthened by lignin and cellulose. The cell's protoplast then disintegrates and the cell dies—leaving arrays of abutting, empty cells that can serve as pipelines for water and minerals.

Tracheids are elongated cells, with a rather narrow diameter and tapered, overlapping ends **(Figure 33.7A).** Water can move from cell to cell through openings called pits. Usually, a pit in one cell is opposite a pit of an adjacent cell, so water seeps laterally from tracheid to tracheid.

Vessel members are joined end to end in tubelike multicellular columns called **vessels (Figure 33.7B).** Like tracheids, vessel members have pits through which water can move from cell to cell. However, they also have other structural adaptations that enhance water flow. They have a wider inside diameter than tracheids, and as vessel members mature, enzymes break down portions of their end walls, producing perforations. Some vessel members have a single, large perforation, so that the end is completely open. Others have a cluster of small, round perforations or ladderlike bars that extend across the open end **(Figure 33.7C).** The predictability of the perforation patterns suggests that this process is under precise genetic control.

Fossils show that the forerunners of modern plant species had only tracheids for water transport. Today, tracheids are still the only conducting cells in most ferns, all gymnosperms, and basal angiosperms such as *Amborella* and some water lilies. Most other angiosperms have both tracheids and vessel members, however. Presumably, the evolution of vessel members conferred an adaptive advantage by increasing the efficiency with which water and minerals move throughout the plant.

Xylem also contains parenchyma cells and sclerenchyma fibers. The parenchyma cells help transport minerals through vessel members and tracheids. Sclerenchyma fibers function like steel cables in concrete, helping keep the xylem tissue fairly rigid and lending overall structural support to the plant.

PHLOEM: A TISSUE THAT TRANSPORTS SUGARS AND OTHER SOLUTES The vascular tissue **phloem** (*phloios* = tree bark) transports solutes, notably the sugars made in photosynthesis, throughout the plant. The main conducting cells of phloem are **sieve-tube members (Figure 33.8),** which connect end to end, forming a **sieve tube.** As the name implies, their end walls, called sieve plates, are laced with openings. In flowering plants the phloem is strengthened by fibers and sclereids.

Immature sieve-tube members contain the usual plant organelles. Over time, however, the cell nucleus and internal membranes in plastids break down, mitochondria shrink, and the cytoplasm is reduced to a thin layer lining the interior surface of the cell wall. Even without a nucleus, sieve-tube members live up to several years in most plants, and much longer in some trees.

In many flowering plants, specialized parenchyma cells called **companion cells** are connected to mature sieve-tube members by plasmodesmata. Unlike sieve-tube members, companion cells retain their nucleus when mature. They assist sieve-tube members both with the uptake of sugars and with the unloading of sugars in tissues that are growing or that store food. They may also help regulate the metabolism of mature sieve-tube members. Chapter 35 returns to the functions of phloem cells.

Dermal Tissues Protect Plant Surfaces

A complex tissue called **epidermis** covers the primary plant body in a single continuous layer **(Figure 33.9A)** or sometimes in multiple layers of tightly packed cells. The outer surface of epidermal cell walls is coated with waxes that are embedded in cutin, a network of chemically linked fats. Epidermal cells secrete this coating, or **cuticle,** which resists water loss and helps fend off attacks by microbes. A cuticle coats all external plant parts except the very tips of the shoot and most absorptive parts of roots. Other root regions have an extremely thin cuticle.

Some epidermal cells are modified in ways that represent major adaptations for plants. Young stems, leaves, flower parts, and even some roots have pairs of crescent-shaped **guard cells** **(Figure 33.9B).** Unlike other epidermal cells, guard cells contain chloroplasts and so can carry out photosynthesis. In addition, the porelike openings between guard cells, termed **stomata** (singular, *stoma*), play another crucial role. Carbon dioxide for photosynthesis enters plants through open stomata, while water vapor and oxygen exit the plant by the same route. As described more fully in Chapter 35, mechanisms that regulate the opening and closing of stomata are essential to maintaining an appropriate balance between the intake of CO_2 and the loss of water vapor from plant tissues.

FIGURE 33.9 **Structure and examples of epidermal tissue.** **(A)** Cross section of leaf epidermis from a bush lily *(Clivia miniata)*. **(B)** Scanning electron micrograph of a leaf surface, showing cuticle-covered epidermal cells and stomata. **(C)** Root hairs, trichomes which develop from root epidermis.

DISCOVERING HOW GENES CONTROL STOMATA With their exact spacing and vital role in regulating gas exchange between a plant and its environment, stomata have captured the interest of geneticists probing the molecular underpinnings of plant development. Working with *Arabidopsis thaliana* (thale cress), researchers have identified an enzyme—encoded by the gene *YDA*—that appears to exert overall control over where and how many stomata form. In mutant plants with a defective enzyme, the epidermis is blanketed with stomata packed side by side. The plants often die early in development or are stunted and appear fuzzy—hence the enzyme's name, YODA, recalling the short, hairy Star Wars character. In nonmutated wild-type plants, unequal divisions of precursor cells produce one smaller and one larger daughter cell, and the smaller one gives rise to a stoma's two guard cells. (The larger cell either divides again or becomes

an underlying epidermal cell.) When the YODA enzyme is activated (by phosphorylation), it triggers a cascade of reactions that, by some as-yet-unknown mechanism, either promote or restrict these asymmetric divisions.

Many plants also can apparently modify their stomata in response to changing levels of carbon dioxide in the environment. A flurry of research on this topic began when plant physiologist F. Ian Woodward of Sheffield University hypothesized that a rising concentration of CO_2 in the atmosphere—a hallmark of global climate change—acts as a trigger for the development of fewer stomata in leaves, because under such conditions plants would not require as many stomata to obtain adequate CO_2. When Woodward examined herbarium specimens collected over a recent 200-year period during which atmospheric CO_2 has steadily increased, the number of stomata in leaves of the test specimens had indeed declined. Subsequent research has confirmed that plants can reduce or increase the number of stomata in response to external CO_2 levels. Apparently, a biochemical signal from a plant's mature leaves influences the development of new leaves, adjusting the number of stomata to meet demand. Experiments have identified at least one gene that has a central role in these events, and more studies are underway to elucidate the control pathways.

OTHER EPIDERMAL SPECIALIZATIONS Single-celled or multicellular outgrowths, collectively called **trichomes,** give the stems or leaves of some plants a hairy appearance. Some trichomes exude sugars that attract insect pollinators. Leaf trichomes of members of the genus *Urtica,* the stinging nettles, provide protection by injecting an irritating toxin into the skin of animals that brush against the plant, or try to eat it. **Root hairs,** which develop as extensions in the outer wall of root epidermal cells **(Figure 33.9C),** are also trichomes. As we noted earlier, root hairs absorb much of a plant's water and minerals from the soil.

The epidermal cells of flower petals (which are modified leaves) synthesize pigments that are partly responsible for a blossom's colors. However, molecular studies have revealed that flower colors and their intensity or brightness also depend on the shape of the epidermal cells, as described in *Insights from the Molecular Revolution.*

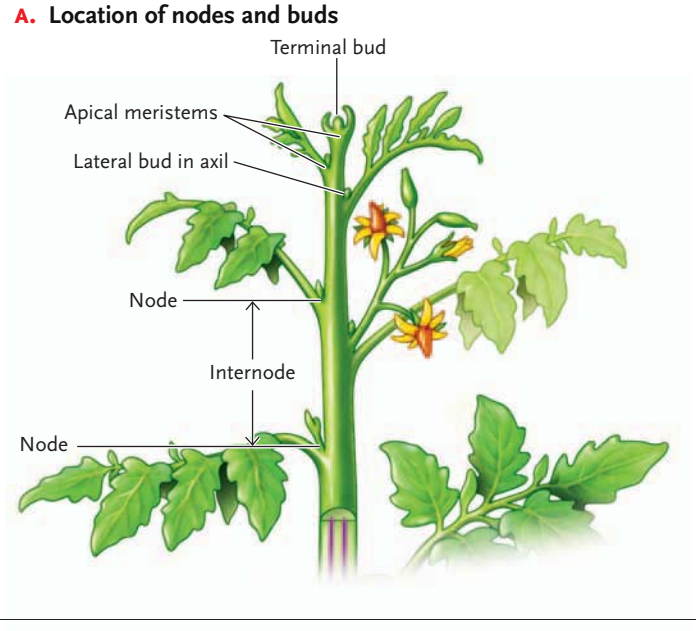
3. **What are the cellular components and functions of the dermal tissue system?**

33.3 Primary Shoot Systems



A flowering plant's primary shoot system consists of the main stem and leaves. In this section we take a closer look at how the constituent parts of the primary shoot system are organized and how they grow and function. Chapter 36 discusses the positional cues that guide key aspects of the plant body's growth.

Stems Are Adapted to Provide Support, Routes for Vascular Tissues, Storage, and New Growth

Stems incorporate evolutionary adaptations that serve four main functions. First, stems provide mechanical support, generally along a vertical ("upright") axis, for body parts such as leaves and flowers. Second, stems house the vascular tissues (xylem and phloem), which transport water and dissolved minerals, hormones, products of photosynthesis, and other substances throughout the plant. Third, stems often have modifications for storing water and food. And finally, buds and specific stem regions contain meristematic tissue that gives rise to new cells of the shoot.

THE MODULAR ORGANIZATION OF A STEM As Section 33.1 noted, we can think of a stem as a set of modules. **Figure 33.10A** shows the two basic elements of each stem module, a *node* and an *internode.* A **node** is where one or more leaves attach to a stem. An **internode** is the area between two nodes. The upper angle between the stem and an attached leaf is an **axil.** New primary growth occurs in the embryonic shoots called buds. A **terminal bud** occurs at the apex of each stem **(Figure 33.10B). Lateral buds** in the leaf axils produce new branches or shoots that give rise to flowers.

Shaping Up Flower Color

Different pigments in flowers produce different colors, but are pigments the whole color story? A molecular study of flower color in snapdragons *(Antirrhinum majus)* provided a surprising answer. Ken-ichi Noda of the Nippon Oil Company in Japan and Beverley J. Glover and her colleagues at the John Innes Centre in England were interested in a mutant snapdragon called *mixta,* which produces pale red flower petals with a dull, flat surface **(Figure 1)** rather than the deep red, velvety petals of wild-type plants **(Figure 2).**

The investigators isolated, cloned, and sequenced the *mixta* gene. Its sequence closely resembles a regulatory gene that activates genes in some other plants. The similarities suggested that the normal snapdragon gene also codes for a regulatory protein that produces normal flower color. When a transposable element inserts in the gene, the regulatory protein is lost (see Section 15.5).

Research Question

How does the regulatory protein govern flower color?

Experiments

At first Noda and his colleagues thought the protein regulated production of anthocyanin, a pigment that gives flowers a red color, and that loss of the protein in mutant plants hampered anthocyanin production. They discarded this hypothesis when both the wild-type and *mixta* plants were found to have normal levels of anthocyanin. However, microscopic examination of flower petals revealed that wild-type and *mixta* epidermal cells are shaped differently. Normal plants have conical epidermal cells, with the tip of the cone pointing outward and giving the petals a velvety appearance. Epidermal cells of *mixta* mutants have a flat, irregular surface that produces a dull appearance. **Figure 3** shows the surface of a variegated flower petal, which has both conical and flat cells. This structural difference suggested that in wild-type petals, the cone tips act as prisms that make the red pigment clearly visible, while the irregular surface of the mutant cells scatters light and mutes the pigment color.

As a test, the research team removed the cell walls from the epidermal petal cells, a step that eliminated differences in cell shape. Both the normal and mutant cells had the same intense, red color.

Conclusion

Based on their investigations, the researchers proposed that the regulatory protein encoded in the normal *MIXTA* gene activates other genes whose protein products in some way produce the conical cell shape that enhances color intensity.

THINK LIKE A SCIENTIST What are logical next steps in exploring the drivers of epidermal cell shape in *A. majus* petals?

OVERVIEW OF STEM GROWTH Several general patterns of growth evolved in flowering plants. In eudicots, most growth in a stem's length occurs directly below the apical meristem, as internode cells divide and elongate. Internode cells nearest the apex are most active, so the most visible new growth occurs at the ends of stems. By contrast, in grasses and some other monocots the upper cells of an internode stop dividing as the newly formed internode elongates, and cell division is limited to a meristematic region at the base of the internode. The stems of bamboo and other grasses elongate as the growth of such meristems "pushes up" the internodes. This adaptation allows grasses to rapidly grow back after grazing by herbivores (or being chopped off by a lawnmower), because the meristem is not removed.

Terminal buds release a hormone that inhibits the growth of nearby lateral buds, a phenomenon called **apical**

dominance. Gardeners who want a bushier plant can stimulate lateral bud growth by periodically cutting off the terminal bud. The flow of hormone signals from the apical meristem then dwindles to a level low enough that lateral buds begin to grow. In nature, apical dominance is an adaptation that directs the plant's resources into growing up toward the light.

PRIMARY GROWTH AND STRUCTURE OF A STEM Primary growth of a shoot and its parts begins in the shoot apical meristem. In addition to giving rise to stem tissue, the shoot apical meristem also periodically generates shoot primordia, bulges that are the first developmental stages of leaves, additional shoots, and reproductive structures such as flowers.

A shoot apical meristem is a dome-shaped mass of cells. When one cell divides, one of its daughter cells becomes an **initial** that remains as part of the meristem. The other daughter cell, called a **derivative,** will be the source of specialized cells. In this way initials function much like stem cells in animals. They replenish the supply of initials in the meristem and also provide derivatives that result in a plant's new growth. **Figure 33.11** shows the sequence for a eudicot shoot.

As derivatives differentiate, they give rise to three **primary meristems:** *protoderm, procambium,* and *ground meristem* (see Figure 33.11). These meristems are relatively unspecialized tissues producing cells that differentiate in turn into specialized cells and tissues. In eudicots, the primary meristems are also responsible for elongation of the plant body. Some monocots, such as palms, have a *primary thickening meristem* (just under the protoderm) that contributes to both stem elongation and its lateral growth.

How do the genetically identical cells of an apical meristem give rise to three types of primary meristem cells, and ultimately to all the specialized cells of the plant? *Focus on Basic Research* describes some experiments that are probing the genetic mechanisms underlying meristem activity.

Each primary meristem occupies a different position in the shoot tip, as shown in Figure 33.11A. Outermost is **protoderm,** a meristem that will produce the stem's epidermis. While protoderm cells divide and the resulting derivatives are maturing, the shoot tip continues to grow. Eventually, the protoderm cells differentiate into specific types of epidermal cells, including guard cells and trichomes.

Inward from the protoderm is the **ground meristem,** which will give rise to ground tissue, most of which is parenchyma. **Procambium,** which produces the primary vascular tissues, exists as threadlike strands of cells within the ground meristem. Procambial cells are long and thin, and their spatial orientation foreshadows the future function of the tissues they produce. In most plants, inner procambial cells give rise to xylem and outer procambial cells to phloem. In plants with secondary growth, a thin region of procambium between the primary xylem and phloem remains undifferentiated. As described shortly, later on it will give rise to a lateral meristem.

The developing vascular tissues become organized into **vascular bundles,** multistranded cords of primary xylem and phloem. Wrapped or capped by sclerenchyma, the bundles thread lengthwise through the parenchyma, forming a **stele** (Greek *stele* = pillar; some botanists prefer to call vascular bundles in the shoot the *vascular cylinder*). The stele runs vertically. The ground tissue outside it forms a **cortex,** while tissue inside it is called **pith (Figure 33.12A).** As leaves and buds appear

along a stem, some vascular bundles in the stem branch off into these developing tissues.

Both cortex and pith are mainly parenchyma, and in some plants the pith parenchyma stores starch. In the stems of most monocots, vascular bundles are dispersed through the ground tissue **(Figure 33.12B),** so separate cortical and pith regions do not form. In some monocots, including bamboo, the pith breaks down, leaving the stem with a hollow core. The hollow stems of some hard-walled bamboo species are used to make bamboo flutes.

STEM MODIFICATIONS Evolution has produced a range of stem specializations, including structures modified for reproduction, food storage, or both **(Figure 33.13).** An onion or a garlic head is a *bulb,* a modified shoot that consists of a bud with fleshy leaves. *Tubers* are stem regions enlarged by the presence of starch-storing parenchyma cells; examples of plants that form tubers are the potato and the cassava (the source of tapioca). The "eyes" of a potato are buds at nodes of the modified stem, and the regions between eyes are internodes. Many grasses, ground ivies, and some weeds are difficult to eradicate because they have *rhizomes*—long under-

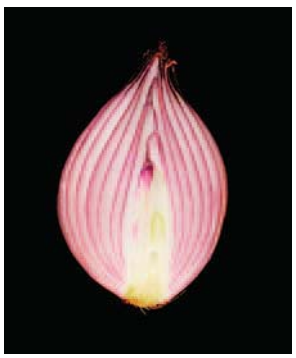
Homeobox Genes: How the Meristem Gives Its Marching Orders

How do descendants of some dividing cells in a shoot apical meristem (SAM) "know" to become stem tissues, while others embark on the developmental path that produces leaves or other shoot parts? The full answer to this question is not yet known, but research teams around the world are studying a genetic mechanism that appears to guide the process.

Working with SAM tissue from maize (*Zea mays,* generally known in North America as corn), investigators have identified more than a dozen regulatory genes whose protein products activate groups of other genes in differentiating cells. Some genes that act in this way to guide development along a particular path are called *homeotic genes,* because they contain a nucleotide sequence called the homeobox. As described in Chapter 16, the homeobox is the part of a homeotic gene that codes for a homeodomain—a sequence of amino acids in a transcription factor. The homeodomain binds to regulatory regions of certain genes; this binding regulates transcription of such genes, turning them on or off. Homeobox genes were first discovered in studies of how legs, antennae, and other structures develop in the fruit fly *Drosophila melanogaster.*

Sarah Hake of the Plant Gene Expression Center (United States Department of Agriculture) was curious about the action of a homeotic gene in maize that is known as *knotted-1 (KN-1).* Normally, the *KN-1* gene is expressed in apical meristems, where it keeps the meristem in an undifferentiated state. When a mutated form of the gene, *kn-1,* is expressed, however, the mutation causes abnormal knobby growths on leaves—hence the gene's name. Hake's research helped establish that *KN-1* defines developmental pathways that unfold in meristems. For example, when Hake cloned the *KN-1* gene and inserted it into tobacco leaf cells, the cells *de*differentiated and began acting like meristem cells. As they divided, they produced lines that could differentiate into leaves and stems.



Subsequent studies of *KN-1* in species as diverse as sunflowers and garden peas have led to the identification of the family of what are now called knotted-1-like genes, all of which encode regulatory proteins that influence developmental pathways. As in maize, some are typically expressed in SAM tissue. In sunflower, tomato, and perhaps other species, knotted-1-like genes also appear to be expressed in differentiated plant parts including leaves, flowers, stems, and even roots. The early work on SAM tissue and homeobox genes in maize has blossomed into a wide-ranging investigation of the molecular signals that shape plant architecture.

ground stems that can extend as much as half a meter deep into the soil and rapidly produce new shoots when existing ones are pulled out. The pungent, starchy "root" of ginger is a rhizome also. Crocuses and some other ornamental plants develop elongated, fleshy underground stems called *corms,* another starch-storage adaptation. Tubers, rhizomes, and corms all have meristematic tissue at nodes from which new plants can be propagated—a vegetative (asexual) reproductive mode. Other plants, including the strawberry, reproduce vegetatively via slender stems called *stolons,* which grow along the soil surface. New plants arise at nodes along the stolon.

Leaves Are Adapted for Photosynthesis, Gas Exchange, and Conserving Water

Each spring a mature maple tree heralds the new season by unfurling roughly 100,000 leaves. Some other tree species produce leaves by the millions. For these and most other plants, leaves are multifaceted organs with evolutionary adaptations that make them the main sites of photosynthesis and permit them to exchange gases and limit the loss of water by evaporation.

LEAF MORPHOLOGY AND ANATOMY Externally, the most conspicuous part of a leaf is its thin, flattened **blade,** which provides a large surface area for absorbing sunlight and carbon dioxide **(Figure 33.14A).** In many eudicot leaves, the blade narrows to a stalklike **petiole,** which attaches the leaf to a stem. Petioles can be long, short, or in between, depending on the species. The stalks of celery and rhubarb are especially fleshy petioles. Unless a leaf's petiole is very short, it holds the leaf away from the stem and helps prevent individual leaves from shading one another. Most monocot leaves lack a petiole. Instead, in species such as rye grass or corn, the blade is long and narrow and its base simply forms a sheath around the stem.

Studies show that in general, leaves of flowering plants are oriented on the stem axis so that they can capture the maximum amount of sunlight. Chapter 37 describes how the stems and leaves of some plants change position to follow the sun's movement during the course of a day.

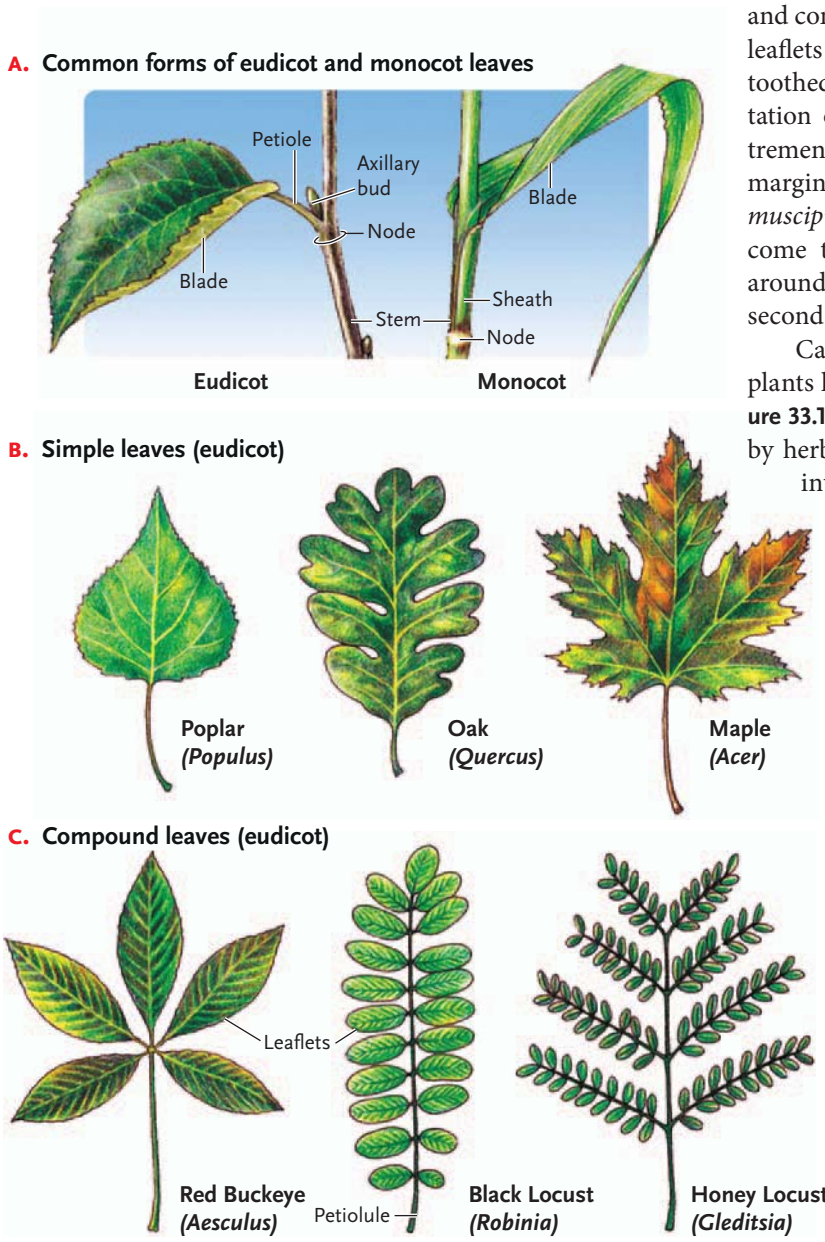

FIGURE 33.14 **Leaf forms.** **(A)** Common forms of eudicot and monocot leaves. **(B)** Examples of simple eudicot leaves. **(C)** Examples of compound eudicot leaves.

© Cengage Learning 2014

LEAF MODIFICATIONS Leaf forms are based on two basic patterns: simple leaves, which have a single blade **(Figure 33.14B),** and compound leaves, in which the blade is divided into smaller leaflets **(Figure 33.14C).** Leaf edges or margins may be smooth, toothed, or lobed. As with other plant parts, however, the adaptation of land plants to different environments has produced tremendous variety in leaf morphology. For instance, spiny margins on the leaves of the carnivorous Venus flytrap *(Dionaea muscipula)* **(Figure 33.15A)** prevent the escape of insects that become trapped when the seemingly hinged leaves snap shut around them—a movement that takes only about a tenth of a second.

Cactus leaves are modified as spines, while leaves of other plants have trichomes that take the form of hairs or hooks **(Figure 33.15B)**—all possible adaptations for defense against grazing by herbivores. Leaves or parts of leaves also may be modified into tendrils, like those of the sweet pea **(Figure 33.15C),** or other structures. Epidermal cells on the leaves of the saltbush *Atriplex spongiosa* form balloon-like structures **(Figure 33.15D)** that contain concentrated Na^+ and Cl^- taken up from the salty soil. Eventually, the salt-filled epidermal cells burst or fall off the leaf, releasing the salt to the outside. This adaptation helps control the salt concentration in the plant's tissues—another example of the link between structure, function, and the environment in which a plant lives.

LEAF PRIMARY GROWTH AND INTERNAL STRUCTURE In both flowering plants and gymnosperms, leaves develop on sides of the shoot apical meristem. Initially, meristematic cells near the apex divide and their derivatives elongate. The resulting bulge enlarges into a thin, rudimentary leaf, or **leaf primordium** (see Figure 33.11). As the plant grows and internodes elongate, the leaves that form from leaf primordia become spaced at intervals along the length of a stem.

Leaf tissues typically have several layers **(Figure 33.16).** Uppermost is epidermis, with cuticle covering its outer surface. Just beneath the epidermis is **mesophyll** (*mesos* = middle; *phyllon* = leaf), ground tissue composed of loosely packed parenchyma cells that contain chloroplasts. The leaves of many plants,

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

especially eudicots, contain two layers of mesophyll. *Palisade mesophyll* cells contain more chloroplasts and are arranged in compact columns with smaller air spaces between them, typically toward the upper leaf surface. *Spongy mesophyll,* which tends to be located toward the underside of a leaf, consists of irregularly arranged cells with a conspicuous network of air spaces that gives it a spongy appearance. Air spaces between mesophyll cells enhance the uptake of carbon dioxide and release of oxygen during photosynthesis and account for 15% to 50% of a leaf's volume. Mesophyll also contains collenchyma and sclerenchyma cells, which support the leaf blade.

Below the mesophyll is another cuticle-covered epidermal layer. Except in grasses and a few other plants, this layer contains most of the stomata through which water vapor exits the leaf and carbon dioxide enters. For example, the upper surface of an apple leaf has no stomata, while a square centimeter of the lower surface has more than 20,000. A square centimeter of the upper epidermis of a tomato leaf has about 1,200 stomata, whereas the same area of the lower epidermis has 13,000. The positioning of stomata on the side of the leaf that faces away from the sun may be an adaptation limiting water loss by evaporation through stomatal openings.

Vascular bundles form a lacy network of **veins** throughout the leaf. Eudicot leaves typically have a branching vein pattern; in monocot leaves, veins tend to run in parallel arrays.

In temperate regions, most leaves are temporary structures. In deciduous (*deciduus* = that which falls off) species such as birches and maples, hormonal signals cause the leaves to drop from the stem as days shorten in autumn. Other temperate species, such as camellias or hollies, as well as conifers, also drop leaves, but they appear "evergreen" because the leaves may persist for several years and do not all drop at the same time.

Plant Shoots May Have Juvenile and Adult Forms

Leaf shape and other shoot characteristics can mirror the progress of a long-lived plant through its life cycle. Plants that live many years may spend part of their lives in a juvenile phase, then shift to a mature, or adult phase. The differences between juveniles and adults often are reflected in leaf size and shape, in the arrangement of leaves on the stem, or in a change from vegetative growth to a reproductive stage—or sometimes all three. Plants in the genus *Eucalyptus* display a wide range of such variations **(Figure 33.17).** For example, in the yellow gum (*E. doratoxylon* or *E. erythrocorys*) the leaves of a mature tree are bluish-green, long and slender with long petioles, and occur in alternating positions on a stem. By contrast, the leaves of a growing seedling are oval with a pale grayish surface, have little or no petiole, and occur opposite one another on the stem. A Southern magnolia tree *(Magnolia grandiflora)* doesn't flower until its juvenile phase ends, which can be 20 years or more from the time the *M. grandiflora* seed sprouts. In fact, most woody plants must attain a certain size before their meristem

FIGURE 33.17 Age-related phase changes in *Eucalyptus* globulus. Juvenile leaves (left) are oval; mature leaves are elongated.

tissue can respond to the hormonal signals that govern flower development, a topic we consider in Chapter 37.

Phase changes provide more examples of the plasticity that characterizes plant development. They almost certainly are associated with changes in the expression of genes that control the development of stem nodes, leaf and flower buds, and other basic aspects of plant growth.

STUDY BREAK 33.3

1. Describe the functions of stems and stem structure, and list the basic steps in primary growth of stems.
2. Explain the general function of leaves and how leaf anatomy supports this role in eudicots and monocots.
3. Describe the steps in primary growth of a leaf and the structures that result from the process.
4. Describe two examples of the life phases of long-lived plant species.

THINK OUTSIDE THE BOOK

On your own or with classmates, make a list of at least five vegetables and five fruits that have not been discussed in this chapter and that you have eaten or seen in the market. Using library resources or the Internet, identify the source plant's genus and species, then describe which anatomical part of the plant each fruit or vegetable is, and identify which tissue or tissues make up the fruit or vegetable. Then describe each item's function in the plant.

33.4 Root Systems

Plants have to absorb enough water and dissolved minerals to sustain growth and routine cellular maintenance, a task that requires a tremendous root surface. In one study, measurements of the root system of a rye plant *(Secale cereale)* that had been growing for only four months had a surface area of more than

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

700 m^2—about 130 times greater than the surface area of its shoot system. The roots of carrots, sugar beets, and most other plants also store nutrients produced in photosynthesis, some to be used by root cells and some to be transported later to cells of the shoot. As a root system penetrates downward and spreads out, it also anchors the aboveground parts.

Different Types of Root Systems Are Specialized for Particular Functions

Most eudicots begin life with a **taproot system**—a single main root, or taproot, that is adapted for storage and smaller branching roots called **lateral roots (Figure 33.18A).** As the main root grows downward, its diameter increases, and the lateral roots emerge along the length of its older, differentiated regions. The youngest lateral roots are near the root tip. Carrots and dandelions have a taproot system, as do many pines and other conifers. The taproot system of a longleaf pine *(Pinus palustris)* can penetrate 4 meters or more into the soil.

In grasses and many other monocots, the first, embryonic root (called the *radicle*) dies after a brief time and its role is assumed by **adventitious roots** that arose from the young plant's stem. "Adventitious" refers to any structure arising at an unusual location, Eventually a monocot's adventitious roots form a **fibrous root system** in which several main roots branch to form a dense mass of smaller ones **(Figure 33.18B).** Fibrous root systems are adapted to absorb water and nutrients from the upper layers of soil, and tend to spread out laterally from the base of the stem. Fibrous roots are important ecologically because dense root networks help hold topsoil in place and prevent erosion. During the 1930s, drought, overgrazing by livestock, and intensive farming in the American Midwest destroyed hundreds of thousands of acres of native prairie grasses, contributing to soil erosion on a massive scale. Swirling clouds of soil particles prompted journalists to name the area the Dust Bowl.

Adventitious roots can also arise from leaves. Those of some climbing plants, including ivies (*Hedera* spp.) produce a gluey substance (from trichomes) that allows them to cling to vertical surfaces **(Figure 33.18C).** The *prop roots* of a corn plant are adventitious roots that develop from the shoot node nearest the soil surface; they both support the plant and absorb water and nutrients. Mangroves and other trees that grow in marshy habitats often have huge prop roots, which develop from branches as well as from the main stem **(Figure 33.18D).**

Root Structure Is Specialized for Underground Growth

Like shoots, roots have distinct anatomical parts, each with a specific function. In most plants, primary growth of roots begins when an embryonic root emerges from a germinating seed and its meristems become active. **Figure 33.19** shows the structure of a root tip. Notice that the root apical meristem terminates in a dome-shaped cell mass, the **root cap.** The meristem produces the cap, which in turn surrounds and protects the meristem as the root elongates through the soil. Certain cells in the cap respond to gravity, which guides the root tip downward. Cap cells also secrete a polysaccharide-rich substance that lubricates the tip and eases the growing root's passage through the soil. Outer root cap cells are continually abraded off and replaced by new cells at the cap's base.

ZONES OF PRIMARY GROWTH IN THE ROOT Primary growth in roots takes place in successive stages, beginning at the root tip and progressing upward. Just inside the root cap some roots have a small clump of apical meristem cells called the **quiescent center.** Unlike other meristematic cells, cells of the quiescent center divide very slowly unless the root cap or the apical meristem is injured, then they become active and can regenerate the

damaged part. The quiescent center also may include cells that synthesize plant hormones that control root development.

The root apical meristem and the actively dividing cells behind it form the **zone of cell division.** As in the stem, cells of the apical meristem segregate into three primary meristems. Cells in the center of the root tip become the procambium; those just outside the procambium become ground meristem; and those on the periphery of the apical meristem become protoderm.

The zone of cell division merges into the **zone of elongation.** Most of the increase in a root's length comes about here as cells become longer as their vacuoles fill with water. This "hydraulic" elongation pushes the root cap and apical meristem through the soil as much as several centimeters a day.

Above the zone of elongation, cells do not increase in length but they may differentiate further and take on specialized roles in the **zone of maturation.** For instance, epidermal cells in this zone give rise to root hairs, and the procambium, ground meristem, and protoderm complete their differentiation here.

TISSUES OF THE ROOT SYSTEM Coupled with primary growth of the shoot, primary root growth produces a unified system of vascular pipelines extending from root tip to shoot tip. The root procambium produces cells

that mature into the root's xylem and phloem **(Figure 33.20).** Ground meristem gives rise to the root's cortex, its ground tissue of starch-storing parenchyma cells that surround the stele. In eudicots, the stele runs through the center of the root (see Figure 33.20A). In corn and some other monocots, the stele forms a ring that divides the ground tissue into cortex and pith (see Figure 33.20B).

The cortex contains air spaces that allow oxygen to reach all of the living root cells. Numerous plasmodesmata connect the cytoplasm of adjacent cells of the cortex. In many flowering plants, the outer root cortex cells give rise to an **exodermis,** a narrow band of cells beneath the epidermis. Among other functions, the exodermis may limit water losses from roots and help regulate the absorption of ions. The innermost layer of the root cortex is the **endodermis,** a thin, selectively permeable barrier that helps control the movement of water and dissolved minerals into the stele. Chapter 34 looks in more detail at the roles of exodermis and endodermis.

Between the stele and the endodermis is the **pericycle,** consisting of one or more layers of parenchyma cells that can still function as meristem. The pericycle gives rise to lateral roots **(Figure 33.21).** In response to chemical growth regulators, rudimentary roots, or **root primordia,** arise at specific sites in the pericycle. Gradually, the lateral roots emerge and grow out through the cortex and epidermis, aided by enzymes released by the root primordium that help break down the intervening cells. The distribution and frequency of lateral root formation partly control the overall shape of the root system—and the extent of the soil area it can penetrate.

In some cells in the developing root epidermis, the outer surface becomes extended into root hairs (see Figure 33.19). Root hairs can be more than a centimeter long and can form in less than a day. Collectively, the thousands or millions of them on a plant's roots greatly increase the plant's absorptive surface. Root hair structure supports this essential function. Each hair is a slender tube with thin walls made sticky on their surface by a coating of pectin. Soil particles tend to adhere to the wall, providing an intimate association between the hair and the surrounding earth, thus facilitating the uptake of water molecules and mineral ions from soil. When plants are transplanted, rough handling can tear off much of the fragile absorptive surface. Unable to take up enough water and minerals, the transplant may die before new root hairs can form.

STUDY BREAK 33.4

1. **Compare the two general types of root systems.**
2. **Describe the zones of primary growth in roots.**
3. **Describe the various tissues that arise in a root system and their functions.**

33.5 Secondary Growth

Primary growth produces the primary body parts of a seed plant—its root and stem systems. In plants that have secondary growth, the tissues we know as wood and bark add girth to roots and stems over two or more growing seasons. In such plant species, including trees and shrubs, every so often mitosis is reactivated in two types of lateral meristems, or *cambia* (singular, cambium). Over time, their activity makes older stems and roots more massive. One of the lateral meristems, **vascular cambium,** produces secondary xylem and phloem. The other lateral meristem, called **cork cambium,** produces **cork,** a secondary epidermis that is a major ingredient in bark.

Vascular Cambium Gives Rise to Secondary Growth in Stems

After a woody plant's stem completes its primary growth, each vascular bundle contains a layer of undifferentiated cells between the primary xylem and phloem. These cells, along with parenchyma cells between the bundles, eventually give rise to a cylinder of vascular cambium that encircles the xylem and pith of the stem **(Figure 33.22).** Vascular cambium consists of two types of initials (which, recall, are the dividing cells in a meristem). Secondary growth takes place mainly as these cells divide in a plane parallel to the vascular cambium, adding girth to the stem. One type of initials give rise to secondary xylem and phloem cells that mainly conduct fluid vertically through a stem. Secondary xylem forms on the inner face of the vascular cambium and secondary phloem forms on the outer face. Other dividing initials produce *rays*—horizontal columns of living parenchyma cells arranged like spokes of a wheel. Ray parenchyma stores carbohydrates or helps move solutes horizontally across the stem. In conifers, rays help transport the sticky resins commonly called *pitch.*

Primary and secondary growth in a stem

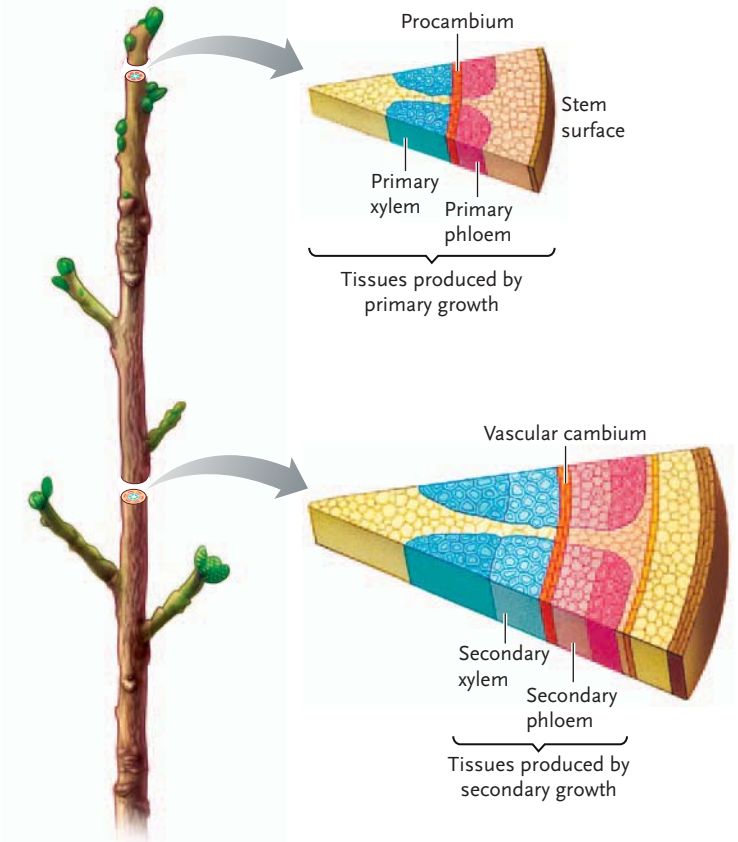

FIGURE 33.22 **Secondary and primary growth compared.** In a woody plant, primary growth resumes each spring at the terminal and lateral buds. Secondary growth resumes at the vascular cambium inside the stem.
© Cengage Learning 2014

With time, a great deal of secondary xylem forms inside the ring of vascular cambium. This hard secondary xylem is **wood.** Outside the vascular cambium, some secondary phloem also is added each year **(Figure 33.23).** (The primary phloem cells, which have thin walls, are destroyed as they are pushed outward by secondary growth.) As a stem's diameter increases, the enlarging mass of new tissue eventually ruptures the cortex. Parts of it split away and carry epidermis with them. Cork cambium replaces the lost epidermis with cork.

Bark consists of the tissues sandwiched between the vascular cambium and the stem surface. It includes the secondary phloem and the **periderm** (*peri* = surrounding; *derma* = skin), which consists of cork, cork cambium, and secondary cortex **(Figure 33.24).** Tubular openings (called *lenticels*) develop in the periderm. They function a bit like snorkels, permitting exchanges of oxygen and carbon dioxide between the living tissues and the outside air.

Girdling a tree by removing a belt of bark around the trunk is lethal if it destroys the vascular cambium and secondary phloem layer, preventing nutrients from photosynthesis in leaves from reaching the tree's roots. Natural corks used to seal bottles are manufactured from the especially thick outer bark of the cork oak, *Quercus suber.*

As a tree ages, changes unfold in the appearance and function of the wood itself. In the center of its older stems and roots is **heartwood,** dry tissue that no longer transports water and solutes and is a storage depot for some defensive compounds. In time, these compounds—including resins, oils, gums, and tannins—clog and fill in the oldest xylem pipelines. Typically they darken heartwood, strengthen it, and make it more aromatic and resistant to decay or wood-boring insects. **Sapwood** is located between heartwood and the vascular cambium. Compared with heartwood, it is wet and not as strong.

In regions that have large seasonal differences in temperature, trees produce secondary xylem seasonally, with larger-diameter cells produced in spring and smaller-diameter cells in summer. This "spring wood" and "summer wood" reflect light differently, and it is possible to identify them as alternating light and dark bands that represent annual growth layers—the "tree rings" pictured in **Figure 33.25.**

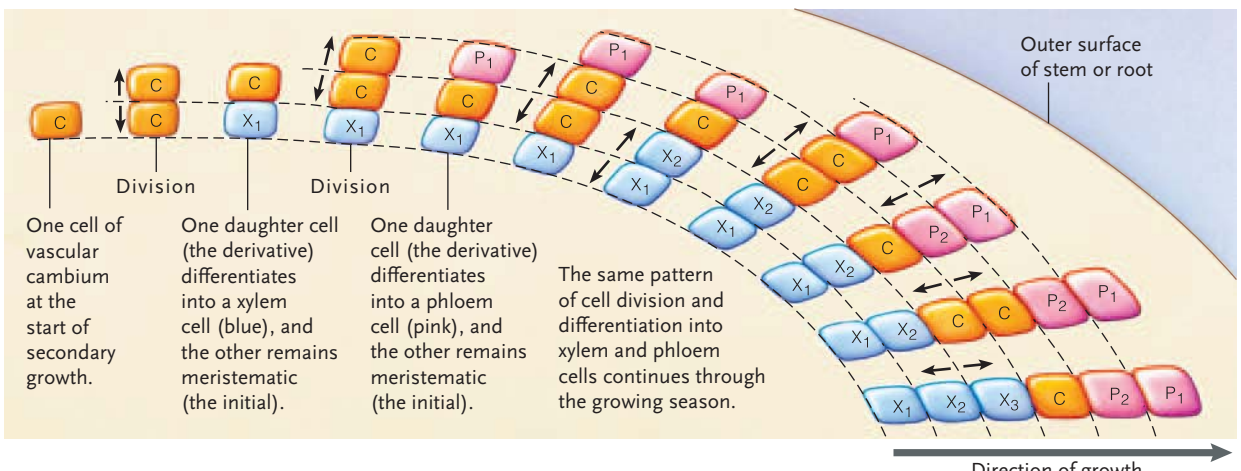

FIGURE 33.23
Relationship between the vascular cambium and its derivative cells (secondary xylem and phloem). The drawing shows stem growth through successive seasons. Notice how the ongoing divisions displace the cambial cells, moving them steadily outward even as the core of xylem increases the stem or root thickness.

Secondary Growth Can Also Occur in Roots

The roots of grasses, palms, and other monocots are almost always the product of primary growth alone. In plants with roots that have secondary growth, the continuous ring of vascular cambium develops differently than it does in stems. When their primary growth is done, these roots have a layer of residual procambium between the xylem and phloem of the stele (**Figure 33.26,** step 1). The vascular cambium arises in part from this residual cambium, and in part from the pericycle (step 2). Eventually, the cambial tissues arising from the procambium and those arising from the pericycle merge into a complete cylinder of vascular cambium (step 3). The vascular cambium functions in roots as it

1 At the close of primary growth, the root's procambium has given rise to primary xylem and phloem. Thick root cortex surrounds thin layers of pericycle and endodermis. The epidermis is the outermost layer of the root.

2 Procambium gives rise to the pericycle and distinct regions of vascular cambium. One region gives rise to secondary xylem; the other gives rise to secondary phloem.

3 The mature stele forms as secondary xylem and phloem enlarge and vascular cambium becomes sandwiched between them. The pericycle forms the outer layer of the stele. Xylem rays develop, primary xylem is crushed by the expanding secondary phloem, and the epidermis and underlying root cortex begin to slough away.

4 Outer cells of the pericycle give rise to cork cambium, from which a layered periderm develops. Bark consists of all the tissues outside the vascular cambium, including secondary phloem.

FIGURE 33.26

does in stems, giving rise to secondary xylem to the inside and secondary phloem to the outside. As secondary xylem accumulates, older roots can become extremely thick and woody. Their ongoing secondary growth is powerful enough to break through concrete sidewalks and even dislodge the foundations of homes.

Cork cambium also forms in roots, where it is produced first by the pericycle and later by initials in secondary phloem. In many woody eudicots and all gymnosperms, most of the root epidermis and cortex fall away, and the surface consists entirely of periderm (step 4).

Secondary Growth Is an Adaptive Response

Plants, like all living organisms, compete for resources, and woody stems and roots confer some advantages. Plants with masses of leaves supported by taller, stronger stems that defy the pull of gravity can intercept more of the light energy from the sun. With a greater energy supply for photosynthesis, they have the metabolic means to increase their root and shoot systems, and thus are better able to acquire resources—and ultimately to reproduce successfully.

During both primary and secondary growth **(Figure 33.27),** the development of new tissues and organs maintains a balance between the shoot system and root system. Leaves and other photosynthetic parts of the shoot must supply root cells with enough sugars to support their metabolism, and roots must provide shoot structures with water and minerals. As long as a plant is growing, this balance is maintained, even as the complexity of the root and shoot systems increases, whether the plant lives for only a few months or—like some bristlecone pines—for 6,000 years.

STUDY BREAK 33.5

1. **Explain the nature of secondary growth and where it typically occurs in plants.**
2. **Describe the components of vascular cambium and their roles in secondary growth in stems, including the development of tissues such as bark, cork, and wood.**
3. **Compare secondary growth in stems and in roots.**

UNANSWERED QUESTIONS

How are stem cell reservoirs sustained?

As you have learned in this chapter, a special feature of plants is their ability to continuously grow and generate new organs such as leaves and flowers throughout their life cycle. This unique developmental strategy, which enables plants to flexibly adapt to changing environmental conditions, requires that they continuously produce a supply of new cells from meristems at their growing shoot and root tips. The source of new cells within each meristem is the stem cell reservoir, a small pool of cells that are not committed to a particular organ or tissue fate. During the normal course of plant development, the stem cells slowly divide to replenish the reservoir while simultaneously producing daughter cells that form the different types of tissues and organs.

Because plants such as sequoias can grow and develop for hundreds or even thousands of years, stem cell reservoirs are long lasting and must be highly stable over time. Although it has been demonstrated that mutations that cause excess loss or accumulation of stem cells profoundly affect plant development and architecture, it is not well understood how plant stem cell reservoirs are sustained. Research has shown that the unique identity of shoot stem cell is conferred by a signal from the cells beneath them, which are known as niche cells, because they provide a supportive microenvironment for their stem cell neighbors. In turn the stem cells send a negative signal to the niche cells, via an extracellular signal transduction pathway, to limit their activity. This feedback loop maintains the stem cell reservoir at a relatively constant size despite the continuous departure of daughter cells to form tissues and organs. Yet despite its critical importance for plant development, many gaps in our understanding of this regulatory process remain. Key objectives for the future will be to identify all of the components of the stem cell signaling pathways and their outputs at the level of meristem cell division and proliferation, and to determine how additional regulatory elements such as hormones and epigenetic factors modulate the activity of the feedback loop.

THINK LIKE A SCIENTIST Root meristems generate the underground root system whereas shoot meristems produce the aboveground stems, leaves, and flowers. Considering that they give rise to different tissues, how much overlap might exist between the molecular signatures of stem cells in the root and shoot?

Jennifer Fletcher

Jennifer Fletcher is a research geneticist at the USDA-ARS Plant Gene Expression Center and an adjunct associate professor of plant biology at the University of California, Berkeley. Her research focuses on the molecular genetics of shoot and flower development in *Arabidopsis*. To learn more about Fletcher's work, visit http://www.pgec.usda.gov/Fletcher/fletchlab.html.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

33.1 Plant Structure and Growth: An Overview

- The vascular plant body consists of an aboveground shoot system and an underground root system (Figure 33.2).
- Meristems (Figure 33.3) give rise to the plant body and are responsible for a plant's lifelong growth. When a meristem cell divides, one daughter remains an initial that continues to function as meristem. The other daughter is a derivative that differentiates.
- Primary growth of roots and shoots originates at apical meristems. In plants that show secondary growth, lateral meristems increase the diameter of stems and roots.
- The two major classes of flowering plants (angiosperms) are monocots and eudicots (Table 33.1).

Animation: Morphology of a tomato plant

Animation: Eudicots and monocots

33.2 The Three Plant Tissue Systems

- Growing plant cells form secondary walls inside the primary walls. Maturing cells become specialized for specific functions, some of which are carried out by walls of dead cells.
- Ground tissues make up most of the plant body, vascular tissues serve in transport, and dermal tissue forms a protective cover. Of the three types of ground tissues, parenchyma is active in photosynthesis, storage, and other tasks. Collenchyma and sclerenchyma provide mechanical support (Figure 33.5).
- Xylem and phloem are vascular tissues. Xylem conducts water and solutes and consists of conducting cells called tracheids and vessel members (Figure 33.7). In phloem, the food-conducting tissue, living cells called sieve-tube members join end to end in sieve tubes (Figure 33.8).
- The dermal tissue, epidermis (Figure 33.9), is coated with a waxy cuticle that restricts water loss. Water vapor and other gases enter and leave the plant through pores called stomata, which are flanked by specialized epidermal cells called guard cells. Epidermal specializations also include trichomes such as root hairs.

33.3 Primary Shoot Systems

- The primary shoot system consists of the main stem, leaves, and buds, plus any attached flowers and fruits. Stems provide mechanical support, house vascular tissues, and may store food and fluid.
- Stems are organized into modular segments. Nodes are points where leaves and buds are attached; internodes fall between nodes (Figure 33.10A). The terminal bud at a shoot tip consists of shoot apical meristem. Meristem tissue in buds gives rise to leaves, flowers, or both (Figure 33.10B). Apical meristem tissue also occurs just above the root tip.
- Derivatives of the apical meristem produce three primary meristems (Figure 33.11). Protoderm makes the stem's epidermis, procambium gives rise to primary xylem and phloem, and ground meristem gives rise to ground tissue.
- Vascular tissues are organized into vascular bundles, with phloem surrounding xylem in each bundle (Figure 33.12). The bundles form a stele (vascular cylinder). Monocot and eudicot leaves have blades

of different forms, all providing a large surface area for absorbing sunlight and carbon dioxide (Figures 33.14 and 33.16). Leaf modifications are adaptive responses to environmental selection pressures (Figure 33.15). Leaf characteristics such as shape or arrangement may change over the life cycle of a long-lived plant (Figure 33.17).

Animation: Vascular tissues

Animation: Leaf organization

33.4 Root Systems

- Roots absorb water and minerals and conduct them to aerial plant parts; they anchor and sometimes support the plant and often store food. Root morphologies include taproot systems, fibrous root systems, and adventitious roots (Figure 33.18).
- During primary growth of a root, the primary meristem and actively dividing cells make up the zone of cell division, which merges into the zone of elongation. Past the zone of elongation, cells may differentiate in the zone of cell maturation (Figure 33.19).
- A root's xylem and phloem usually are arranged as a central stele (Figure 33.20). Parenchyma outside the stele forms the root cortex. The root endodermis also wraps around the stele. Inside it the pericycle contains parenchyma that can function as meristem. The pericycle gives rise to root primordia from which lateral roots emerge (Figure 33.21). Root hairs greatly increase the absorptive surface of roots.

Animation: Root systems

Animation: Root organization

33.5 Secondary Growth

- Secondary growth makes older stems and roots woody and more massive via the activity of vascular cambium and cork cambium.
- Vascular cambium consists of fusiform initials, which generate secondary xylem and phloem, and ray initials, which produce parenchyma cells aligned in horizontal xylem rays (Figures 33.22 and 33.23). Secondary growth takes place as these cells divide.
- Cork cambium produces cork, which replaces epidermis lost when stems increase in diameter. Together, cork cambium and cork make up the periderm (Figure 33.24), the outer portion of bark.
- In root secondary growth, a thin layer of procambium cells between the xylem and phloem differentiates into vascular cambium (Figure 33.26), which gives rise to secondary xylem and phloem. The pericycle produces root cork cambium.

UNDERSTAND & APPLY

Test Your Knowledge

1. With respect to growth, plants differ from animals in that:
   a. plant growth involves only an increase in the total number of the organism's cells.
   b. plant cells remain roughly the same size after cell division, whereas animal cells increase in size after they form.
   c. all plants form woody tissues during growth.
   d. plants have indeterminate growth; animals have determinate growth.
   e. plants can grow only when young; animals grow throughout their life.
2. Identify the correct pairing of a plant tissue and its function.
   a. epidermis: rigid support
   b. xylem: sugar transport
   c. parenchyma: photosynthesis, respiration
   d. phloem: water and mineral transport
   e. periderm: control of gas exchange
3. Identify the correct pairing of a structure and its component(s).
   a. epidermis: companion cells
   b. phloem: sieve-tube members
   c. sclerenchyma: nonlignified cell walls
   d. secondary cell wall: cuticle
   e. parenchyma: sclereids
4. Which of the following is *not* part of a stem?
   a. petiole
   b. pith
   c. xylem
   d. procambium
   e. ground meristem
5. Which of the following would be absent in a eudicot leaf?
   a. spongy mesophyll
   b. palisade mesophyll
   c. pericycle
   d. vascular bundles
   e. stoma
6. A student left a carrot in her refrigerator. Three weeks later she noticed slender white fibers growing from its surface. They were not a fungus. Instead they represented:
   a. lateral roots on a taproot.
   b. adventitious roots.
   c. root hairs on a fibrous root.
   d. root hairs on a lateral root.
   e. young prop roots.
7. Which of the following is *not* a structure that results from secondary plant growth?
   a. periderm
   b. sapwood
   c. cork
   d. pith
   e. heartwood
8. Which characteristic do monocots and eudicots share?
   a. the position of the vascular bundles
   b. the pattern of leaf veins
   c. the number of grooves in the pollen grains
   d. the number of cotyledons
   e. the formation of flowers
9. A student forgets to water his plant and the leaves start to droop. The structures first affected by water loss and now not functioning are the:
   a. sieve tubes.
   b. sclereids and fibers.
   c. vessel members and tracheids.
   d. companion cells.
   e. guard cells and stoma.
10. The greatest mitotic activity in a root takes place in the:
    a. zone of maturation.
    b. zone of cell division.
    c. zone of elongation.
    d. root cap.
    e. endodermis.

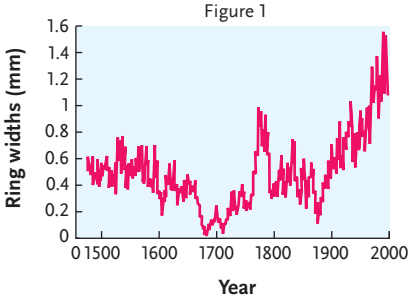
Discuss the Concepts

1. The spines of cacti are modified leaves. Cacti are adapted to arid habitats in which relatively few other plant species grow. What kinds of selection pressures may have operated to favor the evolution of spinelike cactus leaves?
2. While camping you notice a "Do Not Litter" sign nailed onto the trunk of a mature oak tree about 7 feet off the ground. When you return five years later, will the sign be at the same height, or will the tree's growth have raised it higher?
3. Peaches, cherries, and other fruits with pits are produced only on secondary branches that are one year old. To renew the fruiting wood on a peach tree, how often would you prune it? Where on a branch would you make the cut, and why?
4. African violets and some other flowering plants are propagated commercially using leaf cuttings. Initially, a leaf detached from a parent plant is placed in a growth medium. In time, adventitious shoots and roots develop from the leaf blade, producing a new plant. Which cells in the original leaf tissue are the most likely to give rise to the new structures? What property of the cells makes this propagation method possible?



Design an Experiment

The sticky cinquefoil *(Potentilla glandulosa)* is a small, deciduous plant with bright yellow flowers that lives throughout the American West, and its leaf phenotype can vary depending on environmental conditions. Inland, where there are dramatic seasonal temperature swings and unpredictable droughts, plants shed their large "summer leaves" in autumn when the temperature begins to drop. In the spring new leaves are smaller and develop in a compact rosette. This phenotype persists for several months and is thought to be an adaptation that makes the plants drought-resistant (because less water evaporates from reduced leaf surfaces). By contrast, the leaves of *P. glandulosa* plants growing in a coastal climate are always large. In their habitat, seasonal temperature swings are not as great and the annual cycle of winter rain and summer drought is highly predictable. Suppose you decide to explore the hypothesis that the coastal population is genetically capable of exhibiting the same seasonal shift in leaf morphology as the inland plants. Would you need access to a greenhouse where you can control variables, or would it be just as easy to do experiments in the wild? Explain your reasoning and outline your experimental design—including the variable or variables you will test in the first experiment.

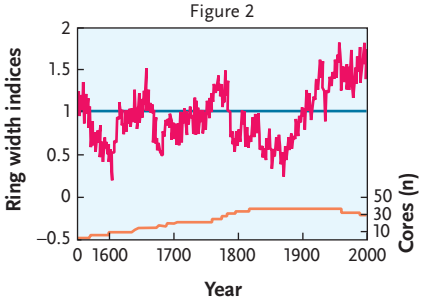
Interpret the Data

Rings from long-lived trees may track centuries of annual changes in climatic conditions such as temperature, rainfall, or both. Dendrochronology studies show that Siberian pines *(Pinus sibirica)* growing at high elevations (2,450 m) in the Tarbagatay Pass region of Mongolia may live 500 years, or longer. Growth is faster and rings are wider in warmer years. The reverse is true in cooler years. A research team led by Gordon C. Jacoby of the Tree-Ring Laboratory at the Lamont-Doherty Earth Observatory examined 450 years of *P. sibirica* tree ring data to determine whether the rings provided evidence of a recent climate warming trend in the area. **Figure 1** shows the growth fluctuations in a single tree between the years of 1550 and 1995.

Figure 1

The upper line in **Figure 2** shows the aggregated growth fluctuations of a larger sample of the trees during the same period.

Figure 2



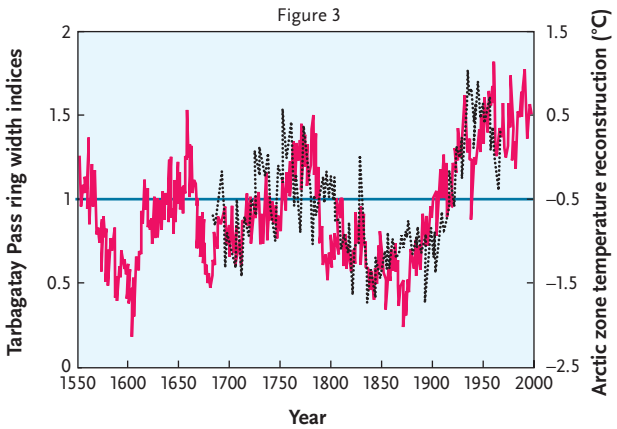


Figure 3 correlates the aggregated growth information (solid line) with a reconstruction of annual temperature fluctuations in the region (dotted line).

Figure 3

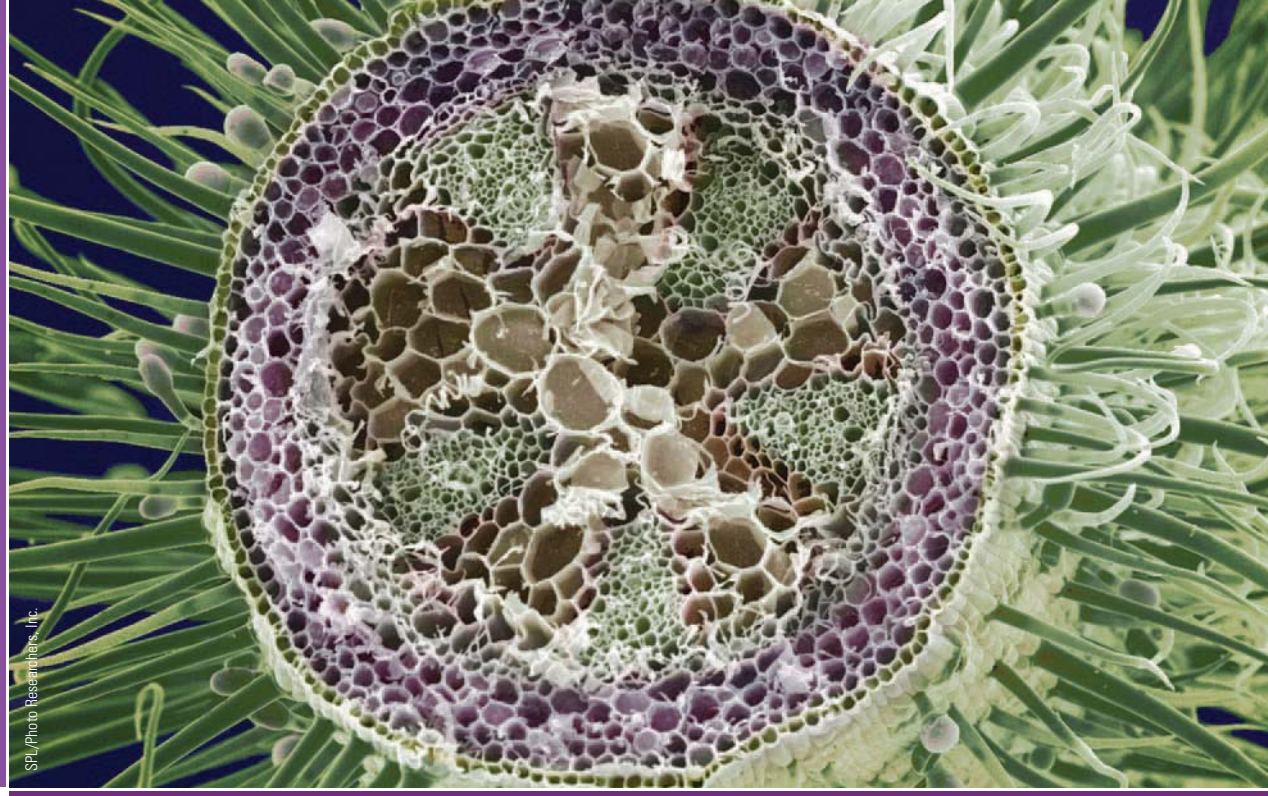
1. Based on the graphed data, what do you think the research team concluded from this experiment?
2. The researchers included a graph of growth data for a single tree in their research report. Why would such information be relevant?
3. In Figure 2, what does the rising trend of the lower line signify? Speculate about why the researchers included that information.
4. In their published report, the researchers included a note that several major volcanic eruptions occurred in the middle of the nineteenth century, spewing massive amounts of smoke and ash into Earth's atmosphere. Why is that fact important for interpreting the graph data?



Source: From G. Jacoby *et al.* 1996. Mongolian tree rings and 20th century-warming. *Science* 273:771–777.

Apply Evolutionary Thinking

The first angiosperms may originally have been small, treelike plants in tropical regions, but eventually they began diversifying rapidly into other habitats where early gymnosperms flourished. South African botanist William Bond proposed the "slow seedling" hypothesis to help explain this evolutionary change, and botanists continue to refine it. The hypothesis proposes that angiosperms were able to encroach on many habitats where ancient gymnosperms lived, in part because flowering species increasingly evolved adaptations that made them fast-growing herbaceous plants. Gymnosperms grow more slowly. Based on your reading of this chapter and Chapter 29, what are some structural and biochemical features of gymnosperms (such as conifers) that might result in slower growth, putting them at a competitive disadvantage in this scenario?

Cross section of the root of a geranium *(Pelargonium)* showing vessels that transport water and nutrients in plants. In this false-color SEM, large-diameter vessels are part of the xylem, which carries water and minerals. Nestled close to xylem vessels are bundles of the smaller transport tubes of phloem, called sieve tubes, which transport sugars.

STUDY OUTLINE

34.1 Principles of Water and Solute Movement in Plants

34.2 Transport in Roots

34.3 Transport of Water and Minerals in the Xylem

34.4 Transport of Organic Substances in the Phloem

Transport in Plants

Why it matters . . . The coast redwood, *Sequoia sempervirens,* takes life to extremes. Redwood trees can live for more than 2,000 years, and they can grow taller than any other organism on Earth—110 meters (361 feet) or more **(Figure 34.1).** Scientists estimate that each day these giants move thousands of liters of water—with its cargo of dissolved nutrients—between roots and leaves against the pull of gravity and without any sort of pump. Even in much smaller plants, such a physiological feat seems to challenge the laws of physics.

In fact, however, just the opposite is true. The evolutionary adaptations by which redwoods and other plants move water, sugar, and other solutes through their bodies rely on mechanisms common in living systems, from diffusion and active transport to the cumulative effects of physical interactions such as cohesion and evaporation. In this chapter you will learn how such mechanisms and the two specialized transport tissues in vascular plants, xylem and phloem, jointly solve a fundamental biological problem—the need to acquire materials from the environment and distribute them throughout the plant body.

Our discussion begins with a brief review of the principles of water and solute movement in plants, a topic introduced in Chapter 6. Next we examine how those principles operate as water and minerals move in the xylem from roots to shoot parts. Last we consider how the phloem transports sugar and other organic substances from their sources to the locations where they are used in a plant's diverse metabolic activities.

34.1 Principles of Water and Solute Movement in Plants

In plants, as in all organisms, the movement of water and solutes begins at the level of individual cells and relies on mechanisms such as osmosis and the operation of transport proteins in the plasma membrane. Once water and nutrients enter a plant's vascular tissues, other mechanisms carry them between various regions of the plant body in response to changing demands for those substances. Ultimately, these materials move by way of the integrated activities of the individual cells, tissues, and organs of a single, smoothly functioning organism—the whole plant.

Plant transport mechanisms fall into two general categories—those for long-distance transport throughout the plant, and those for moving substances short distances, as between cells **(Figure 34.2).** Long-distance transport mechanisms, which may be passive or active, move substances in vascular pipelines between roots and shoot parts. For example, xylem carries water and dissolved minerals from roots to other plant parts, including leaves, by way of largely passive mechanisms. Active transport mechanisms in living cells move phloem and the carbohydrates it contains from photosynthesizing leaves and stems into roots and other structures. Phloem also carries a variety of other substances including hormones, amino acids, fatty acids, and the nucleic acid RNA, which may be an important long-distance signaling molecule in plants (see Chapter 37).

Short-distance transport mechanisms move substances to and from vascular tissues and into and between cells across membranes. For example, water and dissolved minerals enter roots by crossing the cell membranes of root hairs. Similarly, most of the mineral ions and water taken up by roots enter the xylem, whereas a smaller portion moves laterally into the cells that make up root and stem tissues. Some absorbed ions that reach leaves also cross laterally into the phloem in leaf veins. Other examples of short distance transport include sugar molecules in phloem moving into metabolically active cells across plasma membranes and the uptake by leaf cells of minerals in sprayed fertilizers.

Before looking in more detail at long-distance transport in xylem and phloem, we consider the short-distance mechanisms that move water and solutes into and out of specific cells in roots, leaves, and stems. Keep in mind that the primary plant cell wall does not prevent most solutes from moving into plant cells. The majority can diffuse through the wall, and some—including small molecules and some large ones, such as proteins, RNAs, and virus particles—cross it by way of the plasmodesmata that connect adjacent cells (see Section 5.4).

A. Long-distance transport throughout the plant
Vascular tissues—xylem and phloem—distribute substances throughout the plant, sometimes over great distances.

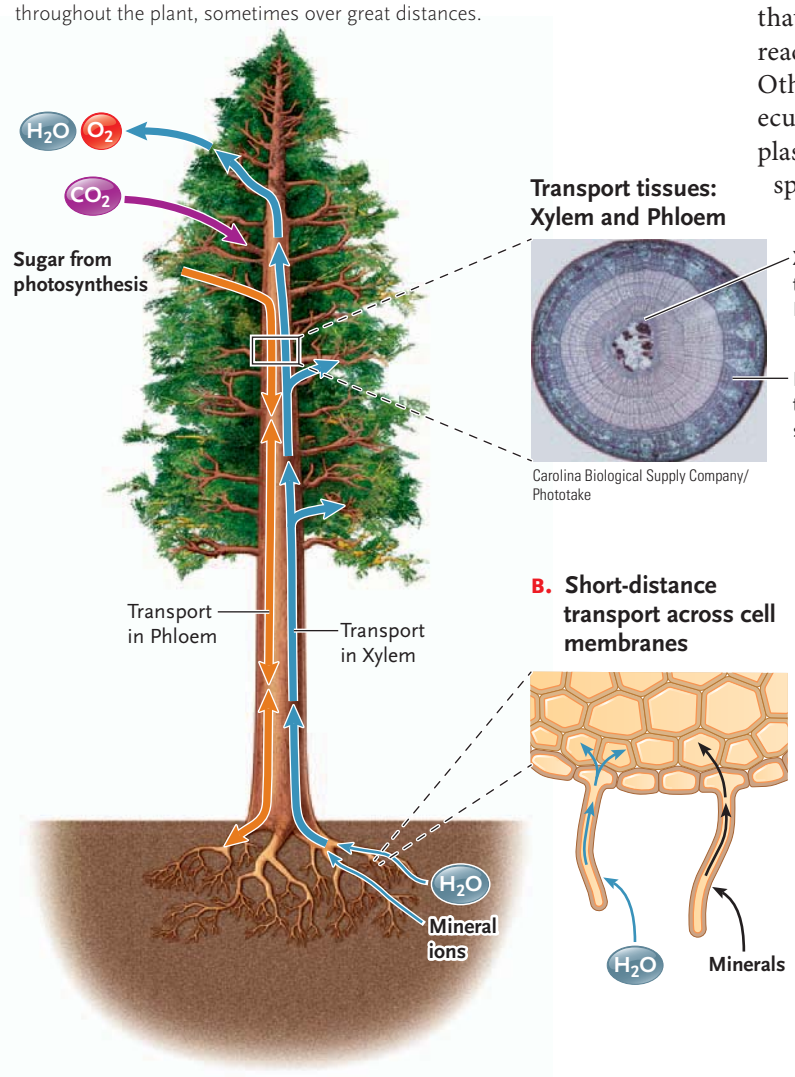

FIGURE 34.2 Overview of transport routes in plants. (A) Long-distance transport of water, minerals, and organic substances. **(B)** Short-distance transport of substances through and between plant cells. Short-distance transport includes movement of water, minerals, sugars, and other materials through and between cells and into and out of xylem and phloem. The diagram illustrates the uptake of soil water and solutes by plant root hairs.

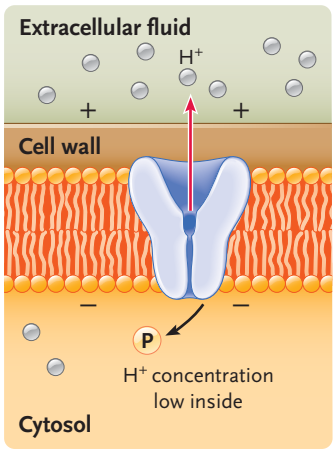
Both Passive and Active Mechanisms Move Substances into and out of Plant Cells

Recall from Chapter 6 that two general mechanisms transport water and solutes across the cell plasma membrane. To recap that discussion, in *passive transport,* substances move down a concentration gradient or, if the substance is an ion, down an electrochemical gradient (see Section 6.3). *Active transport* requires the cell to expend energy in moving substances *against* a gradient, usually by hydrolysis of ATP. Ions and some larger molecules cross cell membranes assisted by transport proteins embedded in the membrane.

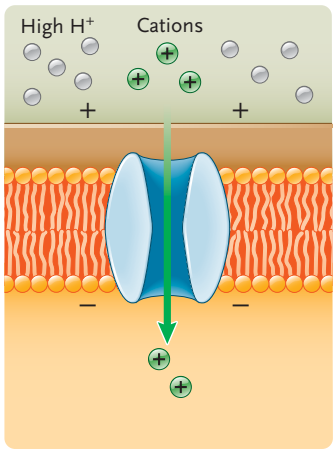
An electrochemical gradient exists across a cell membrane when there is both a concentration difference and an electrical charge difference on the two sides of the membrane. This situation occurs when an ion is more concentrated on one side of a cell's plasma membrane (see Section 6.4). For example, the hydrogen ions outside the cell in **Figure 34.3** contribute a slight positive charge to the fluid outside the cell. In general, the ionic makeup of a plant cell's cytoplasm is such that the cytoplasm is slightly more negative than the fluid outside the cell. This charge difference, the *membrane potential,* is a potential source of energy—that is, ion movements down an electrochemical gradient can perform cellular work.



As you may recall from Section 6.4, the hydrolysis of ATP in the cell cytoplasm provides the energy that drives the active transport of substances into and out of cells, including plant cells. To review this mechanism briefly, hydrogen ions (protons), which tend to be more concentrated outside the cell than in the negatively charged cytoplasm, play a central role in the process. First, a proton pump pushes H^+ across the plasma membrane against its electrochemical gradient, from the inside to the outside of the cell **(Figure 34.3A).** As protons accumulate outside the cell, the electrochemical gradient becomes steeper and significant potential energy is available. Crucial solutes such as cations (positively charged ions) often are more concentrated in the extracellular fluid. One result of the increased charge difference created by proton pumping is that cations follow the electrochemical gradient into the cell, moving through channel proteins **(Figure 34.3B).** In plants, these cations include mineral ions that have essential roles in metabolism.

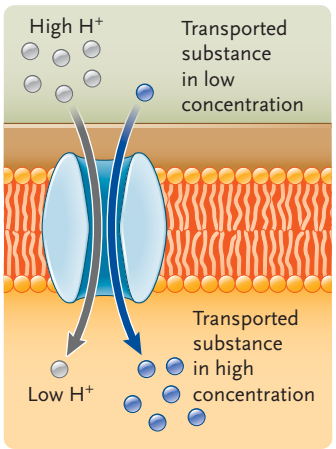
The H^+ gradient also powers *secondary active transport,* in which an ion's concentration gradient is the energy source for active transport of another substance. The two secondary mechanisms, called *symport* and *antiport,* actively transport ions, sugars, and amino acids into and out of plant cells against their concentration gradients. In **symport**—also called cotransport—the potential energy released as H^+ follows its gradient into the cell is coupled to the uptake of another ion or molecule **(Figure 34.3C).** This is how plant cells take up important anions such as nitrate (NO_3^-) and potassium (K^+). Most organic substances that enter plant cells move in by symport as well.

In **antiport,** energy released as H^+ diffuses into the cell and powers the active transport of a second molecule, such as Ca^{2+}, in the opposite direction, *out of* the cell **(Figure 34.3D).** One of antiport's key functions is to remove excess Na^+, which readily diffuses into plant cells through channel proteins. If the Na^+ were not eliminated, it would quickly build up to toxic levels.



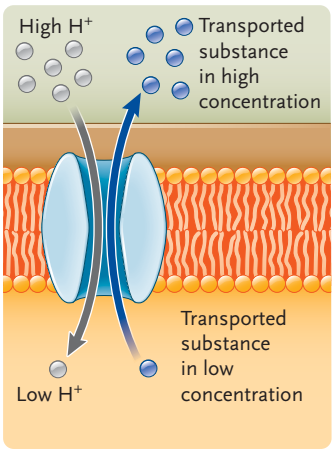
Both passive and active transport are selective—they move specific substances. Two factors govern this specificity. First, only

A. H^+ pumped against its electrochemical gradient



A proton pump moves hydrogen ions (H^+) out of the cytoplasm, creating an H^+ gradient that provides energy for transporting other ions and molecules such as sugar into the plant cell. A phosphate group (P) bound earlier to the transporter is released as the ions move to the side of higher concentration.

B. Uptake of cations



Some cations, such as NH_4^+, enter the cell through selective channel proteins, following the electrochemical gradient created by H^+ pumping.

C. Symport

In symport, the inward diffusion of H^+ is coupled with the simultaneous active transport of another substance into the cell.

D. Antiport

In antiport, H^+ moving into the cell powers the movement of another solute in the opposite direction.

molecules in a particular size range can pass through a particular type of channel. Second, the distribution of charges along the inside of the channel may affect which ions can pass through. A channel that permits cations such as Na^+ to pass through easily may completely bar anions such as Cl^- and vice versa.

Relatively speaking, only small amounts of mineral ions and other solutes move into and out of plant cells. As we see next, water is another matter. Large volumes of water enter and exit a plant's cells and tissues by way of osmosis.

In Plants, Water Moves by Bulk Flow and by Osmosis

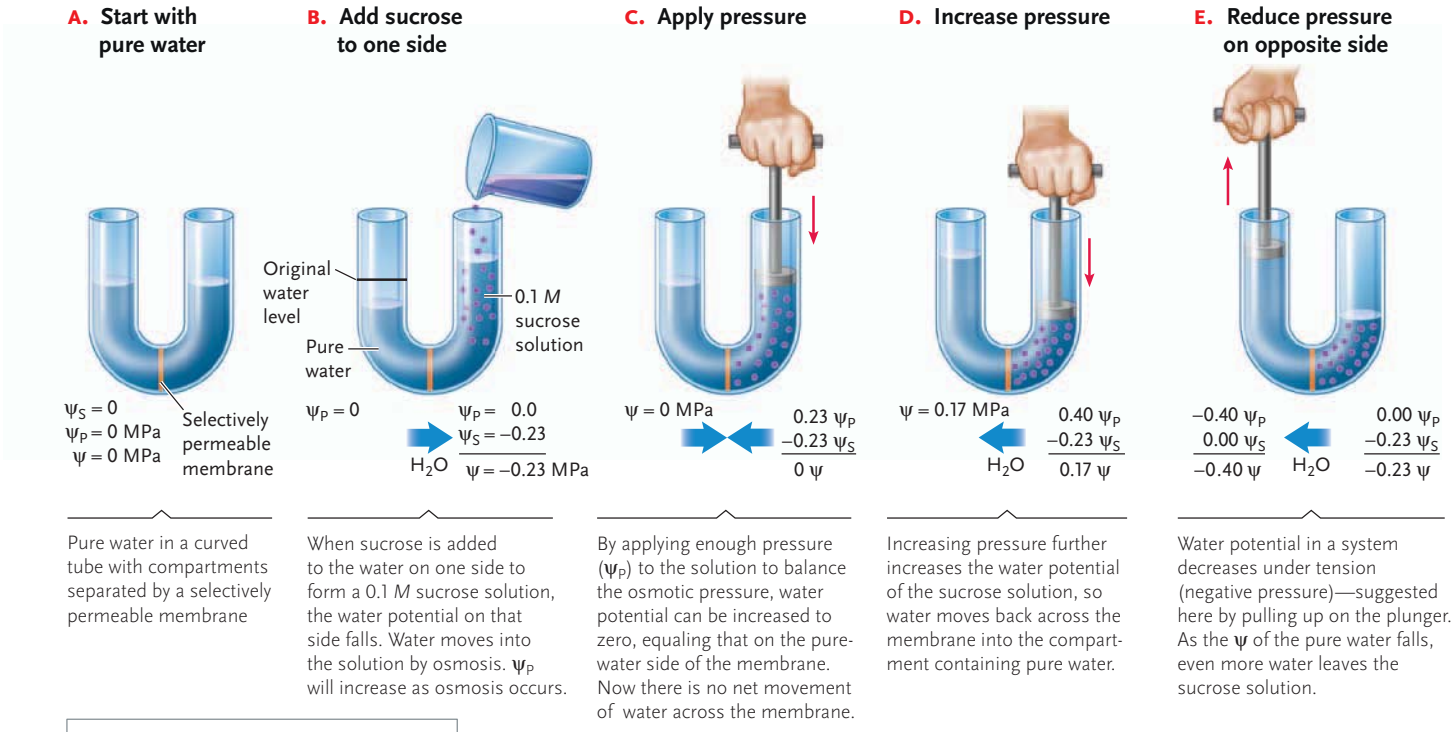
The movement of water into and through plant cells and tissues is one of the most important aspects of plant physiology. Inside a plant's tubelike vascular tissues, large amounts of water or any other fluid travel by **bulk flow**—the group movement of molecules in response to a difference in pressure between two locations, like water in a closed plumbing system gushing from an open faucet. For example, the dilute solution of water and ions that flows in the xylem, called **xylem sap,** moves by bulk flow from roots to shoot parts. The solution is pulled upward through the plant body in a process that relies on the cohesion of water molecules. We will consider that process more fully later in this chapter. In the meantime, we turn to osmosis, the short-distance mechanism for moving water.

You may recall from Section 6.3 that **osmosis** moves water into and out of cells across a selectively permeable membrane. The potential energy in water underlies the phenomenon of osmosis. "Potential energy," remember, is simply stored energy. In water, potential energy is associated with the inherent capacity of water molecules to move from one site to another when conditions dictate. This potential energy, called **water potential,** is symbolized by the Greek letter Ψ (*psi,* pronounced "sye"). By convention, pure water at normal atmospheric pressure and temperature has a Ψ value of zero. Shifts away from this baseline propel water into or out of cells. For example, if Ψ is higher outside the cell than inside, water tends to flow into the cell. In plants, two factors that strongly influence water potential shifts—and thus water movements—are the presence of solutes and physical pressure.

The effect of dissolved solutes on water's tendency to cross a membrane is called *solute potential,* symbolized by Ψ_S. The effect of physical pressure on water is called *pressure potential,* symbolized by Ψ_P. The sum of solute potential and pressure potential largely determine water potential—the likelihood that water will enter or leave a plant cell. The equation $\Psi = \Psi_P + \Psi_S$ represents these combined effects.

The relationship between water potential and solute potential is important to understanding transport phenomena in plants because water tends to move from regions where there are relatively few solutes and water potential is higher to regions where there are more solutes and water potential is lower. Solutes are usually more concentrated inside plant cells than in the fluid surrounding them. This means the water potential is higher outside plant cells than inside them, so water tends to enter the cells. This in fact is the mechanism that draws soil water into a plant's roots.

The osmotic flow of water into a plant cell cannot continue indefinitely, however, because eventually physical pressure counterbalances it. The wall around a plant cell strictly limits how much the cell can expand. Accordingly, as water moves into plant cells, the pressure inside them increases. This pressure, called **turgor pressure,** represents the pressure potential inside a plant cell. It rises until it is high enough to prevent more water from entering a cell by osmosis. In effect, turgor pressure has increased the water potential inside the cell until it equals the potential of the water outside the cell.



Plant physiologists measure water potential in units of pressure called **megapascals** (MPa). The baseline is standard atmospheric pressure, so the water potential of pure water at standard atmospheric pressure is written as 0 MPa. Measurement of MPa can be used to describe how different conditions of solute potential and pressure potential affect water flow **(Figure 34.4).** As Figure 34.4 shows, adding solutes (such as sucrose) to a quantity of pure water reduces the water's MPa (because its relative concentration is lower). On the other hand, increasing pressure increases MPa, and the balance of these two factors determines the MPa of any particular water sample. When a barrier that admits water but not solutes separates two water samples of unequal MPa, water will flow from a solution of higher MPa to a solution of lower MPa. With these principles in mind, consider now how they operate in living plant cells.

Recall from Section 5.4 that a plant cell has relatively little cytoplasm, in a thin layer next to the plasma membrane. Filling most of the cell's volume is at least one large **central vacuole** that is surrounded by a vacuolar membrane, the **tonoplast.** The central vacuole contains a dilute solution of sugars, salts, proteins, and other organic molecules. The water in this solution is essential for maintaining appropriate turgor pressure in the cell. When external solutes enter a plant cell's cytoplasm, active transport moves many solutes from the cytoplasm into the central vacuole through channels in the tonoplast. Water follows the solutes into the vacuole by osmosis until turgor pressure increases the water potential inside the cell to equal that outside the cell, as already described. On the other hand, the turgid central vacuole can be a water reservoir when the medium around a plant cell becomes hypertonic to the cell (has a higher solute concentration). In a hypertonic environment, although water tends to flow rapidly out of the cell cytoplasm, it is quickly replaced by water from the central vacuole.

The Discovery of Aquaporins Explained Rapid Water Movements across Cell Membranes

A plant cell must compensate fairly quickly for water gains or losses caused by changes in osmotic flow. This means that when osmotic conditions change, a large amount of water must move rapidly across plant cell membranes. How does water move so rapidly across cell membranes? Researchers working with red

FIGURE 34.4 **The relationship between osmosis and water potential.** If the water potential is higher on one side of a selectively permeable membrane, water will cross the membrane to the area of lower water potential. This diagram shows pure water on one side of a selectively permeable membrane and a simple sucrose solution on the other side. In an organism, however, the selectively permeable membranes of cells are rarely if ever in contact with pure water.

TIPs and PIPs—the Osmosis Express

Researchers working with red blood cells discovered that the plasma membranes of these animal cells contained channel proteins that allowed water to move across the membrane. The flow occurred osmotically, from higher to lower concentration, but much more rapidly than in normal osmosis. The channels were named aquaporins. Plant physiologists became intrigued by the presence of a structurally similar protein called TIP (tonoplast intrinsic protein) in the tonoplast, the cell membrane enclosing the vacuole. Such channels would explain how water can flow rapidly into and out of the vacuole.

Research Question

Are TIPs plant aquaporins?

Experiments

Christophe Maurel and his colleagues at the University of California, San Diego, designed an experiment to test the hypothesis that TIPs function as aquaporins in plants. Their experimental design included several steps.

1. The team began by isolating a gene that encodes a TIP in *Arabidopsis thaliana* plants and cloned the gene's coding sequence. They then used genetic engineering techniques to generate mRNAs from the sequence.
2. To ensure that no other plant protein could affect the outcome of their experiments, they next inserted the TIP mRNA into oocytes of *Xenopus laevis* (the African clawed frog), which normally are only slightly permeable to water.
3. When the test oocytes were placed in a hypotonic medium they quickly swelled and ruptured, a response that did not occur in controls lacking the TIP mRNA.

Conclusion

These results supported the conclusion that the TIP protein forms an aquaporin. In its normal location in the plant cell tonoplast, TIP apparently allows water to move readily in either direction as osmotic conditions shift.

Since this early research, various subtypes of aquaporins have been found in representatives of all land plant groups. Collectively they are called membrane-intrinsic proteins, or MIPS. The MIPs include an assortment of TIPs, numerous PIPs, or plasma membrane intrinsic proteins, and several others. In *Arabidopsis* alone, 35 MIPs have been identified.

THINK LIKE A SCIENTIST Different MIP genes are expressed in cells of different plant parts. Would you expect MIP gene expression to be influenced by environmental factors?

blood cells found channel proteins that allow the bulk flow of water across cell membranes—a mechanism much speedier than normal osmosis. Chapter 6 introduced these channels, which were named **aquaporins.** As described in *Insights from the Molecular Revolution,* the discovery of aquaporins in animal cells led plant scientists to investigate similar proteins in plant cells, and we now know that various aquaporins occur in the tonoplast and the plasma membrane. Most have major roles in maintaining water balance in cells. In roots they facilitate the uptake of water and its movement into the xylem. Accumulating research evidence suggests that plant aquaporins are important in a wide variety of physiological functions.

Water Stress Can Lead to Wilting

The water mechanics we have been discussing have major implications for land plants. For instance, the drooping of leaves and stems called **wilting** occurs when environmental conditions cause a plant to lose more water than it gains. Conditions that lead to wilting include dry soil, in which case the water potential in the soil falls below that in the plant. Then the turgor pressure inside the cells falls, and the protoplast shrinks away from the cell wall.

As long as the Ψ of soil is higher than that in root epidermal cells, water will follow the Ψ gradient and enter root cells, making them turgid, or firm **(Figure 34.5A).** On the other hand, placing a cell in a sucrose solution can cause the protoplast to shrink **(Figure 34.5B).** As we see in the next section, water and solutes entering roots may move through the plant body by several routes.

2. **What is "water potential," and why is it important with respect to plant cells?**

34.2 Transport in Roots

Soil around roots provides a plant's water and minerals, but roots do not simply "soak up" these essential substances. Instead, water and minerals that enter roots first travel laterally through the root cortex to the root xylem. Only then do they begin their journey upward to stems, leaves, and other tissues.

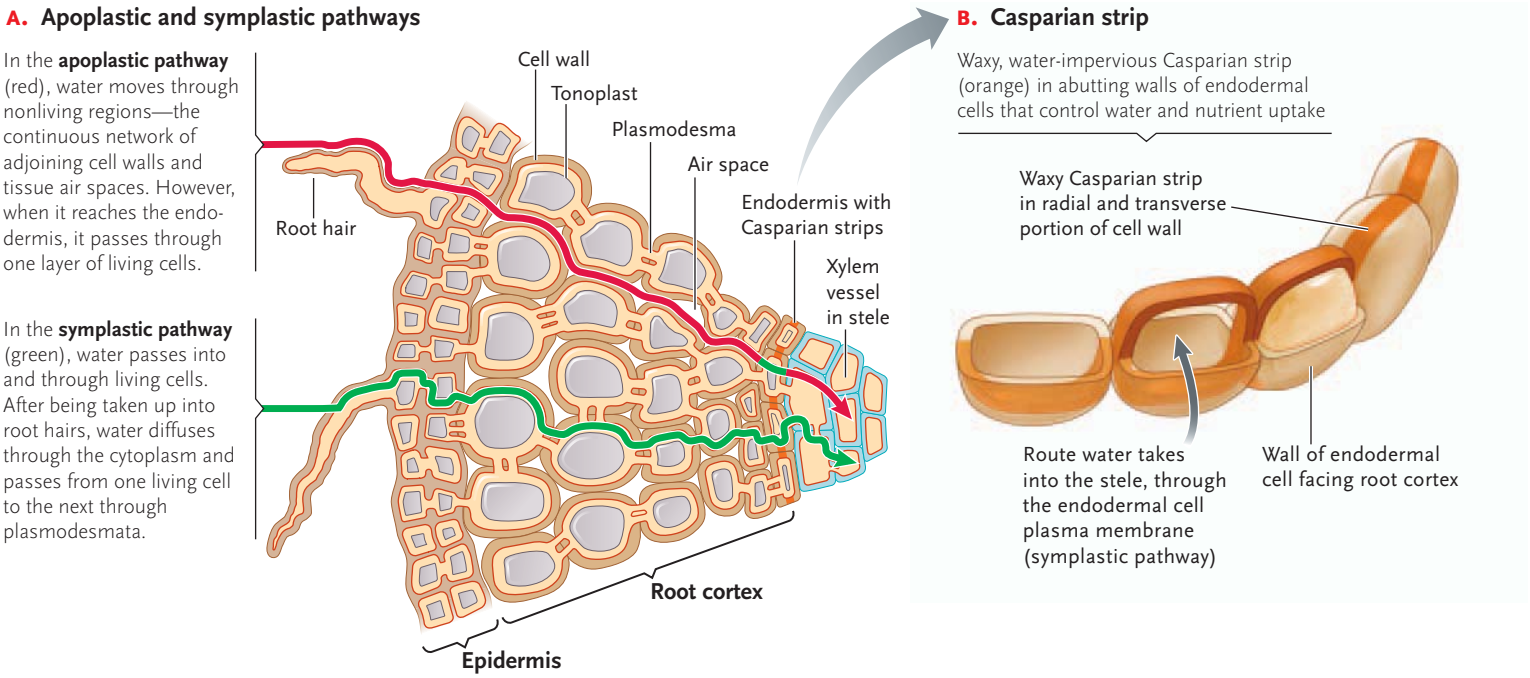
Water Travels to the Root Xylem by Two Main Pathways

Soil water always enters a root through the root epidermis. Once inside a root, however, water may take one of two main routes into the root xylem, traveling either through living cells or in extracellular areas of the root **(Figure 34.6A).** The extracellular route passes through a continuous network of adjoining cell walls and air spaces in root tissue but does not cross cell membranes. This route is called the *apoplast* (roughly, "not including cells"), and water in them follows an **apoplastic pathway.** Plant physiologists refer to a plant's living parts as the *symplast* ("within cells") and water moving through roots in the **symplastic pathway** moves from cell to cell through the open channels of plasmodesmata. Water also can diffuse across root cell plasma membranes or enter cells through membrane aquaporins. Because this *transmembrane pathway* requires repeated crossings of cell membranes, it is most efficient over short distances.

When water enters a root, some diffuses into epidermal cells, entering the symplast. But a great deal of the water taken up by plant roots moves into the apoplast, moving along through cell walls and intercellular spaces. This apoplastic water (and any solutes dissolved in it) travels rapidly inward until it encounters the endodermis, the sheetlike single layer of cells that separates the root cortex from the stele. Cells in the root cortex generally have air spaces between them (which helps aerate the tissue), but endodermal cells are tightly packed. Each endodermal cell also has a **Casparian strip** in its radial and transverse walls, positioned somewhat like a band of packing material around the contents of a package **(Figure 34.6B).** The strip is impregnated with suberin, a waxy substance impermeable to water. Thus the Casparian strip blocks the apoplastic pathway at the endodermis, preventing water and solutes in the apoplast from automatically passing on into the stele. Instead, if molecules are to move into the stele, they must detour across the plasma membranes of endodermal cells, entering the cells (and the symplast) where the wall is not blanketed by a Casparian strip. From there water and solutes can pass through plasmodesmata to cells in the outer layer of the stele (the pericycle), then on into the xylem.



Although water molecules can easily cross an endodermal cell's plasma membrane, the semipermeable membrane allows only a subset of the solutes in soil water to cross. Undesirable solutes may be barred, whereas desirable ones may move into the cell by facilitated diffusion or active transport. Conversely, the endodermis prevents needed substances in the xylem from leaking out, back into the root cortex. In this way the endodermis provides important control over which substances enter and leave a plant's vascular tissue. The roots of most flowering plants also have a second layer of cells with Casparian strips just inside the root epidermis. This layer, the exodermis, functions like the endodermis.

Roots Take Up Ions by Active Transport

Mineral ions in soil water also enter roots through the epidermis. Some enter the apoplast along with water, but most ions important for plant nutrition tend to be considerably more

FIGURE 34.6 **Pathways for the movement of water into roots. (A)** Water can enter roots by way of the apoplast or symplast. Ions also enter roots via these two pathways, but must be actively transported into a cell—and the symplastic pathway—when they reach the impervious Casparian strips of the endodermis **(B).** The roots of most flowering plants have both an endodermis surrounding the stele and an exodermis just beneath the epidermis. Both cell layers have a Casparian strip, which helps control the uptake of water and dissolved nutrients.

concentrated in roots than in the surrounding soil, so they cannot follow a concentration gradient into root epidermal cells. Instead the epidermal cells actively transport ions inward—that is, ions enter the symplast immediately. They travel to the xylem via the symplastic or transmembrane pathways. Other ions can still move inward following the apoplastic pathway until they reach the Casparian strip of the endodermis. To contribute to the plant's nutrition, however, they must be actively transported from the exodermis into cells of the root cortex and, as just described, from the endodermis into the stele. In short, mechanisms that control which solutes will be absorbed by root cells ultimately determine which solutes will be distributed through the plant.

Once an ion reaches the stele, it diffuses from cell to cell until it is "loaded" into the xylem. Experiments to determine whether the loading is passive (by diffusion) or active have been inconclusive, so the details of this final step are not entirely clear. Because the xylem's conducting elements are not living, water and ions in effect reenter the apoplastic pathway when they reach either tracheids or vessels. Once in the xylem, water can move laterally to and from tissues or travel upward in the conducting elements. Minerals are distributed to living cells and taken up by active transport. The following section examines how this "distribution of the mineral wealth" takes place.

STUDY BREAK 34.2

1. **Explain two key differences in how the apoplastic and symplastic pathways route substances laterally in roots.**
2. **How does an ion enter a root hair and then move to the xylem?**

34.3 Transport of Water and Minerals in the Xylem

We return now to the question that opened this chapter: how does the solution of water and minerals called xylem sap move—100 m or more in the tallest trees—from roots to stems, then into leaves? Xylem sap is mostly water, and we know that it moves upward by bulk flow through the tracheids and vessels in xylem. Yet because mature xylem cells are dead, they cannot expend energy to move water into and through the plant shoot. Instead, the driving force for the upward movement of xylem sap from root to shoot is the water potential gradient between leaves and the air. Sunlight and other factors affect the gradient, which causes water to evaporate from leaves and other aerial plant parts. Experiments show that only a small fraction of the water in xylem sap is used in a plant's growth and metabolism. The rest evaporates from the epidermis of aboveground plant parts. This loss of water vapor from aerial plant parts is called **transpiration.** As described next, transpiration drives the ascent of sap.

The Mechanical Properties of Water Have Key Roles in Its Transport

Chapter 2 introduced several biologically important mechanical properties of water. Two of them interest us here. First, water molecules are strongly *cohesive:* they tend to form hydrogen bonds with one another. Second, water molecules are *adhesive:* they form hydrogen bonds with molecules of other substances, including the carbohydrates in plant cell walls. Water's cohesive and adhesive forces jointly pull water molecules into exceedingly small spaces, such as crevices in cell walls or narrow tubes such as xylem vessels in roots, stems, and leaves. In 1914, plant physiologist Henry Dixon explained the ascent of sap in terms of the relationship between transpiration and water's mechanical properties. His model of xylem transport is now called the **cohesion–tension mechanism of water transport (Figure 34.7).**

According to the cohesion–tension model, water transport begins as water evaporates from the walls of mesophyll cells of leaves and into the intercellular spaces. This water vapor diffuses outward through open stomata, the minute passageways in the leaf surface. As water molecules exit the leaf, they are replaced by others from the mesophyll cell cytoplasm. The water loss gradually reduces the water potential in a transpiring cell below the water potential in the leaf xylem. Now, water from the xylem in the leaf veins follows the gradient into cells, replacing the water lost in transpiration.

In the xylem, water molecules are confined in narrow, tubular xylem cells. The water molecules form a long chain, like a string of weak magnets, held together by hydrogen bonds between individual molecules. When a water molecule moves out of a leaf vein into the mesophyll, its hydrogen bonds with the next molecule in line stretch but do not break. The stretching creates *tension*—a negative pressure potential—in the column. Adhesion of the water column to xylem vessel walls adds to the tension. Under continuous tension from above, the entire column of water molecules in xylem is drawn upward, in a fashion somewhat analogous to the way water moves up through a drinking straw. Botanists refer to this root-to-shoot flow as the *transpiration stream*.

Transpiration continues regardless of whether evaporating water is replenished by water rapidly taken up from the soil. Wilting is visible evidence that the water-potential gradient between soil and a plant's shoot parts has shifted. Remember that as soil dries out, the remaining water molecules are held ever more tightly by the soil particles. In effect, the action of soil particles reduces the water potential in the soil surrounding plant roots, and as this happens the roots take up water more slowly. However, because the water that evaporates from the plant's leaves is no longer being fully replaced, the leaves wilt as turgor pressure drops. Reducing the water potential in soil by adding solutes such as NaCl and other salts can have the same wilting effect. When the water potential in the soil finally equals that in leaf cells, a gradient no longer exists. Then movement of water from the soil into roots and up to the leaves comes to a halt.

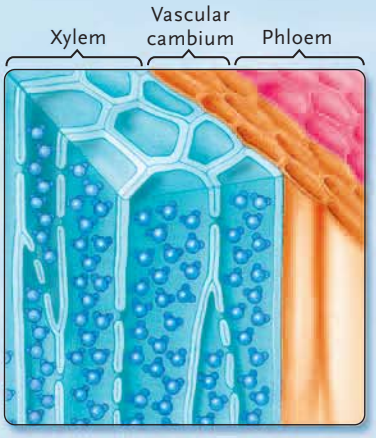
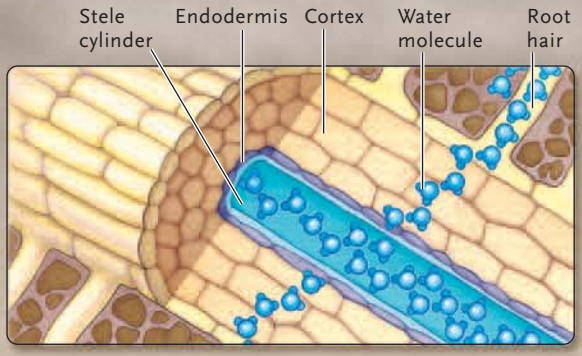
CLOSER LOOK

FIGURE 34.7 Cohesion–Tension Mechanism of Water Transport



A. The driving force of water movement from roots to above-ground plant parts and into dry air.

Water potential ψ is generally quite low in the atmosphere, about –95 MPa. Transpiration (evaporation) of water molecules from leaves and other above-ground plant parts is the driving force of water movement. Much of this water exits into the atmosphere through stomata. The process puts the water in the xylem sap in a state of tension that extends from roots to leaves. Water molecules are not shown to scale.



B. Cohesion of water molecules in the xylem of roots, stems, and leaves.

The collective strength of hydrogen bonds among water molecules, which are confined within the tracheids and vessels in xylem, imparts cohesion to the water. Hence the narrow columns of water in xylem resist rupturing under the continuous tension.

C. Water uptake from soil by roots.

As long as water molecules continue to escape by transpiration, that tension will drive the uptake of replacement water molecules from soil water.

SUMMARY In the cohesion–tension mechanism of water transport, transpiration—the evaporation of water from shoot parts—creates tension on the water in xylem sap. This tension, which extends from leaf to root, pulls columns of hydrogen-bonded water molecules upward. Water molecules are not shown to scale.

THINK LIKE A SCIENTIST Measurements of xylem pressure have typically been obtained indirectly, using external apparatus such as pressure chambers. Why not use direct measurements instead?

Leaf Anatomy Contributes to Cohesion–Tension Forces

Leaf anatomy is key to the processes that move water upward into plants. To begin with, as much as two-thirds of a leaf's volume consists of air spaces that facilitate gas exchange. Thus there is a large internal surface area for evaporation. Leaves also may have thousands to millions of stomata, through which water vapor can escape. Both these factors increase transpiration. Also, every square centimeter of a leaf contains thousands of tiny xylem veins, so that most leaf cells lie within half a millimeter of a vein. This close proximity ensures a ready supply of water to cells and the spaces between them, sites from which the water can readily evaporate.

As water evaporates from a leaf, surface tension at the interface between the water film and the air in the leaf space translates into negative pressure that draws water from the leaf veins. This tension is multiplied many times over in all of the leaves and xylem veins of a plant. It increases further as the plant's metabolically active cells take up xylem sap.

In the Tallest Trees, the Cohesion–Tension Mechanism May Reach Its Physical Limit

A variety of experiments have tested the premises of the cohesion–tension model, and thus far the data strongly support it. For example, the model predicts that xylem sap will begin to move upward at the top of a tree early in the day when water begins to evaporate from leaves. Experiments with several different tree species have confirmed that this is the case. The experiments also showed that sap transport peaks at midday when evaporation is greatest, then tapers off in the evening as evaporative water loss slows.

Other experiments have probed the relationship between xylem transport and tree height. George W. Koch at Northern Arizona University and his colleagues studied several of the tallest living redwoods, including one that towers nearly 113 m above the forest floor. When the scientists measured the maximum tension exerted in the xylem sap in twigs at the treetops, they discovered that it approached the known physical limit at which the bonds between water molecules in a column of water in a conifer's xylem will rupture. Based on this finding and other evidence, the team has predicted that the maximum height for a healthy redwood tree is 122 to 130 m—so the tallest living redwoods may grow taller still.

Root Pressure Contributes to Upward Water Movement in Some Plants

The cohesion–tension mechanism accounts for upward water movement in tall trees. In some nonwoody plant species, however—lawn grasses, for instance—a positive pressure can develop in roots and force xylem sap upward. This **root pressure** operates under conditions that reduce transpiration, such as high humidity or low light. In fact, the mechanism that produces root pressure often operates at night, when transpiration slows or stops. Then, active transport of ions into the stele sets up a water potential gradient across the endodermis. Because the Casparian strip of the endodermis tends to prevent ions from moving back into the root cortex, the water potential difference becomes quite large. It can move enough water and dissolved solutes into the xylem to produce a relatively high positive pressure. Although not sufficient to force water to the top of a very tall plant, in some smaller plant species root pressure is strong enough to force water out of leaf openings, in a process called **guttation (Figure 34.8).** Pushed up and out of vein endings by root pressure, tiny droplets of water that look like dew in the early morning emerge from modified stomata at the margins of leaves.

Stomata Regulate the Loss of Water by Transpiration

Three environmental conditions have major effects on the rate of transpiration: relative humidity, air temperature, and air movement. Relative humidity is a measure of the amount of water vapor in air. The less water vapor in the air, the more evaporates from leaves (because the water potential is higher in the leaves than in the dry air). Rising air temperature at the leaf surface also speeds

Dr. John D. Cunningham/Visuals Unlimited, Inc.

evaporation. Although evaporation cools the leaf somewhat, the amount of water lost can double for each 10°C-rise in air temperature. Air moving across the leaf surface carries water vapor away from the surface and so makes a steeper gradient. Together these factors explain why on extremely hot, dry, breezy days, the leaves of certain plants must completely replace their water each hour.

Even when conditions are not so drastic, more than 90% of the water moving into a leaf can be lost through transpiration. About 2% of the water remaining in the leaf is used in photosynthesis and other activities. These measurements emphasize the need for controls over transpiration, for if water loss exceeds water uptake by roots, the resulting dehydration of plant tissues interferes with normal functioning, and the plant may wilt and die.

The cuticle-covered epidermis of leaves and stems reduces the rate of water loss from aboveground plant parts, but it also limits the rate at which CO_2 for photosynthesis can diffuse into the leaf. The functioning of stomata also affects a plant's water balance. When stomata are open, carbon dioxide can be absorbed, but unless the relative humidity of external air is 100%, water always moves out. However, plants have evolved adaptations that balance water loss with CO_2 uptake. This "transpiration–photosynthesis compromise" involves the regulation of transpiration and gas exchange by opening and closing stomata as environmental conditions change.

OPENING AND CLOSING OF STOMATA Two guard cells flank each stomatal opening **(Figure 34.9).** Their elastic walls are reinforced by parallel strands of cellulose microfibrils that wrap around the walls in a radial pattern, an arrangement that often is likened to the steel belts in a radial tire. The inner walls are thicker and less elastic than the outer walls.

The opening and closing of stomata provide good examples of a symport mechanism (see Figure 34.3C). Stomata open when potassium ions (K^+) flow into the guard cells through ion channels **(Figure 34.10).** As a first step, an active transport pump in the plasma membrane begins pumping H^+ ions out of the guard cells. Recall from Section 34.1 that H^+ pumped out of the cell can then follow its concentration gradient back into the cell. This inward flow of H^+ powers the active transport of K^+ into the guard cell. As a result, the K^+ concentration in turgid guard cells may be four to eight times higher than that in flaccid ("limp") guard cells. Water follows inward by osmosis. As turgor pressure builds in the guard cells, the supportive "belts" of cellulose microfibrils in the outer cell walls prevent the cells from expanding to the side. Instead each cell elongates as the microfibrils move farther apart. As a result, the two elongating cells bow away from each other and create a stoma ("mouth") between them. Stomata close when the H^+ active transport protein stops pumping. K^+ flows passively out of the guard cells, and water follows by osmosis. When the water content of the guard cells dwindles, turgor pressure drops. The guard cells collapse against each other, closing the stomata.

In most plants, stomata open at first light, stay open during daylight, and close at night. Experiments have shown that guard cells respond to a number of environmental and chemical signals, any of which can induce the ion flows that open and close stomata. These signals include light, CO_2 concentration in the air spaces inside leaves, and the amount of water available to the plant.

LIGHT AND CO_2 CONCENTRATION Light induces stomata to open through stimulation of blue-light receptors, probably located in the plasma membrane of guard cells. When stimulated,

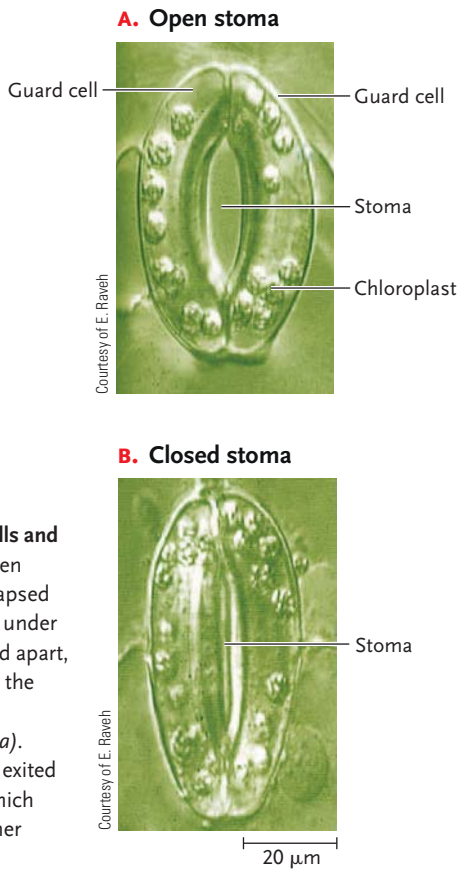

FIGURE 34.9 Guard cells and stomatal action. (A) An open stoma. Water entered collapsed guard cells, which swelled under turgor pressure and moved apart, thus forming the stoma in the needlelike leaf of the rock needlebush *(Hakea gibbosa)*. **(B)** A closed stoma. Water exited the swollen guard cells, which collapsed against each other and closed the stoma.

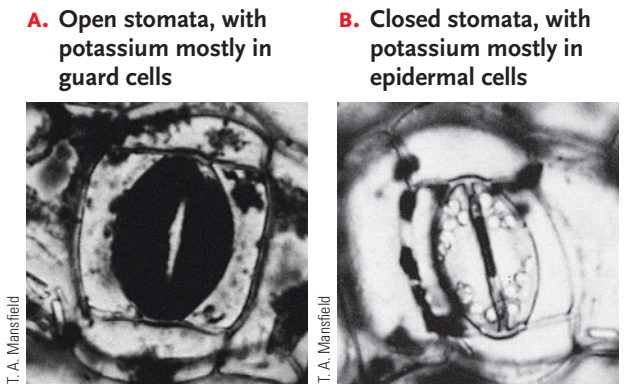

FIGURE 34.10 Evidence for potassium accumulation in stomatal guard cells undergoing expansion. Strips from the leaf epidermis of a dayflower *(Commelina communis)* were immersed in a solution containing a stain that binds preferentially with potassium ions. **(A)** In leaf samples with open stomata, most of the potassium was concentrated in the guard cells. **(B)** In leaf samples with closed stomata, little potassium was in guard cells; most was present in adjacent epidermal cells.

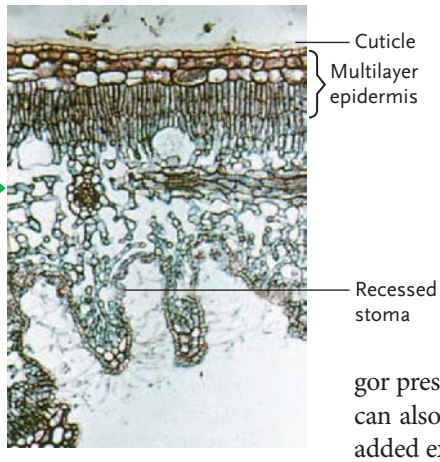
the receptors start the chain of events leading to stomatal opening by triggering activity of the H^+ pumps. Also, as photosynthesis begins in response to light, CO_2 concentration drops in the leaf air spaces as chloroplasts use the gas in carbohydrate production. In some way, this drop in CO_2 concentration sets off the series of events increasing the flow of K^+ into guard cells and furthers stomatal opening. The effects of reduced CO_2 concentration have been tested by placing plants in the dark in air containing no CO_2. Even in the absence of light, as the CO_2 concentration falls in leaves, guard cells swell and the stomata open.



Normally, when the sun goes down, a plant's demand for CO_2 drops as photosynthesis comes to a halt. Yet aerobic respiration continues to produce CO_2, which accumulates in leaves. As CO_2 concentration rises, and the blue-light wavelengths that activated the H^+ pumps wane, K^+ is lost from the guard cells and they collapse, closing the stomata. Thus, at night transpiration is reduced and water is conserved.

FIGURE 34.11 **Some adaptations that enable plants to survive water stress. (A)** Oleanders *(Nerium oleander)* are adapted to arid conditions. **(B)** As shown in the micrograph, oleander leaves have recessed stomata on their lower surface and a multilayer epidermis covered by a thick cuticle on the upper surface. **(C)** Like many other cacti, the leaves of the Graham dog cactus *(Opuntia grahamii)* are modified into spines that protrude from the underlying stem. Transpiration and photosynthesis occur in the green stems. **(D)** *Sedum*, a CAM plant, in which the stomata open only at night.

WATER STRESS As long as water is readily available to a plant's roots, the stomata remain open during daylight. However, if water loss stresses a plant, the stomata close or open only slightly, regardless of light intensity or CO_2 concentration. Stomata arose relatively early in land-plant evolution, probably about 400 mya (million years ago), and the first ones, in nonvascular plants, were simple open pores. For a variety of reasons stomata have proven tricky to study, and only recently did Tim J. Brodribb and his colleague Scott A. M. McAdam at the University of Tasmania show that in seedless vascular plants such as ferns, stomata operate by basic hydraulics—opening when the water content of their leaves reaches a certain level and closing when it falls below that level. The mechanism in seed plants is more complex. Experiments on these plants have shown that the stress-related closing of stomata depends on a hormone, abscisic acid (ABA) that is released by roots when water is unavailable. This mechanism seems especially important in nonwoody plants. In some elegant studies, test plants were suspended in containers so that only one-half the root system received water. Even though the roots with access to water could absorb enough water to satisfy the needs of all the plants' leaves, the stomata still closed. Tissue analysis revealed that water-stressed roots rapidly synthesize ABA. Transported through the xylem, this hormone stimulates K^+ loss by guard cells, and water moves out of the cell by osmosis (enhanced by aquaporins) so the stomata close. Mesophyll cells also take up ABA from the xylem and release it, with the same effects on stomata, when their turgor pressure falls because of excessive water loss. ABA can also cause stomata to close when the hormone is added experimentally to leaves.

THE BIOLOGICAL CLOCK Besides responding to light, CO_2 concentration, and water stress, stomata apparently open and close on a regular daily schedule imposed by a biological clock. Even when plants are placed in continuous darkness, their stomata open and close (for a time) in a cycle that roughly matches the day/night cycle of Earth. Such *circadian rhythms* (*circa* = around; *dies* = day) are also common in animals, and several, including wake/sleep cycles in mammals, are known to be controlled by hormones—a topic pursued in Chapter 40.

In Dry Climates, Plants Exhibit Various Adaptations for Conserving Water

Many plants have other evolutionary adaptations that conserve water, including modifications in structure or physiology **(Figure 34.11).** Oleanders, for example, have stomata on the underside of the leaf at the bottom of pitlike areas of the leaf epidermis lined by hairlike trichomes (Figure 34.11B).

Sunken stomata are less exposed to drying breezes, and trichomes help retain water vapor at the pore opening, so that water evaporates from the leaf much more slowly.

The leaves of *xerophytes*—plants adapted to hot, dry environments in which water stress can be severe—have a thickened cuticle that gives them a leathery feel and enhances protection against evaporative water loss. An example is mesquite *(Prosopis).* In still other plants that live in arid landscapes, such as cacti, stems are thick, leaflike pads covered by sharp spines that actually are modified leaves (Figure 34.11C). These structural alterations reduce the surface area for transpiration. In some plants, coping with water stress includes a capacity to resist *cavitation,* the formation of physiologically dangerous air bubbles in xylem mentioned in Section 33.2.

An interesting variation on water-conservation mechanisms occurs in CAM plants, including cacti, orchids, and most succulents. As discussed in Section 9.4, **crassulacean acid metabolism** (CAM) is a biochemical variation of photosynthesis that was discovered in a member of the family Crassulaceae. CAM plants generally have fewer stomata than other types of plants, and their stomata typically follow a reversed schedule. They are closed during the day when temperatures are higher and the relative humidity is lower, and open at night. At night, the plant temporarily fixes carbon dioxide by converting it to malate, an organic acid. In the daytime, the CO_2 is released from malate and diffuses into chloroplasts, so photosynthesis takes place even though a CAM plant's stomata are closed. This adaptation prevents heavy evaporative water losses during the heat of the day.

STUDY BREAK 34.3

1. Explain the key steps in the cohesion–tension mechanism of water transport in a plant.
2. How and when do stomata open and close? In what ways is their functioning important to a plant's ability to manage water loss?

THINK OUTSIDE THE BOOK

Cavitation, the formation of a bubble-like space in a tracheid or xylem vessel, is a serious risk for plants under water stress. Collaboratively or individually, research the causes and effects of cavitation. Can it be caused by environmental factors other than water stress? Is it possible for such a break in the column of water molecules to "heal"?

34.4 Transport of Organic Substances in the Phloem

A plant's phloem is another major long-distance transport system, and a superhighway at that: it carries huge amounts of carbohydrates, lesser but vital amounts of amino acids, fatty acids, and other organic compounds, and still other essential substances such as hormones. And unlike the xylem's unidirectional upward flow, the phloem transports substances throughout the plant to wherever they are used or stored. Organic compounds and water in the sieve tubes of phloem are under pressure and driven by concentration gradients.

Organic Compounds Are Stored and Transported in Different Forms

Plants synthesize various kinds of organic compounds, including large amounts of carbohydrates that are stored mainly as starch. Plant cells must often export these compounds for use in distant cells. Yet, with a few exceptions, macromolecules such as starches, proteins, and fat molecules are too large to cross cell membranes and leave the cells where they are made. They also may be too insoluble in water to be transported to other regions of the plant body. Consequently, in leaves and other plant parts, specific reactions convert organic compounds to transportable forms. For example, hydrolysis of starch liberates glucose units, which combine with fructose to form sucrose—the main form in which sugars are transported through the phloem of most plants. Proteins are broken down into amino acids, and lipids converted into fatty acids. These forms are also better able to cross cell membranes by passive or active mechanisms.

Organic Solutes Move by Translocation

In plants, the long-distance transport of substances is called **translocation.** Botanists most often use this term to refer to the distribution of sucrose and other organic compounds by phloem, and they understand the mechanism best in flowering plants. The phloem of flowering plants contains interconnecting sieve tubes formed by living sieve-tube member cells (see Figure 33.8). Sieve tubes lie end to end within vascular bundles, and they extend through all parts of the plant. Water and organic compounds, collectively called **phloem sap,** flow rapidly through large pores on the sieve tubes' end walls—another example of a structural adaptation that suits a particular function.

Phloem Sap Moves from Source to Sink under Pressure

Over the decades, plant physiologists have proposed several mechanisms of translocation, but it was the tiny aphid, an insect pest, that helped demonstrate that organic compounds flow under pressure in the phloem. An aphid attacks plant leaves and stems, forcing its needlelike stylet (a mouthpart) into sieve tubes to obtain the dissolved sugars and other nutrients inside. Numerous experiments with aphids have shown that in most plant species, sucrose is the main carbohydrate being translocated through the phloem. Studies also verify that the contents of sieve tubes are under high pressure, often five times as much as in an automobile tire. **Figure 34.12** explains a simple and innovative experiment that provided direct confirmation that phloem

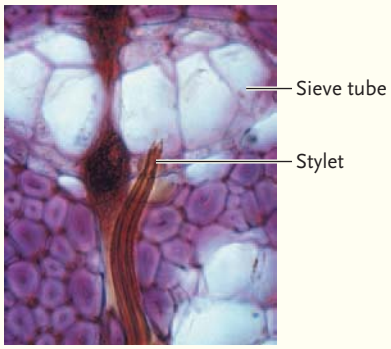
FIGURE 34.12 **Experimental Research**

Translocation Pressure

Hypothesis: High pressure forces phloem sap to flow through sieve tubes from a source to a sink.



Experiment: In the late 1970s, John Wright and Donald Fisher at the University of Georgia devised an experiment to directly measure the turgor pressure in sieve tubes of weeping willow saplings *(Salix babylonica)* under nondestructive conditions, using aphids that feed on *S. babylonica* in the wild. Weeping willow saplings were grown in a greenhouse under natural conditions of light and moisture. Aphids were placed on the trees and allowed to begin feeding by inserting their stylets into sieve tubes in the normal fashion. After being anesthetized by exposure to high concentrations of carbon dioxide, the aphids' bodies were cut away and only their stylets were left embedded in the sieve tubes. A tiny pressure-measuring device called a micromanometer then was glued over the end of each stylet. The micromanometer registered the volume and pressure of phloem sap as it was exuded from the stylet over time periods ranging from 30 to 90 minutes.

A. Aphid releasing honeydew

Martin H. Zimmermann

B. Micrograph of aphid stylet in sieve tube

Martin H. Zimmermann

Results: In nearly all cases, a high volume of pressurized sap flowed through the severed stylets into the micromanometer during the test periods.

Conclusion: The evidence supports pressure flow as the mechanism that moves phloem sap through sieve tubes.

Other experiments have confirmed that both turgor pressure and the concentration of sucrose are highest in sieve tubes closest to the sap source. Phloem sap also moves most rapidly closest to the source, where pressure is highest.

THINK LIKE A SCIENTIST For a plant, phloem sap represents a considerable, metabolically crucial investment. Have plants evolved defenses that counteract insect feeding on phloem sap?

Source: J. P. Wright and D. B. Fisher. 1980. The direct measurement of sieve tube turgor pressure using severed aphid stylets. *Plant Physiology* 65:1133–1135.

© Cengage Learning 2014

sap flows under pressure. When a live aphid feeds on phloem sap, this pressure forces the fluid through the aphid's gut and (minus nutrients absorbed) out its anus as a sticky liquid waste called "honeydew." A car parked under an aphid-infested tree might get spattered with honeydew droplets, thanks to the high fluid pressure in the tree's phloem.

Much of what plant physiologists know about the transport of phloem sap has come from studies of sucrose transport in flowering plants. A fundamental discovery is that in flowering plants sucrose-laden phloem sap flows from a starting location, called the *source,* to cells in another site, called the *sink,* along gradients of decreasing solute concentration and pressure. A **source** is any region of the plant where organic substances are produced or released from storage and loaded into the phloem's sieve-tube system. A **sink** is any region where cells use or store organic substances unloaded from the sieve-tube system. What causes the sugar sucrose and other solutes produced in leaf mesophyll to flow from a source to a sink? In flowering plants, the **pressure flow mechanism** builds up at the source end of a sieve-tube system and pushes those solutes by bulk flow toward a sink, where cells remove them. **Figure 34.13** summarizes this mechanism, using sucrose as an example.

Mature photosynthesizing leaves are sources. Another example is a tulip bulb. In spring, stored food is mobilized for transport upward to growing plant parts, but after the plants bloom, the bulb becomes a sink as sugars manufactured in the tulip plant's leaves are translocated into it for storage. Young leaves, roots, and developing fruits generally start out as sinks, becoming sources later when the season changes or the plant enters a new developmental phase. (As these latter examples show, the direction of translocation is reversible.) In general, sinks receive organic compounds from sources closest to them. Hence, the lower leaves on a rose bush may supply sucrose to roots, whereas leaves farther up the shoot supply the shoot tip.

Substances carried in phloem must be loaded into sieve-tube members at sources and unloaded from them at sinks, and both processes have prompted a great deal of research. We know, for example, that in some plants the solutes produced in leaf mesophyll move between the symplast (from cell to cell via plasmodesmata) and the apoplast (adjoining cell walls and air spaces). In addition, active transport mechanisms have a major role in the movement of solutes into and out of cells. Consider sucrose. After this sugar forms inside leaf mesophyll cells, it is exported and travels to sieve tubes and their adjacent companion cells, which interact so closely they often are considered a functional unit. Experiments with tobacco and some other species show that exported sucrose soon leaves the symplast and enters the apoplast next to a small phloem vein. Next, it is actively pumped into companion cells by symport, in which H^+ ions move into the cell through the same carrier that takes up the sugar molecules. Companion cells shuttle the sugar into sieve-tube members.

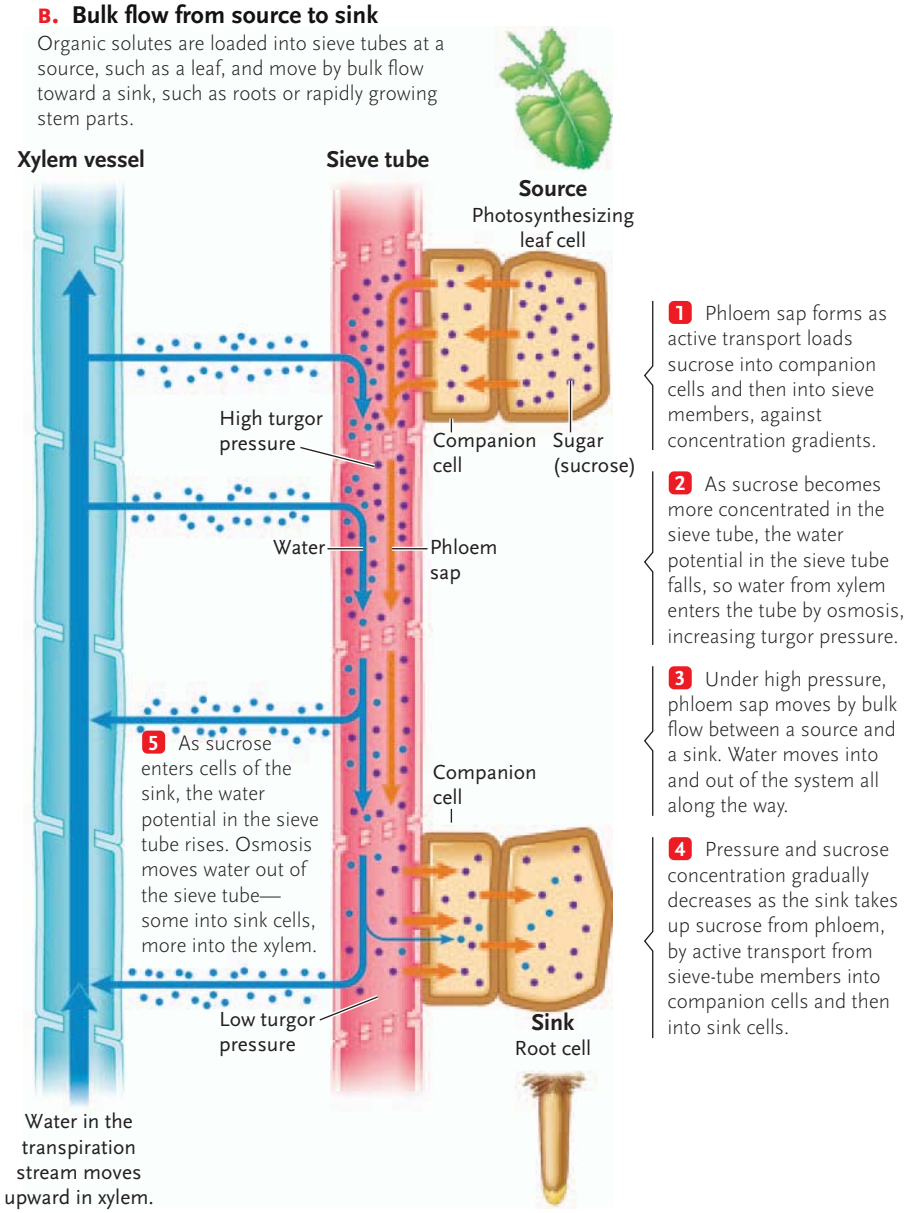
CLOSER LOOK

FIGURE 34.13 The Pressure Flow Mechanism in the Phloem of Flowering Plants.



A. Loading at a source

Photosynthetic cells in leaves are a common source of carbohydrates that must be distributed through a plant. Small, soluble forms of these compounds move from the cells into phloem (in a leaf vein).

B. Bulk flow from source to sink

Organic solutes are loaded into sieve tubes at a source, such as a leaf, and move by bulk flow toward a sink, such as roots or rapidly growing stem parts.

SUMMARY In the pressure flow mechanism, organic solutes are loaded into sieve tubes at a source, such as a leaf, and move by bulk flow toward a sink, such as roots or rapidly growing stem parts.

THINK LIKE A SCIENTIST At a sink, the unloading of sucrose occurs by active transport. What sort of channel(s) is/are involved?

© Cengage Learning 2014

In some plants, companion cells become modified into **transfer cells** that facilitate the short-distance transport of various organic solutes from the apoplast into the symplast. Transfer cells generally form when large amounts of solutes must be loaded or unloaded into the phloem, and they move substances through plasmodesmata to sieve-tube members. As a transfer cell is forming, parts of the cell wall grow inward like pleats. This structural feature increases the surface area available for taking up solutes. The underlying plasma membrane, packed with transport proteins covers the ingrowths. Transfer cells also enhance solute transport between living cells in the xylem, and they occur in glandlike tissues that secrete nectar. Plant physiologists have discovered transfer cells in species from most taxonomic groups in the plant kingdom, as well as in fungi and algae. Transfer cells are unusual in that they arise from differentiated cells instead of from meristem cells like other types of plant cells. Researchers are working to discover the molecular mechanisms that trigger this mode of development.

When sucrose is loaded into sieve tubes, its concentration rises inside the tubes. Thus the water potential falls, and water flows into the sieve tubes by osmosis. In fact, the phloem typically carries a great deal of water. As water enters sieve tubes, turgor pressure in the tubes increases, and the sucrose-rich fluid moves by bulk flow into the increasingly larger sieve tubes of larger veins.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Eventually, the fluid is pushed out of the leaf into the stem and toward a sink. When sucrose is unloaded at the sink, the water potential in sieve tubes rises, so water tends to flow out of the tubes by osmosis into the surrounding cells, where the water potential is lower. Some of this water "follows the solutes" into sink cells, whereas much more enters the xylem and is recirculated.

Sieve tubes are mostly passive conduits for translocation. The system works because companion cells supply much of the energy that loads sucrose and other solutes at the source, and because solutes are removed at their sinks. As sucrose (and water) enters a sink, for example, its concentration in sieve tubes falls, as does the pressure potential. Thus for sucrose and other solutes transported in the phloem, there is always a gradient of concentration from source to sink—and a pressure gradient that keeps the solute moving along.

As noted previously, phloem sap moving through a plant carries a wide variety of substances, including hormones, amino acids, organic acids, and agricultural chemicals. The phloem also transports organic nitrogen compounds and mineral ions that are withdrawn from dying leaves and stored for reuse in root tissue.

The transport functions of xylem and phloem are closely integrated with phenomena discussed later in this unit—reproduction and embryonic development, and the hormonal regulation of plant growth.

STUDY BREAK 34.4

1. **Compare and contrast translocation and transpiration.**
2. **Using sucrose as your example, summarize how a substance moves from a source into sieve tubes and then is unloaded at a sink. What is this mechanism called, and why?**

THINK OUTSIDE THE BOOK

The direction of phloem transport to or from a leaf may shift several times over the course of its lifespan. Collectively or on your own, research these types of changes. When are leaves sinks, and what triggers a leaf's shift to become a source? How does the development of flowers and fruit beyond a leaf affect the direction of phloem transport?

UNANSWERED QUESTIONS

How Can Metabolomics Advance Plant Science?

Plants collectively synthesize an estimated 200,000 to 1 million different chemicals. Harnessing this remarkable biosynthetic power will become increasingly important given burgeoning human population growth and the associated need for increased production of nutritious and safe food and for replacing petroleum-based fuels, plastics, and other materials with renewable alternatives. Still, many of the substances plants make are not yet chemically characterized. Both basic science and practical "metabolic engineering" applications will be served by a more complete understanding of the metabolic capabilities of plant tissues.

A key strategy is to identify and quantify the compounds that are part of target biosynthetic pathways. Innovations in instrumentation and bioinformatics (use of computational and statistical methods in the study of biological molecules) are now enabling scientists to study the chemical makeup of hundreds, even thousands of metabolites in plant tissues. These advances have launched a discipline called *metabolomics,* which essentially is the study of the small molecule composition of a biological system. There may be thousands of different compounds in an extract from a single tissue type, and the process of characterizing them involves two basic steps—separating them, and then detecting the separated molecules. Although there are a growing number of innovations, gas and liquid chromatography (for separation) and mass spectrometry (for detection) are the most commonly used approaches. A single chromatography/spectrometry run can provide a readout of hundreds of compounds and their relative levels or absolute concentrations.

The potential applications of metabolomics are vast, and plant scientists have taken a leading role in developing the field. Considerable research is focused on plant storage products such as the starch and protein found in wheat grain. These compounds make up 20% of human caloric intake, and increasing their production is an important step for enhancing global food security. Plant starch is also the major source of biofuels in the United States, therefore massive investments into research on manipulating starch production has been made. In my laboratory at the University of California at Davis, my colleagues and I use metabolomics to pinpoint compounds that may influence higher levels of storage product synthesis in wheat and other crops. For example, metabolite profiles of plant genotypes that accumulate higher levels of the desired storage product are compared with those that make less. Analysis of metabolites that vary synchronously with the low or high product phenotype may indicate important control points in the pathways. Enzymes catalyzing these steps would be good targets for genetic manipulation to alter accumulation.

Researchers also are tapping metabolomics to address an array of fundamental biological questions in diverse fields such as medicine, environmental science, human nutrition, and food safety. Still, many challenges lie ahead, most of which reflect the complexity of plant metabolism. For instance, because the compounds plants produce vary enormously in their physical and chemical properties, no single extraction and separation technology exists that can measure them all. We must also improve our tools for spatial resolution of metabolites—for example, to see whether a molecule of interest is sequestered within a tissue type or an organelle. Because such data are crucial both for accurate analysis and effective metabolic engineering, researchers are now developing cell-type and even organellar metabolomics to link metabolites with cell-specific processes. A third major need involves analytical refinements that improve the accuracy with which chemical structures revealed by mass spectrometry are classified. At present, more than 60% of the analytes identified from mass spectrometry are classified as "unknown." Among other benefits, advances will help researchers distinguish signatures of endogenous molecules from artifacts of extraction and processing.

THINK LIKE A SCIENTIST The metabolite signature of a tissue is a result of genetic and environmental factors. To identify metabolites that may enhance survival under environmental stress, researchers may compare the metabolite profiles of a stress-sensitive crop plant to stress-tolerant species that may be their wild, nondomesticated relatives. How would you design an experiment to identify the subset of metabolites that may underscore tolerance? What factors must you take into account?

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

34.1 Principles of Water and Solute Movement in Plants

- Plants have mechanisms for moving water and solutes long-distance from the root to shoot or vice versa, and over short distances from cell to cell (Figure 34.2).
- Both passive and active mechanisms move substances into and out of plant cells. Solutes generally are transported by carriers, either passively down a concentration or electrochemical gradient (in the case of ions), or actively against a gradient, which requires ATP energy. An H^+ gradient creates the membrane potential that drives the cross-membrane transport of many ions or molecules (Figure 34.3).
- Most organic substances enter plant cells by symport, in which the energy of the H^+ gradient is coupled with uptake of a different solute. Some substances cross the plant cell membrane by antiport, in which energy of the H^+ gradient powers movement of a second solute out of cells.
- Driven by water potential (Ψ), water crosses plant cell membranes by osmosis, moving from regions where water potential is higher to regions where it is lower.
- Water potential is the sum of turgor pressure and solute potential. Water potential is measured in megapascals (MPa) (Figures 34.4 and 34.5).
- Water and solutes also move by osmosis into and out of the cell's central vacuole, transported from the cytoplasm across the tonoplast. Aquaporins enhance osmosis across the tonoplast and plasma membrane. Water in the central vacuole is vital for maintaining turgor pressure inside a plant cell.
- Bulk flow of fluid occurs when pressure at one point in a system changes with respect to another point in the system.

Animation: Interdependent processes

34.2 Transport in Roots

- Water and mineral ions entering roots travel laterally through the root cortex to the root xylem, following one or more of three major routes: the apoplastic pathway, the symplastic pathway, and the transmembrane pathway (Figure 34.6A).
- In the apoplastic pathway, water entering roots diffuses between root epidermal cells. Absorbed water and solutes then enter either the symplastic or transmembrane pathway, both of which pass through cells.
- Casparian strips form a barrier that forces water and ions in the apoplast to pass through cells to enter the stele. Ions diffuse from cell to cell to reach the xylem. Roots of many flowering plants have an exodermis, a second cell layer with Casparian strips, just inside the root epidermis (Figure 34.6B).

Animation: Root functioning

Animation: Structure of Roots

34.3 Transport of Water and Minerals in the Xylem

- In xylem, tension generated by transpiration extends down from leaves to roots. By the cohesion–tension mechanism of water transport, water molecules are pulled upward by tension created as water exits a plant's leaves (Figure 34.7).
- In tall trees, negative pressure generated in the shoot drives bulk flow of xylem sap. In some herbaceous species, positive pressure may develop in roots and force xylem sap upward (Figure 34.8).
- Transpiration and CO_2 uptake occur mostly through stomata. Relative humidity, air temperature, and air movement at the leaf surface affect the transpiration rate (Figure 34.9).
- Most plants lose water and take up CO_2 during the day, when stomata are open. At night, when stomata close, plants conserve water and the inward movement of CO_2 falls.
- Stomata open in response to falling levels of CO_2 in leaves and also to incoming light wavelengths that activate photoreceptors in guard cells.
- Activation of photoreceptors triggers active transport of K^+ into guard cells. Simultaneous entry of anions such as Cl^- and synthesis of negatively charged organic acids increase the solute concentration, lowering the water potential so that water enters by osmosis. As turgor pressure builds, guard cells swell and draw apart, producing the stomatal opening (Figure 34.10).
- Guard cells close when light wavelengths used for photosynthesis wane. The stomata of water-stressed plants close regardless of light or CO_2 needs, possibly under the influence of the plant hormone ABA. The leaves of species native to arid environments typically have water-conserving adaptations (Figure 34.11).

Animation: Transpiration

Animation: Tension-Cohesion Model

34.4 Transport of Organic Substances in the Phloem

- In flowering plants, phloem sap is translocated in sieve-tube members. Differences in pressure between sources and sink regions drive the flow (Figure 34.12).
- In leaves, the sugar sucrose is actively transported into companion cells next to sieve-tube members, then loaded into the sieve tubes through plasmodesmata. In some plants, transfer cells take up materials and pass them to sieve-tube members.

Transfer cells in xylem enhance the transport of solutes between tissues.

- As the sucrose concentration increases in the sieve tubes, water potential decreases. The resulting influx of water increases pressure inside the sieve tubes, so phloem sap flows in bulk toward the sink, where sucrose and water are unloaded (Figure 34.13).

Animation: Pressure Flow Hypothesis

UNDERSTAND & APPLY

Test Your Knowledge

1. Antiport transport mechanisms:
   a. move dissolved materials by osmosis.
   b. transport molecules in the opposite direction of H^+ transported by proton pumps.
   c. transport molecules in the same direction as H^+ is pumped.
   d. are not affected by the size of molecules to be transported.
   e. are not affected by the charge of molecules to be transported.
2. Which of the following does *not* have a role in transporting materials between plant cells?
   a. the stele
   b. symport
   c. the cell membrane
   d. stomata
   e. transport proteins
3. Turgor pressure is best expressed as the:
   a. movement of water into a cell by osmosis.
   b. driving force for osmotic movement of water (Ψ).
   c. group movement of large numbers of molecules because of a difference in pressure between two locations.
   d. equivalent of water potential.
   e. pressure exerted by fluid inside a plant cell against the cell wall.
4. Water potential is:
   a. the driving force for the osmotic movement of water into plant cells.
   b. higher in a solution that has more solute molecules relative to water molecules.
   c. a measure of the physical pressure required to halt osmotic water movement across a membrane.
   d. a measure of the combined effects of a solution's pressure potential and its solute potential.
   e. the functional equivalent of turgor pressure.
5. To regulate the flow of water and minerals in the root, the:
   a. Casparian strip of endodermal cells blocks the apoplastic pathway, forcing water and solutes to cross cell plasma membranes in order to pass into the stele.
   b. apoplastic pathway is expanded, allowing a greater variety of substances to move into the stele.
   c. symplastic pathway is modified in ways that make plasma membranes of root cortex cells more permeable to water and solutes.
   d. symplastic pathway shuts down entirely so that substances can move only through the apoplast.
   e. transmembrane pathway augments transport via the apoplast, shunting substances around cells.
6. An indoor gardener leaving for vacation completely wraps a potted plant with clear plastic. Temperature and light are left at low intensities. The effect of this strategy is to:
   a. halt photosynthesis.
   b. reduce transpiration.
   c. cause guard cells to shrink and stomata to open.
   d. destroy cohesion of water molecules in the xylem.
   e. increase evaporation from leaf mesophyll cells.
7. In seed plants, stomata open when:
   a. water has moved out of the leaf by osmosis.
   b. K^+ flows out of guard cells.
   c. turgor pressure in the guard cells lessens.
   d. the H^+ active transport protein stops pumping.
   e. outward flow of H^+ sets up a concentration gradient that moves K^+ in via symport.
8. A factor that contributes to the movement of water up a plant stem is:
   a. active transport of water into the root hairs.
   b. an increase in the water potential in the leaf's mesophyll layer.
   c. cohesion of water molecules in stem and leaf xylem.
   d. evaporation of water molecules from the walls of cells in root epidermis and cortex and in the stele.
   e. absorption of raindrops on a leaf's epidermis.
9. In translocation of sucrose-rich phloem sap:
   a. the sap flows toward a source as pressure builds up at a sink.
   b. crassulacean acid metabolism reduces the rate of photosynthesis.
   c. companion cells use energy to load solutes at a source and the solutes then follow their concentration gradients to sinks.
   d. sucrose diffuses into companion cells whereas H^+ simultaneously leaves the cells by a different route.
   e. companion cells pump sucrose into sieve-tube members.
10. In Vermont in early spring, miles of leafless sugar maple trees have buckets hanging from "spigots" tapped into their xylem to capture the sugary xylem sap, which is the fluid raw material for making maple syrup. Select the statement(s) below that best applies to this phenomenon.
    a. Transpiration is pulling the sap upward from the roots.
    b. Just as phloem can contain a great deal of water, xylem typically contains a great deal of sucrose.
    c. Root pressure probably is forcing the xylem sap upward in the tree.
    d. Transfer cells move excess sucrose from phloem into the xylem.

Discuss the Concepts

1. Many popular houseplants are native to tropical rain forests. Among other characteristics, many nonwoody species have extraordinarily broad-bladed leaves, some so ample that indigenous people use them as umbrellas. What environmental conditions might make a broad leaf adaptive in tropical regions, and why?
2. Insects such as aphids that prey on plants by feeding on phloem sap generally attack only young shoot parts. Other than the relative ease of piercing less mature tissues, suggest a reason why it may be more adaptive for these animals to focus their feeding effort on younger leaves and stems.
3. So-called systemic insecticides often are mixed with water and applied to the soil in which a plant grows. The chemicals are effective against sucking insects no matter which plant tissue the insects attack, but often do not work as well against chewing insects. Propose a reason for this difference.

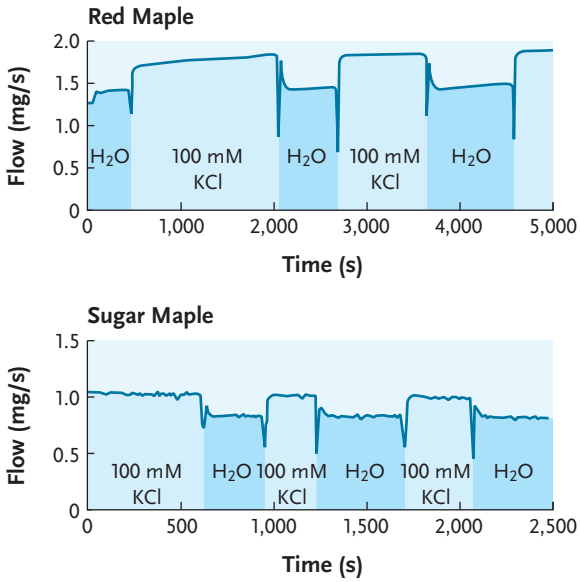
4. Concerns about global climate change and the greenhouse effect center on rising levels of greenhouse gases, including atmospheric carbon dioxide. Plants use CO_2 for photosynthesis, and laboratory studies suggest that increased CO_2 levels could cause a rise in photosynthetic activity. However, as one environmentalist noted, "What plants do in environmental chambers may not happen in nature, where there are many other interacting variables." Strictly from the standpoint of physiological effects, what are some possible ramifications of a rapid doubling of atmospheric CO_2 on plants in temperate environments? In arid environments?



Design an Experiment

CAM plants typically open their stomata at night instead of during the daytime, in part to limit transpiration on hot days. They include some, but not all, species of succulents (such as cacti and members of the genus *Sedum*). One mild spring afternoon while working in a mountain desert of eastern Oregon you discover a new species of succulent, and although you immediately assume that it is a CAM plant, a quick look with your field microscope reveals that its stomata are wide open. Then you remember that when CAM plants have access to plenty of moisture and are exposed to mild nighttime temperatures, they may shift temporarily to a more common mode of photosynthesis (see Section 9.4). During this period their stomata open during the day and close at night. Your collecting permit allows you to gather a few specimens, which you take back to your lab for testing. Design a simple experiment to determine the basic photosynthetic strategy of the new species, and explain how it will provide the information you seek.

Interpret the Data

As you already know, photosynthesizing plant cells require water delivered in the xylem. Recent experiments have revealed that the concentration of ions, especially potassium (K^+) in xylem water influences the velocity of water flow through the xylem, possibly by affecting the pit membranes between xylem vessels.

Roots take up K^+ in soil water, but phloem sap also contains K^+ that "recycles" back to the xylem. M. A. Zwieniecki and his colleagues hypothesized that changes in the flow of ions from phloem to xylem can alter the velocity (flow rate) at which water moves through the xylem. Working with red maples *(Acer rubrum)* and sugar maples *(Acer saccharum),* they devised a girdling experiment that would prevent the recycling of phloem K^+ to xylem without disrupting the movement of xylem water. (Recall that girdling a tree or branch stops the movement of phloem sap beyond the cut.) The experimental design included an apparatus for maintaining normal pressure in the xylem and for adding either deionized water or water containing potassium chloride (KCl), a source of ions, to it. After experimental testing on 43 tree branches, they obtained results for xylem sap flow through the branches as shown in the graphs below.

© Cengage Learning 2014

1. What do the different colored blocks represent?
2. Do the results support or not support a hypothesis that the flow rate of xylem sap slows in response to a decline in ion concentration (KCl)?
3. Were results substantially similar or substantially different for the two species used in the experiment?

Apply Evolutionary Concepts

A variety of structural features of land plants reflect the conflicting demands for conserving water and taking in carbon dioxide for photosynthesis. Identify at least four fundamental structural adaptations that help resolve this dilemma and explain how each one contributes to a land plant's survival.

STUDY OUTLINE

35.1 Plant Nutritional Requirements
35.2 Soil
35.3 Root Adaptations for Obtaining and Absorbing Nutrients

Plant Nutrition

Why it matters . . . Tropical rainforests are remarkable for many reasons, but for biologists the key one may be that they are among the most biologically diverse ecosystems on Earth. In addition to containing countless thousands of species of animals, fungi, protists, and prokaryotes, these lush domains are dense with broadleaved, evergreen trees; sinuous vines; and other vegetation. With rain a near-daily event, it may not seem surprising that the trees' foliage is a deep, luxuriant green **(Figure 35.1).**

Yet tropical rainforests are demanding places for plants to survive, in large part because the soil is chronically deficient in nutrients necessary for plant metabolism. This nutrient scarcity is a direct outcome of the incessant rain and the high acidity of tropical rainforest soil. There is ample moisture in the upper layer of soil, but in acidic soil minerals vital to plant metabolism, such as potassium, calcium, magnesium, and phosphorus, are subject to **leaching**—being washed into deeper soil levels that are not as accessible to plant roots. In addition, in the warm, moist environment of a tropical rainforest, bacteria and fungi speedily decompose fallen leaves and other organic remains. Just as rapidly, established trees and vines take up any nutrients these decomposers have released, leaving few or none to enrich the soil. As falling rain dissolves some atmospheric CO_2, it creates carbonic acid—a type of "acid rain"—that exacerbates the leaching problem even more.

Such poor soil and the near perpetual twilight at the forest floor make it extremely difficult for small shrubs and herbaceous plants to survive there. Nearly all such plants climb upward as vines using the tree trunks for mechanical support, or they live attached to the upper branches of taller species, where they can absorb needed minerals from falling dust or from the surfaces of other plants. These intricate adaptations to a particular environment allow the plants to secure energy and raw materials and to use both for growth and development.

FIGURE 35.1 **A lush tropical rainforest growing in Southeast Asia.**

Tropical rainforests are not unique in posing nutritional challenges for plants. In fact, plants rarely have ready access to a full complement of necessary resources. In a rainforest, the carbon, hydrogen, and oxygen plants need for photosynthesis are relatively easy to come by: plants there usually get enough carbon from the CO_2 in air, and their roots can take up enough water to gain the necessary hydrogen and oxygen. But soils in other environments are frequently dry, making water a limited resource, and almost nowhere in nature do soils hold lavish amounts of dissolved minerals such as nitrogen, calcium, and others that are vital for a plant's survival. In response to the challenge of obtaining nutrients, plants have evolved the range of structural and physiological adaptations that we consider in this chapter.

35.1 Plant Nutritional Requirements

No organism grows normally when deprived of a chemical element essential for its metabolism. In the latter half of the nineteenth century, plant physiologists exploited rapid advances in chemistry to probe both the chemical composition of plants and the essential nutrients plants need to survive. In recent times researchers have brought to bear sophisticated methods to expand our understanding of the range of plant nutrients, including those required only in trace amounts.

Plants Require Macronutrients and Micronutrients for Their Metabolism

By weight, the tissues of most plants are more than 90% water. Early researchers could obtain a rough idea of the composition of a plant's dry weight by burning the plant and then analyzing the ash. This method typically yielded a long list of elements, but the results were flawed. Chemical reactions during burning can dissipate quantities of some important elements, such as nitrogen. Also, plants take up a variety of ions that they do not use; depending on the minerals present in the soil where a plant grows, a plant's tissues can contain nonnutritive elements such as gold, lead, arsenic, and uranium.

STUDYING PLANT NUTRITION USING HYDROPONICS In 1860, German plant physiologist Julius von Sachs pioneered an experimental method for identifying the minerals absorbed into plant tissues that are essential for plant growth. Sachs carefully measured amounts of compounds containing specific minerals and mixed them in different combinations with pure water. He then grew plants in the solutions, a method now called **hydroponic culture** (*hydro* = water; *ponos* = work). By eliminating one element at a time and observing the results, Sachs deduced a list of six essential plant nutrients, in descending order of the amount required: nitrogen, potassium, calcium, magnesium, phosphorus, and sulfur.

Sachs's innovative research paved the way for decades of increasingly sophisticated studies of plant nutrition, and the eventual identification of many more essential plant nutrients. In the spirit of his work, one basic experimental method involves growing a plant in a solution containing a complete spectrum of known and possible essential nutrients **(Figure 35.2A).** The healthy plant is then transferred to a solution that is identical, except that it lacks one element having an unknown nutritional role **(Figure 35.2B).** Abnormal growth of the plant in this solution is evidence that the missing element is essential. If the plant grows normally, the missing element may not be essential; however, only further experimentation can confirm this hypothesis.

In a typical, modern hydroponic apparatus, the nutrient solution is refreshed regularly, and air is bubbled into it to supply oxygen to the roots. Without sufficient oxygen for respiration, the plants' roots do not absorb nutrients efficiently. (The same effect occurs in poorly aerated soil.) Variations of this technique are used on a commercial scale to grow some vegetables, such as lettuce and tomatoes.

ESSENTIAL MACRONUTRIENTS AND MICRONUTRIENTS Hydroponics research has revealed that plants generally require 17 essential elements **(Table 35.1).** By definition, an **essential element** is necessary for normal growth and reproduction, cannot be functionally replaced by a different element, and has one or more roles in plant metabolism. With enough sunlight and the 17 essential elements, plants can synthesize all the compounds they need.

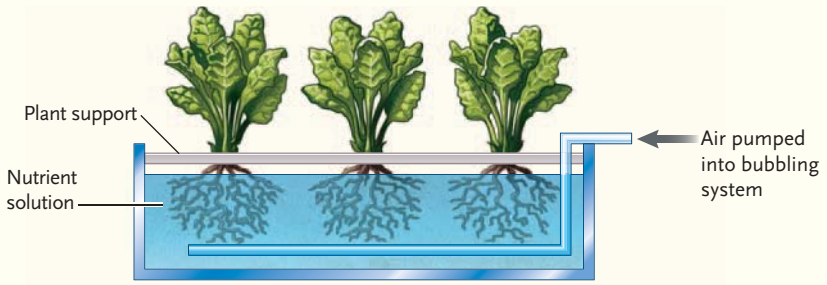

FIGURE 35.2 **Research Method**

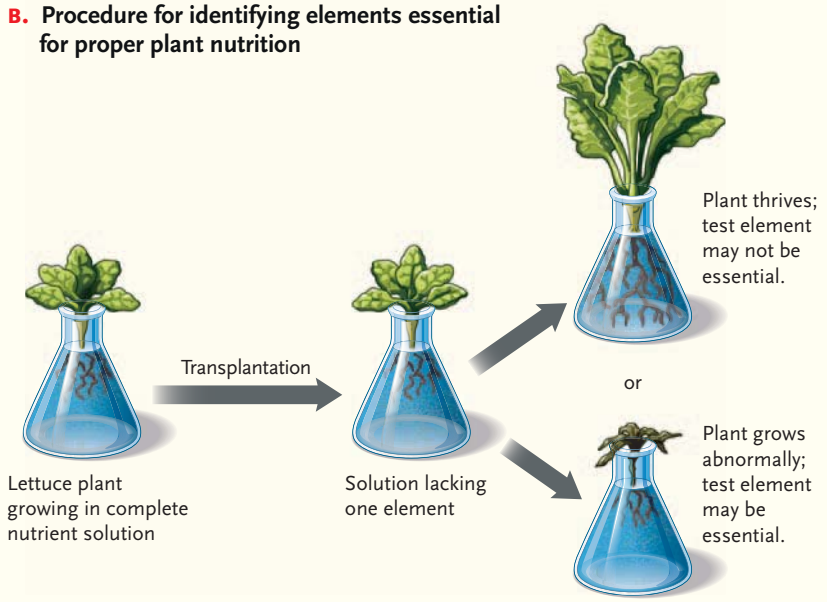
Hydroponic Culture



Purpose: In studies of plant nutritional requirements, using hydroponic culture allows a researcher to manipulate and precisely define the types and amounts of specific nutrients that are available to test plants.

Protocol: In a typical hydroponic apparatus, many plants are grown in a single solution containing pure water and a defined mix of mineral nutrients. The solution is replaced or refreshed as needed and is aerated with a bubbling system.

A. Basic components of a hydroponic apparatus

B. Procedure for identifying elements essential for proper plant nutrition

A "complete" solution contains all the known and suspected essential plant nutrients. An "incomplete" solution contains all but one of the same nutrients, in the same amounts. For experiments, researchers first grow plants in a complete solution, then transplant some of the plants to an incomplete solution.

Interpreting the Results: Normal growth of test plants suggests that the missing nutrient is not essential, whereas abnormal growth is evidence that the missing nutrient may be essential.

© Cengage Learning 2014

Nine of the essential elements are **macronutrients,** meaning that plants incorporate relatively large amounts of them into their tissues. Three of these elements—carbon, hydrogen, and oxygen—account for about 96% of a plant's dry mass. Together, these three elements are the key components of lipids and of carbohydrates such as cellulose; with the addition of nitrogen, they form the basic building blocks of proteins and nucleic acids. Plants also use phosphorus in constructing nucleic acids, ATP, and phospholipids, and they use potassium for functions ranging from enzyme activation to mechanisms that control the opening and closing of stomata. Rounding out the list of macronutrients are calcium, sulfur, and magnesium. All macronutrients except carbon, hydrogen, and oxygen are classified as minerals, which chemists usually define as elements or compounds formed by geological processes and that have a crystalline structure. Minerals are available to plants through the soil as ions dissolved in water, and most minerals that serve as nutrients in plants are derived from the weathering of rocks and inorganic particles in the Earth's crust.

The other elements essential to plants are also minerals, and are classed as **micronutrients** because plants require them only in trace amounts. Nevertheless, they are just as vital as macronutrients to a plant's health and survival. For example, 5 metric tons of potatoes contain roughly the amount of copper in a single copper-plated penny—yet without it, potato plants are sickly and do not produce normal tubers.

Chlorine, generally present in soil in its anionic form Cl^- (chloride), was identified as a micronutrient nearly a century after Sachs's experiments. Chloride functions in some reactions of photosynthesis and (along with K^+) in the opening and closing of stomata, among other roles. The researchers who discovered its importance in plant nutrition performed hydroponic culture experiments in a California laboratory near the Pacific Ocean, where the air, like coastal air everywhere, contains sodium chloride. The investigators found that their test plants could obtain tiny but sufficient quantities of chloride from the air, as well as from sweat (which also contains NaCl) on the researchers' own hands. Great care had to be taken to exclude chlorine from the test plants' growing environment to prove that it was essential.

In some cases, plant seeds contain enough of certain trace minerals to sustain the adult plant. For example, nickel (Ni^{2+}) is a component of urease, the enzyme required to hydrolyze urea. Urea is a toxic by-product of the breakdown of nitrogenous compounds, and it will kill cells if it accumulates. In the late 1980s, investigators found that barley seeds contain enough nickel to sustain

TABLE 35.1 Essential Plant Nutrients and Their Functions

Element	Commonly Absorbed Forms	Some Known Functions	Some Deficiency Symptoms
Macronutrients			
Carbon*	CO_2	Raw materials for photosynthesis	Rarely deficient
Hydrogen*	H_2O		No symptoms; available from water
Oxygen*	O_2, H_2O, CO_2		No symptoms; available from water and CO_2
Nitrogen	NO_3^-, NH_4^+	Component of proteins, nucleic acids, coenzymes, chlorophylls	Stunted growth; light-green newer leaves; older leaves yellow and die (chlorosis)
Phosphorus	$H_2PO_4^-$, HPO_4^{2-}	Component of nucleic acids, phospholipids, ATP, several coenzymes	Purplish veins; stunted growth; fewer seeds, fruits
Potassium	K^+	Activation of enzymes; key role in maintaining water-solute balance and so influences osmosis	Reduced growth; curled, mottled, or spotted older leaves; burned leaf edges; weakened plant
Calcium	Ca^{2+}	Roles in formation and maintenance of cell walls and in membrane permeability; enzyme cofactor	Leaves deformed; terminal buds die; poor root growth
Sulfur	SO_4^{2-}	Component of most proteins, coenzyme A	Light-green or yellowed leaves; reduced growth
Magnesium	Mg^{2+}	Component of chlorophyll; activation of enzymes	Chlorosis; drooping leaves
Micronutrients			
Chlorine	Cl^-	Role in root and shoot growth, and in photosynthesis	Wilting; chlorosis; some leaves die (deficiency not seen in nature)
Iron	Fe^{2+}, Fe^{3+}	Roles in chlorophyll synthesis, electron transport; component of cytochrome	Chlorosis; yellow and green striping in grasses
Boron	H_3BO_3	Roles in germination, flowering, fruiting, cell division, nitrogen metabolism	Terminal buds, lateral branches die; leaves thicken, curl, and become brittle
Manganese	Mn^{2+}	Role in chlorophyll synthesis; coenzyme action	Dark veins, but leaves whiten and fall off
Zinc	Zn^{2+}	Role in formation of auxin, chloroplasts, and starch; enzyme component	Chlorosis; mottled or bronzed leaves; abnormal roots
Copper	Cu^+, Cu^{2+}	Component of several enzymes	Chlorosis; dead spots in leaves; stunted growth
Molybdenum	MoO_4^{2-}	Component of enzyme used in nitrogen metabolism	Pale green, rolled or cupped leaves
Nickel	Ni^{2+}	Component of enzyme required to break down urea generated during nitrogen metabolism	Dead spots on leaf tips (deficiency not seen in nature)

*Carbon, hydrogen, and oxygen are the nonmineral plant nutrients. All others are minerals.

© Cengage Learning 2014

two complete generations of barley plants. Plants grown in the absence of nickel did not begin to show signs of nickel deficiency until the third generation.

Besides the 17 essential elements, some species of plants may require additional micronutrients. Experiments suggest that many, perhaps most, plants adapted to hot, dry conditions require sodium; many plants that photosynthesize by the C_4 pathway (see Section 9.4) appear to be in this group. A few plant species require selenium, which is also an essential micronutrient for animals. Horsetails *(Equisetum)* require silicon, and some grasses (such as wheat) may also need it. Scientists continue to discover additional micronutrients for specific plant groups.

Both micronutrients and macronutrients play vital roles in plant metabolism. Many function as cofactors or coenzymes in protein synthesis, starch synthesis, photosynthesis, and aerobic respiration. As you read in Section 34.1, some also have a role in creating solute concentration gradients across plasma membranes, which are responsible for the osmotic movement of water.

Nutrient Deficiencies Cause Abnormalities in Plant Structure and Function

Plants differ in the quantity of each nutrient they require—the amount of an essential element that is adequate for one plant species may be insufficient for another. Lettuce and other leafy plants require more nitrogen and magnesium than do other plant types, for example, and alfalfa requires significantly more potassium than do lawn grasses. An adequate amount of an essential element for one plant may even be harmful to another. For example, the amount of boron required for normal growth of sugar beets is toxic for soybeans. For these reasons, the nutrient content of soils is an important factor in determining which plants will grow well in a given location.

Plants that are deficient in one or more of the essential elements develop characteristic symptoms (Table 35.1 lists some observable symptoms of nutrient deficiencies). The symptoms give some indication of the metabolic roles the missing elements play. Deficiency symptoms typically include stunted growth, abnormal leaf color, dead spots on leaves, or abnormally formed stems **(Figure 35.3).** For instance, iron is a component of the cytochromes on which the cellular electron transfer system depends, and it plays a role in reactions that synthesize chlorophyll. Iron deficiency causes **chlorosis,** a yellowing of plant tissues that results from a lack of chlorophyll (see Figure 35.3B). Because ionic iron (Fe^{3+}) is relatively insoluble in water, gardeners often fertilize plants with a soluble iron compound called chelated iron to stave off or cure chlorosis. Similarly, because magnesium is a necessary component of chlorophyll, a plant deficient in this element has fewer chloroplasts than normal in its leaves and other photosynthetic parts. It appears paler green than normal, and its growth is stunted because of reduced photosynthesis (see Figure 35.3C).

Plants that lack adequate nitrogen may also become chlorotic (see Figure 35.3D), with older leaves yellowing first because the nitrogen is preferentially shunted to younger, actively growing plant parts. This adaptation is not surprising, given nitrogen's central role in the synthesis of amino acids, chlorophylls, and other compounds vital to plant metabolism. With some other mineral deficiencies, young leaves are the first to show symptoms. These kinds of observations underscore the point that plants use different nutrients in specific, often metabolically complex ways.

Soils are more likely to be deficient in nitrogen, phosphorus, potassium, or some other essential mineral than to contain too much, and farmers and gardeners typically add nutrients to suit the types of plants they wish to cultivate. They may observe the deficiency symptoms of plants grown in their locale or have

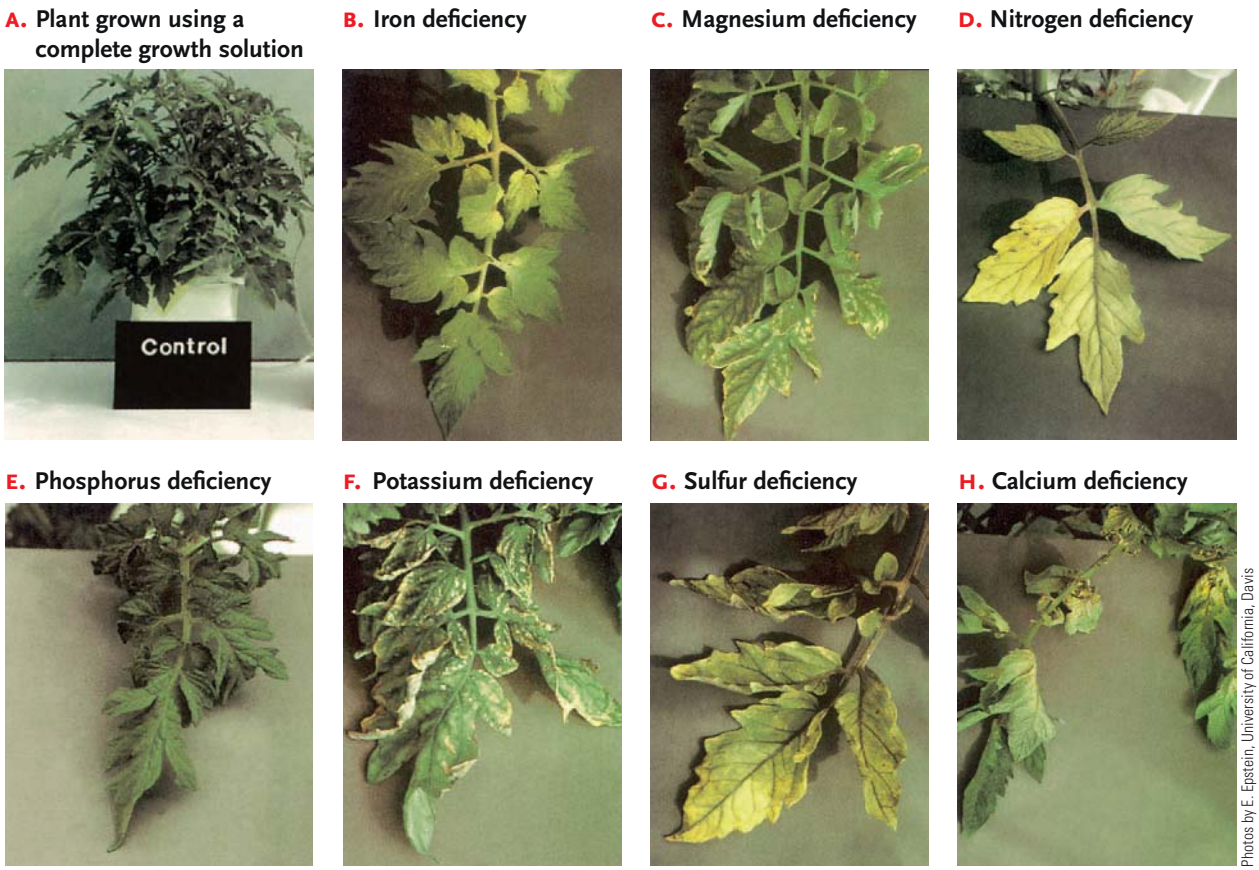

FIGURE 35.3 **Leaves and stems of tomato plants showing visual symptoms of seven different mineral deficiencies.** The plants were grown in the laboratory, where the experimenter could control which nutrients were available.

soil tested in a laboratory, then choose a fertilizer with the appropriate balance of nutrients to compensate for the deficiencies. Packages of commercial fertilizers use a numerical shorthand (for example, 15-30-15) to indicate the percentages of nitrogen, phosphorus, and potassium they contain.

STUDY BREAK 35.1

1. What are the two main categories of the essential elements plants need? Give several examples of each.
2. Do all plants require the same basic nutrients in the same amounts? Explain.

THINK OUTSIDE THE BOOK

Symptoms of a plant nutrient deficiency rarely if ever show up in wild plants. Instead they generally are limited to species cultivated as food crops or common house and garden plants. On your own or with fellow students, develop a hypothesis to explain why this difference exists and describe an experiment that would test your hypothesis.

35.2 Soil

Soil anchors plant roots and is the main source of the inorganic nutrients plants require. It also is the source of water for most plants, and of oxygen for respiration in root cells. The physical texture of soil is a factor in whether root systems have access to sufficient water and dissolved oxygen. Together, physical and chemical properties of soils have a major impact on the ability of plants to grow, survive, and reproduce in particular habitats.

The Components of a Soil and the Size of the Particles Determine Its Properties

Soil is a complex mix of mineral particles, chemical compounds, ions, decomposing organic matter, air, water, and assorted living organisms. Most soils develop from the physical or chemical weathering of rock (which also liberates mineral ions). The different kinds of soil particles range in size from sand (2.0–0.02 mm) to silt (0.02–0.002 mm) and clay (diameter less than 0.002 mm). These mineral particles usually are mixed with various organic components, including **humus**—decomposing parts of plants and animals, animal droppings, and other organic matter. Dry humus has a loose, crumbly texture. It can absorb a great deal of water and thus contributes to the capacity of soil to hold water. Organic molecules in humus are reservoirs of nutrients, including nitrogen, phosphorus, and sulfur, that are vital to living plants.

The relative proportions of the different sizes of mineral particles give soil its basic texture—gritty if the soil is largely sand, smooth if silt predominates, and dense and heavy if clay is the major component. A soil's texture in turn helps determine the number and volume of pores—air spaces—that it contains. The relative amounts of sand, silt, and clay determine whether a soil is sticky when wet, with few air spaces (mostly clay), or dries quickly and may wash or blow away (mostly sand). Clay soils are more than 30% clay, whereas sandy soils contain less than 20% clay or silt.

The piles of bagged humus for sale at garden centers each spring reflect the fact that the amount of humus in a soil also affects plant growth. Its plentiful organic material feeds decomposers whose metabolic activities in turn release minerals that plant roots can take up, but that is not its only value in soil. Humus helps retain soil water and, with its loose texture, helps aerate soil as well. Well-aerated soils containing roughly equal proportions of humus, sand, silt, and clay are **loams,** and they are the soils in which most plants do best.

In Turn, Plants and Other Organisms Influence Soil Features

A square meter of fertile soil contains trillions of bacteria, hundreds of millions of fungi, and several million nematodes, plus an array of other worms and insects. It also contains dead plant roots, leaves, and other parts. Bacteria and fungi decompose this and other organic matter on and in the soil and burrowing creatures such as earthworms aerate the soil. On the other hand, the roots and other tissues of plants may play a key role in shaping the characteristics and composition of soil, including the abundance of soil-dwelling organisms.

Experiments document these soil-shaping activities. For example, Edward Ayres and his colleagues at Colorado State University's Natural Resource Ecology Laboratory studied soil properties in Colorado's San Juan Mountains, where stands of trembling aspen *(Populus tremuloides),* lodgepole pine *(Pinus contorta),* or Engelmann spruce *(Picea engelmannii)* live in close proximity. *P. tremuloides* trees have a more open growth form than pines and spruce trees do, all their leaves drop each year in autumn, and previous research had shown that *P. tremuloides* leaf litter has about twice the nitrogen content of the other two species. With these facts in mind, the Ayres team hypothesized that in their four study areas, such species-specific characteristics would influence the physical, chemical, and biological properties of the soil. The data they gathered supported parts of their hypothesis and also raised questions. For example, they found that in all study areas, the soil in which the aspens grew was significantly warmer—a difference that the team attributed to increased sunlight reaching the ground through the relatively open aspen canopies. The soil littered with aspen leaves also contained more nitrate—a form of nitrogen that plant roots can readily take up—than the nearby soil where the lignin-rich needlelike leaves of pines and spruces accumulated. The study was not designed to attempt a comprehensive analysis of the diversity of the soil's bacterial, fungal, and microscopic animal communities, but the researchers did document markedly different arrays of soil-dwelling organisms associated with the aspens, pines, and spruces in each study area. Clearly, we have a

lot more to learn about the intricate interactions between plants, soils, and communities of soil organisms.

As soils develop naturally, they tend to take on a characteristic vertical profile, with a series of layers or **horizons (Figure 35.4).** Each horizon has a distinct texture and composition that varies with soil type. The top layer of surface litter—organic matter like twigs and leaves, animal dung, and fungi—is accordingly called the *O horizon.* **Topsoil,** the most fertile layer, occurs just below and forms the *A horizon.* This fairly loose layer may be less than a centimeter deep on steep slopes to more than a meter deep in grasslands. It consists of humus mixed with mineral particles and is where the roots of most herbaceous plants are located. Below the topsoil is the **subsoil** or *B horizon,* a layer of larger soil particles containing relatively little organic matter. Mineral ions, including those that serve as nutrients in plants, tend to accumulate in the B horizon, and mature tree roots generally extend down into this layer. Under it is the *C horizon,* a layer of mineral particles and rock fragments that extends down to bedrock.

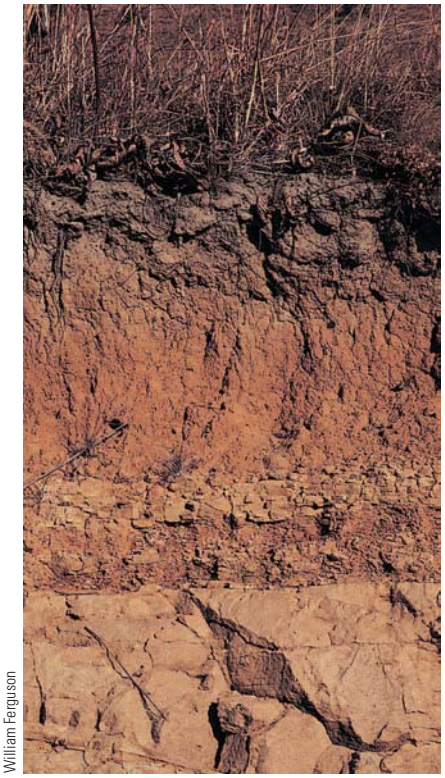

FIGURE 35.4 **Soil horizons in a grassland.**

Regions where the topsoil is naturally deep and rich in humus are ideal for agriculture. Prime examples are the vast former grasslands of the North American Midwest and Ukraine now converted to fields of corn, wheat, soybeans, and other crops. Modern cultivation practices that sharply reduce erosion have helped maintain this soil resource. In arid regions, chronic, sparse rainfall generally correlates with low natural soil humus, and agriculture is only possible with intensive irrigation and soil management. Nor can agriculture flourish for long on land cleared of a tropical rainforest, because of the soil leaching and lack of nutrients described in the chapter introduction.

The Characteristics of Soil Affect Root–Soil Interactions

Roots are superbly adapted to penetrate soil and extract needed nutrients from it, but they also are quite sensitive to variations in the properties of soil. In the following section, we consider some adaptations plants have evolved in many otherwise inhospitable soil environments. First, however, we consider the general ways in which soil composition influences the ability of plant roots to obtain water and minerals.

WATER AVAILABILITY As water flows into and through soil, gravity pulls much of the water down through the spaces between soil particles into deeper soil layers. This available water is part of the **soil solution (Figure 35.5),** a combination of water and dissolved substances that coats soil particles and partially fills pore spaces. The solution develops through ionic interactions between water molecules and soil particles. Clay particles and the organic components in soil (especially proteins) often bear negatively charged ions on their surfaces. The negative charges attract the polar water molecules, which form hydrogen bonds with the soil particles (see Section 2.4).

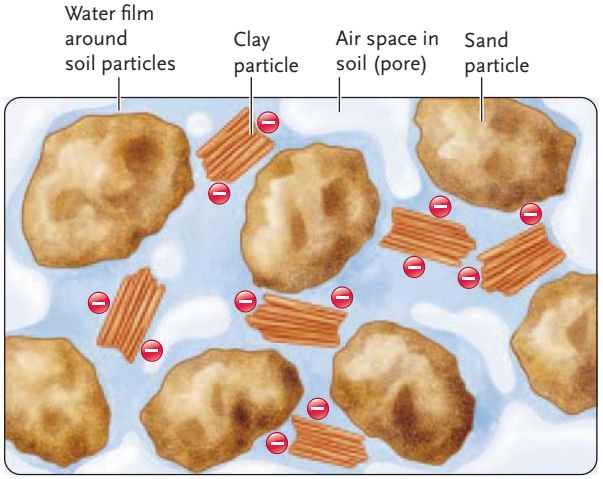

FIGURE 35.5 **Location of the soil solution.** Negatively charged ions on the surfaces of soil particles attract water molecules, which coat the particles and fill spaces between them (blue). Hydrogen bonds between water and soil components counteract the pull of gravity and help hold some water in the soil spaces.

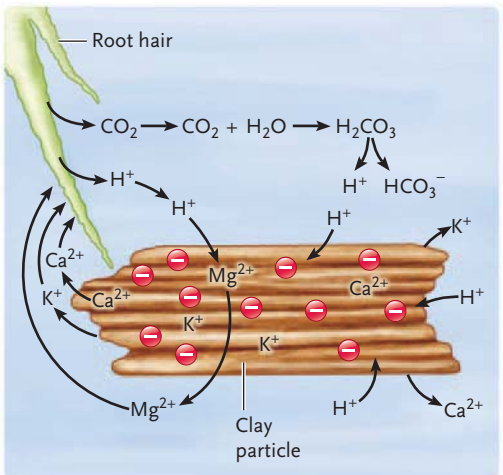
Unless a soil is irrigated, the amount of water in the soil solution depends largely on the amount and pattern of precipitation (rain or snow) in a region. How much of this water is actually available to plants depends on the soil's composition—the size of the air spaces in which water can accumulate and the proportions of water-attracting particles of clay and organic matter. By volume, soil is about one-half solid particles and one-half air space.

The type and size of the particles in a given soil has a major effect on how well plants will grow there. Sand particles are small and sandy soil has relatively large air spaces, so water drains rapidly below the top two soil horizons, where most plant roots are located. Soils rich in clay or humus often hold quite a bit of water, but in the case of clay, ample water is not necessarily an advantage for plants. Whereas a humus-rich soil contains lots of air spaces, the closely layered particles in clay allow few air spaces—and what spaces there are tend to hold tightly the water that enters them. The lack of air spaces in clay soils also severely limits supplies of oxygen available to roots for cellular respiration, and the plant's metabolic activity suffers. Thus, few plants can flourish in clay soils, even when water content is high. (Overwatered houseplants die because their roots are similarly "smothered" by water.) Plants do not fare much better in drier clay-rich soils, because roots cannot extract the existing water and cannot easily penetrate the densely packed clay. These characteristics explain why good agricultural soils tend to be sandy or silty loams, which contain a mix of humus and coarse and fine particles.

As you learned in Chapter 33, root hairs are specialized extensions of root epidermal cells; they directly contact the soil solution and allow roots to absorb water (and dissolved ions). And as you saw in Section 34.2, differences in water potential govern the osmotic movement of water into plant roots. The soil solution usually contains fewer dissolved solutes than does the water in the cells of plant roots. Accordingly, water tends to move from wet soil, where water potential is higher, into roots, where the water potential is lower. The water potential in clay soils is significantly lower than in other soil types, even when clay is relatively wet. As roots extract water from clay soil, the water potential may fall below that in a plant's roots, making it impossible for water to diffuse into the roots. Water still continues to evaporate from leaves and to be used in photosynthesis, however, so the plant eventually wilts. Plants that survive in deserts or in salty soils have adaptations that permit their roots to absorb water even when osmotic conditions in soil do not favor water movement into the plant.

MINERAL AVAILABILITY Some mineral nutrients enter plant roots as cations (positively charged ions) and some as anions (negatively charged ions). Although both cations and anions may be present in soil solutions, they are not equally available to plants.



Cations such as magnesium (Mg^{2+}), calcium (Ca^{2+}), and potassium (K^+) cannot easily enter roots because they are attracted by the net negative charges on the surfaces of soil particles. To varying degrees, they become reversibly bound to negative ions on the surfaces. Attraction in this form is called *adsorption*. Roots do acquire cations, however, through **cation exchange.** In this mechanism one cation, usually H^+, replaces a soil cation **(Figure 35.6A, B).** The protons (H^+) come from two main sources. Respiring root cells release carbon dioxide, which dissolves in the soil solution, yielding carbonic acid (H_2CO_3). Subsequent reactions ionize H_2CO_3 to produce bicarbonate (HCO_3^-) and H^+. Reactions involving organic acids inside roots also produce H^+, which is excreted. As H^+ enters the soil solution, it displaces adsorbed mineral cations attached to clay and humus, freeing them to move into roots. Other types of cations may also participate in this type of exchange, as shown in Figure 35.6.

By contrast, anions in the soil solution, such as nitrate (NO_3^-), sulfate (SO_4^{2-}), and phosphate (PO_4^{3-}), are only weakly bound to soil particles, and so they generally move fairly freely into root hairs. However, because they are so weakly bound compared with cations, anions are more subject to loss from soil by leaching.

FIGURE 35.6 Cation exchange on the surface of a clay particle (A). When cations come into contact with the negatively charged surface of the particle, they become adsorbed. As one type of cation, such as H^+, becomes adsorbed, other ions are liberated and can be taken up by plant roots. A farmer in rural Thailand sprinkling gypsum on a plowed field **(B)**. Gypsum, a complex compound of calcium, sulfur, and other elements, may alter the chemical characteristics of soil in various ways, including increasing the availability to plant roots of calcium and sulfur, reducing acidity, and counteracting excess sodium.

Plants Poised for Environmental Cleanup

Scientists have long been seeking efficient modes of *phytoremediation,* the use of plants to remove pollutants from the environment. One target is the highly toxic compound methylmercury (MeHg), which is present in coastal soils and wetlands contaminated by industrial wastes containing an ionic form of the element mercury called Hg(II). Bacteria in contaminated sediments metabolize Hg(II) and generate MeHg as a metabolic by-product. Once MeHg forms, it enters the food web and eventually becomes concentrated in tissues of fishes and other animals. In humans, MeHg can lead to degeneration of the nervous system. It causes most cases of mercury poisoning from consuming contaminated fish.

In the 1990s a team of scientists including Scott Bizily and Richard Meagher at the University of Georgia decided to try to create genetically modified plants capable of detoxifying mercury-contaminated soil and wetlands. It was already known that bacteria in contaminated sediments possess two genes, *merA* and *merB,* which encode enzymes that convert MeHg into elemental mercury (Hg)—a relatively inert, much less dangerous substance. Clones of both these bacterial mercury-resistance genes were available. After modifying the cloned genes so that plants could express them, the team used a vector (the bacterium *Rhizobium radiobacter*) to introduce each gene into several different sets of *Arabidopsis thaliana* plants (thale cress). They obtained three groups of transgenic plants: some that were *merA* only, some that were *merB* only, and some that were *merA* and *merB.* Seeds from each group were grown (along with wild-type controls) in five different growth media—one containing no mercury and the other four containing increasing concentrations of methylmercury. Wild-type and *merA* seeds germinated and grew only in the mercury-free growth medium. The *merB* seedlings fared somewhat better: they germinated and grew briefly even at the highest concentrations of MeHg, but then died. By contrast, seeds with the *merA/merB* genotype germinated at high MeHg concentrations, producing seedlings that grew into robust plants **(Figure).** In later tests *merA/merB* plants were grown in chambers in which the chemical composition of the air was monitored. This study revealed that the doubly transgenic plants also were transpiring large amounts of Hg. These findings implied that *A. thaliana* plants having both *merA* and *merB* genes were able to take up the toxic methylmercury and convert it to a harmless form. Meagher and his colleagues now are experimenting with ways of increasing the efficiency of phytoremediating enzymes when plant cells express *merA* and *merB.* They also are studying the mechanisms by which ionic mercury taken up by roots may be transported via the xylem to leaves and other shoot parts. The goal is to engineer plants that accumulate large quantities of mercury in aboveground tissues that can be harvested, leaving the living plant to continue its "work" of detoxifying a contaminated landscape.

The pH of soil affects the availability of some mineral ions. Soil pH is a function of the balance between cation exchange and other processes that raise or lower the concentration of H^+ in soil. As noted earlier, in areas that receive heavy rainfall, soils tend to become acidic (that is, they have a pH of less than 7). This acidification occurs in part because moisture promotes the rapid decay of organic material in humus; as the material decomposes, it releases its organic acids. Acid precipitation, which results from the release of sulfur and nitrogen oxides into the air (in large measure from the burning of fossil fuels and industrial emissions), also contributes to soil acidification. By contrast, the soil in arid regions, where precipitation is low, often is alkaline (the pH is greater than 7).

Although most plants are not directly sensitive to soil pH, chemical reactions in very acid (pH <5.5) or very alkaline (pH >9.5) soils can have a major impact on whether plant roots take up various mineral cations. For example, experiments have showed that in the presence of OH^- in alkaline soil, calcium and phosphate ions react to form insoluble calcium phosphates. The phosphate captured in these compounds is as unavailable to roots as if it were completely absent from the soil.

For a soil to sustain plant life over long periods, the mineral ions that plants take up must be replenished naturally or artificially (see Figure 35.6B). Over the long run, some mineral nutrients enter the soil from the ongoing weathering of rocks and smaller bits of minerals. In the shorter run, minerals, carbon, and some other nutrients are returned to the soil by the decomposition of organisms and their parts or wastes. Airborne compounds, such as sulfur in volcanic and industrial emissions, may enter soil when they dissolve in rain and fall to earth. Minerals, including compounds of nitrogen and phosphorus, may also enter soil in fertilizers.

Although the use of commercial fertilizers maintains high crop yields, agricultural chemicals do not add humus to the soil. Their use can also cause serious pollution problems, as when nitrogen-rich runoff from agricultural fields promotes the serious overgrowth of algae in lakes and bays. In many parts of the world, industrial pollutants such as cadmium, lead, and mercury are increasingly serious soil contaminants. The use of plants to remove such materials from soil, called *phytoremediation,* is the topic of this chapter's *Focus on Applied Research.*

STUDY BREAK 35.2

1. Why is humus an important component of fertile soil?
2. How does the composition of a soil affect a plant's ability to take up water?
3. What factors affect a plant's ability to absorb minerals from the soil?

35.3 Root Adaptations for Obtaining and Absorbing Nutrients

Soil managed for agriculture can be plowed, precisely irrigated, and chemically adjusted to provide air, water, and nutrients in optimal quantities for a particular crop. By contrast, in natural habitats, wide variations in soil minerals, humus, pH, the presence of other organisms, and other factors influence the availability of essential elements. Although adequate carbon, hydrogen, and oxygen are typically available from the air and soil water, other essential elements that must be obtained from soil may not be as abundant. In particular, nitrogen, phosphorus, and potassium are often relatively scarce. The evolutionary solutions to these challenges include an array of adaptations in the structure and functioning of plant roots.

Root Systems Allow Plants to Locate and Absorb Essential Nutrients

Immobile organisms such as plants must locate nutrients in their immediate environment, and for plants the adaptive solution to this problem is an extensive root system. Roots make up 20% to 50% of the dry weight of many plants, and even more in species growing where water or nutrients are especially scarce, such as arctic tundra. As long as a plant lives, its root system continues to grow, branching out through the surrounding soil. Roots do not necessarily grow *deeper* as a root system branches out, however. In arid regions, a shallow-but-broad root system may be better positioned to take up water from occasional rains that may never penetrate below the first few inches of soil.

You may recall from Section 34.2 that roots take up ions in the regions just behind the root tips, where root hairs are present. These diminutive absorptive structures, shown in Figure 33.9C, are a major adaptation for the uptake of mineral ions and water. Over successive growing seasons, long-lived plants such as trees can develop millions, even billions, of root tips, each one a potential absorption site. In a plant such as a mature red oak *(Quercus rubra),* which has a vast root system, the total number of root hairs is astronomical. Even in young plants, root hairs greatly increase the root surface area available for absorbing water and ions. Recently a team led by Chinese researcher Keke Yi uncovered a genetic "master switch" that regulates the growth of root hairs. Experiments with *Arabidopsis thaliana* plants revealed that the activity of a transcription factor called RSL4 (for root-hair defective 6-like 4) activates downstream genes that promote the growth of long root hairs, while the absence of RSL4 stunts root hair growth. Apparently, expression of the *rsl4* gene is modulated by external cues, including soil phosphate levels and signals from the plant hormone auxin you will read more about in Chapter 37.

Chapter 34 also mentioned another plant adaptation for gaining access to mineral ions—ion-specific transport proteins in plant cell membranes by which the cells selectively absorb ions from soil. For example, from studies of plants such as *Arabidopsis thaliana,* a weed that has become a key model organism for plant research, we know that transport channels for potassium ions (K^+) are embedded in the cell membranes of root cortical cells. Such ion transporters absorb more or less of a particular ion depending on chemical conditions in the surrounding soil.

The Discovery That Roots Also Secrete Substances into Soil Expands Our Understanding of Plant Adaptations for Obtaining Nutrients

In addition to acquiring substances from the surrounding soil, roots of various plant species also release into soil a long list of organic compounds, including carbohydrates, amino acids, various organic and fatty acids, as well as enzymes and other proteins. Today experiments are revealing the details of how such "root exudates" may improve a plant's access to particular nutrients. For example, a study headed by Corey D. Broeckling of Colorado State University showed that the roots of *A. thaliana* and *Medicago trunculata* (a legume commonly called barrel medic) secrete organic compounds that help determine which species of soil fungi can thrive near the roots. As you will read shortly, such fungi are partners in symbiotic relationships that help nourish many plant species. Similarly, Eric Paterson and his coworkers at the University of Aberdeen in Scotland found that roots of barley plants *(Hordeum vulgare)* exposed to above-normal nitrogen increased their release of organic substances that promote the growth of soil organisms that convert nitrogen into a chemical form plant roots can absorb. Other compounds released by roots enhance the uptake of phosphate.

Nutrients Move into and through the Plant Body by Several Routes

Plants obtain carbon, hydrogen, and oxygen from the air, but most mineral ions enter plant roots passively along with the water in which they are dissolved. Some enter root cells immediately. Others travel in solution *between* cells—in the apoplast—until they meet the endodermis sheathing the root's stele (see Figure 34.6). At the endodermis, the ions are actively transported into the endodermal cells and then into the xylem for transport throughout the plant. Inside cells, most mineral ions

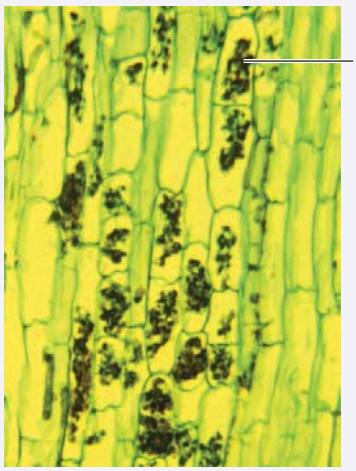
Getting to the Roots of Plant Nutrition



One way that mycorrhizal fungi benefit their host plants is by increasing the amount of phosphate plants take up from the soil.

Research Question

At the molecular level, how do the fungi accomplish this beneficial process?

Experiments

Maria J. Harrison and Marianne L. van Buuren at the Samuel Roberts Noble Foundation in Ardmore, Oklahoma, were able to identify a gene in one of these fungi that encodes a phosphate transport protein.

Science VU/R. Hussey/Visuals Unlimited

FIGURE **Photomicrograph of *Glomus versiforme* hyphae penetrating a leek root.**

Starting with a cDNA library prepared from a plant that had been colonized by the mycorrhizal fungus *Glomus versiforme* **(Figure),** Harrison and van Buuren probed the plant-derived cDNA with a gene that encodes a phosphate transporter in yeast. They hoped to determine whether any cDNA sequences were similar to the yeast gene. (As Section 18.1 describes, a cDNA library is a cloned collection of DNA sequences derived from mRNAs, so it represents sequences that encode proteins.) The transport protein encoded by the yeast gene is embedded in the plasma membrane, where it moves phosphate ions into yeast cells by active transport.

When mixed with the plant-derived cDNA sequences, the probe did indeed pair with one of the cDNA sequences. Subsequent sequencing of the segment revealed that the cDNA coded for a protein with a structure typical of many eukaryotic and prokaryotic membrane transport proteins.

To eliminate the possibility that the probe was identifying a plant cDNA in the library rather than one from the mycorrhizal fungus, the investigators next used the identified cDNA to probe a preparation containing all the DNA of a plant that had not been colonized by *Glomus.* No pairing occurred with any of the plant DNA fragments, confirming that the cDNA represented a gene from the fungus. Additional experiments supported this finding.

Harrison and van Buuren carried their investigation further to see whether the fungal gene actually encoded a phosphate transport protein. For this set of experiments, the investigators used a yeast mutant with a nonfunctional phosphate transporter. Because these mutant yeast cells can't readily take in phosphate, they grow very slowly, even in a phosphate-rich culture medium.

The researchers added the *Glomus* gene to the mutants under conditions that increased the likelihood yeast cells would take up and incorporate the DNA. The yeast cells then began to grow normally, indicating that they could now synthesize a functional phosphate transporter. When radioactive phosphate ions were added to the culture, the cells rapidly became labeled, confirming that they were taking up phosphate ions at a much greater rate than untreated mutants.

Conclusion

This study was the first to reveal the molecular basis of phosphate transport by the mycorrhizal fungi. More recent work with potato plants *(Solanum tuberosum)* has identified a gene encoding a phosphate transporter protein that is expressed in parts of potato roots where mycorrhizae form.

THINK LIKE A SCIENTIST How might having a greater understanding of phosphate transport by mycorrhizal fungi be useful in agronomy (the scientific management of soil properties and crop production)?

Source: M. J. Harrison and M. L. van Buuren. 1995. A phosphate transporter from the mycorrhizal fungus *Glomus versiforme*. *Nature* 378:626–629.

enter vacuoles or remain in the cytoplasm, where they are immediately available for metabolic reactions.

Some nutrients, such as nitrogen-containing ions, move in phloem from site to site in the plant, as dictated by growth and seasonal needs. In plants that shed their leaves in autumn, before the leaves age and fall significant amounts of nitrogen, phosphorus, potassium, and magnesium move out of them and into twigs and branches. This evolutionary adaptation conserves the nutrients, which will be used in new growth the next season. Likewise, in late summer, mineral ions move to the roots and lower stem tissues of perennial range grasses that typically die back during the winter. These activities are regulated by hormonal signals, which are the topic of Chapter 37.

Given the essential role of roots in a plant's nutritional survival, it is not surprising that research is uncovering an ever-growing list of root adaptations for exploiting and enhancing nutrient resources in soil. We now take a closer look at two of these adaptations—the associations called *mycorrhizae* and interactions with nitrogen-fixing microorganisms.

Mycorrhizae and Nitrogen-Fixing Bacteria: Adaptive Interactions That Increase Plant Access to Scarce Nutrients

The course of plant evolution has resulted in vitally important symbioses that enhance access to nutrients. **Mycorrhizae** are crucial symbiotic associations between a fungus and the roots of a plant (see Section 30.3). They promote the uptake of water and nutritionally vital ions—especially phosphate—in most species of plants. As shown in Figure 30.17, the fungal partner in the as-

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

sociation often grows as a network of hyphal filaments around and beyond the plant's roots. Collectively, the hyphae provide a tremendous surface area for absorbing ions from a large volume of soil. As with plant roots, transport proteins shepherd ions into hyphae. Experiments have verified that hyphal transport proteins are encoded by the DNA of the fungus, not that of the plant (as described in *Insights from the Molecular Revolution*). Some of the plant's sugars and nitrogenous compounds nourish the fungus, and as the root grows, it uses some of the minerals that the fungus has secured. In other types of mycorrhizae, the fungus actually lives inside cells of the root cortex. Orchids, for example, depend on this type of mutualistic association. And, as you will see shortly, some other plants gain access to adequate nitrogen by way of mutually beneficial associations with bacteria.

Plants Depend on Bacteria for an Adequate Supply of Usable Nitrogen

It might seem that plants live surrounded by nitrogen. For example, nitrogen steadily enters the soil in organic compounds released when dead organisms and animal wastes decompose. Dried blood is about 12% nitrogen by weight—although the nitrogen is bound up in complex organic molecules such as amino acids and proteins. Air contains plenty of gaseous nitrogen—this N_2 is almost 80% by volume—but plants cannot extract it because they lack the enzyme necessary to break apart the three covalent bonds in each N_2 molecule ($N{\equiv}N$). Plants can absorb atmospheric nitrogen that reaches the soil in the form of nitrate, NO_3^-, and ammonium ion, NH_4^+, and experiments show that roots of at least some plant species directly take up amino acids. Even so, lack of nitrogen is the single most common limit to plant growth because there usually is not nearly enough nitrogen available in these forms to meet plants' ongoing needs.

Instead, the main natural processes that replenish soil nitrogen and convert it to an absorbable form are carried out by bacteria. These processes, which we'll now consider, are part of the *nitrogen cycle,* the global movement of nitrogen in its various chemical forms from the environment to organisms and back to the environment, which is described in Chapter 54.

PRODUCTION AND ASSIMILATION OF AMMONIUM AND NITRATE The incorporation of atmospheric nitrogen into compounds that plants can take up is called **nitrogen fixation. Figure 35.7** summarizes the basic steps. Metabolic pathways of *nitrogen-fixing bacteria* living in the soil or in mutualistic association with plant roots add hydrogen to atmospheric N_2, producing two molecules of NH_3 (ammonia) and one H_2 for each N_2 molecule. The process requires a substantial input of ATP and is catalyzed by the enzyme nitrogenase. In a final step, H_2O and NH_3 react, forming NH_4^+ (ammonium) and OH^-.

Another bacterial process, called **ammonification,** also produces NH_4^+ when soil bacteria known as *ammonifying bacteria* break down decaying organic matter. In this way, nitrogen already incorporated into plants and other organisms is recycled.

Although plants use NH_4^+ to synthesize organic compounds, most plants absorb nitrogen in the form of nitrate,

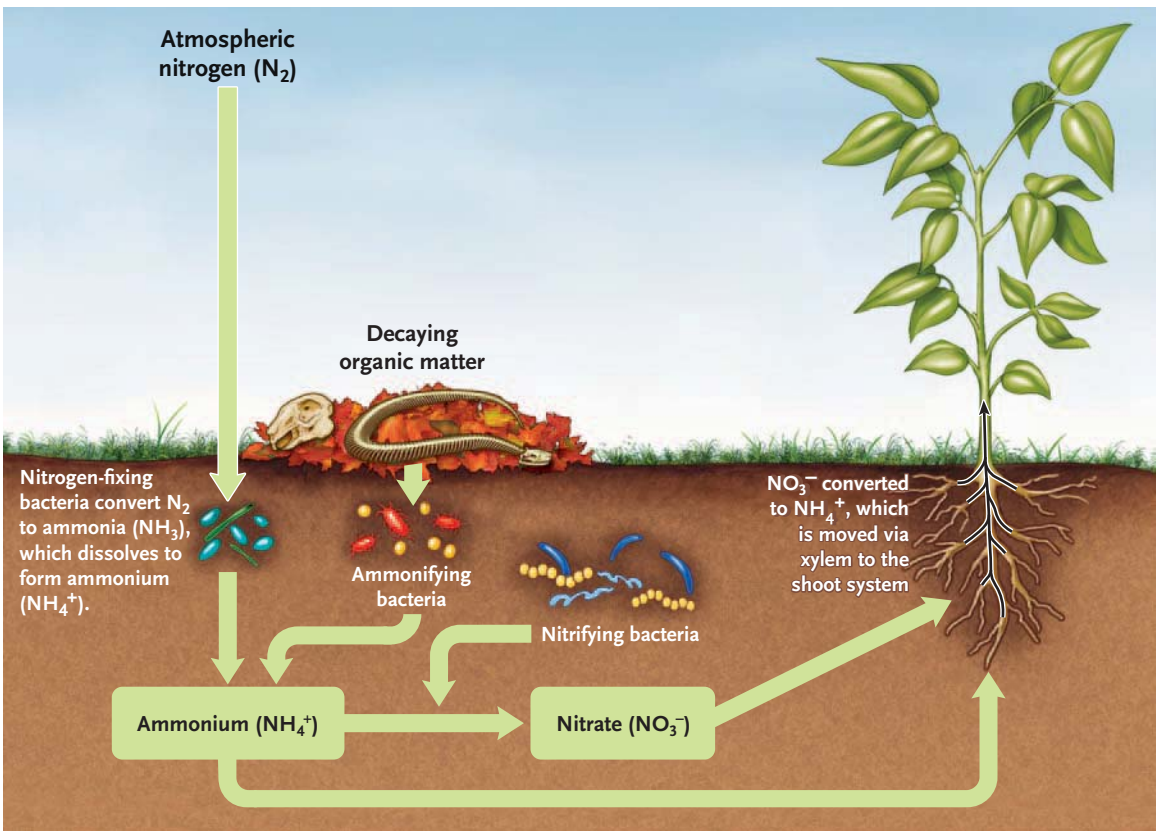


FIGURE 35.7 How plants obtain nitrogen from soil. Many commercial nitrogen fertilizers are in the chemical form of nitrate, which plant roots readily take up, or in the form of ammonium, which nitrifying bacteria convert to nitrate.

FIGURE 35.8 The beneficial effect of root nodules. (A) Root nodules on a soybean plant *(Glycine max)*. **(B)** Soybean plants growing in nitrogen-poor soil. The plants on the right were inoculated with *Rhizobium* cells and developed root nodules. **(C)** False-color transmission electron micrograph showing membrane-bound bacteroids (red) in a root nodule cell. Membranes that enclose the bacteroids appear blue. The large yellow-green structure is the cell's nucleus.

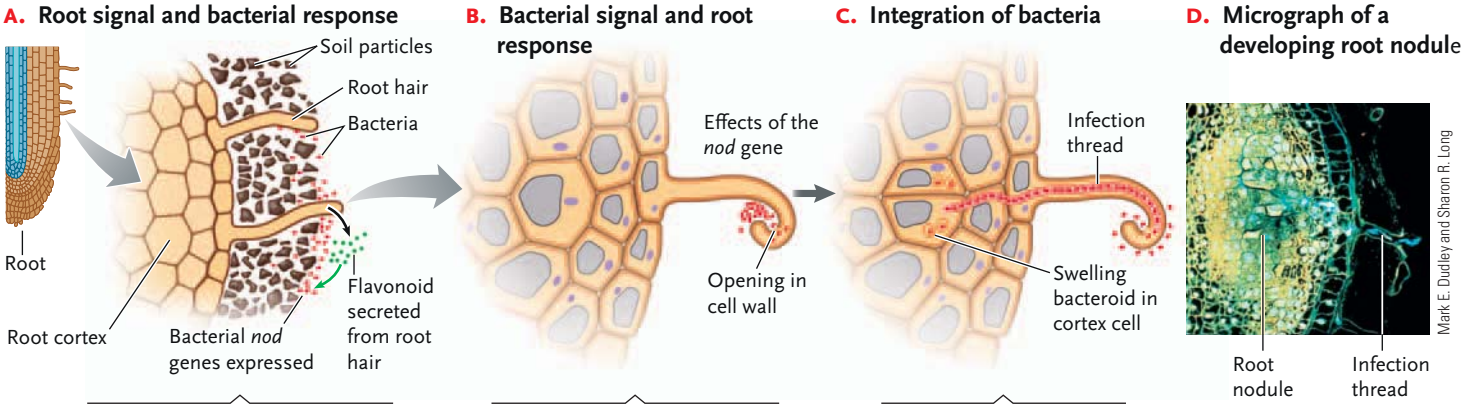
NO_3^-. Nitrate is produced in soil by **nitrification,** in which NH_4^+ is oxidized to NO_3^-. Soils generally teem with *nitrifying bacteria,* which carry out this process. Because of ongoing nitrification, nitrate is far more abundant than ammonium in most soils. Usually, the only soils from which plant roots take up ammonium directly are highly acidic, such as in bogs, where the low pH is toxic to nitrifying bacteria.

NITROGEN ASSIMILATION Once inside root cells, absorbed NO_3^- is converted by a multistep process back to NH_4^+. In this form, nitrogen is rapidly used to synthesize organic molecules, mainly amino acids. These molecules pass into the xylem, which transports them throughout the plant. In some plants, the nitrogen-rich precursors for needed substances travel in xylem to leaves, where different organic molecules are synthesized. Those molecules travel to other plant cells in the phloem.

NITROGEN FIXATION IN PLANT–BACTERIA ASSOCIATIONS Although some nitrogen-fixing bacteria live free in the soil, by far the largest percentage of nitrogen is fixed by species of *Rhizobium* and *Bradyrhizobium,* which form mutualistic associations with the roots of plants in the legume family. The host plant supplies organic molecules that the bacteria use for cellular respiration, and the bacteria supply NH_4^+ that the plant uses to produce proteins and other nitrogenous molecules. In legumes—a large family that includes peas, beans, clover, alfalfa, and alders, among others—the nitrogen-fixing bacteria reside in **root nodules,** localized swellings on roots **(Figure 35.8).** Farmers may exploit root nodules to increase soil nitrogen by rotating crops (for example, planting soybeans and corn in alternating years). When the legume crop is harvested, the root nodules and other tissues remaining in the soil enrich its nitrogen content.

For a plant, an association with nitrogen-fixing bacteria offers the selective advantage of a steady source of absorbable nitrogen. Decades of research have revealed the details of how this remarkable relationship unfolds. Usually, a single species of nitrogen-fixing bacteria colonizes a single legume species, drawn to the plant's roots by chemical attractants—primarily compounds called flavonoids—that the roots secrete. Through a sequence of exchanged molecular signals, bacteria are able to penetrate a root hair and form a colony inside the root cortex.

An association between a soybean plant *(Glycine max)* and a bacterium *(Bradyrhizobium japonicum)* illustrates the process. In response to a specific flavonoid released by soybean roots, bacterial genes called *nod* genes (for *nodule*) begin to be expressed **(Figure 35.9A).** Products of the *nod* gene cause the tip of the root hair to curl toward the bacteria and trigger the release of bacterial enzymes that break down the root hair cell wall **(Figure 35.9B).** As bacteria enter the cell and multiply, the plasma membrane forms a tube called an **infection thread** that extends into the root cortex, allowing the bacteria to invade cortex cells **(Figure 35.9C).** The enclosed bacteria, now called **bacteroids,** enlarge and become immobile. Stimulated by still other *nod* gene products, cells of the root cortex begin to divide. This region of proliferating cortex cells forms the root nodule **(Figure 35.9D).** Typically, each cell in a root nodule contains several thousand bacteroids; the plant takes up some of the nitrogen fixed by the bacteroids, and the bacteroids use some compounds produced by the plant.



Inside bacteroids, N_2 is reduced to NH_4^+ (ammonium) using ATP produced by cellular respiration. The process is catalyzed by nitrogenase. Ammonium is highly toxic to cells if it accumulates, however. Thus, NH_4^+ is moved out of bacteroids into the surrounding nodule cells immediately and converted to other compounds, such as the amino acids glutamine and asparagine.

One factor encoded by the bacterial *nod* genes stimulates plant nodule cells to produce a protein called **leghemoglobin** ("legume hemoglobin"). Like the hemoglobin of animal red blood cells, leghemoglobin contains a reddish, iron-containing

CLOSER LOOK

FIGURE 35.9 Root nodule formation in legumes.

Soybean root releases a flavonoid; *Rhizobium nod* genes are expressed in response.

Products of the *nod* gene cause the root hair tip to curl; bacterial enzymes break down the cell wall.

An infection thread develops and bacterioids form as *Rhizobium* bacteria become enclosed in root cortex cells.

SUMMARY Legume root nodules typically form as a result of a mutualistic association with the nitrogen-fixing bacteria *Rhizobium* and *Bradyrhizobium*. The association develops as the products of bacterial *nod* genes allow bacteria to infect root cortex cells and proliferate there.

THINK LIKE A SCIENTIST Do all nodule-forming bacteria rely on *nod* gene products for gaining access to root cortex cells?

© Cengage Learning 2014

heme group that binds oxygen. Its color gives root nodules a pinkish cast (see Figure 35.8). Leghemoglobin picks up oxygen at the cell surface and shuttles it inward to the bacteroids. This method of oxygen delivery is vital, because nitrogenase, the enzyme responsible for nitrogen fixation, is irreversibly inhibited by excess O_2. Leghemoglobin delivers just enough oxygen to maintain bacteroid respiration without shutting down the action of nitrogenase.

Some Plants Obtain Nutrients in Unusual Ways

The Venus flytrap, the cobra lily, and various species of sundews are members of a curious group of plants that obtain nitrogen and other nutrients by trapping and digesting animals. A few species of tropical pitcher plants even capture and digest mice and small rats. Such "carnivorous" ("meat eating") plants have become adapted to survive in nutrient-deficient, and especially nitrogen-deficient, environments such as boggy and sandy areas through elaborate mechanisms for extracellular digestion and absorption. The cobra lily (*Darlingtonia californica;* **Figure 35.10A**) is a good example. Its leaves form a "pitcher" that is partly filled with digestive enzymes. Insects lured in by attractive odors often wander deeper into the pitcher, encountering downward-pointing leaf hairs that have a slick, waxy coating and speed the insect's descent into the pool of enzymes. The plant then absorbs monomers released as the animal tissues are digested.

Dodders **(Figure 35.10B)** and thousands of other species of flowering plants are parasites that obtain some or all of their nutrients from the tissues of other plants. Parasitic species develop *haustorial roots* (similar to the haustoria of fungi described in Chapter 30) that penetrate deep into the host plant and tap into its vascular tissues. Although some parasitic plants, like mistletoe, contain chlorophyll and thus can photosynthesize, dodders and other nonphotosynthesizers rob the host of sugars as well as water and minerals.

The snow plant *(Sarcodes sanguinea)* shows a variation on this theme. As its deep red color suggests **(Figure 35.10C),** it lacks chlorophyll, but it doesn't have haustorial roots. Instead, the snow plant's roots take up nutrients from mycorrhizae they "share" with the roots of nearby conifers.

Epiphytes, such as the tropical orchid pictured in **Figure 35.10D,** are not parasitic even though they grow on other plants. Some trap falling debris and rainwater among their leaves, whereas their roots (including mycorrhizae, in the case of the orchid) invade the moist leaf litter and absorb nutrients from it as the litter decomposes. In temperate forests, many mosses and lichens are epiphytes.

These and other strategies plants have evolved for obtaining nutrients and water are only part of the survival equation, however. Plants use nutrients not only for growth and maintenance, but also, of course, for building structures such as pollen, flowers, and seeds used in reproduction—our topic in Chapter 36.

FIGURE 35.10 **Some plants with unusual adaptations for obtaining nutrients. (A)** Cobra lily *(Darlingtonia californica)*, a carnivorous plant. The patterns formed by light shining through the plant's pitcherlike leaves are thought to confuse insects that have entered the pitcher, making an exit more difficult. **(B)** A parasitic dodder, one of the more than 150 *Cuscuta* species. Dodders have slender yellow-orange stems that twine around the host plant before producing haustorial roots that absorb nutrients and water from the host's xylem and phloem. **(C)** Snow plant *(Sarcodes sanguinea)*, which pops up in the deep humus of shady conifer forests after snow has melted in spring. This species lacks chlorophyll and does not photosynthesize. Instead its roots intertwine with hyphae of soil fungi that also form associations with the roots of nearby conifers. Radiocarbon studies have shown that the fungi take up sugars and other nutrients from the trees and pass a portion of this food to the snow plant. **(D)** The lady-of-the-night orchid *(Brassavola nodosa)*, a tropical epiphyte.

STUDY BREAK 35.3

1. What is a mycorrhiza, and why are mycorrhizal associations so vital to many plants?
2. Distinguish between nitrogen fixation, ammonification, and nitrification.
3. Summarize the mechanism by which associations with bacteria supply nitrogen to plants such as legumes.

THINK OUTSIDE THE BOOK

Botanists have identified a large number of plants that trap and digest small animals. Working with fellow students, do some research online or in the library to develop a list of at least five different variations in the trapping mechanism. Which plant structure or structures have been modified to form each type of trap?

UNANSWERED QUESTIONS

What is the role of organic nitrogen in plant nutrition and nitrogen cycling?

The classical model of nitrogen (N) cycling in plant ecology has been that plants take up nitrogen in inorganic forms—nitrate and ammonium—made available by microbial conversion of organic N to mineral N. This process of nitrogen mineralization involves the decomposition of organic nitrogenous substances—including proteins, DNA, and RNA—released into the soil from dead organisms. This classical model assumes that plants cannot compete with soil microorganisms for mineral nitrogen,

Copyright 2012 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

but rather only have access to what remains after microbial decomposers satisfy their own demand for nitrogen and release excess nitrogen extracted from the organic matter they consume. In recent years, however, studies on nitrogen mineralization in low-N soils, such as those in many arctic tundra ecosystems, have shown that mineralization rates can be too low to account for the amount of nitrogen taken up by plants in nitrogen-poor environments. This finding raised a basic question about nitrogen cycling in arctic tundra and other low-nitrogen environments: how do plants acquire nitrogen from soils where nitrogen mineralization rates are too low to meet plant demand?

Since the mid-1990s, evidence has mounted that plants can bypass the microbial nitrogen mineralization step of the classical nitrogen cycling model. Instead of relying solely on inorganic forms of nitrogen such as nitrate, plants may also derive nitrogen from organic molecules such as amino acids released into the soil solution as decomposer microorganisms degrade proteinaceous organic matter. The finding that many plants indeed can take up amino acids has raised the possibility that the uptake of organic nitrogen may be an important component of plant nitrogen budgets in low-N environments, such as arctic tundra. First discovered in arctic tundra plants, amino acid uptake has since been reported for plants in a variety of habitats. Further, we now know that roots possess specific amino acid transporters that can take up a variety of amino acids, and recent studies suggest that root amino acid transport is a trait that can be induced by low nitrogen availability.

Although these discoveries have forced researchers to develop more complete models of nitrogen cycling and uptake by plants, much remains to be learned. For example, what controls amino acid availability in soil? Can plants take up organic nitrogen forms other than amino acids? What controls the availability of these other N forms? In my laboratory we are studying a range of phenomena that bear on all these questions, including the extent to which major organic nitrogen sources such as proteins and chitin contribute to nitrogen availability in soils in different places at different times. For this research, we are measuring the activity of microbial enzymes responsible for breaking down different organic nitrogen sources in soils from a variety of environments, and comparing the enzyme activities to overall nitrogen mineralization rates. We are also examining basic aspects of soil chemistry, such as acidity, to try to determine the specific organic nitrogen forms microbes are consuming and mineralizing under different conditions. Our initial findings indicate that proteins, once thought to be the predominant form of organic nitrogen that microorganisms degrade, may be a less important source of nitrogen in many environments, particularly in acidic soils. Instead, in such low pH soil environments, the breakdown of chitin may be much more important in nitrogen cycling. Acidic soils are fairly common in nature, and this finding raises the possibility that plants growing in such soils may be able to acquire nitrogen by taking up chitin breakdown products. This hypothesis remains untested. As researchers in my laboratory and elsewhere probe it and other questions, the answers will greatly expand our understanding of nitrogen cycling in general, and of specific plant adaptations for gaining access to this essential nutrient.

THINK LIKE A SCIENTIST Soil microorganisms consume nitrogen-containing organic compounds, and mineralize nitrogen in the process, even after their own nitrogen demands are satisfied. Why don't these microorganisms stop breaking down nitrogenous organic compounds once their metabolic needs are met?

Michael Weintraub

Michael Weintraub is an assistant professor of soil ecology in the University of Toledo's Department of Environmental Sciences. His research focuses on developing a mechanistic understanding of key soil processes, to gain insight into how terrestrial ecosystems function, and to predict how they will respond to disturbances such as climate change and nitrogen deposition. To learn more about his work, go to http://www.eeescience.utoledo.edu/Faculty/weintraub/ESELab.htm.

REVIEW KEY CONCEPTS

To access the course materials and companion resources for this text, please visit www.cengagebrain.com.

35.1 Plant Nutritional Requirements

- Plants require 17 essential nutrients (Table 35.1). With enough sunlight and these nutrients, plants can synthesize all the compounds they require to survive.
- Nine essential elements are macronutrients, required in relatively large amounts. Of these, carbon, hydrogen, oxygen, and nitrogen are the main building blocks in the synthesis of carbohydrates, lipids, proteins, and nucleic acids. Macronutrients dissolved in the soil solution are nitrogen, potassium, calcium, magnesium, phosphorus, and sulfur.
- Plants require essential micronutrients in much smaller amounts. Known micronutrients are chlorine, iron, boron, manganese, zinc, copper, molybdenum, and nickel.
- Each plant species requires specific amounts of specific nutrients. Typical deficiency symptoms are stunted growth, yellowing or other abnormal changes in leaf color, dead spots on leaves, or abnormally formed stems (Figure 35.3).
- Most mineral ions enter plant roots dissolved in water. Inside cells, most mineral ions enter vacuoles or the cell cytoplasm, where they are available for metabolism. Some elements, such as nitrogen and potassium, are mobile—they can move from site to site in phloem as the plant grows.

35.2 Soil

- Soil consists of sand, silt, and clay particles, usually held together by humus and other organic components. Humus absorbs considerable water and contributes to the water-holding capacity of soil.
- The relative proportions of various soil mineral particles and humus give soil its basic texture and structure. The best agricultural soils are loams that contain clay, sand, silt, and humus in roughly equal proportions. Topsoil is the most fertile soil layer (Figure 35.4).
- Soil particles are thinly coated by the soil solution, a mixture of water and solutes (Figure 35.5). Root hairs and other root epidermal cells absorb water and solutes from this solution.
- The amount of water available to plant roots depends mainly on the relative proportions of different soil components. Water moves quickly through sandy soils, whereas soils rich in clay and humus tend to hold water.
- Cations are adsorbed on the negatively charged surfaces of soil particles, potentially limiting their uptake by roots. Cation exchange, in which mineral cations are replaced by H^+, helps make these nutrients available to plants (Figure 35.6). Anions are more

weakly bound to soil particles; they move more readily into root hairs but also are more apt to leach out of topsoil. In nature, the soil solution surrounding plant roots generally contains only tiny amounts of essential mineral ions.

- Plants influence the physical, chemical, and biological features of soil, as when dead plant parts decompose and substances they contain enter the soil (Figure 35.7).

Animation: Uptake of nutrients by plants

35.3 Root Adaptations for Obtaining and Absorbing Nutrients

- Numerous adaptations help plants solve the problems of obtaining and absorbing nutrients. Roots penetrate the soil towards nutrients and water; huge numbers of root hairs increase the root's absorptive surface. Ion-specific transporters in root cortical cells adjust the plant's uptake of particular ions. Mycorrhizal associations between fungi and plant roots enhance the absorption of nutrients, notably phosphorus.
- Nitrogen usually is the scarcest nutrient in soil, and nitrogen-fixing bacteria produce much of the usable soil nitrogen. Nitrogen fixation reduces atmospheric N_2 to NH_4^+ (ammonium) in a reaction that requires nitrogenase as a catalyst. Nitrifying bacteria rapidly convert NH_4^+ to nitrate, the form in which the roots of most plants absorb nitrogen (Figure 35.7).
- In legumes and a few other species, nitrogen-fixing bacteria reside in root nodules in a mutualistic association (Figure 35.8).
- Bacteria (bacteroids) enclosed in a root nodule reduce N_2 to NH_4^+ (Figure 35.9). The toxic NH_4^+ is moved out of the bacteroids and converted to nitrogen-rich, nontoxic compounds such as amino acids. In plants that do not form root nodules, nitrate absorbed by roots is reduced to ammonium, which then is converted to nontoxic forms.
- In many plant species, root cells synthesize amino acids and other organic nitrogenous compounds, and these molecules are transported in phloem throughout the plant. In some plants, the nitrogen-rich precursors travel in xylem to leaves, where different organic molecules are synthesized. Those molecules move to other cells in phloem.
- A few plant species have evolved alternative mechanisms for obtaining some or all of their nutrients (Figure 35.10). Carnivorous plants have structures that physically trap insects or other small animals, and produce solutions of enzymes that digest the animal tissues, releasing absorbable nutrients.
- Some plant species parasitize other plants. The parasite may or may not contain chlorophyll and carry out photosynthesis; species that do not photosynthesize obtain all of their nutrition from the host. Epiphytes grow on other plants but obtain nutrients independently.

Animation: Nitrogen cycle

UNDERSTAND & APPLY

Test Your Knowledge

1. Which best applies to a micronutrient?
   a. It makes up 96% of the plant's dry mass.
   b. It cannot be replaced artificially.
   c. It is early on the periodic chart compared with macronutrients.
   d. It is required in large amounts during sunlight hours.
   e. It is an essential element.
2. Nutrient runoff from fertilizing lush lawns often causes "algal blooms" in nearby lakes, making swimming impossible. The fertilizer components most likely to have caused the blooms are:
   a. iron, magnesium, and nitrogen.
   b. nitrogen, phosphorus, and sulfur.
   c. nitrogen, potassium, and phosphorus.
   d. selenium, magnesium, and potassium.
   e. nitrogen, magnesium, and nickel.
3. Which of the following are *not* among the ideal soil conditions for growing crops?
   a. extremely large air spaces
   b. sandy or silty loam
   c. blend of sand and clay
   d. less than 5% humus
   e. thick topsoil
4. Which of the following processes contributes to the uptake of mineral ions by plant roots?
   a. chlorosis
   b. osmosis
   c. cation exchange
   d. anion leaching
   e. growth of root hairs
5. Which of the following does *not* influence soil pH?
   a. rainfall
   b. hydroponic growth
   c. release of sulfur and nitrogen oxides into the air
   d. decomposition of organisms
   e. weathering of rock
6. Which of the following is a common process that makes usable nitrogen available to plants?
   a. nitrogen-fixing bacteria synthesizing nitrate
   b. ammonifying bacteria using ammonium to produce nitrate
   c. nitrifying bacteria converting NH_4^+ to NO_3^-
   d. the direct absorption of NH_4^+ by root hairs
   e. the absorption of atmospheric N_2 into the xylem
7. The *nod* genes in the bacteria in soybean nodules allow the bacteria to fix nitrogen. Which of the following, if any, is *not* a step in this process?
   a. The products of *nod* genes cause cells of the root cortex to divide and become the root nodule in which bacteroids fix nitrogen for the plant.
   b. In the cortex cells bacteria enlarge and become immobile, forming bacteroids.
   c. Bacteria enter the root hair cell and multiply, causing the cell plasma membrane to form an infection thread that extends into the root cortex.
   d. Roots release flavonoid, which turns on the expression of bacterial *nod* genes. Products of *nod* genes cause the tip of the root hair to curl toward the bacteria.
   e. Root hairs trigger release of bacterial enzymes that break down root hair cell walls.
8. Being "carnivorous" is a plant adaptation to obtain:
   a. oxygen.
   b. phosphorus.
   c. potassium.
   d. nitrogen.
   e. carbon.
9. Haustorial roots are characteristic of plants that are:
   a. parasites.
   b. epiphytes.
   c. nitrate fixers.
   d. leghemoglobin users.
   e. carnivorous.

10. Identify the correct match of a nutrient with its function.
    a. chlorine: component of several enzymes
    b. potassium: component of nucleic acids
    c. phosphorus: component of most proteins
    d. manganese: role in shoot and root growth
    e. calcium: maintenance of cell walls and membrane permeability

Discuss the Concepts

1. If you want to study factors that affect plant nutrition in nature, what would be the advantages and disadvantages of using a hydroponic culture method?
2. Gardeners often add a humus-rich "soil conditioner" to garden plots before they plant. Adding the conditioner helps aerate the soil, and the decomposing organic materials in humus provide nutrients. If the plot is for annual plants, it often must be reconditioned year after year, even though the gardener faithfully pulls weeds, fertilizes seedlings, applies chemicals to curtail disease-causing soil microbes, and immediately tosses out the mature plants (along with any plant debris) when they have finished bearing. Suggest some reasons why reconditioning is necessary in this scenario, and some strategies that could help limit the need for it.
3. One effect of acid rain is to dissolve rock, liberating minerals into soil. Accordingly, can a case be made that acid rain confers environmental benefits as well as doing harm? What are some other factors, especially with regard to plant adaptations for gaining nutrients, that bear on this question?
4. Using Table 35.1 as a guide, describe some of the known roles of nitrogen, phosphorus, and potassium in plant function. What are some of the signs that a plant suffers a deficiency in those elements?

Design an Experiment

A plant in your garden is undersized and develops chlorotic leaves even though you fertilize it with a mixture that contains nitrogen, potassium, and phosphorus. After determining that the plant receives enough sunlight for photosynthesis, you next decide to test whether its mineral nutrition is adequate. What specific hypothesis will your experiment test? How will your experimental design test the hypothesis?

Interpret the Data

Numerous studies have shown that the particular plant species growing in a soil influence the soil's chemical properties. With this in mind, in the study of Colorado mountain soil mentioned in Section 35.2, the researchers expected to find differences in the study area's soil chemistry depending on which of the three main tree species—trembling aspen *(Populus tremuloides),* lodgepole pine *(Pinus contorta),* and Engelmann spruce *(Picea engelmannii)*—was dominant at a particular site. One factor that affects soil chemistry is the chemical composition of the leaf litter that falls to the ground and decomposes. The **Table** that follows shows values for leaf litter quality as a function of the litter's nitrogen, carbon, cellulose, and lignin content. For each species it also shows the biomass of fine roots (less than 1 mm diameter) and coarse roots (more than 1 mm diameter) in the upper 10 cm of soil.

1. Based on these values, summarize the findings for aspen trees, compared with the pines and spruce trees in the sample.
2. Overall, how does the ratio of lignin to nitrogen in leaf litter seem to correlate with total litter nitrogen content?
3. Did the root biomass among the three tree species differ significantly?

Leaf Litter Quality and Root Biomass of Tree Species in a High-Elevation Forest in Colorado

	Litter N (%)	Litter C (%)	Litter C:N	Litter Cellulose (%)	Litter Lignin (%)	Litter Lignin:N	Fine Root Biomass (g/m^2)	Coarse Root Biomass (g/m^2)
Aspen	0.84±0.08	49.4±0.4	60.4±5.2	42.1±3.0	20.2±2.2	24.1±1.2	321±47	422±134

Apply Evolutionary Thinking

This chapter's *Focus on Applied Research* discusses phytoremediation, the use of plants to remove environmental pollutants such as heavy metals. Some plant species are "hyperaccumulaters" that take up arsenic and other metallic contaminants and sequester such toxins in shoot parts. How might this activity confer a selective advantage?

Reproduction and Development in Flowering Plants

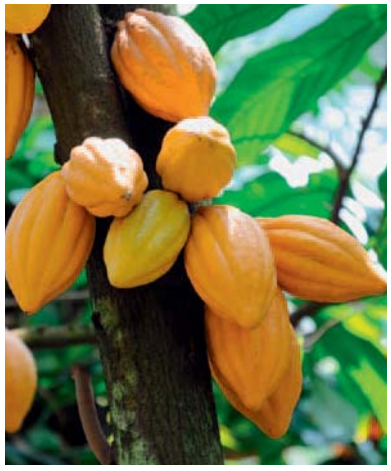
STUDY OUTLINE

36.1 Overview of Flowering Plant Reproduction

36.2 The Formation of Flowers and Gametes

36.3 Pollination, Fertilization, and Germination

36.4 Asexual Reproduction of Flowering Plants



36.5 Early Development of Plant Form and Function

Why it matters . . . Chocolate, a confection beloved by humans with a sweet tooth, gets its start within the fruits of *Theobroma cacao,* a small flowering tree. *T. cacao* evolved in the undergrowth of tropical rainforests in Central America, where the Maya and Aztec peoples domesticated it and incorporated it into their religious and cultural life. Today cacao trees flourish on vast plantations in the tropical lowlands of Central and South America, the West Indies, West Africa, and New Guinea. Unlike most angiosperms, which produce flowers at the tips of floral shoots, *T. cacao* flowers grow directly from buds on the tree trunk. Small flying insects called midges pollinate the flowers. Pollination, in turn, is the first step toward fertilization of the eggs, and within about six months, large, podlike fruits develop from them **(Figure 36.1).** Each fruit contains from 20 to 60 seeds—the cacao "beans" that manufacturers process into cocoa, eating chocolate, and other products.

Angiosperms have elaborate reproductive systems housed in their flowers—systems that produce, protect, and nourish sperm, eggs, and developing embryos. As with *T. cacao,* the flowers of many species also attract animal pollinators that function in bringing sperm and egg together. Once a new individual forms and begins

to grow, finely regulated gene interactions guide the development of all a plant's parts.

Like the seeds of other flowering plants, cacao seeds result from sexual reproduction—the union of sperm and eggs that are produced by meiosis (see Section 11.1). As Section 11.2 describes in greater detail, this reproductive mode yields genetically diverse offspring. This diversity, in turn, provides an adaptive advantage in a changing environment, because it increases the chance that as change occurs—perhaps a shift in climate, or the appearance of a new predator or pathogen—at least some offspring will grow to maturity and reproduce successfully. *T. cacao* and many other plants are reproductively flexible, however. Under certain circumstances, they can also reproduce asexually, so that individuals of the new generation are genetically identical (clones) of their parents.

In the first three sections of this chapter, we will focus on sexual reproduction, which dominates the life cycle of flowering plants. We then consider asexual reproduction and conclude with a discussion of early plant development.

36.1 Overview of Flowering Plant Reproduction

In plants as in animals, sexual reproduction occurs when male and female haploid gametes unite to create a diploid fertilized egg. This fertilized egg—the zygote—then embarks on its gene-guided course of growth and development. As described in Chapter 10, animals grow mainly by mitosis, which increases the number of body cells, and the newly formed cells end up roughly the same size as the parent cell. Plants, however, grow larger by two mechanisms. Mitotic cell divisions in meristems generate new cells, but then the newly formed cells rapidly increase in size—especially length—expanding until they are much *larger* than the parent cell. Section 36.4 explains how this cell expansion occurs. Ultimately, as in animals, each daughter cell differentiates and becomes cell specialized for its particular function.

Once an angiosperm zygote has formed, early development generates an embryo enclosed within a seed. This embryo already contains early versions of the basic plant tissue systems, so the embryo technically is already a **sporophyte**—the diploid, spore-producing body of a plant described in Section 28.1. When most people look at a plant—say a cherry tree or a rose bush—what they think of as "the plant" is the sporophyte pictured at the top of **Figure 36.2.**

At some point during an angiosperm sporophyte's growth and development, one or more of its vegetative shoots undergo changes in structure and function and become reproductive shoots. These *floral shoots* will give rise to a flower or inflorescence (a group of flowers on the same floral shoot), and certain cells in the flowers will divide by meiosis. Unlike meiosis in animals, however, meiosis in plants does not yield haploid gam-

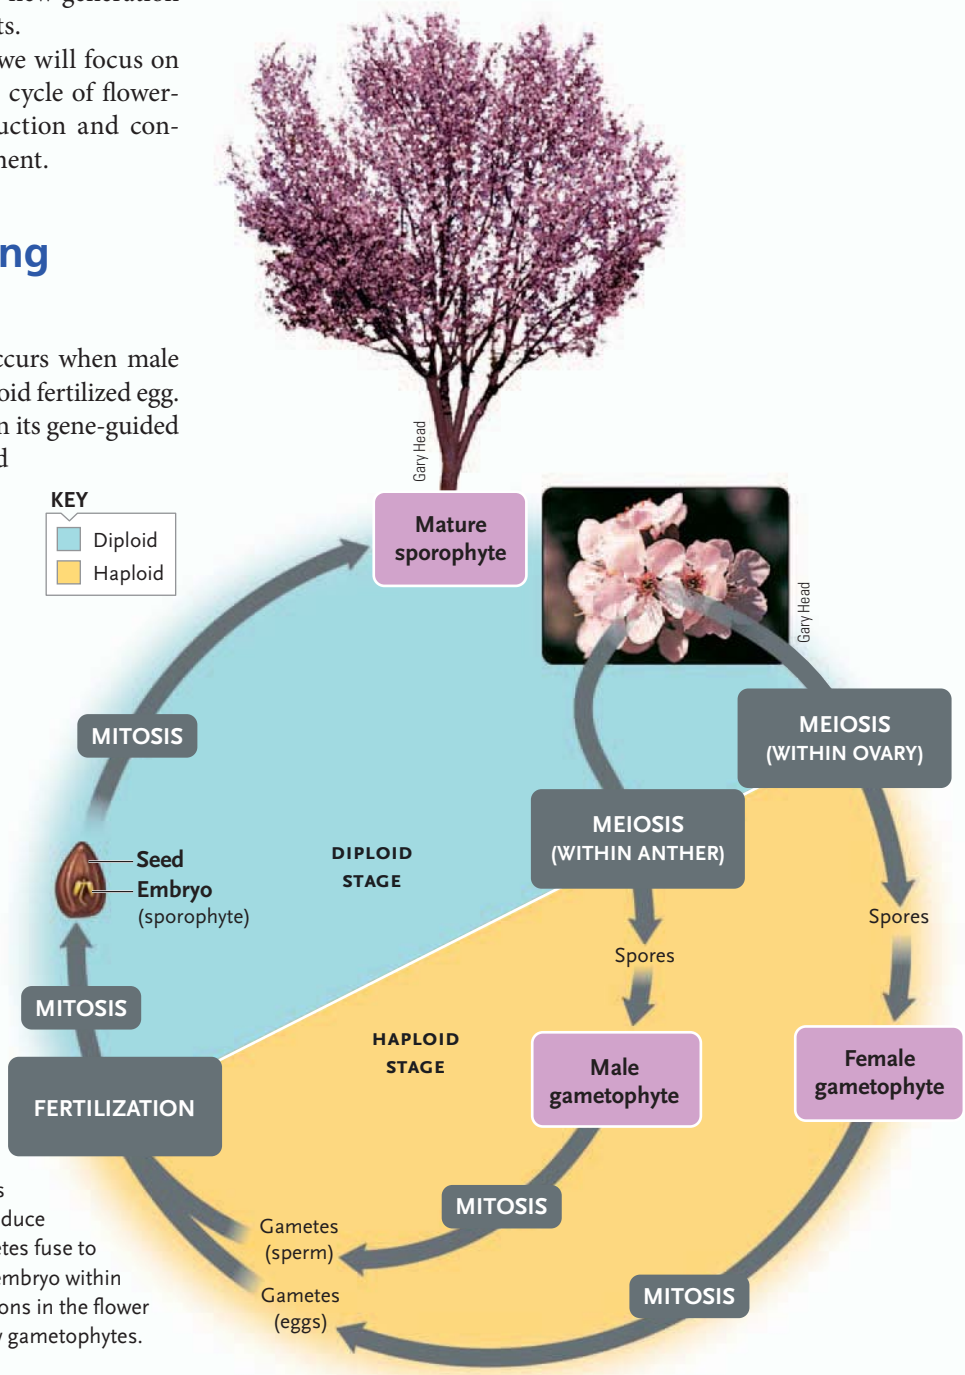

FIGURE 36.2 Overview of the flowering-plant life cycle, using the cherry *(Prunus)* as an example. This type of reproductive cycle, alternation of generations, has a haploid phase in which multicellular gametophytes produce gametes and a diploid phase that begins when two gametes fuse to form a zygote. This zygote develops into a multicellular embryo within a seed and then into a mature sporophyte. Meiotic divisions in the flower of the sporophyte produce spores, which give rise to new gametophytes.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

etes. Instead, meiosis gives rise to haploid **spores,** walled cells that subsequently divide by mitosis. By way of these mitotic divisions, each spore grows into a multicellular—but still haploid—**gametophyte.** Although the term gametophyte means "gamete-producing plant," the gametophyte of a vascular plant is a tiny structure that produces haploid sex cells, the gametes, also by mitosis. Male gametophytes produce sperm cells, the male gametes of flowering plants; female gametophytes produce eggs. This division of a life cycle into a diploid, spore-producing generation and a haploid, gamete-producing one is called **alternation of generations.**

In virtually all plants, the gametophyte and sporophyte are strikingly different from one another in both function and structure. As Chapter 28 describes in detail, the course of plant evolution has been marked by a trend toward a larger and more nutritionally independent sporophyte. For instance, in bryophytes (mosses and liverworts), the sporophyte is usually smaller than the gametophyte, growing out of the gametophyte and obtaining nutrients from it (see Section 28.2). This relationship changed as vascular plants evolved. In ferns, which are seedless vascular plants, the gametophyte is much smaller than the sporophyte and is free-living for much of its life, and in most fern species the gametophyte nourishes itself by photosynthesis. In angiosperms and other seed plants, however, gametophytes are not independent "plants." Instead they are small structures that are retained *inside* the sporophyte for all or part of their lives. The female gametophyte of a flowering plant usually consists of only seven cells that are embedded in floral tissues, as you will read shortly. Male gametophytes consist of only three cells. They are released into the environment as pollen grains so small that they are measured in micrometers. The pollen grain matures when it reaches a compatible ovule. When fertilization ensues, an embryo develops within a seed.

As you will read later on in this chapter, sporophytes may also reproduce asexually by several means, all of which produce genetically identical offspring. We turn now to our consideration of sexual reproduction in angiosperms, beginning with the crucial step in which flowers develop.

STUDY BREAK 36.1

1. What are the two "alternating generations" of plants?
2. How do these two life phases differ in structure and function?

36.2 The Formation of Flowers and Gametes

Flowering marks a developmental shift for an angiosperm. Chemical signals—triggered in part by environmental cues such as day length and temperature—travel to the apical meristem of a shoot and trigger changes in cell activity there. The shoot stops its vegetative growth and undergoes further changes that transform it into a floral shoot capable of giving rise to floral organs.

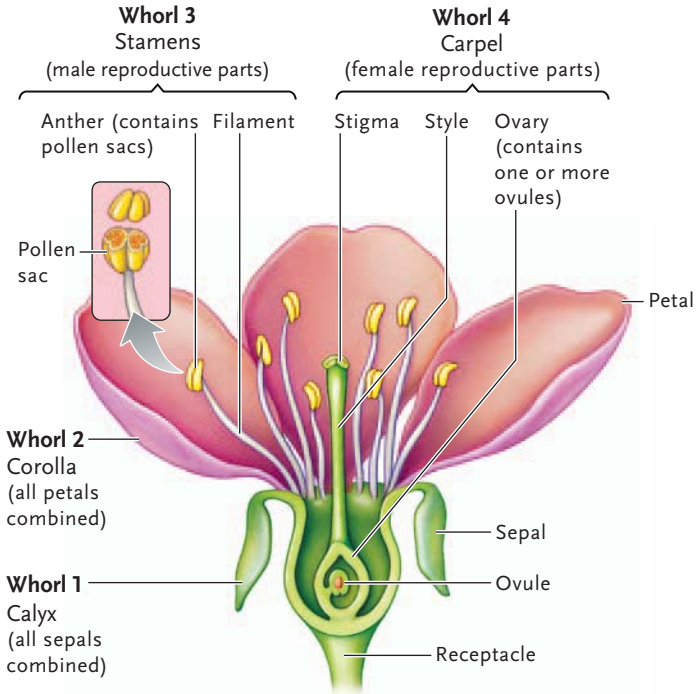

FIGURE 36.3 Structure of a cherry *(Prunus)* flower, with the four whorls indicated. Like the flowers of many angiosperms, it has a single carpel and several stamens. The anthers of each stamen produce haploid pollen. The stigma of the carpel receives the pollen, and the ovule inside the ovary contains the haploid egg. In this diagram, two of the cherry flower's five petals have been removed. For clarity, this diagram shows a single ovule, but as the text notes, flowers of many angiosperm species contain multiple ovules.

In Angiosperms, Flowers Contain the Organs for Sexual Reproduction

A flower develops from the end of the floral shoot, called the **receptacle.** In a "typical" flower, cells in the receptacle differentiate to produce four types of concentric tissue regions called *whorls* **(Figure 36.3).** Flowers with all four whorls are called **complete flowers (Figure 36.4A).** The two outer whorls consist of

nonfertile, vegetative structures. The outermost whorl (whorl 1), the **calyx,** is made up of leaflike **sepals.** The calyx is usually green, and, early in the flower's development, it encloses all the other parts, as in an unopened rose bud. The next whorl, the **corolla,** includes the **petals.** Corollas usually are the "showy" parts of flowers with distinctive colors, patterning, and shapes. These features often function in attracting bees and other animal pollinators.

A flower's two inner whorls are specialized for making gametes. Inside the corolla is the whorl of **stamens** (whorl 3), in which male gametophytes form. In almost all living flowering plant species, a stamen consists of a slender **filament** (stalk) capped by a bilobed **anther.** Each anther contains four **pollen sacs,** in which pollen develops.

The innermost whorl (whorl 4) consists of parts associated with the formation and fertilization of eggs. These parts, sometimes collectively called the *pistil,* include one or more **carpels,** in which female gametophytes form. The lower part of a carpel is the **ovary.** Inside it is one or more **ovules,** in which an egg develops and fertilization takes place. In many flowers that have more than one carpel, the carpels fuse into a single, common ovary containing multiple ovules. Typically, the carpel's slender **style** widens at its upper end, terminating in the **stigma,** which serves as a landing platform for pollen. Fused carpels may share a single stigma and style, or each may retain separate ones. The name angiosperm ("seed vessel") refers to the carpel.

The arrangement and number of whorl types varies in different species. In some species flowers lack one or more of the whorls, and thus botanists describe them as **incomplete flowers (Figure 36.4B).** Botanists also distinguish flowers on the basis of the sexual parts they contain. Most angiosperms produce **perfect flowers,** which have both kinds of sexual parts—that is, both stamens and carpels. **Imperfect flowers** have stamens or carpels, but not both. (Notice that all imperfect flowers are also incomplete because they lack one of the whorls.) Species with imperfect flowers are further divided according to whether individual plants produce both sexual types of flowers, or only one. In **monoecious** (*mono-* = one; *oikia* = house) species, such as oaks, each plant has some "male" flowers with only stamens and some "female" flowers with only carpels. In **dioecious** ("two houses") species, such as willows, a given plant produces flowers having only stamens or only carpels. With this basic angiosperm reproductive anatomy in mind, we can consider the processes by which male and female gametes come into being.

Pollen Grains Arise from Microspores in Anthers

Most of a flowering plant's reproductive life cycle, from production of sperm and eggs to production of a mature seed, takes place within its flowers. **Figure 36.5** summarizes this cycle as it unfolds in a perfect flower. The microspores that give rise to male gametophytes are produced in a flower bud's anthers (see Figure 36.5, left). The pollen sacs inside each anther hold diploid microsporocytes (or *microspore mother cells*); each microsporocyte undergoes meiosis and eventually produces four small haploid **microspores.** Like most plant cells, the microspores are walled, and inside its wall each microspore divides again, this time by mitosis. The result is an immature, haploid male gametophyte—a **pollen grain.**

Of the two nuclei produced by the mitotic division of a microspore, one again divides. After this second round of mitosis the male gametophyte consists of three cells—two sperm cells plus a third cell that controls the development of a **pollen tube (Figure 36.6A).** As you can see in Figure 36.5, step 5, when pollen lands on a stigma, this tube grows through the tissues of a carpel and carries the sperm cells to the ovary. A mature male gametophyte consists of the pollen tube and sperm cells—the male gametes. Once the pollen tube and sperm cells have formed, the stage is set for fertilization, which we discuss more thoroughly in Section 36.3.

The walls of pollen grains are hardened by the decay-resistant polymer *sporopollenin,* and are tough enough to protect the male gametophyte during the somewhat precarious journey from anther to stigma. These walls are so distinctive that the family to which a plant belongs often can be identified from pollen alone—based on the size and wall sculpturing of the grains, as well as the number of pores in the wall **(Figure 36.6B–D).** Because they withstand decay, pollen grains fossilize well and can provide revealing clues about the evolution of seed plants and the ecological communities that lived in the past.

Eggs and Other Cells of Female Gametophytes Arise from Megaspores

Meanwhile, in the ovary of a flower, one or more dome-shaped masses form on the inner wall. Each mass becomes an ovule (see Figure 36.5, right), which, if all goes well, develops into a seed. Only one ovule forms in the carpel of some flowers, such as the cherry. Dozens, hundreds, or thousands may form in the carpels of other flowers, such as those of a bell pepper plant *(Capsicum annuum).* At one end, the ovule has a small opening, called the **micropyle.**

Inside the cell mass, a diploid megasporocyte (or *megaspore mother cell*) divides by meiosis, forming four haploid **megaspores.** In most species, three of these megaspores disintegrate. The remaining megaspore enlarges and develops into the female gametophyte in a sequence of steps tracked in Figure 36.5.

First, three rounds of mitosis occur *without* cytoplasmic division; the result is a single cell with eight nuclei arranged in two groups of four. Next, one nucleus in each group migrates to the center of the cell; these two **polar nuclei** ("polar" because they migrate from opposite ends of the cell) may fuse or remain separate. The cytoplasm then divides, and a cell wall forms around the two polar nuclei, forming a single large endosperm mother cell (also called the *central cell*). A wall also forms around each of the other nuclei. Three of these walled nuclei

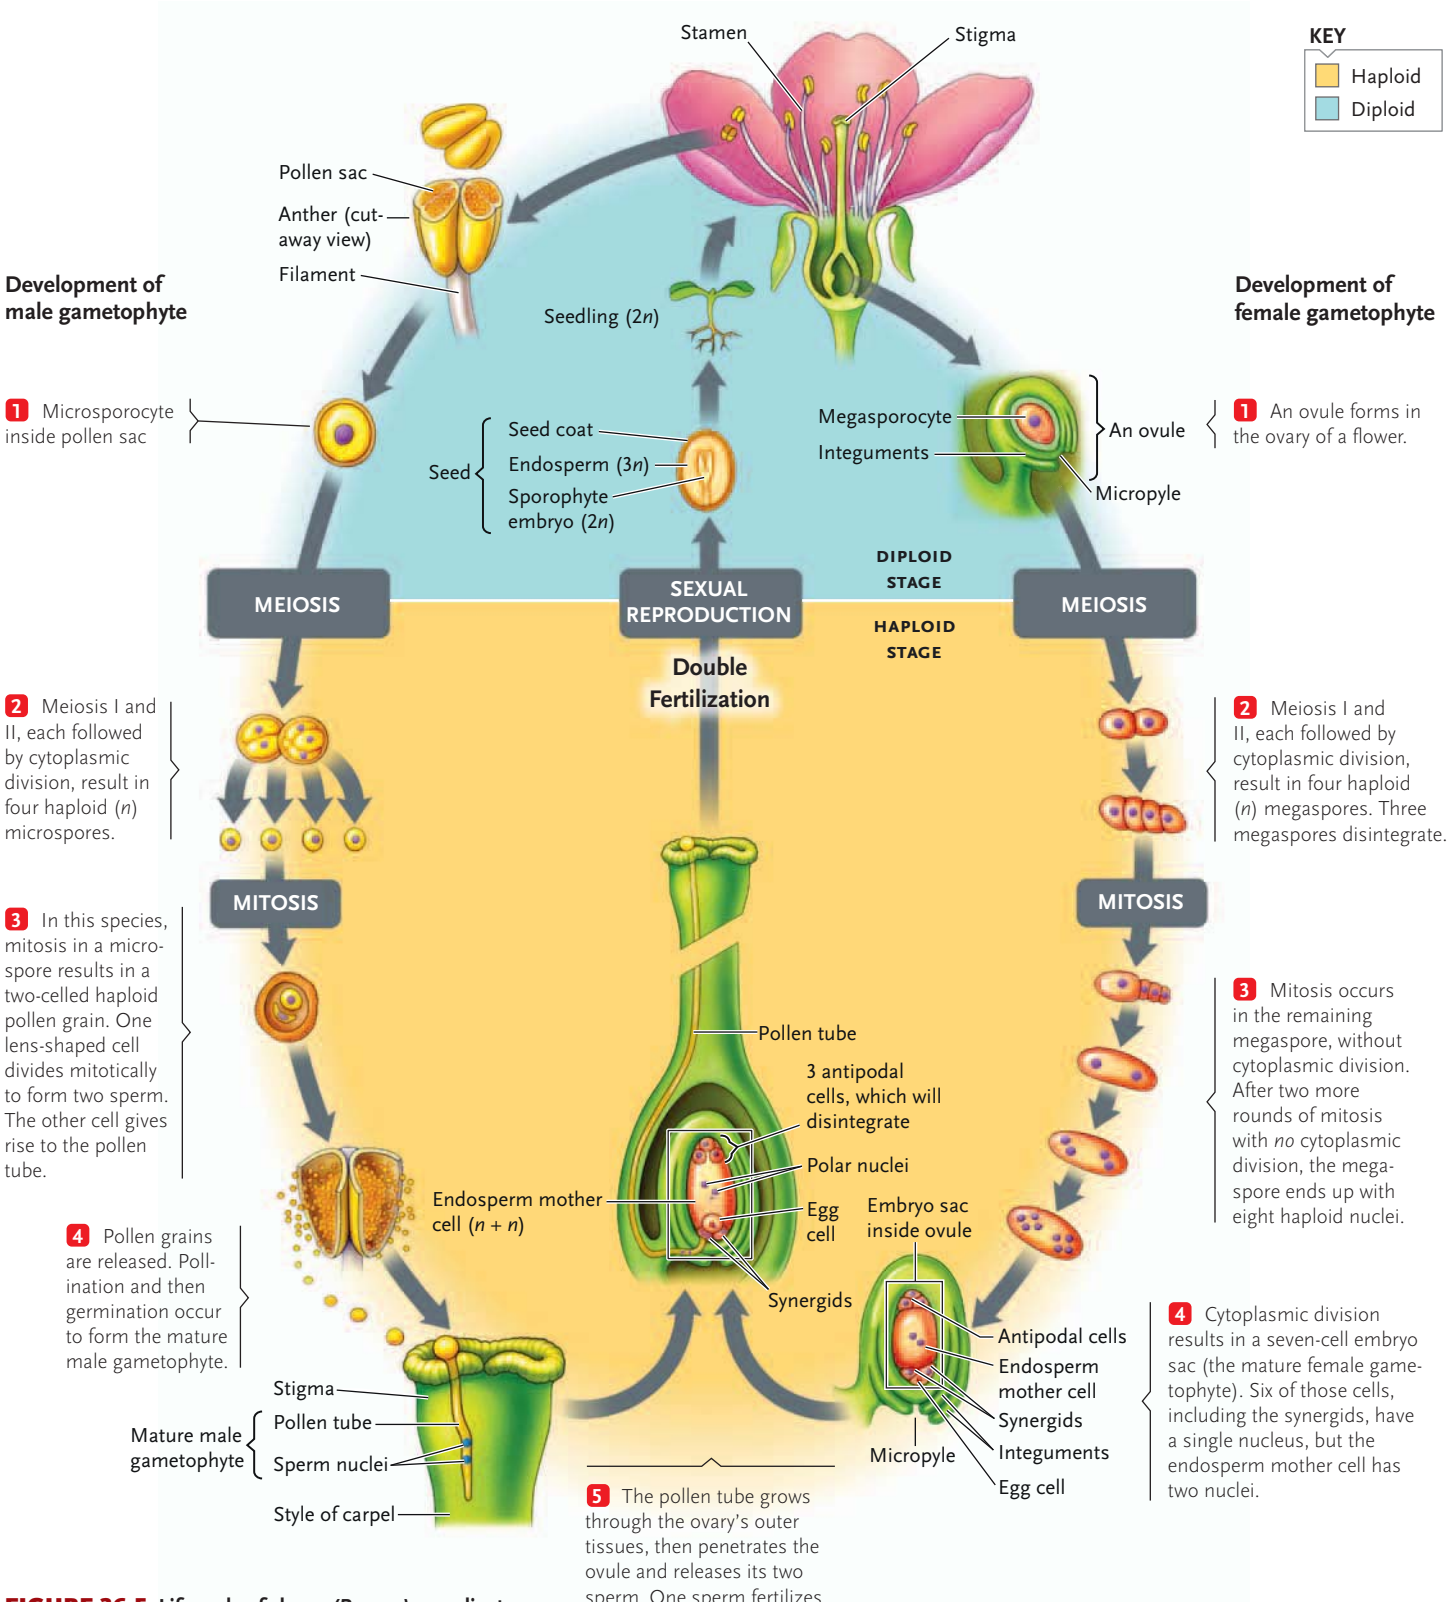

FIGURE 36.5 Life cycle of cherry *(Prunus)*, a eudicot. Pollen grains develop in pollen sacs in the anthers (left, steps 1–3). An embryo sac develops in the single ovule in the cherry flower's ovary, and a haploid egg forms within the embryo sac (right, steps 1–4). When a pollen grain is released and contacts the stigma (left, step 4), it germinates and produces a pollen tube containing two haploid sperm. The tube penetrates the stigma, then grows to the ovary and penetrates the ovule (step 5). Eventually double fertilization occurs, giving rise to an embryonic sporophyte and endosperm that become encased together in a seed coat.

become *antipodal cells,* which eventually disintegrate. Three others form a cluster (called the "egg apparatus") near the micropyle; one of them is an **egg cell** that may eventually be fertilized. The other two, called *synergids,* will have a role in fertilization. The eventual result of all these events is an **embryo sac** containing seven cells and eight nuclei. This embryo sac is the female gametophyte.

DISCOVERING HOW CHEMICAL CUES GUIDE EMBRYO SAC DEVELOPMENT How do the four different types of embryo sac cells become differentiated, allowing them to fulfill their respective reproductive functions? A study led by Gabriela C. Pagnussat at the University of California, Davis has provided some insights into this mechanism. Working with *Arabidopsis thaliana* plants, Pagnussat and her colleagues demonstrated that the plant hormone auxin, already known for other growth effects in plants (described in Chapter 37), is a major factor in determining the identity and roles of cells and nuclei within the embryo sac. The team determined that when mitosis begins in a megaspore, an auxin gradient is established along the future axis of the developing embryo sac. The highest auxin concentration occurs near the micropyle, where the pollen tube will enter the ovule. As mitotic cell divisions continue, each of the eight products develops as an egg, synergid, polar nucleus, or antipodal cell depending on its position within the auxin gradient. Thus the egg cell and synergids develop where auxin is most concentrated, the antipodal cells develop where auxin is lowest, and the polar nuclei develop where there is an intermediate auxin concentration **(Figure 36.7).** Auxin can be said to provide *positional information* for embryo sac development, a topic we return to in Section 36.5.

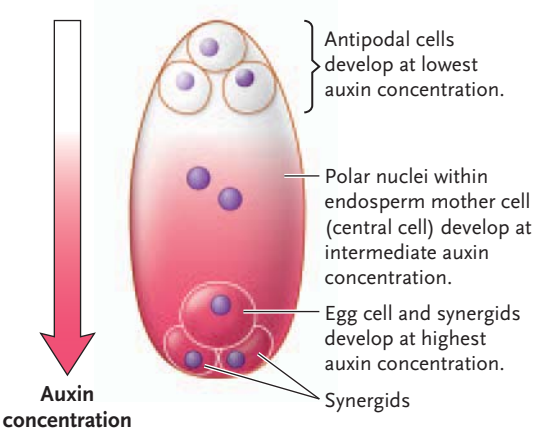

FIGURE 36.7 Model for patterning of the female gametophyte by an auxin gradient. A study by Gabriela Pagnussat and coworkers showed that the concentration of auxin (indicated in red) determined the fate of cells in the developing gametophyte. Where auxin was most concentrated, cells became specialized as synergids. At the lowest concentration, they became antipodal cells. Egg cells developed in between these two extremes.

OTHER OPTIONS FOR EMBRYO SAC DEVELOPMENT In about a third of flowering plants, biologists have observed variations in the events that produce a female gametophyte. In lilies, for example, changes in the sequence of cell divisions produce several cells with triploid nuclei. The egg cell is not involved, however, so such differences do not affect reproduction. They may be important in the development and functioning of other embryonic tissues.

The formation of gametophytes sets the stage for events by which a seed plant may complete its life cycle. As we see next, pollination is the next crucial step.

STUDY BREAK 36.2

1. **What is the biological role of flowers, and what fundamental developmental shift must occur before an angiosperm can produce a flower?**
2. **Explain the steps leading to the formation of a mature male gametophyte, beginning with microsporocytes in a flower's anthers. Which structures are diploid and which haploid?**
3. **Trace the development of a female gametophyte, beginning with the megasporocyte in an ovule of a flower's ovary. Which structures are diploid and which haploid?**

36.3 Pollination, Fertilization, and Germination

The process by which plants produce seeds—which have the potential to give rise to new individuals—begins with **pollination,** when pollen grains make contact with the stigma of a flower. Air or water currents, birds, bats, insects, or other agents make the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

transfer. (Section 29.2 discussed the complex relationship between some flowering plants and their animal pollinators.)

Pollination is the first in a series of events leading to *fertilization,* the fusion of the haploid nuclei of an egg and sperm inside the flower's ovary. The resulting embryo and its ovule mature into a seed housing a young diploid sporophyte, and when the seed sprouts, or *germinates,* the sporophyte begins to grow. Before these events can unfold, however, certain "compatibility" requirements must be met.

Pollination Requires Compatible Pollen and Female Tissues

Even after pollen reaches a stigma, in most cases pollination and fertilization can take place only if the pollen and stigma are compatible. For example, if pollen from one species lands on a stigma from another, chemical incompatibilities usually prevent pollen tubes from developing.

In different angiosperm taxa, various mechanisms have evolved that limit or prevent inbreeding. For example, in monoecious species—in which, recall, individual plants produce flowers having either male *or* female reproductive parts—the stigmas of "female" flowers may be receptive to pollen a day or two before or after stamens of "male" flowers release pollen. In another mechanism, even when the sperm-bearing pollen and a stigma are "ready" at the same time, pollination may not lead to fertilization unless the pollen and stigma belong to genetically distinct individuals. In one such scenario, when pollen from a given plant lands on that plant's own stigma, a pollen tube may begin to develop, but stop before reaching the embryo sac. This **self-incompatibility** is a biochemical recognition and rejection process that prevents self-fertilization, and it apparently results from interactions between proteins encoded by *S* (self) genes.

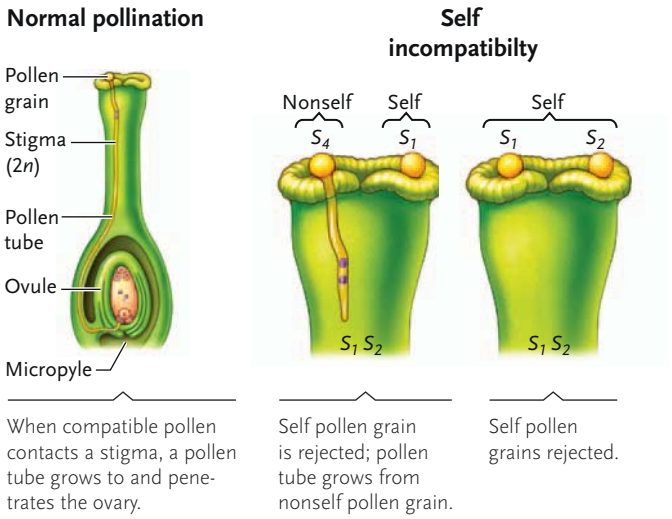

FIGURE 36.8 Self-incompatibility. When a pollen grain has an *S* allele that matches one in the stigma (which is diploid), the result is a biochemical response that prevents fertilization—in this illustration, by preventing the growth of a pollen tube.

© Cengage Learning 2014

Research has shown that *S* genes usually have multiple alleles—in some species there may be hundreds—and a common type of incompatibility occurs when pollen and stigma carry an identical *S* allele. The result is a biochemical signal that prevents proper formation of the pollen tube **(Figure 36.8).** For example, studies on plants of the mustard family have revealed that pollen contacting an incompatible stigma produces a protein that prevents the stigma from hydrating the relatively dry pollen grain, an essential step if the pollen tube is to grow. A wide range of self-incompatibility responses has been discovered, however. In cacao, for instance, when incompatible pollen contacts a stigma, a pollen tube grows normally but a hormonal response soon causes the flower to drop off the plant, preventing fertilization.

Self-incompatibility prevents inbreeding and promotes genetic variation, which is the raw material for natural selection and adaptation. Even so, many flowering plants do self-pollinate, either partly or exclusively, because that mode, too, has benefits in some circumstances. (Mendel's peas are a classic example.) For instance, "selfing" may help preserve adaptive traits in a population. It also reduces or eliminates a plant's reliance on wind, water, or animals for pollination, and thus ensures that seeds will form when conditions for cross-pollination are unfavorable, such as when pollinators or potential mates are scarce.

Double Fertilization Occurs in Flowering Plants

If a pollen grain lands on a compatible stigma, it absorbs moisture and germinates a pollen tube, which burrows through the stigma and style toward an ovule (see Figure 36.5 and **Figure 36.9A**). Chemical cues from the two synergid cells lying close to the egg cell help guide the pollen tube toward its destination. Before or during these events, the pollen grain's haploid sperm-producing cell divides by mitosis, forming two haploid sperm. When the pollen tube reaches the ovule, it enters through the micropyle and an opening forms in its tip. By this time one synergid has begun to die (an example of programmed cell death), and the two sperm are released into the disintegrating cell's cytoplasm. Experiments suggest that elements of the synergid's cytoskeleton guide the sperm cells onward, one to the egg cell and the other to the endosperm mother cell.

Next there occurs a remarkable sequence of events called **double fertilization (Figure 36.9B),** which has been observed only in flowering plants and (in a somewhat different version) in the gnetophyte *Ephedra* (see Section 29.2). Typically, one sperm nucleus fuses with the egg to form a diploid ($2n$) zygote. The other sperm nucleus fuses with the endosperm mother cell, forming a cell with a triploid ($3n$) nucleus. Tissues derived from that $3n$ cell are called **endosperm** (*endon* = within; *sperma* = seed). The endosperm nourishes the embryo and, in monocots, the seedling, until its leaves form and photosynthesis has begun.

The evolution of embryo-nourishing endosperm in angiosperms coincided with reduced size of the female gametophyte (see Figure 28.7). In other land plants, such as gymnosperms

CLOSER LOOK

FIGURE 36.9 Pollination and double fertilization.

Step 1. When compatible pollen contacts a stigma, chemical signals guide a pollen tube toward the ovary. The tube contains two haploid sperm nuclei.

Step 2. The growing pollen tube penetrates the ovary, reaches the micropyle, and passes through it into the ovule. At this point the sperm nuclei are released.

Step 1. One haploid sperm nucleus enters the endosperm mother (central) cell ($n + n$), forming a triploid ($3n$) cell from which nutritive endosperm develops. Later a seed will form as a seed coat encases the endosperm and embryonic sporophyte (see Figure 36.5).

Step 2. The other haploid sperm nucleus migrates through a synergid to the haploid egg. The egg is fertilized as its nucleus fuses with the sperm nucleus. The result is a diploid ($2n$) embryonic sporophyte.

SUMMARY Pollination of a compatible stigma triggers the growth of a pollen tube that delivers two haploid sperm nuclei to the ovule within an ovary. There one sperm nucleus fertilizes the egg and the other nucleus "fertilizes" the endosperm mother cell, triggering the development of endosperm. This process of double fertilization yields an embryonic sporophyte along with endosperm to nourish it.

THINK LIKE A SCIENTIST How can we learn more about chemical signals that guide the migration of a pollen tube toward the ovule?

© Cengage Learning 2014

and ferns, the gametophyte itself contains enough stored food to nourish the embryonic sporophytes. This observation suggests an adaptive advantage of double fertilization. While other seed plants expend energy on the development of a relatively large, nutrient-rich gametophyte that may or may not successfully contribute to reproduction, an angiosperm does not expend energy in filling an ovule with food reserves until after an egg has been fertilized.

The Embryonic Sporophyte Develops inside a Seed

When the zygote first forms, it starts to develop and elongate even before mitosis begins. For example, in shepherd's purse *(Capsella),* shown in **Figure 36.10,** most of the organelles in the zygote, including the nucleus, become housed in the top half of the cell, while a vacuole takes up most of the lower half (see Figure 36.10, step 1). The first round of mitosis divides the zygote into an upper *apical cell* and a lower *basal cell.* The apical cell then gives rise to the multicellular embryo, while most descendants of the basal cell form a simple row of cells, the **suspensor,** which transfers nutrients from the parent plant to the embryo (step 2).

The first apical cell divisions produce a globe-shaped structure attached to the suspensor. As they continue to grow, embryos of *Capsella* and other eudicots become heart-shaped (step 3). Each lobe of the "heart" is a developing cotyledon (seed leaf), which will provide nutrients for growing tissues in a germinating seedling. Typically, the two cotyledons absorb much of the nutrient-storing endosperm and become plump and fleshy. For instance, mature seeds of a sunflower *(Helianthus annuus)* have no endosperm at all. In some eudicots, however,

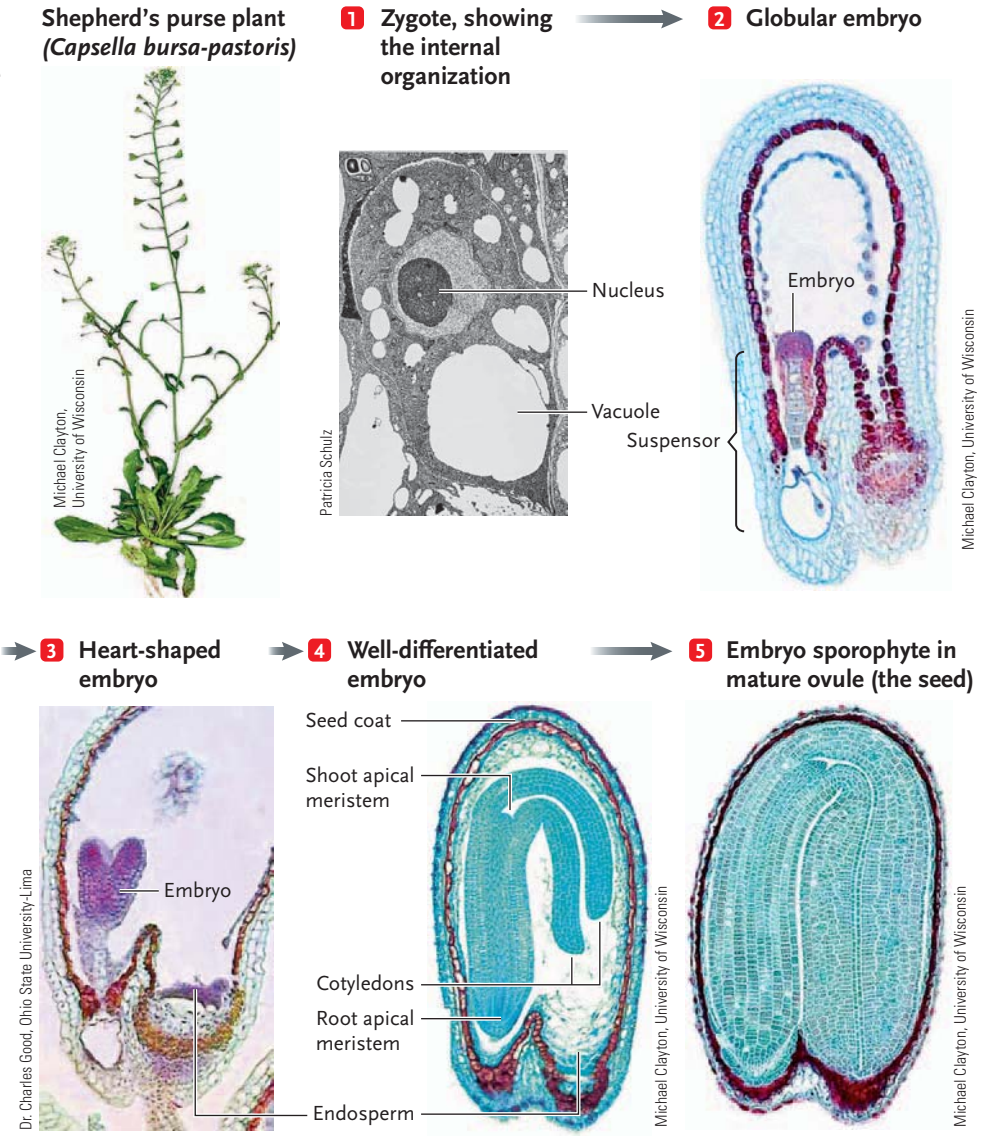

FIGURE 36.10 **Stages in the embryonic development of shepherd's purse *(Capsella bursa-pastoris)*, a eudicot.** The micrographs are not to the same scale. Figure 36.19 shows more detail of the development of early plant embryos.

the cotyledons remain as slender structures; they produce enzymes that digest the seed's ample endosperm and transfer the liberated nutrients to the seedling. Monocots have one large cotyledon; in many monocot species, especially grasses such as corn and rice, the cotyledon absorbs the endosperm after germination, when the embryo inside the seed begins to grow.

A **seed** is a mature ovule. By the time the ovule is mature, its integument has developed into a protective **seed coat.** The embryo inside the seed has a lengthwise axis with a root apical meristem at one end and a shoot apical meristem at the other (steps 4 and 5).

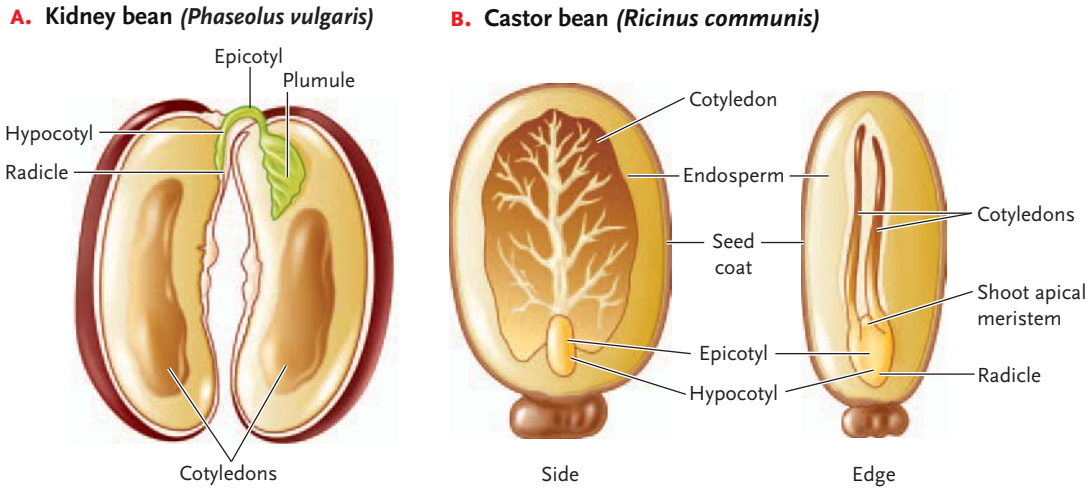

Figure 36.11A and **Figure 36.11B** show the structural organization of seeds of two eudicots, the kidney bean *(Phaseolus vulgaris)* and the castor bean plant *(Ricinus communis).* The embryo makes up nearly all of both types of seeds. A mature kidney bean embryo has broad, fleshy cotyledons, and none of the seed's endosperm remains to nourish it. A castor bean embryo has much thinner cotyledons that are surrounded by endosperm, but in other ways the embryos are quite similar. The **radicle,** or embryonic root, is located near the micropyle, where the pollen tube entered the ovule prior to fertilization. The radicle attaches to the cotyledon at a region of cells called the **hypocotyl.** Beyond the hypocotyl is the **epicotyl,** which has the shoot apical meristem at its tip and which often bears a cluster of tiny foliage leaves, the **plumule.** At germination, when the root and shoot first elongate and emerge from the seed, the cotyledons are positioned at the first stem node with the epicotyl above them and the hypocotyl below them.

Deconstructing the seed of a monocot can be a bit more complex. To begin with, we see a great deal of variation in the cotyledons of monocots—some are large and plump with stored endosperm, while others (such as seeds of orchids and onions) are extremely small and contain little or no food stores for the embryo. **Figure 36.11C** shows the specialized seed of a grass—corn—which includes several structures not seen in the seeds of other angiosperm taxa. Housed inside a kernel (a type of fruit called a *grain*) a corn seed contains a large store of endosperm. The embryo has only one very large cotyledon, a shield-shaped mass called a **scutellum,** which absorbs nutrients from the endosperm. In monocot embryos generally, protective tissues blanket the root and shoot apical meristems, and in grasses the shoot apical meristem and plumule are covered by a **coleoptile,** a sheath of cells that protects them during upward growth through the soil. A similar covering, the **coleorhiza,** sheathes the radicle until it breaks out of the seed coat and enters the soil as the young plant's primary root.

Fruits Protect Seeds and Aid Seed Dispersal

Like the corn seed in its kernel, most angiosperm seeds are housed inside fruits, which provide protection and often aid seed dispersal. A **fruit** is a matured or ripened ovary. Usually, a fruit begins to develop after pollination and the subsequent fertilization of an egg in a flower's ovule. The start of ovule growth after fertilization is called "fruit set." The fruit wall, called the **pericarp,** develops from the ovary wall and can have several layers. Hormones in pollen grains provide the initial stimulus

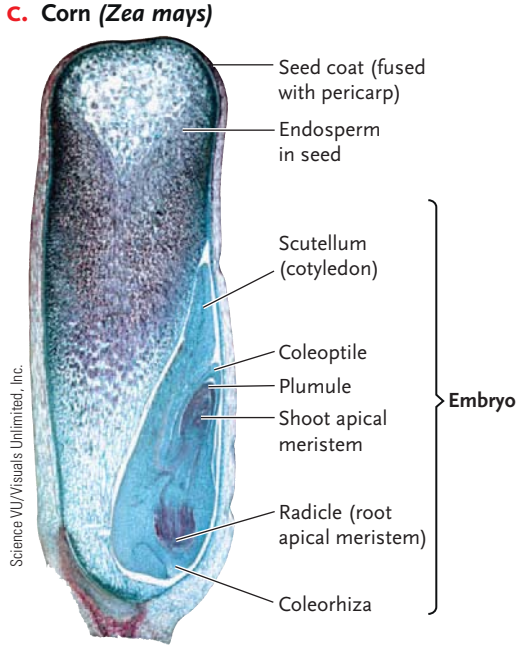

FIGURE 36.11 The structure of eudicot and monocot seeds. Eudicot seeds have two cotyledons, which store food absorbed from the endosperm, but the timing of this function varies in different species. **(A)** The cotyledons of a kidney bean *(Phaseolus vulgaris)* take up nutrients from endosperm while the seed develops, becoming fleshy. **(B)** In the castor bean *(Ricinus communis)*, the endosperm is thick and the cotyledons are thin until the seed germinates, when the cotyledons begin to take up endosperm nutrients. **(C)** A kernel of corn *(Zea mays)* contains a representative monocot seed, which has been isolated here and is shown in longitudinal section. Monocot seeds have a single cotyledon, which develops into a shield-shaped scutellum that absorbs nutrients from endosperm.

© Cengage Learning 2014

that turns on the genetic machinery leading to fruit development; additional signals come from hormones produced by the developing seeds.

Fruits are extremely diverse, and biologists classify them into types based on combinations of structural features. A major defining feature is the nature of the pericarp, which may be fleshy (as in peaches) or dry (as in a hazelnut). A fruit also is classified according to the number of ovaries or flowers from which it develops. **Simple fruits** develop from a single ovary. In many of them, such as peaches, tomatoes, and the cacao fruits pictured in Figure 36.1, at least one layer of the pericarp is fleshy and juicy. Other simple fruits, including grains and nuts, have a thin, dry pericarp, which may be fused to the seed coat (like it is in corn). The garden pea *(Pisum sativa)* is a simple fruit, the peas being the seeds and the surrounding shell the pericarp. **Aggregate fruits** are formed from several ovaries in a single flower. Examples are raspberries and strawberries, which develop from clusters of individual ovaries. Strawberries also qualify as *accessory* fruits, in which floral parts in addition to each ovary become incorporated as the fruit develops. For instance, anatomically, the fleshy part of a strawberry is an expanded receptacle (the end of the floral shoot) and the strawberry fruits are the tiny, dry nubbins (called *achenes*) you see embedded in the fleshy tissue of each berry. *Multiple fruits* develop from several ovaries in multiple flowers. For example, a pineapple is a multiple fruit that develops from the enlarged ovaries of several flowers clustered together in an inflorescence. **Figure 36.12** shows examples of some different types of fruits.

Fruits not only protect seeds—they also aid seed dispersal in specific environments. For example, maple fruits have wing-like extensions for dispersal (see Figure 36.12E). When the fruit drops, the wings cause it to spin sideways and downward and also can carry it away on a breeze. This aerodynamic property propels maple seeds to new locations, where they will not have to compete with the parent tree for water and minerals. Fruits also may have hooks, spines, hairs, or sticky surfaces, and they are ferried to new locations when they adhere to feathers, fur, or blue jeans of animals that brush against them. Fleshy fruits such as blueberries are nutritious food for many animals, and their seeds are adapted for surviving digestive enzymes in the animal gut. The enzymes remove just enough of the hard seed coats to increase the chance of successful germination when the seeds are expelled from the animal's body in feces.

Seed Germination Continues the Life Cycle

A mature seed is essentially dehydrated. On average, water accounts for only about 10% of its weight—too little for cell expansion or metabolism. Germination gets underway when the seed begins to soak up water. The hydrated embryo then resumes growth. Ideally, a seed germinates when external conditions favor the survival of the embryo and growth of the new sporophyte. This timing is important, because once germination is underway the embryo loses the protection of the seed coat and other structures that surround it. Overall, the amount of soil moisture and oxygen, the temperature, day length, and other environmental factors influence when germination takes place.

In some species, the life cycle may include a period of seed **dormancy** (*dormire* = to sleep), in which the seed's metabolic activity is suspended. The conditions required for dormant seeds to germinate vary widely. Depending on the species, seeds may require minimum periods of daylight or darkness, repeated soaking, mechanical abrasion, or exposure to certain enzymes, the high heat of a fire, or a freeze–thaw cycle before they finally break dormancy. A control system based on the hormone abscisic acid, or ABA, underlies the shift from active metabolism to dormancy, and then reactivation and germination. When environmental conditions—perhaps too-cold temperature or drought—do not favor the survival of a potential seedling, seeds produce high levels of ABA. The hormone in turn stimulates synthesis of a transcription factor that turns on germination-inhibiting genes. When conditions eventually favor a seedling's survival, the genes switch off and dormancy ends. Kenji Miura of the University of Tsukuba in Japan and Mike Hasegawa at Purdue University recently discovered that this reversal occurs when a regulatory protein binds the transcription factor. Then, the germination-inhibiting genes are no longer expressed and germination can begin.

In some desert plants, hormones in the seed coat inhibit growth of a seedling until heavy rains flush them away. This adaptation ensures that seeds germinate only when there is enough water in the soil to support growth of the plant through the flowering and seed production stages before the soil dries again. Many plants in harsh environments, such as deserts, cycle from germination to growth, flowering, and seed development in the space of a few weeks and their offspring remain dormant as seeds until conditions once again favor germination and growth.

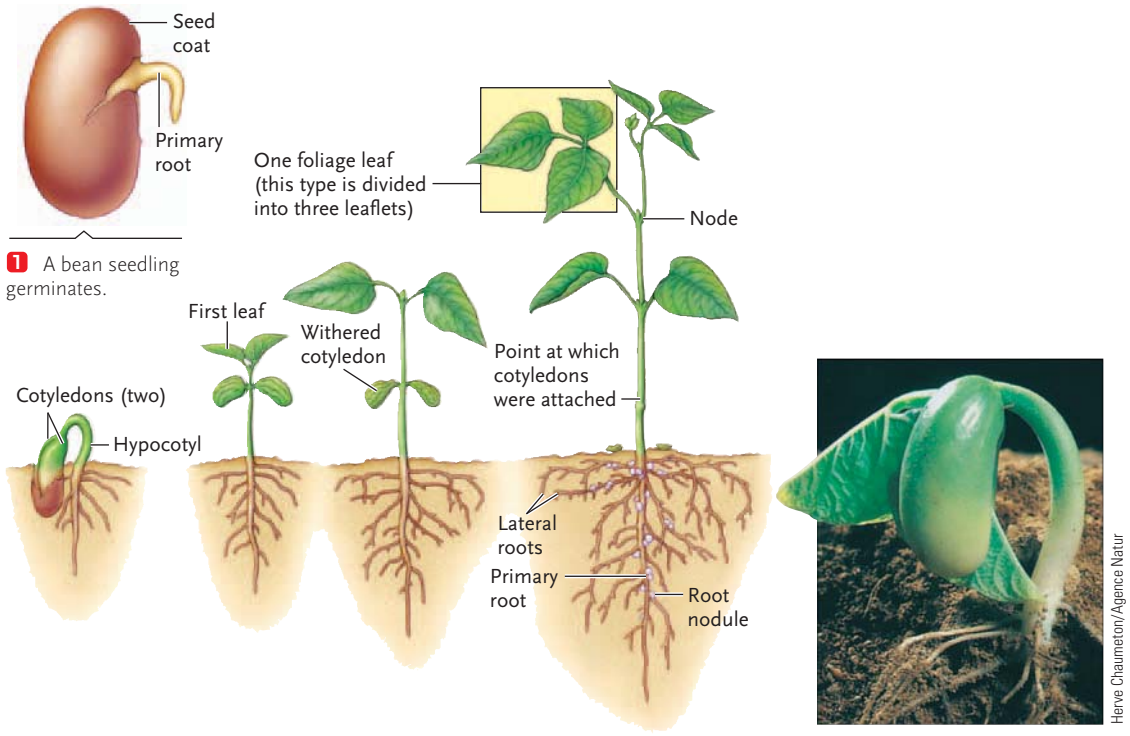
Seeds of some species appear to remain viable for amazing lengths of time. Thousand-year-old lotus seeds *(Nelumbo lutea)* discovered in a dry lakebed have germinated trouble-free. And in one startling case, seeds of arctic lupine *(Lupinus arcticus)* were discovered along with fecal material in 10,000-year-old lemming burrows. When the seeds were thawed, they germinated readily as well.

Germination begins with **imbibition,** in which water molecules move into the seed, attracted to hydrophilic groups of stored proteins. As water enters, the seed swells, the coat ruptures, and the radicle begins its downward growth into the soil. Within this general framework, however, there are many variations among plants.

Once the seed coat splits, water and oxygen move more easily into the seed. Metabolism switches into high gear as cells divide and elongate to produce the seedling. Stable enzymes that were synthesized before dormancy become active; other enzymes are produced as the genes encoding them begin to be expressed. Among other roles, the increased gene activity and enzyme production mobilize the seed's food reserves in cotyledons or endosperm. Nutrients released by the enzymes sustain the rapidly developing seedling until its root and shoot systems are established.

The events of seed germination have been studied extensively in grains, and **Figure 36.13** illustrates them in barley. The seed's endosperm is separated from the pericarp by a thin layer of cells called the **aleurone.** As a hydrating seed imbibes water, the embryo produces a *gibberellin,* a hormone that stimulates aleurone cells to manufacture and secrete hydrolytic enzymes. Some of these enzymes digest components of endosperm cell walls; others digest proteins, nucleic acids, and starch of the endosperm, releasing nutrient molecules for use by cells of the young root and shoot. Although it is clear that nutrient reserves are also mobilized by metabolic activity in eudicots and in gymnosperms, the details of the process are not well understood.



Inside a germinating seed, embryonic root cells are generally the first to divide and elongate, giving rise to the radicle. When the radicle emerges from the seed coat as the primary root, germination is complete. **Figure 36.14** and **Figure 36.15** depict the stages of early development in a kidney bean, a eudicot, and in corn, a monocot. As the young plant grows, its development continues to be influenced by interactions of hormones and environmental factors, as you will read in Chapter 37.

Most plants give rise to large numbers of seeds because, in the wild, only a tiny fraction of seeds survive, germinate, and eventually grow into another mature plant. Also, flowers, seeds, and fruits represent major investments of plant resources. Asexual reproduction, discussed next, is a more "economical" means by which many plants can propagate themselves.

STUDY BREAK 36.3

1. **Explain the sequence of events in a flowering plant that begins with formation of a pollen tube and culminates with the formation of a diploid zygote and the 3*n* cell that will give rise to endosperm in a seed.**
2. **Early angiosperm embryos undergo a series of general changes as a seed matures. Summarize this sequence, then describe the structural differences that develop in the seeds of monocots and eudicots.**
3. **Germination begins when a seed imbibes water. What are the next key biochemical and developmental events that bring an angiosperm's life cycle full circle?**

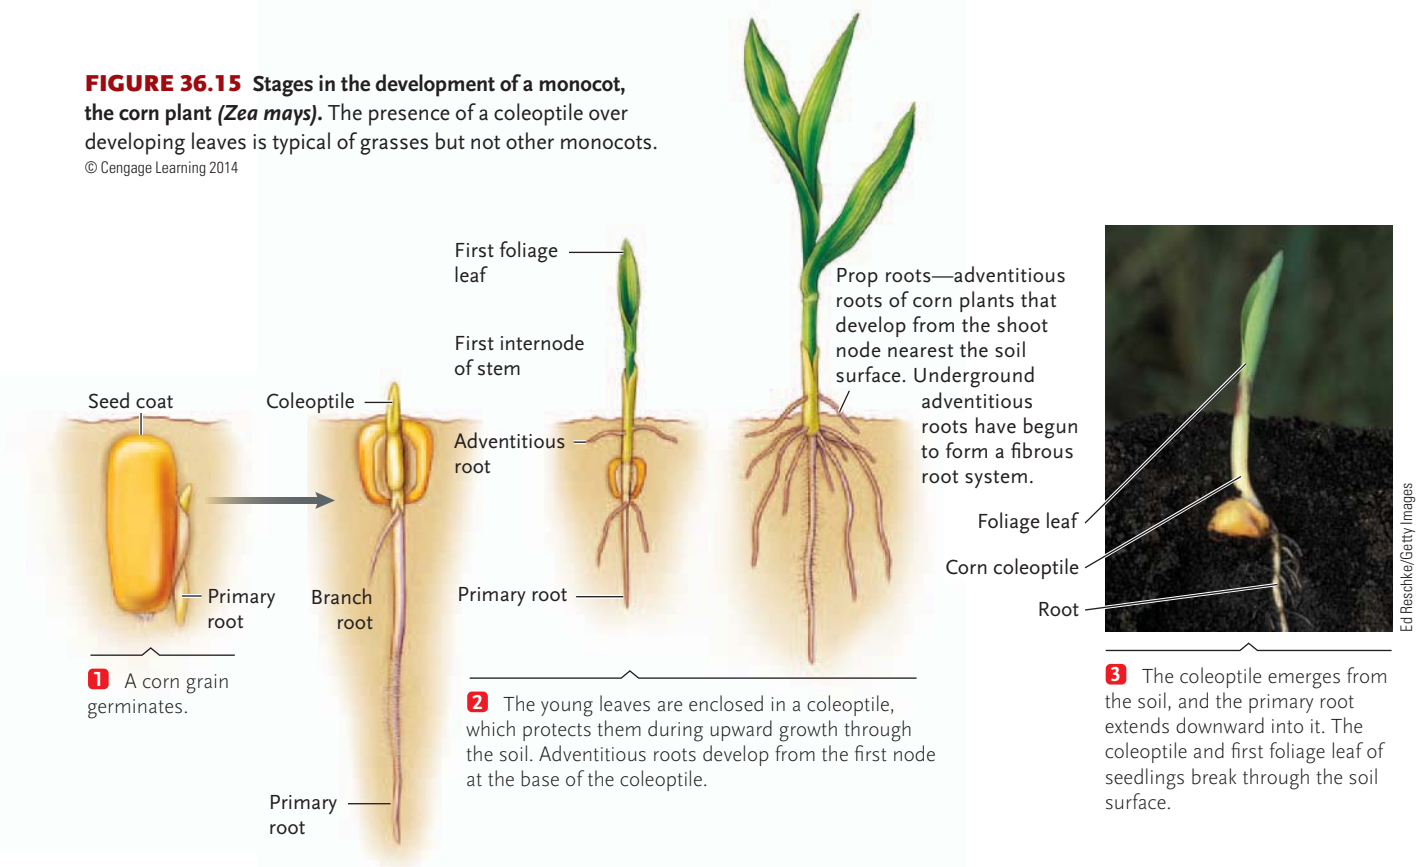
1 A bean seedling germinates.

2 Food-storing cotyledons are lifted above the soil surface when cells of the hypocotyl elongate. The hypocotyl becomes hook-shaped and forces a channel through the soil as it grows. At the soil surface, the hook straightens in response to light. For several days, cells of the cotyledons carry out photosynthesis; then the cotyledons wither and drop off. Photosynthesis is taken over by the first leaves that develop along the stem and later by foliage leaves.



3 Leaves break through the seed coat.

THINK OUTSIDE THE BOOK

For many perennial plant species in temperate and high-latitude regions, dormancy is a major adaptation for surviving low winter temperatures. However, cold winters do not occur at tropical latitudes. Using library or Internet research sources, find out if there are environmental conditions that trigger automatic dormancy in wild-growing tropical plants. What implications do your findings have for gardeners in your area who want to grow tropical species year round?

36.4 Asexual Reproduction of Flowering Plants

As we mentioned in Section 36.1, many flowering plants have the capacity for both sexual and asexual reproduction. Some flowering plants, including some citrus species and the grass variety known as Kentucky blue grass *(Poa pratensis),* can reproduce asexually through a mechanism called **apomixis,** in which there is no union of haploid maternal and paternal gametes. Typically, an embryo develops from an unfertilized egg (which is diploid due to a related shift in embryo sac development) or from diploid cells in the ovule tissue around the embryo sac. The resulting seed is said to contain a **somatic embryo,** which is genetically identical to the parent.

Another asexual alternative is **vegetative reproduction,** in which a new, genetically identical individual develops from a parent plant's nonreproductive tissue, usually a bit of meristematic tissue in a bud on the root or stem. Some of the stem modifications described in Section 33.3 function in this way. For instance, although strawberries can reproduce sexually by way of seeds, new roots and shoots also develop at each node along the stolons ("runners") a strawberry plant sends out. Likewise, new plantlets develop from "suckers" that sprout from the roots of blackberry bushes and "eyes" in the tubers of potatoes, or from buds on the short underground stems of onions and lilies.

Vegetative reproduction relies on an intriguing property of plants—namely, that many fully differentiated plant cells are **totipotent** (*totus* = all; *potens* = powerful). That is, they have the genetic potential to develop into a whole, fully functional plant. Under appropriate conditions, a totipotent cell can *dedifferentiate;* it returns to an unspecialized embryonic state, and the genetic program that guides the development of a new individual is turned on.

Vegetative Reproduction Is Common in Nature

Various plant species have developed different mechanisms for vegetative reproduction. In **fragmentation,** cells in a piece of the parent plant dedifferentiate and then can regenerate missing plant parts. Many gardeners have discovered to their frustration that a chunk of dandelion root left in the soil can rapidly grow into a new dandelion plant in this way. When a leaf falls or is torn away from a jade plant (*Crassula* species), a new plant can develop from meristematic tissue that is adjacent to the wound surface in the detached leaf. The "mother of thousands" plant, *Kalanchoe daigremontiana,* produces a wealth of seeds, while more or less simultaneously meristematic tissue in notches along the leaf margin gives rise to tiny plantlets **(Figure 36.16)** that eventually fall to the ground, where they can sprout roots and grow to maturity.

Ed Reschke

FIGURE 36.16 ***Kalanchoe daigremontiana*, the mother-of-thousands plant.** Each tiny plant growing from the leaf margin can become a new, independent adult plant.

In wild plant species, most types of asexual reproduction result in offspring located near the parent. As already noted, these clonal populations lack the variability provided by sexual reproduction, variation that enhances the odds for survival when environmental conditions change. Yet asexual reproduction offers an advantage in some situations. It usually requires less energy than producing complex reproductive structures such as seeds and showy flowers to attract pollinators. Moreover, clones are likely to be well suited to the environment in which the parent grows. In addition, it may allow the rapid colonization of disturbed habitats, where seeds might be blown or washed away.

Plant Cell Culture

Purpose: To determine if differentiated plant cells can be returned to a totipotent state.

Protocol: Fragments of tissue are excised from a plant and grown in a medium that contains all required nutrients. The procedure disrupts normal interactions among the excised cells. They dedifferentiate, forming an unorganized callus. When cells removed from the callus are grown in a medium containing nutrients and hormones, some develop into plantlets.

Interpreting the Results: Because some cells derived from the callus can give rise to plantlets, they must have regained totipotency.

Many Commercial Growers and Gardeners Use Artificial Vegetative Reproduction

For centuries, gardeners and farmers have used asexual plant propagation to grow particular crops and trees and some ornamental plants. They routinely use *cuttings,* pieces of stems or leaves, to generate new plants. Placed in water or moist soil, a cutting may sprout roots within days or a few weeks. Virtually the entire world supply of commercially sold bananas is harvested from plants grown from cuttings of a single variety called the "Cavendish banana." Because the tens of millions of plants that produce this banana are genetically uniform, the plants lack genetic diversity that would provide some measure of adaptive insurance against harmful fungi and other pests. As a result, by some estimates bananas are the most heavily pesticide-treated fruit in the global marketplace.

Fruit trees and wine grapes often are propagated by grafting a bud or branch from a plant with desirable fruit traits—the *scion*—and joining it to a root or stem from a plant with useful root traits—the *stock.* A grafted plant usually produces flowers and fruit identical to those of the scion's parent plant. The scion of a grafted wine grape or walnut variety may be chosen for the quality of its fruit, and the stock for its hardy, disease-resistant root system **(Figure 36.17).** Vegetative propagation can also be used to grow plants from single cells. Rose bushes and fruit trees from nurseries and commercially important fruits and vegetables such as Bartlett pears, McIntosh apples, Thompson seedless grapes, and asparagus come from plants produced vegetatively in tissue culture conditions that cause their cells to dedifferentiate to an embryonic stage.

VEGETATIVE PROPAGATION IN TISSUE CULTURE In groundbreaking experiments in the 1950s, Frederick C. Steward explored the totipotency of plant cells. Together with his coworkers at Cornell University, Steward propagated whole carrot plants in the laboratory by culturing carrot root phloem. Later researchers confirmed that almost any plant cell that has a nucleus and lacks a secondary cell wall may be totipotent.

The method of plant tissue culture Steward pioneered is simple in its general outlines **(Figure 36.18).** Bits of tissue are excised from a plant and grown in a nutrient medium. The procedure disrupts normal interactions between cells in the tissue sample, and the cells dedifferentiate and form an unorganized, white cell

mass called a **callus.** When cultured with nutrients and growth hormones, some cells of the callus regain totipotency and develop into plantlets with roots and shoots.

Steward's work laid the foundation for large-scale commercial applications of plant tissue culture, as well as for a whole new field of research on *somatic embryogenesis* in plants. Single cells derived from a callus generated from shoot meristem are placed in a medium containing nutrients and hormones that promote cell differentiation. With some species, totipotent cells in the sample eventually give rise to diploid somatic embryos that can be packaged with nutrients and hormones in artificial "seeds" (see Figure 36.18). Endowed with the same traits as their parent, crop plants grown from somatic embryos are genetically uniform.

However, mutations often occur in the DNA of somatic embryos derived from callus culture. Screening techniques can identify such *somaclonal* mutants with desirable traits—for example, resistance to a disease that attacks wild-type plants of the same species. In plants that are infected with viruses, callus cultures can be restricted to virus-free cells and thus generate virus-free clones. Tissue culture propagation can then produce hundreds or thousands of identical plants from a single specimen. This technique, called **somaclonal selection,** is now a staple tool in efforts to improve major food crops, such as corn, wheat, rice, and soybeans. It is also being used to rapidly increase stocks of hybrid orchids, lilies, and other valued ornamental plants. The yellow and orange tomatoes that have become common in produce markets are the fruits of plants developed by somaclonal selection.

Research on tobacco and some other species has shown that plants can also be regenerated by **protoplast fusion.** In this method, the walls of living cells in solution are first digested away by enzymes, leaving the protoplasts. Then the protoplasts are induced to fuse, either by applying an electric current, a laser beam, or chemical additives to the solution, which briefly "loosen" the plasma membranes. The resulting cell (now 4*n,* or tetraploid) is transferred to a solid nutrient medium and allowed to develop into a callus, then individual callus cells are stimulated to develop into embryos. If the fused protoplasts come from somatic cells of a single species, the embryos often grow into fertile plants. It has proven more difficult to grow fertile hybrids from fused protoplasts of different species and genera, probably because there are species-specific signals that govern key physiological functions. Even so, this method has produced the pomato, a cross between a potato and a tomato.

Regardless of how it comes into being, an embryonic sporophyte changes significantly as it begins the developmental journey toward maturity, when it will be capable of reproducing. Next we explore what researchers are learning about these developmental changes.

STUDY BREAK 36.4

1. **Describe three modes of asexual reproduction that occur in flowering plants.**
2. **What is totipotency, and how do methods of tissue culture exploit this property of plant cells?**

36.5 Early Development of Plant Form and Function

Unlike animals, plants have specialized body parts such as leaves and flowers that may arise from meristems throughout an individual's life—sometimes for thousands of years. Accordingly, in plants the biological role of embryonic development is not to generate the tissues and organs of the adult, but to establish a basic body plan—the root–shoot axis and the radial, "outside-to-inside" organization of epidermal, ground, and vascular tissues (see Section 33.1)—and the precursors of the primary meristems. Though they may sound simple, these fundamentals and the stages beyond them all depend on an intricately orchestrated sequence of molecular events that plant scientists are exploring through sophisticated experimentation.

One of the most fruitful approaches has been the study of plants with natural or induced gene mutations that block or otherwise affect steps in development—and accordingly give researchers insight into the developmental roles of the normal, wild-type versions of those abnormal genes. Some of these genes are **homeotic genes,** regulatory genes in the genome of an organism that encode transcription factors. The transcription factors are proteins that control the expression of other genes, which in turn direct events in development (see Chapter 16 for a general introduction, and *Focus on Research* in Chapter 33). While researchers work with various species to probe the genetic underpinnings of early plant development, the thale cress *(Arabidopsis thaliana)* has become a favorite model organism for plant genetic research (see *Focus on Basic Research*).

Within Hours, an Early Plant Embryo's Basic Body Plan Is Established

The entire *A. thaliana* genome has been sequenced, providing a powerful molecular "database" for determining how various genes contribute to shaping the plant body. Experimenters' ability to trace the expression of specific genes has shed considerable light on how the root–shoot axis is set and how the three basic plant tissue systems arise.

THE ROOT–SHOOT AXIS Shortly after fertilization gives rise to an *A. thaliana* zygote, the single cell divides. Electron microscopy shows that, as with the *Capsella* zygote described earlier, this first round of mitosis produces a small apical cell and a larger basal cell **(Figure 36.19A).** The apical cell receives the lion's share of the cytoplasm, while the basal cell receives the zygote's large vacuole and less cytoplasm. Researchers have confirmed that in this asymmetrical division of the zygote, the daughter cells receive different mixes of mRNAs—the gene transcripts that will be translated into proteins.

Translation of differing mRNAs produces proteins that include several transcription factors. As these factors trigger the expression of differing genes, distinct biochemical pathways unfold in the two cells in ways that establish the organization of the plant body. For example, a basal cell initially exports a
