List of Colour Plates

All colour plates appear between 468 and 469.

16.1

Hair loss over legs and perineum associated

31.6

Haemorrhage at the sole ulcer site and in

with steatorrhea and diarrhoea.

white line.

16.2

Alopecia due to poorly dispersed fats from

31.7

Typical sole ulcer.

milk subsitute.

31.8

Heel ulcer and early sole ulcer haemorrhage.

16.3

Rumen bloat and chronic scour.

31.9

Typical white line separation with impacted stone.

16.4

Calf *in extremis*.

31.10

Rings on a cow’s horns demonstrate disruption

16.5

Abomasum at necropsy.

of horn formation in the periparturient animal.

16.6

Chronic peri-weaning calf diarrhoea.

31.11

Cows prefer to walk on the soft surface of a

23.1

Lumen and keratinized lining in teat duct.

rubber mat.

23.2

Signs of clinical mastitis.

31.12

Cows walking along the grass verge to avoid

27.1

Early stages of bovine herpes mammillitis.

the stony track.

27.2

Bovine herpes mammillitis (two days).

31.13

Digital dermatitis and slurry heel.

27.3

Bovine herpes mammillitis (four days).

31.14

A vertical fissure.

27.4

Bovine herpes mammillitis and scab formation.

31.15

Axial wall fissure.

27.5

Bovine herpes mammillitis (about seven days).

31.16

Interdigital necrobacillosis.

27.6

Bovine herpes mammillitis (about two weeks).

31.17

The chronic ‘hairy wart’ form of digital dermatitis.

27.7

Bovine herpes mammillitis (two to three

31.18–19

Necrosis of the apex of the pedal bone.

weeks).

31.20

Insertion of a tube to flush and drain deep

27.8

Bovine herpes mammillitis – teat after

pedal infections.

shedding necrotic tissue.

40.1

Classification and grading of embryos.

27.9

Pseudocowpox.

44.1

Anthrax bacillium.

27.10

Pseudocowpox lesion (seven days).

44.2

Blackleg due to *Clostridium chauveoi*.

27.11

Pseudocowpox (10–12 days).

44.3

Endocarditis.

27.12

Pseudocowpox scab.

50.1

Generalized *Trichophyton verrucosum* infection.

27.13–16

Atypical Pseudocowpox lesions.

50.2

Trichophyton verrucosum infection on calf’s head.

27.17

Cowpox showing vesicle development.

50.3

Linognathus vituli lice and ova on calf.

27.18

Cowpox following vesicle rupture.

50.4

Sarcoptes scabiei infection.

27.19

Cowpox with scab formation.

50.5–6

Generalized sarcoptic scabies.

27.20

Severe cowpox.

50.7

Nodular lesions of demodicosis.

27.21

Staphylococcus aureus infection of teat.

50.8–9

Viral papillomatosis.

27.22

Teat chaps.

50.10

Pruritis/pyrexia/haemorrhagic syndrome.

27.23

Photosensitization of the teat.

50.11–12

Severe photodermatitis.

27.24

Foot-and-mouth disease – vesiculation of the teat.

50.13–14

Dermatophilosis.

27.25

Pseudocowpox infection with cowpox infection.

52.1

Cyclopia.

27.26

Pseudocowpox infection with bovine herpes

52.2

Esotropia: (a) early; (b) marked.

mammillitis.

52.3

Epibulbar dermoid.

27.27

Blackspot of a teat orifice.

52.4

Infectious bovine keratoconjunctivitis.

27.28

Mud abrasion of the teat.

52.5

Squamous cell carcinoma.

27.29

Ringworm lesions.

52.6

Anterior uveitis secondary to septicaemia of

27.30

Thelitis and serous exudate in peractute mastitis.

undetermined aetiology.

27.31

Filamentous papillomatosis of the teat.

52.7

Congenital cataract.

27.32

Nodular papillomatosis of the teat.

52.8

Lens discision.

31.1

Hoof with corium removed.

52.9

Papillary coloboma.

31.2

Cross-section of white line.

52.10

Normal bovine fundus.

31.3

Gross claw overgrowth.

52.11

Severe papilloedema with disc haemorrhages.

31.4

Overgrowth from the sole.

65.1

Acupuncture to treat anoestrus.

31.5

White line across a square-ended toe.

65.2

Stomach 36 acupuncture point.

a Figures on a different basis to previously.

began to operate as fully independent businesses from 1 April 2000. There has since been more rationalization and mergers, with one group involved in milk purchase in Scotland, England and Wales becoming known as British Milk. Some milk purchasers now have their headquarters outside the UK.

The last few years have seen many milk purchasers buying milk from individual farmers or small groups or farmer clubs. In the early part of the twenty-first century the number of purchasers has been reducing and farmers are starting to combine in co-operatives to provide more negotiating power with the purchasers. Milk is now purchased in varying ways, but is usually paid for according to its composition, cell count and bacterial count (undertaken in the UK by a Bactoscan, see Chapter 25). There are also seasonality payments.

Milk utilization

Fig. 4.2

A modern butter-making creamery produces and packs 5 tonnes of butter an hour.

While milk production has increased over the last 25
years, milk consumption has slightly reduced. The
amount used as liquid milk has declined from 73 to 45
per cent. However, because of quotas this percentage

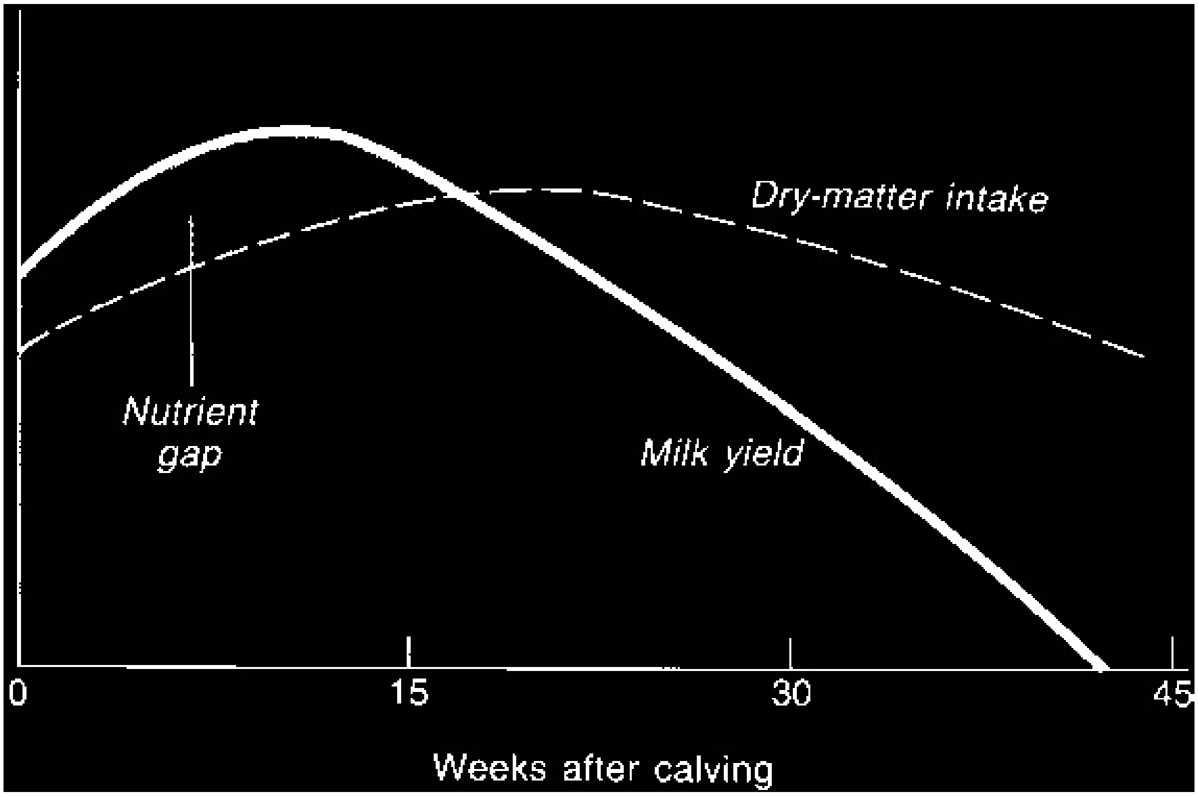
able within the rumen and is given as quickly degrad-
This will contribute about 28 MJ of ME per kg live-
able protein (QDP) and slowly degradable protein
weight loss. Estimated energy requirements are shown
(SDP). These two (QDP + SDP) form what is known as
in Table 4.9. Thus, for example, a 600 kg Friesian cow
the effective rumen degradable protein (ERDP). A cow
producing 20 kg/day of milk, in calf and gaining 0.5 kg/
has a need for both rumen degradable protein (both
day liveweight would require:
quick and slow) and rumen undegradable protein.



Different feeds contain different proportions or ratings

for the first 120 days of lactation. As yield declines and

of these. Thus silage is about 80 per cent degradable and
appetite increases then balance should be reached
soya is about 60 per cent degradable. Also, degradabil-

the rest of the EU finally in 2001. The EU also decided

farmers feed at least partly to yield. In most instances

to ban the use of fishmeal in ruminant diets from 1

January 2001, resulting in the loss of a major practical

source of UDP. However, it may return.

Feeding strategies

Many textbooks have been written on strategies for feeding dairy cows. The main principles are (i) to maximize DMI and (ii) to provide the cow's requirements as cheaply as possible. These two requirements are associated as the higher the DMI then the lower the energy concentration in the diet and hence the cheaper the production of the ration.

In early lactation of high-yielding cows, it will be difficult to satisfy their requirements within appetite. This

will result in a loss of bodyweight, perhaps 0.5 kg/day,

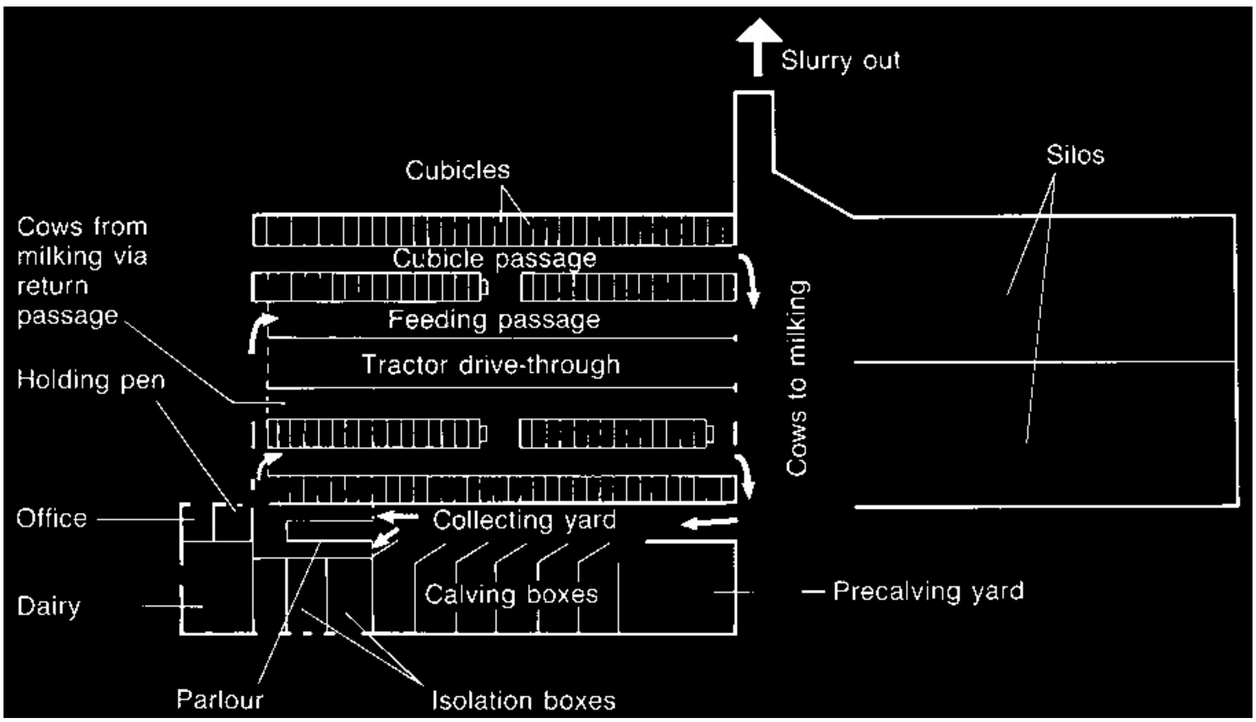

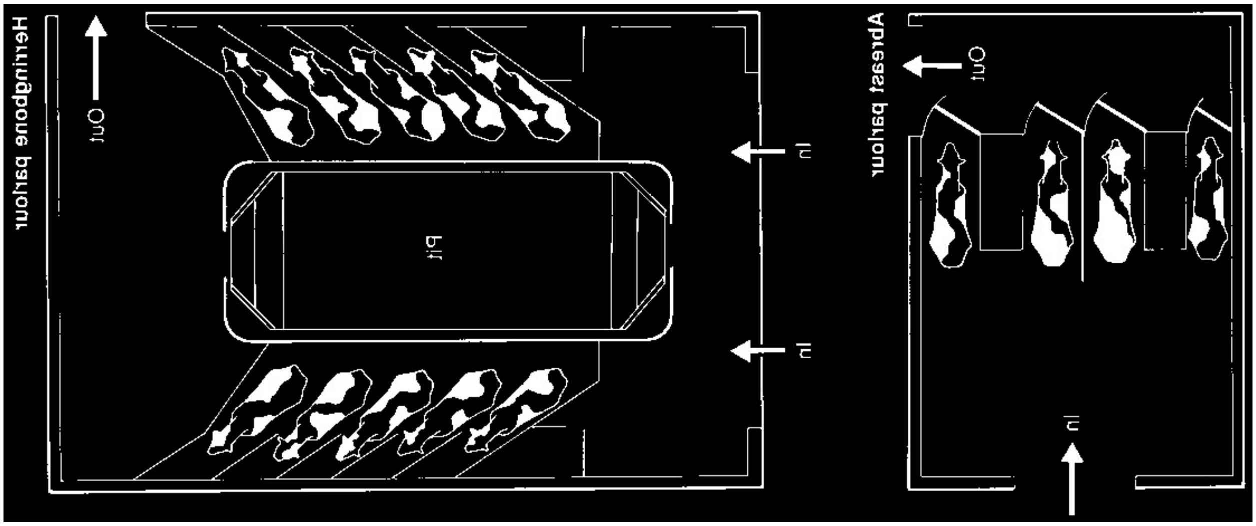

Fig. 4.17

Typical layout of a dairy unit.

feeding barn, food storage area, calving and isolation boxes, slurry handling area and various collecting yards and access concrete. A typical set of dairy buildings is shown in Fig. 4.17.

Important considerations when designing a dairy unit include the following.

- Cow-free access for the milk tanker so that collection can be made at any time.
- Good cow flow so that cows come from the bedded area through the parlour and back with a minimum of narrow passages and sharp corners.

• Good feeding access so that cows can be fed without having to work amongst them.

• Access to silage storage areas away from the cows so that silage making can take place while the cows are in the yards or in for milking.

• Good handling arrangements for veterinary treatment and AI.

• Adequate slurry storage as spreading may be restricted in nitrogen vulnerable zones.

• Thought should be given to the way the buildings blend in with the surroundings. Choice of materials and site are important.

• Adequate loose boxes for calving, sick animals, etc.

Parlour and dairy

This is the key to the whole dairy unit, being used twice (or three times) a day 365 days of the year. Cowsheds are very labour intensive and outdated while rotary parlours in the past have proved unreliable, with no benefits over a static parlour but are now becoming more common again. Automatic (robotic) parlours are also now being introduced. Figure 4.18 shows the most common parlours used, an abreast and a herringbone parlour.

Fig. 4.18

An abreast and a herringbone parlour.

The most simple parlour is the abreast, which is particularly suitable for herds of up to 80 cows with one man milking either with three milking units and six standings or six units and six standings. The cows enter and leave one at a time so a degree of individual treatment for a slow milker or slow eater is possible. The parlour should have a loft above to hold the concentrates, which fall by gravity to the feeder situated between each pair of cows. Milking rate will be about 30–40 cows/hour.

In a herringbone parlour, by far the most common, the milker stands in a pit, which removes most of the bending required. The cows come in and out of the parlour in batches and stand at an angle to the pit on either side. A herringbone parlour is suitable for any sized herd and one man could comfortably milk 100 cows in two hours with a 10 : 10 herringbone, i.e. 10 milking units, 10 standings. For 300 cows or more larger herringbones with two or three milkers are common. A loft above the parlour will hold the concentrates and each standing will have a feeder. In some parlours feeding has been discontinued.

Automatic cluster removers (ACRs) are now available that make it possible for one man to handle more machines without the danger of overmilking.

Fig. 4.19

A feed/sleep arrangement with metal cubicles.

In any parlour the work routine is to let the cow or group of cows in, feed them, dry wipe the udder or wash

and dry if dirty, wash the udder, test the foremilk, attach
3 tonnes per cow), which creates work to cart in and
the cluster, remove the cluster, teat dip or spray, trans-

driving through the cows and it is also possible to split

4.14). They can result in rapid improvement of locomo-

tion scores, and considerably reduce lameness due to

white line disease and solar ulceration (Hughes, 2000).

However, mastitis levels can rapidly increase, particu-

larly due to *Strep. uberis* and *E. coli*, unless great care is taken in producing a satisfactory straw bed. The keys to

success include making available a large quantity of

straw for each cow (about 2.5–3 tonnes) and ensuring

that it is kept dry when stored and the bed remains dry.

Regular cleaning out every 4–6 weeks may help prevent

mastitis problems, but this is possibly less important than

the quality of the straw used. Good ventilation is also

required to help keep the straw bed dry.

Feed storage area

The major item here is the silage storage facility. This can range from a tower silo to a simple hardcore pad.

Fig. 4.20

A metal cubicle division.

Construction of a simple silo is worthwhile to make handling easier and to prevent waste. Clamp silos are the most common and are usually constructed with a concrete base and walls of earth, sleepers or concrete. Safety is essential and in Britain walls must be up to DEFRA (Department for the Environment, Food and Rural Affairs) standards bearing in mind the walls have to contain not only the weight of the silage but also pressure from the tractor when consolidating the clamp. For open silos, guide rails must be provided 900 mm above the wall and for roofed silos sufficient height (5.5 m) must be allowed for tractor clearance. All effluent must be contained in a sealed tank that can be pumped out. For self-feeding of silage the height of clamp must not

cows can be restrained for veterinary treatment or

insemination. They require a separate air space.

Boxes should be reasonably spacious and must have

a tying-up ring or some other method to aid cow

restraint. Walls must be rendered so that disinfection

can take place. It is also useful to have a water bowl and

feed rack, tractor access for cleaning out and, maybe, a

milking point so that cows can be milked in the box.

Sick cows may die or have to be destroyed in the boxes

so good access for the slaughterer’s lorry is essential.

For a herd with spread calving pattern, one box for every 40–50 cows should suffice. Placing hinges and a swinging gate against a wall with the fixed end about 0.5 m (2 ft) from a corner is a useful method of restraint. It allows the gate to be swung round to restrain a cow between the gate and the wall.

Fig. 4.23

Sleep and feed arrangements.

Slurry

With more and more farmers using a loose housing and cubicle system, disposal of slurry is becoming an increasing problem. Also, water authorities are rightly are to be stored they must be kept in buildings which demanding more control of pollution. A dairy cow will can be made vermin-free so that the feed remains clean produce about 7000–8000 l (7–8 m3) of slurry over a and dry.

winter. This has quite a high fertilizer value (10 000 l will contain 25 kg N, 10 kg P2O5, 45 kg K2O) but much of this will be lost by leaching if it is spread during the winter

yard (reprinted from Hughes, 2000).

Slurry is usually scraped with a tractor-mounted squeegy to the store. The store must be able to cope with slurry, water, waste feed and bedding. It will reduce the volume considerably if clean water from roofs is diverted to a separate soak-away or drain.

Long-term storage can be provided in a sealed tower or a storage compound. With a slurry tower, the slurry is scraped into a reception pit and then pumped into the sealed tower. This is kept agitated to prevent settling or crusting of material. For emptying, the slurry runs back by gravity to the reception pit and is then pumped into the slurry spreader. It provides a good pollution-free system but is expensive to install and can create problems if management is not good leading to crusting and blockage of pumps.

By contrast the storage compound, although not

cheap to construct, provides a simple-to-manage system

throughout the rearing period.

A detailed description of the management and

targets required for autumn-born heifers reared to

months. It is known that the average life expectancy

calve at two years is given in this chapter. The pattern

of two-year calvers is greater and the lifetime milk

of growth and targets for weight-for-age for spring-born

production higher than heifers calving at three years

heifers calving at two years are similar. There is less

(Table 4.17).

pressure to maintain steady weight gains when the aim

There are a few circumstances when it is preferable is to calve at an older age and there are periods when

to adopt a policy of calving heifers at two and a half to

lower growth rates are acceptable.

three years. Calving at an older age reduces the man-

agement pressures imposed by the two-year system and

Age at calving

permits the utilization of marginal land unsuitable

for cropping. It also enables replacements to be taken

from cows of high genetic merit even if they calve

The younger a heifer is at calving the less land, housing

later in the season. Calving at three years can only be

higher incidence of calving problems can be expected

and subsequent milk yields are disappointing. With

a high stocking rate of 0.4 ha/livestock unit, the area

Month of calving

of land required for each replacement unit is 0.4 ha for

heifers calving at two years, 0.5 ha for heifers calving

Most dairy farmers plan to calve their heifers in a batch at two and a half years and 0.7 ha for heifers calving at at one season of the year. Autumn-calving herds find three years. When the stocking rate is 0.5 ha/livestock difficulty in maintaining this seasonality in the pattern unit the area required for heifers calving at three years of calving unless either herd fertility is high or a is twice that required for heifers calving at two. The proportion of the calves reared for replacements are housing and capital required to sustain a two year system taken from heifers. The optimum month of calving is also reduced. For instance, a 100 cow, autumn-calving varies with the relative prices of milk and compound herd calving at two years needs 40 replacements requir- feed and with the management pressures from other ing accommodation for calves and yearling heifers. enterprises. Once the optimum month of calving for a However, a similar herd calving at three years must herd has been established the heifers should be mated maintain 60 heifers and house the third-year heifers to calve at the same time or shortly before the earliest during their third winter when space requirements are

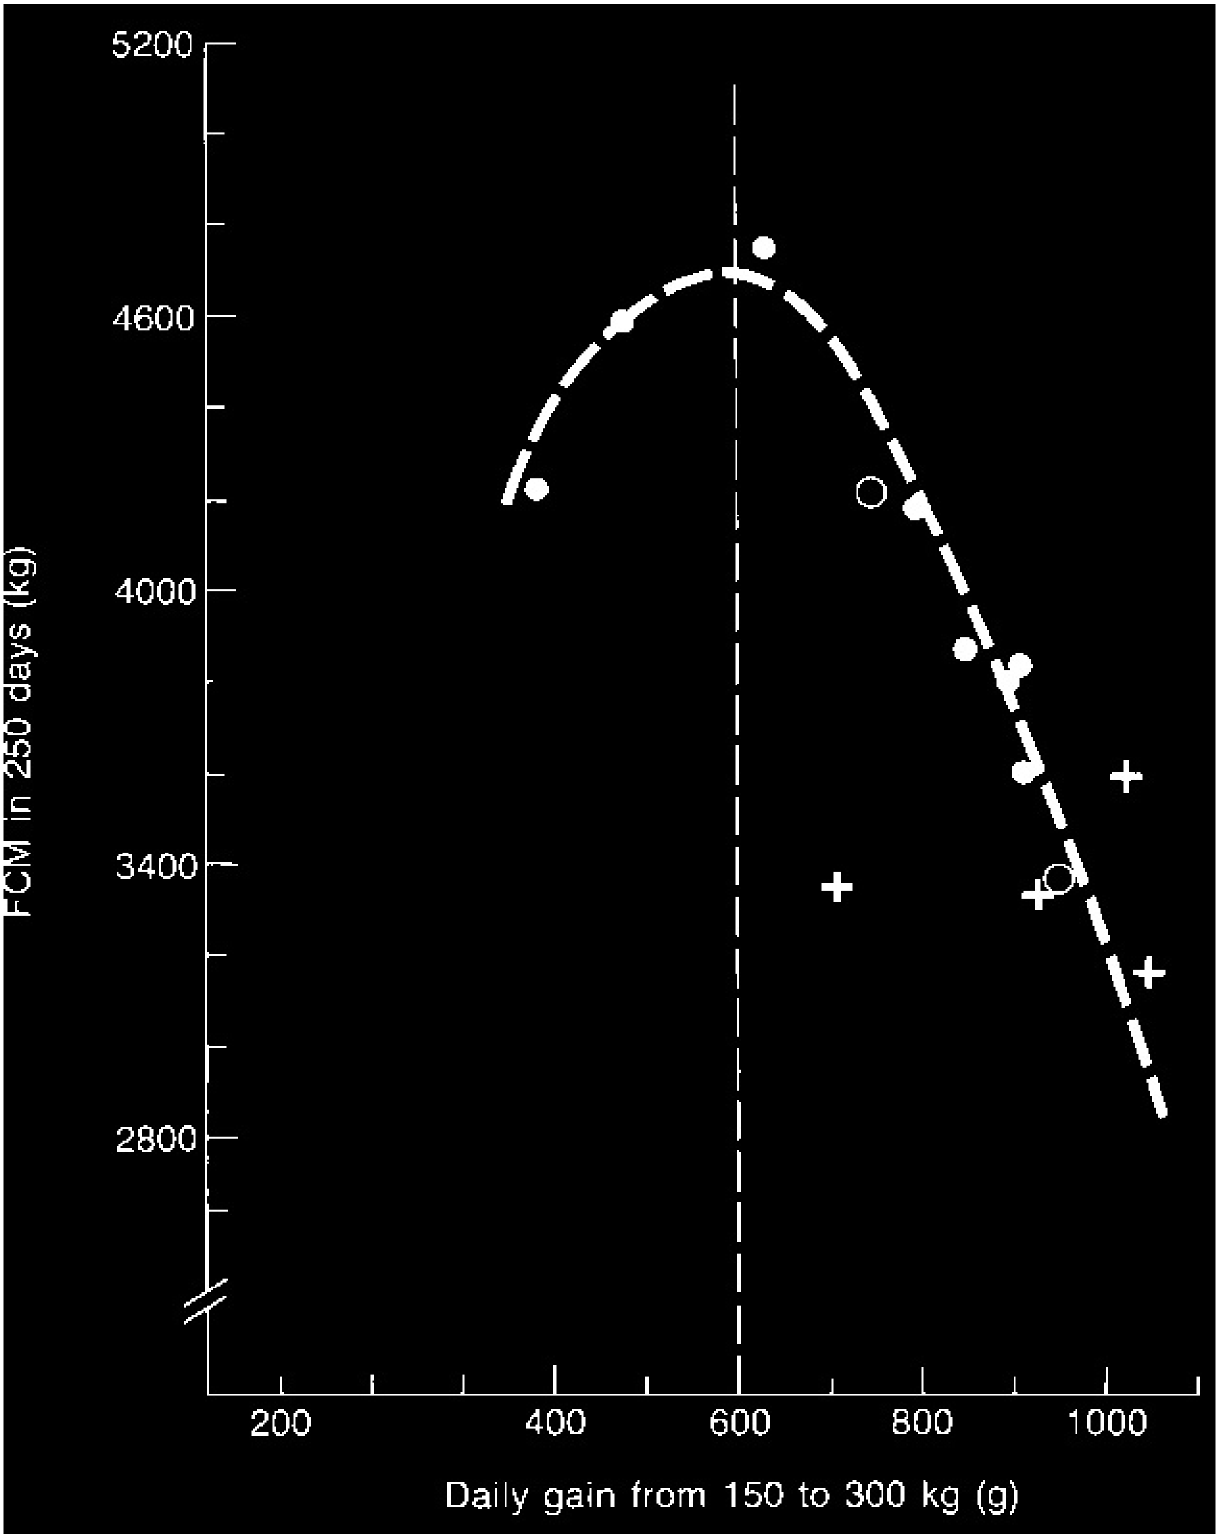
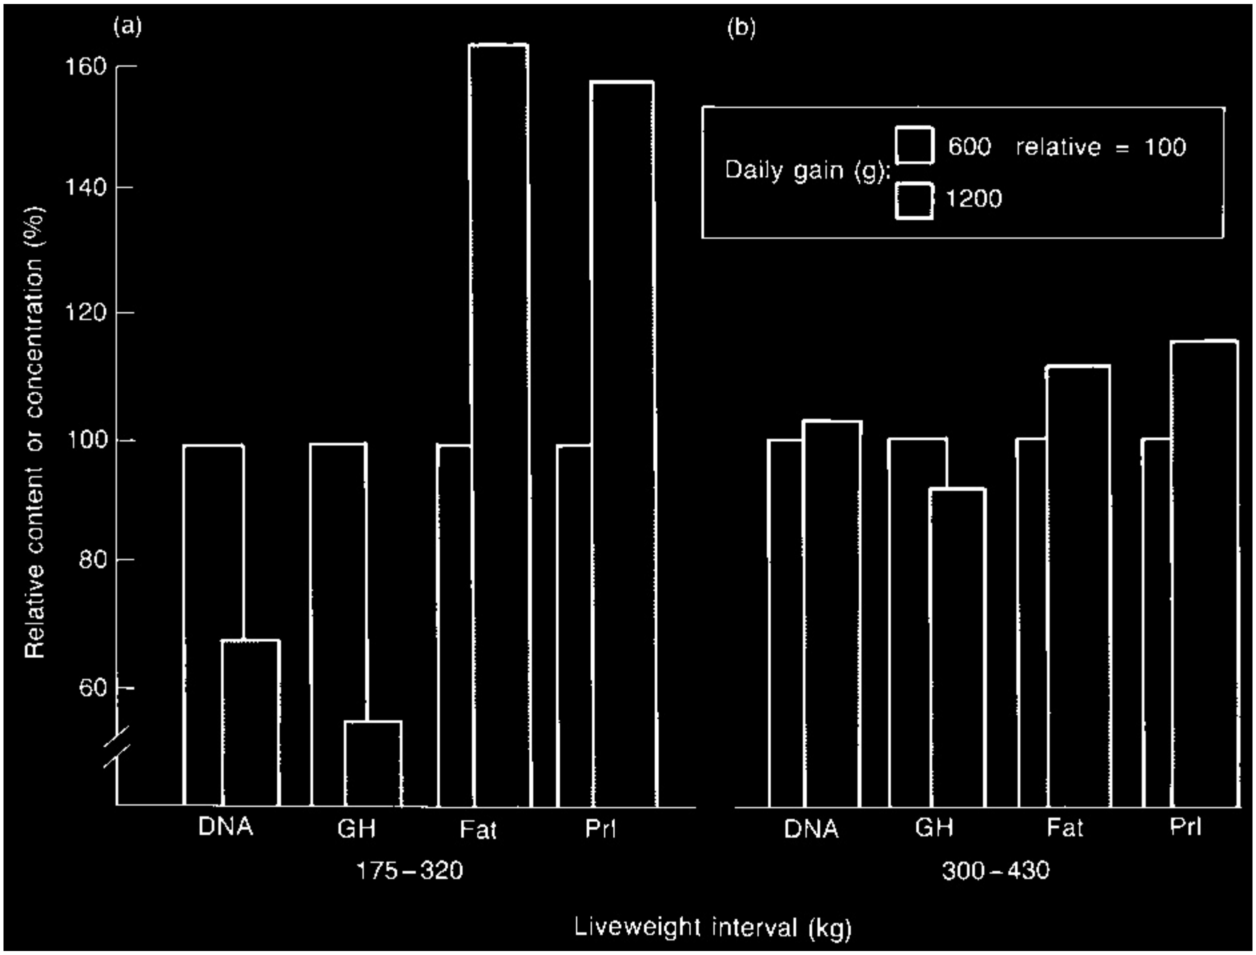
growth and development is under hormonal control
against lungworm prior to turnout (see p. 274).

and serum concentrations of some of the hormones





involved are affected by plane of nutrition (Sejrsen & Foldager, 1992; Sejrsen, 1994). It is likely that the negative influence of a high plane of nutrition on mammary growth is caused by changes in the secretion of these hormones. Rapid growth before puberty has been shown to coincide with impaired development of the mammary epithelium, decreased serum growth hormone and elevated serum prolactin concentrations

(Foldager & Sejrsen, 1982). After puberty there is little or no effect (Fig. 5.3).

Summary evidence from recent studies at ADAS Bridgets suggests that there are production and economic benefits from restricting the rate of liveweight gain (to around 0.7 kg/day) in the prepubertal period, in terms of subsequent milk yield performance, with little or no loss in terms of onset of puberty or first calving age and weight. There is also a potential benefit to be gained from a period of cheaper feeding followed by compensatory growth.

Grazing systems

Ideally, calves should be turned out to pasture with a low level of parasite challenge. Up to late June this can be classified as land that falls into one of the following categories: new seeds after an arable rotation and grassland used only for conservation in the previous year.

After mid July a pasture can be assumed clean if either it is an aftermath or not grazed by cattle earlier in the year (Chapters 19, 60).

If parasite-free calves are turned out to and remain on a clean pasture it should be safe to graze for the

remainder of the season. Unfortunately, in intensive

dairy systems it is seldom possible to provide clean

scouring (gastroenteritis) (see Chapter 14), pneu-

systems may be adopted. Semi-intensive and intensive

monia (see Chapter 17) and worms (roundworms,

calf rearing systems found in the tropics include the

following.

• Single suckling for beef calves where the objective is to achieve greatest calf growth rates and conversion of milk to meat.

• Dairy ranching where calves are separated at night and the cows are milked once in the morning and limited or restricted suckling is allowed throughout the day. If management will allow evening milking, suckling all night and separating the cow and calf during the day is a better option, as carried out by some pastoralists.

In the tropics calves may be reared inside, outside or a combination of both. Calves can be reared outside all year, though a number of disadvantages are associated with outside rearing on grass paddocks.

• It is difficult to keep grass sufficiently young and nutritious for calves.

• It is difficult to keep calves free from internal parasites if they are grazing in small enclosed areas.

• Environmental stress (temperature and radiation) can be high, even if good shading is available.

The combination of poor nutrition, parasites and climatic stress is a major constraint to calf rearing. Adequate nutrition is the key to success and to enabling a stable host–parasite relationship to be established.

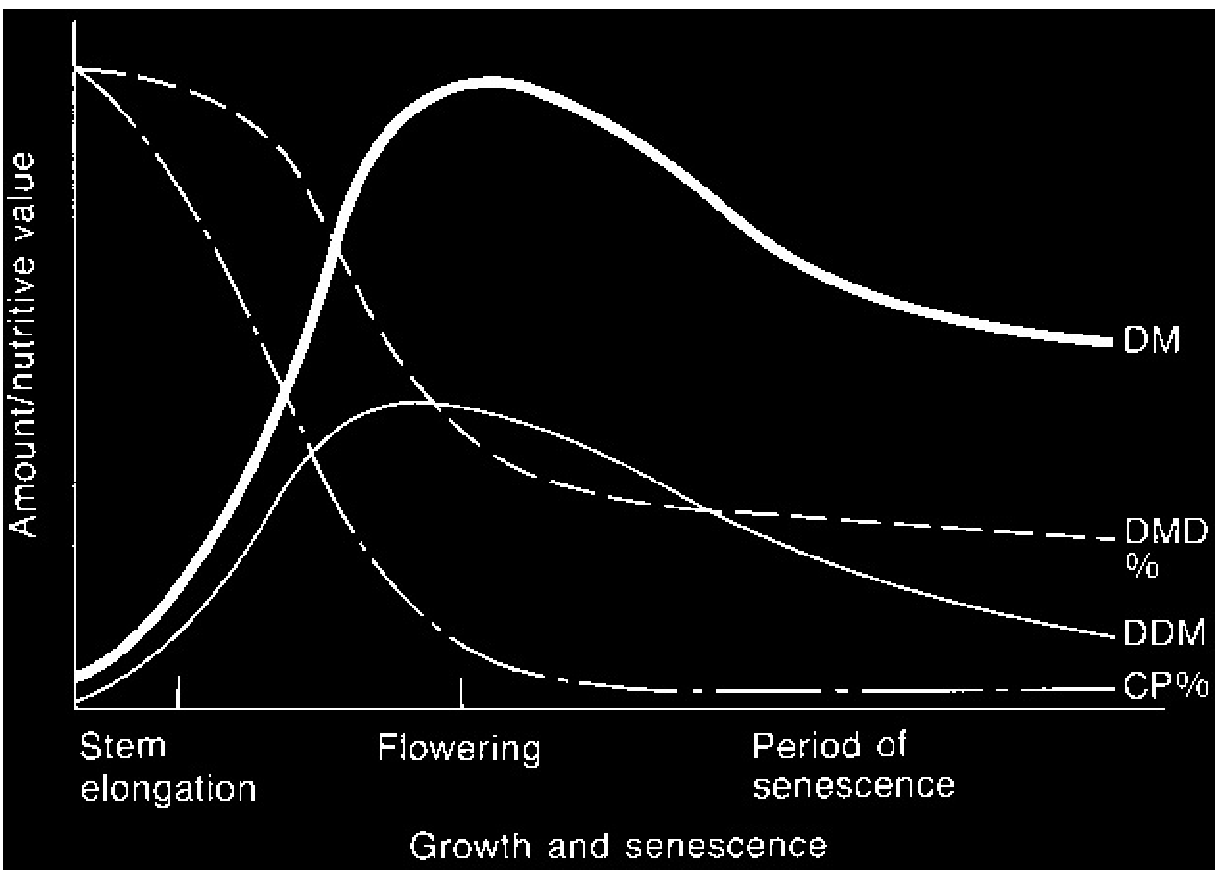
delayed.

production.



Grass production

Grass represents the major link between the sun as the
ultimate source of energy and the grazing animal. For
the grass, however, the grazing animal can be regarded
as a parasite. It is thus important that this relationship
is not a destructive one for the grass. Animal produc-
tivity depends on a vigorous grass sward and manage-
ment must safeguard the viability of the herbage above
all else.

The factors that determine grassland dry matter pro-
ductions are amount of light, leaf area, efficiency of
species, amount of carbon dioxide, temperature, water
and nutrients.

In the short term the manager can determine leaf

Fig. 6.3

Generalized changes in the amount and nutritive value

area and nutrient level and in the longer term the

104

strategic position relative to other animals.

Energy requirements of lactating cattle

105

Van Soest (1994) classified cattle feeding habit as

Protein requirements

106

being one of grazing fresh grass, rather than browsing

Microbial protein synthesis

107

trees and shrubs. Cattle have a greater need for water

Metabolizable protein

108

than other ruminants, possibly because they retain fibre

Requirements for metabolizable protein

110

for relatively long periods in the rumen. A high free-

Composition of feeds

111

water content, typically around 90 per cent, is essential

Cellulosic and non-cellulosic feeds

111

for optimal bacterial activity. In addition, there is less

Energy and protein in feeds

112

absorption of water in the large intestine and a higher

Physical form

113

water content in the faeces than with sheep and goats.

Feed preservation

114

The bovine is a relatively unselective eater compared

Drying

114

Ensiling

114

with the other ruminants. This may be a disadvantage

Primary and secondary fermentations

115

when tree and shrub leaves are abundant at a time

Typical analytical composition of silage

116

when pasture supply is scarce because of drought. But

Additives for silage

116

the bovine can and does browse. In situations of excess

Additives for hay and moist grain

117

food supply over consumption, selective eating occurs.

Feed processing

117

In temperate regions of the world, a constant supply

Physical processing of roughages

117

of feed throughout the year is achieved by preserving

Chemical processing of roughages

117

excess herbage growth as hay or as silage. This activity,

liable to pass on down the tract and out in the faeces. The rate of passage out of the rumen can influence the extent to which fibrous particles are actually digested. The faster the rate of passage, the lower the actual, relative to the potential, digestibility.

The same concept applies to protein, especially that fraction which is available for microbial fermentation in the rumen. A high-yielding dairy cow, given a high-quality diet with a fast rate of passage of feed through the

rumen, will have a relatively lower fibre digestibility than

a dry cow given less of the same diet, or a diet of lower

energy content. However, the protein in the diet of the

high-yielding cow will have a lower digestibility in the

Fig. 9.2

Typical patterns for the rates of release in the rumen of

rumen, yield less ammonia and provide more unde-

ammonia from the breakdown of protein, and of energy, following graded protein to the abomasum than that in the dry

a meal. The rate of ammonia release should match as closely as cow's diet (see Table 9.13). Paradoxically, the lower the

possible that of energy, either by reducing the amount of quickly actual, relative to potential, digestibility in the rumen,

degraded protein in the diet, or by increasing the quantity of the worse off the animal is with respect to energy, but the

better off it is likely to be with respect to protein.

Actual and potential digestion

Optimizing digestion in the rumen

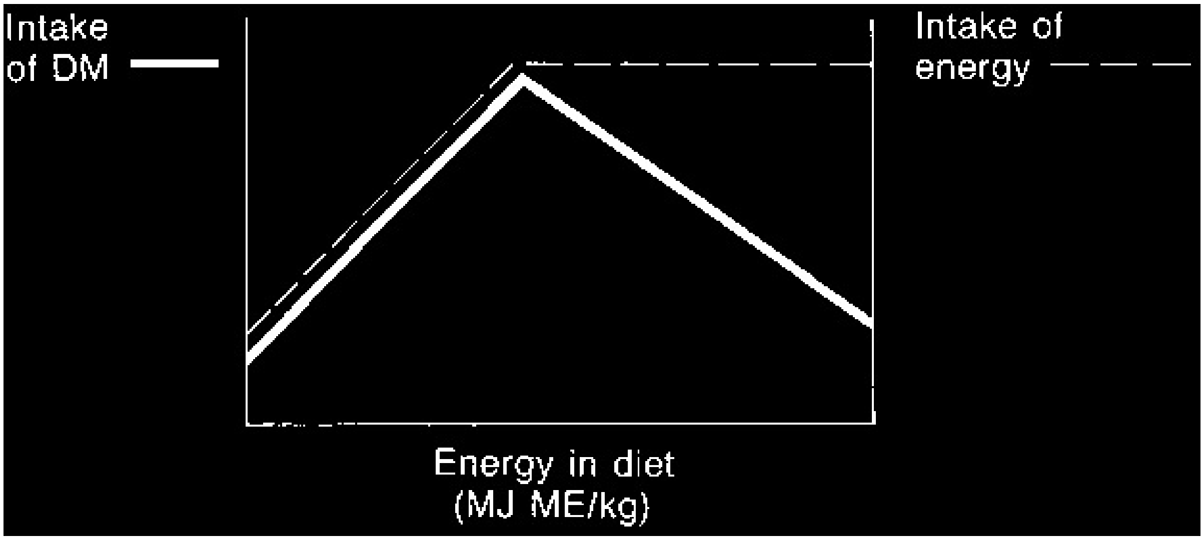
Fibre that has been reduced to a small enough particle

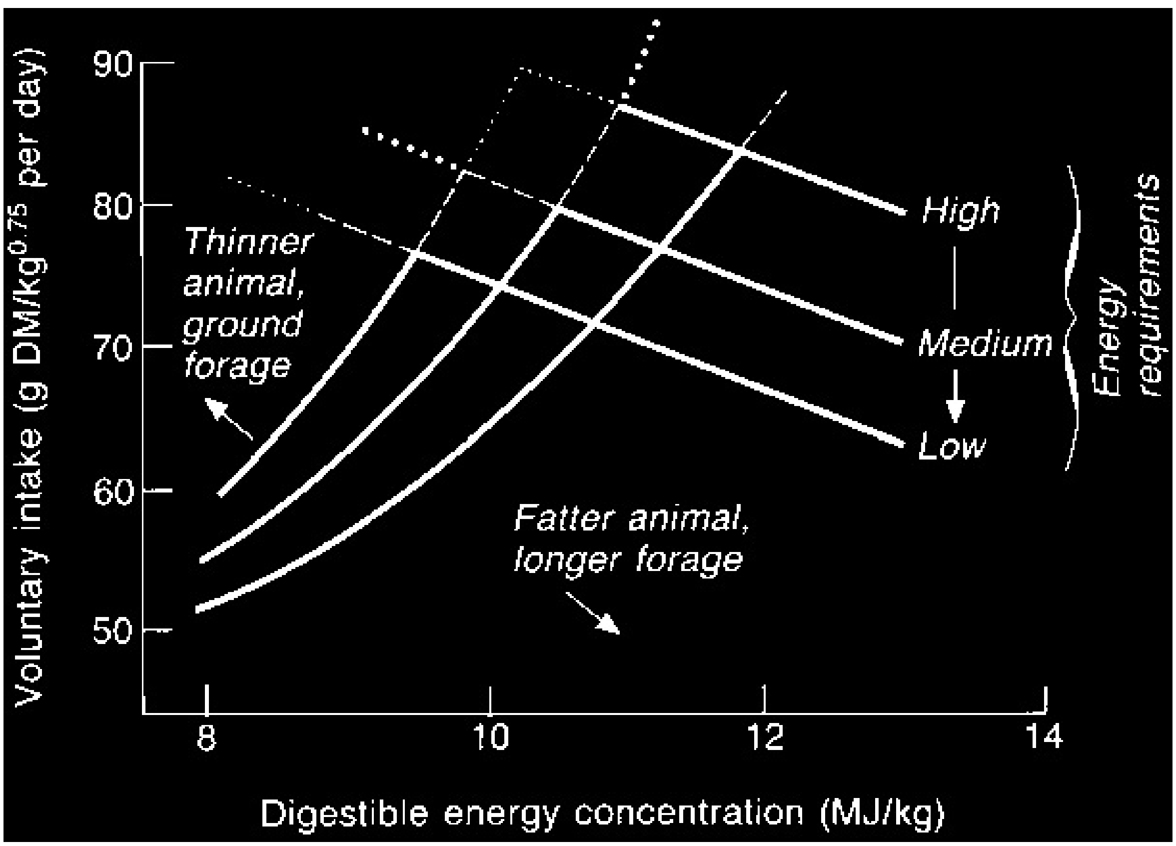
It follows from the above discussion that the following

size at which it can pass out of the rumen, and which principles need to be adopted in order to optimize the

has also resisted being digested by microbial activity, is

fermentation in the rumen:





• Cell wall is the principal source of digestible energy

in the diet of the bovine, and conditions in the

rumen should be optimal for its digestion.

• Sufficient saliva must be produced to maintain

rumen pH above pH 6.5, otherwise cell wall diges-

tion will be reduced.

• Adequate degradable protein must be supplied to

meet the requirements for microbial protein syn-

thesis (see section on protein requirements, p. 106).

• Supplementary energy in the form of starch or

Fig. 9.3

Simplified relationship between the energy content of

sugar must not interfere with the maintenance of

the diet and feed intake. As the energy content of the diet

the above conditions in the rumen (see section on

increases, dry matter intake will increase until it reaches a

feeding management, p. 118).

maximum. If energy content increases further, dry matter intake is reduced because metabolic factors, rather than the bulk, or When cell wall digestion is optimized, then feed intake

‘fill’, of the diet now control intake.

is likely to be maximal, at least with respect to fibrous

feeds (see below).

Feed intake

Most diets for cattle are offered in excess of the amount

the animal actually consumes, although there are situa-

tions where the amount of feed offered each day is

restricted intentionally. Two such situations are readily

apparent: the dry cow and the suckler cow in late lac-

tation. Both situations require that the animal does not

overeat and become excessively fat.

The concept of voluntary feed intake is discussed in

this section, that is, the amount of feed the animal will

eat when offered an excess supply so that about 10 to

15 per cent of the daily amount offered is refused.

Fig. 9.4

Composite diagram of the relationships between

intake and animal and feed factors in ruminants. At any given

energy content, intake is higher for cows that have a greater

Is feed intake under control?

requirement for energy (or potential milk production). Also, intake of dry matter is greater the thinner the cow, and the smaller the The fact that cattle can become overfat suggests that particle size of the feed. Source: Forbes (1983), reproduced with feed intake is under relatively imprecise control.

permission of CABI International.

Equally, sparse availability of range pastures or the

provision of very low quality roughages as the sole

feeds can lead to inadequate levels of feed intake and

chronic undernutrition. The animal can suffer from

lite such as acetate in blood), but the signals to cease

deprivation because it is unable to ingest, or digest,

eating may be physical (bulkiness of the food or restric-

enough nutrients daily to meet its requirements for

tion of rumen capacity by the fatness of the animal) or

maintenance of body weight. Nevertheless, there is evi-

metabolic (concentrations of absorbed nutrients in

dence that cattle eat to satisfy their demand for energy

blood), depending on the type of food. These concepts

to maintain weight and produce tissue growth or milk.

are discussed in more detail below.

The generalized relationships between the energy

content of the diet and dry matter intake (Figs 9.3 and

Concentrates

9.4) suggest that signals received by the brain when
the animal’s energy needs are met in turn elicit the
With concentrates, satiety occurs long before the capac-
response to cease eating. Perhaps cattle eat as much as
ity of the rumen is reached. Intake is determined by the
possible whilst at the same time attempting to minimize
animal’s capacity to metabolize the nutrients absorbed

high-energy diets where physical limitations do not

apply (see below).

Roughages

With roughage feeds the volume of the rumen usually

restricts intake. Thus intake is proportional to the

volume of the rumen – the larger the rumen, the more

feed is consumed. Larger animals eat more than smaller

animals because their rumen volumes are greater.

Rumen capacity

Animals with large rumen capacities relative to their

total body weight eat more roughage than those with

relatively smaller rumen volumes. The implications are

Fig. 9.5

Variations in the ratio of material soluble in acid pepsin

that calves should be reared on diets that encourage

(cell contents) to digestible fibre (cell wall) in three forages of the rumen development, and cattle should be selected for

same digestibility, but differing in intake. Source: Osbourn (1967), large rumen capacities. Channel Island cattle (Jersey,

reproduced with permission of the British Grassland Society.

Guernsey) typically eat more food relative to their body weight than Holstein cattle because, although they

weigh much less, their rumen capacities are relatively

greater. Thinner cattle tend to eat relatively more than

fatter cattle (Fig. 9.4).

Digestibility of forages

Digestibility or energy concentration of forage feeds

exerts a large influence on feed intake (Fig. 9.5).

However,

the relationship between intake and

digestibility is much less evident for silages than for

dried forages, where the pattern of fermentation in the

silo, particularly the presence or absence of residual

Fig. 9.6

be expressed per kilogramme liveweight rather than

per hectare. It follows that stocking rate, a commonly

used but empirical and inflexible way of describing

herbage allowance, should not be expressed as num-

ber of animals per hectare, but as kilogrammes of

liveweight per hectare (see section on feeding manage-

ment, p. 118).

The relationship between herbage allowance and

intake holds for animals in different physiological

states, and for legumes as well as grasses (Fig. 9.9).

Studies of grazing behaviour and herbage intake by

animals grazed on adjacent monocultures of grass and

clover demonstrated that the grazing bovine has a

of the desirable anaerobic bacteria that are present on the crop in the field in relatively small numbers. As much air as possible should be removed from the crop at the time of ensiling, so that residual oxygen is exhausted as rapidly as possible. This is achieved by first chopping the crop as it is harvested from the field, by consolidating it once the crop is in the silo and finally by sealing it completely using a plastic sheet.

Primary and secondary fermentations

It is important to distinguish between primary and secondary fermentations, and to recognize that both are quite distinct from the process of aerobic spoilage that

Fig. 9.19

Typical changes in the content of fermentation acids

occurs on exposure of silage to the air at the time of

in silage as a result of secondary fermentation.

feed-out.

Primary fermentation essentially comprises the con-

version of sugars or WSC, mainly fructose and glucose,

to lactic and other acids as the result of the metabolism

of bacteria. This process can be rapid and completed in

nant product. Acidity increases as the conversion of

a few days.

sugars to acids continues.

Secondary fermentation, which sometimes follows

Wilted grass silages generally undergo less extensive

fermentations and consequently have higher pH values

than wetter silages, residual (i.e. unfermented) WSC,

lower concentrations of fermentation acids and less

ammonia–N (Table 9.23).

Additives for silage

The main objective in applying an additive at the time

of harvest is to prevent the multiplication of clostridia.

The lactic acid bacteria are more tolerant of acid con-

ditions than are the clostridia, so traditionally their

growth has been inhibited by direct acidification of the

crop with an organic acid such as formic, or an inorganic

acid such as sulphuric. The former is relatively more

expensive, but it does have a specific antimicrobial

action against clostridia, whilst sulphuric acid acts solely

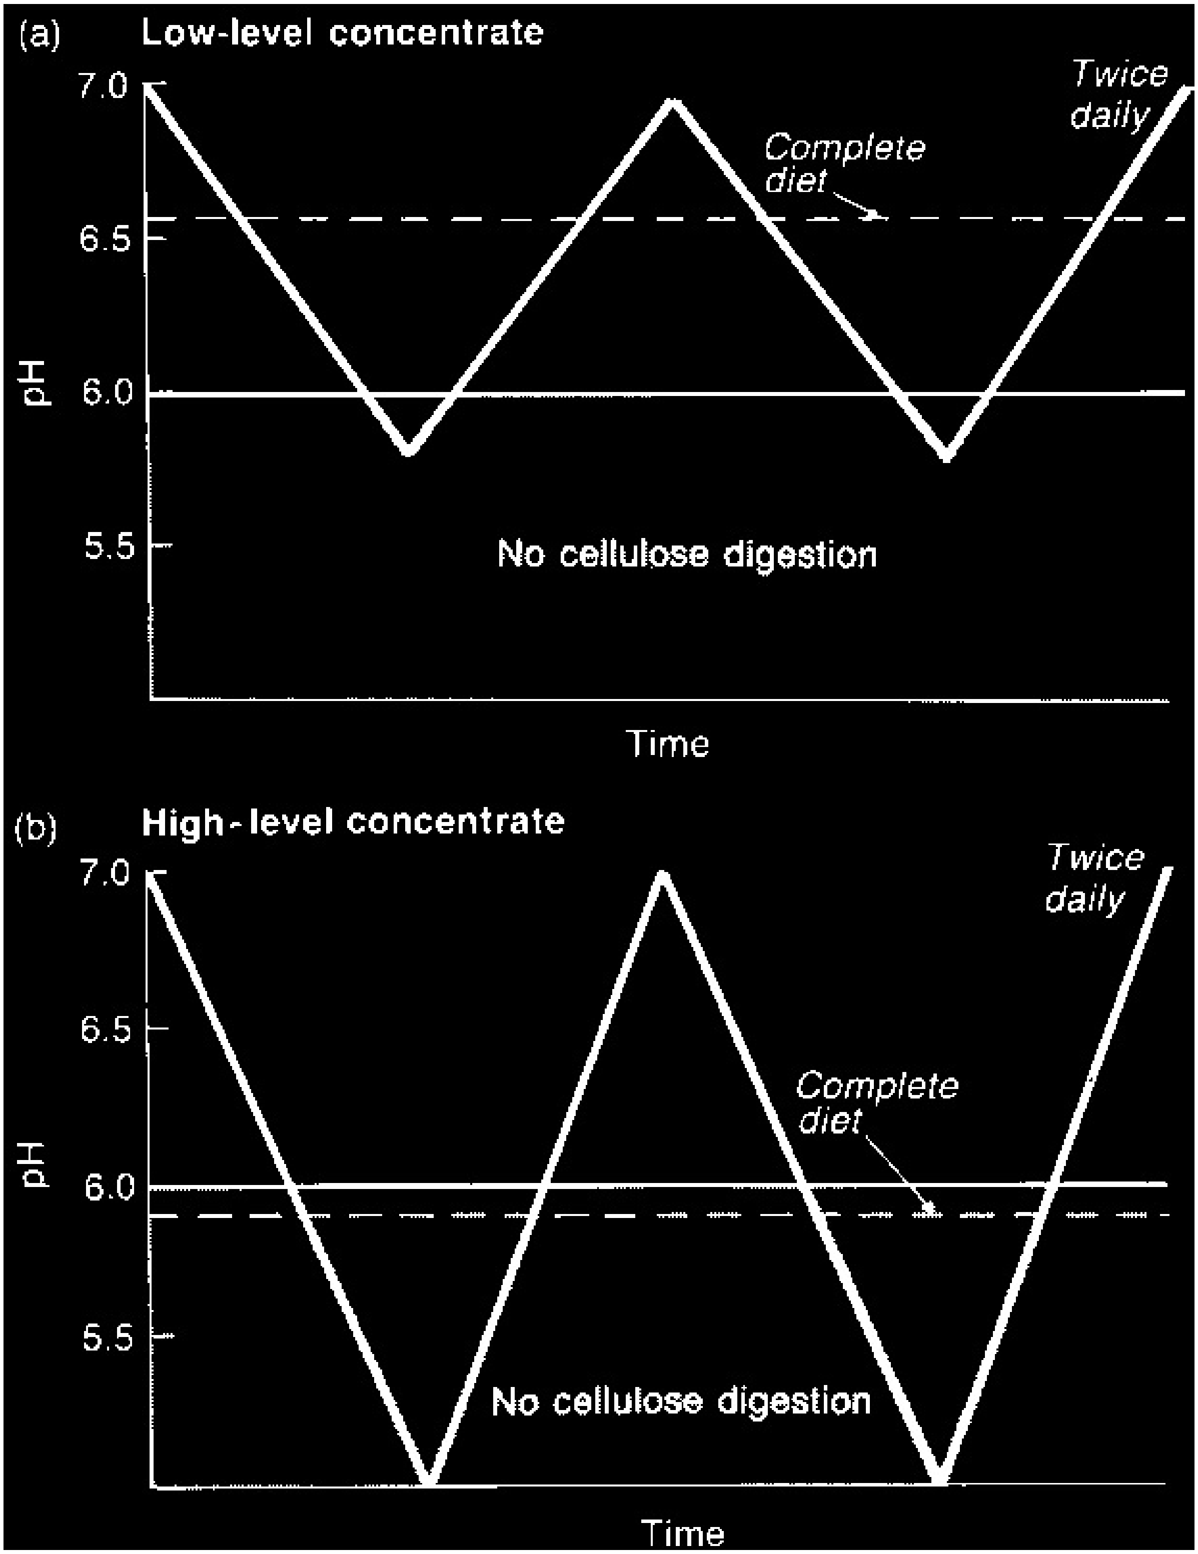
total day's allocation in up to 12 feeds per day; cows not



In practice, higher-yielding cows in the herd eat more silage and it is important that the silage is on offer

ad libitum otherwise these animals are underfed. Peak lactation yields tend to be lower than in herds given

concentrates to yield, but the rate of decline in yield

post-peak tends also to be slower than in herds fed to

yield, giving a flatter lactation curve for flat-rate

feeding.

Total mixed rations or complete diets

The main principle of complete diet feeding is that the

animal receives an intimate mix of slowly and rapidly

fermented feeds, thus balancing the inflow to the rumen

of feeds with widely differing rates of fermentation and

(it is hoped) thereby maintaining stable conditions in

the rumen.

However, with high proportions of concentrates in

the mix, the level of acidity in the rumen may be so high

that fibre digestion is permanently depressed (Fig.

9.21). In this situation, the proportion of propionate in

the rumen volatile fatty acids is elevated and as a result

cows tend to gain in weight and produce milk of rela-

tively low fat content. Overfat cows with fatty livers were a feature of early mismanagement of herds given

Fig. 9.21

melanism successively dilutes coat colour from normal

agouti to albinism. Multiple alleles may contribute to the

variation in clinical expression of many diseases.

Recessive genes

They are also a common form of inheritance in many

disease-related biochemical variants.

A single gene does not show in a carrier because of the

normal dominant gene. The defect only appears with

a double dose. Neither parent is affected yet the defect

Irregular inheritance

has come from both parents.

In carrier matings one in four of the offspring are

Many, indeed most, genetic diseases of cattle are

normal (RR), two are carriers (Rr), and one will be

inherited irregularly. They do not provide simple

in farms that have used carrier males recently. Thus

the outbreaks and frequencies will be patchy with

some farms heavily affected and others with few or no

Epidemiology and control

defects. This often renders measurement of the *incidence of a defect in a breed difficult. A useful guide*

Breeds are generally organized hierarchically. A few

is that a defect attracts notice when around 1 per cent

top herds supply bulls to less influential breeders who

of calves are affected in the breed so that about 18–20

in turn supply commercial producers. If a harmful

per cent of animals are carriers.

gene spreads in the top strata these bulls spread carriers

Reduction in frequency can be rapid if the initial

through the breed. Similarly, if the defect is eliminated

frequency is high but is slower as the frequency de-

from the top herds then sires free from the defective

creases or if the initial frequency is low. Thus breed-

gene slowly reduce the defect in the other herds. The

ers can rapidly reduce a recessive defect at high levels

origin and increase of a harmful mutant in the top herds

but eliminating it completely is very difficult.

is probably due to mutation and genetic drift.

The main difficulty in selecting against a recessive is

Control is the sum of the control efforts of individual

defect is confined to a particular family within a herd

or to the progeny of certain dams.

Introduction

In most cases the history will show a much lower inci-

dence of any inherited defect in crossbred animals than

Most farmers will, at times, have calves that show
in pedigree ones. Some genetic problems are noted as
defects of a varying degree at birth. Such defects,
being very common in certain breeds or families within
although congenital, may be due to genetic or environ-
the breed and this aids a tentative diagnosis of the con-
mental factors or their interaction. The overall level of
dition, e.g. hip dysplasia in Herefords (see p. 453). The
incidence of congenital defects ranges considerably in
history should be indicative of a relationship between
surveys from 0.2 to 3.0 per cent. It should be remem-
the condition and mating systems rather than the time
bered that genetic defects are not always apparent at
of year, disease incidents, etc. The reuse of the same
birth. The incidence of all specific defects is very small,
bull in repeat sire–dam matings may also indicate the
but detailed investigation of any anatomical system will
inherited nature of the condition and its mode of inher-
often show slight deviations from the norm. Genetic
itance, as also can sire–daughter or sire–half-sister
causes can be inherited on a dominant, recessive or

matings, but these involve a considerable period of time

additive basis and often they are influenced by the envi-

before any mode of inheritance can be suggested or

ronment. In many cases all that can be said about a par-

confirmed.

ticular condition is that it is familial. Factors connected

hypertrophy.

with a tight curly hair coat. At post-mortem examina-

tion there is vascular congestion of the liver, spleen

and lung with diffuse streaking of the entire

Patent ductus arteriosus

myocardium. It appears to be a genetic condition,

Although patent during intra-uterine life, the ductus

possibly associated with a simple autosomal recessive

arteriosus closes within a day of birth and at least by

mode of inheritance.

Blood disorders

then it should not be repeated and bulls should be used

which do not carry the BLAD gene.

Factor XI deficiency

Simmental hereditary thrombopathy

The main congenital coagulation deficiency reported in

cattle involves factor XI (plasma thromboplastin

A bleeding disorder resulting from impaired aggrega-
antecedent). It has been reported in North America and
tion of platelets has been diagnosed in Simmental-sired
recently in Britain. It has been shown to be present in
cattle. The signs may not be manifested early in life,
some Holstein–Friesian breed lines and is transmitted
although later it causes a prolonged bleeding time after
as an autosomal recessive trait. Factor XI protein is con-
even minor trauma. These animals become severely
cerned at an early stage of the contact or intrinsic acti-
debilitated or die. The problem has mainly been
vation pathway of blood coagulation. This pathway
recorded in Canada, where it is recorded sporadically
converges with the extrinsic one due to tissue damage,
in the cattle population. The data available suggest that
resulting in the activation of factor X. Following acti-
the inheritance is the result of the inheritance of at least
vation the factor converts prothrombin to thrombin,
two genes rather than a simple Medelian recessive.

ST inhibits water absorption via cyclic-GMP and LT, acting via cyclic-AMP, blocks absorption of sodium ions and water along the glucose-independent carrier system. The glucose-dependent carrier system is not affected by either toxin.*

lumen. Malabsorption also occurs when morphological changes reduce the absorbing surface area. The best example of such morphological change is villus stunting produced by viral enteritis. The mature villous enterocytes can be regarded as the functional compartment of the small intestine, with absorption as one of the principal functions. A substantial reduction in the number of villous enterocytes causes a corresponding loss of function. Furthermore, crypt hyperplasia occurs in viral infections and immature secretory cells migrate onto the villus, increasing secretory capacity. In addition to loss of absorptive capacity there is also loss of digestive capacity, therefore maldigestion occurs, which *can lead to an osmotically induced diarrhoea.*

Intestinal motility

Increased intestinal motility may contribute to the

Fig. 14.6

Line drawing illustrating the effects of heat-labile

development of diarrhoea, resulting in decreased

enterotoxin (LT) on the secretion of sodium ions by crypt ente-transit time and insufficient time for normal absorption.

rocytes. LT increases production of intracellular cyclic-AMP and this stimulates secretion of sodium ions, which carry with them The role of motility is now considered to be less

into the gut lumen despite fasting. Faeces are

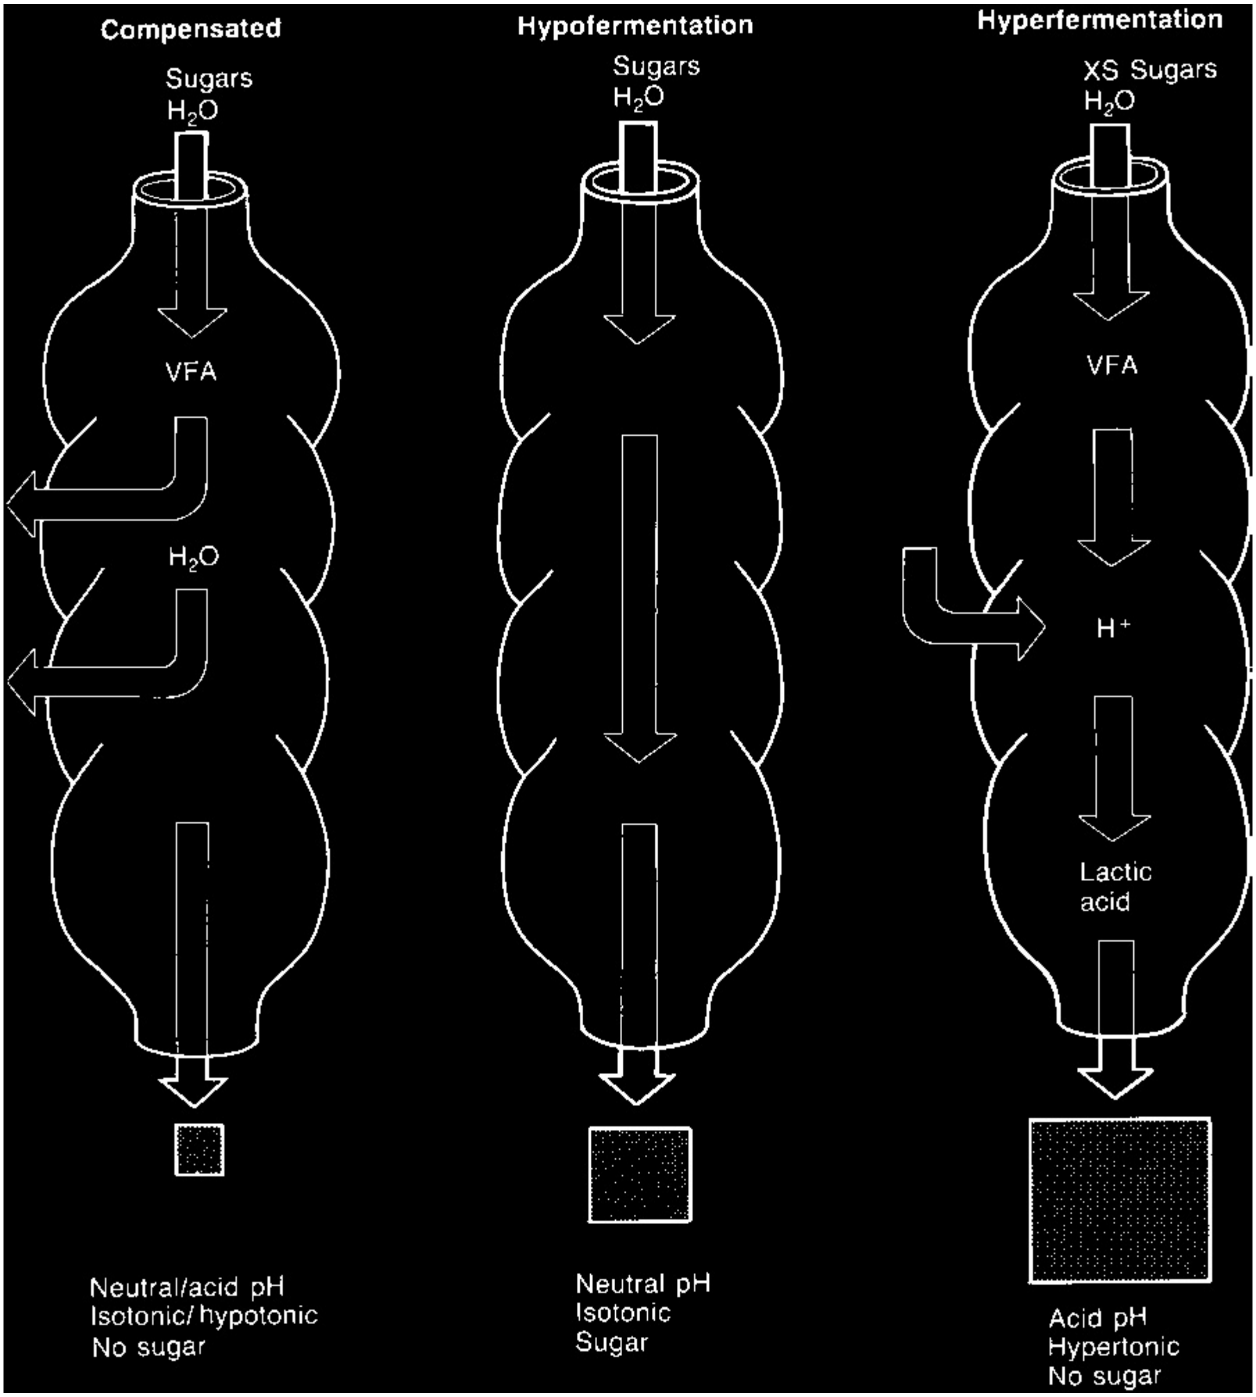

Fig. 14.8

Three alternative conse-

quences of a small intestinal maldiges-

tion and malabsorption, as seen in rotavirus infection. In the 'compensated' situation, the colonic flora is well developed and microbial fermentation of the moderate amounts of malabsorbed carbohydrate yields volatile fatty acids (VFA). These are rapidly absorbed, stimulating water absorption and promoting colonic compensation so that diarrhoea does not occur. If the colon and colonic flora are poorly developed there is hypofermentation and consequently no compensation, and diarrhoea occurs. If the colonic flora is well developed and is overloaded with sugar, hyperfermentation occurs and lactic acid is produced that promotes osmotic diarrhoea. Source: Argenzio (1984).

sodium and chloride ions and considerable losses of bicarbonate and potassium ions. There was loss of body weight, 12.7 per cent between onset of diarrhoea and death. Plasma volume decreased by 40 per cent leading to a 39 per cent increase in haematocrit and a 33 per cent increase in plasma protein concentration. The increase in plasma protein concentration was lower, possibly because of protein loss by catabolism or by leakage into the intestinal lumen. Both these values vary widely between individuals and are of little value in assessing severity of fluid loss.

Contraction of plasma volume gives rise to the clinical signs of sunken eyes and 'tenting' of skin folds; it leads to a fall in arterial blood pressure, which stimulates peripheral vasoconstriction. Peripheral vasoconstriction, in its turn, leads to poor tissue perfusion with blood, localized ischaemia and lower metabolic activity so that the temperature of peripheral tissues falls, approaching ambient temperature prior to death; the *extremities, the ears and mouth, feel cold. Rectal tem-*

perature increases until near to death when it falls

rapidly to below normal.

Acidosis is an important consequence of diarrhoea

and a number of factors contribute to its development.

A major factor is loss of bicarbonate ions in faeces and,

additionally, there may be absorption of acids produced

by microbial fermentation of lactose in the large intes-

tine. Loss of extracellular fluid (dehydration) causes

decreased perfusion of the kidney with blood, causing

reduced renal function, which leads to decreased excre-

tion of hydrogen ions by the kidney. Finally, lactic aci-

dosis may develop because of increased production of

lactate following peripheral hypoxia, and decreased uti-

bolic acidosis develop in more severely affected calves
which limits the helpful actions of aldosterone.

Infectious agents

The elucidation of the infectious causes of calf diarrhoea has been a major area of progress over the last 30 years. For many years, salmonellas were the only *known cause, but in 1967 it became clear that a small*

number of strains of E. coli caused a watery diarrhoea and subsequently these came to be known as enterotoxigenic E. coli (ETEC). Rotavirus was the first viral enteropathogen to be recognized, followed by coronavirus, and more recently Breda virus. Approximately

20 years ago, Cryptosporidium parvum was found to

cause diarrhoea in calves. Most recently, E. coli have been identified that cause diarrhoea without producing

enterotoxins; these include strains that infect the large

Calves usually become infected with coronavirus when

recorded beneficial results from good hygiene.

they are between one and three weeks old, although

Unlike dairy herds, most beef cattle have a seasonal

disease may occur in calves up to three months of

calving pattern with over 90 per cent of the cows calving

age. Transmission of infection is by the faecal–oral

during a nine week period, which presents problems

route. Calves develop diarrhoea in a manner virtually

with stocking levels in farm buildings and calving

accommodation. Beef cattle should calve outdoors

wherever possible. Newly-calved cows and their calves

should be moved to clean pastures as soon as possible

after birth. The stocking density on these pastures

should be kept as low as practicable to prevent envi-

ronmental contamination and build-up of infection.

Problems with rotavirus diarrhoea usually appear

during the second half of the calving period and are

often associated with adverse weather conditions

during early spring or late autumn, when young calves *are crowded in sheltered areas of the field facilitating*

build-up of infection. Infection builds up rapidly in

housed beef herds where poor building design and lack

of sufficient straw bedding material aggravate over-

stocked conditions. The provision of a dry, well-bedded

creep area for calves may reduce the level of challenge

but is not sufficent to prevent disease.

To assist good hygiene, calving accommodation and

research laboratory they can be identified by electron microscopic examination of faeces concentrated by centrifugation.

Escherichia coli

Three groups of E. coli have been identified that appear to cause diarrhoea in calves. Strains that elaborate a *heat-labile enterotoxin or a heat-stable enterotoxin are called the enterotoxigenic E. coli (ETEC). A second collection of strains exists that colonize the small intestinal mucosa and cause diarrhoea, but do not elaborate enterotoxins. Characteristically, these strains attach closely to the luminal surface of enterocytes, often in cup-shaped depressions or on cytoplasmic protrusions, described as 'pedestals'. This attachment of bacteria to the enterocyte surface usually results in the microvilli being effaced and the lesion has been named the 'attaching and effacing' (AE) lesion (Fig. 14.15). Comparable strains cause diarrhoea in children and are called enteropathogenic E. coli (EPEC). It is appropriate to use this term for equivalent calf strains, but care is required because the term enteropathogenic E. coli has been used in the veterinary literature for many years to describe strains associated with diarrhoea, regardless of their pathogenic mechanism.*

A third group of strains colonizes the surface of the large intestine and causes a mild dysentery. These strains also cause AE lesions but because they cause *blood to be lost into the lumen of the large intestine,*

they are called enterohaemorrhagic E. coli (EHEC);

once again comparable strains cause a similar disease

in children. Some EPEC and EHEC, but not all,

produce a toxin that kills Vero cells in vitro and is called Verocytotoxin (VT) or Shiga-like toxin (SLT). This

Fig. 14.14

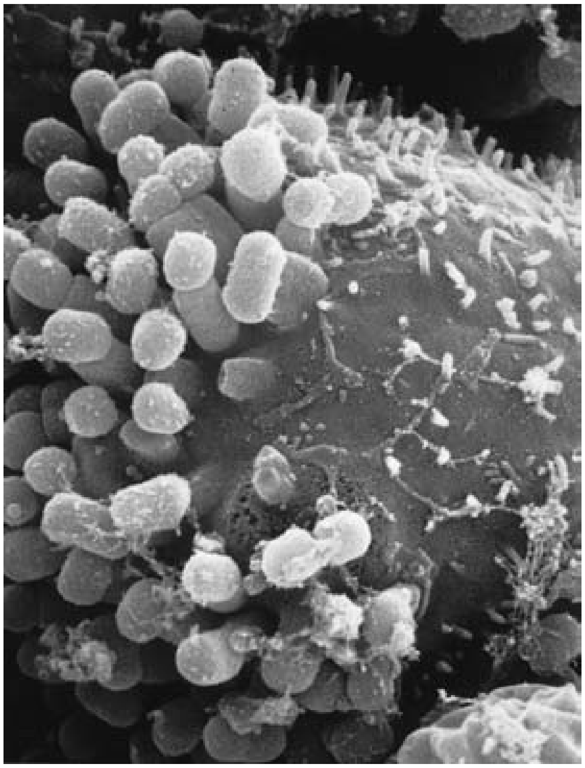
infection and damage by bovine astroviruses.

VTEC have been isolated from calves with diarrhoea,



Enterotoxigenic E. coli possess two virulence attributes (determinants) that distinguish them from non-pathogenic strains: ability to adhere to the mucosal surface of enterocytes and, as mentioned previously, ability to produce enterotoxins (see Fig. 14.4). Adhesion is mediated by filamentous protein structures called fimbriae, sometimes called pili or adhesins, which bind to specific receptors on the enterocyte cell membrane. Adhesion mediated by fimbriae does not bring the bacterium in close contact with the enterocyte *luminal surface as is the case of EPEC and EHEC. The microvilli are unaltered and 'cups' and 'pedestals' are not seen. The presence of receptors is affected by age, and susceptibility to infection is greatest in the newborn calf when expression of receptors is greatest. These fimbriae are antigenic and so many of them are known by their antigenic name (e.g. K99, F41). Their adhesive ability allows ETEC to overcome the peri-stalsis of the small intestine by sticking to the mucosal surface. The adhesion antigens commonly found in ETEC of calves are K99 and F41; they often occur together but may be present independently. K99+ strains are also capable of inducing diarrhoea in pigs, foals, lambs, goats and possibly other ruminants. Adhe-sion of the bacterium to the enterocyte surface confers another advantage to the bacterium because entero-*

therefore, to diagnose ETEC infection by detecting

either the enterotoxin or the adhesin.

Detection of adhesins forms the basis of the diag-

nostic tests for ETEC because they are easier to detect

but they may also be present in the faeces of healthy

than enterotoxins. Special culture media may be

calves. In an epidemiological study, they were found to

required to encourage ETEC to express adhesins

be as common in the faeces of healthy calves as in the

because, in general, K99 and F41 are poorly produced

faeces of calves with diarrhoea. Therefore, designation

by bacteria in vitro, although they are readily produced of an E. coli as a VTEC may not necessarily define it as by bacteria growing in the gut. Once expressed they can

Fig. 14.17

Prevalence of pathogenic agents in calf diarrhoea.

These survey data have been reproduced by numer-

ous monitoring organizations over the past 15 years

which clearly indicates the important role of rotavirus

and coronavirus in neonatal enteritis. Vaccination is

highly effective against these viral causes of diarrhoea *but the need for annual vaccination and perceived high cost have resulted in many beef calves remaining unprotected.*

Mixed infections

With the recognition of enteropathogenic agents and the development of diagnostic tests, it has been possible to look at outbreaks of diarrhoea and at individual animals to assess the importance of mixed infections. Results of surveys of faeces of calves with diarrhoea indicate that although single infections may result in

Fig. 14.18

virus, EHEC and cryptosporidia also damage the large

intestine. However, assuming that diarrhoea is more

likely to occur when both the small and large intestines

are damaged, there is a need to study the infectious

agents that damage the large intestine. Diarrhoea was

often associated with infections and lesions throughout

the small and large intestines in a study of the pathol-

ogy of 21 calves with diarrhoea in southern Britain

(Hall et al., 1988); coronavirus and bacteria adherent to the mucosal surface were associated with the lesions in

the large intestine. The results indicate that these bac-

teria, some of which were EHEC, were contributing

to the development of diarrhoea. Evidence from field

studies also suggests that mixed infections are impor-

tant in the development of diarrhoea. In a longitudinal *study of calves, from birth to weaning, only 15 per cent*

of calves that excreted Cryptosporidium sp. and 37 per ***Fig. 14.20***

ileum showing the normal morphology of villi.

homogeneous monolayer over the dome villi (villi asso-

ciated with the Peyer's patches) and so the relative *interaction of salmonellas with M cells and enterocytes is more difficult to assess. It appears, however, that salmonellas will initially interact with the M cells (within 10 minutes of direct inoculation into the distal ileum) and are not taken up by the enterocytes until slightly later (approximately 20 minutes after inoculation). The mechanism of Salmonella invasion has been extensively studied. The bacterial genes involved in invasion are clustered together at one site on the chromosome, which has been named Salmonella pathogenicity island 1 (SPI-1). SPI-1 encodes a type 3 protein secretion system (TTSS-1: so called after comparison to two previously described secretion systems), regulatory*

Signs

lower abdomen is distended, often on the right as well

The majority of ulcers in calves are subclinical although

some may haemorrhage, producing melaena and *anaemia, which is occasionally fatal. Others produce a localized peritonitis of the abomasal serosa, whilst perforating ulcers lead to acute peritonitis and death. The three-week-old Friesian calf in Plate 16.4 was recumbent, in considerable pain, with a subnormal temperature (37.5°C) and sunken eyes. Regurgitated rumen contents are visible at the mouth. Death followed within two hours, despite abomasal drainage, lavage and parenteral metoclopramide. On post mortem*

Body temperature regulation in cattle is well devel-
putting them into the same air space that is the main
oped, so they can tolerate both heat and cold (Webster,
reason for the problem of pneumonia in intensively
1981a). However, draughts in buildings can result in
reared calf systems. It is not always accepted that the
chilling, which increases the metabolic rate and perhaps
number of calves in a single air space is more important

reduces resistance to infection (Webster, 1981b), but
than the air space or floor area per calf. However, over-
high relative humidity on its own does not chill cattle
crowding is a major factor in allowing disease develop-
(Webster, 1979). Webster (1981b) therefore postulated
ment and spread. Other factors involved in increasing
that the main effect of weather was compounded by the
disease levels are the inadequate cleaning and disinfec-
building itself. Thus a badly constructed building with
tion of the building between batches, as well as not
poor ventilation would reduce ventilation rate, and the
allowing the accommodation sufficient rest between
water-carrying capacity of the air would be detrimen-
calf intakes. In some cases younger animals are mixed
tally affected by bad ventilation and possibly poor
with an older group, thereby allowing transmission of
drainage. Such conditions could lead to the relative
micro-organisms from the old, apparently clinically
humidity remaining at more than 90 per cent for several
normal animals. Economic considerations may also
days, and this in turn would increase the survival and

influence the picture if there is a reluctance to employ

spread of pathogenic organisms. Some support for this

preventive measures such as vaccination, etc. Several

view has been obtained by work showing an increased

management procedures such as castration, disbudding

survival of small airborne bacteria at high relative

and weaning all appear to have an effect on the level of

humidities (Jones & Webster, 1981). There is thus an

disease. The importance of microbial agents is indirectly

268 • Chapter 19

Parasitic gastroenteritis normally occurs when calves or non-immune older cattle are grazed on pastures on which a large number of infective larvae are present. Typical cases occur in dairy herds where autumn-borne replacement calves are put out to graze for the first time in April or May. The pastures used are frequently close

inhibiting

to the farmhouse to enable both ease of inspection and rehousing should weather conditions deteriorate. For *these reasons the same fields frequently have the same*

use each year. The calves remain on the fields until mid-

summer, excreting eggs that initiate the midsummer

larval increase. At that point, when grass in such pad-

docks requires resting, the farmer has aftergrass avail-

F

able after conservation for silage or hay. The calves

early July. At that time, pasture which has not been pre-

days. Such boluses are usually administered by balling-

viously used for cattle grazing that year is available,

after grass has been taken for silage making or some

other form of conservation.

The calves are given anthelmintic treatment before being moved to it. The timing of the treatment can vary with the pharmacokinetics of the anthelmintic used and its effect on nematode eggs if contamination of the aftergrass is to be avoided. For instance, the longer acting benzimidazole anthelmintics (e.g. oxfendazole, albendazole, fenbendazole) are ovicidal within a few hours after treatment and their slow rate of excretion means that cattle are protected from infection with susceptible parasites for approximately 30 hours after treatment. They can therefore be put back safely onto the contaminated grazing for 24 hours after treatment before transfer to the aftergrass. The same technique can be applied with avermectins and moxidectin, which

Comparisons between methods have rarely been con-

factors that influence Cu status should not be ignored.

ducted but one at least showed no advantage in calf

Copper absorption in cattle is as sensitive to Mo inhi-

growth for oral Co versus injected B12 (Judson et al., bition as it is in sheep and the equations derived for

1981).

grazing sheep to predict Cu absorption (Suttle, 1983b)

Administration of Co on a group basis via licks con-

should give an approximate weighting for cattle. High

taining 0.1 per cent Co or mineral mixes containing up

S intakes from the diet (Suttle, 1983a) or drinking water

to 0.4 per cent Co may provide an inexpensive means

(Smart et al., 1986) also suppress Cu absorption. Poor of prevention but could not be guaranteed to protect

Cu absorption, and hence disorders, will therefore be

all individuals. The best long-term strategy on certain

more common on lush, immature, S-rich swards than on

soil types will be to apply Co salts, such as hydrated

brown, mature swards and in wet than in dry seasons.

$CoSO_4$, at 2–3 kg/ha, every three to four years.

Copper is also absorbed better from hay than from

Responses may, however, be short-lived on sandy soils

fresh grass of similar S content (Suttle, 1983b). Ensiled *and negligible on calcareous or recently limed soils con-*

grass is a good source of absorbable Cu while S con-

taining >1 g Mn/kg DM because most of the Co

centrations are low (about 2 g/kg DM), but availability

becomes 'fixed' in the soil.

probably falls rapidly as concentrations rise to 3 g/kg

There is virtually no risk of overdosing with cobalt,

DM if cattle share the characteristics of sheep (Suttle,

but this should not be used as an excuse to overfeed Co

1983a). High iron (Fe) concentrations also lower Cu

to animals whose capacity to synthesize and absorb B12

status in cattle (Bremner et al., 1987; Phillippo et al., is strictly limited.

1987b; Gengelbach et al., 1997), are often raised in

spring and autumn pastures and have been implicated

in incidents of hypocuprosis (Jarvis & Austin, 1983;

Copper disorders

McFarlane et al., 1990). There is debate over whether

(see also Chapter 18)

or not the Fe ¥ Cu antagonism requires the presence of

moderate amounts of dietary S (Suttle, 1988).

Aetiology (see p. 254)

The principal determinants of hypocuprosis in

Most Cu-responsive disorders in cattle are induced:

grazing cattle are therefore raised soil Mo, alkaline soil

they are induced in the rumen where the anaerobic

pH (which encourages Mo uptake), sward immaturity,

degradation of sulphur(S)-rich, fibrous feeds leaves

high rainfall (or irrigation), heavy fertilizer N use and

little of the ingested Cu in a soluble form. After

high soil ingestion, rather than the Cu content of the

weaning, less than 10 per cent of the total Cu input is

soil or herbage, on all but the most impoverished, sandy

absorbed during passage down the gastrointestinal tract

soils.

and the percentage can be reduced to as little as 1–2 per

Shortage of absorbable Cu leads to (i) rapid deple-

cent by small increments in dietary Mo (Underwood &

tion of liver stores, (ii) a lowering of caeruloplasmin Suttle, 1999). Again it is transformations in the rumen

synthesis and a drop in plasma Cu (i.e. deficiency) and that are pivotal: extrapolating from sheep, it appears

(iii) a reduction in cuproenzyme activities in the ery-

that the progressive substitution of S2- for O2- in molyb-

throcyte and tissues (dysfuntion). Although cytochrome date creates thiomolybdates, which complex Cu and

oxidase and superoxide dismutase have been the most

bind it to the solid phase. Surplus trithiomolybdate

studied, others such as lysyl oxidase and dopamine

(MoOS3) is absorbable and capable of changing the dis-

hydroxylase will almost certainly follow the non-

tribution of Cu in the blood and tissues (Underwood &

vitamin E with parenteral Se reduced the incidence of

retained placenta in one instance in which the separate

Cattle deprived of elements such as Mn and Zn under
treatments were ineffective, but Se alone reduced the
experimental conditions develop diverse clinical symp-
prevalence of metritis and cystic ovaries (Harrison
toms, but the diets used contained far less Mn and Zn
et al., 1984). In the treatment of acute myopathy at
than the levels provided by the vast majority of natural
turnout, McMurray and McEldowney (1977) found that
diets (Underwood & Suttle, 1999). Field cases of Mn
vitamin E (2.8 mg/kg liveweight) was less effective than
and Zn deprivation would require either an abundance
Se (0.0625 mg/kg liveweight) and added nothing when
of dietary antagonists which impair the utilization of
given with Se. In this situation cattle of low vitamin E
the element or other factors which massively increase
status were turned onto grass of naturally high vitamin
animal needs for Mn and Zn. There is a possibility that
E concentration. The variable responses to vitamin E

found in the vitamin E status of housed cattle.

both elements and that fine grinding of cereals might

have a similar end result (Suttle, 2000). In the field, soil

Selenium toxicity (see p. 943)

ingestion provides a rich adventitious source of man-

ganese while access to galvanized feed and drinking

Disorders occur naturally either when pastures contain

troughs provides additional Zn, further reducing the

plant species (e.g. Astragalus) which accumulate sele-

risk of disorders. Little attention has therefore been

nium avidly from normal soils (‘Blind staggers’) or

given to reliable assessment of Mn and Zn status in the

when a combination of selenium-rich soil and high pH

animal. Serum Mn and Zn concentrations are probably

allows high levels of selenium to accumulate in normal

reasonable indices of deficiency (Table 21.1), but mar-

plant species (‘Alkali disease’) (O’Toole & Raisbeck,

ginal concentrations cannot yet be set with certainty for

1995). Accidental toxicity can be caused by errors in

the former; liver values are poor indicators of status for

adding the small amounts of selenium needed to sup-

both Mn and Zn (Underwood & Suttle, 1999). Assess-
plement feeds, exposure to multiple supplementary
ment of hypozincaemia is complicated by the fall in
sources and multiple doses (e.g. Se-supplemented
values which accompanies the acute phase of microbial
anthelmintics) and failure to scale oral drenches or par-
infections; this complication can be ruled out by dis-
enteral injections carefully to liveweight. Because sele-
carding results for samples with raised haptoglobin or
nium is well absorbed, the oral route poses almost as
fibrinogen levels or high Cu : Zn ratios (>3–4). Inter-
big a threat as the parenteral route. Selenium is a cumu-
vention with Mn and Zn supplements is rarely neces-
lative poison and tolerable daily intakes and dietary
sary and use of expensive chelated sources is unlikely
concentrations decrease as duration of exposure in-

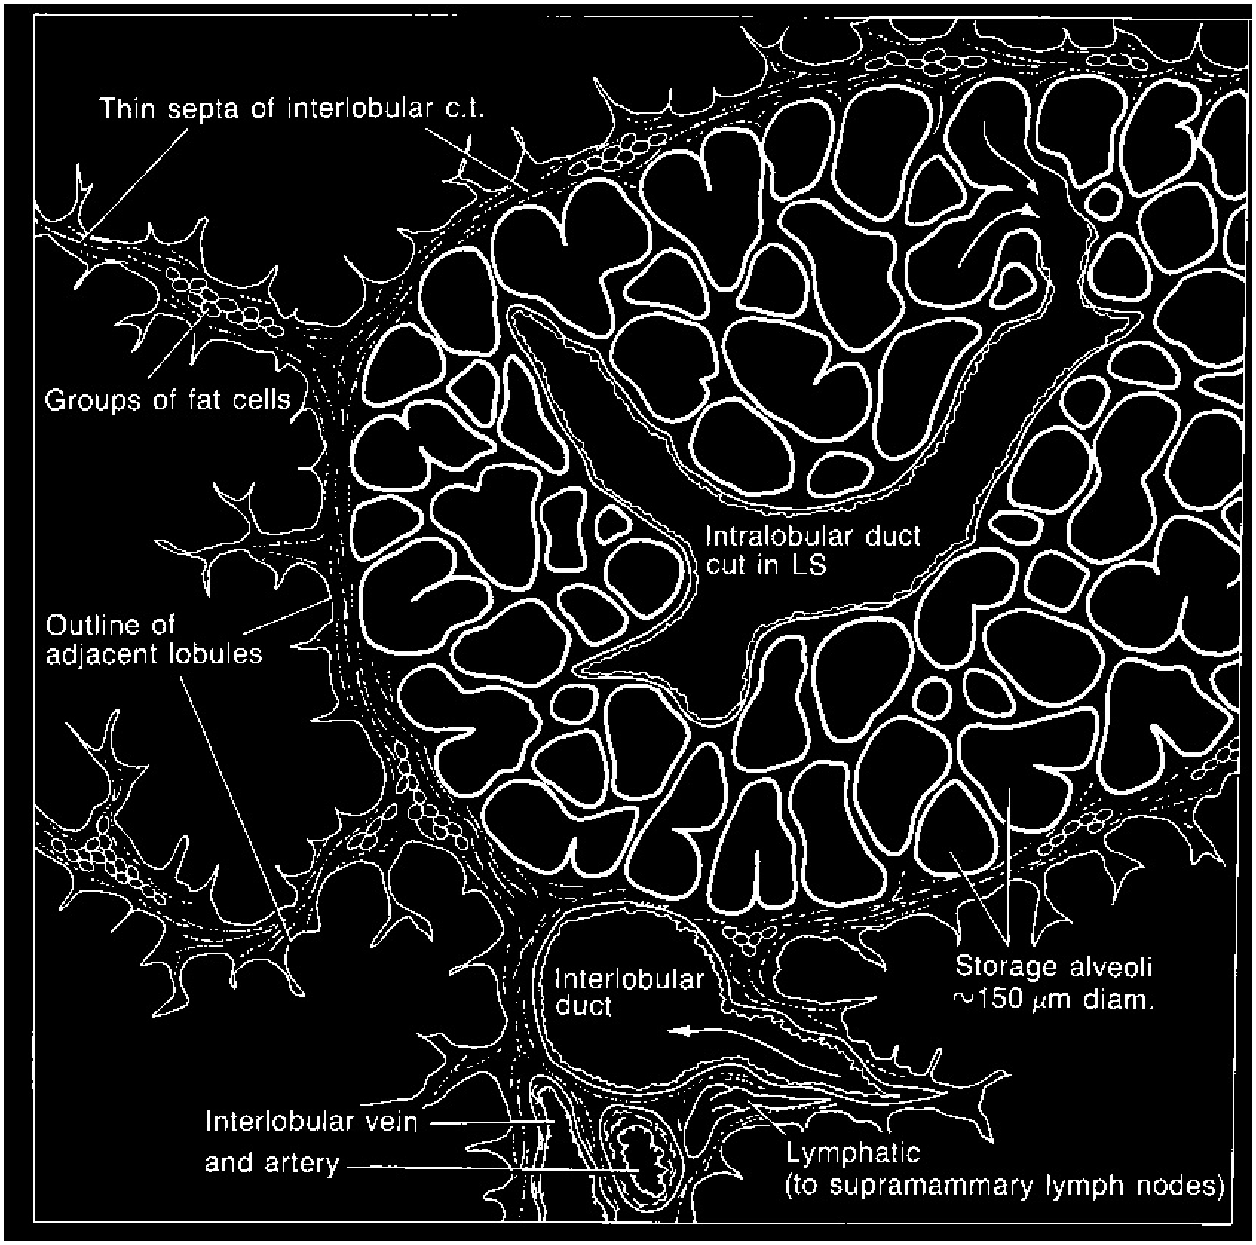
elastic tissues. Thus in section the lumen is a narrow



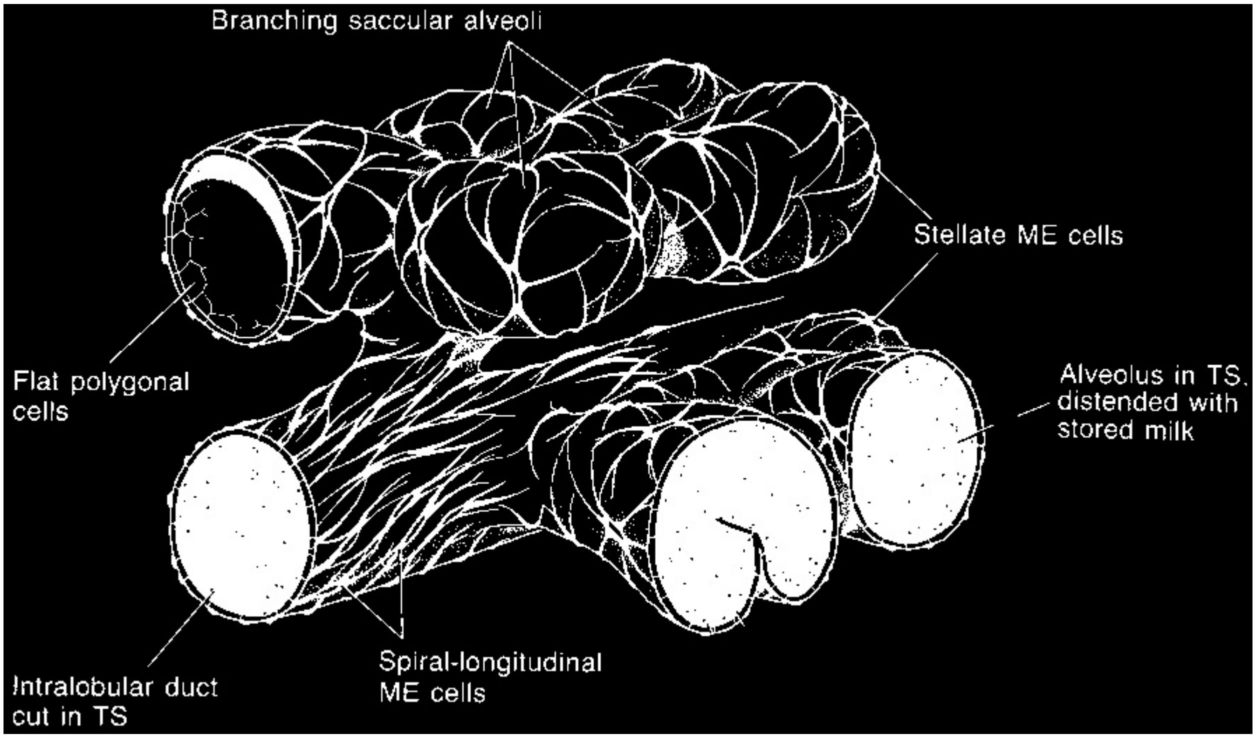


Fig. 22.3

Histological features of the lactating udder, showing large polyhedral lobules supported by thin septa of connective tissue carrying the distributing service vessels: interlobular ducts emerging (at lower right) from lobules, arteries supplying and veins draining the dense networks of perialveolar capillaries. Nearby collecting lymphatics carry a considerable flow of afferent lymph rich in lymphoeytes, neutrophils and macrophages and during infections, e.g.

mastitis, carrying antigens that induce immune responses in the supramammary lymph nodes. In each lobule the alveoli tend to be similar in size, but are generally smaller, averaging 60 mm across, with a tall cobbled epithelium in lobules that released milk at the previous lactation. When fully distended with milk, as shown, alveoli approach 150 mm in diameter and have a thin stretched lining. Smaller profiles represent alveoli slices in oblique to tangential planes. Intralobular ducts drain milk from alveoli (curved arrows), but unless fortuitously sliced in longitudinal section are almost indistinguishable from the alveoli, being comparable in width and lined by identical secretory epithelium. c.t., connective tissue; LS, longitudinal section (diagram by E.H. Batten).

Fig. 22.4

Diagram showing several branching milk-distended alveoli of the lactating udder draining into a relatively *wide intralobular duct. In the sectioned profiles fat droplets in the milk are shown white against a black background. Contraction of the network of stellate myoepithelial cells (cytoplasm black, nuclei white) expels milk from the alveoli into the intralobular ducts. In turn these become shortened and compressed by the contraction of the spirally aligned myoepithelial cells, which propel milk towards the larger interlobular ducts. ME, myoepithelial cells; TS, transverse section (after Linzell, 1961).*

Fig. 22.5

Diagram of a vertical section of a cow's teat, showing on the left factors that protect against mechanical trauma during suckling or milking, and on the right defences against ascending infection by bacteria from the skin surface (curved arrow) entering the teat canal.

Milk normally contains shed epithelial cells, from both alveoli and ducts, squames from the teat canal, small lymphocytes (SL), macrophages (MØ) and neutrophils (PMN). As phagocytes the last two cell types often contain small droplets of fat ingested from the milk. Subepithelial plasma cells occur near the ring of nodular lymphoid tissue that surrounds the rosette or inner end of the teat canal, where the stratified, keratinizing lining gives way to a bilayered cuboidal epithelium of the teat cistern. Insert right summarizes the early response to mastitis-forming bacteria experimentally introduced into the teat *canal. Bacteria (1) are ingested by milk macrophages (2), which release enzymes that damage and loosen the inner layer of the epithelium and neutrophil chemotactic factor (NCF), which induces (3) within 4 hours the emigration of large numbers of PMN from the subepithelial capillaries and venules. After insinuating through the cisternal epithelium the PMN (4) join with the macrophages in the ingestion and killing of bacteria. with microvilli (Fig. 22.6). In the junctional region

perhaps be regarded as an appendage of the udder

rather than vice versa! Indeed, the readjustment of

physiological processes that occurs in order to meet the

extra metabolic demands of lactation involves not just

differentiation and activation of mammary tissue but

extends to changes throughout the body. Not the least *of these is the hormonal regulation of nutrient utilization and partitioning between the mammary gland and other organs.*

Milk is a complex secretion and its production is under complex control. By understanding the underlying physiology, the relevance of correct nutritional and husbandry practices in maintaining health and optimizing performance may be better appreciated.

Mammogenesis

Mammogenesis may be defined as the growth and differentiation of the mammary gland to the stage prior to active secretion. Since milk yield is ultimately dependent on the number of secretory cells and their activity, factors that influence the former during mammogene-

production level

Although sucking and milking are the most potent and natural stimuli to elicit the milk ejection reflex, udder washing and even visual and auditory cues associated with milking routines can substitute, as the reflex becomes conditioned by experience. Stressful stimuli which involve the release of catecholamines and activity of the sympathetic nervous system can have negative influences on oxytocin release, mammary blood flow and oxytocin binding to myoepithelial cells, thereby inhibiting milk ejection. Myoepithelial cells also contract to an extent in response to direct mechanical stimuli, independently of oxytocin release. Palpation of the udder (or butting by calves) may trigger this local so-called 'tap reflex'.

Galactopoiesis

Frequent milk let-down and its removal from alveolar lumina assists in the maintenance of milk production (galactopoiesis) by preventing 'end product inhibition'. Nevertheless, the continued secretion of milk also *depends on a continued hormonal drive, which induces*

and maintains the synthetic enzyme complement of

secretory cells and also ensures an adequate supply of

substrates. The chief hormones implicated in the main-

tenance of lactation are different from those responsi-

ble for lactogenesis.

The essential role of the pituitary gland in the main-

tenance of lactation in all mammals has long been rec-

ronment. The bovine teat canal varies in length from 4 to 18 mm, with a median of 12 mm. It has a heavily keratinized surface and the keratin lining is crucial to the maintenance of its barrier function (Plate 23.1). Keratin traps bacteria as they try to penetrate the teat canal. Excess keratin is removed by shear forces during the milking process and this is a normal event. If there are poor shear forces, excess keratin and bacteria are not

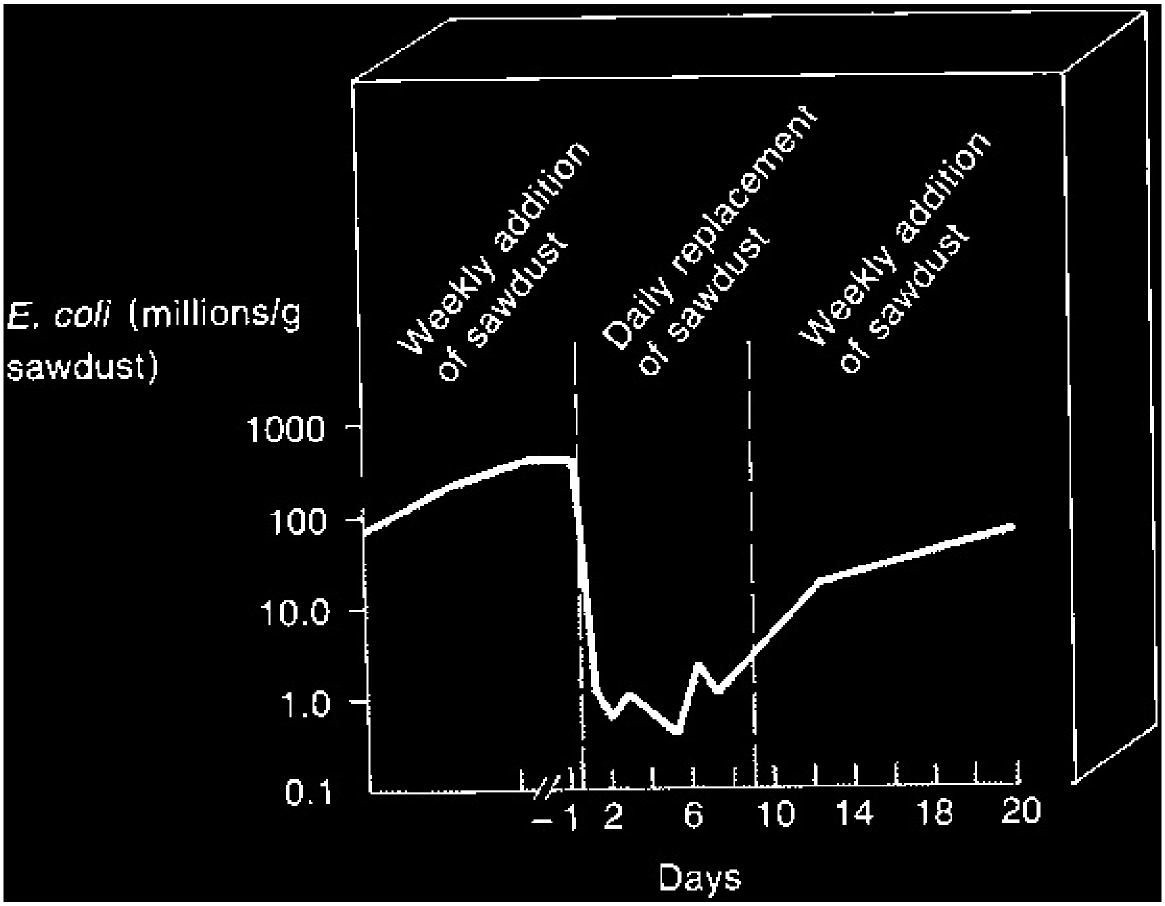
taken after treatment or at drying-off and calving.



Individual cow cell count or other diagnostic tests can be used to identify chronically infected animals for culling, treatment during lactation and other options, although such animals might be identifiable via an examination of clinical records. In the majority of herds the records are unfortunately inadequate for such a purpose. When using individual cow cell counts or other indirect tests the variation in inflammation should be remembered. Confident diagnosis on a single sample *is not possible. The changes in these measures due to lactation stage and yield are also relevant. Cell counts in colostrum and in dry-cow secretion are naturally elevated and diagnostically unreliable. As lactation declines and yield falls cell count and electrical conductivity increase slightly. Milk composition and cell count may remain permanently altered or elevated in*

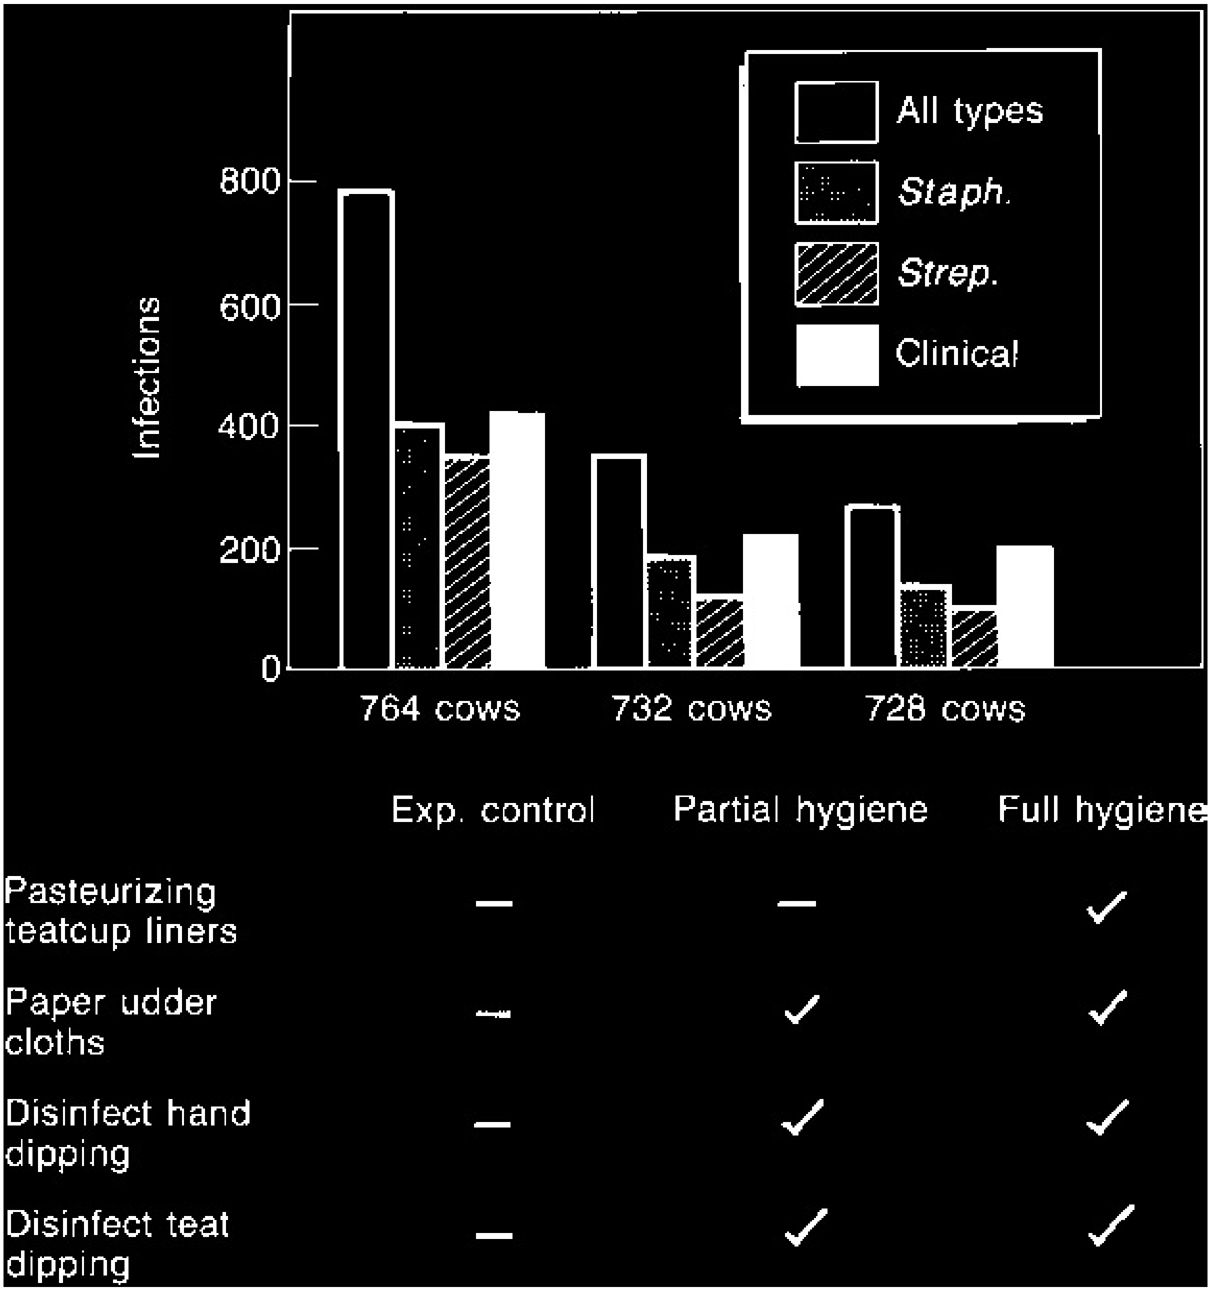
cleaned and bedded.

Since multiplication in the litter is a crucial factor in

There is unequivocal evidence that the events occurring

increasing challenge to the teat surface, regular removal

at milking time influence the incidence of mastitis.



These influences may be via the hygiene practised at

milking time or because of effects of the milking

machine per se. For details on how the milking machine can affect mastitis see Chapter 26.

Milking hygiene

The milk secreted by infected cows contains varying numbers of pathogenic micro-organisms. Herd milking provides opportunities for the transmission of these bacteria between udder quarters and cows via the milking machine itself, the milker's hands or cloths. Various techniques can be employed at milking time to reduce transmission including:

(1)

Using disinfected water for teat washing.

(2)

Employing individual paper towels or cloths for teat drying.

(3)

Wearing clean rubber gloves.

(4)

Applying a suitable disinfectant to the teat surface after milking.

(5)

Disinfecting or heat treating the cluster between

cow (Fig. 25.3; Blowey, 1983). This has the advantage

The wide variety of criteria that can be used to monitor mastitis are shown in Table 25.10, which is part of a 'league table' taken from a herd recording programme (Blowey, 1984). Bulk milk cell count is clearly the traditionally used parameter, but this is mainly a reflection of subclinical Staph. aureus, Strep.uberis or Strep. agalactiae contagious mastitis. It provides relatively little information on the incidence of environmental mastitis. The percentage of cows affected gives the proportion of cows in the herd that have been clinically affected by mastitis during a 12-month recording period. Any one of these cows may have had mastitis in one or more quarters and any one quarter may have had two, three or more mastitis incidents over a 12-month period. Defining a case as one quarter affected once, and a remission of clinical signs for six days or more being needed before a new case commences, then the case incidence of mastitis can be calculated. As far

Fig. 25.3

Fig. 26.3

Recorder milking machine.

Milking machine testing

Milking machines are tested to assess whether they are in good mechanical condition and conform to working standards as laid down by the standards institution of that country where used. Static and dynamic tests are used.

Static test

This type of test has been carried out for many years. It is basically an engineer's test to check for correct functioning of the components of the machine. The machine is set for milking and plastic bungs placed in the liner mouthpieces. No milk flows and, therefore, the test does not give an indication of how the machine will perform during milking.

There are three measurements to look for when interpreting a static test report:

(1)

Effective reserve. Vacuum within the plant is *created by the vacuum pump. Air is used by the*

pulsators, air holes in the claws and leaks in the

plant, etc. The spare vacuum capacity left after

compensating for these leakages is called the

effective reserve. The effective reserve is used to

and there is a set of standards for the maximum

consumption allowed. It is worth checking that the

results of the test are within the normal range.

Fig. 26.5

Vacuum changes (cyclic fluctuations) at the teat end

during milk flow.

Practical tips

As a veterinary surgeon in practice there are two simple

ways of checking the effective reserve of a machine:

(1)

Put plant in milking position with plastic bungs in

the liners. For every five units, open one and let air

in. If the effective reserve is sufficient the vacuum

level, as read at the vacuum gauge, should not

drop by more than 2 kPa (about 3/

Fig. 26.6

Vacuum changes (irregular fluctuations) at the teat

4

inch Hg)

(O'Shea, 1982).

end during milk flow. Source: Nyhan (1968).

(2)

Again put plant in milking position with plastic

bungs in the liners. By letting air in the plant, via

the gate valve, drop vacuum to 33 kPa (10 inches

Hg). Close off air leakage. The vacuum should

return to 50 kPa (15 inches Hg) within 3 seconds

(Mein, 1984).

Dynamic test

Dynamic testing was indicated in only 1 per cent of

herds (O'Callaghan et al., 1982) where there was a mastitis problem and the static test had revealed no faults.

At that time, equipment was either very sophisticated

and expensive (UV recorder) or crude (pulsation pen

recorder). In recent years, with the advent of computer

Fig. 26.7

Liner slip at the teat end during milk flow. LS, liner

technology, new recording machines specially designed

slip; 2.5 kg, flow rate of 2.5 kg/min.

for dynamic testing have been developed.

In dynamic testing the vacuum level is measured at *the clawpiece and other areas of the machine, e.g. the*

recorder jar, throughout the milking of a number of

• Irregular fluctuations: occur as a result of changes in cows. This allows the determination of what is happen-airflow during milking, which leads to a drop in

ing when milk and air are flowing in the machine and

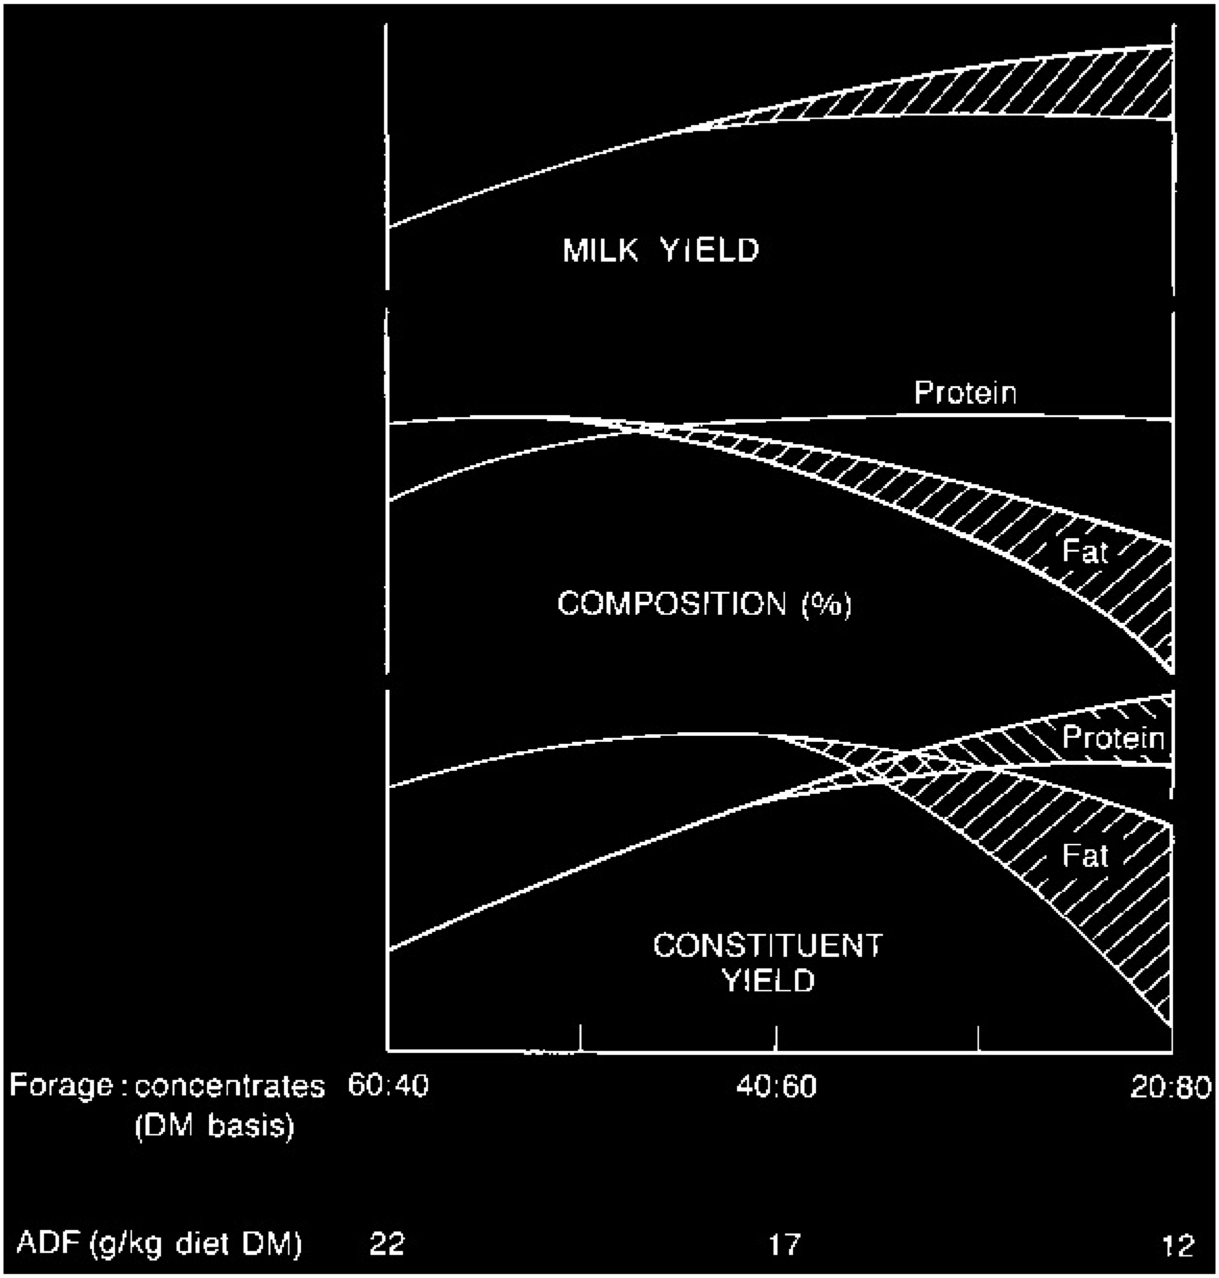
mented and as such causes less depression of milk fat,

• Starch, for example barley and maize.

compared with other more rapidly fermented starch



and milk quality, but this will depend on the economic milk price : concentrate cost ratio prevailing at the time, and a full discussion is well outside the scope of this review.

Of course, low forage intakes may not occur intentionally. Poor quality fodder such as very wet, very acid or very butyric silages will depress intakes and thereby increase the concentrate : forage ratio. A more common problem is probably inadequate access. Self-feeding consolidated silage, particularly behind an electric wire, may depress intakes of even good quality material by as much as 5–10 per cent and could further exacerbate the problem.

There is no requirement for 'long fibre' in the basal ration to maintain milk quality, and diets containing long fibre length generally give the same milk quality as finely chopped silage (Thomas, 1984). However, there is some evidence that silage diets give better milk quality than rations of equal metabolizable energy intake based on hay. Fine grinding of forage will *depress milk fat when used as the sole ration, but if used*

epithelium which constantly undergoes keratinization.

Limitations of vaccination

389

A slightly projecting fold marks the proximal end of

the teat canal, the Furstenberg's rosette area. The teat

cistern (sinus) is the cavity directly proximal to the teat

canal, and this continues into the parenchyma of the

Introduction

udder as the gland cistern (lactiferous sinus), which pos-

sesses a two-layered columnar epithelium. The secre-

The examination of immunological methods to increase tory tissue is divided into lobes which are composed resistance of the dairy cow to pathogens which cause of lobules and there is an extensive duct system. The mastitis has been ongoing for almost a century. This is epithelium of secretory alveoli is a single layer of a controversial area of bovine immunity with the exis-cuboidal cells. The alveoli are surrounded by a stromal tence of two schools of thought on the role of immuno-layer which is more pronounced in the non-lactating logical intervention in mastitis control programmes. gland.

The first believes it is not possible to generate protec-tive immunity in the mammary gland and control meas-ures should be based on management, therapeutic strategies and genetic selection (Mellenberger, 1977).

Defence mechanisms of the gland

The second opinion is vaccination has a role in a mastitis control programme (Colditz & Watson, 1985). Non-specific and specific defence mechanisms exist in The latter view, founded on an improved knowledge of the bovine mammary gland (Outteridge & Lee, 1988).

Hoof trimming. Cut one should not be made too short.

upright position. The horn to be removed in cut two lies beneath the line AB (Fig. 31.5), which is a line joining cut one to the base of the heel. The first part of cut two can be performed by removing part of the wall using hoof clippers, but later stages should be carried out with a hoof knife, using thumb pressure to check this area of the sole regularly for signs of softening. A softening of the horn should not occur, but if it does then trimming must stop. There will only be a few millimetres of horn before the corium is penetrated and exposure of the corium in this area of the foot can lead to quite severe and protracted lameness.

If cut one was in the correct position it should be possible to remove horn from the sole surface of the toe until the white line and adjacent wall are once again clearly visible at the toe. The wall is now the weight *bearing surface. It is important that this is achieved, otherwise the weaker white line structure would become weight bearing, with obvious adverse consequences.*

It is vital that cut one does not make the hoof too short; this scenario is shown in Fig. 31.6. Because cut one was too short, a line drawn from the top of cut one to the bottom of the heel (AB in Fig. 31.6) would lead to exposure of the corium at the toe and this can produce severe lameness.

Cut three

Fig. 31.7

Hoof trimming. Cut three and the finished foot.

Cut three consists of removing any axial overgrowth of the sole, followed by dishing the axial sole surface of both claws (Fig. 31.7a), so that weight bearing beneath the flexor tuberosity of the pedal bone is minimized.

Cut three also slightly increases the space between the longer. This usually means removing additional horn digits. This makes impaction by dirt and foreign bodies from the outer claw of hind feet and the inner claw of less likely, decreasing the incidence of diseases such as front feet, bringing the legs back to the upright position.

acts as a disinfectant and drying agent.

Vertical fissures (sandcracks)

Hoof disorders

Vertical fissures occur as a result of damage to a small

area of the periople and underlying coronary band.

Foreign body penetration of the sole

Horn formation is disrupted at that point, although the

Typical foreign bodies are stones (especially sharp

adjacent horn continues to grow. This leaves a gap (the

flints), nails (particularly those with flat heads), frag-

vertical fissure) running down the hoof wall from the

ments of wood, glass or tin and occasionally even the

barrier bruises the scapular region. Associated injuries

can include fractures of the scapular neck or acromium.

Radial paralysis

Clinical signs and diagnosis

Aetiology and pathogenesis

Suprascapular paralysis causes few clinical signs ini-

The nerve (roots C7–T1) is damaged in its distal portion

tially. The shoulder joint may be slightly abducted and

secondarily to humeral shaft fractures, which tend to be

Cattle maintained in lateral recumbency under general

anaesthesia should have soft supporting surfaces and

the down forelimb should be extended forwards to

reduce the pressure on the vasculature to the lower

parts of the limb. Also, the upper foreleg should not be

roped tightly down against the table, whereby it would

increase pressure on the lower leg.

Femoral paralysis

Aetiology and pathology

The femoral nerve (L4–6 spinal nerve roots) has a short *course, ramifying in the iliopsoas and quadriceps*

muscles. It is liable to damage in the oversized fetus of

large-framed breeds (Simmental, Charolais, Holstein)

Fig. 32.1

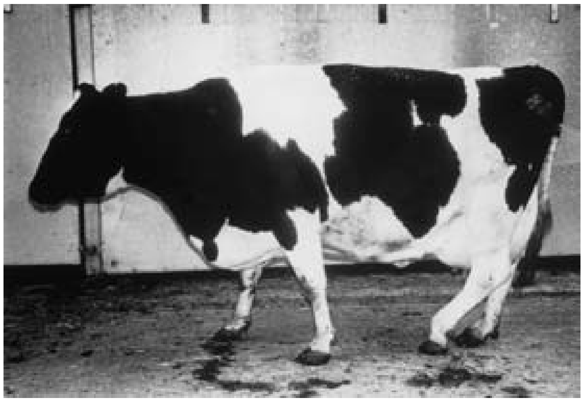
care should be continued for several days. Breeding

cast to the fetlock.



***Downner cow syndrome** (see p. 797)*

Defined as ‘a cow down in sternal recumbency for unknown reasons’, the syndrome usually affects high-yielding dairy cows in the first 48 hours postpartum. In the UK the incidence appears to be increasing as a result of overcrowding in cubicle houses (see p. 43). Veterinary attention may not be sought for 24 hours, as a response to calcium borogluconate therapy is awaited. The condition has a multiple aetiology including traumatic, metabolic, neurological and toxic infectious causes. The following are examples:

• Traumatic: sacroiliac luxation and subluxation,

cast materials varies, plaster of Paris being poor,

Deltalite/Scotchcast fair with some mottling, and Cuttercast/Baycast is excellent.

Extension bars have sometimes been incorporated into external casts. These U-shaped metal stirrups have the curved part of the U distal to the toes, so that weight is borne by the bar and transferred proximally to the cast, into which the two arms of the extension bar are buried during cast application. Such a device is only useful if there is a specific indication to avoid weight bearing by the digits. The effective increase in limb *length makes standing up and ambulation more diffi-*

cult. A modification is the hanging cast. This device

comprises one or more intramedullary pins that are

drilled through the proximal fracture fragment, and

onto which a U-shaped bar is fitted after the usual

external immobilization has been applied. When weight

is borne, it is transferred proximally to load bearing by

the proximal fracture site, so that the fracture site is not

stressed.

Thomas extension splints may be put on either fore-

limb or hindlimb. Good padding is essential both at the

points (axilla, inguinum) where maximal pressure will

be applied, as well as at any contact points more dis-

tally. The Thomas extension splint must be 'made to

measure' for the individual case (e.g. circumference of

proximal and distal rings, length of cranial and caudal

tion of forced traction in dystokia. The usual site is the

fracture involving the acetabulum. The simplest method

of treatment is confinement, which has a low success

rate. Alternatively, the femoral head may be resected to

permit development of a pseudoarthrosis, but lameness

usually persists along with obvious muscle atrophy and

compensatory conformational changes in the contra-

lateral limb. Finally, internal fixation by Knowles pins *or lag screws has been successful but requires intraop-erative radiography to ensure the correct direction of insertion from the lateral aspect of the greater femoral trochanter.*

Vertebral fractures

Aetiology and pathology

Elsewhere in this chapter, reference is made to long bone fractures and growth plate separation (p. 444) resulting from excessive traction during dystokia. But vertebral fractures due to forced traction, usually in an exotic beef breed such as Charolais, can lead to fracture and/or luxations in the caudal thoracic or cranial lumbar region (preferentially T12–L3). The common form is a fracture of the caudal physis of T13 (Schub & Killeen, 1988).

Postmortem changes include perirenal and

Vaginal palpation should be performed in mature cows and recently calved heifers.

Clinical diagnosis of acetabular fractures, which tend to involve the dorsal rim, is difficult as the localized crepitus must be distinguished from coxofemoral dislo-

cation (in which the greater femoral trochanteric position is abnormal) and femoral neck or physeal fractures (which may be suspected from the increased mobility of the hip region in the affected limb). Radiography is essential for diagnosis in some cases, but, due to size and equipment constraints, is rarely feasible.

Other differential diagnoses include pelvic bruising leading to heamatoma formation and pelvic abscessation.

Haematomas rarely cause lameness, while abscesses tend to have a more gradual onset and a protracted course. Several sites of pelvic fractures can lead to nerve trunk (sciatic, femoral, obturator) and blood vascular damage (middle uterine artery, internal pudendal, internal iliac arteries and veins).

Fractures of the bodies of the ischium and pubis invariably involve the obturator foramen, usually also the obturator nerve, and are serious in that marked pain and discomfort tend to cause prolonged periods of recumbency and a reluctance to stand. Commonly, both bones are fractured, making the pelvis unstable, and *healing is then unlikely. In some cases, healing is liable*

to be accompanied by excessive callus formation. This

sometimes extends to produce hip osteoarthritis and a

persistent lameness.

week. Surgery is preferably carried out in the standing case as an aseptic procedure following sedation and local analgesia. A large udder or a difficult temperament makes recumbency (affected side down) necessary in some cases. The surgical site is superficial to the most distal palpable point of the medial patellar ligament, close to its insertion into the tibial tuberosity.

A 4 cm (11/2 inch) long vertical skin incision is made cranial to the ligament. A tenotome is inserted just deep to the ligament with the blade in a vertical position. A Hey Groves knife, with a blunt rounded point, is ideal for this surgery. The conventional disposable scalpel blade and (Bard) handle are unsuitable since slight movement easily results in breakage and loss of the *blade. The cutting edge is rotated through 90° towards*

the skin and the medial patellar ligament is sectioned

diameter polyvinyl drainpipe may be placed on a well-

padded limb to immobilize the flexed joints in *maximum extension. Such a splint in a neonatal calf must be checked by weekly removal and replacement. The toes should be left exposed to encourage weight bearing and walking. If the stance is not corrected in four weeks, surgery is indicated.*

More severe cases will only respond to desmotomy, which should be undertaken at two to three weeks old, after the immediate neonatal stress period. Correction of carpal flexion is possible at the mediopalmar side of the carpus by an initial longitudinal incision through the retinaculum flexorum, exposure of the superficial part of the superficial flexor, and by complete transection of the retinaculum flexorum, which also involves section of the radial carpal flexor. If normal extension is not

metacarpophalangeal joints of the forelimbs.

Clinical signs and diagnosis

Steers and young bulls are predominantly affected.

Some lesions cause no clinical signs, while others

produce a mild progressive lameness. Some lesions heal

following production of fibrocartilage. This accounts for

the larger percentage of lesions in autopsies than in

clinical series of lame cattle. Other lesions progress to

become a secondary degenerative osteoarthritis or

degenerative joint disease (DJD). Exacerbations of a

mild slight lameness have been attributed to additional

joint trauma. If warranted, a doubtful case may be

radiographed, but cartilaginous defects are unlikely to *be demonstrated unless pneumoarthography is per-*

formed. Suspicious evidence of osteochondrosis is the

lage and erosions in subchondral bone.

Degenerative arthritis

Aetiology and pathology

Degenerative arthritis (degenerative joint disease,

DJD) is attributed to a 'wear-and-tear' phenomenon.

This chronic non-infectious disease involves primary

degeneration of articular cartilage, generally accom-

panied by secondary sclerosis and eburnation of sub-

chondral bone, peripheral osteophyte formation and

surrounding soft tissue proliferation.

Though a common incidental finding at slaughter, its

primary clinical significance is as a cause of progressive

debilitating lameness involving major weight-bearing

joints. In one study of the stifle and hip joints of cattle

Fig. 32.11

The result is extensive loss of tages over either phenylbutazone or aspirin for arthri-articular cartilage, acute synovitis, thickening of the*

colostral intake) are at higher risk. Lameness becomes severe after a few days.

Radiology is not a great aid to diagnosis, as the only initial abnormality is the soft tissue swelling. After two to three weeks, changes suggestive of joint destruction are apparent.

Arthrocentesis is a more valuable aid to diagnosis in early cases. Apart from an increased volume, synovial fluid in a calf with joint ill is turbid, clots, and has a loose flaky character in the mucin precipitate. The protein *content is >5 g/dl and a Giemsa smear reveals an almost pure (98 per cent) and massive population of polymorphonuclear lymphocytes. Taken aseptically, synovial fluid may be submitted for culture, but is often problematical with this particular material (see p. 457). Differential diagnosis must be made from physeal and intra-articular fractures.*

Treatment and prevention

Early and vigorous treatment is essential in joint ill. High therapeutic levels of systemic antibiotics should be given for two to three weeks. Intra-articular antibiotic medication is usually contraindicated, as the blood supply ensures adequate concentrations are obtained in synovia following systemic injection. Suitable antibiotics include penicillin, ampicillin and tetracyclines. Joint lavage with a sterile polyionic solution or

bursitis.

Septic arthritis in a major weight-bearing joint causes

Organisms commonly recovered from septic arthritis

a rapidly progressive disease with severe lameness,

in adult cattle include A. pyogenes, E. coli, Staphylo-swelling and localized pain. In contrast to DJD, the

animal may be anorexic and milk yield can drop

abruptly in dairy cattle. Crepitus is not usually appar-

ent. Arthrocentesis reveals a flocculent or purulent fluid

that clots. It has a high leucocyte count of which over

90 per cent are polymorphs. The protein content often

exceeds 8 g/dl and the mucin precipitate is abnormally

flocculent.

A category 'suspect septic' refers to an early septic

process associated with obvious lameness but appar-

ently normal yellow synovia. The presence again of a *high percentage of neutrophils in a dense leucocyte population is confirmation of early septic arthritis.*

Radiography in early (<10 days duration) septic arthritis is usually unhelpful. Ultrasound, on the other hand, can delineate the limits and physical nature of the fluid. From 14 days onwards, subchondral bone destruction and a peripheral periostitis are suggestive of joint sepsis.

Culture of synovial fluid is frequently negative in terms of isolation of pathogens, especially if antimicrobial therapy has already started. It is helpful if synovia is immediately inoculated into a diphasic culture bottle with sodium polyanetholsulphonate to enhance recovery of the organism. Culture of synovial biopsy material is usually more rewarding but is frequently impractical.

Treatment and prevention

The prognosis for septic arthritis is guarded or poor. Early aggressive treatment is essential. Parenteral

neurectomy.

muscle is awkward, complete tibial neurectomy has been advocated (Boyd & Weaver, 1967). Surgery is performed under sedation and epidural block, or general anaesthesia. The site is the lateral thigh, between the two heads of the biceps femoris muscle. The tibial and peroneal nerves are identified by stimulation by forceps or by electrical means. Tibial nerve stimulation causes hock extension and fetlock and digital flexion. The tibial nerve should have a 2 cm (1 inch) portion removed at its most proximal point. Complications following this surgery are uncommon.

In a very con- The swelling is usually symmetrical. Hair loss and taminated environment such damage, arising from skin excoriation are evident. Usually the skin is not broken. Occasionally, a central area of skin sloughs, permitting a dirty red–brown material to escape. At this time, septic infection can supervene and a purulent discharge may be noted for several days before granulation tissue fills the cavity of the false bursa.*

Clinical signs and diagnosis

The distribution of the swelling and absence of lameness are almost characteristic (Fig. 32.16). An infectious tarsitis causes a more diffuse swelling and obvious lameness, as will a tarsal bone fracture. Tarsal hydrarthrosis first causes synovial distension of the joint capsule cranially and medially, then both medial and *lateral to the caudal border of the tibiotarsal bone, and*

cranial to the base of the calcaneus. Tarsal hydrarthro-

sis is a cosmetic blemish and causes no lameness.

Treatment and prevention

The seasonal occurrence of tarsal bursitis, becoming

increasingly severe during the housed period and dis-

appearing in the summer grazing months, is evidence

phosphorus imbalance is also involved. Vitamin

D-deficient diets may be identified on some farms

where feed is home-mixed.

Clinical signs and diagnosis of rickets

Calves have enlarged metaphyses and growth plates of

the long bones, especially the distal metatarsus and

metacarpus, fetlock and pastern. The swellings are

rather painful to pressure. The costochondral junction

exhibits the classical 'rickety rosary' in calves. Radio-

graphic changes include a widened area of radiolucency

at the growth plate with flaring of the distal metaphy-

ses, usually in the carpus, pastern and fetlock.

The diagnosis rests on the soft tissue swelling at

Fig. 32.18

lameness may reflect pain due to subcutaneous absces-

cattle, but necrosis of the ground substance, resulting

from folding of the cell columns and loss of continuity,

has been noted histologically in housed fattening cattle.

Poor-quality, uncomfortable floor surfaces predispose

rapidly fattening cattle with limited exercise space to

physeal dysplasia.

Gross pathology reveals some subcutaneous oedema

and red or red–grey discoloration around the growth

plate, which is either necrotic or, in severe cases, puru-

lent. In its most severe form the growth plate undergoes

separation.

Copper deficiency or a combined copper–molybde-

num deficiency (see pp. 254, 298) has also been associ-

ated with physeal dysplasia as a result of defective

collagen formation. The abnormal collagen does not

permit normal mineralization. The result is stiffness and

lameness in calves with a characteristic distal metatarsal

swelling. Another result is an increased incidence of

long bone fractures.

Clinical signs and diagnosis

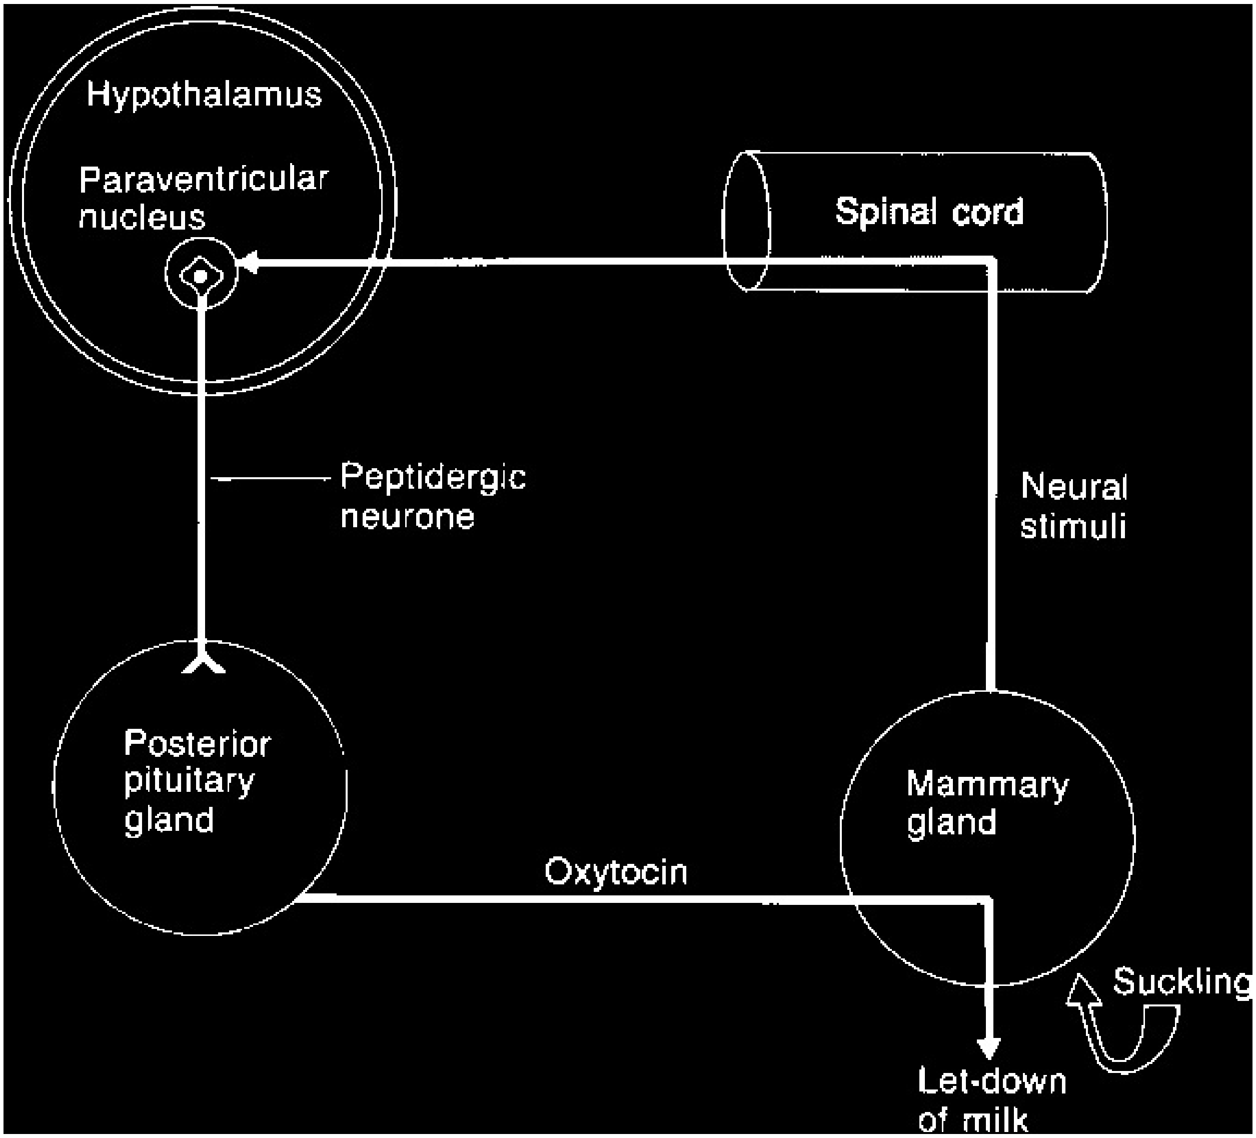

Fig. 33.1

This diagrammatic representation of a typical peptidergic neurone depicts: (i) the uptake of neural signals by dendrites; (ii) the uptake of endocrine signals by specific *receptors located either in the cell membrane (for water-soluble hormones: peptides, proteins) or in the nucleus (for lipid-soluble hormones: steroids, thyroid hormones); (iii) the endocrine response to signals (synthesis, transport and storage of regulatory peptide); (iv) the neural response to signals (generation and conduction of action potential, which is responsible for the discharge of the regulatory peptide).*

before they are transported down the axon to the nerve terminals where they are stored pending release. The peptidergic neurones retain the electrophysiological properties of nervous tissue and they use their electrical activity to release the peptides.

A typical peptidergic neurone (Fig. 33.1) has many hundreds of synapses and through these it receives neural inputs (information) from most parts of the brain. (It also receives information from humoral *inputs; we shall return to this topic later.) The neural and humoral inputs may be stimulatory or inhibitory; at any one moment the response of the peptidergic neurone will reflect its assessment of the current inter-play between the synergistic and conflicting stimuli. When the stimulatory inputs exceed a critical threshold an action potential is generated, the nerve impulse passes down the axon and it causes the release of the (stored) peptide at the nerve terminals. Usually, the nerve terminals are in close apposition to capillaries with highly fenestrated walls that allow the peptide*

Fig. 33.2

release.

A simple example to illustrate the physiological phe-

neurones whose cell bodies are located (principally) in

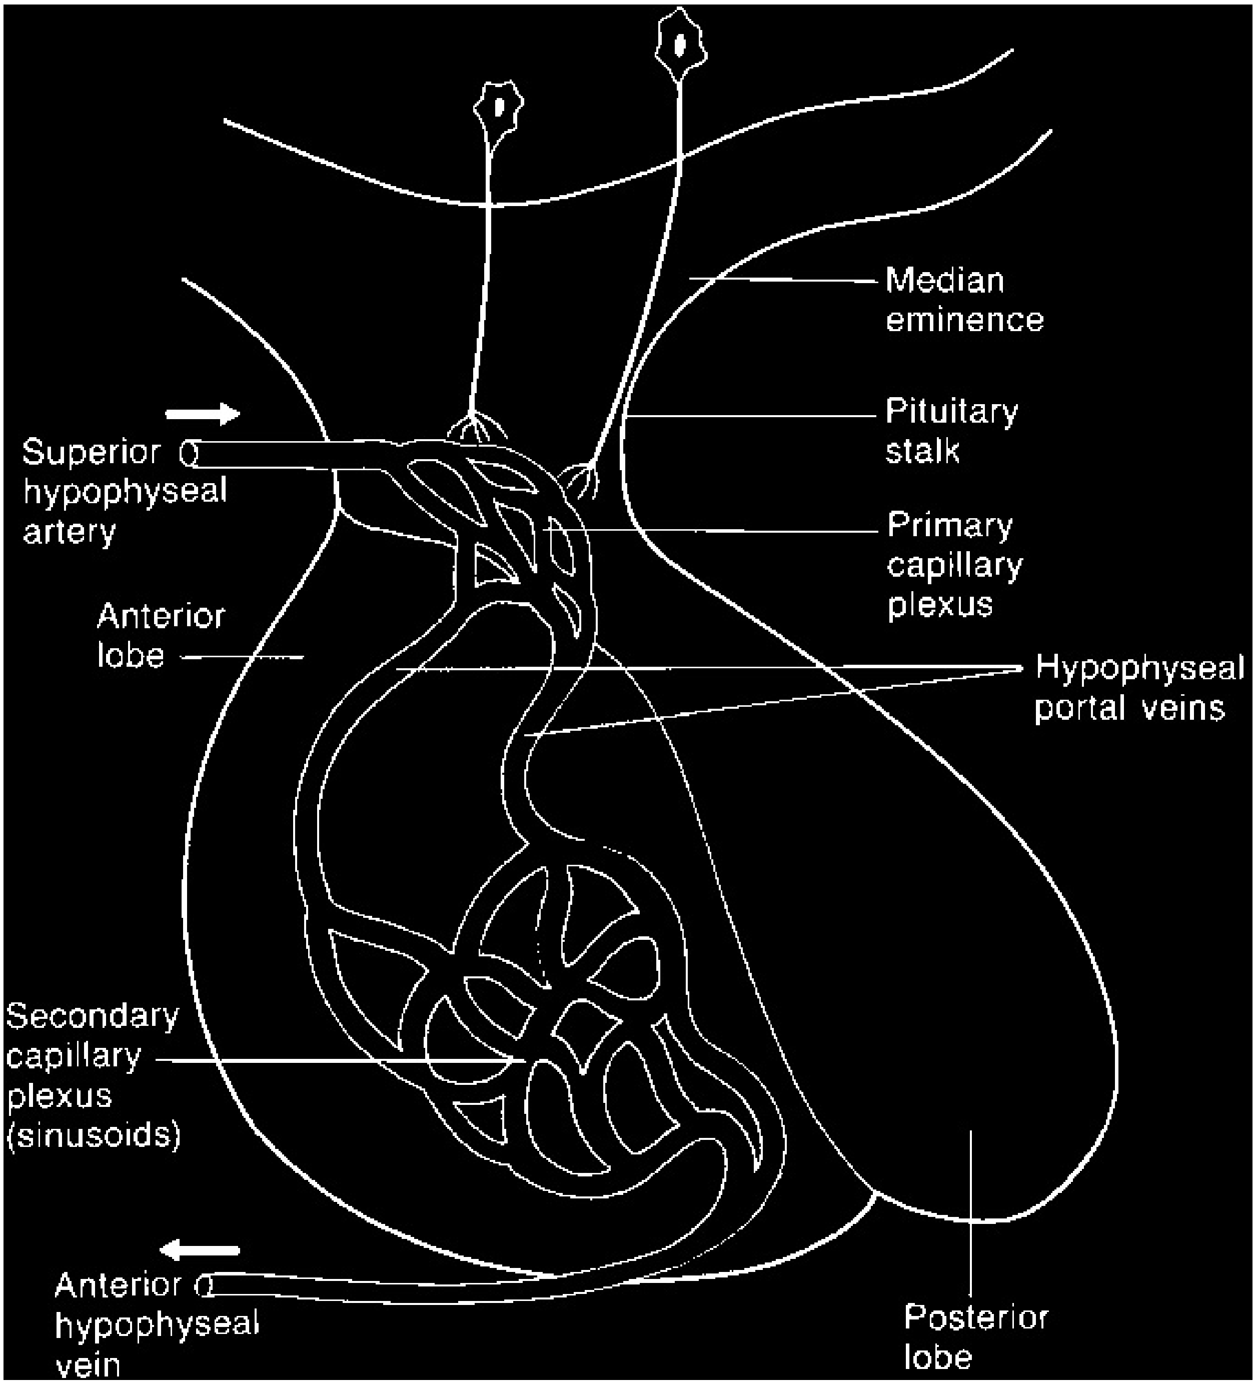
nomena just described is the milk ejection reflex (Fig.

the paired paraventricular nuclei in the hypothalamus

33.2). This reflex depends on a suckling-induced release *and whose axons pass through the pituitary stalk into*

of oxytocin. Oxytocin is produced by peptidergic

the posterior pituitary gland. Suckling evokes sensory



impulses that travel via the spinal cord to the brain where they converge on the paraventricular nuclei and generate the impulses in the peptidergic neurones that lead to the release of oxytocin from the nerve endings in the posterior pituitary gland. The reflex is completed when the oxytocin in the blood perfusing the mammary gland induces ‘let down’ of milk. Conceptually, this is neuroendocrine regulation at its simplest: the neurone that ‘reads’ the afferent sensory message also produces and releases the effector hormone. This is possible only because the posterior pituitary gland, which arises as a downgrowth of neural tissue from the floor of the third ventricle, retains a direct neural link with the hypothalamus.

The anterior pituitary gland

The anterior pituitary gland (adenohypophysis) arises as an upgrowth from the roof of the primitive mouth and, therefore, it does not have a direct neural link with the hypothalamus. A vascular route has to be used to bring the regulatory peptides from the hypothalamus to the adenohypophysis. A specialized arrangement of

Fig. 33.3

The primary capillary plexus, the hypophyseal

the vasculature, the hypothalmo–hypophyseal portal

portal veins and the secondary capillary plexus form the

external walls of the capillaries in the primary plexus.

From this the blood is drained by the hypophyseal

portal veins, which pass down the pituitary stalk to end

in a secondary plexus (the sinusoidal capillaries) within

the anterior pituitary gland (Fig. 33.3). From there the

plexus, the hypophyseal portal veins and the secondary *blood returns to the general circulation via the anterior*

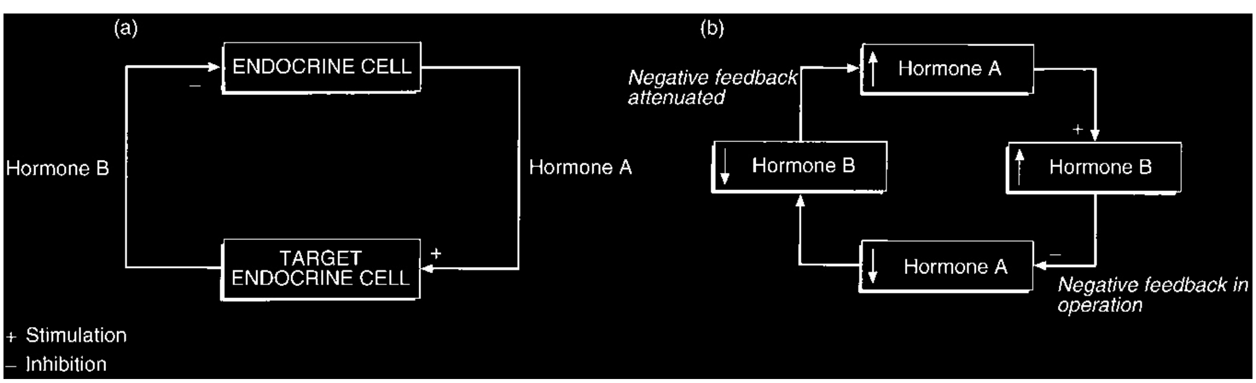

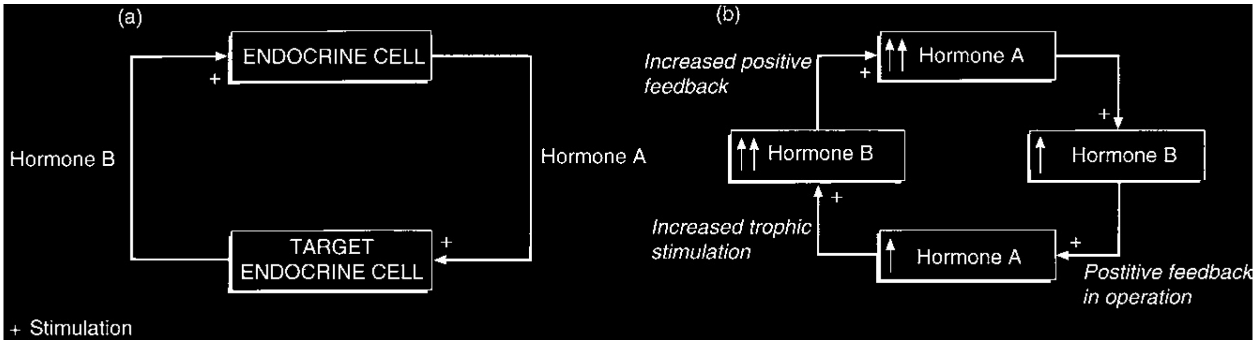

Fig. 33.4

Negative feedback. Example: hormone A, FSH; hormone B, oestrogen. FSH stimulates the production of oestrogen by the granulosa cells of the ovarian follicle. The oestrogen exerts an inhibitory effect on the release of FSH by the pituitary gland. When the oestrogen declines the negative feedback is attenuated and secretion of FSH is increased.

Fig. 33.5

Positive feedback. Example: the gonadotrophins FSH and LH (hormone A) stimulate the secretion of oestrogen (hormone B) by the granulosa cells of the preovulatory ovarian follicle (see Fig. 33.24). The rapidly rising concentration of oestrogen (the 'oestrogen surge') stimulates the hypothalamus and the pituitary gland to release a surge of gonadotrophins that is responsible for ovulation.

(see p. 492). Alternatively, the hormone stimulus may decrease the sensitivity of the target tissue because it increases the degradation and/or decreases the synthesis of receptors; for instance, GnRH can 'down regulate' its own receptors in the adenohypophysis, especially when the gonadotropes are subjected to constant stimulation rather than pulsatile stimulation by the releasing hormone (see p. 497).

The inherent mode of secretion of hormones in the neuroendocrine system is pulsatile and it is controlled by an oscillator or pulse generator in the hypothalamus. The activity of the pulse generator can be modulated both by neural inputs and by feedback signals from the median eminence, the pituitary gland and the gonads. In turn, the pulse generator will seek to ensure that the characteristics of the signals emanating from the pituitary gland and the gonads are altered so as to elicit the appropriate responses from target tissues in the reproductive tract. In that way the hypothalamus exercises *fine tuning as well as gross control over reproductive events such as puberty, gametogenesis, oestrus, pregnancy, parturition and lactation.*

Before we deal with the neuroendocrine regulation of those processes, it is appropriate to mention three systemic conditions that can constrain the reproductive system: energy balance, stress and neural–immune interactions.

Systemic constraints on reproduction

Energy balance

Although reproduction is critical for the survival of the

Fig. 33.10

Preovulatory surge of LH on day 18 of the oestrous

species, processes that are of more immediate impor-

cycle in a cow. (Redrawn from Rahe et al., 1980).

tance for the survival of the individual take top priority when an animal allocates available metabolic fuels among various energy-consuming activities (Fig. 33. 12). Hence, changes in the availability of metabolic fuels affect reproductive functions, through actions at multi-

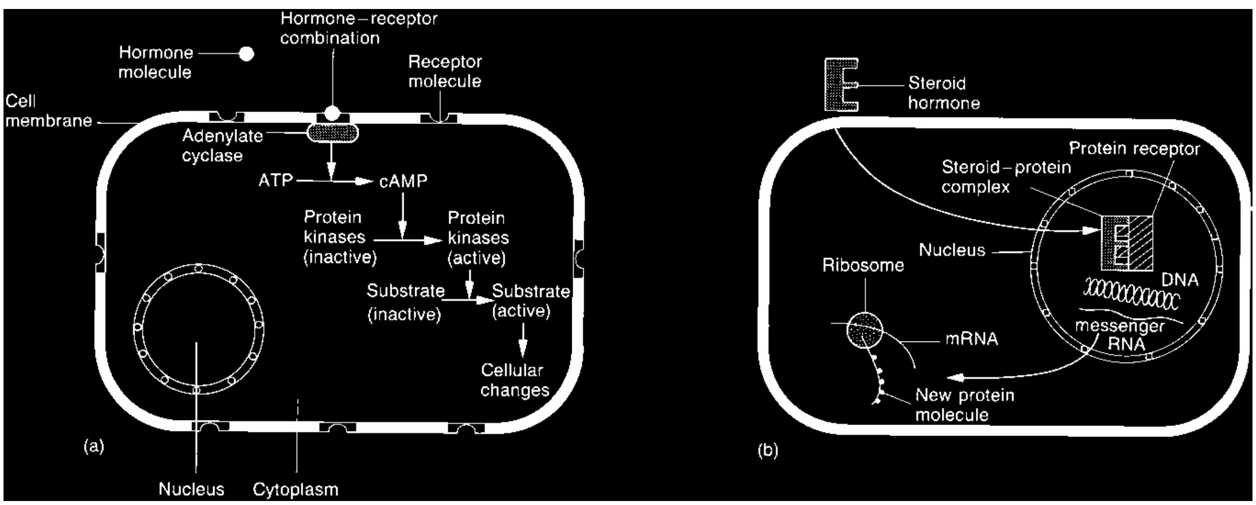

Fig. 33.11

Interaction of hormones with target cells. In (a) a glycoprotein (the 'first messenger') binds with receptors in the cell membrane and activates adenylate cyclase in the membrane. Adenylate cyclase converts ATP to cyclic AMP (the 'second messenger') which, in turn, activates various protein kinases. The *resultant cascade of enzymatic activity produces the characteristic cell response to the endocrine signal. In (b) a steroid hormone enters the nucleus where it binds to its receptor. The receptor–hormone complex binds to a particular region of DNA and activates particular genes. The activated genes promote the synthesis of particular messenger RNA molecules that pass from the nucleus to the cytoplasm where they induce the synthesis of proteins (mainly enzymes) that are responsible for the characteristic actions of that hormone in that cell type.*
