The seminiferous tubules are about 200 mm in diameter and they may be up to 70 cm long; they open at both ends into the rete testis (Fig. 33.15). The tubules contain two populations of cells: (i) a fixed population of non-proliferating somatic cells, the Sertoli cells, and (ii) a migratory population of proliferating, differentiating germ cells (Fig. 33.16).

Sertoli cells

The Sertoli cells have been described as the 'backbone' of the tubule. They are columnar cells that rest on the basement membrane and extend the full depth of the epithelial layer; they envelop the developing germ cells in deep recesses in their lateral walls and, ultimately, in their luminal surfaces. The Sertoli cells continually alter shape to accommodate the morphological changes in

reaction.

There is no doubt that an intact hypothalamic–

pituitary–testicular axis is essential for normal testicu-

lar function; however, apart from the fact that FSH is

essential for the initiation of the process in immature

animals, it is unclear what specific roles in the process

of spermatogenesis are played by the individual *hormones that constitute the axis. On the basis of*

information available in the literature, the following

deductions have gained wide acceptance:

• Differentiating germ cells lack hormone receptors

and, therefore, they are not affected directly by the

hormones.

bull is an exception in that the bulk of the water has been absorbed by the efferent ducts before the contents reach the epididymis. The secretions from the epithelial cells of the initial and middle segments induce significant alterations in the functions and composition of most of the component parts of the spermatozoon. The principal functional changes are the acquisition of pro-

gressive motility and the ability to fertilize an egg. Fine structural changes have been observed in the plasma membrane, the acrosomal membranes, the nucleus and the tail. Changes in the composition of the plasma membrane appear to be central to the process of maturation of the spermatozoon as it passes through the epididymis; in particular, its protein composition is altered either by adsorption of components from the epididymal fluid or by modification or loss of existing components in response to enzymatic activity of the

Fig. 33.23

Changes in concentrations of gonadotrophins (a) and ovarian steroids (b) in *peripheral plasma during a 21-day oestrous cycle in the cow. During most of the cycle progesterone (P4) secreted by the corpus luteum (CL) is the dominant hormone, exercising strong negative feedback on the hypothalamic–pituitary axis. However, the tonic concentrations of gonadotrophins released during the luteal phase induce two waves of follicles that are associated with small peaks of oestrogen (1, 2). When the CL regresses, the concentration of P4 declines (3) and oestrogen concentration climbs to a peak, the oestrogen surge (4), which triggers a surge of gonadotrophins (5) that induces ovulation.*

Fig. 33.30

Dominant follicle becomes the ovulatory follicle. When luteolysis occurs, the LH *pulses attain the frequency that is required to progress the dominant follicle to ovulation. FSH induces mitosis and stimulates aromatase activity in granulosa cells and they secrete oestradiol and inhibin: within the follicle, oestradiol binds to receptors (ER) in granulosa cells in which it (1) up-regulates ER and receptors of FSH(FSHR), stimulates aromatase activity, mitosis and secretion of IGF-1: systemically, both oestradiol and inhibin depress FSH*

secretion by the pituitary gland (negative feedback). (2) Granulosa cells have high number FSHR [see (4) in Figure 30.29]. (3) The low levels of FSH continue to induce mitosis and to stimulate aromatase activity in granulosa cells (thus producing oestradiol and enlarging the antrum). FSH (4) and oestradiol (1) stimulate granulosa cells to secrete more IGF-1 – which, in turn, (5) enhances the steroidogenic and mitotic actions of FSH and oestradiol on granulosa cells, and enhances the steroidogenic action of LH on theca cells. FSH

(6) in creases the number of LH receptors (LHR) on granulosa cell. The cell division and the secretory activity accelerate the expansion of the dominant follicle: it may be 16 to 18 mm in diameter at the preovulatory stage. The rapid increase in secretion of oestrogen induced by the activities of LH, FSH and IGF-1 leads to a surge of oestrogen (7) which evokes, by positive feedback (8), coincident surges of the gonadotrophins (large surge of LH, smaller surge of FSH) and, consequently, ovulation (9).

Fig. 33.31

Interrelationships between the hypothalamus, pituitary gland, ovary and uterus during the oestrous cycle. When the corpus luteum (CL) regresses at the end of a cycle (A), the hypothalamus and pituitary gland are released from the strong negative feedback exerted by progesterone (P4) throughout the luteal phase of the cycle. FSH and LH stimulate the growth and secretory activity of a dominant ovarian follicle (B) that secretes increasing quantities of oestradiol (E2). The initial low concentrations of E2 have a negative feedback effect until the preovulatory follicle produces a surge of oestrogen (C) that exerts a positive feedback and results in a surge of LH that causes ovulation (D). A new CL develops under the trophic influence of both LH and, perhaps, prolactin (PRL). It secretes P4 and E2 that reassert a strong negative feedback effect on the hypothalamic–pituitary axis. In addition, the P4 causes an accumulation of fatty acid precursors in the endometrium (1). After day 10, E2 induces the synthesis of prostaglandin from the stored precursors (2). Finally, oxytocin (OT) causes the release of the PGF2a (3), which is transferred from the uterus to the ipsilateral ovary by a countercurrent mechanism (see Fig. 33.32) and induces luteolysis (F). (See Fig. 33.23 for changes in concentrations of the hormones in the peripheral plasma.)

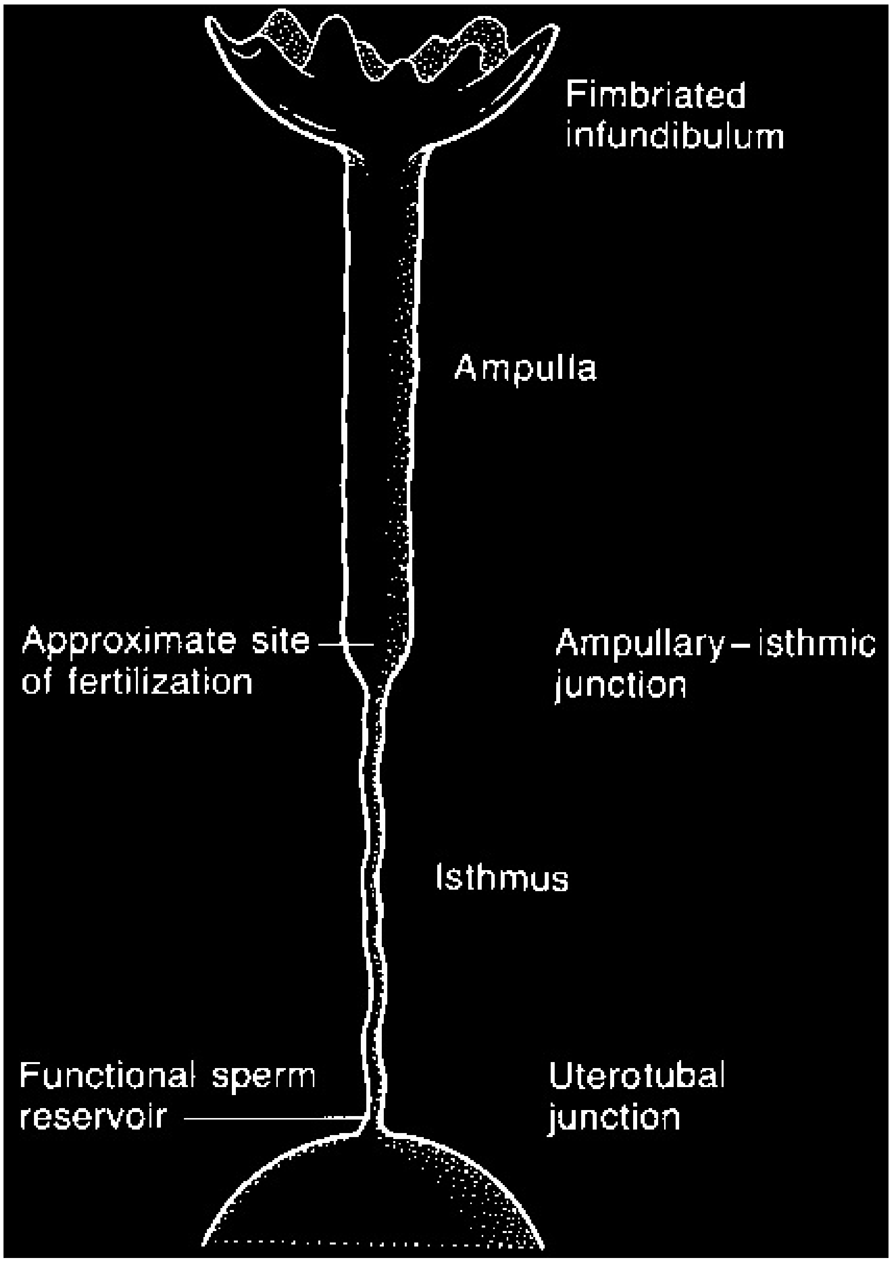
follicular waves have revealed that the prime require-

the pituitary gland to the continued stimulation (see

ment is ‘to have a recently selected dominant follicle of

p. 477). Therapeutic regimes should be planned with

short duration dominance at the end of a progestagen



or PGF2a treatment regimen' (Roche et al., 1999). Thus, the objective of current research efforts is to validate a

regimen that will regulate both the luteal and follicular

components of the periovulatory phase.

As mentioned, the response of the corpus luteum to

an exogenous luteolysin depends on the stage of its

development, and even when it is fully responsive the

intervals from treatment to oestrus and ovulation can

vary by some days depending on the stage of develop-

ment of the dominant follicle at the time of treatment.

For instance, if the current largest follicle is no longer

functionally dominant, clinical response will be delayed

until the dominant follicle of the next wave does the

business up to a week later. Scientists have shown that

it is possible to manipulate follicular waves to deliver

ovulation within a time span that would satisfy the level

of predictability required to make fixed-time insemina-

tion a viable proposition. However, the problem

remains that some of the procedures that have been

employed under 'laboratory conditions' do not lend

themselves to ready application under field conditions.

tion available and it will be simpler to introduce routine sampling where this is indicated.

Fig. 35.3

Dominant follicle on right ovary bordering the CL.

There are two separate but overlapping aspects of diagnosis:

- *Stage 1: assessment of ovarian status to determine whether the case is true anoestrus, in which there is no ovulatory activity, or in which cyclicity is prevented by a persistent corpus luteum or other progesterone producing structure; or silent or unobserved oestrus, in which ovarian cycles are taking place.*
- *Stage 2: assessment of the causes of the condition.*

Stage 1: assessment of ovarian status

Since the word 'cycle' implies repetition, theory would

Fig. 35.4

of low progesterone' is expected to be from day 18 through oestrus (day 0) to day 4. This definition applies to the majority of cows in a normal population and is needed to form a basis for rational diagnosis, but its use should be tempered by the realization that no definition will fit all cases (Bloomfield et al. , 1986).

The first step is to take a history of the case. Relevant information, required for both stages of diagnosis, is shown in Box 35.6.

The next step is to find out if there is functional luteal tissue present in the ovaries. The traditional way to do this is to palpate the ovaries per rectum, but there are now several choices. One is to carry out a single or a series of milk progesterone assays, which gives a quick,

Fig. 35.5

Long-standing follicular cyst.

reliable result. Another is ultrasound scanning, which allows the user to observe functional luteal tissue in the ovary (Figs 35.1–35.4) (Omran et al. , 1988; Boyd & Omran 1991). The choice of method will depend on circumstances as each method has advantages and disadvantages.

Rectal palpation is immediate, simple, requires little restraint of the cow and, if part of a regular visit, is relatively cheap. It also allows other observations to be made on other parts of the reproductive tract and on the animal's general condition. There is minimal risk of misidentification of the animal, a danger always present *when samples are taken for analysis. On the other hand, it is a less accurate indicator of luteal function than a progesterone assay. Real-time ultrasound scanning is a*

Fig. 35.6

Follicles on right ovary.

valuable tool that, in experienced hands, is capable of giving a very accurate picture of ovaries and uterus (Figs 35.1–35.13).

Rectal palpation alone, when undertaken by an experienced clinician, can be relatively accurate. For example, Dawson (1975) compared the findings made by rectal palpation shortly before slaughter with post-mortem observations. He identified accurately 125 (89 per cent) of 141 ovaries with corpora lutea. The errors were mainly in cows with small corpora lutea and also some with cysts or follicles. However, others have suggested that rectal examinations alone are less accurate. On the basis of milk progesterone assays (which were assumed to be correct) Ott et al. (1986) summarized their own and other workers' results, as shown in Table

cows.

Chapter 34 (see p. 521).

Where economics allow the hospitalization and

intensive investigation and therapy of repeat breeder *cows in referral centres (now very uncommon in the UK), the owner should be given a definite prognosis as soon as possible to minimize the cost involved in keeping and treating cows over several weeks. Much of this cost is due to the fact that once an animal has been served there is little positive that can be done except to monitor changes until pregnancy or non-pregnancy is confirmed. With modern diagnostic methods such as ultrasound scanning it is now possible to reduce the waiting time from service to diagnosis of non-pregnancy to a minimum of 25–30 days, and milk pro-*

Prognosis

From the client's point of view successful treatment means that the cow becomes pregnant; this is a two-stage process. Firstly, the cow has to return to normal reproductive function and secondly she has to conceive and remain pregnant. While the first stage is mainly the responsibility of the veterinarian, the second stage often depends on the farmer and farm staff. Where poor husbandry (i.e. feeding, housing or breeding management) is thought to be causing return to service, prog-

gesterone analysis can be used to give an indication of

nosis must be guarded because it is often a difficult

preputial defects and orthopaedic problems. It is important not to belittle the problems of diagnosis, for example an early manifestation of either corkscrew penis or a venous drainage defect could conceivably be masked by the overzealous application of an artificial vagina. Observation of the natural service behaviour of the bull should generally avoid this error although some young bulls can display penile abnormalities intermittently. As ever prognosis, treatment and prevention depend upon the exact diagnosis.

In order to understand penile problems fully a brief

discussion of the anatomy and physiology of erection in

the bull (Fig. 38.11) is necessary.

Intromission can only be achieved if the penis is fully

erect. This is a stiffening process brought about by the

filling of the corpus cavernosum penis with blood

pumped in by the ischiocavernosus penis muscle. Since

drainage of the corpus cavernosum penis is very slow

in normal bulls, blood pressure in the corpus caver-

nosum penis builds up well in excess of that in a car tyre

damaged and infected (Long & Dubra, 1972; Fig. 38.12).

The breeds most commonly affected are the Aberdeen Angus and polled Hereford, which have no retractor preputiae muscle, and the Bos indicus breeds and crosses (Larsen & Bellenger, 1971). Ubiquitous organisms such as Arcanobacterium (Actinomyces) pyogenes and Staphylococcus aureus can often be isolated from such lesions. The smegma produced by the bull is very tacky and the authors know of at least one case where the problem was caused by the firm matting of the hairs over the preputial orifice due to this substance, with

Failure to locate vulva or enter vagina

Psychogenic problems: There would appear to be two distinct problems:

- *Neck or side mounting;*
- *Normal mounting, but without success, the bull being incapable of inserting the penis into the vagina despite a good erection and apparently normal seeking movements, even to the extent of touching the vulva.*

The aetiology for both these conditions, especially the former, is obscure though neck mounting is not uncommon in young inexperienced bulls. However, they usually quickly move round to the rear of the cow. For the latter one could hypothesise either that this could be an early manifestation of a premature partial drainage defect of the corpus cavernosum penis or that there was an inadequate sensitivity of the penile tip (possibly acquired traumatically or by infection) resulting in a lack of appreciation of the position of the penis relative to the vulva.

A diagnosis of psychogenic depression of libido must

be tentative because it is based on a failure to obtain

avoided if at all possible.

In some cases, however, they persist much longer and

some become eroded and infected (Walker, 1980).

Persistent frenulum: The penile frenulum,

which

Treatment depends on the extent and severity of the

normally attaches the free end of the penis to the

tumour. A small single pedunculated tumour is clearly

prepuce of the prepubertal bull, is normally 'lost' during

much easier to deal with than a large, sessile,

early puberty, possibly breaking during play and/or

cauliflower-like lesion. Most authorities advise surgery

masturbation. Occasionally, this does not occur and

in severe cases, but it is essential to avoid weakening or

its persistence prevents the tip of the penis straigh-

rupturing the tunica albuginea (Walker, 1980), since this

tening on erection. It is usually bent ventrally and

can result in blood escaping at service and this setback

caudally. Although this is not a common condition

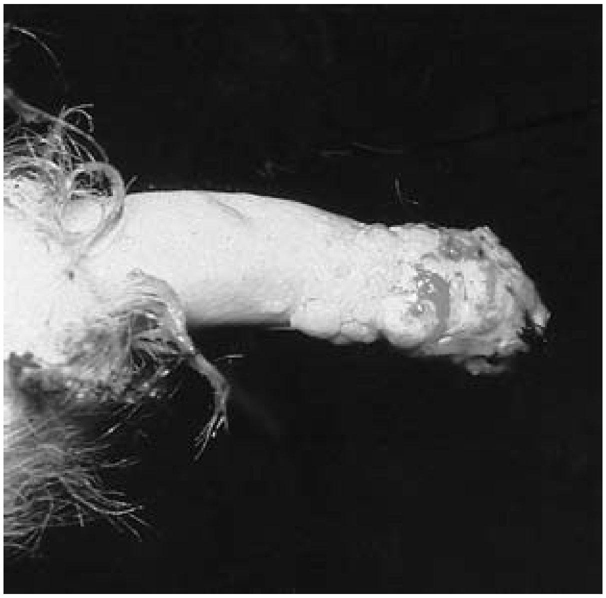
to surgery has been seen by one of the authors. Note

diagnosis is easy, as is treatment, which involves simple

that possible leakage from the corpus spongiosum penis

surgery.

(CSP) into the terminal part of the urethral lumen has



defects is largely academic at present since there is no treatment and the prognosis for all of these is hopeless.

***Corkscrew penis**: This is one of the most dramatic defects and is often diagnosed by the client. Spiral deviation of the penis within the vagina at ejaculation is physiological but in the clinical condition the spiral deviation precedes intromission and so prevents service. This is most commonly seen in beef bulls of around four years of age (Blockey & Taylor, 1984). In all cases the spiral is anticlockwise and can almost comprise a complete circle. However, it does present with* *varying degrees of severity from intermittent spiralling (which can present problems with diagnosis) to being so severe that spiral deviation occurs while the penis is still in the prepuce and it may then prevent protrusion. Usually it does not occur until the penis makes contact with the vulva of the cow. It should be remembered that spiral deviation has been described as occurring after entry into the vagina immediately prior to ejaculation*

Fig. 38.15

Fibropapilloma on the tip of the penis.

in bulls with apparently normal mating behaviour (Ashdown & Pearson, 1973b). The only known treat-ment is surgical and there are a variety of techniques, all of which depend on either fixing the dorsal apical also been described. This could also cause spurting of ligament to the dorsal aspect of the penis or addition-blood from the penis at service (Ashdown & Majeed, ally stiffening it by the insertion of fascia lata or carbon 1978). Since these lesions are transmissible, segregation fibres. The latter are placed between the ligament and of affected cattle, especially heifers, from a young bull *tunica albuginea (Mobini et al. , 1982). Postoperative is advisable. case. In other words, the main effect of overuse is to

this size. We therefore recommend collecting semen

exhaust the epididymal reserves. However, at very high

from ‘borderline cases’ if there are likely to be other

and sustained mating pressures a slower return to

normal number of spermatozoa per ejaculate may be

found. Furthermore, it has also been noted that as the

number of ejaculates increases, sperm motility tends to

fall. In addition, the likelihood of an occasional

azoospermic ejaculate increases (Salisbury & Van

Demark, 1961). Finally, there is some information indicating that young bulls given a diet below maintenance for energy take considerably longer to replenish their sperm reserves. This is particularly relevant to young post sale bulls, which are purchased in very good body condition and then put outside with cows in a hard environment, thereby losing condition rapidly. By inference such bulls take considerably longer to replenish their sperm reserves (Salisbury & Van Demark, 1961). The

infertile. A further diagnostic aid that may prove of

value is the determination of the chromosomal consti-

tution of the animal.

As already mentioned, care must also be taken not

to jump to conclusions. Surprisingly good quality semen *has been collected from bulls with disappointingly small scrotal circumferences. However, such occasions are rare, so that in general the prognosis for the 'small testes syndrome' is poor. As far as the unilateral condition is concerned this is more problematical since the animal is often fertile. Here every attempt to obtain as reliable a history as possible should be made in order to differentiate between hypoplasia and atrophy because of the strong evidence of the heritable nature of hypoplasia. If the diagnosis is hypoplasia the owner should be advised that such stock are only fit for the production of 'slaughter generation' animals.*

Testicular degeneration and atrophy

In many infertile animals the main histological finding is the absence of dividing spermatogenic cells, the Sertoli cells and interstitial cells still being present. This ***Fig. 38.18***

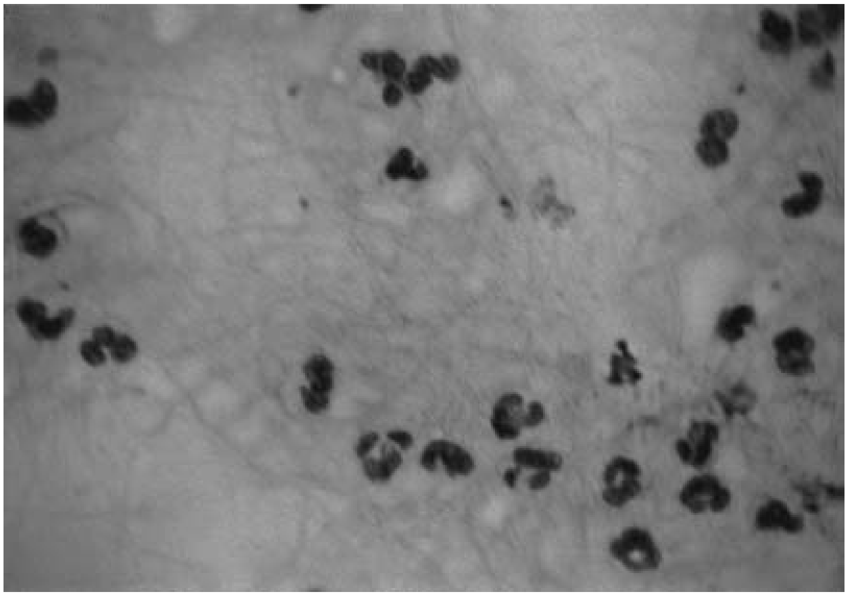

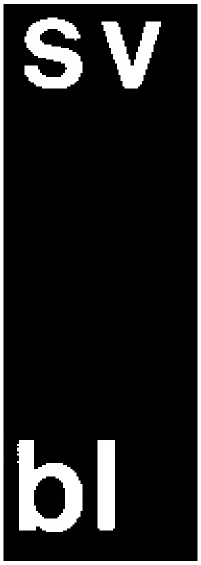

Fig. 38.21

White blood cells in semen (methylene blue) (¥700).

Abnormalities of the accessory sex glands

The accessory sex glands consist of the seminal vesicles, ampullae, prostate and bulbourethral glands.

As already mentioned, abnormalities of the seminal vesicles are the most commonly diagnosed condition. Segmental aplasia of the seminal vesicle occurs and often appears to be related to a congenital defect (Blom, 1979a,b). Numerous infectious agents have been isolated and implicated in the aetiology of seminal vesiculitis in the bull, such as members of the Chlamydia *group, Mycoplasma bovigenitalium and Mycoplasma bovis (La Faunce & McEntee, 1982). However, in severe clinically recognizable cases the most common organism isolated is Arcanobacterium pyogenes (Arthur, 1960; McCauley, 1980). Some authors believe that these infections of the seminal vesicles are secondary to congenital defects. Diagnosis of these abnormalities is firstly dependent upon rectal palpation (where enlargement, firmness, pain and adhesions may be detected in the case of seminal vesiculitis) and ultrasonic scanning; and secondly upon laboratory tests, particularly the examination of semen for white blood cells which indicate the presence of inflammation (Fig.*

Fig. 38.22

Real-time ultrasound of the seminal vesicle. sv,

penis, leading to adhesions. The disease is caused by
with pregnancy.

bovine herpes virus type 1 (BHV1) which can be sub-
The proper time for insemination is in the last period
divided in strains with preference for the respiratory or
of the standing heat. Cows are selected for insemina-
genital tracts respectively. Diagnosis is made by demon-
tion by observation of the herd at least twice daily
stration of the virus in secreta from respiratory and/or
during moments of quiescence: observation during
genital tracts up to 14 days after infection, and by serol-
periods of even limited excitation (for example during
ogy. However, sensitivity and specificity of serological
collecting for milking) can lead to the insemination of
tests applied in various countries differ considerably.
cows not in heat and thus to disappointing fertility
The agent may survive in favourable conditions (high
results. Several aids have been applied to improve heat
relative humidity, low temperatures) for 30 days in the
detection such as electronic pedometers, heat mount
environment. BHV1 is easily transmitted by semen. AI
detector pads, spotter bulls, etc. However, careful
centres in the EU must be free of IBR: only serologi-

observation of the herd and proper records of heat

cally negative animals are allowed as BHV1 infections

periods undoubtedly form the backbone of good fertil-

lead usually to latency. Latently infected animals are

ity results (see Chapter 41b). Harmful side effects of

improper insemination are infections and/or injuries of

are serologically positive for BHV1, but some seroneg-

the genital tract, which are dealt with in Chapter 36.

ative latently infected cows have also been reported.

However, the sensitivities of the tests applied in these

animals are doubtful. Straub (see Horzinek, 1990)

Diseases transmissible by semen

described seronegative latently infected animals after

(and/or mentioned in

the application of a one hour incubation serum neu-

tralization test with a limited sensitivity: the animals

trade certificates)

would probably have been positive with sensitive tests.

It is thought that seronegative latently infected animals

Table 39.1 summarizes the diseases in this category.

develop during the period of maternal immunity after
an infection with a very low dose of BHV1 and they
Foot-and-mouth disease (FMD) (see also p. 700)
should exist in very low prevalence in endemic areas.
However, Switzerland, Denmark and Austria became
This is a highly contagious disease of cloven-hoofed
free of IBR: these countries eliminated the virus from
animals characterized by high fever followed by vesi-
their cattle populations without unexpected disease
cles on the mucosa of mouth and tongue, the feet and
outbreaks caused by serologically negative latently
the udder. FMD is caused by a picornavirus comprising
infected animals. The straightforward isolation of posi-
seven serotypes; infection with one serotype does not
tive animals was successful. So the problem of serologi-
induce immunity to other serotypes. In order to prevent
cally negative latently infected animals is very limited
spread of the disease in a country immediate recogni-
or even non-existent.
tion of the clinical picture is essential. For a positive
diagnosis the demonstration of FMD viral antigen by

indirect sandwich ELISA techniques, preferably in the

can occur via the semen. The virus survives in the

ogy. Persistently infected animals transmit the virus

environment for limited periods.

during their lifetime and infect sentinel animals easily.

Transiently viraemic animals, however, transmit the

Malignant catarrhal fever (MCF) (see also p. 935)

disease to a limited extent. These primary infections

might lead to prolonged periods of viraemia (up to 40

MCF is a sporadically, almost invariably fatal disease of

days), the presence of virus in bronchoalveolar wash-

cattle of all ages. The disease is characterized by high

ings (up to 56 days after infection) and in semen even

fever, bright red coloration of all mucous membranes, *after seroconversion has taken place. Therefore, the risk*

enlarged superficial lymph nodes and very often diar-

for transmission of BVDV by semen is substantial. One

rhoea. A herpes virus (BHV3) causes the disease.

exceptional bull has been described that shed BVDV

Diagnosis in live animals is by clinical signs, and by PCR

in the semen over prolonged periods (11 months),

on heparinized blood. Culture of the virus is not possi-

although the animal was serologically positive. This

ble, therefore information on the resistance of the virus

unusual pattern might be explained by a primary infec-

against environmental influences is not available. Cow

tion during puberty or an intrauterine infection around

to cow transmission has never been reported. Trans-

the time of maturation of the immune system. There is

mission by semen is therefore very unlikely.

information that this phenomenon might occur more

frequently. The agent survives for some days in the envi-

Bluetongue (BT) (see also p. 691)

ronment. Transmission by semen is easy. AI centres

only accept bulls that are not persistently infected.

BT occurs mainly in small ruminants but may occur in
However, because some infectious routes for the intro-
cattle as well. If clinically overt (many infections pass
duction of BVDV are not completely understood, in
unnoticed in cattle) the disease is characterized by
endemic areas BVDV might infect bulls in an AI
fever, facial oedema, haemorrhages and ulceration of
station. Where there is unintended infection of AI bulls
the mucous membranes. An orbivirus consisting of 24
the infection passes subclinically and, as this disease is
serogroups causes the disease. The virus is identified by
easily transmitted by semen, it is very important to test
culture and by PCR techniques on blood samples of
for BVDV. Monthly tests for serologically negative
febrile animals. The agent is transmitted by insects of
donor bulls and, in the case of seroconversion, ensur-
the genus Culicoides; transmission from cow to cow
ing the semen is free from BVDV might be the only
has not been reported. Transmission by semen is very
solution.
unlikely.

Enzootic bovine leukosis (EBL) (see also p. 693)

Akabane virus (see also p. 580)

EBL is found clinically by enlarged lymph nodes or

Infections of Akabane virus were shown to cause spo-

other lymphosarcomas, or by lymphocytosis in the

radic epizootics of premature births and developmen-

peripheral blood in the minority (some 30 per cent) of

tal deformities in the new born (arthrogryposis-

infected animals. Infections for the greater part pass

Problem

Issues to consider

Solution options

No reference heat

Poor heat detection

Abandon programme and restart

Poor behavioural signs

Provide artificial CL through exogenous

progesterone supplementation

Poor synchrony

Re-attempt

Poor superovulatory response

Nutrition

Check ration and adjust nutrition

Mineral status

Check mineral status and adjust supplementation

Type of FSH

Try alternative type of FSH

Drug dose/regime

Increase drug dose or alter regime

Unfertilized ova

Semen quality

Check bull history/try different sire

Insemination technique

Check technique

Semen handling/thawing

Check technique

Donor/bull interaction

Try different sire

Insemination timing

Add additional AI session and extra straws

Poor ovum quality

Check nutrition/mineral status/body condition loss

Overstimulation

Reduce FSH dose

Defective uterine environment

Infection – antibiotic therapy and/or return to oestrus

Hormonal – difficult to identify/resolve

Superovulation drug

Try alternative product

Poor recovery

Catheter position

Check technique

(normal breeding history)

Leakage past cuff

Check cuff inflation/integrity of cuff

Inadequate flow

Raise tip of uterine horn higher than cuff position

If above fails reposition catheter

(Note: risk of embryo loss in this procedure)

Luteinized follicles

Poor recovery

As above plus

('problem breeder' history)

Blocked oviducts

Defective gamete transport

eases may result in poor reproductive performance, for example bovine herpes I (BHVI) infection (see pp. 289, 579) and bovine viral diarrhoea (BVD) (see pp. 578, 853).

Obviously, it is essential to rectify any infectious problem before attempting to improve herd reproductive performance by other means.

Nutritional management

Nutritional status is of major importance in the maintenance of a high rate of reproductive performance. The nutrition of cattle is covered more comprehensively in specialized texts and only the basic principles are described here.

Whilst specific deficiencies of micronutrients are common under particular circumstances and can affect fertility, under normal conditions dietary energy appears to be the main factor limiting reproductive performance. However, other nutritional deficiencies occur but are usually confined to localities or even individual herds. These include problems with manganese, selenium and cobalt (see Chapter 18) and some vitamins,

Fig. 41.1

duction in cattle where this is not covered in the chap-

Prostaglandins have been used to control the

ters on general fertility. The discussion includes control

oestrous cycle in several different ways. Some possible

of the oestrous cycle, the establishment and mainte-

methods are given below:

nance of pregnancy and induction and postponement of

parturition.

(1)

Following rectal examination, only those cows

with a corpus luteum are injected. These cows should

Control of the oestrous cycle

then show oestrus and ovulate three to five days later.

This method has the disadvantage that it is time-

The control of the oestrous cycle is dependent on

consuming and that rectal palpation involves added

manipulation of the hormonal events occurring during

expense. The results also depend on the accuracy of

the normal ovarian/oestrous cycle. The over-riding event

detection of corpora lutea by rectal palpation.

controlling the development of an ovarian follicle

(2)

All cattle are observed for oestrus over a seven-

to the point of ovulation in the cyclic cow is believed to

day period, serving any that show oestrus. The rest are

be the process of luteolysis or decrease in progesterone

injected with prostaglandin on the following day and

secretion occurring between days 17 and 18 of the

may be inseminated either once or twice at fixed

normal cycle (see Fig. 42.1). This fall in peripheral *times or at observed oestrus. The reason for the initial*

progesterone concentrations may be manipulated arti-

seven-day observation period is that there is a period

ficially in three ways:

of about seven days in the cycle (day 18 to day 0 and

(1)

(4)

A further method of using prostaglandins that

a dominant follicle being present at the time of induc-

has been quite popular is the so-called '11/2 method'.

tion of luteolysis seven days after the administration

Cows are injected with prostaglandin and those that

of the GnRH. Regimes involving this approach to

show oestrus are inseminated. Those that have not been

'priming' of the oestrous cycle have been tested in the

seen in oestrus are injected again 11 days after the first

UK (Mawhinney et al., 1996). In most cases a second

injection and may be inseminated either at a fixed

administration of GnRH has been used in an attempt

time(s) or at observed oestrus. Although requiring

to further synchronize the timing of ovulation after

further effort in terms of oestrous detection, this

luteolysis. The second GnRH is administered 48 to 56

method tends to give better results than the 'two plus *hours after prostaglandin administration, with insemi-*

two' regimen and is the current method of choice. Its

nation being carried out 18 to 24 hours after the post

main advantage, however, is the reduction in cost by the

luteolytic GnRH (Roche, 1999).

reduction of both the number of treatments used and

the number of inseminations per cow.

Use of progestagens

The third method of controlling the cycle is to simulate

the function of the corpus luteum by the administration

Trophic hormone and

of progesterone or one of its derivatives. In this method,

prostaglandin combinations

gonadotrophin release, and hence ovarian follicular

Gonadotrophin releasing hormone (GnRH) or its

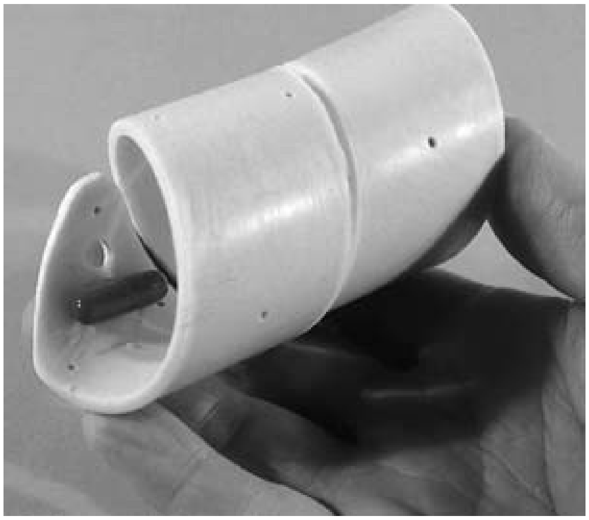
maturation, is suppressed until progesterone with-

analogues can be used to reprogram the developing

drawal. If progesterone is used to treat a group of cows

waves of ovarian follicles to maximize the possibility of

and then it is withdrawn from all cows simultaneously,



this will theoretically synchronize ovulation in the whole group.

In order to synchronize a group of randomly cycling cows effectively, it is necessary to treat them with progesterone for a period at least equivalent to the length of the natural luteal phase, i.e. 16 days. This is because exogenous progesterone has little or no effect on the life span of the natural corpus luteum and therefore, in a small proportion of cases, the natural corpus luteum might outlive a short-term progesterone treatment, resulting in a failure of synchrony. However, it has been shown that longer-term progesterone treatments (18–21 days) result in poor pregnancy rates. It is *thought that this is due to adverse changes in the intra-*

uterine environment that may inhibit sperm transport.

Shorter-term progesterone treatments (7 to 12 days)

generally result in more acceptable pregnancy rates,

Unfortunately, short-term progesterone treatment does

Fig. 42.3

A progesterone-releasing intravaginal device (PRID).

not control the cycle adequately since, if treatment is

started early in the cycle, the natural corpus luteum

may outlast the progesterone treatment. Therefore, it is

often necessary to incorporate a luteolytic agent with

short-term progesterone treatments in order to elimi-

covered by a layer of grey inert silastic (Fig. 42.3) in

nate any existing corpus luteum.

which 1.55 mg progesterone is impregnated. A gelatin

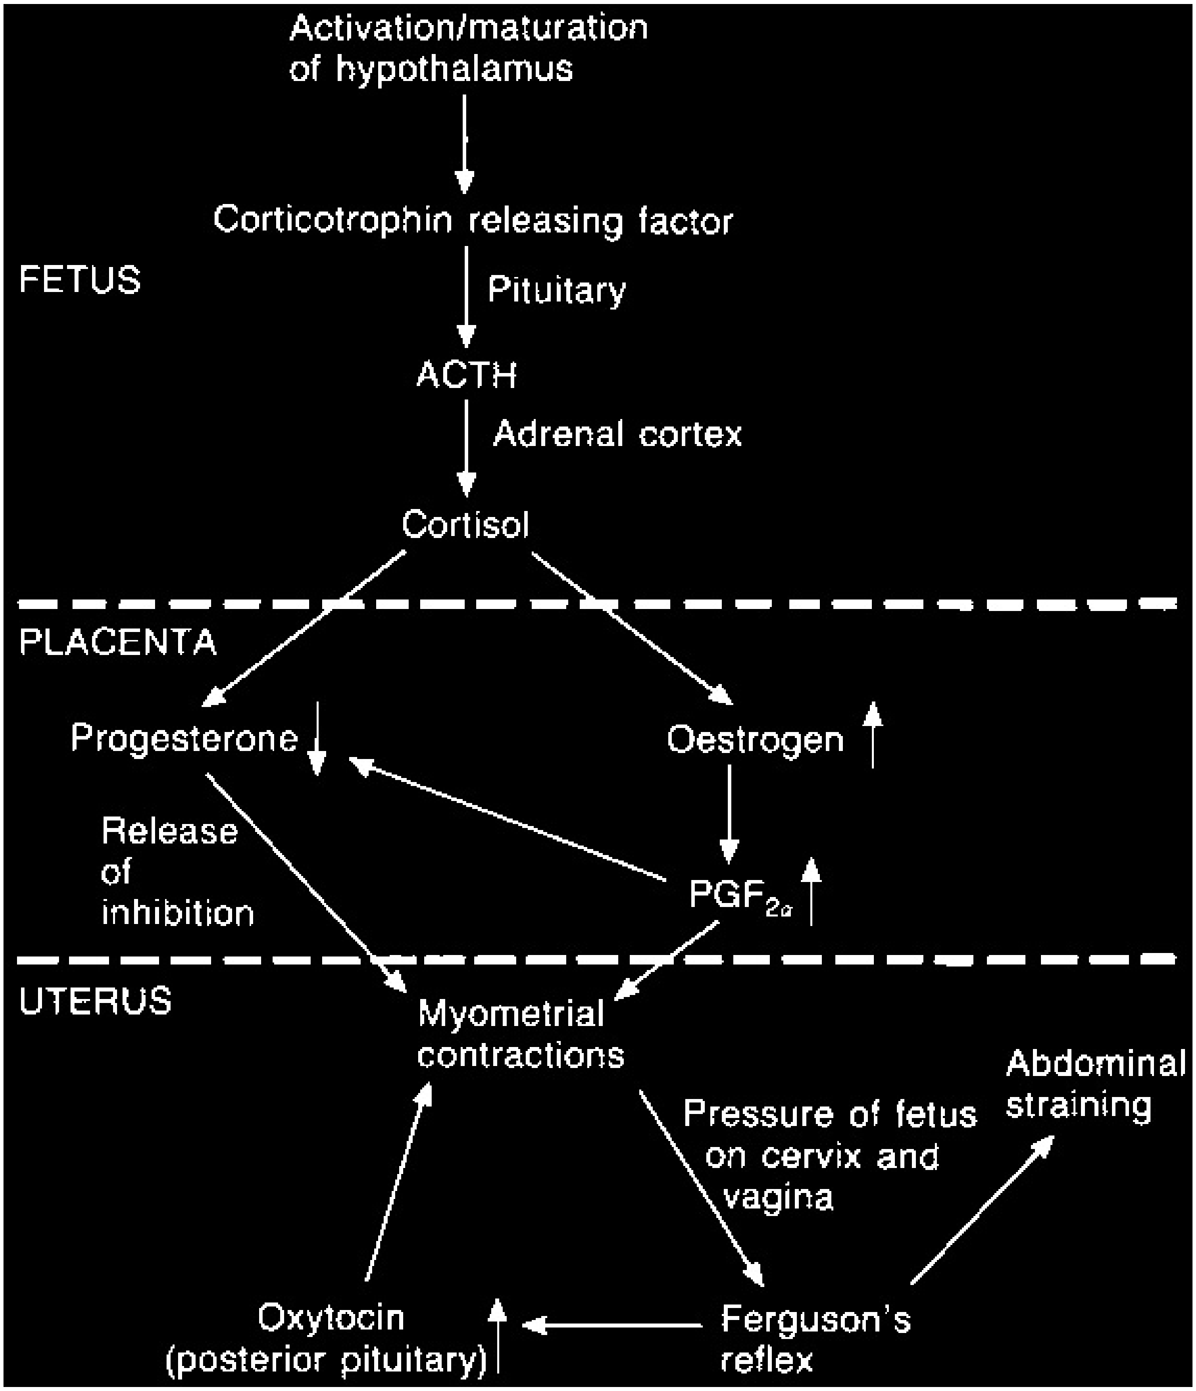
Secondly, cows can be induced to calve at a time when were enhanced by 9.4 per cent when compared with supervision is most readily available. Thirdly, if it is untreated controls. This benefit rose to 30 per cent in suspected that a high calf birth weight might result in cows treated at third and subsequent services. dystokia, early induction may alleviate the problem.



Oestrogens

There is no clear evidence that exogenous oestrogen is effective in inducing parturition in cows, although in *one trial cited by First (1979) treatment with oestradiol-17b before corticosteroid treatment shortened the time to delivery and reduced the variation between cows.*

Prostaglandins

Prostaglandins, both PGF2a and synthetic analogues, may be used to induce parturition in cows, although treatment before day 270 of gestation is not recommended. Parturition usually occurs between one and eight days after injection, but at an average of three days. A higher incidence of retained placenta compared to non-treated cows may be expected.

A study under UK conditions (Murray et al., 1984) used a treatment regimen whereby cows were injected with 20 mg dexamethasone and those that had not calved 10 days later received an injection of 0.5 mg cloprostenol (an analogue of PGF2a). Although there was a high incidence of retained placenta, this did not

FMD virus is believed to have occurred in 1981 when

Fig. 43.11

A recently ruptured vesicle in the

mouth of a cow with foot-and-mouth disease,

showing epithelial separation.

In tracing the movement of FMD between countries,

and identifying specific strains of FMD virus, molecular

epidemiology has proved very valuable (Samuel et al. , 1997). By precisely characterizing the RNA of an outbreak strain by its nucleotide sequence, it is possible to

show its relationship to strains previously isolated in

other countries or in use in vaccines. For instance, in

Europe between 1970 and 1990 there were a number of

FMD outbreaks attributed to the use of improperly

inactivated vaccines and escape of virus from estab-

lishments producing vaccine. In several instances bio-

chemical analysis of the outbreak strains showed a clear

identity with a vaccine strain in contemporary use.

Monoclonal antibodies, which specifically identify

herds adjudged to be at greatest risk.

the virus intradermally into the tongue and this is a

An infected bovine can excrete up to log105.1 infectious doses50/day by the respiratory route and can provide a potent source of FMD virus to the remaining uninfected cattle in the herd. This may be sufficient to overcome a waning vaccinal immunity.

The incubation period for FMD can be up to 14 days with low infecting doses and with strains of virus of low virulence. However, as the quantity of virus in the environment of an FMD outbreak increases, the incubation period in cattle decreases. For susceptible cattle in *contact with an infected animal it is frequently between two and four days.*

Clinical signs

The incubation period is between two and 14 days, depending on the route of infection, the dose, the strain of virus and the susceptibility of the host. Following an initial pyrexia in the region of 40°C (104°F), lasting one or two days, a variable number of vesicles develop on the tongue, hard palate, dental pad, lips, muzzle, coronary band and interdigital space. Vesicles may also be seen on the teats, particularly of lactating cows. Young calves may die before the development of vesicles because of a predilection by the virus to invade and destroy the cells of the developing heart muscle.

The vesicles in the mouth quickly rupture, usually

Fig. 43.13

laboratory examinations. As emphasized earlier, such

procedures should not be undertaken until anthrax has

been eliminated.

Pathology

Because of the peracute/acute nature of the disease

Treatment and prevention

in cattle, there is little opportunity for ante-mortem

laboratory examinations. It may be possible to detect

Bacillus anthracis is sensitive to a number of antibiotics organisms in appropriately stained smears of peripheral blood, but sufficient numbers of organisms are only likely to be present during the later stages of the disease. A haematological examination may reveal a leucocytosis and a shift to the left, but because of the relatively short course of the disease, these changes are not marked.

Before a necropsy is carried out on an animal that has died suddenly or after a very short illness, it is essential that anthrax be eliminated, to prevent contamination of the environment and ensure proper disposal of

and treatment of animals during the early stages of the disease is likely to be successful, although severely ailing animals are unlikely to recover. Greenough (1965) successfully treated animals with 5 megaunits of penicillin alone or with streptomycin. The recommended dosage of penicillin is 10 000 units/kg body weight administered twice daily for at least three to five days. Streptomycin, in 4–5 g doses, should also be administered twice daily for the same period. Lincoln et al. (1964) consider that septicaemic anthrax is best

treated with a combination of large doses of penicillin
the carcass. Thus a careful evaluation of the circum-
and streptomycin twice daily, although oxytetracycline
stances and a thorough preliminary examination of the
and chlortetracycline are the next antibiotics of choice.

Bailey (1953) also recommends tetracycline for the

Oedema of tissues
Ischaemic necrosis

Diagnosis and prognosis

Having completed a thorough examination of the recumbent animal that has recently calved and eliminated disease, obvious injury or starvation as a cause of the recumbency, the two most likely problems to be affecting the cow are (i) pressure syndrome (ischaemic necrosis) or (ii) calving paralysis. These cows will be alert, in sternal recumbency, and some will be attempting to rise or crawling along the ground. Appetite for food and water will be good. At this stage it is essential for the clinician to attempt a more exact diagnosis and offer a prognosis. One of the most important inputs that will aid recovery is tender loving care (TLC). The ability and willingness of the stockworker to nurse and attend these cases will be the most important element in successful treatment. So knowledge of the farm and its staff is essential in forming a prognosis, as is the ability to provide soft bedding such as deep litter or a nearby paddock. Diagnosis will be helped if the animal is raised using a Bagshawe hoist and it can be observed *if the cow can take weight on one or both hindlimbs and*

if either or both hindlimbs are abnormal. Abnormali-

ties to observe include the following:

• Flexion of fetlock and extension of the hock, which

will indicate paralysis of the tibial, peroneal or

sciatic nerve (pp. 438, 439).

Fig. 46.3

Pathogenesis of ischaemic necrosis (from Andrews,

• Abduction of one or both hindlimbs will indicate

1986).

obturator nerve paralysis (p. 438).

• Swelling of the upper hindlimb musculature of one

leg would indicate severe pressure syndrome. If the

pressure syndrome is so severe that muscle swelling

is obvious and one upper hindlimb is larger than the

other, prognosis for that limb is hopeless.

Calving paralysis: If the cow has not risen since calving

has never experienced the disease.

New techniques (PCR, DNA fingerprinting, ELISA, *among others) in manipulating mycoplasms have led to*

new thinking about the phylogeny of the group. Where

there were individual species, the organisms now

have been grouped into 'clusters'. Economically the

Mycoplasma mycoides cluster is the most important,

containing as it does, Mycoplasma mycoides subspecies mycoides, small colony type (M. mycoides), the large colony type that infects goats and to a lesser extent

sheep and M. mycoides capri, another of the agents that causes contagious caprine pleuropneumonia.

It has been possible to trace the introduction of the

infection into many countries. Indeed, in some cases the

identity of the infected animal is known! There is,

however, some dispute about the entry of the disease

into Africa. French workers believe that the infection

was introduced when Bos indicus crossed into the con-

tinent from Asia; it did not get to southern Africa in this

way and there is evidence that it did not exist in East

Africa before the invasion of General Napier into

Ethiopia in 1868.

The Dutch Ambassador to the Cape Colony, with the

The animal stands with elbows When the infection is introduced into a susceptible abducted and the neck stretched out, the mouth open herd there can be a great variation in response, from a and the tongue protruding (Fig. 49.2). From time to severe, massive, acute outbreak of disease involving up time it may emit a soft, moist cough. The pleurisy causes to 60 per cent of the animals in the herd with 40–50 per severe pain and the animal will grunt if the chest is cent of the affected animals dying, to a much less severe problem, involving less than half of the herd with few animals severely affected and a low mortality. Recovered animals are resistant to further infection. In many of these recovered animals sequestra may be seen: a sequestrum is a piece of diseased lung that has become separated from neighbouring healthy tissue and surrounded by a fibrous capsule. In a closed herd, in which no action is taken, it is not uncommon for the disease to die out. Recently there has been a move towards *treating clinically sick animals. The effects of this treat-*

ment on sequestrum formation are not known but it is

thought that it might prevent the animals from devel-

oping a proper sequestrum and so prolong the period

in which the animal can pass on the infection.
