Note

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the publisher nor the editors assumes any liability for any injury and/or damage.

List of tables and figures

Table 1.1	Major internal parasites of horses	95
Table 1.2	Equine trypanosomosis	108
Table 2.1	Immunodeficiencies described in the horse	135
Table 3.1	Guide to the typical composition of common feedstuffs	155
Table 3.2	Guide to the size of various parts of the gastrointestinal tract in horses as well as the duration of ingesta passage	165
Table 3.3	Guide to the duration of feed intake in horses and ponies	165
Table 3.4	Principal differences between feeding roughage and concentrate feed	166
Table 3.5	Guide to the daily intake and turnover of water and electrolytes	168
Table 3.6	Guide to the minimum daily nutrient requirements of horses	172
Table 3.7	Guide to the minimum water needs of horses per kg of feed DM consumed and the water provided by pasture herbage per kg herbage DM	173
Table 3.8	Guide to the minimum supplementary water requirements of mares (liters daily per mare)	174
Table 3.9	Sweat production	175
Table 3.10	Guide to the composition of sweat	175
Table 3.11	Guide to endogenous mineral losses by horses, average availability and the minimum mineral requirements for maintenance per kg BW/day	181
Table 3.12	Guide to the mineral and vitamin requirements of horses per kg feed for a horse of mature weight 500 kg	182
Table 3.13	Guide to the energy requirements above maintenance for various activities	195
Table 3.14	Guide to the recommendations for the supply of working horses with digestible energy and digestible crude protein	195
Table 3.15	Recommendation for the minimum daily mineral requirements of adult working horses	197
Table 3.16	Guide to the recommendations for the daily supply of working horses with trace elements and vitamins	198
Table 3.17	Recommended requirements of DE and CP on a daily basis for growing horses (500 kg mature weight) with varying average daily gains	204
Table 3.18	Recommended minimum requirements (based on the NRC, 1989) of calcium, phosphorus, magnesium, potassium, vitamin A and copper on a daily basis for growing horses (500 kg mature weight)	204
Table 3.19	Typical range in pasture composition (northern temperate) (mg or g/kg DM)	207

Table 3.20	Example of a daily tube feeding schedule that has been used for a 200 kg pony with hyperlipemia	220
Table 4.1	Bacterial pathogens isolated from various sites of infection	227
Table 4.2	Empirical antimicrobial selection based on knowledge of bacterial pathogen	228
Table 4.3	Suggested guidelines for the interpretation of minimum inhibitory concentration (MIC) ($\mu\text{g/mL}$) of antimicrobial agents based on bacterial isolates of equine origin, apart from fluoroquinolones which relate to isolates of canine origin	229
Table 4.4	Process(es) of elimination and pharmacokinetic parameters describing the disposition of antimicrobial agents in horses	235
Table 4.5	Usual dosage regimens for antimicrobial agents used in horses	237
Table 4.6	Drugs and drug doses commonly used for extradural analgesia	255
Table 4.7	Mediators and modulators of inflammation	263
Table 4.8	Classification of anti-inflammatory and anti-arthritis drugs	264
Table 4.9	Structural classification of NSAIDs	264
Table 4.10	Pharmacologic actions, therapeutic uses and toxic effects of NSAIDs	267
Table 4.11	Elimination half-life ($t_{1/2\beta}$) of NSAIDs (h)	271
Table 4.12	Relative potencies of corticosteroids (cortisol = 1) and biological half-life values in the horse	277
Table 4.13	Plants with potential to poison horses	287
Table 4.14	Potential toxicants in horses	293
Table 4.15	The principal families of venomous snakes	295
Table 4.16	FEI list of thresholds (2005)	299
Table 6.1	Normal eruption times of deciduous and permanent teeth in the horse	403
Table 7.1	Normal BALF cytology	431
Figure 7.1	RAO therapy objectives	435
Table 7.2	Frequency of isolation of bacteria from pneumonia or pleuropneumonia cases (USA and UK)	443
Table 7.3	Antibiotics for use in lower respiratory tract infectious disease	443
Table 7.4	Guidelines for minimum inlet and outlet areas per horse for box stalls and barns (meters)	448
Table 7.5	Aerobiology of hays and silages	448
Table 7.6	Aerobiology of fresh bedding materials	449
Table 8.1	Equine heart disease	456
Table 8.2	Cardiac murmurs and their causes	460
Table 8.3	Summary of diagnostic techniques in equine cardiology	461
Table 8.4	Normal M mode echocardiographic values for adult horses	461
Table 8.5	Normal interval durations in the equine ECG (lead II)	464
Table 8.6	Dosages of drugs used for management of cardiac arrhythmias in the horse	465
Table 8.7	Physiologic arrhythmias in the horse	465
Table 8.8	Supraventricular and ventricular arrhythmias in the horse	467
Table 8.9	Echocardiographic findings in acquired valvular heart disease in the horse	475
Table 8.10	Drugs used for the management of congestive heart failure in horses	477
Table 9.1	Causes of hemolytic anemia	493
Table 10.1	Analgesics for control of acute abdominal pain	545
Table 10.2	Dosage, safety and efficacy of commonly used equine anthelmintics	593
Table 10.3	Diagnostic tests for equine liver disease	611
Table 10.4	Histology of hepatic lesions	615
Table 11.1	Principal endocrine glands and hormones	629

Table 11.2	Expected responses to TSH stimulation test using IV bovine TSH administered IM in normal horses	652
Table 11.3	Classification of pony diabetics based on insulin and glucose data following oral glucose administration	655
Table 12.1	Chemical characteristics of normal equine urine and changes associated with disease	666
Table 12.2	Sedimentary characteristics of normal equine urine and changes associated with disease	666
Table 12.3	Fractional excretion ratios of the major electrolytes as calculated from serum and urinary creatinine	674
Table 12.4	Causes and laboratory features of polyuria	699
Table 14.1	Treatment schedule for retention of placental membranes	787
Table 14.2	Scoring system for electrolyte concentrations in mammary secretions	793
Table 14.3	Management guidelines for selected causes of high-risk pregnancies	799
Table 14.4	Normal hematology values for neonatal full-term foals	803
Table 14.5	Normal clinical chemistry values for neonatal full-term foals	810
Table 14.6	Normal serum electrolyte concentrations for neonatal full-term foals (mean \pm 2 SD)	810
Table 14.7	Normal arterial blood gas values for neonatal full-term foals in lateral recumbency (mean \pm SEM)	810
Table 14.8	Types of immediate transfusion reactions	816
Table 14.9	Modified APGAR scoring system	819
Table 14.10	Clinicopathologic conditions associated with peri partum hypoxia	820
Table 14.11	Characteristics of prematurity in the foal	825
Table 14.12	Symptomatic treatment of complications associated with prematurity	826
Table 14.13	Local and systemic effects of endotoxin	828
Table 14.14	Guidelines for treatment of neonatal septicemia	832
Table 14.15	Monitoring procedures for parenteral nutrition	845
Figure 14.1	Flow chart for cardiopulmonary resuscitation	850
Table 14.16	Equipment required for a neonatal crash cart	851
Table 14.17	Dosages for emergency drugs in foals	852
Table 14.18	Cardiac emergencies in foals	856
Table 14.19	Equipment for neonatal intensive care	862
Table 15.1	Techniques for diagnostic local anesthesia	875
Table 15.2	Fracture stabilization for transport to treatment facility	890
Table 15.3	Corticosteroids used in treatment of osteoarthritis	931
Table 15.4	Hyaluronan products commercially available for administration to horses	933
Table 16.1	A practical scheme for examination of horses with a potential back injury	1099
Table 16.2	Conditions to be considered in differential diagnosis of a thoracolumbar disorder	1101
Table 16.3	Conditions of the thoracolumbar spine that may directly cause back problems in the horse	1102
Table 16.4	Conditions alleged to cause back problems in horses for which there is currently no definitive scientific evidence	1103
Table 16.5	Techniques known to be used to treat back problems in horses	1103
Table 17.1	Guidelines for selected anticonvulsant drugs used to treat seizures in adult horses and foals	1108

Table 19.1	Dosages for subconjunctival injections	1175
Figure 21.1	A front view of the head of a horse showing the two lines joining the base of the ears and the centre of the orbit on the opposite side	1241
Table 23.1	Physical parameters frequently evaluated in intensive care horses	1258
Table 23.2	Fluid compartments in adult horses	1259
Table 23.3	Interpretation of packed cell volume and total plasma protein concentrations	1261
Table 23.4	Reference intervals for serum urea nitrogen, creatinine and electrolyte concentrations in adult horses	1261
Table 23.5	Normal blood pressure in adult horses	1262
Table 23.6	Reference intervals for blood gas analysis in horses	1270
Table 23.7	Interpretation of blood gas analysis and acid–base status	1270
Table 23.8	Composition and indications for use of intravenous fluids	1273
Table 23.9	Pharmaceutical preparations for the critically ill equine patient	1282
Table 23.10	Clinical signs of dehydration and estimated fluid lost in a 400 kg horse	1295
Table 23.11	Evaluation of packed cell volume (PCV) and total plasma protein (TPP)	1295
Table 23.12	Characteristics and treatment of acute respiratory distress	1301
Table 23.13	Common abnormalities of urinalysis and their causes	1305
Table 23.14	Recipe for hyperalimentation diet	1310
Table 23.15	General description of common colic etiologies and their treatment	1315
Table 23.16	Abnormalities of the gastrointestinal tract in the colic patient	1317
Table 23.17	Clinicopathologic evaluation of the colic patient	1318
Table 23.18	Analgesics for abdominal pain	1320
Table 23.19	Common cathartic drugs used for treatment of equine abdominal diseases	1321
Figure 23.1	Main level plan of the intensive care/neonatal unit at New Bolton Center	1324
Figure 23.2	Partial plan of the neonatal unit at New Bolton Center	1325

List of boxes

- Box 2.1 A glossary of immunologic terms 114
- Box 2.2 Groups of immunodeficiencies 137
- Box 3.1 Suggestions for routine analysis in assessing general feed quality 163
- Box 4.1 Corticosteroids: Pharmacological actions and side effects in the horse 278
- Box 4.2 Corticosteroids: Contraindications or special care in use 278
- Box 4.3 Glucocorticoids: Actions relating to anti-inflammatory properties 280
- Box 4.4 Glucocorticoids: Formulations available for clinical use 281
- Box 4.5 Annex IV to the FEI Veterinary Regulations (2005) 298
- Box 5.1 Classification of burns according to severity 344
- Box 7.1 Interpretation of bacterial isolates from tracheal lavage samples 441
- Box 7.2 Grading of exercise-induced pulmonary hemorrhage 451
- Box 8.1 Clinical signs associated with cardiac diseases in the horse 457
- Box 8.2 Parameters used to describe and classify cardiac murmurs in the horse 459
- Box 8.3 Negative prognostic indicators for horses with atrial fibrillation 469
- Box 8.4 Treatment regimen for atrial fibrillation using quinidine sulfate 470
- Box 8.5 Protocol for the emergency treatment of rapid supraventricular tachycardia induced by quinidine sulfate 470
- Box 8.6 Congenital cardiac defects in the horse 472
- Box 8.7 Technique for pericardiocentesis 479
- Box 9.1 Differential diagnosis for neutrophilia 507
- Box 9.2 Differential diagnosis for neutropenia 508
- Box 9.3 Proper intravenous catheter use 522
- Box 10.1 Differential diagnosis of chronic weight loss in the horse 586
- Box 10.2 Oral glucose and D-xylose absorption test protocols 588
- Box 11.1 Protocols for ACTH challenge 632
- Box 11.2 Protocols for the dexamethasone suppression test 636
- Box 12.1 Definitions of urologic terms 660
- Box 12.2 Common alterations of urine color 667
- Box 12.3 Water deprivation test 669
- Box 12.4 The Blondheim test for myoglobinuria 671
- Box 12.5 Examples of factors associated with the development of acute renal failure in the horse 683
- Box 12.6 Causes of hematuria 696
- Box 12.7 Causes of hemoglobinuria 696
- Box 12.8 Categories of neurogenic dysuria 708

Box 13.1	Minimal contamination breeding techniques	735
Box 13.2	Removal of retained placenta	759
Box 14.1	Periparturient conditions associated with high-risk pregnancy	789
Box 14.2	Database for high-risk pregnancies	797
Box 14.3	Supplies for foaling cart	799
Box 14.4	Management of parturition	800
Box 14.5	Peri partum conditions associated with neonatal foal asphyxia	818
Box 14.6	Therapeutic plan for hypoxia-induced disorders in foals	822
Box 14.7	Clinical conditions associated with neonatal septicemia	830
Box 14.8	Indications for nutritional support in the foal	838
Box 14.9	Complications associated with nutritional support	842
Box 14.10	Sample calculations for a 45 kg foal receiving parenteral alimentation	843
Box 14.11	Complications associated with mechanical ventilation	847
Box 14.12	Suggested pharmacy inventory	866
Box 15.1	Osteoarthritis—diagnosis	929
Box 15.2	Osteoarthritis—treatment summary	930
Box 15.3	Properties of hyaluronan	934
Box 15.4	Septic arthritis following intra-articular drug administration	938
Box 15.5	Primary treatment for septic arthritis	940
Box 15.6	Commonly used systemic antibiotics for septic arthritis	941
Box 15.7	Septic arthritis—summary	943
Box 15.8	Extracorporeal shock wave therapy	1018
Box 16.1	The multi-step exercise test for Standardbred racehorses	1086
Box 16.2	The one-step exercise test for Standardbred racehorses	1087
Box 16.3	The two- to three-step exercise test for Thoroughbreds	1088
Box 17.1	Treatment aims in horses showing clinical signs of tetanus	1119
Box 20.1	Rules of tumor management	1212
Box 21.1	Doses of sedative drugs and their combinations with opioids	1231
Box 21.2	Doses of some common premedicant and induction agents	1235
Box 22.1	The written report of the pre-purchase examination	1253
Box 23.1	Guidelines for clinical assessment of hydration status and effective circulating volume	1260
Box 23.2	Procedure for the measurement of central venous pressure	1264
Box 23.3	Conditions associated with electrolyte and metabolic imbalances in horses	1266
Box 23.4	Common causes of acute renal failure in the horse	1304
Box 23.5	Goals of therapy in laminitis	1311
Box 23.6	Basic questions regarding the history of a colic patient	1316

Introduction

It is a formidable undertaking to produce a book that aims to serve as a ready reference for equine practitioners while at the same time providing sufficient detail for it to be comprehensive without becoming a turgid reference book. The first edition of *The Equine Manual* appeared in 1995 and proved to be popular with clinicians, students and others who spend much of their lives working with horses. The publishers of that edition, W.B. Saunders Company, are now part of Elsevier, who decided that the time had come for an updated and revised second edition. This is it.

We have increased the size of the book to accommodate additional chapters that we felt were missing from the first edition. This time there are chapters devoted to anesthesia, pre-purchase examination, and intensive care medicine. There are sections on wound care, skin grafts and euthanasia; on new techniques ranging from contact lenses to blood and plasma therapy, and DNA technology. There is even a glossary of immunologic terms for those who may feel a little compromised in that area. All chapters have been updated and modified, and many completely revised. The Consultant Editors are world authorities in their fields and have attracted some impressive teams of co-authors with a wealth of applied clinical experience.

The editors took the view that indexing and cross-referencing were critical in a book of this nature. We have tried therefore to provide key words, which are shown in bold type, and a comprehensive, detailed index. A systems approach has been adopted in the 23 chapters, and an indication of contents is listed at the start of each. We have deliberately omitted all but a very few literature references as we feel there are other sources of information readily available for the research worker or the clinician who needs greater detail. A list of abbreviations can be found at the back of the book.

We want to acknowledge the amazing commitment and dedication of our Consultant Editors. They have worked with determination and perseverance, and the flow across continents of emails with attachments relating to this book has been impressive. Each deadline was met and the editors can only express their admiration and gratitude to all authors for achieving what often seemed like impossible targets. The participation of so many authors means, of course, that there will be some variation in style and emphasis, and some duplication, but we have endeavored to reduce distractions to a minimum.

Our focus has been to provide an easy reference for the veterinarian at the farm gate, for the clinician preparing for rounds or wishing to check back on the day, for the veterinary or equine studies undergraduate who needs ready access to relevant and topical information, and for technicians, farriers, nutritionalists, behavioralists, dentists, nurses and other specialized paraprofessionals who want knowledge and facts about the diagnosis, treatment, prevention and control of diseases and disorders in equines. In fact, it is a book for anyone wanting to know more about the health of the horse.

Reference is made in the book to specific agents, drugs and vaccines which could be used in the treatment or prevention of a particular condition. Mention of any agent in this manual does not, of course, imply endorsement of the product, and no guarantee can be given regarding any recommendations made by any contributor. As always, the clinical judgment of the attending veterinarian remains paramount.

We welcome your comments, criticisms and suggestions for changes in the hope that these will help us to improve future editions.

Chapter contents

INTRODUCTION 1	Infections with <i>Clostridium perfringens</i> Type A, <i>Cl. difficile</i> and <i>Bacteroides fragilis</i> 61	<i>Pseudomonas</i> 93
VIRAL DISEASES 4	Dermatophilosis 62	<i>Klebsiella</i> 94
Equine herpesviruses 4	Salmonellosis 63	Mastitis 94
Equine influenza 13	Clostridiosis 65	MAJOR INTERNAL PARASITES OF HORSES 95
Equine rhino/rhinitis viruses 18	Clostridial necrotizing cellulitis/myositis 66	Helminth parasites 95
Equine adenovirus 19	Botulism 67	Introduction 95
Equine viral arteritis 20	Tetanus 70	Strongylosis/ cyathostomiasis 96
African horse sickness and equine encephalosis 25	Anthrax 73	Parascariasis 101
Equine infectious anemia 29	Streptococcal infections 75	Strongyloidosis 102
Equine rabies 32	<i>Corynebacterium pseudotuberculosis</i> 81	Lungworm infection 103
Vesicular stomatitis 35	Glanders 83	<i>Oxyuris equi</i> infection 105
Togaviral and flaviviral encephalitides 37	<i>Histoplasma farciminosum</i> 85	Tapeworm infections 105
Rotavirus 44	Melioidosis 85	Bots 106
Hendra virus 47	Ehrlichiosis 86	OTHER INTERNAL PARASITES OF HORSES 106
BACTERIAL DISEASES OF THE NEONATE AND YOUNG FOAL 49	Potomac horse fever (equine monocytic ehrlichiosis) 86	Trichostrongylosis 106
Introduction 49	Equine ehrlichiosis (equine granulocytic ehrlichiosis) 87	Habronemiasis 106
Actinobacillosis (shigellosis, equulosis) 49	Lyme disease (borreliosis) 88	Fascioliasis 107
Colibacillosis 51	Pyoderma and saddle sores or galls 89	Hydatidosis 107
Salmonellosis 53	Fistulous withers and poll evil 89	Alimentary protozoa 107
Enterotoxemia 54	Leptospirosis 90	Blood protozoa 108
Listeriosis 56	Contagious equine metritis 92	Piroplasmiasis (babesiosis) 108
BACTERIAL DISEASES OF THE OLDER FOAL AND ADULT 57	Other bacterial infections of the reproductive tract and mastitis 93	Trypanosomiasis 108
Introduction 57		Tissue protozoa 109
<i>Rhodococcus equi</i> 57		Equine protozoal myeloencephalitis 109
Tyzzer's disease 60		Neosporosis 110

INTRODUCTION

During the last decade the increase in the international movement of horses and trade in semen has contributed significantly to the spread of equine

infectious diseases. While trade is the main reason for international travel, extensive temporary movement of horses takes place for competition and breeding purposes. Influenza, equine herpesvirus, strangles, equine arteritis virus, contagious equine metritis, piroplasmosis and Venezuelan encephalitis virus are among the infectious agents that have been spread as a result of international movement. In certain instances, mandatory testing prior to importation has been abolished in order to facilitate trade, and in others horses and semen have been incorrectly certified as disease free.

Veterinarians should inform their clients of the risks and advise them to test imported horses before mixing them with their own stock. It is not known how **West Nile virus (WNV)** (*q.v.*) was introduced into the United States in 1999 but this virus has now become endemic in the Western hemisphere. In 2002 over 14 000 equine cases were reported with a fatality rate of around 30%. The problem was considered of sufficient magnitude to warrant the production of a vaccine, and mass vaccination of horses in the USA has been undertaken.

Vaccination is one of the most cost effective methods of controlling many infectious diseases. Novel technologies offer opportunities for improving existing vaccines particularly where there are genuine reasons for concern about safety and/or efficacy. Recombinant vaccines are particularly attractive to manufacturers when handling viruses that are human pathogens such as the alphaviruses **eastern encephalitis virus (EEV)**, **western encephalitis virus (WEV)** and **Venezuelan encephalitis virus (VEV)** (*q.v.*) and the flaviviruses **Japanese encephalitis virus (JEV)** and **WNV** (*q.v.*).

Recombinants allow vaccine production under low biocontainment conditions as there is no requirement for large-scale production of a dangerous pathogen. Canarypox virus vector vaccines have recently been licensed for WNV and equine influenza. Such recombinants express the inserted foreign gene(s) in the absence of productive viral replication. A live temperature sensitive **intranasal vaccine** against **equine influenza** is now available in North America and like the live recombinant canarypox virus vaccine it provides partial clinical protection in the absence of high levels of serum antibody. This suggests that both vaccines are inducing protective cellular immune responses (*q.v.*) or priming the immune system so that an effective anamnestic response is rapidly induced on exposure to natural challenge.

Traditionally it has been possible to predict the level of protection that the influenza vaccination has induced by measuring the horse's levels of antibody against the hemagglutinin. These new vaccines present a challenge to virologists who now need to determine other correlates of protection and develop reproducible methods of quantifying them. Clinicians need not only to inform and advise their clients about alternatives to classical vaccines but also to evaluate them carefully in the field. Second generation vaccines are often more expensive than conventional products. Some products fail to fulfill expectations and their performance in the field does not always reflect the results of experimental challenge studies.

New developments that have the potential significantly to improve the control of certain diseases include a live temperature sensitive **equine herpesvirus 1** (*q.v.*) **vaccine**, which protects against respiratory infection and viremia, and a gene-deleted live vaccine for **equine arteritis virus** (*q.v.*), which allows serologic discrimination between vaccinated and infected horses. The advent

of reverse genetics should facilitate the development of **live attenuated equine influenza vaccines** that can be easily updated as new strains of virus emerge.

The correct treatment and management of a disease depends on an accurate, specific diagnosis. Conditions that are clinically indistinguishable nevertheless frequently necessitate different therapy and management procedures. The latter are particularly important in the case of viral disease. Although there are **no antiviral drugs** available at present for administration to horses it is important to identify which virus is involved in a disease outbreak. In the case of a training yard experiencing an outbreak of viral respiratory disease, where the aim is to minimize the sequelae and loss of training days, far more stringent management procedures are required if the causal agent is equine herpesvirus 1 than if it is equine rhinitis virus.

The ongoing incorporation of the **polymerase chain reaction (PCR)** as a routine test in diagnostic laboratories is of major benefit to clinicians in the prompt treatment and management of disease. PCR is a method of amplifying the amount of nucleic acid in a sample. Over a million copies of a specific target DNA sequence can be synthesized in a few hours. Thus viruses and bacteria that can take days or even weeks to propagate in the laboratory can be detected using PCR within 24 h. PCR is an invaluable diagnostic tool. However, it detects the target DNA independently of whether the infectious agent is active, latent or dead and the significance of positive results occasionally needs careful consideration. Furthermore, this sensitive technique carries with it a risk of **false positive** results due to contamination at the time of collection or in a laboratory. It is important that clinicians adopt the correct procedures when collecting samples and submit their material to a reputable laboratory in order to ensure the reliability of the results.

The use of antimicrobials and anthelmintics has increased significantly in veterinary practice. These products need to be used in a responsible manner to ensure their continuing effectiveness. **Multi drug resistance** among *Salmonella* and *Pseudomonas* spp. (*q.v.*) isolated from horses has been documented. Methicillin resistant *Staphylococcus aureus* (MRSA) is a major threat to human patients in hospitals and has been isolated from both horses and personnel in equine hospitals. Many national veterinary associations have now drawn up codes of practice for the judicious use of antimicrobials. It is important that clinicians comply with these codes.

The emergence of **anthelmintic resistance** (*q.v.*) is seriously jeopardizing parasite control in many parts of the world. Clinicians need to inform their clients that increasing anthelmintic treatment can lead to the development of resistance and to educate them in management procedures that reduce selection pressure. They also need to monitor resistance and report treatment failure to the product manufacturers and to their national collating centers. Failure to highlight resistance will result in complacency and a failure to invest in the development of new products.

In recent times there has been a huge increase not just in the international movement of horses but also of veterinarians who travel all over the world to work in practices and hospitals and to manage stud farms and racing establishments. Thus, veterinarians need to be familiar with the clinical signs and methods of diagnosis of diseases that occur in different parts of the world, for

example African horse sickness, Japanese encephalitis, glanders, rabies, vesicular stomatitis, babesiosis, trypanosomosis, anthrax and Potomac horse fever (*q.v.*). Veterinarians also need to know which diseases are **notifiable** in the country in which they are practicing and to be familiar with voluntary “Codes of Practice” such as exist for the control of several bacterial and viral diseases in the United Kingdom, Ireland, Italy, Germany and France (*q.v.*).

The recent emergence of **WNV** (*q.v.*) as a significant pathogen of horses and humans in the Western hemisphere illustrates the need for ongoing cooperation between the veterinary profession, the medical profession and colleagues in Public Health. Australia’s exotic disease preparedness was put to the test with the emergence of **Hendra virus** (*q.v.*) in 1994, a disease previously unknown anywhere in the world. Veterinarians, doctors and scientists worked together to control the outbreak, allay public fears, develop rapid diagnostic tests and determine the method of virus spread. We are all at risk from the introduction of exotic diseases and from the emergence of new pathogens. Technological advancements increase our capability each year but the control of infectious disease continues to be a major challenge.

VIRAL DISEASES

EQUINE HERPESVIRUSES

Equine herpesviruses are endemic in horse populations worldwide. Equine herpesvirus abortions result in significant financial loss to horse breeders each year and herpesvirus respiratory disease is a major cause of loss of performance in racehorses and in competition horses.

Etiology

Herpesviruses are enveloped DNA viruses. There are five equine herpesviruses. **Equine herpesvirus 1 (EHV-1)** is associated with respiratory disease, abortion and a neurologic syndrome. **Equine herpesvirus 3 (EHV-3)** causes coital exanthema and **equine herpesvirus 4 (EHV-4)**, formerly known as EHV-1 subtype 2, is a respiratory pathogen that has occasionally been associated with abortion. Neither equine herpesvirus 2 (EHV-2) nor equine herpesvirus 5 (EHV-5) has been conclusively implicated in a disease syndrome.

EHV-1 and EHV-4 are more closely related to each other than either is to EHV-2 or EHV-3. They can be differentiated by DNA restriction endonuclease analysis and PCR using type specific primers, or immunofluorescence using specific monoclonal antibodies.

The nucleotide sequence of the entire EHV-4 genome has been determined, as have the sequences of the genomes of two different isolates of EHV-1, one associated with abortion and the second with neurologic disease. It is hoped that the availability of these sequence data will facilitate the identification of virulence markers.

Epidemiology

Serologic studies indicate that infection with EHV-1 and EHV-4 is **universally common** and that most horses are exposed to these viruses early in life.

EHV-4 is more commonly associated with respiratory disease than EHV-1. It is also associated with sporadic abortion but very rarely with neurologic disease.

EHV-4 respiratory disease is endemic in horse populations worldwide. Although the immune response elicited by respiratory EHV-4 infection is not very durable, repeated exposure does lead to a gradual build-up of immunity. Clinical disease is most prevalent in **young stock**.

The rate of virus spread varies with the age of the horses, the type of husbandry and the training regimen. The spread of the disease in a group of **yearlings** in a barn can be rapid (within a week) with a morbidity rate of up to 100%. In older horses, virus spread is slower. It is not unusual for EHV-4 to circulate in a training yard for several months with a few different horses becoming infected each week. Infection in **older horses** is often subclinical but can result in a loss of performance.

EHV-1 is more virulent than EHV-4, and respiratory disease caused by EHV-1 is usually more severe. EHV-1 spreads more rapidly, the morbidity rate is higher and infection can result in neurologic disorders.

Both **sporadic and multiple abortions** due to EHV-1 infection occur each stud season in countries where horse breeding is an important industry. It is widely accepted that abortion is usually **preceded by a respiratory infection** that is often subclinical or so mild that it is not readily observed by handlers. Mares in **mixed yards** are most at risk as horses or ponies can be exposed to the virus at race meetings, shows, hunts or sales and serve as a source of infection for brood mares.

The average incubation period is 3 wk but it has been shown to vary between 9 days and 4 mo. However, it is not feasible to place an upper limit on the incubation period as EHV-1, like all herpesviruses, has the ability to establish a **latent infection** and to reactivate at any stage during the host's lifetime. Abattoir surveys suggest that the majority of adult horses are latently infected. **Stress factors** such as transport over long distances or illness may induce a reactivation of latent virus and precipitate abortion.

Although abortion due to EHV-1 infection usually occurs during the last third of pregnancy, it has been recorded as early as 4 mo and a foal may be carried to term and **born alive but infected**.

Fetuses aborted as a result of EHV-1 infection are **heavily contaminated** with virus and serve as a source of infection to other horses that come in contact with them. Thus, **multiple abortions** often follow the abortion of a fetus in a field where several pregnant mares are grazing. Up to 100% of mares exposed to virus on a stud farm may abort but the morbidity rate is usually lower.

EHV-1 abortion appears to stimulate a durable protective immune response and it is unusual for a mare to abort more than once following exposure to EHV-1.

Abortions due to EHV-4 infection are uncommon and usually sporadic in nature.

EHV-1 neurologic disease is uncommon but since it was first recognized in 1966 it has been recorded in all parts of the world where large numbers of horses are maintained. A few cases occur annually in many countries. The disease has occurred in association with respiratory disease and/or abortion in

competition yards, in training yards and on stud farms. Outbreaks have been recorded on stud farms with no concurrent cases of EHV-1 abortion.

Horses of all ages and both sexes can be affected but **recently foaled mares** seem to be most susceptible. Morbidity may be as high as 100% in some groups of horses. The disease can be **fatal** and severely affected cases necessitate euthanasia. **Direct contact** seems to be necessary for transmission of virus. Affected horses may remain viremic for extended periods and in some outbreaks new cases arise over several months.

EHV-4 has only rarely been isolated from cases of neurologic disease and its role in the etiology of the disease needs to be elucidated.

Outbreaks of **coital exanthema** caused by infection with **EHV-3** are frequently observed during the breeding season. Transmission is primarily by the **venereal** route. Clinically, stallions are less severely affected than mares but many show a **reactivation of latent virus** each season and infect the mares they cover. Lesions are sometimes observed on the mammary glands of mares and the muzzles of foals.

EHV-2 is endemic worldwide and is commonly isolated from **healthy** horses. Sick foals shed large quantities of EHV-2 and the virus has been associated with **keratoconjunctivitis** (*q.v.*).

Clinical signs

Respiratory disease

Respiratory disease caused by EHV-1 and EHV-4 is characterized by a transient elevation of temperature to 38.9–40.0°C, inappetance, nasal discharge, pharyngitis, depression and sometimes limb edema. Affected horses usually give a few coughs but coughing is not a major feature of uncomplicated EHV respiratory disease. There may be slight enlargement of the mandibular and retropharyngeal lymph nodes. Horses frequently suffer from **secondary bacterial infections**, which prolong the recovery time.

Abortion

Abortion usually occurs without any premonitory signs and **the placenta is not retained**. The mare's subsequent **fertility is unimpaired**.

Foals that are infected in utero but survive to full term are usually abnormal from birth and show signs of acute respiratory distress. Their mucous membranes are often jaundiced. They usually die before 2 wk of age.

Neurologic syndrome

Neurologic signs usually occur 7–10 days after an episode of respiratory disease. At the time when the nervous signs are evident, the horse usually shows no signs of respiratory disease and its body temperature and appetite are normal. Nervous signs vary from **mild ataxia** followed by complete recovery to **fatal paralysis**. Early signs may include stiffness, posterior incoordination and urinary incontinence. Uveitis, hypopyon, subcutaneous edema of the hindlimbs, colic, diarrhea, and scrotal edema and prolapse of the penis (*q.v.*) are sometimes encountered. These may be followed by sternal and then lateral recumbency, dyspnea, convulsions and death. Sudden death with no prior clinical signs has been recorded.

Pulmonary vasculotropic form

Several cases of **generalized peracute EHV-1 disease** have been reported in young adult horses. Neurologic signs are absent and the main clinical sign is respiratory distress. There is a high mortality rate and affected horses may be found dead.

Coital exanthema

Coital exanthema is manifested by **vesicles** that become pustular and ulcerate. Scabs develop which persist for 2–3 wk and may leave white scars. Mares develop **lesions on the vulva**, on the vaginal mucosa and on the perineal skin around the anus. In severe cases the lesions may extend to the hindquarters and hindlimbs. The mare may experience extreme **irritation on urinating**.

Stallions tend to be less susceptible than mares but lesions may occur on the prepuce and penis resulting in an **unwillingness to cover**. The lesions usually heal within 2 wk.

Pathogenesis

Abortion

Our current understanding of the mechanism by which a virus is transported to the fetus is that EHV-1 **infected peripheral blood mononuclear cells**, predominantly monocytes and T lymphocytes, carry virus to sites of replication such as the endothelium of endometrial blood vessels. Studies using PCR indicate that the virus establishes a **latent infection** in leukocytes but the factors involved in **reactivation** of virus and the activation of endothelial cells to facilitate the adhesion of their surface receptors to infected leukocytes need to be elucidated.

It appears that fetal infection is not a prerequisite for EHV-1 induced abortion and a severe infection of the endometrium can result in **extensive thrombosis** and ischemic infarction (*q.v.*) which in turn lead to premature placental separation and abortion of a **virologically negative fetus**. However, this appears to be relatively uncommon and in most cases the virus is transferred across the uteroplacental barrier, the fetal viscera are infected and a fetus with characteristic necrotic lesions and significant virus load is expelled. It has been suggested that it is the **endotheliotropism** of the virus strain that determines the degree of thrombosis and thus the outcome of virus challenge. However, not all abortigenic isolates are endotheliotropic and it is likely that the outcome of infection is also influenced by host factors.

Neurologic disease

Outbreaks of EHV-1 paralysis are much more uncommon than outbreaks of respiratory disease or abortion and the factors which predispose to their occurrence have not been identified. The occurrence of large abortion storms without concurrent neurologic signs militates against the size of the virus challenge being the predominant factor.

EHV-1 differs from several other herpesviruses in that it does not appear to be primarily neurotropic. The severity of the clinical signs can be correlated to the degeneration of neural tissue but this degeneration is due to **hypoxia** initiated by **vasculitis**. Damage to vessel walls leads to a flow of plasma proteins into perivascular sites impeding the exchange of blood and tissue metabolites

in adjacent areas. In the central nervous system (CNS) this results in **malacia** (*q.v.*). It has been suggested that the condition may be the result of an immunologic process and that inflammatory changes in the CNS may be a reaction to virus antigen and antibody complexes.

Post mortem findings

Abortion

The most consistent lesions in aborted fetuses and foals that die soon after birth are severe pulmonary edema, petechiation of the mucous membranes, excessive fluid in the pleural and peritoneal cavities, jaundice, splenomegaly and areas of focal necrosis in the liver.

Microscopically, the lesions are bronchiolitis, pneumonitis and necrosis of the spleen and liver. **Acidophilic intranuclear inclusion bodies** are found in the affected tissues and the presence of EHV antigen may be detected by immunohistochemical methods such as immunofluorescence and immunoperoxidase.

Fetuses aborted prior to the sixth month of gestation are often severely autolyzed. In such cases the classic lesions of EHV-1 abortion may not be present but the intranuclear inclusion bodies will be observed on histologic examination.

Neurologic disease

Gross pathologic findings in horses with the neurologic syndrome are often minimal. There is usually congestion of the mucous membranes and petechial, ecchymotic and hemorrhagic changes are often widespread. Hemorrhage around the spinal nerve roots is a common finding. Foci of malacia in the brain and spinal cord may be visible macroscopically. Intussusception (*q.v.*) has been observed in foals.

The predominant histopathologic changes are **vasculitis** and **degeneration of nervous tissue**. A non-suppurative inflammation of the blood vessels is accompanied by thrombosis and hemorrhage and exudation of plasma into the perivascular tissues. The arteries and arterioles of the CNS are principally affected but vasculitis is sometimes evident elsewhere in the body, for example in the endometrium of pregnant mares, uvea and lungs. Veins are affected less frequently but sometimes more severely.

Axons in the brain and spinal cord are often swollen and dystrophic. Foci of malacia in both gray and white matter, gliosis and neuronal degeneration are the most consistent findings in the CNS.

Pulmonary vasculotropic form

This form of EHV-1 disease is characterized by vasculitis, hemorrhage and edema in the lungs.

Diagnosis

Respiratory disease

Upper respiratory tract infection caused by EHV must be differentiated from equine rhinovirus, equine influenza virus, equine arteritis virus, bacterial infections and allergic rhinitis (*q.v.*).

Serologic diagnosis can be made on the basis of a significant rise (4-fold or greater) in antibody titer, which requires the collection of blood samples during the **acute stage** of the disease and 10–14 days later. The majority of diagnostic laboratories routinely use the complement fixation test (CFT) for the measurement of EHV antibodies. CF antibodies against EHV-1 and EHV-4 tend to reach a peak 10–14 days post infection and usually decline to their original level within 3 mo. Serum neutralizing (SN) antibody titers persist for longer than CF antibodies and are a less reliable indicator of recent exposure.

Because of close antigenic relatedness, infections with EHV-1 and EHV-4 are difficult to differentiate on the basis of serology. A **type specific enzyme-linked immunosorbent assay (ELISA)** has been used extensively in epidemiologic surveys but it is not quantitative and has not replaced more conventional techniques in the majority of diagnostic laboratories.

Equine herpesviruses are isolated in tissue culture. EHV-1 will grow on a variety of commercially available cell lines such as rabbit kidney cells (RK13) but EHV-4 is more fastidious and with a few exceptions tends to grow only on cells of equine origin. Virus isolates can be typed by immunofluorescence with specific monoclonal antibodies or by PCR. PCR can also be used for **rapid virus detection** in diagnostic samples and in some laboratories has been shown to be more sensitive than virus isolation. Some caution must be exercised in the interpretation of positive PCR results for blood samples as **leukocytes are a site of latency** for EHV-1 and EHV-4. The isolation of EHV-1 or EHV-4 from a **nasal swab** depends on the amount of virus the horse is shedding at the time of sampling. Although virus isolation is sometimes achieved within 24 h, it can take 2 wk or more. PCR can yield a result in less than a day.

Abortion

Diagnosis of EHV abortion is routinely based on **post mortem examination** of the fetus and on virus isolation. Samples of liver, lung, spleen, adrenal, thymus and kidney from **every** aborted fetus should be submitted to a **virus isolation laboratory** for routine screening for EHV. This also applies to the remainder of any fetus that has been partially eaten by predators as the virus can survive for several weeks in a moist environment.

A fetus aborted as a result of EHV infection is usually heavily contaminated with virus. Thus, EHV-1 can often be isolated from positive cases and typed within 48 h. EHV-4 tends to grow more slowly than EHV-1 in tissue culture. Most laboratories passage fetal tissue for at least 1 wk in tissue culture before they declare them negative. PCR is type specific and can be used to detect virus within 24 h of receipt of tissue samples.

The recent finding that naturally infected mares can abort **virologically negative fetuses** poses a problem for both pathologists and virologists and indicates the importance of **placental examination**.

It is not possible to diagnose EHV abortion by serologic examination. Some mares do not have a significant antibody titer at the time they abort. Alternatively, a mare may have a significant antibody titer due to exposure to virus by vaccination or by a natural infection that did not induce abortion.

EHV infection in neonatal foals can be confirmed by the isolation of virus from a nasal swab or heparinized blood. Serologic examination is not a suitable means of diagnosis.

Neurologic disease

As the nervous signs do not manifest for about 10 days post infection, the majority of horses suffering from EHV neurologic disease have high antibody titers against the virus. Thus, the examination of a **single serum sample** is often a useful diagnostic aid. Some mares are slow to seroconvert and examination of paired sera is necessary in a minority of cases.

In the case of an outbreak of the neurologic form of the disease, it is usually possible to isolate EHV-1 from the nasal secretions and leukocytes of some of the affected horses. **Heparinized blood samples** (a minimum of 20 mL per horse) are particularly useful as many horses experience prolonged viremia.

If horses die or are euthanased, a diagnosis can be made by **pathologic investigation**. EHV-1 antigen may be detected using immunoperoxidase or immunofluorescence techniques and virus can be isolated from the brain or spinal cord.

Coital exanthema

EHV-3 can be isolated from swabs of the ulcerative lesions. The virus usually only grows in cells of equine origin.

Antibodies against EHV-3 can be measured by complement fixation or serum neutralization. Most affected horses have significant antibody titers against the virus.

*Management and control**Respiratory disease*

Both killed and live attenuated EHV-1 vaccines were widely used for many years to protect horses against equine herpesvirus respiratory disease, but their use met with only limited success. More recently, **vaccines** containing **both EHV-1 and EHV-4** (e.g. Duvaxyn EHV 1,4 [Fort Dodge Animal Health] and Resequin [Intervet], available in Europe, and Prestige [Intervet] and Equi Guard [Boehringer Ingelheim] available in the USA) have been introduced and although they reduce virus shedding, they **do not necessarily offer complete protection** against clinical disease. However, regular use of such vaccines at strategic times in a training program (such as prior to or when there is a break in intensive training periods and attendance at race meetings) appears to lessen the effects of virus challenge and decrease the recovery time.

The **serologic monitoring** of horses on a regular basis serves as a useful aid to the early detection of EHV in a yard. If EHV is detected, it is of the **utmost importance** to have the virus type determined in a **specialist laboratory** by PCR or other reliable method.

It is rarely practical or advisable to close a yard with an EHV-4 problem, but it is usually possible to control the disease by **careful monitoring** of all the horses and identification and isolation of those that are affected. Horses with clinical respiratory disease and those that show signs of depression or inappetance should be **isolated** from healthy horses and adequately **rested** before a gradual return to full work. The use of antibiotics, mucolytics and bronchodilators may be indicated in horses with **secondary bacterial infection**.

Return to work too soon may result in **chronic respiratory problems** or the **reactivation and shedding** of latent virus. Because the virus usually spreads

quite slowly in a group of horses it is not unusual for some horses from an infected yard to continue to perform well. However, care must be taken not to over-stress subclinically infected animals. Serologic testing will help to identify these horses.

EHV-1 respiratory disease constitutes a greater threat to a training yard than EHV-4. Because of the abortigenic potential of the virus, no horse should be allowed to move from an infected yard to one that contains brood mares. When deciding whether or not to close the yard it should be remembered that EHV-1 can cause **paralysis** and that there is some evidence to suggest that stressing animals that are incubating the virus may precipitate this condition.

Abortion

A combination of good management and vaccination helps to reduce the threat of EHV abortion. The regular use of a **vaccine of proven efficacy**, preferably containing both EHV-1 and EHV-4 (e.g. Duvaxyn EHV 1,4 [Fort Dodge]), during each gestation period is recommended. There are many vaccines on the market but only one product, Duvaxyn EHV 1,4, is currently licensed in the EU for use in the prevention of EHV-1 associated abortions. Similarly, only Pneumabort K + 1B (Fort Dodge) and Prodigy (Intervet) have an abortion claim in the USA. A live temperature sensitive EHV-1 vaccine has recently been developed in the UK and the experimental data look promising. This vaccine protected pregnant mares for up to 6 mo after a single intranasal inoculation. In comparison the inactivated vaccines need to be administered at 5, 7 and 9 mo of each gestation.

Properly vaccinated mares rarely abort due to EHV infection unless they are **stressed** or exposed to a **large virus challenge** and multiple abortions on studs with a stringent vaccination policy are uncommon. Commercial studs should be advised not to accept unvaccinated pregnant mares or, if this is not possible, to keep them isolated (i.e. in a separate field or barn) from other mares.

Wherever possible, brood mares should not be kept in close proximity to other horses such as racehorses, showjumpers, yearlings and children's ponies. If mares are kept on **mixed premises** they should always be handled **before** other horses. Horses returning from sales, race meetings and competitions should be **isolated** from the brood mares.

It is important to **minimize stress** to pregnant mares. There is a risk in transporting heavily pregnant mares over long distances. All pregnant mares, particularly those that have traveled long distances and those from sales yards, should be **isolated** on arrival at a stud. Horse boxes should be regularly cleaned and disinfected with a product which is active against herpesviruses.

All cases of abortion, stillbirth or foal death within 14 days of birth should be treated as suspect virus abortion. The fetus and the placenta should be submitted to a recognized diagnostic centre for pathologic investigation. The mare should be placed in isolation in case she is shedding virus. If she aborted in a stable, the bedding should be sprayed with disinfectant such as Virkon (Antec International) at a dilution of 1:100 and left for 48h, after which it can be removed and burned. If she aborted in a field in the company of other mares, these mares should be isolated until further investigation is completed. No horse should be removed from the premises until the possibility of virus abortion has been excluded.

Common **Codes of Practice*** exist for the control of contagious equine reproductive diseases in the United Kingdom, Ireland, France, Germany and Italy. It is likely that these Codes will extend to all member states of the European Community in the future.

The correct procedure for the management of herpesvirus abortion is documented in the Code and is applicable to any premises where the owner is concerned to reduce the spread of the disease. The major points in the Code concern the **movement of horses from the infected premises**. All pregnant mares must remain on the infected stud **until they foal**. All other horses must remain on the stud until 1 mo after the last abortion. At this time, the infected stud's own non-pregnant mares, including those that aborted, can visit other studs to be covered subject to the full agreement of the receiving stud. The receiving stud should keep these mares isolated from pregnant mares.

The sampling of horses on infected premises for virus isolation and serologic examination for evidence of exposure to virus will assist a breeder in making decisions about the movement of horses within the stud farm. The cohorts of the mare that aborted should be isolated from other pregnant mares. Pregnant mares should be divided into small groups to minimize the spread of virus. If possible, each pregnant mare should be allotted a separate field or paddock so that if she aborts, her fetus does not serve as a source of virus for other pregnant mares.

Neurologic disease

If the neurologic form of EHV disease is confirmed, **no movement** should be allowed on or off the infected premises. All horses should be **rested** immediately as stress exacerbates the condition. In the case of a stud farm, **covering should cease** and because of the abortigenic potential of the virus, pregnant mares should be divided into small groups and kept on the premises until they have foaled.

The **treatment** of the neurologic disease is predominantly supportive and with good nursing care the majority of affected horses will recover. **Ataxic horses** (*q.v.*) should be stabled with deep bedding. **Recumbent horses** should be propped up in the sternal position if possible. Horses in **lateral recumbency** should be rolled frequently. **Abdominal slings** are useful to decrease muscle damage and the development of decubital ulcers.

Inappetent horses may need to be fed by stomach tube. Manual emptying of the rectum and bladder catheterization may be necessary. Immunosuppressive doses of corticosteroids have been administered during some outbreaks on the basis that this might prevent immune-mediated vasculitis. Neither the efficacy of this therapy nor that of anti-inflammatory drugs (flunixin meglumine, DMSO), vitamin E and aciclovir has been determined. Mildly uncoordinated

**Codes of Practice on Equine Venereal Diseases* available from: The Thoroughbred Breeders' Association, Stanstead House, The Avenue, Newmarket, Suffolk CB8 9AA, UK; Welfare and Breeds Department, British Horse Society, British Equestrian Centre, Stanely Deerpark, Kenilworth, Warwickshire CV8 2X2, UK; Syndicat des Eleveurs de Chevaux de Sang de France, 257 Rue du Jour se Leve, 92100 Boulogne, France; Direktorium fur Vollblutzucht und Rennen EV, Rennbahnstrasse 154, 5000 Koln 60, Germany; The Irish Thoroughbred Breeders Association, Greenhills, Kill Co. Kildare, Ireland; Associazione Nazionale Allevatori Cavalli Purosangue, Via del Caravaggio 3, 20144 Milano, Italy.

horses often recover within a few days, but horses that become recumbent usually take much longer and may never recover completely.

The decision to allow movement on and off the premises should only be taken when there is no evidence by serologic examination or by virus isolation that the virus is still circulating. This may take several months.

Coital exanthema

Aciclovir is not licensed for use in horses but is efficacious at the concentrations used in ointments for herpetic ulcers in humans. Antimicrobial ointments may also be applied to the affected areas to control secondary bacterial infection. Covering should cease until the lesions have healed.

EQUINE INFLUENZA

Etiology

Equine influenza viruses are RNA viruses of the orthomyxovirus group. They are categorized as **type A** on the basis of the antigenicity of their internal proteins and are divided into two subtypes on the basis of the antigenicity of the surface proteins **hemagglutinin (H)** and **neuraminidase (N)**. H and N account for 25% and 10% of the viral protein mass respectively.

Influenza viruses are codified according to their type, host species, subtype, and place and year of isolation. This is often followed in parentheses by the H and N subtypes. Thus the prototype of equine 1 influenza viruses is designated A/equine 1/Prague 56 (H7N7) and the prototype of equine 2 influenza viruses is designated A/equine 2/Miami 63 (H3N8).

The genes encoding H and N frequently mutate giving rise to **antigenic drift**. Influenza viruses are also subject to major changes in antigenic composition known as **antigenic shift**. This can occur due to reassortment of the H and N genes.

Equine influenza viruses are very labile and show **very little resistance to disinfectants** customarily used for viral infections.

Epidemiology

Although equine influenza is often associated with disease epidemics, it also causes sporadic outbreaks of disease in populations that are partially immune and is a persistent problem in parts of Europe and North America. Outbreaks of disease have been reported in South America but the disease has not yet been recorded in Australia, Iceland or New Zealand.

Equine influenza is contracted by **inhalation**. There is no evidence that horses become chronically infected with the virus. Epidemics often start at equestrian events where horses congregate in large numbers. The disease is then disseminated over a wide area following the dispersal of horses after the event. The incubation period varies from 1 to 5 days and depends primarily on the size of the virus challenge. The virus is **extremely contagious**. The short incubation period and persistent coughing, which releases large amounts of virus into the atmosphere, contribute to the rapid spread of the disease.

In a susceptible group of horses, morbidity can be as high as 100%. Mortality is usually low but can be as high as 10% in **foals, donkeys and affected horses that are not adequately rested**. The severity of the disease depends primarily on the immune status of the horses at the time of exposure, the environment and the amount of stress to which the animals are subjected.

Antigenic variation and failure to vaccinate are major contributing factors to influenza epidemics in countries where the disease is endemic but the most devastating epidemics occur when influenza virus is introduced into an immunologically naïve population. In India in 1987, over 27 000 Equidae were affected and several hundred animals died. In South Africa in 1986 race meetings were canceled for over 5 mo because of the influenza epidemic that resulted from the introduction of the virus into the country for the first time. In the 1989 epidemic in northeastern China, the overall morbidity rate was 80%; the mortality rate was 20%, but rose to 35% in certain groups.

Equine 1 influenza virus was first isolated in Czechoslovakia in 1956 and was subsequently detected in several European countries and in America. Although two international surveys have indicated that no equine 1 influenza viruses have been isolated anywhere in the world for more than a decade, there is some serologic evidence to suggest that they still persist. A/equine 1/Prague 56 or similar H7N7 virus is still included in influenza vaccines in many countries.

Equine 2 influenza virus was first isolated in Miami in 1963 and has continued to cause outbreaks of disease in Europe and North America ever since. Type 2 influenza viruses are less stable than type 1. Antigenic variants can give rise to **large-scale disease epidemics** such as occurred in 1979–1981 in Europe and in North America. The antigenic variant responsible for these epidemics was subsequently incorporated into the vaccines and annual vaccination for racehorses and competition horses became mandatory in several European countries.

Following the implementation of a mandatory vaccination policy in 1980, equine influenza was not diagnosed in Ireland and the UK for almost a decade. In 1989 both countries experienced an influenza epidemic. Genetic analysis of one of the viruses isolated in the UK, A/equine 2/Suffolk 89, demonstrated that it was significantly different from the prototype strain of the previous epidemic, A/equine 2/Fontainebleau 79. This led to a recommendation that A/equine/Suffolk 89 or similar isolate be included in influenza vaccines.

Further analysis of influenza A H3N8 viruses isolated in different continents demonstrated that there was an acceleration of H evolution in the late 1980s and that **two separate lineages** evolved. These have been designated European and American, based on the predominant geographic origin of the viruses. Co-circulation of viruses from both lineages can occur; for example, in the UK a European strain A/equine/Newmarket/2/93 was isolated at the same time as A/equine/Newmarket/1/93—an American strain from horses in the same yard. There is some evidence to suggest that the differences between the American and European lineages are sufficient to compromise cross-lineage protection after vaccination or infection.

Equine influenza viruses appear to be more stable than their human counterparts and no antigenic shift due to reassortment has been described in influenza viruses isolated from horses. Only viruses with the combinations H7N7 and H3N8 have been described in horses. However, shifts may occur not

only by genetic reassortment but also by mutation of an avian virus or other mammalian virus so that it becomes infectious for horses. The 1989 epidemic in northeastern China appears to have been caused by a virus that is more closely related to the influenza viruses of **aquatic birds** than to other equine influenza viruses. The prototype virus from this epidemic, A/equine 2/Jillin 89 (H3N8), is thought to be the latest mammalian influenza virus to emerge from the avian influenza gene pool, although it is no longer infectious to ducks which reduces the possibility of spread by aquatic birds during migratory flights. In 2004, there was a suggestion from the University of Florida that a strain of equine influenza virus may have infected dogs.

Clinical signs

Both subtypes of equine influenza viruses produce similar clinical signs in horses, but equine 2 infections are usually more severe. The first sign is an elevation in body **temperature** (up to 41°C) which is usually **biphasic**. This is followed within a few hours to a maximum of 2 days by a **dry deep cough**.

The other most commonly observed clinical signs are a **serous nasal discharge**, which may become mucopurulent due to secondary bacterial infection, myalgia, inappetance and enlarged mandibular lymph nodes. Edema of the legs and scrotum is sometimes observed and spasmodic and impaction colic (*q.v.*) have been reported.

Horses usually recover clinically from uncomplicated influenza within 10 days but coughing may persist for longer. **Secondary bacterial infection** prolongs the recovery period. Pneumonia (*q.v.*) may occur in foals, horses that are stressed by strenuous exercise, and **donkeys**, which are more susceptible to influenza than horses.

Equine 2 viruses are more pneumotropic than equine 1 viruses and have also been associated with **myocarditis** (*q.v.*). Pregnant mares may **abort** or resorb the fetus as a result of fever. Sequelae of equine influenza can include chronic pharyngitis, chronic bronchiolitis, alveolar emphysema which can contribute to chronic obstructive pulmonary disease (COPD), sinusitis and guttural pouch infections (*q.v.*).

Equine influenza may be **mild or even asymptomatic** in horses protected by recent or regular vaccination or by previous exposure.

Pathogenesis

The virus infects the **ciliated respiratory epithelial** cells, which become vacuolated, edematous and lose their cilia before being desquamated. This impairment of the clearance mechanism **increases the susceptibility** of the respiratory tract to **secondary bacterial invasion**. Damage to the respiratory epithelial cells can occur within 1 day after the onset of symptoms. Regeneration may begin a few days later but complete resolution may take up to a month, long after the horse appears clinically normal.

Diagnosis

The classical signs of influenza that are seen in unvaccinated horses are easy to recognize. The two major features of the disease are its **rapid spread** and the **dry deep cough**.

Diagnosis of equine influenza in a vaccinated population is more difficult as the clinical signs may resemble more closely those caused by other pathogens such as equine rhinovirus, equine herpesvirus or bacterial infection (*q.v.*) than classical influenza. A definitive diagnosis can only be made by **isolation or detection of the virus** from/in nasopharyngeal swabs or by **serologic examination**.

To isolate virus, **nasal secretions** collected in virus transport medium during the **acute phase** of infection should be kept cold **but not frozen** and transported to a specialist laboratory as quickly as possible. The samples are inoculated into the allantoic or amniotic sacs of 8–12-day-old chick embryos. After incubation at 33°C for 3 days the amniotic or allantoic fluids are harvested and tested for hemagglutinating activity. Some laboratories also isolate influenza virus using cell monolayers.

The presence of influenza virus can be confirmed and its antigen type determined by hemagglutination inhibition (HI) using **specific antisera**. Faster ELISA such as the Directigen Flu A (DFA) test have been developed for the detection of **influenza antigen**. The DFA takes approximately 15 min and is simple to perform. It requires no specialized equipment and can be performed by personnel that are not specially trained in virologic techniques. However, it is less sensitive than PCR; PCR requires a longer time to get a result than DFA but is considerably faster than virus isolation. **Virus isolation** remains essential for ongoing **strain surveillance**. In a recent study evaluating different viral detection methods in nasal secretions collected after experimental challenge, viral isolation and RT-PCR proved to be the most sensitive methods. The DFA test was the least sensitive method.

Clotted blood samples are required for serologic examination. Using the HI test, a sample taken in the acute stages of the disease can be compared with a sample taken 10–14 days later and a significant rise in type-specific antibodies will be readily detectable. Seroconversion can also be detected by single radial hemolysis (SRH). The HI test is simpler and less time consuming but the SRH is easier to standardize between laboratories.

Management

The standard recommended time for the management of equine influenza is **1 wk of complete rest for every day of elevated temperature** followed by a **gradual return to full work**. Some clinicians like to administer a course of antibiotics or sulfonamides to prevent secondary bacterial infections. Others, wary of the development of antibiotic resistance, prefer to treat secondary bacterial infections as they arise. A non-steroidal anti-inflammatory drug (NSAID) can be used in cases with high fevers to prevent excess pulmonary inflammation and abortion in mares.

In racing stables, the size of the yard, the vaccination history of the horses and the severity of the challenge should be taken into account when deciding whether or not to **close the yard** temporarily. Because of the **highly contagious** nature of the virus it is often advisable to close smaller yards, as the majority of horses will be exposed to the virus within a week. Moreover, resting the horses will reduce the severity of the clinical signs, decrease virus excretion, prevent the build-up of a large virus challenge in the yard, reduce the recovery period and minimize chronic sequelae.

In a larger yard with an intensive vaccination policy it may not be economically feasible to close the entire yard. In such a yard, virus spread will be slower, some of the horses will be asymptomatic and some remain capable of running good races. However, the trainer should always be warned that influenza virus is **pneumotropic** and that **working infected horses** will exacerbate the disease. It will also increase **virus shedding** which will serve as a risk to other horses.

Vaccination

Vaccinated horses are less susceptible to the disease than unvaccinated or inadequately vaccinated horses. During an extensive outbreak in Sweden in 1979, 1000 of 1300 horses under surveillance developed clinical signs, but whereas only 3% of horses that had received two or more doses of vaccine developed clinical signs, 98% of unvaccinated horses developed influenza.

In recent outbreaks, resistance to the disease has been shown to correlate well with the vaccination history and the antibody titers at the time of exposure. Young horses that have never been vaccinated or have only had a primary course and one or two boosters show classical signs of influenza, whereas in the same yards older competition horses that have been vaccinated regularly show no clinical signs. Racing yards that vaccinate every 4–6 mo are **less affected** than yards that vaccinate annually.

The majority of equine influenza vaccines that are currently available are **inactivated**. These vaccines contain either whole or subunit viral antigens, usually combined with an adjuvant such as aluminum hydroxide or carbomer. Equine influenza vaccines containing immune stimulating complexes (ISCOMs) are also available. These vaccines contain virus proteins attached to a matrix comprised of a glycoside Quil A extracted from the bark of a South American tree, *Quillaja saponaria molina*.

In North America a cold-adapted, temperature sensitive, **modified live vaccine** is available. This vaccine is administered **intranasally**. A single dose provides complete protection against challenge with homologous wild type virus for up to 3 mo and partial clinical protection for 6 mo or longer, in the absence of high titers of induced antibody. The vaccine does not provide sterile immunity and the mechanism of protection is not fully understood.

A **canarypox vector vaccine** expressing the H of a representative of both the European and American lineages has recently been licensed in Europe and may prove to be more effective than inactivated vaccines. It should stimulate cell-mediated immunity as well as humoral immunity.

Given that antigenic drift can compromise vaccine efficacy, vaccines need to be updated regularly to include virus strains that are representative of those circulating in the field. Since 1995, the recommendations of the World Organization for Animal Health, the Office International des Épizooties (OIE) have been to remove ancient isolates (for example Miami/63) and introduce recent isolates representative of the American and European lineages. Only **vaccines that have been updated in line with these recommendations should be used**.

It is advisable to vaccinate young horses, particularly racehorses and other competition horses, at **6 mo intervals** for several years after the primary course of three vaccinations. An annual booster will usually suffice for older

horses such as showjumpers and brood mares that have been vaccinated regularly since they were foals. Brood mares should be vaccinated in the **latter stages of pregnancy** but not later than 2 wk prior to foaling. This will ensure a good supply of colostral antibodies for the foal. Maternal immunity can last up to 6 mo.

Vaccination in the presence of **maternal antibodies** is not recommended as they interfere with the immune response. Furthermore it has been suggested that **repeat vaccination** in the face of maternal antibodies may be detrimental and interfere with the humoral response to vaccination many months after these antibodies have waned. It is advisable to monitor the antibody titers of foals and start the vaccination program when the maternal antibodies have declined to a negligible level.

Annual vaccination for racehorses and competition horses is mandatory in several countries. Although this helps to reduce the risk of influenza epidemics (it is estimated that >70% of the population need to be fully vaccinated to prevent epidemics) **annual vaccination in a training yard is unlikely to protect against clinical influenza**. The majority of horses in a yard need to have high antibody titers against influenza to withstand virus challenge. Such titers can be achieved by more regular vaccination (*q.v.*).

Serologic monitoring of the horses enables a clinician to decide on the most appropriate vaccination regimen. There are frequently a small number of horses in a yard that respond poorly to vaccination and have persistently low antibody titers. Such horses are often instrumental in starting an influenza outbreak in a yard.

Most influenza vaccines are marketed with and without **tetanus toxoid** (*q.v.*). The immune response elicited by tetanus toxoid is much more durable than that induced by influenza antigen. It is inadvisable to administer tetanus toxoid more frequently than the vaccine manufacturers recommend. In an intensive influenza vaccination program, vaccines containing **influenza virus alone** should be routinely administered and a tetanus toxoid booster administered at intervals of not less than 12 mo and preferably at 24–27 mo intervals. Horses should always be rested for a few days after vaccination.

EQUINE RHINO/RHINITIS VIRUSES

Equine rhinitis viruses, formerly known as equine rhinoviruses, belong to the family Picornaviridae, as do human rhinoviruses, frequently associated with the common cold. Serologic studies indicate a **high prevalence** of these viruses worldwide and it is likely that the majority of horses are exposed to rhinitis viruses at some stage in their lives.

Several different types of equine rhinitis viruses have been identified of which the virus formerly known as equine rhinovirus 1 appears to be the most clinically significant. This virus has recently been renamed **equine rhinitis A virus (ERAV)** and on the basis of its close relationship to foot-and-mouth disease virus (FMDV) has been classified as an Aphthovirus.

Equine rhinovirus 2 has been renamed **equine rhinitis B virus 1 (ERBV1)** and reclassified as the sole member of a new genus **Erbovirus**. It has been suggested that **equine rhinovirus 3** should also be assigned to this genus and renamed **ERBV2**.

Most of the clinical information available concerns ERAV, which is spread by **aerosols** and by **direct contact**. The incubation period is 2–8 days. Viremia is a regular feature and usually persists for 4–5 days. Virus is shed in **urine** for prolonged periods of time and this has led to the suggestion that the urinary tract may become persistently infected.

ERAV can cause **upper respiratory tract** disease characterized by fever, inappetence and a **copious nasal discharge**. There is a greater incidence of colds in children than in adults and similarly ERAV is more likely to cause disease in **young horses**. Upper respiratory tract disease due to ERAV infection is a significant problem in 2-year-olds in training. It is most prevalent in the autumn/fall and winter months. The virus appears to circulate constantly in most racehorse populations and the disease often occurs when horses are **stressed by intensive work** such as before their first race. Infection with another agent such as equine herpesvirus can also predispose a horse to ERAV infection.

ERAV spreads quite slowly and active cases of disease may occur in a training yard for several months. The lower respiratory tract does not seem to be very susceptible to rhinitis viruses and horses will usually recover from an uncomplicated ERAV infection within a week. However, **inadequate resting** of horses with ERAV disease increases their susceptibility to **secondary bacterial infection** that prolongs the recovery period. Rhinoviruses have been isolated from sinus fluids collected from people with acute sinusitis and it is possible that ERAV infection may contribute to the development of **sinusitis** (*q.v.*) in the horse.

ERAV infection in older horses is often subclinical but may contribute to a **loss of performance**. A high incidence of significant ERAV antibody titers is a common finding in yards presented to the clinician with problems of loss of performance.

People working with horses can be infected with ERAV but clinical signs have not been documented.

The laboratory diagnosis of ERAV is routinely based on **serologic examination** by CFT or by serum neutralization test (SNT) but the virus can sometimes be isolated from nasal swabs, blood, feces or urine. Detection of virus by PCR in nasal swabs has proven to be more sensitive than virus isolation.

Equine rhinitis viruses, like human rhinoviruses, are quite stable and can survive for weeks on a variety of surfaces in the environment. Management of the disease should include attention to stable hygiene and the use of a disinfectant with proven efficacy against rhinitis/rhinoviruses. None of the vaccines currently available contains equine rhinitis viruses.

EQUINE ADENOVIRUS

Serologic surveys for equine adenovirus indicate that infection is widespread but that the majority of infections do not result in clinical disease. However, **adenovirus pneumonia** is well documented in Arabian foals and the virus has been isolated from foals of other breeds with respiratory disease and from clinically normal foals.

Adenovirus infection is the most prevalent cause of death in Arabian foals with **combined immune deficiency** (CID) (*q.v.*). The disorder is inherited as an autosomal recessive trait and is characterized by the absence of functional

B and T lymphocytes. The foals are very susceptible to adenovirus, as well as to bacteria such as *Streptococcus zooepidemicus*, *Corynebacterium pyogenes*, *Escherichia coli*, *Staphylococcus aureus*, *Actinobacillus equuli*, *Pseudomonas* spp. and *Bacillus* spp. and to the protozoan *Pneumocystis carinii* (q.v.), and usually die before reaching 5 mo of age.

Adenovirus infection in foals with immunodeficiency is characterized by intermittent fever, rhinitis, conjunctivitis, pneumonia and, less frequently, diarrhea. Foals appear normal at birth but develop clinical signs between 2 and 6 wk of age and usually die within 2 wk. Hematologic examination reveals severe lymphopenia.

At **necropsy**, necrotizing bronchitis, bronchiolitis, interstitial pneumonia, as well as fibrin and hyalin membranes within the alveoli, are observed. Foci of abscess formation due to bacterial infection are frequently present. The lymph nodes, spleen and thymus are small with virtually no germinal centers. Large basophilic intranuclear inclusion bodies occur in respiratory epithelial cells and sometimes in the epithelial cells of the salivary glands and ducts, the conjunctiva, the pancreas, the bladder and the small intestine. Adenovirus can usually be isolated from the lung tissue. Primary equine kidney cells are the cell line of choice for virus isolation.

Several virus challenge studies have illustrated that immunocompetent foals exposed to adenovirus by the respiratory route develop respiratory disease. **Colostrum-deprived foals** are more susceptible to pneumonia. Post mortem lesions in such foals are similar to those in the CID foals described above but their lymphoid systems are normal.

Immunocompetent foals exposed to adenovirus by natural infection may develop conjunctivitis, dyspnea, fever, coughing and diarrhea. Uncomplicated adenovirus is rarely fatal but deaths due to combined infections of adenovirus and various bacteria have been recorded.

Adenovirus infection does not appear to be a significant problem in adult horses but it has occasionally been associated with upper respiratory tract disease, ocular discharge and soft feces in racehorses. In such cases a diagnosis may be confirmed by isolation of virus from nasal, ocular or rectal swabs and by serologic examination of **paired blood samples** collected 10–14 days apart. Hemagglutination inhibition is probably the most widely used serologic assay for the detection of equine adenovirus.

EQUINE VIRAL ARTERITIS

Introduction

Serologic surveys indicate that the equine arteritis virus (EAV) is widely distributed throughout the world. However, clinical disease is a relatively rare occurrence. It is the **abortigenic potential** of the virus that causes international concern and often leads to restrictions on movement of seropositive horses. The 1984 outbreak in Thoroughbreds in Kentucky led to a temporary embargo on the export of horses of all breeds from the USA to the tripartite countries (UK, France and Ireland). However, current international movement restrictions relate primarily to carrier stallions and infected semen.

Etiology

EAV is an enveloped spherical RNA virus of the genus Arterivirus, family Arteriviridae, order Nidovirales. Porcine reproductive and respiratory syndrome virus (PRRSV), another important veterinary pathogen, has been classified in the same genus. Only one serotype of EAV has been identified but genetic heterogeneity among strains has been detected by the determination of their nucleotide sequences.

Epidemiology

The first recognized outbreak of equine viral arteritis (EVA) occurred on a Standardbred stud in Bucyrus, Ohio, in 1953 but descriptions of the disease “**epizootic cellulitis-pinkeye**” in the veterinary literature date back to the late nineteenth century. In spite of the apparent worldwide distribution of EAV, disease outbreaks appear to be infrequent and sporadic in nature. Serologic evidence of exposure has been reported in America, Africa, Australia and Europe. Evidence of exposure to EAV has been reported in Standardbreds, Thoroughbreds, Quarter Horses, Arabians and Warmbloods.

Considerable variation in the prevalence of seropositive horses occurs between certain breeds within a country. In America, Australia and New Zealand, EAV is endemic in Standardbred horses but rare in Thoroughbred horses. Serologic surveys in the USA indicate that 70–90% of Standardbred mares but only 3% of Thoroughbred mares are seropositive. In Australia, 73% of Standardbred stallions tested seropositive compared with 8% of Thoroughbred stallions and 1% of Thoroughbred mares and racehorses.

The reason for the high prevalence of serologically positive horses in the Standardbred population is unknown. Experimental infection does not suggest that Standardbreds are more susceptible than Thoroughbred horses and in France there is a similar prevalence of EAV antibody in Thoroughbred and Standardbred horses.

The disease has not been recorded in a clinical form in Japan or Iceland but outbreaks have been recorded in several European countries including Switzerland, France, Poland and Spain, as well as in the USA and Canada. The first recorded outbreak of clinical EVA in the UK was reported in 1993. The first in Thoroughbred horses in North America occurred in Kentucky in 1984 and was a source of major international concern throughout the industry.

The virus is transmitted by the **respiratory** and **venereal** routes, and to a lesser extent by indirect contact with **fomites**. Virus may be shed for up to 16 days in nasal secretions and respiratory transmission can lead to widespread dissemination of virus, particularly where large numbers of horses are congregated together, for example, at race tracks, stud farms or sales. **Aborted fetuses** are heavily contaminated with virus and are a source of infection.

Carrier stallions play a critical role in the spread of the virus. A high proportion of EAV-infected stallions (1:3) may become long-term carriers and shed virus constantly in the sperm-rich portion of their semen. The establishment and maintenance of the carrier state appears to be **testosterone dependent**. The carrier state has not been identified in the sexually immature colt. The virus persists in the accessory sex glands and is eliminated within 26 days of castration. Although some carrier stallions spontaneously cease to shed

virus, others may continue to shed for their lifetime. Such stallions do not appear to be viremic nor do they shed virus in nasal secretions or urine.

It appears that **all susceptible mares bred to chronic carrier stallions become infected with virus** and outbreaks frequently start when a carrier stallion covers a susceptible mare. Initial **venereal transmission** is followed by **lateral spread** of virus via the **respiratory route**. The incubation period after venereal exposure is usually approximately 1 wk. The incubation period after respiratory exposure varies from 3 to 14 days.

There is no evidence of a carrier state in mares although virus shedding from the vagina of experimentally infected mares has been reported. Foals born to mares that were exposed to EAV when pregnant do not appear to become carriers.

The virus remains **infective in frozen semen** and artificial insemination (AI) has proved to be a highly effective mechanism of virus transmission. In the outbreak in the UK in 1993 mares inseminated artificially exhibited more severe clinical signs than those bred naturally. Some outbreaks have been due to the international trade of incorrectly certified semen.

The mortality rate in natural outbreaks of EAV is very low; mortality has only been reported in young foals. The ratio of clinical to subclinical infection, when infection was acquired following venereal exposure, has varied from 1.4:1 to 1:6 in different outbreaks. The highest morbidity rates have been reported where large numbers of horses are stabled together in the same air space.

The protective immune response elicited by natural infection with EAV appears to be very durable, perhaps permanent. Maternal immunity in foals born to immune mares declines after 2–6 mo.

Clinical signs

Clinical signs of EAV infection are extremely variable and the majority of infections appear to be **subclinical**. The most common clinical signs are fever, depression, inappetence, limb edema especially of the hindlimbs, stiffness in gait, inflammation of conjunctivae (“pink-eye”) and nasal mucous membranes, urticarial rashes and edematous plaques, ocular and nasal discharge, palpebral edema and edema of the orbital fossa. Edema of the mammary gland is frequently seen in mares and the majority of stallions develop scrotal edema. All or any combination of these clinical signs may occur in different outbreaks.

The predominant clinical signs in an outbreak may depend on the virus strain. For example, in 1993 conjunctivitis was a primary feature of an outbreak of EVA in the UK but in the same year urticaria was the main clinical sign observed in a major outbreak in North America.

Abortion may occur in mares in mid to late gestation. Stallions may experience a temporary decrease in fertility due to pyrexia and scrotal edema. This **sub fertility**, which is associated with both a reduction in the sperm count and morphologic changes, has been demonstrated to persist for up to 17 wk in experimentally infected stallions.

The most severe form of natural infection described occurred in the 1953 outbreak in Bucyrus, Ohio, when there was a 50% abortion rate in pregnant mares. Abortions occurred 10–34 days after exposure to virus and in 33% of cases were not associated with any other clinical abnormality. There were no

confirmed cases of EAV abortion during the 1984 outbreak in Kentucky but abortion has been a feature of subsequent outbreaks in the USA and Canada. Abortion rates of up to 50% have been reported during outbreaks of EVA on stud farms in Europe.

Post-mortem findings

The gross and microscopic lesions associated with EVA are consistent with the predilection of the virus for the media of the arteries. In the original Bucyrus outbreak, edema, congestion and petechial hemorrhages of the lymph nodes, the subcutaneous tissues and many of the organs were noted. The predominant microscopic lesion was a **widespread necrotizing arteritis**.

Pathologic examination of the aborted fetuses revealed edema of the lungs, increased pleural fluid and petechial hemorrhages of the pleural and peritoneal surfaces. Cardiac myodystrophy and hemorrhages and edema of the brain have been observed in fetuses from other outbreaks. A severe necrotizing arteritis in the placenta was described during an outbreak of EVA in Thoroughbred mares in Oklahoma in 1987. Fetuses aborted as a result of arteritis are often partly autolyzed.

Diagnosis

The diagnosis of EVA cannot be made based solely on the clinical signs without corroborative virus isolation and/or serology. The variability in pathogenicity among strains of EAV means that the absence of clinical signs cannot be taken as evidence of the absence of virus infection.

The detection of EAV in some equine populations, for example, in Irish Thoroughbreds in 2003, relied solely on serology. **Serologic diagnosis** of EAV infection is based on seroconversion. A **clotted blood sample** should be collected during the acute stages of the disease and a second convalescent sample should be taken 14–28 days later. Samples should be submitted to a reputable laboratory where the SNT is carried out in accordance with OIE standards. The SNT is the internationally recognized test but ELISA and CF tests have also been developed. ELISA tests are more rapid than the SNT but appear to have some specificity problems.

The virus can be isolated from nasal secretions, semen, urine, buffy coats and fetal tissues using a variety of cell lines including rabbit kidney cells (RK13). Nasal swabs and fetal tissue should be placed in **virus transport medium**, which is available from most specialist diagnostic laboratories. All samples should be kept cool and transported to the laboratory as quickly as possible. Recovery of virus from experimentally infected horses rarely presents a problem but it is sometimes difficult to isolate virus from naturally infected horses.

Virus isolation from the sperm rich fraction of **ejaculates** is an effective means of detecting a shedding stallion, as is test breeding. The isolation rate from dismount samples is not of equivalent accuracy and the testing of the pre-sperm fraction is likely to lead to false negative results.

The **shedding status** of a putative carrier stallion can also be determined by breeding him to **two seronegative test mares**. The mares are bled 14 and 28 days after covering and the sera checked for the presence of antibodies against EAV.

PCR can be used to amplify EAV nucleotide sequences to facilitate their detection in seminal plasma. Some laboratories have found PCR to be more sensitive than virus isolation. All shedding stallions identified to date are seropositive by the SNT.

Management and control

Adequate rest, with supportive therapy if necessary, allows the majority of horses to make a speedy and uneventful recovery. To minimize the risk of the development of **chronic carriers** it is particularly important that affected stallions are allowed several weeks of sexual rest. It is also important to control pyrexia in the stallion as this may lead to a temporary loss of fertility. Gonadotropin-releasing hormone (GnRH) antagonists (*q.v.*) have a potential role in the treatment of carrier stallions but a causal relationship between treatment and permanent cessation of shedding has yet to be established.

The spread of EAV can be limited by **restriction of movement** of horses from affected premises until there is no virologic evidence of active virus infection. Carrier stallions should only be allowed to breed under very restricted circumstances. In Kentucky, carrier stallions are kept physically isolated and bred only to mares that are seropositive to EAV as a result of previous exposure to virus by vaccination not less than 3 wk previously or by natural infection. Similar control programs are conducted in New York State, France and New Zealand.

A **modified live EAV vaccine** Arvac (Fort Dodge) is available in North America and a killed vaccine Artervac (Fort Dodge) is available in some European countries. The live vaccine has been used extensively in the Kentucky and New York Thoroughbred EVA control programs. It is derived by serial passage of the prototype Bucyrus strain in a variety of different cell lines and is not recommended for use in pregnant mares or in foals less than 6 wk of age but is considered safe for use in stallions and in barren mares. Safety studies have shown that vaccinated stallions may experience a temporary reduction in the percentage of sperm with normal morphology 2–3 wk after vaccination but no other significant effects on semen quality were observed. Vaccine virus can be isolated sporadically from the blood and nasopharynx of some stallions but it does not appear to be shed in the semen. The vaccine appears to protect horses against clinical disease but does not prevent virus infection, replication or shedding. **Vaccinated mares can be covered by a carrier stallion and are protected against clinical disease.**

The killed EAV vaccine is available in the UK for use in all horses and in France, Germany and Ireland where it is only permitted for use in stallions. In countries where the vaccine is available it is recommended that all stallions be vaccinated annually.

All stallions should be serologically tested immediately prior to and 2–3 wk after vaccination in order to be able to prove that their antibody titer is a consequence of vaccination and not natural infection. The keeping of adequate **records** obviates the need for investigations into the carrier status of the horse at a future date, particularly if the owner wishes to sell or export the horse.

Within the EU, the common **Codes of Practice** (*q.v.*) for the control of equine reproductive diseases in the UK, France, Germany, Ireland and Italy recommend that all mares be serologically tested within 28 days prior to covering and

that all imported animals be subjected to a serologic test for EVA. Any seropositive stallion must be isolated and his carrier status established. Seropositive mares should be subjected to two serum neutralization tests not less than 14 days apart. Their antibody titers should be stable or falling prior to release from isolation. Because of the lack of carrier status in the mare, a barren mare with stable or falling titers does not represent a significant risk to other horses and can be covered. Pregnant seropositive mares should be kept in isolation until they foal unless it can be established that they are seropositive as a result of exposure to virus prior to the pregnancy.

Breeders who practice artificial insemination of non-Thoroughbred mares should only use semen from stallions that are seronegative for EAV or that have been shown conclusively not to be shedding virus at the time of semen collection.

AFRICAN HORSE SICKNESS AND EQUINE ENCEPHALOSIS

Introduction

African horse sickness (AHS) is a **highly fatal**, infectious, arthropod-borne disease of horses, mules and donkeys. There are four recognized forms of the disease but most of the clinical signs and lesions result from impairment of the respiratory and circulatory systems.

African horse sickness virus (AHSV) is enzootic in most of Africa south of the Sahara. It occasionally spreads to other areas with devastating effects on the susceptible equine population. The disease appears to be capable of persisting anywhere in the world when the climatic conditions favor the multiplication of the vector and its survival during the winter months. Epidemics have occurred in the Middle East, Asia and the Mediterranean countries including Spain, Portugal and Morocco.

Etiology

AHS is caused by a double-stranded, RNA icosahedral virus belonging to the Reoviridae family, genus Orbivirus. It is related to bluetongue and Ibaraki viruses. **Nine different serotypes** of AHSV have been identified. They can be attenuated for use as vaccines by passage in mice and in tissue culture.

The virus is destroyed by heating it to 70°C for 5 min or 50°C for 10 min or by treatment with acetic or citric acid. However, it can persist for **several months** in putrefied blood. Equine encephalosis viruses (EEV) constitute a serogroup of the genus Orbivirus.

Epidemiology

In **endemic areas of Africa**, AHS occurs periodically during hot weather following heavy rains. The disease was confined to the African continent until 1944 when it spread to Palestine, Syria and Jordan. In 1959 there was a major epizootic in Iran, West Pakistan and Afghanistan that spread eastward to India and westward through Turkey to the eastern Mediterranean including Cyprus. The fatality rate among affected animals was nearly 90% and an estimated total of 300 000 Equidae died of the disease. In 1966 and 1967, AHS spread up to Northern Africa and into Spain but was controlled by slaughter of infected

animals and by an extensive vaccination program. All of these outbreaks outside Africa and an outbreak in Saudi Arabia in 1989 were due to AHSV type 9.

An outbreak in the Iberian Peninsula in 1987 was due to AHSV type 4 and was the first time this virus type had been recorded outside Africa. The outbreak began in August after the importation of **zebras** from Namibia to a safari park near Madrid. Zebras are quite resistant to AHS and may serve as a source of infection for more susceptible Equidae. The disease affected eight premises and 146 Equidae died or had to be destroyed. Approximately 36 000 animals were vaccinated. More than a year after the last death, however, a new outbreak of AHS was detected over 600 km away in Andalusia. Approximately 18 000 Equidae were vaccinated but the disease recurred again in the summer and autumn of 1989 in the same area causing the death of more than a thousand Equidae. It spread to the Algarve in Portugal and to Morocco. Mandatory vaccination of all Equidae was implemented in Portugal and no subsequent cases of AHS have been identified since 1989. The disease persisted in Morocco where outbreaks were reported in 1990 and 1991. In Spain, compulsory vaccination of all Equidae in Andalusia was begun in 1990 and the last positive case was recorded in November of that year.

Until recently *Culicoides imicola* (*C. imicola*) was considered the only field vector for AHSV but it now appears that *Culicoides bolitinos* (*C. bolitinos*) may be a significant vector in certain high-lying regions of South Africa.

The **seasonal nature** of AHS reflects the activity of the biting midge. The midge becomes infected by feeding on a viremic animal. The virus localizes in the salivary glands and is transmitted when the midge feeds on susceptible animals. The midge remains infected for life.

The life cycle of the *Culicoides* is divided into four stages: egg, larva, pupa and adult. The adult midges live for approximately 21 days during hot, wet months and feed on horses and other large animals from dusk until just after dawn. The midges are weak fliers but they can be carried for long distances in the **wind**. Outbreaks of AHS usually cease after a spell of cold weather, which kills the midges. New cases rarely appear more than 10 days after frost.

Culicoides overwinters in the larval stage but there is no evidence that transovarial and transtadial transmission of AHSV takes place. This suggests that there is another as yet **unidentified reservoir** in enzootic areas that serves as a source of infection for adult midges when they appear in the spring. Antibodies against AHSV have been detected in a variety of domestic and wild animals in Africa including elephants, sheep and goats but the virus has never been isolated from these species. AHSV has been isolated from dogs and camels in Egypt. It has been suggested that donkeys may have been responsible for the persistence of AHS in Spain between 1987 and 1988. Donkeys are less susceptible to the disease than horses and can experience persistent viremia.

The virus has also been isolated from other species of *Culicoides* that are more common in northern Europe and the UK than *C. imicola* and *C. bolitinos*.

C. pulicaris, *C. obsoletus* and *C. nubeculus* species, which are prevalent in the UK, can be **experimentally infected** with AHSV and *C. nubeculus* can transmit the virus. It is possible that these species could play a role in the transmission of virus if it were introduced into the UK or other northern European countries. The primary vector of bluetongue virus in the USA, *C. variipennis*,

has been shown experimentally to transmit AHSV. The virus has also been isolated from mosquitoes and ticks, which may play a role in the transmission of the disease.

EEV also appears to be transmitted by *Culicoides* midges and to date has only been identified in South Africa.

Clinical signs

Four forms of the disease have been described; acute or pulmonary, subacute or cardiac, mixed, and a mild form known as horse sickness fever.

The **acute or pulmonary form** is usually seen in susceptible animals during severe epizootics. After a 3–5 day incubation period the horse experiences an acute febrile reaction that may last only 24–48 h with temperatures as high as 40°C. The fever is followed by respiratory signs associated with pulmonary edema, which include tachypnea, paroxysms of coughing and frothy nasal discharge. The horse may experience great difficulty in walking and lower its head after the slightest exertion.

In the agonal stage the white, sometimes blood-tinged nasal discharge is voluminous and at the time of death a frothy liquid may flow from the horse's mouth. The total course of the disease is 4–5 days and the animal literally drowns in its own fluids. The mortality rate is approximately 90%.

The **subacute or cardiac form** of the disease is more common in enzootic areas. The incubation period lasts 5–20 days and is followed by a febrile reaction for about 5 days. Characteristic edematous swellings develop in the head region especially in the supraorbital fossa and the eyelids. The edema frequently extends to the neck and chest but is not gravity dependent. Petechial hemorrhages may develop on the ventral surface of the tongue and on the conjunctiva. Abdominal pain often results from hemorrhage in the gastrointestinal tract. Dyspnea may be observed but horses rarely present frothy nasal discharge. The mortality rate is approximately 50%.

The **mixed form** of AHS is a combination of the cardiac and pulmonary forms. The outbreaks in Spain and Portugal in the late 1980s were characterized by the mixed form in which either the cardiac or pulmonary form prevailed. Clinical signs were consistent with cardiorespiratory failure with progressive pulmonary edema.

Horse sickness fever is the mildest form of AHS. It is observed in donkeys, zebras and immunized horses. It presents as a febrile response sometimes accompanied by slight dyspnea.

It is thought that infection is usually subclinical but pyrexia, enteritis, abortion, jaundice and death due to cerebral edema and myocarditis have been recorded.

Post mortem findings

In the majority of field cases of AHS the gross lesions are consistent with both cardiac and pulmonary involvement. However, there are certain lesions that characterize each form of the disease. The **pulmonary form** is characterized by edema of the lungs and hydrothorax. It is possible to find 3–5 L of fluid in the chest cavity. The lungs are hypertrophic with interstitial and alveolar edema. The lumen of the trachea usually contains froth and a whitish or

yellowish foam is almost invariably present in the nostrils. Other lesions may include submucosal congestion of the fundus of the stomach and slight ascites.

The **cardiac form** is characterized by a yellow gelatinous edema of the supraorbital fossa, the intermandibular space and along the fascia of the muscle bundles in the frontal, cervical and sternal regions. There is marked hydropericardium. The pericardial sac may contain more than 2 L of yellowish fluid. Hemorrhages of the epicardium and endocardium are common and the lungs may be congested. Hydrothorax and ascites are sometimes present. Hyperemia of the glandular fundus of the stomach, perirenal edema, hyperemia and hemorrhages in the mucosa and serosa of the large and small intestines, subcapsular hemorrhage of the spleen and hypertrophy of the mediastinal and mesenteric lymph nodes are also commonly seen.

Diagnosis

In enzootic areas, familiarity with the disease may permit a presumptive diagnosis on the basis of clinical signs and gross lesions. However, because of the various forms in which the disease appears and the potential to confuse some of the clinical signs and lesions with those of equine infectious anemia, piroplasmosis, purpura hemorrhagica (*q.v.*) or poisoning, a confirmed laboratory diagnosis is essential.

Virus can be isolated from heparinized blood samples collected from the live animal or tissues collected at post mortem examination. The **spleen** is the tissue of choice but virus has been isolated from lung, liver and bone marrow. In the outbreak in Spain, AHSV was isolated from the **bone marrow** in the tail of a carcass that had been buried for several weeks. However, to maximize the chances of isolating virus, tissue samples should be placed in **virus transport medium** and kept cool while they are transported as quickly as possible to a virology laboratory.

Isolation of AHSV is achieved by intracerebral inoculation of suckling mice or by inoculation of monkey kidney cell lines (VERO and MS) or embryonated hen eggs. Virus isolation can be a slow process necessitating several passages in tissue culture or mice. An **indirect sandwich ELISA** that allows the identification of AHSV antigen within a day or two has been developed.

Virus isolation should be performed in parallel with the ELISA, as it is necessary to isolate the virus to determine its antigenic type. Isolates are typed by virus neutralization with type-specific antisera.

Clotted blood samples should be submitted to the laboratory for serologic examination. Serologic tests for the detection of antibody against AHSV include immunoblotting, CFT, the SNT and ELISA. At present the CFT and an indirect ELISA are the prescribed tests for international trade. The majority of countries require that Equidae from a country that has experienced an outbreak of AHS test negative prior to importation.

A high CF antibody titer is a good indication of fairly recent exposure to virus by natural infection or by vaccination because CF antibodies are not particularly durable and often start to decrease after 6 or 7 wk. SN antibodies take longer to rise but they are more durable. Horses with a negligible titer by the CFT are often positive by SNT and ELISA.

Horses that have been exposed to virus by natural infection mount a greater and more durable antibody response than those exposed to virus by vaccination. Approximately 7.57% of horses do not mount a detectable antibody response when they receive their first dose of vaccine. However, when a booster is administered an anamnestic response is elicited and they usually seroconvert within a week.

If EEV is suspected, virus can be isolated from blood or tissue samples on baby hamster kidney (BHK) cells or detected using a group-specific ELISA. A CFT and an SNT have been developed for measuring antibodies.

Control and eradication

Eradication of AHSV in enzootic areas is not feasible as it is impossible to control the vector and the reservoir host has not been identified. However, it has been possible to control and eradicate the virus outside Africa. Stringent management procedures must be implemented to prevent the spread of AHS in susceptible populations, requiring the cooperation of all sections of the community.

When the disease is confirmed there must be a **total ban on the movement** of Equidae including the cancellation of all horse shows, sales, race meetings and other gathering of Equidae. Strenuous efforts must be made to identify all infected animals and slaughter them. Horse owners should be advised to **stable** their horses from early evening until morning when the *Culicoides* are most active and to spray horses and stables with appropriate **insect repellents** and insecticides. The closing of stable doors and the gauzing of windows have been shown to lead to a 14-fold reduction in numbers of *C. bolitinos* and *C. imicola* entering stables.

Immediate vaccination of all Equidae and proper identification of vaccinated animals must be undertaken to control an outbreak of AHS. Before the viral serotype is identified it is necessary to use a polyvalent vaccine but a monovalent vaccine can be employed when the virus has been typed. An inactivated vaccine appears to be effective but is more expensive than the traditional live attenuated vaccines.

A **control program** is essential to verify that the virus has been eradicated from an affected area. The main features of such a program are the regular clinical examination of sentinel horses, the investigation of deaths among Equidae and the monitoring of the *Culicoides* population.

EQUINE INFECTIOUS ANEMIA

Introduction

Equine infectious anemia (EIA) occurs in horse populations worldwide and is characterized by antigenic variability of the causal virus and by persistent infection. Affected animals remain viremic and often suffer irregularly recurring episodes of disease. They become lifelong carriers of the virus. EIA is sometimes referred to as “**swamp fever**” as most outbreaks occur in warm wet areas where hematophagous insects that transmit the virus are abundant.

Etiology

The EIA virus belongs to the Retroviridae family that includes the human T lymphotropic virus (HTLV) and the human immunodeficiency virus (HIV)

or AIDS virus. It is a lentivirus and, like other members of this subfamily such as maedi visna virus and caprine arthritis virus, is associated with persistent and debilitating infections. Persistent replication of the virus within the host leads to the periodic emergence of **novel antigenic strains** of EIA. The virus is stable in refrigerated serum but is inactivated by heat (56°C), detergents and organic solvents such as ether.

Epidemiology

EIA was first described in France in 1843 and has subsequently been reported in horses, mules and donkeys in Asia, Africa, North and South America, Australia and occasionally in many European countries including the UK, France and Italy.

The virus is **mechanically transmitted** by biting flies or by contaminated needles, teeth rasps, stomach tubes and any other instrument that may cause abrasion. Several outbreaks due to contaminated sampling equipment have been recorded in **serum production horses**.

All infected horses serve as a potential source of virus for other susceptible horses. Viremia peaks when horses are pyrexia and is usually low when horses appear healthy, thus the role of inapparent carriers in perpetuating the disease may not be very significant.

Horseflies (*Tabanus* spp.), deer flies (*Chrysomya* spp.), stable flies (*Stomoxys* spp.) and mosquitoes transmit the virus but, because of their large mouthparts, **horseflies** are the most effective natural vectors of EIA. Transmission of EIA is dependent on the interrupted feeding of the vector because the virus does not remain viable in the arthropod for more than 4 h. Horsefly bites are painful which increases the likelihood of interrupted feeding. Although most horseflies interrupted when feeding will return to the same horse unless there is another horse in close proximity, cases of EIA sometimes occur at a considerable distance from an initial outbreak as this vector can travel several miles in a very short period of time.

As few as 10 horsefly bites are sufficient to transmit EIA from infected horses to susceptible cohorts and a single horsefly has transmitted EIA from an acutely infected pony to a susceptible pony. Because of the prevalence of insect vectors, natural outbreaks of EIA usually occur during the summer and early autumn in low-lying marshy areas and river valleys.

Transmission of EIA can occur **transplacentally** but this is more likely if a mare is clinically ill during the gestation period than if she is an inapparent carrier. Foals may become infected after birth by ingesting **virus-contaminated colostrum or milk**.

When conditions are ideal for spread, the morbidity of EIA can approach 100% in a group of horses and the mortality may be as high as 30%.

Clinical signs

The disease may take an acute, chronic or subclinical course. The incubation period varies from a few days to more than 3 mo. The **acute form** is usually associated with the introduction of the virus into a susceptible herd. However, the emergence of a new antigenic variant can give rise to acute clinical signs in a carrier. Characteristic features of the disease are fever, edema of the

dependent parts, hemorrhagic diarrhea, jaundice, petechial hemorrhage on the mucous membranes, anemia and death.

Symptoms of the **chronic form** include progressive anemia, loss of condition, weakness and tachycardia after exercise. Typically, the affected horse suffers recurrent episodes of fever, weakness, anemia, weight loss and edema that may last only a few days or persist for weeks. Sometimes the anemia and edema become more pronounced with succeeding episodes of disease. Recurrences are often stress related and may be provoked by malnutrition, overwork or surgery. The majority occur within the first 3 mo after initial infection. The frequency and severity of the clinical episodes of disease usually decrease with time and most horses become inapparent carriers.

Pathogenesis

The periodic nature of EIA appears to be due to **antigenic change** of the surface glycoprotein of the virus and the periodic release of new strains that evade the host's immune system. In general there is no cross-neutralization between different variants. When a new variant is released there is some delay before the horse adapts and produces antibodies that neutralize the virus.

The virus appears to have a predilection for macrophages and monocytes that provide a vehicle for dissemination to a variety of organs including the liver, kidney, adrenal, brain and heart. The **anemia** in EIA results from hemolysis of erythrocytes to which the virus has adhered and from impairment of bone marrow function. The **glomerulitis** (*q.v.*) of horses with acute EIA appears to be due to the deposition of circulating virus-antibody complexes in the kidney. These complexes may also be responsible for damage to the reticuloendothelial system leading to hemorrhage and edema.

Post mortem findings

The gross lesions commonly seen include enlargement of the liver with accentuated lobular structure, enlargement of the spleen, lymphadenopathy, anemia, jaundice, emaciation, edema and serosal hemorrhages. In chronic cases, emaciation and anemia may be the only gross findings. Lesions are difficult to find in inapparent carriers.

The most characteristic microscopic lesions are **interstitial mononuclear cell infiltrations** in the liver, kidney and spleen. These are most prominent in the periportal areas of the liver. The severity of the hepatic lesions is usually related to the frequency of recurrences of disease. The infiltrates increase when the clinical signs are severe and as much as one third of the liver may be comprised of mononuclear cell infiltrates. The Kupffer cells become enlarged and laden with hemosiderin. These lesions frequently disappear in inapparent carriers.

Generalized **hemosiderosis** (*q.v.*) is common as is glomerulitis. Virus is present in greatest concentration in the liver, spleen and bone marrow.

Diagnosis

Hematologic tests such as a platelet count, a differential white blood cell count, the determination of packed cell volume and a sideroleukocyte count may be helpful indicators in EIA diagnoses but are not pathognomonic.

The virus can be isolated in equine macrophages or equine dermal cells or detected by PCR but the **Coggins test** (*q.v.*), an agar gel immunodiffusion test, has since its development in 1970 formed the basis of most control programs for EIA. The antigen used in the Coggins test, the p36 viral core protein, is very stable and reacts with serum from horses infected with different variants. False negatives have been recorded in a small number of inapparent carriers. Also, although the precipitating antibodies detected by the Coggins test are usually present at the time of onset of symptoms, sometimes they may not be at a detectable level until later (up to 10 days).

More recently developed tests include an **ELISA** that appears to be more sensitive than the Coggins test. However, at present the Coggins test is regarded as the most reliable serologic test for EIA and although some countries will accept a negative ELISA, most countries require a horse to have a negative Coggins test result prior to importation.

Management and control

The antigenic variation of the virus presents a major obstacle to the development of an efficacious vaccine. **No vaccine** of proven efficacy is currently available. Blood transfusions and fluid therapy may assist in recovery from clinical disease but there is no effective means of eliminating EIA virus from an infected horse. The prevention of EIA is based primarily on the detection of infected horses by the Coggins test and their **isolation** from other horses. Since infected horses are the only known reservoir of the virus it is quite feasible to eradicate EIA from an area by testing and slaughter of reactors. The testing of all incoming horses will help to maintain the disease-free status. **Control of vectors** by drainage of swampy areas and by the strategic use of insecticides may help to limit the spread of the disease.

EIA is a **notifiable disease** in many countries including those in the EU, Canada, Sweden and certain states in Australia. Seropositive horses are destroyed in some countries including France and Germany. There is a voluntary control scheme in operation in Canada where horse owners receive financial compensation for slaughter of infected horses. In the USA, the slaughter of infected horses is not compulsory but there is a requirement for a negative test prior to interstate movement of horses. By contrast, within the EU, testing for EIA is only compulsory for horses moving from premises where the disease has occurred. However, all horse owners should be advised to have horses tested prior to introduction to their premises.

EQUINE RABIES

The incidence of rabies in horses, compared with that in many other animals, is low but the disease is of importance because rabid horses may serve as a source of infection for humans. Infected horses may become aggressive and although there are few reports on virus shedding by rabid horses the death of humans infected by rabid horses has been reported. Risks to veterinarians, handlers and other exposed people and animals should always be considered.

Etiology

Rabies is caused by a neurotropic rhabdovirus that belongs to the genus *Lyssavirus*. Several strains of rabies virus have been identified using

monoclonal antibodies, and non-pathogenic variants can be selected by growing virus in the presence of neutralizing monoclonal antibodies. The virus is **quite fragile** and is readily destroyed by heat, desiccation, ultraviolet light and most disinfectants. It can, however, survive in a refrigerated carcass for several days.

Epidemiology

Rabies occurs throughout most of the world including South America, the USA, Canada and Continental Europe. It is absent from Australia, Japan, Scandinavia, the UK, Ireland and some other countries.

Most warm-blooded animals are susceptible to rabies. Enzootic dog rabies is a major problem in developing countries. The incidence of rabies in people is far higher in these countries than in developed countries where wild animals are the main reservoir of virus.

Horses are moderately susceptible to rabies and usually become infected by the bite of a rabid animal. Infection by inhalation, such as may occur in a cave inhabited by rabid bats, or by the oral or transplacental route is unlikely to play a significant role in the epidemiology of the disease in horses. Rabid dogs and cats are a threat to horses and other domestic animals but **wild animals** are the most likely source of virus in many countries. **Foxes** are the most common reservoirs of the virus in Europe. **Skunks and raccoons** are a major source of infection in parts of the USA and **vampire bats** infect horses in South America. There is some evidence to suggest that the use of a modified live virus rabies vaccine was associated with the induction of rabies in horses during 1981–1982 in the USA. Live rabies vaccines are no longer recommended for use in horses.

Pathogenesis

Rabies virus enters the body by salivary contamination of a bite wound. The virus replicates in the muscle at the site of the bite before invading the **axons** of the peripheral nerves and spreading centripetally to the brainstem and spinal cord. Once the virus enters the **spinal cord** it spreads rapidly throughout the CNS. It is thought that the cerebrospinal fluid may be involved in the spread of the virus at this stage. The virus replicates in the CNS and spreads centrifugally along peripheral nerves to other parts of the body. High concentrations of virus are shed in the **saliva**.

As the virus is present in the nervous system for much of the course of the disease the immunologic response to infection is often minimal.

Clinical signs

The incubation period usually varies from 2 to 9 wk but can extend to 15 mo. The clinical signs are extremely variable and rabies should be considered in the differential diagnosis when a horse is presented with rapidly progressive neurologic disease, especially in countries where rabies is endemic.

Terminally, the signs are those of **diffuse CNS disease** but documented cases indicate that the early signs differ greatly between individuals. They include lameness, pyrexia, anorexia, muscle tremors, colic, ataxia, profuse salivation, teeth grinding and frequent whinnying.

Two clinical forms of rabies are recognized in the horse as in other species: the dumb or paralytic form due primarily to damage to the spinal cord, and the furious form due primarily to damage to the brain. This categorization refers only to the major manifestations of the disease and many cases exhibit clinical features of both types.

Horses that develop the **dumb form** often have ascending paralysis, ataxia and fecal and urinary incontinence. They have difficulty standing, become recumbent, make paddling movement with their forelegs and die. Horses that develop the **furious form** of the disease behave erratically and may attack and bite humans, other animals and inanimate objects. They may bite themselves at a particular site of the body. Such cases usually deteriorate rapidly and paralysis, convulsions and death ensue.

Equine rabies usually has a short course. It is rarely longer than a week and sometimes death occurs as early as 12 h after onset. Rabies is virtually always **fatal in unvaccinated horses** although there is one report of a donkey that recovered from an experimental infection after an illness lasting 11 days.

Diagnosis

Ante mortem laboratory examinations are of limited diagnostic value. Measurement of antibody titers against rabies in serum or cerebrospinal fluid, or examination of skin biopsies or corneal smears by immunofluorescence may give a diagnostic positive result but a negative result does not preclude rabies as a possible diagnosis.

The post mortem diagnosis of rabies can be made from examination of the **brain** using fluorescein-conjugated rabbit antiserum raised against the rabies virus. This test is reported to identify at least 98% of positive cases but testing of sections of the spinal cord is sometimes indicated, especially in horses that had the dumb form of the disease. Histologic examination for the presence of **Negri bodies**, the characteristic large eosinophilic cytoplasmic inclusions that occur in ganglion cells and neurons, is reported to identify 85% of positive cases.

Prevention and control

Countries that are free of rabies maintain this status by the rigorous enforcement of import regulations. The elimination of stray dogs and cats, together with the immunization of pets, plays a major role in the control of the disease in developing countries. In South America, immunization of cattle and the killing of vampire bats by the intraruminal administration of anticoagulants to cattle are widely practiced. In North America and Europe, wildlife control is being replaced by immunization of wildlife as a more humane way of controlling the disease. Baits impregnated with vaccines have been used successfully to vaccinate foxes in Europe.

Several killed rabies vaccines are approved for use in horses in the USA and annual vaccination is recommended. If a **vaccinated horse** is bitten by an animal that may be rabid, it should be **revaccinated immediately** and kept under observation for 90 days.

If an **unvaccinated horse** is bitten it should **not** be vaccinated immediately but isolated for 6 mo and vaccinated 1 mo before the end of quarantine. If at

any stage exposure to rabies is confirmed **the horse should be euthanased immediately**.

People caring for a suspect case should be immunized against the virus. Immunization should also be considered for anyone who has had contact with the horse in the recent past. Veterinarians should take particular care in endemic areas when conducting oral/dental treatments. If a person is bitten by a rabid horse the wound should be thoroughly scrubbed with soap and water and both rabies immune globulin (RIG) and human diploid cell vaccine (HDCV) should be administered as soon as possible.

VESICULAR STOMATITIS

Vesicular stomatitis is characterized by the development of vesicles on the feet and mouth. In horses it is associated with a **very painful lameness** and in cattle and swine it can be confused clinically with foot and mouth disease.

Etiology

Vesicular stomatitis virus (VSV) belongs to the same family as rabies virus, the Rhabdoviridae. Two serotypes have been associated with disease in horses in the USA: the New Jersey type and the Indiana type. There is extensive genetic diversity of viruses within these serotypes but the diseases they induce appear to be clinically indistinguishable.

The majority of outbreaks of vesicular stomatitis (VS) in the USA have been associated with the New Jersey serotype. Many virologists believe that there are additional serotypes of VSV but others maintain that these are variants of the Indiana type. High temperatures (50–60°C) rapidly inactivate the virus, as do common disinfectants such as phenols, formalin and quaternary ammonia compounds.

Epidemiology

Horses, cattle and pigs are susceptible to vesicular stomatitis. Sheep and goats are much more resistant. The disease may be transmitted to people.

The disease occurs in the Western hemisphere and is endemic to Central America, the southern USA and Colombia, Peru, Ecuador and Venezuela. It occurs seasonally every year in Mexico, Central America, northern South America and Ossawa Island, Georgia, in the USA. Major outbreaks in the USA occur irregularly. Outbreaks associated with the New Jersey type have occurred in the southeastern states and outbreaks associated with both the New Jersey type and the Indiana type have occurred in the southwestern states. The 1995 and 1998 outbreaks occurred in the western States and affected 365 and 380 ranches respectively. In 2004 an outbreak was confirmed in horses in Texas. Horses are more susceptible to New Jersey and Indiana type VS than cattle and in one large outbreak 44.7% of horses were infected compared to 4.5% cattle on affected farms.

The **mode of transmission** of the virus is not fully understood. The virus cannot penetrate intact skin but can enter through abrasions, wounds and mucous membranes, thus the feeding of poor quality rough forage that causes abrasions in the mouth facilitates virus spread.

Transmission may occur by **direct contact**, and **saliva and vesicular fluid** from clinically affected animals are highly infective. However, several outbreaks have occurred in horses that have had no contact with infected animals and it is widely believed that the virus is transmitted by **insect vectors**. In support of this theory the virus has been isolated from sand flies, horn flies, black flies and mosquitoes, and experimental evidence exists that VSV can be transmitted by black flies to swine. Disease outbreaks usually occur in August and September when these insects are abundant. Very few outbreaks have been recorded after the onset of cold weather with frost.

The disease is prevalent in low-lying wooded areas with heavy rainfall. In a survey in Utah in 1982 it was shown that horses stabled in an environment with some type of insect control were much less likely to contract the disease than horses kept on pasture near a river. Trajectory analysis of winds suggests that carriage of infected insects on the **wind** may play a role in the spread of the disease.

The **reservoir** of the virus is unknown although there is serologic evidence of infection of many wild mammals including elk, deer, feral pigs, skunks and raccoons. It has also been suggested that the reservoir may be a plant or insect and that vertebrates are only accidental hosts. There is a spatiotemporal association between grasshopper outbreaks and VS epizootics and cattle fed VSV-infected grasshoppers can develop VS.

People who have contact with infected animals, particularly those who routinely examine the mouth of infected animals, who have abrasions on their hands or arms and who have exposure to infected saliva through the eye or skin, are at risk of contracting the disease. A higher risk is associated with examining horses than cattle. Since the disease in humans resembles **influenza**, many rural cases are probably never diagnosed. Serologic studies in Georgia, New Mexico and Panama have revealed that 25–90% of farmers in some areas have antibodies against VSV.

Pathogenesis and clinical signs

Following a 2–8 day incubation period, there is pyrexia and inflammation of the mucosa of the mouth and tongue with the formation of vesicles. The vesicles rupture and leave **ulcers**. The resultant irritation leads to **salivation** and a reluctance to eat. This can result in considerable loss of condition. This is frequently the stage at which the clinician is consulted, i.e. vesicular lesions are not observed but the horse is anorexic and salivating excessively and the lesions are ulcerated or crusted.

In severe cases, ulcers may develop on the nasopharynx, larynx and turbinates, resulting in **epistaxis and respiratory distress**. Lesions may also be found on the mammary glands of lactating mares and the prepuce of male horses. Ulceration of the coronary band is common and results in lameness, which in severe cases may culminate in the sloughing of the hoof.

Unless complicated by secondary bacterial infection the oral lesions usually heal within a couple of weeks. Lesions on the feet may take longer because of secondary infection and trauma. Lameness may persist if a horse develops a severe coronitis and cracked hoof walls. Mortality is rare but may occur if there is severe secondary bacterial infection of the mouth, which prevents the animal from eating or drinking.

Diagnosis

A definitive diagnosis of vesicular stomatitis can be made by isolating the virus from the **vesicular fluid** or by **serologic examination** of two blood samples collected 10–14 days apart. Seroconversion can be detected by the ELISA, CFT or by SNT.

Management and control

Vesicular stomatitis is a notifiable disease in the USA and in the EU. Infected horses should be **isolated** and supplied with ample water and soft palatable feed. The use of systemic antibiotics may be indicated if the horse has secondary bacterial infection. Fluid therapy and nasogastric tube feeding are indicated if the horse is unable to eat or drink. During an outbreak care should be taken to avoid any injury or abrasions to the hoofs. Involvement of the feet may necessitate treatment similar to that employed in cases of laminitis (*q.v.*).

The disease is rarely fatal and usually runs its course in a couple of weeks. If VS is present in an area, insect control, the removal of animals from wooded pasture and their confinement in stables will help to curtail the spread of the virus. In the USA all livestock on affected premises are quarantined for several weeks until they no longer pose a threat to other livestock.

VS has been classified by the OIE as a list A disease because it is clinically indistinguishable from foot and mouth disease. Thus, VS is subject to stringent control measures wherever it occurs and can result in trade restrictions.

TOGAVIRAL AND FLAVIVIRAL ENCEPHALITIDES

Etiology

The togaviruses are small, enveloped RNA viruses. Within the family **Togaviridae**, viruses of the alphavirus genus including **eastern encephalitis virus (EEV)**, **western encephalitis virus (WEV)** and **Venezuelan encephalitis virus (VEV)** are associated with encephalitis in horses.

Japanese encephalitis virus (JEV) and **West Nile virus (WNV)** are members of the genus *Flavivirus* of the family *Flaviviridae*. The flaviviruses are small, enveloped RNA viruses that were considered a genus within the *Togaviridae* family before they were reclassified because of lack of antigenic relatedness and differences in biochemistry and replication strategy.

The alphaviruses and most flaviviruses including JEV are classified biologically as arboviruses because they are transmitted by **arthropods**. These viruses are geographically restricted by the availability of appropriate vectors and reservoir hosts. They can extend to new areas, for example WNV in North America, by the emergence of more virulent or more efficiently transmitted strains.

Epidemiology

Alphavirus encephalomyelitis was first described on the eastern coast of the USA in 1931. The etiologic agent was not identified as a virus until 1933, the same year that it was shown that the diseases on the east and west coasts of the USA were produced by two antigenically distinct viruses. The virus isolated during an epizootic in California, when approximately 3000 horses died, became known

as WEV and the virus isolated during an epizootic along the Atlantic seaboard became known as EEV. These viruses have been responsible for devastating periodically recurring epizootics and sporadic outbreaks of disease in the Western hemisphere.

Eastern encephalitis (EE) occurs in the eastern half of North America but it is not, as originally thought, restricted to the Atlantic seaboard. Epizootics have occurred largely in the seaboard states, especially New Jersey and Massachusetts, but also in the southeastern states (Georgia, Florida and Louisiana), the Caribbean, Panama, Central America and South America.

The distribution of **WEV** is more widespread than that of EEV, encompassing virtually all of North and South America. Large-scale epizootics have occurred in Canada and in western and central USA. It is estimated that over 180 000 horses died in a series of outbreaks in California in the 1930s. A few cases, but no epidemics, have occurred in eastern USA. A variant of WEV, the Highland J virus, has been reported in Florida.

VEV was first isolated in Venezuela in 1936 and has been shown to be antigenically distinct from WEV and EEV. Subsequent large outbreaks of disease were reported in Venezuela, Colombia, Ecuador, Peru, Trinidad, Central America and the USA.

JEV is a major problem in most of Asia. Epizootics are most commonly encountered in China, Korea, Japan and the eastern province of the Soviet Union. The virus has been found in the Western Province of Papua New Guinea and northern Australia.

WNV was first isolated in 1937 in Uganda and was subsequently identified in birds, humans and horses in Africa, Asia, the Middle East and the Mediterranean region. In 1999, WNV was isolated for the first time in North America. Clinical cases and deaths associated with WNV infection were confirmed in humans, horses and birds in a limited geographic area extending from New York. Within three years there was complete transcontinental movement of WNV. The means by which WNV was introduced into the USA is unknown but American isolates are closely related to a virus isolated in Israel in 1998.

The virus is now permanently established in the Western hemisphere. In 2003, almost 10 000 human cases were reported to the Centers for Disease Control (CDC). In 2002, there were 14 717 equine cases, and over 5000 equine cases were reported in 2003. Outbreaks have occurred in Europe. In Tuscany, Italy, in 1998 there were 14 clinical cases in a wetland area that is a breeding ground for migratory birds. In the Camargue, a similar environment in France, there were 58 cases of equine encephalitis in 2000. However, the virus has not become endemic in Europe.

WEV, EEV, VEV, JEV and WNV have **sylvatic life cycles**, involving bird and rodent reservoirs and insect vectors. Transmission of these viruses to the horse is nearly always by the bite of an infected **mosquito**. The mosquito ingests infected blood from the amplification host. The virus replicates in the cells of the mid-gut and travels via the hemolymph or nerves to the salivary glands. This extrinsic incubation period varies from 3 days to 2 wk. The mosquito remains infected for life and its longevity does not appear to be affected by the presence of the virus.

Culex tarsalis mosquitoes, which maintain WEV, breed prolifically throughout the summer in flood pools, rice fields, lake sides and irrigated places. They

feed readily on birds, horses and, to a lesser extent, people. In contrast, *Culiseta melanura*, which transmits EEV from bird to bird, breeds in saltwater swamps and does not travel far from its habitat. It rarely feeds on horses or people. EEV is transmitted from birds to humans and horses by other species of mosquitoes. These factors may explain in part why EEV is less prevalent than WEV.

There are many different subtypes and strains of VEV, some of which (the sylvatic viruses) appear to be non-pathogenic for horses while others (the epizootic viruses) can cause disease epizootics. Different strains of sylvatic VEV replicate in specific types of *Culex* mosquitoes which breed in swamps and have only limited movement. Epizootic strains of VEV are transmitted by many species of mosquitoes and other hematophagous insects including black flies (*Simulium* spp.). The diverse feeding preferences of the many vectors of epizootic strains of Venezuelan encephalitis (VE) contribute to the **widespread dissemination** of the virus.

JEV is transmitted by *Culex tritaeniorhynchus* and other related mosquitoes.

Over 40 mosquito species are competent vectors for WNV. *Culex* mosquitoes, particularly *Culex pipiens*, appear primarily responsible for epizootic transmission. **Ticks** may also serve as vectors for WNV.

The distribution of togaviruses and flaviviruses is governed by their transmission cycles. Epidemics occur at irregular intervals. In temperate zones they usually occur in mid to late summer and in the tropics they occur during the wet season. High humidity and moderately warm temperatures favor the long life and mobility of mosquitoes. Epizootics usually halt if the weather becomes cold or if there is a drought. Thus, in northern temperate regions if the first cases of encephalitis are diagnosed in late September a full-scale epizootic is unlikely to occur. Overwintering mosquitoes contribute to virus maintenance. Vertical transmission of WNV has been demonstrated in some species of mosquitoes.

Alterations in the environment and human behavior contribute to changing patterns of disease. Mosquitoes can be carried on **surface winds** at temperatures of 13°C or higher. They land when they encounter a cold front or rain. In this way climatic change leads to variation in the location and timing of outbreaks from year to year. Similarly **human management** of land affects the incidence of the disease such that clearance of land and drainage of marshes and swamps can destroy mosquito habitats while poorly managed irrigation systems can create new mosquito breeding sites. Periods of drought often lead to an increase in the amount of **stagnant water** available as breeding sites.

The distribution of the viruses is also governed by the **movement** of the amplification or reservoir hosts. Swamp-dwelling birds such as the red-winged blackbird are the reservoirs for EEV although passerine birds that fly into the swamps may also become infected. The passerine birds such as swallows, sparrows and blackbirds that amplify and transmit WEV may transport the virus over considerable distances. The sylvatic varieties of VEV are amplified in rodents such as the rice rat, the spiny rat and the cotton rat. Natural wildlife reservoirs for the epizootic varieties have not been identified.

Horses and people are **dead-end hosts** for WEV and usually EEV. They do not develop significantly high viremias to infect mosquitoes and to maintain the cycle. This is also true of the sylvatic varieties of VEV but not of the epizootic varieties. Horses experience high titer viremias when infected with an epizootic strain of VEV and play an important role as amplification hosts. They shed

virus in **nasal and ocular secretions, saliva and milk**. Virus transmission can occur by **aerosol**.

During an epizootic of VE large numbers of horses become infected within a short space of time. The disease can spread up to 32km per day and epizootics usually cease when **susceptible horses** are no longer available to support the disease.

The major amplification hosts of JEV are water birds, such as the black crowned night heron and egrets. Pigs also serve as efficient amplifying hosts and the spread of the virus in the last three decades is thought to be due, at least in part, to the expansion of the pig breeding industry in Asia. **Horses and people appear to be dead-end hosts.**

WNV is amplified by both wetland and terrestrial birds and has been isolated from crows, cranes, mallards, doves, eagles, robins and many other species in the USA. Crows appear to be highly susceptible and thousands of deaths in crows and other wild birds have been recorded in the USA since the introduction of WNV. Recent European outbreaks differ in that they do not appear to have been preceded by notification of any increase in deaths among wild birds. The first report of such deaths concerned the 1998 outbreak in storks in Israel and it has been suggested that European birds may have adapted to certain strains of WNV and that the epidemic nature of the disease in the USA may have been due to the lack of avian adaptation or to a more virulent virus strain.

The comparison of the amino acid sequence of the envelope protein of the European WNV isolates and viruses from Israel in 1998 and the USA in 1999 showed only two amino acid changes that are linked to attenuation in other flaviviruses. WNV has been associated with illness and death of mammals such as reindeer, mountain goats, squirrels, seals, sheep, new world camelids and dogs but these animals are not thought to play a significant role in the maintenance and amplification of the virus.

Like horses, humans are usually infected by a bite from **mosquitoes**. Horses and humans are considered incidental hosts and horse to human transmission has never been recorded. Also, like horses, humans only appear to experience a **transient viremia** but intrauterine transmission and transmission via blood donation and organ transplants have been reported.

Clinical signs

It is not possible to differentiate between EE, Western encephalitis (WE), VE or Japanese encephalitis (JE) on the basis of clinical findings. Infection with any of these viruses can result in subclinical disease, a generalized febrile illness with depression, anorexia and tachycardia or encephalitic disease, which can be fatal. The initial signs may go undetected and **sudden death** of apparently healthy horses has been reported with VEV infections.

The typical signs of **encephalitic disease** begin with fever and depression. Inappetance and reluctance to drink can result in dramatic weight loss. Hematologic examination often reveals a severe leukopenia. It may take from 12h to 5 days before the neurologic signs develop. Some horses exhibit **transient excitement** and restlessness. They may walk in circles, press their head against fixed objects and chew aimlessly. Intense pruritus has also been recorded. Such horses can be **aggressive**.

This period of hyperactivity is followed by a period of **profound depression**. Typically the horse is unwilling to move and stands with its legs apart, its head drooping or supported on a fixed object. The lower lip becomes pendulous and the tongue may hang out. There may be tremors of the facial muscles and dysphagia. The horse appears to suffer from **faulty perception** and becomes incoordinated and has difficulty in maintaining its balance. Progressive ataxia and weakness result in recumbency. Seizures may occur with spasmodic movements of the legs.

EEV and VEV are typically **more virulent** than WEV, JEV or WNV. Approximately 80% of horses with EE die less than 5 days after the onset of neurologic signs. Those that survive frequently have residual CNS damage such as visual deficits and behavior and learning disabilities. The fatality rate among horses with epizootic VE may reach 80%. The fatality rate of WE is approximately 25% but it can be as high as 50% during some outbreaks. If the clinical course is not prolonged or complicated and the horse does not become recumbent complete recovery is often possible.

Horses that survive paralysis and recumbency are more likely to have **neurologic sequelae**. The fatality rate among horses with JE has been reported as 5% in endemic areas, rising to up to 40% in seasonal epidemics in Japan. Mortality rates of 33% to 45% have been reported among horses in WNV outbreaks in the USA and Europe.

Pathogenesis and pathology

The virus replicates at the site of infection and in the regional lymph nodes. This is followed by a period of **extraneural amplification**, when the virus spreads via the blood to organs such as the liver and spleen. At this time the horse may experience a generalized febrile illness and in many cases the disease is self-limiting. If the virus is not successfully cleared by the reticuloendothelial system it may cross the blood–brain barrier and encephalitis ensues. The gray matter, including the pons, medulla, spinal cord, cerebellum, thalamus and olfactory bulbs are most often affected. The most common post mortem findings are edema and hemorrhage of the brain and spinal cord. Histologic examination reveals neuronal lysis, gliosis, neuronophagia and focal perivascular round cell infiltration. These lesions are not pathognomonic for any of the encephalitis viruses.

Diagnosis

Clinical diagnosis of togaviral or flaviviral encephalomyelitis is based on the clinical signs, the geographic location, the season, a history of contact with vectors and knowledge of other cases in the area. However, **clinical differentiation** from other conditions causing multifocal neurologic defects such as trauma, hepatoencephalopathy, rabies, verminous encephalitis, protozoal myeloencephalitis and bacterial meningoencephalitis may be difficult. Definitive diagnosis of viral encephalomyelitis and identification of the etiologic agent requires **laboratory testing**.

Viruses can be isolated from brain, blood and cerebrospinal fluid. They are also isolated without difficulty from avian blood and mosquitoes. They produce a **cytopathic effect (CPE)** in nearly all vertebrate cells. Baby hamster

kidney cells (BHK-21) and African green monkey kidney cells (VEROs) are widely used. Embryonated eggs are also highly susceptible. Different strains of these viruses may differ in growth characteristics in tissue culture. For example, virulent strains of VEV produce larger plaques in VERO cells than naturally attenuated strains. Viruses can also be detected and typed by PCR. When submitting blood samples to a virus isolation laboratory clinicians should be aware that there is a greater likelihood of isolating virus from a horse in the **early febrile stage** of the disease because viremia has often terminated by the time the nervous signs are manifested.

Serologic diagnosis is based on a specific rise in antibody titer in paired, acute and convalescent samples. Tests used for this purpose include HIT, CFT, virus neutralization (VN), immunodiffusion and ELISA. Because the antibody titers against these viruses rise quite quickly (VN antibodies are often detectable within 7 days post infection) and it may take several days, particularly with VEV, for the horse to exhibit signs of neurologic disorder, it is advisable during an outbreak to collect an **acute serum sample** from any horse with an elevated temperature. Then if the horse shows neurologic signs the second convalescent sample can be collected to confirm the diagnosis. An IgM capture ELISA technique has been developed for some of the encephalitis viruses and permits diagnosis with a single serum sample.

Some sylvatic and epizootic strains of VEV are antigenically closely related and caution should be exercised when interpreting serology results in an area where **sylvatic VE viruses** are endemic, for example in the Florida Everglades. Conclusive virus typing requires PCR or antigenic characterization of an isolate using monoclonal antibodies.

Treatment

Before initiating intensive nursing and treatment, it is wise to evaluate the chance of survival and the possibility of residual CNS damage. The prognosis for a horse with EE or VE is poor. The prognosis for a horse with WE, JE or WN encephalitis is better; with **intensive nursing** many affected horses recover.

In the absence of antiviral agents, supportive measures and symptomatic therapy are the primary modes of therapy. Throughout the therapy it is important to **minimize self-inflicted trauma** by using heavily padded bedding, a padded stall, leg bandages and a padded helmet. Every effort should be made to maintain the horse in sternal recumbency. Slings will restrain the affected horse and prevent the problems associated with prolonged recumbency. If it is not possible to maintain the horse in sternal recumbency or in slings it should be turned on the opposite side every 2h.

Supportive measures include feeding by stomach tube, the administration of balanced fluid solutions and the administration of **cold water** or alcohol baths to decrease pyrexia. It may be necessary to **catheterize the bladder** and to empty the rectum manually. **Secondary bacterial infections** should be treated with appropriate antibiotics. Corticosteroids are sometimes administered to decrease inflammation of the CNS but may make the animal more susceptible to secondary bacterial infection. Osmotic diuretics may decrease intracranial edema in cases with severe progressive depression. The administration of barbiturates, chloral hydrate or diazepam may be indicated to control seizures.

Control

Control of alphavirus and flavivirus can be achieved by **vaccination** and **vector control**. Mosquito habitats can be destroyed by drainage and by the elimination of **stagnant water**. Individual horses can be protected using insect repellents and screens. The incidence of alphavirus and flavivirus encephalitis is much lower in stabled horses than in horses on pasture. Major epizootics sometimes necessitate massive aerial spraying of insecticides. However, this raises environmental concerns and insect resistance may result.

Bivalent (WEV and EEV) and trivalent (WEV, EEV and VEV) **formalin-inactivated vaccines** are available for intradermal and IM administration. A live attenuated VEV strain TC-83 vaccine has proved very effective in the past but has the potential to **revert to virulence**. Thus killed virus vaccines are preferable. Initial vaccination schedules for the inactivated vaccines vary according to manufacturers' recommendations and are followed by annual revaccination prior to the mosquito season. However, in areas with a long mosquito season twice-yearly vaccination is strongly recommended to ensure complete protection. Vaccinating mares during the last month of pregnancy will increase the antibody titer of the colostrum. Because the duration of maternal immunity is very variable and can interfere with the foal's ability to mount an antibody response to vaccination, it is advisable to check the antibody titer of the foal before beginning its vaccination program.

An inactivated vaccine for JE produced by Kaketsuken and Nisseiken is available in many Asian countries where there is mass vaccination of racehorses. A live attenuated vaccine has been used in China. In some areas of Japan, pigs have been vaccinated against JE to reduce their threat as amplification hosts.

In 2002, an inactivated WNV vaccine, West Nile-Innovator (Fort Dodge), was licensed in the USA. It is recommended that horses receive two initial doses 3–6 wk apart before the mosquito season and thereafter an annual booster. However, many clinicians administer more than one booster per year. A booster should always be given just prior to the start of the mosquito season. More recently a **canarypox virus vector vaccine** for WNV (Recombitek) was approved by the United States Drug Administration (USDA) for use in horses. The manufacturers, Merial, have demonstrated that two doses at 5 wk intervals conferred significant protection to horses against WNV viremia.

A good **surveillance system**, including surveys of the size of the mosquito populations, the detection of virus in vectors and in reservoir hosts and the close monitoring of strategically situated sentinel flocks of domestic birds, is an invaluable aid to the prediction and prevention of epizootics. Such a system is in place in several states in the USA for WEV, EEV, VEV and WNV where it facilitates strategic vaccination and vector control. A sentinel pig surveillance system is in place for the detection of JEV in Australasia.

Human health considerations

EEV, WEV, VEV, JEV and WNV cause **encephalitis in humans**. Outbreaks of encephalitis in horses usually precede outbreaks in humans. Thus, it is important that cases of equine encephalitis are rapidly diagnosed and that state officials and the medical profession are alerted to the likelihood of an outbreak in

humans. Veterinary clinicians, like the rest of the public, should be aware of the possibility of contracting encephalitis from mosquitoes during epizootics and from contact with infected horses in the case of VE.

Horses with EE, WE and JE experience low titer viremia and thus are unlikely to transmit the disease to humans via mosquitoes. Horses with VE can serve as an indirect source of infection.

There are numerous reports of laboratory workers contracting encephalitis by aerosol. When performing a post mortem on a suspected case extreme precautions should be taken not to create an aerosol when removing the brain and spinal cord and to avoid puncture wounds with contaminated bones. Laboratory workers should be adequately vaccinated against the type and strain of virus that they are handling.

ROTAVIRUS

Rotaviruses are a major cause of diarrheal illness in infants and young animals in most areas of the world. It is estimated that equine rotavirus is responsible for more than 25% of cases of **foal diarrhea**.

Etiology

Rotaviruses are classified as a genus of the family Reoviridae. Equine rotaviruses belong to group A and are further subdivided into serotypes by neutralization with hyperimmune guinea pig or rabbit antiserum. The rotavirus genome contains 11 segments of double-stranded RNA. These segments are easily visualized by polyacrylamide gel electrophoresis (PAGE) and this procedure has served as a useful epidemiologic tool to differentiate strains. However, some viruses that belong to different serotypes are indistinguishable by PAGE. There is no in vitro marker for virulence.

It appears that cross infection from other species is rare but the genetic relatedness of equine rotavirus strain H-1 to porcine rotaviruses has led to the suggestion that transmission from pigs to horses may occur.

Epidemiology

Rotavirus disease is characterized by high morbidity and low mortality. The virus is highly contagious and is transmitted by the fecal–oral route. The incubation period can be as short as 18 h. The first signs are often **depression** and **failure to suck**. Diarrhea commences between 1 and 5 days post infection.

On affected stud farms the morbidity in foals is usually less than 100% and there is marked individual variation in the severity of the disease. Some foals remain **asymptomatic** while their cohorts become **severely dehydrated**. Foals younger than 4 mo are most susceptible, and foals born to mares that have recently been introduced to a stud farm are often more severely affected than the foals of resident mares. The offspring of some mares appear to be particularly vulnerable each year suggesting that the mare does not have a protective immunity against rotavirus or that there is poor concentration of maternal antibodies against the virus in her colostrum.

Some studs have **recurrent problems** with rotavirus infection. This can be due to **poor hygiene** and bad management or more usually to a **dense stocking**

rate which facilitates a build-up of virus. Rotavirus is frequently detected in the feces of foals that are clinically normal and it appears that the infective dose is an important determinant of the disease. Large quantities of the virus, up to 10^8 infective doses per gram of feces, are shed by affected foals. Virus may be shed prior to onset of diarrhea and after recovery. Other factors that influence the outcome of infection are strain virulence and the age and immune status of the foal.

Rotaviruses are highly resistant and can survive up to 9 mo in a contaminated environment. Thus, they can survive on **contaminated premises** from one breeding season to the next, causing a recurrent disease problem.

Clinical signs

The clinical signs are depression, inappetance, diarrhea, mild colic and dehydration. Pyrexia is not a major feature. Both increased and decreased borborrygmi have been reported. In young foals the **dehydration** can be fatal. Older foals may not exhibit the typical profuse watery diarrhea but show signs of abdominal pain.

Pathogenesis

Rotavirus infects the enterocytes primarily of the jejunum and ileum and causes atrophy of the proximal third of the villi. This leads to **impairment of digestion** and absorption of nutrients. The crypt cells are not infected and secretion progresses normally or is increased as they proliferate in an attempt to replace the damaged cells.

The undigested material results in an **osmotic drain** of body fluid into the intestinal lumen. The osmolarity of the intestinal contents is increased by **bacterial fermentation** of unabsorbed materials. The colon in the foal does not have a fully functioning microflora and is unable to absorb the excess fluid. The result is **profuse diarrhea** and subsequent dehydration.

Duodenal infection has been demonstrated and it has been suggested that mucosal damage combined with altered blood flow and a decrease in the number of goblet cells may cause ulcers. However, a consistent relationship between gastroduodenal ulcer disease (*q.v.*) and rotavirus antigen in the feces has not been demonstrated.

Diagnosis

Rotaviruses are fastidious and difficult to isolate routinely in tissue culture. Infectivity is enhanced if samples are pretreated with trypsin and the cell monolayers propagated in roller tubes in maintenance medium supplemented with trypsin. Diagnosis usually depends on the detection of virus or virus antigen in the **feces**. Two grams of feces should be collected from the rectum if possible. Freshly voided feces can be submitted to the laboratory but rectal swabs are unsuitable. Samples should be kept cool **but not frozen** while they are transported to the laboratory. The samples can be examined for the presence of virus by electron microscopy, which is highly specific but rather insensitive. Other disadvantages of this method of diagnosis include the expense and the need for an experienced operator.

ELISA and latex agglutination kits designed primarily for the detection of human rotavirus provide a very useful means of diagnosing equine rotavirus. They are used extensively by people caring for sick foals who require a rapid diagnosis. It has been suggested that for maximum sensitivity and specificity the method of choice for equine rotavirus diagnosis is the detection of viral RNA by PAGE. However, this is a significantly more time consuming technique than the technically simpler ELISA and latex agglutination tests.

Treatment

Rotavirus enteritis is usually **self-limiting**, lasting a week or so, but it is essential to **replace fluids and electrolytes** lost because of diarrhea. The incorporation of electrolytes in the drinking water is adequate for mildly affected foals. If lactase deficiency is suspected it is important to **reduce milk intake**. Foals may need to be muzzled and fed mares' milk diluted with a glucose and electrolyte solution via a stomach tube. Balanced electrolyte solutions, for example **lactated Ringer's** solution, should be given IV in cases where severe diarrhea and systemic signs are present. One liter of Hartmann's solution (**lactated Ringer's** solution) can be given in a 50 kg BW foal prior to evaluating serum electrolytes and the initiation of a calculated fluid therapy regimen (*q.v.*).

Sequential blood samples should be collected for hematologic and biochemical analysis including an estimation of total plasma protein. The administration of plasma is recommended for foals in danger of circulatory collapse. Acid-base disturbance can be monitored by blood gas and blood pH estimations. IV administration of **sodium bicarbonate solution** will help to correct acidosis but care must be taken as overloading the system can have untoward effects (*q.v.*). Persistent diarrhea can lead to potassium deficiency, which can be corrected by the administration of 8 g/100 kg BW t.i.d. potassium chloride PO.

Intestinal protectants (*q.v.*) such as kaolin (4–8 mL/kg BW b.i.d.) or bismuth subsalicylate (0.5–1 mL/kg BW 3–4 times daily) and **anti-ulcer drugs**, e.g. ranitidine (6.6 mg/kg BW t.i.d. PO, or 2 mg/kg BW b.i.d. IV) or omeprazole (1 mg/kg PO s.i.d.), are sometimes administered to foals with rotavirus diarrhea but **broad-spectrum antibiotics should be avoided** as they inhibit the development of the large intestine microflora. **Probiotics** and **natural yogurt** may help to restore the normal intestinal flora. Dose rate is empirical. Hyperimmune plasma (*q.v.*) can be administered orally or IV in accordance with the producer's recommendations.

Control

Good management will help to prevent a build-up of virus in the environment and decrease the incidence of rotavirus-induced diarrhea. Mares and foals visiting a stud should be **isolated** from resident mares and foals.

Povidone or iodine scrubs should be provided for handwashing and disposable gloves should be worn by anyone handling a foal. The stud farm should supply **disposable protective clothing** for use by the veterinary surgeon.

Rotating mares through a foaling unit can lead to a build-up of virus unless strict attention is paid to cleaning and disinfection procedures. After each foaling, the **foaling box** should be thoroughly cleaned with a pressure spray

and detergent prior to disinfection with a product that is active against rotaviruses, e.g. **phenol** or iodine.

Foals suffering from rotavirus-induced diarrhea should be moved immediately with their dams to an **isolation facility**. The handler in the isolation facility should not be in contact with other healthy horses. Any barn where a case of diarrhea occurs should be **steam cleaned** and disinfected. **Feces should not be spread on pasture.**

Studies in other animals have indicated that antibody in the lumen of the small intestine plays a much greater role than systemic antibody in resistance to rotavirus disease. Thus vaccination against equine rotavirus is aimed at effecting adequate lactogenic immunity. An **inactivated oil adjuvanted vaccine**, Duvaxyn R (Fort Dodge), is available. It is administered by IM injection to mares at 8, 9 and 10 mo of pregnancy. The vaccine appears to be safe and observations in the field suggest that it reduces the incidence and severity of disease. The generation of efficacy data has been complicated by the absence of a challenge model for the virus. Thus the vaccine only has a conditional license in EU countries. Some clinicians administer additional doses of vaccine to mares post foaling and others vaccinate foals. However these vaccination regimens are not included in the manufacturer's recommendations.

HENDRA VIRUS

In 1994, a previously undescribed disease occurred in racing stables in Hendra, a suburb of Brisbane, Australia. One human and 14 horses died. The causal virus was known initially as equine morbillivirus but was renamed Hendra virus.

Etiology

Hendra virus (HV) is the type species of a new genus within the subfamily Paramyxovirinae. It is closely related to **Nipah virus (NV)**, a virus that emerged in 1998 in Malaysia causing fatal encephalitis in humans and respiratory disease in swine.

Epidemiology

The first identified outbreak commenced on the 9th September 1994, when a horse died from **hyperacute respiratory disease** in a Thoroughbred training yard. Within 20 days there were 13 further deaths. Ten in-contact horses died at the yard and a single horse on each of three connected properties died. The trainer of the horses died on the 27th September. He had been closely involved with the affected horses and had abrasions on his hands and arms. His assistant also suffered from respiratory disease but recovered.

In October 1995 the husband of a veterinary surgeon was referred to Brisbane Royal Hospital with encephalitis, paralysis and seizures. He had assisted his wife at the necropsy of two horses in August 1994. One horse died from acute respiratory disease and the other displayed neurologic signs. The horses died 10 days apart and neither gloves nor masks were worn at the necropsy. Subsequent to the necropsy the man contracted meningitis but recovered. He subsequently suffered from persistent fatigue before developing epileptic

seizures and becoming comatose. He was seropositive for Hendra virus and retrospective analysis of archived samples from the horses also demonstrated the presence of the virus. His wife tested seronegative. No direct link between these cases and the outbreak in Hendra was demonstrated.

In 1999 a Thoroughbred mare in Cairns died after an illness lasting 24 h. Another horse that had been her companion for the previous 2 mo remained seronegative.

In 1994 and 1995 over 4000 horses were serologically tested in Queensland. All were seronegative. Wildlife serosurveys of almost 50 species gave negative results with the exception of **flying foxes** (family Pteropodidae), also known as fruit bats. All four species of these Pteropus bats have been shown to be seropositive with over 20% of the population in eastern Australia showing evidence of exposure to HV. The virus has been isolated from the uterus of the bats. They give birth in autumn and were occasionally found in the trees in the paddocks grazed by the affected horses. No disease has been reported in fruit bats but vertical transmission has been demonstrated. Bats of the genus *Pteropus* also appear to be the reservoir for Nipah virus in Malaysia.

Virus was isolated from the **urine** and **oral cavity** of infected horses and from the kidney at necropsy. There was no evidence of virus excretion from the respiratory tract, feces or conjunctiva. Virus was also isolated from the kidneys of the trainer who died in 1994 and from the urine of cats and guinea pigs experimentally inoculated with HV. Although horse to horse transmission appears to have occurred in the training yard in Hendra, it would appear that the virus is not highly contagious and that aerosol transmission is inefficient.

The humans affected had very close contact with infected horses. In Hendra the trainer had tried to clear the air passages of the index case per os and the assistant had restrained the mare in the terminal stages of the disease. The veterinarian's husband in Mackay had not worn gloves or a mask at the necropsy. No bat to human transmission has been reported but it has been suggested that the **Australian paralysis tick**, *Ixodes holocyclus*, could play a role in the transmission of virus from bats to other mammals.

Clinical signs

The incubation period is usually between 8 and 11 days. An **acute respiratory disease** usually results in **death** within 1–3 days. Clinical signs include pyrexia, increased respiratory and heart rates, depression, anorexia and severe pneumonia. Subcutaneous edema, frothy nasal discharge and neurologic signs have also been observed. In the outbreak in Hendra, seven infected horses recovered and three of these showed virtually no clinical signs.

In the first outbreak the trainer and his assistant suffered an influenza-like illness with respiratory disease, fever and myalgia. The trainer died of kidney and heart failure. The man who died in 1995 showed primarily neurologic symptoms culminating in fatal encephalitis.

Pathology

In horses the most significant lesions are **pleural and pericardial edema** and **congestion and ventral consolidation of the lungs**. Hemorrhages are present in the lung parenchyma and in some cases the airways are blocked by foam.

Histologically, the main lesions are interstitial pneumonia and severe vascular degeneration leading to widespread edema. Syncytial giant cells with cytoplasmic inclusion bodies are present in the vascular endothelium.

Diagnosis

The virus can be isolated in cell cultures and immunoperoxidase and immunofluorescence tests exist for virus detection. PCR assays have also been developed. Serologic tests include an SNT and an ELISA.

Control

The virus does not appear to be very contagious. To date, outbreaks have been managed by slaughter of seropositive horses and movement restrictions of horses within a designated control zone surrounding the affected premises. The drug **ribavirin** has been shown to be effective against the virus in vitro and may have potential for use in humans.

BACTERIAL DISEASES OF THE NEONATE AND YOUNG FOAL

INTRODUCTION

Foals that do not receive a sufficient quantity of **colostral antibodies** are at risk from bacteria that can cause septicemia, respiratory, enteric, locomotor or articular disease or concurrent combinations of these conditions. The principal organisms involved are species of *Actinobacillus*, *Clostridium*, *Escherichia*, *Salmonella*, and *Streptococcus*. Infections with other organisms, such as *Klebsiella pneumoniae*, occur sporadically.

The **septicemias** of the newborn foal are largely indistinguishable clinically and have the common features of increasing lassitude, reluctance to stand or feed, hypo- or hyperthermia and the signs of metabolic disturbances and shock, with tachycardia and tachypnea (*q.v.*). A good laboratory can normally demonstrate that the plasma of affected animals is acidotic and hypoglycemic, with IgG level ≤ 800 mg/dL, and that the total and differential white count is abnormal. Determining which organism is producing the septicemia requires blood culture, the materials for which are readily available.

In the very young animal that does not die from septicemia (or severe bacteremia), many of the causal organisms tend to localize and persist, particularly in the joints and tendon sheaths. In the case of the foal, antimicrobial therapy needs to take this fact into account.

ACTINOBACILLOSIS (SHIGELLOSIS, EQUULOSIS)

Etiology

The cause of actinobacillosis is *Actinobacillus equuli*, a Gram-negative coccobacillus approximately $1.5\text{ }\mu\text{m} \times 0.5\text{ }\mu\text{m}$ in size. The cells are arranged in smears of cultures or infected tissues with a typical “**Morse code**” appearance. A relative of *A. equuli*, *A. suis*, produces disease in pigs and has been encountered in normal and sometimes diseased foals and older horses. The two

organisms can be differentiated in the laboratory by their biochemical and other properties.

Epidemiology and pathogenesis

A. equuli is a commensal in the intestine of solipeds. The foal acquires the organism from its dam **in utero**, during or soon after birth, or from its surroundings. Post-natal infection usually occurs via the **umbilicus** or, less frequently, by the oral route. The disease recurs regularly on some premises. The offspring of some mares appear to be particularly vulnerable each year, which suggests that their dams may have a persistent cervical infection. In older foals migrating strongyles may provide a vehicle of entry for *A. equuli*.

Clinical signs

The disease takes either a peracute or an acute course. In peracute cases foals become depressed and drowsy 12–24 h after birth. They show a **reluctance to suck**, become severely dyspneic, collapse and die within hours. The rectal temperature may be elevated (41°C or more) but becomes subnormal before death. There are few distinctive clinical signs.

In **acute cases**, the foal becomes **depressed** and reluctant to suck 24–72 h post partum. Clinical signs may include pyrexia (40°C or more), inflammation of the conjunctivae, an unwillingness to move, diarrhea, hyperpnea and dehydration. Purulent glomerulonephritis (*q.v.*) may result in a **coma** and subsequently sudden death. Localization of the organism in the synovial membranes results in painful swellings in the joints and lameness. All joints can be affected but gonitis and tarsitis are common. Inflammation of the atlanto-occipital joint may result in extension and drooping of the head.

Pathologic findings

There are few distinctive lesions in peracute cases although pulmonary edema, petechial hemorrhages and yellow discoloration of skeletal musculature may be observed. **Miliary pinpoint abscesses** in the renal cortex and adrenals are characteristic of subacute cases. Similar abscesses are sometimes observed in the lungs as is a purulent exudate in affected joints, synovial sheaths and bursae.

Diagnosis

A. equuli can be isolated by blood culture from the septicemic foal. After death the organism can be isolated from the umbilicus, kidney and the musculoskeletal lesions. It can also be isolated from the cervix of some mares by the use of guarded swabs.

Treatment

Affected foals should be provided **aggressive antibiotic therapy** and supportive nursing care including **plasma** if the immunoglobulin level is low, plus nutritional support. Affected foals may be hyperglycemic. It is essential that antibiotic therapy with a broad-spectrum drug be instituted as soon as **bacterial**

septicemia is suspected. These conditions progress extremely rapidly and it is inadvisable to wait for the causal organism to be identified by the laboratory.

If **actinobacillosis** is suspected the therapy of choice is a combination of full doses of penicillin (or potentiated penicillin) and an aminoglycoside (gentamicin [7 mg/kg IV s.i.d.], amikacin [15 mg/kg IV s.i.d.]). Therapy should be continued for at least 2 wk and for 4 wk (or more) if the infection has localized in the joints or lungs. If an aminoglycoside is used, renal function should be monitored because the toxicity of the drug is enhanced in young animals with renal damage.

Control

Attention to hygiene and ventilation of stables is very important. Overcrowding should be avoided. **Foaling areas should be thoroughly cleaned and disinfected between foalings.** *A. equuli* is readily destroyed by the common disinfectants.

The umbilical cord should be allowed to sever spontaneously and the stump should be treated with **antiseptic** as soon as this occurs. The foal should obtain an adequate intake of colostrum during the first day of life. If colostrum is not available, 1 L of plasma should be administered.

Prophylactic antibiotics (gentamicin [7 mg/kg IV s.i.d.], amikacin [15 mg/kg IV s.i.d.]) can be administered to newborn foals on premises where there is a disease outbreak.

COLIBACILLOSIS

Etiology

The cause is *Escherichia coli*; these Gram-negative rods are morphologically typical enterobacteria. Like many other bacteria, *E. coli* can be divided into serogroups on the basis of the specific antigenicity of their somatic and flagellar proteins. Some strains possess **virulence factors**, and it is on these factors that pathogenicity depends.

Epidemiology and pathogenesis

The organism is a notable pathogen of many species of domesticated animals although it is also an inhabitant of the normal gut. Particular serotypes tend to be predominantly associated with particular species of domesticated animal, but can infect other species. The virulence factors of the *E. coli* strains recovered from foals and adult horses have not been identified but the **enteropathogenicity** of some strains of *E. coli* that infect other species of domestic animals and humans has been conclusively linked to the expression of adhesins and cytotoxins by plasmids within the bacteria. In other pathogenic *E. coli* strains, virulence factors, also capable of damaging the enterocyte, are known, although the prevalence, or even the occurrence of such strains in the horse, has yet to be determined.

Approximately 25% of cases of **septicemia** in the foal are caused by *E. coli*. The foal presumably acquires the bacteria from its immediate surroundings at birth. The relative importance of the probable routes of infection (umbilical, oropharyngeal or enteric) remains to be established.

Once access to the host has been gained, most of the pathogenesis in the septicemic disease is probably attributable to **shock** (*q.v.*) induced by endotoxin released from disintegrating bacteria. The main manifestations of endotoxic shock are pyrexia, hypotension and neutropenia.

Clinical and pathologic findings

The disease is very sudden in onset. In foals that are 3–4 days old the disease may take a 1–2 day course but it is usually more rapid still in foals that are less than 2 days old. Severe disease may be present before any clinical signs are observed.

Pyrexia may occur in the very early stages of the disease but the temperature is usually subnormal when the foal undergoes a collapse. The clinical signs are those of septicemia. They include depression, a reluctance to suck, petechiation of mucous membranes, respiratory distress, a progressively weakening pulse and colic.

If the foal survives for a few days individual bacteria and bacterial emboli can localize in the lungs, joints, bones or elsewhere in the body. The long-term prognosis for future athletic performance should be considered guarded for cases with involvement of the joints or bones, particularly if multiple joints are involved. Pathologic findings are typical of septicemia and reflect the time span of the infection.

Diagnosis

A definitive diagnosis can be made by **blood culture**. *E. coli* rapidly invades the carcass from the gut, so post mortem specimens should be taken for bacteriologic examination no later than 1 h after death.

Treatment

Despite the use of antimicrobial drugs and supportive therapy, the prognosis for foals with colibacillosis is not good. *E. coli* strains exposed to selection pressure are often resistant to the well-established antibiotics used in veterinary practice, such as ampicillin, tetracyclines, neomycin and kanamycin. They may be sensitive to trimethoprim—sulfamethoxazole, gentamicin, amikacin, chloramphenicol, quinolones or cephalosporins. Bacterial sensitivities are very useful in determination of the appropriate antibiotic therapy. Aminoglycosides (gentamicin [7 mg/kg IV s.i.d.], amikacin [15 mg/kg IV s.i.d.]) are the drugs of choice but they are nephrotoxic and **renal function** should be monitored.

In some equine neonatal intensive care units (*q.v.*) where *E. coli* is the leading cause of infection, amikacin in combination with penicillin is used if neonatal infection is suspected. This approach is adopted because of the prevalence of resistant organisms in nosocomial infections. Newer antimicrobial molecules, such as the highly active fluoroquinolones (enrofloxacin 4–5 mg/kg PO b.i.d. or 7.5 mg/kg PO s.i.d.), are becoming available for therapy in some countries.

Control

The same measures apply as in the control of actinobacillosis.

SALMONELLOSIS

Etiology

Salmonellosis is a **septicemic or bacteremic enteritis** of the foal that usually appears a few days later than other infections such as actinobacillosis or colibacillosis. The disease is caused by *Salmonella* spp., which are Gram-negative, facultative anaerobic, non-spore-forming rods typical of the enterobacteria.

Epidemiology and pathogenesis

A variety of species of salmonellae are involved in producing disease in the very young foal but currently *S. typhimurium* is most common. The most likely sources of salmonellae for the very young foal are the **dam** (which may be ill or seem entirely normal) or the **immediate surroundings**. The organism can be introduced by clinical cases, carrier animals, feedstuffs, water supplies, fomites, or other species of domesticated or wild animals, including birds. *Salmonella* may be a recurrent problem on some premises.

Carrier horses and other animals play a major role in the transmission of salmonellae. Between 10% and 50% of horses are silent carriers of these organisms. **Stress**, including illness and many veterinary procedures, provokes such animals into **active shedding** of salmonellae. This shedding only stops when the stress subsides and may recommence if the horse is again stressed. It is not clear whether salmonellae persist for the lifetime of the carrier.

The pathogenesis of salmonellosis is described in more detail elsewhere (*q.v.*). The normal flora has had little time to establish itself in the gut of the newborn foal and infection with salmonellae frequently results in septicemia in such animals. Even if septicemia does not occur, bacteremia is a feature of salmonellosis and the localization of the infection anywhere in the body is a common sequel to a diarrheal disease.

Clinical and pathologic findings

The onset is often **sudden** and very young foals may die from **septic shock** (*q.v.*) within hours before diarrhea develops. The initial features are depression, fever, reluctance to suck, weakness, dehydration and cyanotic mucous membranes. Neutropenia and toxic degeneration of lymphocytes are consistently seen. A **persistent watery fetid diarrhea** appears as the disease progresses and some cases develop **purulent bronchopneumonia** with loud rales. The spread of infection to other tissues can result in clinical pyoarthritis, nephritis or meningitis (*q.v.*).

Post mortem findings include severe visceral congestion and petechial hemorrhage in the serosae. A **catarrhal enteritis**, particularly of the ileum, is often seen. The synovias of foals with pyoarthritis contain floccules of pus and those with pneumonia may have minute pulmonary abscesses together with a generalized pulmonary edema.

Diagnosis

Definitive diagnosis of septicemic salmonellosis in the living animal depends on isolating the agent from cultures of the blood and feces. Fecal material should be obtained directly from the rectum. It is important, for epidemiologic

reasons, to determine which serotype (and phage type) is involved, so that the source(s) from which the agent emanated can be established and dealt with or avoided in future.

Treatment

Treatment consists of **maintaining hydration** by the IV and oral administration of fluids containing electrolytes and an energy source such as glucose (*q.v.*), long-term antibiotic therapy based on sensitivity assays, and the administration of intestinal protectants (*q.v.*) such as bismuth. Non-steroidal anti-inflammatory drug therapy, for example flunixin meglumine 1 mg/kg IV s.i.d. or b.i.d., may reduce the signs of endotoxemia.

Some salmonellae (especially *S. typhimurium*) are often **resistant** to several antibiotics simultaneously so antimicrobial sensitivity testing of isolates is imperative. In general, *Salmonella* spp. are sensitive to amikacin, gentamicin, ceftiofur (and other third generation cephalosporins), chloramphenicol, trimethoprim-sulfonamide, and fluoroquinolones.

The ubiquity of salmonellae, their pathogenicity, and the existence of the seemingly normal carrier, all contribute to the difficulty of controlling the disease. The management of the septicemic foal should include **strict isolation** of the foal and its dam and **vigorous disinfection** (sodium hypochlorite, phenols or quaternary ammonium compounds) of their surroundings.

The ability of salmonellae to infect other animals and humans needs to be considered when practical measures to control spread are chosen. The personnel caring for the affected animals should wear disposable overalls, boots and gloves and, if possible, they should not have contact with healthy horses. The equipment, bedding and feedstuffs, etc. for the sick animals should be kept separate from those for healthy horses.

In other species of domesticated animals, **vaccination** with salmonellae of modified virulence has been practiced in some countries and has a welcome degree of success in controlling acute disease. Pregnant mares on premises where there is a disease outbreak or where there is a recurrent problem can be vaccinated 8 wk and 4 wk pre partum. Such vaccines are not universally available, nor will they always protect the newborn animal from an infection leading to septicemia. In addition, the ability of the vaccines to affect the carrier state, or modify its prevalence, is uncertain.

ENTEROTOXEMIA

Clostridia are serious pathogens of the horse. Enterotoxemia in the newborn foal associated with either *Cl. perfringens* type B or type C is reported occasionally but the exact prevalence of the disease is unknown. The specific clostridial enterotoxemias are easier to suspect and confirm in a group of animals of similar age than in an individual.

Etiology

Cl. perfringens is a ubiquitous, large (approximately 4–8 µm long and 1 µm wide) and strictly anaerobic Gram-positive rod, which grows easily in the laboratory if its requirement for anaerobic conditions is met.

Epidemiology and pathogenesis

All the clostridia live in the soil (especially **well-cultivated soil**) and, by extension, in the gut. Animals naturally acquire the vegetative organisms or the spores orally at birth. Pathogenic clostridia have in general two striking characteristics. They release exceptionally **powerful toxins** into their surroundings, and they form **highly resistant spores**.

An imbalance in the relationship between the normal flora of the gut and normal enteric function in the newborn foal may allow an **explosive multiplication** of *Cl. perfringens* B or C so that they reach numbers far in excess of normal. This exceptional occurrence leads to the release of overwhelming amounts of **necrotizing toxin** and subsequent enterotoxemia.

Whereas other pathogenic bacteria tend to produce disease more readily when the newborn animal is compromised for some reason, the pathogenic clostridia tend to affect the animal that is progressing very well. Foals cease to be susceptible to clostridial enterotoxemia when they reach a few weeks of age.

Clinical and pathologic findings

Enterotoxemia in foals a few days old is rapid in onset. The animal quickly enters a state of **profound depression** and very soon has a markedly subnormal body temperature, tachycardia and tachypnea and great abdominal pain. These clinical signs are the consequence of, firstly, a **hemorrhagic, ulcerative necrosis**, most marked in the terminal ileum and, secondly, absorption through the mucosa of the powerfully cytotoxic beta toxin, which is produced by *Cl. perfringens* types B and C. If **death** does not occur quickly, the animal experiences severe diarrhea or, more probably, **dysentery**.

Diagnosis

An overwhelming abundance of *Cl. perfringens* is demonstrable in the **feces** from the diseased foal or in the luminal contents and mucosa at post mortem by staining smears by Gram's method or with specific fluorescent antibody.

The beta toxin can also be demonstrated in the gut contents. A piece of small gut (about 5 cm long) with its cut ends tied off to conserve the contents should be **refrigerated or frozen** as it is transported to the diagnostic laboratory. The toxin is labile and digestible by trypsin.

The smears and gut samples should be collected as soon as possible after death. It should be remembered that clostridia reside in the intestinal tract of normal animals and that merely finding *Cl. perfringens* or beta toxin in the gut or fecal material does not of itself constitute a definitive diagnosis of enterotoxemia.

Treatment and control

The course of enterotoxemia in the foal lasts usually no more than a few hours. Oral or parenteral administration of an antibiotic (such as **metronidazole** 15–20 mg/kg PO t.i.d. or q.i.d.) active against Gram-positive bacteria will usually sharply diminish the numbers of *Cl. perfringens* B or C in the gut. However, it will not decrease the prospectively **fatal quantity** of the beta toxin perhaps already absorbed from the gut.

Attempts can be made to **neutralize** the damaging effects of the beta toxin by the speedy and repeated administration of large doses (exact doses depend on formulation) of appropriate **antitoxin** in the form of an antiserum to either *Cl. perfringens* type B or type C.

In other species of domesticated animals, licensed preparations containing approximately 1200 IU of **anti-beta toxin** are said to be therapeutically effective if given in large doses (e.g. 30 mL per 75 kg). This antiserum can also be used prophylactically to provide passive immunity to a foal that is known to be at risk of contracting the disease. The same end can be achieved by vaccinating the mare a few weeks before foaling with vaccine known to contain *Cl. perfringens* type B or C toxoid. However, the low prevalence of *Cl. perfringens* enterotoxemia in the newborn foal does not justify a general vaccination program in mares.

LISTERIOSIS

Listeria monocytogenes (and *L. ivanovii*) are short Gram-positive rods (approximately 1–2 μm long) that can be grown fairly readily in the laboratory. The organism is ubiquitous in the soil and in the gut of mammals and birds. It has been found in diseased individuals of some 60 species of animal, including humans. The agent is classifiable into serotypes and subtypes, of which 1/2a, 1/2b and 4b appear to be the most pathogenic, as they are regularly isolated from diseased material. *L. monocytogenes* persists in animal or vegetable material at a low pH and multiplies at temperatures from 4°C to 39°C.

The pathogenesis of the various forms of listeriosis is poorly understood but climatic conditions, stress and other concurrent disease all play some part in allowing infection with *L. monocytogenes* to become established in the individual. Multiplication of the organism in the body is cell associated. Typically, ingestion of the organism leads to penetration of the alimentary mucosae and then to one of several possible states, including **subclinical** infection with prolonged excretion of the bacteria in the feces, **bacteremia**, accompanied by localization in various tissues, and **fatal septicemia**.

The **gravid uterus** is particularly susceptible. In early pregnancy, infection simply leads to **abortion** whereas in late pregnancy the fetus is **stillborn** or has a **congenital septicemia** and/or other lesions in the major viscera. In **visceral listeriosis** the liver and cardiac muscle in particular contain multiple, small necrotic foci that are readily visible to the naked eye as whitish specks. Otherwise, in the newborn animal, the disease is a typical **septicemia**, and the rate of recovery depends on the speed with which diagnosis is made and treatment applied.

L. monocytogenes is, for the most part, not particularly susceptible in vitro to many of the common antimicrobial agents but penicillin (40 000 IU/kg IM daily for up to 2 wk) is the drug of choice. Early treatment is most important. *L. monocytogenes* is also susceptible to streptomycin and the tetracyclines. The value of vaccination with either killed or attenuated material is inconclusive. As the disease in the horse is sporadic, most likely to manifest itself as a septicemia in the foal, and, as the protection conferred by infection or vaccination is strongly cell mediated, vaccination of the dam does not appear to be an effective or practical control measure.

BACTERIAL DISEASES OF THE OLDER FOAL AND ADULT

INTRODUCTION

Bacterial infections like salmonellosis or actinobacillosis (*q.v.*) may not arise in foals until they are some weeks or even months old. In such instances the pathologic events in the disease and its clinical course differ from those seen in the youngest animals. Septicemia becomes much less common whereas clinical evidence of alimentary or respiratory involvement is much more marked. Some other bacterial infections also become more prominent at this stage in the foal's life. These infections include those with *Rhodococcus equi*, *Clostridium piliformis*, *Clostridium perfringens* type A, and the putative pathogens, *Cl. difficile* and *Bacteroides fragilis* (*q.v.*).

RHODOCOCCUS EQUI

Rhodococcus equi is a common pathogen of **foals**. The organism can localize in many organs; however, the respiratory tract is most commonly involved. A severe pyogranulomatous pneumonia may ensue.

Etiology

The causative organism was initially isolated from foal lungs in 1973. DNA sequencing identified the genus *Rhodococcus* to be an accurate classification for this bacterium. *R. equi* is a facultative, Gram-positive, pleomorphic rod.

Epidemiology

R. equi has a worldwide distribution and equine disease is common in areas with large horse populations. It is a **soil inhabitant**. Reports of increased incidence of *R. equi* in warm, wet years suggest that moisture may be important for bacterial multiplication.

Heavily stocked horse farms may develop large numbers of organisms in pasture soil. Oral ingestion of the bacterium with multiplication in the gastrointestinal tract adds to the concentration of the bacterium in the environment. On farms with a history of *R. equi* problems, the organism is found not only in soil, but also in barn dust, cobwebs and air. Where weather conditions are appropriate (i.e. dry and windy), a situation exists in which overwhelming exposure to **aerosols** can occur.

The mode of transmission of this disease was originally thought to be solely through oral ingestion, with the consequent development of local ulceration, abscessation and subsequent dissemination to other organ systems. Experimental oral inoculation with large numbers of organisms has not reproduced significant respiratory disease whereas experimental exposure by inhalation has reproduced severe pulmonary disease. Therefore, it is likely that **inhalation** is the mode of transmission of the respiratory disease, and that oral ingestion may result in gastrointestinal lesions or dissemination to lymph nodes, joints or both.

Yearly recurrence of the disease is common, with the number of foals affected on a particular farm ranging from a few to more than 50%. The rate of occurrence is likely to be dependent upon environmental factors, gastrointestinal multiplication, dissemination and host resistance factors. A mortality rate of 80% was not uncommon formerly but improvements in the comprehension, recognition and treatment of the disease have greatly decreased the rate of mortality.

R. equi is most common in foals that are from 2 to 4 mo of age, but it can occur in younger and older foals. The age-related occurrence of the disease is probably related to the decreasing maternally derived immunity of the foal and the fact that the majority of foals reach 2–6 mo of age during the warm, dry months of the year when aerosol exposure is likely to occur. Disease in adults is rare, but has been reported in immunosuppressed individuals. Adult resistance to this disease is likely to be related to the development of an adequate immune response.

Pathogenesis

The pathogenesis of the disease is not completely understood. However, the scavenging of large numbers of organisms by alveolar macrophages and the ineffective killing of the bacteria is integral to the pathogenesis of *R. equi*. Although initial hypotheses regarding the pathogenesis of the disease focused on defects of the cellular immunity of the horse, it now appears that humoral factors play an important role.

The presence of antibodies is important for the process of opsonization. Neutrophils in the presence of *R. equi* antibody result in 95–100% bacterial killing. In the absence of antibody, neutrophilic killing is inadequate. This feature would explain the increased incidence of disease during the period of **decreasing maternal antibodies**. Organisms that escape neutrophilic killing may be ingested by macrophages, where bacterial multiplication may occur. An absence of protective antibody or a massive exposure that overwhelms humoral immunity may lead to disease. **Specific immune plasma** has been shown to reduce the severity of the disease in pony foals that were experimentally infected with *R. equi*.

Clinical findings

The most common clinical picture of the disease is of a progressive pneumonia, the development of which may be acute or gradual. A combination of any of the following signs may be present: pyrexia, depression, anorexia, tachypnea, mucopurulent nasal discharge, cough and abnormal thoracic auscultation. Auscultation varies from marked diffuse crackles and wheezes to minimal cranioventral auscultatory changes and is dependent upon severity and progression of the disease. These signs of lower respiratory disease do not differentiate *R. equi* from other causes of pneumonia. Joint effusions may be identified in conjunction with pneumonia. Lameness is usually absent and synovial fluid analysis is compatible with an immune-mediated synovitis (*q.v.*).

The gastrointestinal form of the disease presents as chronic weight loss or as an unthrifty foal. Diarrhea or abnormal feces can be present. Other forms of the disease that have been reported include septic arthritis, abscessation

(integumentary or abdominal), meningitis, osteomyelitis, pleuritis and valvular endocarditis (*q.v.*).

Clinical pathology

Clinicopathologic findings are generally **non-specific**. Evidence of inflammation is represented by a leukocytosis and a variable elevation in fibrinogen. Some practitioners have reported that elevations in white blood cell (WBC) counts may precede clinical signs of the disease and may be used as an aid to early diagnosis on problem farms. An absence of a leukogram indicating inflammatory processes should not, however, preclude diagnosis in clinically ill foals.

Post mortem findings

The characteristic gross post mortem findings of respiratory disease include **bilateral abscessating bronchopneumonia**. Cranioventral, irregular and multifocal involvement is typical. Abscesses range from millimeters to several centimeters in diameter. A generalized multifocal distribution of abscesses is not uncommon. Abscesses may be present in the bronchial and mediastinal lymph nodes. Pleural empyema may occur, but it is not common. Lesions within the gastrointestinal tract can be located in sites ranging from the stomach to the large colon. Villous atrophy, mucosal necrosis, diphtheritic membranes, ulcerative enterocolitis and abscessation in the mesenteric lymph nodes may be identified. The histologic response is primarily pyogranulomatous. A central core of necrotic debris is surrounded by necrotic neutrophils, with the surrounding tissue infiltrated by macrophages.

Diagnosis

The diagnosis of *R. equi* pneumonia is based on the evidence of clinical respiratory disease, history (including age of onset), confirmed diagnosis in other foals on the farm and the presence of the disease previously.

Transtracheal aspirates are critical to the differentiation of *R. equi* from other causes of pneumonia. Cytologic examination can be very useful in the early recognition of the disease, as cultures require a 48 h growth period. The characteristic, Gram-positive pleomorphic rods may be identified in the aspirate. Bacteriologic examination provides a more definitive diagnosis. Such examinations of peritoneal fluid, feces or both can also be beneficial in the detection of the gastrointestinal disease.

Serologic procedures (ELISA) can be useful; however, a positive reaction is not diagnostic, as normal, exposed foals may have antibodies against *R. equi* antigen. Foals with active *R. equi* infection should be serologically positive.

Radiology and ultrasonography may be useful aids to diagnosis. Pulmonary abscessation may be identified. However, the absence of abscess formation does not rule out the disease.

Treatment

The treatment of *R. equi* pneumonia consists of **specific antibiotic therapy**. In vitro sensitivity results often suggest a wide range of antibiotic sensitivity.

However, in vivo success is achieved only with those antibiotics that reach adequate intracellular levels. A **combination of rifampicin** (5 mg/kg PO b.i.d.) **and erythromycin** (20–30 mg/kg PO q.i.d.) has proved to be a very effective treatment of *R. equi* pneumonia. These antibiotics can be administered orally and attain excellent tissue and intracellular levels. A combination of antibiotics is used because a rapid development of resistance to rifampicin when used alone has been reported. Erythromycin can occasionally produce diarrhea and has been associated with hyperthermia in foals kept outdoors.

Trimethoprim–sulfonamide combinations (5 mg/kg of the trimethoprim portion, b.i.d.) have been suggested in combination with rifampicin when problems are encountered with erythromycin. Two newer generation macrolides have been used—azithromycin (10 mg/kg orally s.i.d. for 5 days followed by q 48 h therapy) or clarithromycin (7.5 mg/kg b.i.d. PO).

In addition to antibiotic therapy, **supportive care** can improve the outcome for the foal, particularly one that is critically ill. Air conditioning can provide relief in hot, humid climates. Nasal insufflation of oxygen, bronchodilators and anti-inflammatory drugs can be considered in specific cases.

Control

An approach to the prevention of the disease should include basic management and health programs. A **reduction in stressful conditions** such as overcrowding, excessive handling, and dust exposure, should be attempted. Adequate stall ventilation is imperative. Appropriate **vaccination programs** may reduce viral infections and subsequent secondary bacterial infections. A reduction in dust exposure may be achieved by watering down or changing the composition of the soil by adding gravel to areas around gates, feeders and waterers.

The use of bacterins has not been universally successful. These results may be influenced by bacterin preparation or by the type of adjuvant used. In addition, the immunologic response to a bacterin may not provide the cellular immunity or local immunity needed for adequate protection. Hyperimmune serum has been shown to reduce the severity of the disease in experimental infections. Boosting a foal's humoral immunity may prove to be beneficial for farms with *R. equi* problems; however, immunoprophylaxis and immunotherapy are expensive and clinical efficiency has not been definitely proven.

TYZZER'S DISEASE

Etiology

The cause of Tyzzer's disease, *Bacillus piliformis*, is the only Gram-negative spore bearing, obligate intracellular bacterium known. The properties of *B. piliformis* have been poorly characterized because it cannot be propagated in artificial media. The organism has been cultivated successfully in the chick embryo and in primary monolayers of hepatocytes. Recently this organism has been reclassified to the *Clostridium* species and now is known as *Clostridium piliformis*.

Epidemiology and pathogenesis

Tyzzer's disease is recorded mainly in populations of laboratory or wild rodents, especially mice, which may constitute the essential reservoir of this

agent. Fatal disease from infection with *Cl. piliformis* has, however, also been noted in the young of many other species, including the horse. The mode of transmission is unclear. It may be that adult horses serve as carriers and shed the moderately resistant bacterial spores. Foals may become infected by ingestion of materials contaminated with infected feces.

Clinical and pathologic findings

The disease occurs sporadically and with low prevalence in foals usually 7–40 days of age. The onset is abrupt and the brief course (1–2 days) is characterized by fever, prostration and finally coma, although some cases also exhibit severe diarrhea, which may be hemorrhagic, and jaundice. These signs, which reflect the presence of a **catarrhal colitis**, enlarged liver and hepatitis with a focal necrosis, are accompanied by marked increases in glutamic oxalacetic transaminase (SGOT), glutamic pyruvate transaminase (SGPT) and lactic dehydrogenase (LDH) in the plasma and a profound leukopenia.

Diagnosis

Confirmation of Tyzzer's disease depends on demonstrating the agent in suitably stained preparations (with Giemsa or Warthin–Starry) made from the **liver or intestinal epithelium**. Histologic examination of the hepatocytes or intestinal epithelium near the necrotic lesions typically reveals bundles of beaded rods with subterminal spores.

Treatment and control

Cl. piliformis is sensitive to all the common antimicrobial drugs used in veterinary practice; aminoglycosides (gentamicin 7 mg/kg IV s.i.d. or amikacin 15 mg/kg IV s.i.d.) may be the most useful for therapy. Since the mode of transmission is unclear, developing a strategy for control of the disease is difficult.

INFECTIONS WITH *CLOSTRIDIUM PERFRINGENS* TYPE A, *CI. DIFFICILE* AND *BACTEROIDES FRAGILIS*

Each of these bacteria is encountered in diarrhea in younger and older foals. *Cl. perfringens* A and *Cl. difficile* both produce **exotoxins** which damage the gut wall and produce acute diarrhea in other species. The conclusion that they are associated with a comparable syndrome in the foal rests principally on the evidence that these organisms are present in higher numbers in diarrheic foals than unaffected animals, and that the toxins are demonstrable in the feces or gut contents. A similar argument is advanced for implicating *B. fragilis*.

Overgrowth in the gut of the clostridia in question occurs **spontaneously** or can be promoted by many factors including an imbalanced or abruptly altered diet, administration of drugs (especially antimicrobial substances) or the activity of other infectious agents, including other bacteria, or even helminths or viruses. The need for therapeutic intervention in diarrheic foals depends on **clinical assessment**. Many foals have a largely self-limiting episode of diarrhea at the time of the mare's first heat after parturition.

DERMATOPHILOSIS

Dermatophilosis (**subcutaneous streptothricosis**) is an exudative dermatitis of animals and, very occasionally, humans. It is most prevalent in ruminants and only occurs sporadically in horses. With the possible exception of sheep, animals in the tropics are more often and more severely affected than those in temperate areas. The condition is sometimes referred to as **rain scald**, **mud fever** or **greasy heel**.

Etiology

The disease is produced by the penetration of *Dermatophilus congolensis* into the epidermis. *D. congolensis* belongs to a large, heterogeneous group of bacteria, the actinomycetes, whose main habitat is the soil. However, *D. congolensis* lives only in the **living tissue of the epidermis**. It is a Gram-positive organism that grows as branching filaments, the hyphal cylinders of which condense in two planes at right angles to each other to give rise to coccoid bodies. These coccoid bodies eventually become highly motile zoospores $\leq 1 \mu\text{m}$ in diameter and are the essential means of dissemination of the pathogen. The filamentous mass—the mycelium—readily fragments.

Epidemiology

The only known **reservoirs** of *D. congolensis* are chronically affected animals. The organism may be present in a quiescent state in the epidermis until local climatic conditions, specifically a period of warm, wet weather, promote further multiplication of the mycelium and the formation of the zoospores. To establish infection in new areas of skin in an infected animal, or in a previously uninfected animal, the motile zoospores, responding to carbon dioxide diffusing through the skin, must penetrate the sebaceous layer and enter the epidermis. They germinate in the epidermis, producing a hypha and ultimately a mycelium.

Minor abrasions of the superficial layers of the skin make an animal more susceptible to infection. The disease is more common in **younger animals** because their sebaceous layer is thinner and can be more readily weakened by prolonged wetting. Biting arthropods such as ticks and flies, which are more prevalent and active in warm, humid conditions, play a part in the mechanical transfer of zoospores. The extent to which sweating by horses favors infection does not appear to have been investigated.

Clinical findings and pathogenesis

Foals and young horses are the most susceptible. Any part of the integument may be involved although the back, shoulders and flanks are usually the most affected. Instances in which the pasterns and coronets were the main areas involved have also been described (**mud fever**).

In the early stages after infection, influxes of neutrophils into the affected skin, inflammatory reactions and the resultant serous exudation mat the hairs of the coat together and produce the characteristic, so-called “**old paintbrush**” appearance of the lesions. These lesions, which are scattered over the skin, coalesce with others to produce circular, raised crusts or scabs up to 2 cm

in diameter. They do not itch and most heal spontaneously within a few weeks though a few may persist indefinitely. The factors that govern the curtailment of spread and subsequent healing of the lesions in about 3 wk or less are imperfectly understood.

Diagnosis

The appearance of the lesions in a clinically affected animal is highly suggestive of **streptothricosis**, which requires differentiation only from the lesions of the early stages of ringworm or pyoderma (*q.v.*).

The diagnosis is easily confirmed by observing the unusual morphology of *D. congolensis* in smears of exudate or scabs that have if necessary been moistened, crushed and teased and stained with methylene blue or Giemsa. Preparations stained by fluorescent antibody are useful when the characteristic sporulating structures are scarce, as they are in material from chronic lesions. Isolation of the organism from affected skin is also comparatively simple if attempted from specimens that contain affected epidermis. Growth of *D. congolensis* in the laboratory is rather slow (taking 2–3 days) but the distinctive colonies, which are often surrounded by a zone of hemolysis, are easily recognized.

Treatment and control

The lesions of streptothricosis usually heal spontaneously, and therapy is required only for severe cases. **Procaine benzylpenicillin** (18 000 IU/kg IM b.i.d.) is the drug of choice.

Since cases of cutaneous streptothricosis in the horse are largely sporadic and much dependent on weather conditions, there has been no requirement for protection by immunologic means. In any case, variability among the antigens of the flagella of the zoospores of *D. congolensis* makes the prospects for a universally applicable vaccine unlikely.

SALMONELLOSIS

Etiology

As in the younger foals, an extensive variety of *Salmonella* spp. (serotypes) can be encountered in the adult horse (including *S. heidelberg*, *S. eimsbuttel*, *S. ohio*, *S. senftenberg*, and *S. enteritidis*) but *S. typhimurium* is still the **most common** salmonella recovered from the horse.

S. abortus equi is a very host-specific organism that historically caused abortion in mares, but which is no longer isolated in either North America or Western Europe, although it is still encountered in horses in Eastern Europe.

Epidemiology and pathogenesis

A horse may be exposed to salmonellae from its ingesta, its surroundings, or from other animals. If the organism succeeds in establishing itself, it may do so sufficiently to create a carrier state or colonize so effectively that enteric and even systemic disease results.

In most cases the infection is confined to the intestine but bacteremia is a feature of the more severe infections. Acute, severe disease can be precipitated

in **latently infected** animals by early weaning, by transportation or hospitalization, overworking or other stresses. On abatement of the stress, excretion of salmonellae normally ceases but resumes if the animal is subjected to further stress. Between 10% and 50% of horses in some populations may be **carriers** of salmonellae. Outbreaks of salmonellosis in transported or hospitalized horses constitute a major problem.

Colonization of the terminal small intestine, the cecum and the colon by salmonellae is greatly favored if peristalsis is poor and if the normal flora (including fusobacteria, *Bacteroides* spp. and lactobacilli) fails to produce acids that inhibit the attachment of the salmonellae to the enterocytes. After attachment, salmonellae enter the epithelial cells, multiply and pass to other cells in the lamina propria. Inflammation and cell damage induce release of prostaglandins, which activate adenyl cyclase, leading to the secretion of excessive volumes of ion-rich fluid into the gut. Continued multiplication of the salmonellae in the mucosa produces a **necrotic enteritis** and diarrhea.

During the course of infection salmonellae multiply in macrophages and enter the lymphatics, lymph nodes, reticuloendothelial system and blood. **Septicemia** ensues in cases of severe infection or where resistance is lacking. If this process is not **rapidly fatal** the agent may localize in other tissues including the lungs and synovia. Infection of the gravid uterus leads to death of the fetus and abortion.

Clinical and pathologic findings

Salmonellosis is a good example of the need to distinguish clearly between infection and disease. Infection with salmonellae can result in a **necrotizing colitis** with bacteremia or in a **carrier state** that can persist for years without overt disease.

Mild attacks of disease in the horse last no more than a few days and are characterized by depression, unwillingness to eat and the passage of soft feces. The acute form is marked by fever, depression, anorexia and severe enteritis, with the passage of fluid and **foul-smelling feces containing casts**. A pregnant mare often aborts. Acute cases die if inadequately treated. Usually, the duration of the clinical disease is approximately 3 wk and, if the horse survives, it may remain a carrier or experience intractable diarrhea for several months. When the diarrhea subsides the horse commonly remains a carrier.

Acidosis, electrolyte imbalance and protein loss from the gut, along with a profound neutropenia, are the prominent clinicopathologic findings. At death the large gut is severely and extensively necrotic and has pseudomembranes. The lumen may contain casts.

Diagnosis

The clinical signs are distinctive but not diagnostic. Bacteriologic confirmation, involving isolation of the salmonellae, **sensitivity testing plus phage typing** of the serotype involved, is necessary not only for clinical but also for epidemiologic reasons as already noted. In the laboratory, culture of a specimen of fecal material is always more likely to lead to the isolation of the organism than the examination of mere rectal swabs. This is true of clinical cases and suspected carriers.

Treatment and control

Clinical cases should be kept in **strict isolation**. The facilities need to be thoroughly disinfected and extreme care must be taken to prevent cross infection of other animals and man. Effective disinfectants include cresols, phenols, sodium hypochlorite and quaternary ammonium.

The prognosis for horses with the acute disease is not good. Supportive treatment, including the parental administration of fluid and electrolytes (*q.v.*), is essential. **Antimicrobial therapy** is complicated by differing resistance patterns, and sensitivity testing of all isolates is **essential**. Currently most *Salmonella* spp. are sensitive to amikacin, ceftriaxone, ciprofloxacin, imipenem, and trimethoprim-sulfamethoxazole.

The efficacy of antimicrobial therapy is, however, controversial as **disturbances of the normal flora** in the gastrointestinal tract may enhance the ability of salmonellae to grow and prolong the course of diarrhea. Many clinicians believe that antimicrobial therapy is of little benefit to horses with diarrhea but may be useful in preventing or counteracting bacteremia.

Attempts should be made to identify the source of the agent, especially if a group of horses is affected. **Detecting the carrier state** in the horse is difficult since many animals affected in this way shed the organism quite erratically and in very low numbers. The bacteriologic examinations may need to be repeated at intervals. Routinely, swabs or fecal material collected from the rectum are incubated in selenite enrichment broth prior to streaking on selected agar. Once isolated, the serotype of an isolate is identified in the laboratory by its biochemical and antigenic properties. Isolates are commonly submitted to specialized laboratories for corroborative identification by antigenic analysis and phage typing.

CLOSTRIDIOSIS

Epidemiology and pathogenesis

Clostridium perfringens is ubiquitously distributed in its vegetative form or as spores in soil and is part of the normal intestinal flora of animals. However, *Cl. perfringens* type A seems best adapted to survive in the soil and forms a very minor part of the normal clostridial flora of the gut of the horse. Nevertheless, in some circumstances, many still unclear, these bacteria can flourish in the equine intestine to form a **major proportion** of the bacterial flora. In that instance, through an abundant production of alpha toxin (and probably other aggressins or toxins), type A can cause acute disease.

As well as severely damaging the **mucosae of the cecum and colon** in horses of all ages, the alpha toxin (a phospholipase C) hydrolyses lecithin in mitochondria and cellular membranes including those of endothelial cells and erythrocytes. **Toxemia** results from absorption of the toxin from the intestinal lumen.

Cl. difficile (*q.v.*) also inhabits the intestinal tract of normal horses and can lead to **enterocolitis** (*q.v.*).

Clinical and pathologic findings

In adults there is an abrupt onset of fever with the production of a profuse, watery and foul-smelling diarrhea or dysentery, severe depression and

dehydration, pallor, jaundice and even hemoglobinuria. The course is rapid and death usually occurs within 48 h of the development of clinical signs. At necropsy there is hemorrhagic typhlitis and colitis. The kidneys are dark, swollen and may have infarcts. The liver is swollen and friable and the lungs are hyperemic, edematous and hemorrhagic. The myocardium contains areas of degenerated muscle that are detectable histologically.

Diagnosis

The involvement of *Cl. perfringens* type A can be confirmed by demonstrating the presence of the **toxin** in abundance in the **fecal excreta** or **gut contents**. As *Cl. perfringens* type A is not commonly isolated from the feces in normal horses, high counts ($\geq 10^4$ /g of fecal material) suggest its predominance in the flora of the small and large intestines and therefore its association with disease. The bacteria can be observed microscopically in suitably stained smears of the fecal excreta or of the luminal contents at post mortem.

Treatment and control

Oral administration of an antibiotic (apart from the aminoglycosides, which do not affect the clostridia) might reduce the number of type A in the gut but therapy requires the administration of **antisera** prepared against *Cl. perfringens* type A, B, C, D or E, all of which produce the alpha toxin. Large volumes of antiserum (approximately 250 mL per dose) are needed, **diluted with a balanced salt solution** and given by slow IV injection to avoid shock.

Because of the **myocardial damage** caused by the alpha toxin, rest for at least a month after recovery is advised. The disease is sporadic and does not seem to warrant prophylactic vaccination with the appropriate toxoid.

CLOSTRIDIAL NECROTIZING CELLULITIS/MYOSITIS

The descriptive but pathologically antiquated terms **wound gas gangrene** and **malignant edema** are still in general use and refer to the activity of clostridia which, given the opportunity, will penetrate and multiply in tissues and produce toxin(s) that exacerbate the spread of the organism. Since this clostridial invasion gives rise to peracute or acute toxemia and/or septicemia, the survival of the affected animal is usually threatened.

Etiology

The clostridia chiefly responsible for necrotizing cellulitis/myositis in the horse are *Cl. perfringens*, *Cl. novyi* and *Cl. septicum*. These clostridia gain access to the subcutis or skeletal musculature or both, anaerobic conditions arise and toxin is produced. The toxin kills incoming neutrophils and so prevents phagocytosis of the rapidly multiplying bacteria.

Epidemiology and pathogenesis

In the horse, **cellulitis/myositis** (*q.v.*) is usually associated with lacerations, abrasions or surgical or inoculation procedures. Instances have been recorded, however, where there is at least circumstantial evidence to suspect the activation

of dormant spores at or near the site where the lesion forms. This phenomenon suggests that the pathogenesis of some equine cases resembles that of blackleg in cattle.

Clinical findings

The extent of the inflammatory damage at the site can become astonishingly extensive within a few hours. Tissue necrosis and vascular damage give rise to a **rapidly enlarging** and at first painful swelling with a **doughy feel**. Within 12–48 h of the start of the infectious process the lesion spreads and is infiltrated with a bloody gelatinous exudate or even gas.

Infections that occur at castration spread along the abdomen and the medial aspect of the hindlimbs. Infection acquired at parturition may also extend to the hindlimbs. Infection of the neck, for example after IM injection, may result in horses being unable to lift their heads and dependent edema of the head. Pyrexia, increased pulse rate, congestion of the mucous membranes, tachypnea, depression and other signs of toxemia and severe bacteremia/septicemia appear. The toxemia, if unchecked, is **lethal**.

Diagnosis

In clostridial cellulitis/myositis, large Gram-positive rods (3–10 μm long by 0.5–1 μm wide) lying singly, in pairs or in short chains among amorphous Gram-negative material from necrotized cells and exudate can be seen in smears of tissue deep within the lesion. No living neutrophils are seen in such aspirates. Immunofluorescent staining of the aspirates with specific antibody will help to determine the causal species.

Because of the propensity of clostridia to invade the carcass from the gut soon after death in any animal, no definitive diagnosis can be based solely on the isolation of the organism post mortem.

Treatment

As soon as the condition is suspected **massive antibiotic and supportive therapy** is needed to save the animal. Clostridia are almost always susceptible to **penicillins** (procaine benzylpenicillin 25 000–30 000 IU/kg IM q 8 h and crystalline benzylpenicillin 25 000–30 000 IU/kg IV q 4 h). Other antimicrobial drugs commonly available to the veterinarian are also efficacious, although as already noted, *Cl. perfringens*, the most common clostridium of wound gas gangrene in the horse, is inherently resistant to the aminoglycosides.

In severe cases, administration of fluids and analgesics is indicated. The identification of the clostridial species involved in producing the lesion is important as it allows for valuable additional therapeutic support to be given to the animal in the form of **specific antitoxin**. Horses infected with *Cl. perfringens* have a higher survival rate than those infected with *Cl. septicum*.

BOTULISM

Etiology

Botulism, a **non-contagious** disease of mammals and birds, is a **flaccid paralysis** of voluntary muscle produced by toxins of *Clostridium botulinum*. All six or

seven types of *Cl. botulinum* are relatively large (approximately $5\text{ }\mu\text{m} \times 0.6\text{ }\mu\text{m}$), motile Gram-positive rods. Like other clostridia, *Cl. botulinum* only grows in anaerobic conditions. The vegetative form of the organism is not notably resistant to chemical or physical agencies but the spore is reliably destroyed only by exposure to steam under pressure for at least 20 min.

Epidemiology and pathogenesis

The **neurotoxins** produced by the different types of *Cl. botulinum* are antigenically distinguishable but their action is the same regardless of source. The types also vary in their ecologic distribution. Types A, B, E and F are essentially dwellers in soils and alkaline muds and the vegetation associated with such places. By contrast, types C and D parasitize the gut of mammals and birds and are only coincidental inhabitants of soils, waters or decaying vegetation. **Types A and B** are involved in equine botulism.

All types of *Cl. botulinum* release toxin when their vegetative cells lyse. In at least some types, production of the toxin, a protein approximately 150 kDa in weight, depends on the presence of the DNA of a bacteriophage within the vegetative cell. The protein forms a complex with another large hemagglutinating molecule of bacterial origin, which may protect the neurotoxin from degradation by proteolytic enzymes in the gut. However, in some types, only exposure to proteolysis in the gut allows the fully active toxic principle to be formed. The toxin is **remarkably poisonous**; it provides some $10^{8.3}$ mouse LD₅₀ per mg N₂. Although the vegetative cell of *Cl. botulinum* must have anaerobic conditions in which to multiply, anaerobic conditions are not necessary for the production of the toxin. It is produced at temperatures as low as 30°C.

Vegetative *Cl. botulinum* and its spores are much more widespread than botulism.

In most instances, botulism follows ingestion of **food contaminated** by toxin. Decomposing carcasses or meat products classically constitute the chief sources of the toxin, but the organism can grow in decaying vegetable matter or in silage or hay that has become spoiled at a stage that will allow *Cl. botulinum* to flourish. Vegetable products in bulk can also be vehicles for the toxin if they contain decomposing rodents. The feeding of brewers' grains contaminated by the toxin has produced the disease.

Although botulism in horses is also known as "**forage poisoning**", *Cl. botulinum*, like other clostridia, can in certain circumstances replicate and produce toxin either in the gut or in suitably anaerobic areas of necrosis in the living animal.

Toxicoinfectious botulism is known to occur in the horse as well as in humans. An association with grass sickness (*q.v.*) has been proposed but never confirmed.

On ingestion, the toxin is exposed to proteolytic enzymes in the gut but it is much less affected by these enzymes than is tetanospasmin, the principal toxin of *Cl. tetani*. It is also partially protected by the hemagglutinin. Because of its potency, only a small quantity of the toxin needs to survive for **lethal amounts** to be absorbed across the alimentary mucosae into the circulation. The toxin is distributed by that route to all parts of the body except the CNS; it cannot pass the blood-brain barrier. The toxin binds to gangliosides at the neuromuscular

junctions of the skeletal muscles. There it prevents the release of acetylcholine in cholinergic nerves, thus preventing transmission of impulses to the muscles. Consequently, affected voluntary muscles remain in a state of continuous, **flaccid paralysis**. The absorbed toxin **continues spreading** in the blood and the animal dies when the muscles required for respiration can no longer contract.

Clinical and pathologic findings

Botulism is a non-contagious disease that occurs sporadically and usually affects **individual** animals. However, large groups of animals are sometimes affected when they are all concurrently exposed to contaminated feed or other similar vehicles of the toxin.

The incubation period (3–17 days) depends on the quantity of toxin in the foodstuff and how much of it is absorbed from the gut. A large dose produces death in 2–3 days, with often no premonitory signs apart from reluctance or failure to eat or drink. In its less peracute form, the disease is characterized at first by tremors and vague weakness, then by the flaccid motor paralysis that involves first the hindlimbs, then the forelimbs, and latterly the head and neck. The affected animal has no fever and is **fully conscious** until it dies 1–4 days after the first appearance of the clinical signs.

When the effective amount of toxin acquired is small the disease can be much milder in nature and its course is more protracted. The animal spends most of its time lying down and eats and drinks with difficulty. Respiration is labored but these cases have much the best prognosis. Mildly affected animals can recover spontaneously after 3–4 wk if tended carefully to prevent respiratory failure and by taking steps to counter the adverse effects of inanition and recumbency.

The **shaker foal syndrome**, which occurs in the USA and the UK in animals 2–8 wk old, is probably a form of **toxicoinfectious botulism**. Experimentally, the administration of *Cl. botulinum* type B toxin produces a similar syndrome in foals.

The condition arises infrequently; even on premises known to be prone to annual recurrence it affects only one or two foals each year. Foals in good condition appear to be most prone to the disease. The onset of marked muscular trembling and weakness of the affected animal is abrupt and eventually the fallen shaker foal can no longer rise unaided, although it is conscious, afebrile and responsive to stimuli. Death from respiratory failure occurs approximately 3 days after the onset of clinical signs. Acidosis has been reported as a feature of the disease and enlargement and mottling of the liver may be evident at post mortem. *Cl. botulinum* may be recovered from gastric ulcers and umbilical and pulmonary abscesses.

Spontaneous toxicoinfectious botulism in adult animals is believed to arise also as a consequence of multiplication of *Cl. botulinum* in **necrotic lesions** or **wounds** in the body. Unlike the case in infants, multiplication of *Cl. botulinum* in the gut of the horse alone does not lead to the toxicoinfectious form of the disease.

Diagnosis

The damage produced by the neurotoxin is a simple biochemical malfunction and there are **no characteristic lesions** at post mortem. Botulism is easier

to suspect and diagnose clinically than bacteriologically, especially when a group of animals are affected. Verification of the true cause in a case of botulism is difficult. It can only be made categorically by demonstrating the toxin in the circulation of the affected animal or, failing that, in the food the animal ate or in the contents of its gut. Mice are susceptible to the toxin and its clinical effect in them can be abolished with the appropriate antitoxin. However, since the mouse is less susceptible to the effect of the toxin than the horse, this biological test can give false negative results. The presence of toxin can also be demonstrated in suitably arranged **immunosorbent assays** in a specialist laboratory. Their sensitivity in the case of the horse is unknown.

The presence of the vegetative forms or the spores of *Cl. botulinum* in a foodstuff or in any part of the carcass of even a suspected case is not by itself adequate evidence of botulism. In an animal that has died from other causes, *Cl. botulinum*, like other clostridia, can rapidly invade the rest of the body from the gut.

Treatment and control

Where *Cl. botulinum* types A and B are predominant as the cause of equine botulism, the disease is sporadic and unpredictable. Routine mass vaccination against this intoxication is not warranted. If the condition is suspected in one of a group of animals, the other members should be **vaccinated** immediately by administering the appropriate **toxoids**.

Clinically affected horses can be slung, purged, fed by stomach tube and given antitoxin. These procedures are more likely to be effective in the milder case. The therapeutic effectiveness of administering **antitoxin** is directly related to the ratio of free to bound toxin in the body. Antitoxin cannot reverse the effects of toxin that has already bound to motor endplates. The prognosis for severe cases is poor.

TETANUS

Etiology

Clostridium tetani is a Gram-positive rod (approximately 2–5 µm long and 0.5 µm wide) and is typical of the toxigenic, sporulating bacteria that comprise this genus of anaerobes. When sporulating, the vegetative organism develops a spherical spore at one end of the cell, giving rise to the characteristic morphologic appearance of “**drumsticks**” in smears. The spores are very resistant to chemicals; even acidified phenol takes 2 h or more to kill them under the most favorable circumstances. Oxidizing disinfectants, such as solutions of iodine, are faster and more reliable but steam under high pressure is the surest method of destroying spores.

Epidemiology and pathogenesis

Cl. tetani is often abundant in **equine feces** but it occurs in the gut of other herbivores and in the soil. The numbers in soils vary greatly, but the organism is especially abundant in warm areas with **rich, well-cultivated soils**.

Tetanus occurs sporadically throughout the world, the prevalence in unprotected populations correlating with the numbers of spores in the soil.

Mammals in general are susceptible to tetanus but, for reasons yet to be determined, the horse is the most susceptible animal and hence at greatest risk of developing the disease. **Humans are also highly susceptible.**

Cl. tetani cannot multiply in any normal tissue, or even in damaged tissue provided an oxidation-reduction potential equal to that of normal blood remains extant. In **damaged tissue**, where necrosis and lowered oxygen tension combine to create a sufficiently anaerobic state, the organism multiplies and toxin is released. So although deep, penetrating and heavily contaminated wounds produce the most favorable circumstances for the organism to flourish, tetanus can develop after even **minimal superficial damage** provided an anaerobic state develops in the infected area. In addition, one component of tetanus toxin—the hemolysin—is itself a necrotizing substance which contributes to the development of the conditions necessary for the replication of the agent and release of the neurotoxin, **tetanospasmin**, the major component of the toxin. The interaction between tetanospasmin and nervous tissue and the way it is distributed in nerves is responsible for the development of the clinical signs of tetanus.

In *Cl. tetani* the gene coding for tetanospasmin is part of a plasmid residing in the cytoplasm of the vegetative cell. The gene product is a polypeptide, which is resistant to heat but readily cleaved by some proteases, including those in gastric juices. Since the peptide is also poorly absorbed from the alimentary tract, ingesting tetanus toxin is harmless, a feature not shared with the toxins from *Cl. botulinum*. To produce tetanus, tetanospasmin must adsorb to the gangliosides that are present in nervous tissue. Once this has occurred, the binding is virtually **irreversible**, which explains why tetanus antitoxin is much more effective prophylactically than therapeutically, even when given in large doses.

When tetanospasmin is released by the organism multiplying in a wound, it enters the local motor and sensory nerves. If the production of toxin is abundant, free toxin also enters the capillary vessels and lymphatic channels. The organism itself does not spread from the site of injury. Tetanospasmin can reach the CNS via the nerves or through the blood. These two possible routes of distribution of the toxin in vivo give rise respectively to: (1) **ascending tetanus**, in which the movement of the toxin is along the motor nerve trunks to the cord, and (2) **descending tetanus**, in which toxin distributed by the vascular system affects the voluntary muscles of the head and subsequently those of the trunk, forelimbs and then hindlimbs. The skeletal muscles of the side of the body with the wound are affected before those of the opposite side.

The action of tetanospasmin in nervous tissue is multiple but its principal activity is to inhibit the release of the neurotransmitters. This feature among other things permits all muscle groups to contract simultaneously when stimulated, in contrast to the normal state where contraction of one muscle is accompanied by relaxation or inertia in its counterpart.

Clinical and pathologic findings

The incubation period in tetanus is very variable. It generally ranges from 1 to 3 wk after the time of the injury, although some cases have been attributed to

wounding that occurred months previously. Usually, the longer the incubation period the more favorable is the prognosis. There is no incontrovertible evidence in the horse that tetanus can occur following activation of latent spores in tissue, as is the case in some other clostridial diseases in domesticated animals.

The clinical signs of tetanus are similar in all susceptible species. The horse usually suffers from **descending tetanus**, which is marked by an inability to retract the **nictitating membranes** and continual spasms in the facial muscles, producing in the affected animal an appearance resembling the lockjaw and the risus sardonicus seen in tetanus in humans. Premonitory signs include continuously pricked ears, stiffness, trembling and increasing difficulty in eating, chewing, and making other natural movements.

As the disease develops **all** muscular responses become exaggerated. Hyperesthesia increases so that the slightest sensory stimulus provokes violent contractions of the skeletal muscles. The limbs are rigid; the forelimbs stick out forward and the hindlimbs back. Sweating is profuse, the heart rate increases and the repeated, uncontrollable spasms interfere with breathing. The body temperature rises in the later stages of the disease when the horse experiences spontaneous convulsions. Eventually the muscular contractions are **violent and continuous** and can be provoked by the most minor external stimulus.

Once the first signs appear, the course is short and these distressing events last no more than about a week before death supervenes. The mortality rate is approximately 80%. Since the disease is produced entirely by biochemical changes in the neurologic control of skeletal muscle, there are no macroscopic or microscopic lesions detectable post mortem in the fatal case apart from the wound. The wound is not always discernible in the carcass.

Diagnosis

The clinical disease is remarkably distinctive. Only eclampsia in the mare (*q.v.*) and laminitis (*q.v.*), in which there is **no prolapse of the nictitating membrane**, are likely to be confused with tetanus. The assistance of the bacteriology laboratory is only required if an attempt is made to culture the organism from deep within the wound, given that it can be discovered, or it is known that surgical interference has recently taken place. The organism can be easily grown and identified in the laboratory. However, the isolation of *Cl. tetani* should be interpreted in relation to the clinical signs. The mere presence of the organism is not irrefutable proof of tetanus.

Treatment and control

Despite the virtually irreversible effect of the toxin on nervous tissue, antitoxin (20 000–50 000 IU, SC or IM s.i.d. or as needed) may parenterally prevent more nervous tissue being drawn into the pathologic process and neutralize all the toxin in the vascular system. Any good effect obtainable from antitoxin is likely to be limited to the earlier stages of the disease. The precipitating wound, if found, should be drained and infused with penicillin. **Penicillin** should also be given repeatedly in large doses (22 000 IU/kg IV q.i.d. or IM b.i.d.) to kill the organism and prevent yet more toxin being released.

The risk of tetanus is so great after wounding or surgery that **immunoprophylaxis** against the disease is essential in horses. Boosting dams with tetanus toxoid approximately 6 wk before parturition enhances the immunity acquired by foals in the colostrum. Foals can also be protected passively by giving antitoxin (approximately 3000 IU) parenterally which protects for approximately 2 wk and can be repeated until the foal is competent enough immunologically to respond actively to tetanus toxoid, as it is when 2–3 mo old.

Tetanus toxoid with adjuvant is a highly potent antigen which induces a durable, active immunity even if given simultaneously with antitoxin, provided separate sites are used for the respective injections. Despite the marked immunogenicity of tetanus toxoid, two doses approximately 4–6 wk apart are needed to produce adequate active immunity against the tetanospasmin. Solid immunity is usually established approximately 2–4 wk after the course is completed.

The immunity created by a course of toxoid also needs to be reinforced at **regular intervals**, these being determined principally by the degree of risk and the immunologic responsiveness of the individual horse. One year after the primary course a boosting dose of toxoid should be given and followed by further doses every 18–36 mo, the timing being dependent on the perceived risk. If required, the laboratory can determine the amount of antibody in the circulation. The minimum level of antitoxin in the circulation deemed to be protective is approximately 0.02 IU/mL.

Despite a satisfactory history of regular immunoprophylaxis in a horse, it is still sensible to administer antitoxin and/or toxoid (according to the known history of the animal) before surgery is attempted or after the occurrence of actual or suspected wounding.

ANTHRAX

The horse, like humans and the pig, is less susceptible to anthrax than ruminants. Nevertheless, when a horse is infected with *Bacillus anthracis* the course of the disease is acute and death usually occurs within days.

Etiology

B. anthracis is a large, non-motile, Gram-positive rod (approximately 4–8 μm long by 1 μm wide). It is a strict aerobe that grows well between 12°C and 44°C and freely produces its highly resistant spores between 15°C and 40°C. The square-ended vegetative cell is surrounded by a large capsule composed of a polyglutamic acid, which is induced by a plasmid. The capsule is always formed in vivo by virulent strains but only in special circumstances in vitro.

Vegetative cells sporulate in the presence of air. The production of spores in the diseased animal is inhibited by buffering and carbon dioxide. Unlike the vegetative forms, the spores are resistant to most disinfectants unless they are applied for lengthy periods at comparatively high temperatures. Peracetic acid is a useful sporicide but the spores are only readily killed by steam under high pressure.

The organism is readily cultivated in the laboratory and produces a highly distinctive growth. Each large, rough colony is non-hemolytic, looks like a piece of frosted glass and, because the bacilli grow in long whorls at the periphery, it has been likened to the **Medusa's head**.

Epidemiology and pathogenesis

The persistence of *B. anthracis* as a threat to animal health depends on a combination of environmental factors. There are well-recognized **enzootic zones** in the world (e.g. parts of the Indian subcontinent, Africa, North and South America) in which circumstances regularly favor the organism. In these areas, the existence of alkaline and calcareous soils with suitable amounts of nitrogen and a combination of a warm temperature (frequently $\geq 15^{\circ}\text{C}$) with periodic wetness promotes abundant multiplication of the vegetative bacilli. Decreases in the humidity and temperature in these enzootic areas promote sporulation and the extensive contamination of the soil and vegetation is further augmented by spores from the carcasses of animals dying from the disease. The spores can survive in soil for more than **60 years**. Repeated, if unpredictable, epidemics of disease occur in these zones unless control measures are implemented.

Outside these zones anthrax is a much more **sporadic** disease, the occurrence of which depends either on exposure to the accidental introduction of spores on vegetable foodstuffs or animal products or to the disturbance of soil contaminated in the past by buried anthrax carcasses. These circumstances prevail in the UK and more generally in Western Europe.

Sometimes in the subtropics or tropics **biting flies** inoculate *B. anthracis* into the skin, but in general anthrax is contracted by **ingesting or inhaling the spores**. When ingested, the spores lodge in the pharyngeal or enteric mucosae, germinate and encapsulate. The capsule prevents phagocytosis and destruction of the cell. The vegetative cells begin to produce toxin. The complete toxin is a complex of substances, which are encoded by a plasmid. One component (Factor I) of the toxin is an adenyl cyclase, which provokes **massive edema** at the site of invasion. This event favors further multiplication and dissemination of the vegetative cells into the lymphatic system. Factor II is a substance for promoting the binding of Factors I and III (a lethal substance) to mammalian cells.

Bacteremia and septicemia occur when the lymphoid tissues can no longer contain the agent. Death usually follows within a few hours. The circulating toxin also produces general impairment of phagocytosis, capillary permeability, irreversible damage to the clotting mechanism, and shock with renal failure. It is important to appreciate that in acute anthrax the production of lethal amounts of the toxin **precedes** septicemia by several hours.

Clinical and pathologic findings

The onset of the disease in the horse is sudden and the course brief with few prodromal indications. Marked, **subcutaneous swellings** develop in the more dependent parts of the neck, thorax, abdomen and genitalia. Fever and extreme depression accompany severe colic and dysentery. Death follows these signs in a day or two. Rigor mortis is incomplete and unclotted, **tarry blood** oozes from the orifices of the body. The pathologic picture is one of hemorrhagic

edema and vascular damage throughout the body. There is hemorrhagic necrosis and gross swelling of all the lymphoid organs.

Diagnosis

In many countries anthrax is a **notifiable disease**, and even a suspicion of its possible occurrence must be reported to the appropriate authorities. Diagnosis in a freshly dead animal is made in the first instance by **microscopic examination of blood smears**.

The blood should be collected from a **small superficial vein** (such as the cephalic) that is likely to ooze little when opened. Swabs of this blood are also normally required. Any leakage from the vessel should be staunched with swabs soaked in strong disinfectant or the vessel should be cauterized. The smears should be reasonably thick and lightly fixed before staining with polychromatic methylene blue (or Giemsa). The slides should be handled with **caution** because spores are likely to be present. The presence of blue, square-ended bacilli surrounded by large pink capsules, which frequently have frilly edges, is conclusive. These bacilli are often in short chains. *B. anthracis* can readily be isolated from the swabs either directly or by scarifying the skin of a laboratory animal such as the guinea pig with the swab.

Treatment and control

B. anthracis is very sensitive to a wide range of antibiotics, including penicillin and the tetracyclines. Penicillin is curative if administered in **massive doses** (40 000–80 000 IU/kg IV q.i.d.) to an animal in the early stages of the disease, before the toxin has produced irreversible damage. They also prevent the development of the disease in other animals within a group deemed to be at risk from exposure to a common source of infection.

In areas where the disease is known to constitute a more or less continuous threat, **annual vaccination** of all grazers is necessary. The **Sterne vaccine** contains viable spores, which produce living cells of *B. anthracis* that lack the genes that encode the capsular material. They cannot therefore encapsulate when they germinate in vivo. Such cells survive only briefly when the spores are inoculated into animals but they live long enough to elaborate toxin. Both Factors II and III are immunogenic and stimulate antibody production. Antibody to the receptor-binding molecule (Factor II) prevents Factors I and III from acting on cells.

If there is even the slightest reason on clinical grounds to suspect anthrax, **great circumspection** is required in handling the case to minimize the risk to all the people and any other animals directly or indirectly associated with it. The carcass should not be the subject of a post mortem examination for this procedure favors a massive release of spores into the environment. Control measures vary in detail from country to country but always include prompt and effective disposal of infectious carcasses, disinfection of buildings, bedding and equipment, and quarantining of contacts, with additional controls on their produce.

STREPTOCOCCAL INFECTIONS

Etiology

Streptococci are probably the most frequently isolated bacterial pathogens of Equidae. The species and subspecies usually encountered are *S. equi* subspecies

equi, *S. equi* subspecies *zooepidemicus* and *S. dysgalactiae* subspecies *equisimilis*. These organisms belong to Lancefield group C, are beta-hemolytic and are readily distinguished by their fermentation behavior in lactose, sorbitol and trehalose as well as by the reactivities of their **M-like proteins** with specific antisera.

S. equi is the most host adapted and causes **strangles** (*q.v.*), a suppurative lymphadenitis of the head and neck of horses of all ages. It is also the most highly conserved with almost no variations in M (SeM) and other proteins. In contrast, strains of *S. zooepidemicus* have highly variable M-like (SzP) proteins and other characteristics, are not host adapted, and are identified from a variety of opportunist infections. *S. equisimilis* is the least commonly isolated equine group C streptococcus and is occasionally isolated from uterine or placental samples and from abscessed lymph nodes and arthritic joints. Equine strains show antigenic variation.

Alpha-hemolytic streptococci have been isolated from aborted fetuses and from lesions of funisitis and placentitis. *S. pneumoniae* capsule type III has been isolated from the airways of young horses in training.

Epidemiology

The highly host-adapted *S. equi* is maintained only in horse populations in which clinical disease is occurring. However, it survives in water for about 30 days and for extended periods in moist discharges. Nevertheless, persisting contamination of the environment is not an important source of the organism in outbreaks or in interepizootic maintenance. **Prolonged carrier states** associated with guttural pouch empyema (*q.v.*) are found in some herds, although the organism commonly disappears from horses in geographic regions for long periods of time only to reappear when an infected horse is introduced. Horses of all ages are affected but the disease is most common and most severe in **young horses**. Pre-existing immunity may ameliorate expression of the disease. *S. equi* is transmitted when discharges from the nose or abscesses contaminate feed or water or when affected foals suckle the mammary gland. Direct nose to nose contact may also result in transmission and contributes to the **highly contagious** character of strangles.

In large groups of horses on breeding farms the most severely affected age groups are foals, weanlings and yearlings. Morbidity in this age group may be up to 100% with a mortality of 1–5%. Older animals show a lower morbidity and mortality.

S. zooepidemicus occurs widely as a mucosal commensal of the nasopharynx and **external genitalia** of the horse and other host animals. An **opportunist pathogen**, it invades mucosal and epithelial surfaces damaged by virus infection or injury. It is the most commonly encountered pyogen in the horse and is isolated frequently from infected wounds and injection sites of older horses and from the **umbilicus** of foals in the first days of life. *S. zooepidemicus* is present in approximately 50% of cases of **cervicitis** and **endometritis** (*q.v.*) in the mare, in which it rapidly replaces *E. coli* that enters the reproductive tract devitalized by dystocia. Pneumovagina, retained placenta (*q.v.*) or an endocrine abnormality such as anestrus associated with pseudopregnancy (*q.v.*) are other abnormalities that predispose to invasion by *S. zooepidemicus*.

Although showing >97% DNA homology with the highly uniform (clonal) *S. equi*, *S. zooepidemicus* shows great variation in its SzP protein and in its colony morphology. In epizootics of nasal catarrh in young horses, isolates of the organism usually produce mucoid colonies with similar SzP proteins, suggesting that more virulent clones have been selected and become widespread.

Pathogenesis and clinical findings

S. equi enters the horse via the **nose and mouth** and attaches to cells in the crypt of the lingual and palatine tonsils. In a few hours it penetrates and is carried to one or more of the lymph nodes that drain the pharyngeal/tonsillar region. Multiplication occurs extracellularly in the lymph node resulting in the formation of long chains of the organism. Large numbers of neutrophils are drawn to the site by complement-derived chemotactic factors. Failure of phagocytosis and killing of the streptococcus appears to be due to a combination of the hyaluronic capsule, antiphagocytic SeM, and Se18.9 proteins.

The incubation period varies from 3 to 14 days after exposure, and clinical signs include sudden onset of fever (39.5–40°C) caused by the pyrogenic exotoxin SePE-I, loss of appetite, halitosis, difficulty in swallowing, intermittent cough, extension of the head and neck, swelling in the submandibular and/or supralaryngeal areas, nasal discharge and inflammation of the lymphoid nodules of the soft palate and tonsillar areas. During the following 3–7 days the swelling in the intermandibular or supratharyngeal areas may increase because of lymphostasis and enlargement of the affected lymph node(s).

The occlusive effect of the **lymph node enlargement** is the source of the disease description “**strangles**”, which in severe cases may result in suffocation unless emergency tracheotomy is performed. In most cases **abscesses** in affected lymph nodes rupture 7–14 days after the first clinical signs. Supratharyngeal lymph node abscesses usually drain into the pharyngeal area resulting in a **copious nasal flow** of purulent material. This drainage may also occur into the **guttural pouch**, which may become distended and palpable posterior to the vertical ramus of the mandible.

Metastasis of purulent material may result in abscess formation in other locations such as the lungs, brain and thoracic or abdominal lymph nodes. This complication has a poor prognosis and is commonly termed “**bastard strangles**” (*q.v.*). Other complications during and after recovery from the typical disease include **purpura hemorrhagica** (*q.v.*), an immune complex-mediated vasculitis that occurs at 1–4 wk, paralysis of the left recurrent laryngeal nerve, anemia possibly associated with hepatic clearance of immune complexes bound to erythrocytes, and myopathy characterized by coagulative necrosis or chronic rhabdomyolysis and atrophy.

Outbreaks of strangles in horse populations with **pre-existing antibody** to *S. equi* may be present as an atypical or catarrhal form of the disease characterized by a slight purulent nasal discharge, cough, occasional slight fever of short duration and abscessation of lymph nodes in a few affected animals. Its progression in a group of horses is much slower than that of the typical disease. Older horses experiencing a secondary infection often exhibit the catarrhal form of strangles.

Approximately 70% of animals develop a solid, **enduring immunity** to the typical disease following recovery from strangles. This immunity is associated in part with mucosal IgG and IgA, and serum opsonic antibodies. Opsonic antibodies are slow to develop and do not attain adequate titers until 6–8 wk after clinical signs appear. Immunity is expressed in the tonsil and blocks further invasion. Nasal shedding of *S. equi* may continue for 3–4 wk following appearance of clinical signs and the organism may remain in the guttural pouch of some recovered animals for months thereafter.

S. zooepidemicus is a constant **secondary invader** of the upper respiratory mucosa as a sequel to influenza or herpes viruses. Many small purulent foci are produced in the lymphoid follicles of the mucosa and the resulting nasal discharge is mucopurulent. The draining lymph nodes often become **enlarged and hardened** and may become abscessed in some animals, but abscessation is much less frequent than in the case of strangles. Affected animals have nasal and ocular discharges, cough, may be slightly febrile and lose body condition. Secondary pneumonia due to *S. zooepidemicus* occurs in a portion of foal populations infected with influenza virus and is responsible for much of the morbidity and mortality in this age group. In **donkeys**, these secondary pneumonias are often fatal.

S. zooepidemicus is occasionally isolated from lesions of pleurisy or peritonitis. It is a common cause of **joint ill** (*q.v.*) in foals that may acquire infection in the birth canal. The organism enters the umbilicus and the ensuing bacteremia results in synovial infection, pyoarthrititis and permanent damage to the joint(s).

In the mare, *S. zooepidemicus* infections of the cervix and uterus are transient and occur shortly after parturition. Dystocia or retention of the placenta (*q.v.*) may result in more persistent infections. However, most mares will recover from endometritis if they go through one or two estrous cycles free of new entry of bacteria into the uterus.

Prevention

The very contagious nature of strangles makes control of spread very difficult. Clinically affected animals as well as animals detected as infected by culture of nasal swabs or washes should be isolated immediately. The first clinical sign is sudden onset of fever to 39.5–41°C. Animals at this stage are not shedding *S. equi* and so may be isolated before transmission to others has occurred. Twice-daily temperature taking is therefore an invaluable aid in minimizing transmission and containing an outbreak.

All containers used for feed or water should be cleaned and disinfected. Surfaces of stalls contaminated with discharges should be similarly cleaned and disinfected. Effective disinfectants are povidone iodine, chlorhexidine gluconate, 0.6% sulfuric acid, glutaraldehyde and phenol (1:200).

Where possible, **fly infestations** should be reduced by use of screens, insecticides and electronic bug poppers. **Contaminated bedding** should be removed to a protected location and covered with a plastic sheet to compost. Cases held in isolation should be handled last and the **animal attendant** should be meticulous about hand and arm washing, removal of coveralls and boots, etc., before leaving the isolation area. **Pasture** upon which cases have grazed should be rested for at least a month before being grazed again by horses.

In large breeding enterprises, weanlings and yearlings should be located in small geographically separated groups remote from areas where mares and stallions are held. Incoming animals should be held in a designated isolation/holding area for 2 wk before release into a group on the farm. Ideally, these animals should be subjected to one or more **nasal swab cultures** during the 2 wk isolation period and rectal temperatures taken twice daily. This aspect of control cannot be overemphasized as the usual source of *S. equi* for uninfected premises is the recently **introduced infected animal**. Nurse mares frequently introduce infection in this way and should be isolated with their adopted foals.

Antibiotics such as a **long-acting penicillin** administered parenterally, e.g. benzathine penicillin (30 000 IU per kg IM q 2 days), or feed supplementation with low levels of tetracycline (60–80 ppm feed) are very effective in preventing or stopping an outbreak. However, **herd immunity will not develop during this time and animals will be highly susceptible to infection when the antimicrobial drug is withdrawn**. Use of low-level tetracycline also carries a slight risk of **antibiotic-induced clostridial enterocolitis** (*q.v.*) should the horse's environment be contaminated with toxigenic strains. Penicillin administration is most effective at the **onset of fever** before abscess development.

Vaccination with acid-extracted M protein or mutanolysin-extracted M protein commercial vaccines is effective in stimulating serum opsonic antibodies when administered in a course of two inoculations. However, these vaccines do not confer a high level of protection in the field against natural challenge. At best, the number of clinical cases is reduced by half and the disease is less severe in those cases that develop. Bacterin-type vaccines often elicit local and systemic reactions to peptidoglycan in bacterial cell walls; M protein extract vaccines contain less peptidoglycan and are better tolerated.

The incomplete protection stimulated by commercial vaccines is probably related to failure to stimulate mucosal IgG and IgA antibodies. Vaccination with live avirulent organisms is often effective in stimulating these antibodies and a high level of resistance to experimental challenge results. However, given that recovery from the naturally occurring disease provides solid protection in only 70% of horses, it is unlikely that vaccines based on live avirulent organisms will protect a much higher percentage than this. Live vaccines have the disadvantage that they may cause large painful abscesses if accidentally introduced into muscle at remote injection sites.

Vaccination of mares has been shown to increase colostral titers of IgG antibodies to SeM protein. Serum titers of these antibodies in suckling foals may thereby be increased.

The multiplicity of M-like (SzP) protein types involved suggests that vaccines developed against *S. zooepidemicus* or *S. equisimilis* must be multivalent or based on conserved epitopes or antigens.

Diagnosis

The clinical signs of classical strangles in which **lymphadenitis** is exhibited are easy to recognize. A pronounced leukocytosis with neutrophilia and fibrinogenemia accompanies the fever. However, **bacteriologic examination** is essential to confirm the diagnosis. Moist nasal swabs may be used to sample the medial nasal mucosa 10–15 cm in from the external meatus of each nostril and

plated on colistin–nalidixic acid (CNA blood agar). Nasal washes obtained by instilling warm physiologic saline (50 mL) into the retronares and collecting the washings that drain into a disposable cup for culture are more sensitive than swabs in detection of *S. equi* since a much larger area of the mucosa is sampled.

The **polymerase chain reaction (PCR)** using primers from the sequence of SeM is now widely used in presumptive detection of *S. equi* in clinical samples. The PCR test is approximately three times **more sensitive** than culture and is **highly specific**. However, in chronic cases of guttural pouch empyema, *S. equi* DNA may persist for days or weeks following bacteriologic cure.

Pus may also be aspirated aseptically from lymph nodes with a needle and syringe. Swabs or pus should be plated without delay. Beta-hemolytic colonies are identified after incubation overnight at 37°C by a combination of Lancefield grouping reaction and fermentation reactions in lactose, sorbitol and trehalose. Assay of convalescent antibody to *S. equi* by ELISA is available in specialized laboratories and is performed with recombinant SeM as antigen.

Serologic examination is helpful in detecting horses with internal abscesses and in confirming a diagnosis of *S. equi*-associated purpura hemorrhagica (*q.v.*). In both of these instances, very high levels of serum antibody are present.

Placentitis and metritis caused by either *S. zooepidemicus* or *S. equisimilis* may be diagnosed in the laboratory by culturing swabs or specimens on CNA agar. Uterine swabs, tampons or biopsies should be cultured, preferably between 10 and 14 days after ovulation. Tracheal aspirates cultured on CNA and stained by the Giemsa method are important in the laboratory confirmation of respiratory *S. zooepidemicus* infections of young horses.

Treatment

The equine group C streptococci are very sensitive to penicillin, ampicillin, erythromycin, chloramphenicol, cephalosporins and tetracyclines. Gentamicin resistance has been noted in *S. zooepidemicus* isolates from equine sources. Where appropriate, strangles is usually treated with IM doses of penicillin of up to 10 million units. Cases treated immediately at time of onset of fever will respond within hours and usually do not develop abscesses. However, since **most cases recover uneventfully and develop enduring immunity**, antibiotic administration is usually reserved for relief of life-threatening lesions that are intruding on the airway or for *S. zooepidemicus* infections in foals complicated by pneumonia.

Although penicillin is very effective for **prophylaxis** of in-contact animals and in treatment of respiratory tract disease caused by the equine group C streptococci, use of antibiotics requires **careful consideration** as they may delay maturation and draining of abscesses and ablate the protective immune response.

Abscesses should not be opened surgically until the capsule and fluid contents can be readily palpated beneath the skin. Insertion of a 16 or 18 gauge needle through surgically prepared skin into the abscess often establishes a tract along which the abscess capsule dissolves and speeds evacuation without the need for surgical incision.

Supportive therapy of strangles cases includes twice-daily cleansing of draining sites and nostrils, application of fly repellents and provision of a

high quality soft, moist feed. Guttural pouch infections (*q.v.*) may require irrigation with surgical antiseptic or penicillin solutions.

Streptococcal endometritis or placentitis may be treated with IM injections of penicillin (22 000 IU/kg BW/day) for 2 wk. Streptococcal placentitis must be treated at the first sign of vaginal discharge but with the caveat that the fetus already may have become septicemic by the time the discharge is noted. Treatment of chronic **streptococcal endometritis** (*q.v.*) is most effective during estrus when the non-specific natural antibacterial clearance mechanisms are most efficient.

Treatment of horses with purpura hemorrhagica includes corticosteroids to reduce polymorphonuclear leukocyte responses and antibiotics to protect against secondary bacterial infection. Blood transfusions (*q.v.*) may be indicated in cases with anemia or thrombocytopenia. Edematous legs should be bandaged.

CORYNEBACTERIUM PSEUDOTUBERCULOSIS

Etiology

Corynebacterium pseudotuberculosis produces a syndrome of ulcerative lymphangitis or abscess formation. Folliculitis and abortion have also been reported. The bacterium is a Gram-positive, non-motile facultative anaerobe that survives well in the environment and can infect other species, including man.

Epidemiology

The disease occurs worldwide in areas where horses are raised. However, there is a marked variation in clinical signs in geographic locations throughout the world. Pectoral, ventral midline, abdominal and inguinal abscesses are frequent presentations in areas of the western USA, whereas ulcerative lymphangitis is more typical elsewhere. The incidence of disease varies from year to year, and outbreaks can occur. Common names for the abscess form of the disease are “pigeon fever”, “pigeon breast”, “dry-land distemper” or “Colorado distemper”.

Folliculitis (contagious pustular dermatitis, “contagious acne” or “**Canadian horsepox**”) caused by *C. pseudotuberculosis* results in pustules that are often distributed in areas where tack or harness make contact with the skin. The disease may be transmitted by **contaminated grooming utensils**. Trauma to the skin, existing folliculitis or seborrhea may predispose the horse to infection. **Ulcerative lymphangitis** is a fairly uncommon disease that is usually associated with poor sanitation. Open draining tracts can be a source of environmental contamination.

Pathogenesis

The organism finds a portal of entry through abraded mucous membranes or compromised skin surfaces such as may be caused by **badly fitting tack**. **Biting insects** may also provide a portal of entry. This phenomenon may explain the seasonal incidence of the disease, particularly for the abscess form.

The infection may establish itself locally or spread via lymph or blood. Entry into the lymphatics of the limb is likely to be through local skin lesions and results in typical ulcerative lymphangitis.

The incubation period for the disease can be long and varies from weeks to months. Exotoxin production by the organism is thought to be significant in abscess formation.

Clinical findings

Typical **abscess formation** occurs most commonly in the pectoral region and occasionally in the abdomen along the ventral midline or in the inguinal region. Abscesses are often thick walled and can progress in size. Ventral or inguinal edema can be seen in association with abscesses. Depression, fever and anorexia may be present but are atypical. Axillary abscesses may result in gait abnormalities before abscesses are identified. Internal abscesses may produce signs of weight loss or abnormal pain.

The lower limb form of the disease may be initially identified as a nondescript swelling that can produce severe lameness. **Subcutaneous nodules** frequently develop, often in the area of the pastern, but they can spread to other sites. Nodules may range from a few mm to several cm in diameter. Ruptured nodules discharge creamy pus and generally result in an ulcer of the skin at the site of rupture. Lymphatics draining the area may become enlarged and firm. Nodules and ulcers can develop along these lymphatics. Recurrence of the disease may occur after resolution.

The papules and pustules of the skin form of the disease usually occur in groups. These are often associated with frequently abraded skin (from harness or tack) but can be more diffuse. Smaller papules may develop into pustules. The rupture of pustules leads to a crust formation. Lesions are usually not pruritic but may be painful.

Clinical pathology and necropsy

Elevations in white blood cell counts or fibrinogen may be identified early in the course of the disease. Chronically diseased animals may be hematologically normal. **Thick-walled abscesses** are a typical post mortem finding. Abscesses generally contain a tan-colored liquid exudate, whereas pustules may contain whitish-green pus. Abscesses are identified along lymphatics in peripheral limbs.

Diagnosis

Characteristic clinical signs such as large abscesses in the pectoral region, ulcerative lymphangitis or cellulitis with multiple small skin erosions of one or more limbs may suggest a *C. pseudotuberculosis* infection. A definitive diagnosis requires bacterial culture. Pure cultures can be obtained from the lesions. Abdominocentesis may identify abdominal abscesses, but normal peritoneal fluid does not rule out their presence. Ultrasonography can be useful in identifying deep abscesses in inguinal abdominal or axillary regions.

Treatment

Surgical incision into, and **open drainage** of abscesses is often required and aids resolution of infection. Pectoral and inguinal abscesses are often very

deep and may require deep incision or the use of large trocar drains. Ultrasonographic localization of abscesses can be beneficial. Daily flushing and local therapy may be required to maintain open drainage.

The efficacy of antibiotic therapy is controversial. The *in vitro* susceptibility of *C. pseudotuberculosis* is broad. Procaine benzylpenicillin (20 000 IU/kg IM b.i.d.), potassium penicillin (20 000–40 000 IU/kg IV q.i.d.) and sulfa-trimethoprim (5 mg/kg of the trimethoprim portion b.i.d.) are commonly used. The failure of antibiotic therapy may be a result of the intracellular nature of the organism or the inability of antibiotics to reach adequate levels in large, thick-walled abscesses. Rifampicin (5 mg/kg PO b.i.d.) and erythromycin (20–30 mg/kg PO q.i.d.) have also been recommended for treatment, as they reach good intracellular levels. The course of therapy, particularly when abscess drainage cannot be achieved, is protracted. Analgesics and anti-inflammatory drugs should be used when pain is present. Reduction of edema and inflammation may improve appetite and reduce the incidence of laminitis (*q.v.*) in the opposite limb.

Control

Improvement of **sanitation** and a reduction in constant **exposure to moisture** are imperative in reducing the incidence of the peripheral limb form of the disease. Preventing skin abrasions from tack or harness is useful. Quarantine or culling of infected horses reduces environmental contamination. *C. pseudotuberculosis* is susceptible to most disinfectants. Fly control and the use of screened stalls may reduce insect vector spread. Claims have been made for the successful application of autogenous bacterins, which have been used on a limited scale without serious adverse effects.

GLANDERS

Glanders is one of the most ancient of all diseases recognized. A scourge of solipeds, glanders was frequently seen in an acute form in the ass, in a subacute form in the mule and in a chronic (or even latent) form in the horse. Because the causal organism, *Burkholderia* (*Pseudomonas*) *mallei* (earlier known as *Bacillus*, *Pfeifferella*, *Loefflerella*, *Malleomyces*, *Actinobacillus* or *Pseudomonas mallei*), survives so poorly outside these hosts, the disease was always most prevalent in horses massed for military purposes or in horses in the growing cities and towns of the second half of the nineteenth century. In London, for example, there were at least 1000 clinical cases of the disease annually in horses in 1900 but some 25 years later there was none in the whole of the UK. The disease now appears to be confined to a few regions in Asia.

B. mallei can produce glanders in a wide range of species including humans and carnivores.

Etiology

B. mallei has few bacteriologic features in common with other members of the genus and its taxonomic position has always been problematic.

Epidemiology and pathogenesis

B. mallei is an obligate parasite that does not survive for more than about 6 wk outside its hosts. It is very sensitive to sunlight and drying even when partly

protected by the purulent exudate it produces in its host. Horses usually acquire the infection by **ingestion or inhalation**.

After penetrating the mucosae passively, the organism, like the tubercle bacillus, has a marked propensity to travel and deposit itself in **lymphatic tissues**. It also infects **pulmonary tissue** where it is associated at first with microscopic inflammatory foci. These foci enlarge to form macroscopic nodules and ultimately larger, **chronic granulomas**. A diffuse interstitial pneumonia can accompany this process. At any point during these events exudates containing the bacilli from the nodules can be discharged into the airways and so reach the upper respiratory tract where they produce nodules in the nasal cavity similar to those in the lungs. These nodules eventually rupture to produce the characteristic **punched-out ulcers** along the nasal septum. The ulcers discharge a gluey, purulent exudate. They can be seen in the congested and even hemorrhagic mucous membrane of the nasal cavity simply by everting the alar cartilage.

The bacilli may also infect the lymphatic tissues of the limbs where they give rise to **farcy**. Farcy comprises a chronic lymphangitis (the “farcy cords”) and lymphadenitis (the “farcy buds”). As in the nasal cavity, these lesions rupture to discharge purulent exudate. The exudate contaminates stables, tack, harness and utensils with *B. mallei* and is thus a major source of infection for other animals and humans. The clinical and pathologic events that follow inhalation (or cutaneous inoculation) of *B. mallei* are similar to those that occur after its ingestion.

Although horses that have apparently recovered from the disease are resistant to further infection, they may suffer the occult form of the disease. In **occult (latent) glanders**, the pulmonary lesions are quiescent but can be provoked by **stress** into renewed development, leading to dissemination of the agent in the body and its release to the exterior. The reactivation of these quiescent lesions in the infected horse explains why in the past the severe strain of military operations was often associated with major outbreaks of the disease in the cavalry.

Although humans are much more resistant to *B. mallei* than Equidae, the organism can produce disease that chronically affects the skin and subcutaneous tissues and can generalize with fatal consequences.

Diagnosis

Clinical glanders is distinctive once the nasal and cutaneous lesions have formed and *B. mallei* is easily recognized in smears from such lesions. It is a Gram-negative, beaded rod approximately 1–5 μm long by 0.5 μm wide. *B. mallei* is easy to grow in the laboratory, but growth is slow even with media such as those containing glycerol which favor it and on which its colonies resemble drops of honey that gradually become brown. Affected horses can also be detected by serologic methods and the **complement fixation test** is generally regarded as the most reliable. However, **counterimmunoelectrophoresis** with appropriate antigen is fast and simple and is said to be as reliable as the technically more complicated CFT.

The **mallein test** can also be employed to detect infected horses. Mallein is a protein produced by *B. mallei* during growth. When it is inoculated

intradermally into the eyelid or instilled into the conjunctival sac, it gives rise to swelling of the eyelid and the formation of a purulent exudate in the eye of a glanderous animal within 24 h. This test, like the CFT, is a prescribed test for international trade and is indispensable in the control of glanders.

Treatment and control

The horse is essential to the persistence of *B. mallei*. Consequently **no convincing case can be made for treating a horse with the confirmed disease or infection**. The destruction of infected animals has eliminated the disease from the horse populations of many areas of the world.

HISTOPLASMA FARCIMINOSUM

Histoplasma farciminosum causes **epizootic lymphangitis**, a condition still encountered in parts of the African and Asian continents. In these enzootic areas new cases usually arise in autumn or winter. This fungal infection has superficial clinical similarities to glanders (as farcy) and ulcerative lymphangitis and for that reason can be considered briefly here. It is a notifiable disease in many countries.

The lesions of epizootic lymphangitis affect the lower limbs, and their distribution and other circumstantial evidence suggests that the infection is acquired from a mycelial phase in the **soil**. The fungus is present in its yeast phase in the thickened and suppurating vessels and aggregates of lymphoid tissue. In this form the agent is an ovoid cell approximately $4 \times 3 \mu\text{m}$. It is irregular in outline due to buds of cytoplasm extruding from the thick cell wall. Infection is thought to be acquired through minor **abrasions or wounds** in the skin. After some weeks, the inflammatory process in the thickening lymphatic vessels leads to local ruptures. Deep ulcers in the skin exude thick pus in which yeast cells can be detected microscopically.

Without treatment the clinical course lasts about a year but affected animals eventually recover. A related organism, *H. capsulatum*, produces histoplasmosis in many areas of the world. Although many infections with *H. capsulatum* are clinically inapparent, frank disease is occasionally seen in the horse in the enzootic areas in the USA.

MELIOIDOSIS

Pseudomonas pseudomallei, the cause of melioidosis, has many more resemblances to *P. aeruginosa* than *Burkholderia mallei*, including a **relative insensitivity to antibiotics**. The organism is widespread in the soils and waters of tropical or subtropical regions of Asia, Australia and elsewhere, but the agent has been detected also in temperate soils.

Most instances of infection with *P. pseudomallei* are contracted from the environment and not from other affected animals, and do not give rise to a clinical condition.

When frank disease does result from infection with *P. pseudomallei*, which is an opportunistic pathogen, it strongly resembles, clinically and pathologically, acute, systemic glanders in most instances. The disease has been observed in a

wide variety of wild and domesticated animals, including, very occasionally, the horse. *P. pseudomallei*, a Gram-negative, bipolar-staining, pleomorphic bacillus may be cultured from abscesses, discharges or blood. It can be differentiated from *B. mallei* by its biochemical characteristics.

There are no vaccines available against melioidosis. Since *P. pseudomallei* is resistant in vitro to many antimicrobial drugs, treatment must be based on the results of sensitivity tests and empiricism. In humans, mild cases of melioidosis have responded to therapy with **tetracyclines**.

EHRlichiosis

Among the bacteria there exists a taxonomic grouping of small coccoid organisms that are obligatory intracellular parasites. These organisms—the **rickettsias**—have the typical structure and most of the enzymes of other bacteria and are Gram-negative. Rickettsias will not grow in artificial media but can be propagated in the yolk sac of the chick embryo or in tissue cultures.

The rickettsiae are well-established **vector-borne pathogens**. They form a heterogeneous group that includes species capable of producing disease in domesticated animals. They are mostly **tick transmitted** and an intermediate host has been identified for several well-characterized rickettsias. Two species of rickettsial pathogens, *Anaplasma phagocytophila* and *Neorickettsia risticii*, produce disease in the horse in parts of North America and Europe.

Potomac horse fever (equine monocytic ehrlichiosis)

Etiology

Neorickettsia risticii (formerly *Ehrlichia risticii*), which has emerged as a pathogen of American horses in the early twenty-first century, is related antigenically to *N. helminthoeca*, the agent of salmon poisoning in dogs. *N. risticii* is a morphologically typical rickettsia and grows well in cultures of macrophages.

Epidemiology and pathogenesis

Serologic evidence indicates that infection with *N. risticii* is widespread in the USA but the disease itself only occurs sporadically and is often confined to an individual animal in a group. Younger animals appear to be less susceptible.

Potomac horse fever (PHF) (*q.v.*) occurs only in the summer and autumn and is most prevalent inland near rivers. The agent is associated with a **trema-tode vector**, which uses freshwater snails and aquatic insects as intermediate hosts, and insectivores (bats and birds) as definitive hosts. The natural route of infection is **oral** through the accidental ingestion of aquatic insects such as **caddis flies**. The disease is infectious but not contagious. An attack induces high levels of antibody and recovered cases are apparently immune to further clinical episodes and probably even infection.

Clinical and pathologic findings

The end of the incubation period of 9–15 days is marked by depression, anorexia and fever. Profuse or even projectile diarrhea follows quickly in about half of the cases; in other affected animals, the diarrhea is milder. Colic,

anasarca, abortion and laminitis also occur in about a third of the cases; the onset of laminitis is regarded as indicating a poor prognosis.

As the syndrome progresses the severest cases go into deep **hypovolemic shock** (*q.v.*). The clinical severity of the disease is variable, but the case fatality rate is approximately 30% in untreated animals.

At the onset of the condition a marked leukopenia is succeeded by a leukocytosis and the increasing packed cell volume (PCV) and plasma protein concentrations are a reflection of the severity of the **diarrhea**. This in turn reflects the extent of the erosive or **ulcerative lesions** seen principally in the cecum and colon but found throughout the gut. Aortic, cardiac and hepatic hemorrhages may be present. Vasculitis and thrombus formation may be seen microscopically.

Diagnosis

Clinically, the disease is difficult to distinguish from an acute attack of salmonellosis or clostridiosis (*q.v.*). However, clinical signs in the proven absence of other pathogens and the clinicopathologic changes (leukocytosis, increased PCV, plasma protein) may assist in diagnosis. *N. risticii* is rarely seen in monocytes in suitably stained blood smears and isolation of the organism in the laboratory is difficult. PHF is diagnosed by PCR on whole blood and/or feces.

The serologic examination of **paired blood samples** collected at an appropriate interval assists in retrospective diagnosis. A rise in antibody titer against *N. risticii* can be determined by immunofluorescent antibody, ELISA or Western blot. The examination of a single sample is of questionable value. The antibody response induced by infection with *N. risticii* appears early in the course of clinical disease and persists for at least a year.

Treatment and control

As with other rickettsial diseases, the **tetracyclines** (8–10 mg/kg IV s.i.d. or b.i.d.) are favored for therapy. No instance of resistance of *N. risticii* to tetracyclines appears to have been recorded. Non-specific supportive therapy, especially to correct the dehydration induced by diarrhea, is also **mandatory** in severe cases. Killed bacteria are effective experimentally in protecting against challenge. In the field, vaccines have shown poor protection.

Equine ehrlichiosis (equine granulocytic ehrlichiosis)

Anaplasma phagocytophila (formerly *Ehrlichia equi*) produces disease in horses in some parts of the USA and Europe and is transmitted by *Ixodes* ticks. **Equine ehrlichiosis** is characterized principally by depression, fever, edema of the legs, ataxia and jaundice. Most of the clinical signs are a result of the **vasculitis** with hemorrhage that the agent produces. Recovered horses are immune and are not carriers.

When the disease is at its peak, the agent is readily observable in the granulocytes. Approximately half of the neutrophils in the circulation can contain the agent in the acute stage of the disease. The organism is usually present as morulae, i.e. loose clusters approximately 3 μm in diameter, of coccoid bacterial cells. Fluoresceinated antibody is also available for the diagnosis of

suspected cases. **Oxytetracycline** (8–10 mg/kg IV s.i.d. or b.i.d.) is effective in curing the disease. No vaccine is available and the disease can be prevented by good tick control.

LYME DISEASE (BORRELIOSIS)

Lyme disease was first described in humans in the northeastern USA in the early 1940s. It took the form of a fever, malaise and shifting arthritis extending over many weeks. Its occurrence correlated with the season of activity of **ticks** of the genus *Ixodes*. The condition has since been reported in other parts of North America, in Europe, including the UK, and Australia. Since its recognition in humans, similar cases have been detected in domesticated animals. The dog is most commonly affected but the horse is also susceptible.

Etiology

The cause of Lyme disease is *Borrelia burgdorferi*, a helically coiled organism some 20 µm long by 0.2 µm wide. The genus *Borrelia* is related to *Treponema* and *Leptospira* (*q.v.*), and with them forms part of a major group of bacteria, the **spirochetes**. These organisms differ significantly from other bacteria in their morphology. The cell is slender, flexuous and helically coiled. It is enclosed in an outer membrane or sheath. This sheath envelops the flagella (the axial filaments) that arise near each pole of the cell and overlap at the centre. The action of the flagella gives rise to the movements of flexion and rotation that are characteristic of the spirochetal cell.

Epidemiology and pathogenesis

Borrelias are **arthropod-borne** parasites of humans and many other species of mammals and birds. *B. burgdorferi* is maintained in, and transmitted by, nymph and adult ticks of the *Ixodes* complex. However, **in the absence of the vector**, *B. burgdorferi* can also be transferred among susceptible animals by blood, urine, synovial fluid or transplacentally. In the USA, *B. burgdorferi* circulates in mice and deer.

Clinical and pathologic findings

Lameness, lymphadenopathy and fever are the cardinal clinical signs and they are accompanied by malaise and inappetance. A characteristic **shifting polyarthritis** develops. In the horse, uveitis and encephalitis have also been recorded in conjunction with the arthritis. In the acute stage of the disease the affected joints are hot, swollen and painful and neutrophils are abundant in the synovial fluid. In general, the disease exhibits the features of an immune complex (type III) reaction and can become chronic.

Diagnosis

The history and clinical syndrome in animals that are or have been in known endemic areas is suggestive of Lyme disease. However, the joints may appear radiographically normal, as do various blood profiles. The agent can be isolated by culture of blood, urine or synovial fluid drawn from an acutely affected

joint. *B. burgdorferi* is difficult to grow in the laboratory and also grows slowly. However, in acute cases the organisms are usually **abundant in the affected joints**. The agent can be recognized by its distinctive morphology using dark-field microscopy or serologically with fluorescein- or peroxidase-labeled antibody. Humoral antibodies can also be measured.

Treatment and control

More is known of the benefit of antimicrobial agents in the treatment of this disease in humans and in the dog than in the horse. In humans, the tetracyclines, penicillins and cephalosporins have all been effective and even chronic cases have responded to IV penicillin. In the dog, antibiotic therapy has been curative when maintained for 21–28 days. **Tetracyclines**, for example doxycycline (10 mg/kg PO b.i.d.), are effective in horses. Serologically positive but clinically normal animals are also treated. A **killed vaccine** is available for use in dogs at risk from the disease in the USA. Annual revaccination is recommended.

Measures to control the **tick infestation** of individual animals, including daily inspection, are recommended (*q.v.*), although searching for the nymphal stage (approximately 1 mm long) is hardly practical.

PYODERMA AND SADDLE SORES OR GALLS

Pyogenic dermatitis in horses is usually associated with *Staphylococcus* spp. (chiefly *S. aureus*) although it may also be caused by other bacteria including *D. congolensis* and *C. pseudotuberculosis* (*q.v.*). The lesions, which vary from superficial and slight to deep and persistent, frequently arise after mechanical injury to the skin from chafing by harness or saddlery. If affected animals are neglected or abused, abscesses, furunculosis, or an indurated proliferative dermatitis may occur.

When the bacterial dermatitis is in its earlier stages, topical antiseptics (such as hexachlorophene or iodine preparations), emollients and shampoos (benzyl benzoate preparations) or antibiotics are helpful. The choice of antibiotics for topical or parenteral treatment should rest on isolation of the causal agent and determination of its sensitivity. *S. aureus* can be resistant to a wide range of antibiotics. **Autogenous vaccines** can be administered in extreme cases.

Historically, *S. aureus* was implicated in **botryomycosis** in the horse in which chronic granulomatous lesions develop in the spermatic cord after castration or in the stump of the tail after docking, usually as a consequence of poor aseptic techniques. The lesions, which can attain a remarkable size, exude pus containing hard coarse granules and abundant staphylococci.

FISTULOUS WITHERS AND POLL EVIL

Fistulous withers and poll evil reflect two features of the genus *Brucella* in horses, namely: (1) the propensity of the organisms to lodge in synovial structures, and (2) the ability of brucellae to infect domesticated species other than their principal host.

The horse is a **coincidental host** of *B. abortus* or *B. suis* and the prevalence of fistulous withers and poll evil in horses in a given region is an indirect

indication of the **respective prevalence** of brucellosis in the cattle or pigs of that region and the extent of contact between horses and the definitive hosts.

Although infection of the **bursae** is most usual, *B. abortus* can also infect other synovial structures such as the joints and tendon sheaths. Infection of the supra-atlantal and supraspinal bursae probably occurs after ingestion of brucellae. Bacterial localization in the synovial membrane causes a clear, thick exudative inflammation leading to swelling of the bursae. The thickening of the chronically inflamed bursal wall is insufficient to prevent its eventual rupture. When rupture does occur, infection with other bacteria, e.g. *Actinomyces bovis*-like anaerobes and other opportunists such as staphylococci, induces **suppurative changes** in the fistulae and the bursa. These chronically discharging lesions constitute a **source** of *B. abortus* to the horse and other animals, including, importantly, cattle.

A diagnosis of poll evil or fistulous withers can be confirmed by isolating *B. abortus* from fluid aspirated from the affected bursa. As these organisms cause brucellosis in man, the material for examination needs to be collected, transported and handled with special care and appropriate containment. Support for the diagnosis can also be achieved by determination of the titer of humoral antibody to *B. abortus* (or *suis*). Once the diagnosis has been confirmed, poll evil or fistulous withers are best treated by **surgical removal** of the bursa.

LEPTOSPIROSIS

Infection with leptospires occurs in all domesticated animals. In endemic areas the majority of infections are clinically inapparent. The horse and the cat are less susceptible to leptospirosis than other domesticated species.

Etiology

Leptospires are related taxonomically to treponemes and borrelias and are principally aquatic saprophytes, which are divided into two species, *Leptospira interrogans* and *L. biflexa*. The former species contains all the pathogenic varieties and it is divisible into groups of serovars on the basis of serologically distinct, superficial antigens. There are some 200 serovars that differ in their pathogenicity for different species of animals and in their geographic distribution throughout the world.

Epidemiology

Leptospires tend not to be highly host adapted and to have maintenance or **reservoir hosts** among small wild animals in the environment. However, in some instances certain serovars have become so well adapted to a particular species that the final host serves also as the maintenance host for the pathogen.

Leptospires are principally transmitted in **urine** and **water**. Serologic evidence of exposure to leptospires is most prevalent in the wetter, warmer parts of the world. Most equine infections are associated with serovars *hardjo*, *icterohaemorrhagiae*, *pomona* or *bratislava*.

Clinical signs

Infection with leptospires usually results in **subclinical disease** but if the infection is acute the horse is pyrexia, depressed, anorexic and jaundiced.

Hemoglobinuria may occur. Leptospirosis in the pregnant mare may result in abortion during, or some weeks after, a clinically vague febrile episode. Several serovars such as *pomona*, *hardjo*, *icterohaemorrhagiae* and *bratislava* have been isolated from aborted equine fetuses.

Months or even years after exposure to leptospires a horse may suffer **periodic ophthalmia** (*q.v.*). Affected horses have repeated attacks of hypopyon, keratitis, conjunctivitis and iridocyclitis that occur in one or both eyes. These lesions are of sufficient severity ultimately to produce blindness. The nature of the whole process is suggestive of a hypersensitivity reaction between the antibodies in the anterior chamber and antigen (probably in tiny amounts) reaching it from elsewhere in the body.

Diagnosis

Leptospires can be detected in specimens of blood or urine by culture or by injection of hamsters or guinea pigs. Leptospires are not exceptionally difficult to grow in the laboratory but their nutritional and cultural requirements are unusual in that they require a pH of 7.0–7.2, long-chain fatty acids, vitamins B₁ and B₁₂, protein (or ammonium salts) and aerobic incubation at 30°C. Appropriate media (usually liquid or semi-solid) for their isolation often contain 5-fluoracil to inhibit other agents that may be present in contaminated material. Growth in the laboratory may require **several weeks**.

When leptospires are present, either as part of an acute episode or as a consequence of **chronic nephritis** (*q.v.*), the organisms are also demonstrable in **urine**, especially if it has been concentrated by centrifugation. Lightly pelleted material when resuspended is examined **microscopically** by dark-field illumination or by UV illumination after the application of fluoresceinated antibody. The helically curved bacteria are up to 30 µm in length but slender in width (0.1 µm). **DNA probes** for the detection of elements of the leptospiral genome are also available.

An increased antibody titer in paired serum samples taken at appropriate intervals during the course of a suspicious episode also assists in diagnosis. Seroconversion can be demonstrated by simple microscopic agglutination tests. However, the availability of a wide choice of suitable antigens is often necessary and the ability to conduct diagnosis by serologic means tends to be restricted to specialized laboratories. In periodic ophthalmia, leptospires cannot be demonstrated in the afflicted eye but there are antibodies against leptospiral antigens in the circulation and especially high titers in the aqueous humor.

Treatment and control

Penicillin (20 000–40 000 IU/kg IV q.i.d.) or the **tetracyclines** (8–10 mg/kg s.i.d. or b.i.d.) are the antibiotics of choice for the treatment of acute leptospirosis and for eliminating the persistent or intermittent leptospiruria that occurs in the chronically affected animal or the carrier animal.

For **periodic ophthalmia** the parenteral administration of an appropriate antibiotic such as penicillin (20 000–40 000 IU/kg IV q.i.d.) or tetracycline (8–10 mg/kg s.i.d. or b.i.d.) should be coupled with the local administration of an anti-inflammatory steroid or non-steroidal agent. Immunization of horses against leptospirosis is not practiced.

CONTAGIOUS EQUINE METRITIS

Etiology

Contagious equine metritis (CEM) (*q.v.*) is a very highly contagious disease of mares that was first described some 15 years ago. It is caused by infection with *Taylorella equigenitalis*, a microaerophilic Gram-negative rod (approximately 1 μm long) that grows slowly (2.5 days) in the laboratory.

Epidemiology and pathogenesis

Spontaneous infection with *T. equigenitalis* in species other than the horse is not known. The organism is an obligate parasite of the surface of the **terminal urethra and its fossa** in the stallion and in the **clitoral sinuses and fossa** of the mare. *T. equigenitalis* has also been isolated from sexually immature animals, some of which might have acquired the infection at birth.

T. equigenitalis is transmitted to susceptible mares by an infected stallion during mating, although transmission by other means (instruments, procedures and attendants) is also possible. Infected stallions do not mount a humoral immune response or give any clinical sign of the infection. Their libido and fertility is unimpaired. The disease is **highly contagious**. A susceptible mare that has been covered by an infected stallion soon develops clinical signs of an acute infection in the reproductive tract.

Contracting infection with *T. equigenitalis* does not preclude a normal pregnancy in the mare although the organism can be isolated from the placenta. Occasionally, inapparent infections in barren or in-foal mares occur.

Clinical and pathologic findings

The clinical signs of the disease in the mare vary from mild to severe. In a typical case, an increasingly copious grayish exudate is discharged from the vulva 2–12 days after the service, soiling the tail and quarters. There is evidence of vaginitis, cervicitis, endometritis and salpingitis. The conception rate in acutely affected animals is low. Fertility is regained when the acute disease abates. After the acute attack ends, however, the mare sheds the organism continuously or intermittently for lengthy periods.

Pathologically, the acute disease is a simple **catarrhal infection** of a mucous membrane with the production of an exudate that is rich in neutrophils and accompanied by edema and infiltration of mononuclear cells into the lamina propria of the mucosa.

Diagnosis

The clinical signs in the acutely affected mare are highly suggestive. The agent (including those organisms phagocytosed by neutrophils) can be observed in simple, stained smears of the exudate that appears during the course of the acute disease. However, since the occurrence of the disease has serious implications for breeders, **isolation of the organism** is essential for a confirmatory diagnosis. For bacteriologic culture, specimens should be obtained by guarded swabbing of the uterus or cervix, the clitoral fossa and/or sinus as appropriate in barren, maiden, post parturient or served mares.

If the mare is pregnant, a swab of the clitoral sinus should be collected. In the stallion, swabs from the terminal urethra, its fossa, the prepuce and penis (including the pre-ejaculatory fluid) are required. To maximize the survival of *T. equigenitalis*, swabs should be held at 4°C in Amies medium (or Stewart's medium) until processed in the laboratory.

Bacteriologic examination can be supplemented by serologic investigation in acutely affected mares to detect humoral antibodies by immunosorbent assays, CFTs, passive hemagglutination tests or simple agglutination tests. These serologic procedures are not suitable for diagnosis of the infected stallion or the chronically infected mare.

Treatment and control

If an animal is infected it must not be mated until it has responded to appropriate treatment and been shown conclusively not to be a carrier. *T. equigenitalis* is sensitive to various antibiotics including those commonly available in veterinary practice. Topically applied nitrofurazone is the treatment of choice. As with other important venereal diseases, however, control best depends upon well-organized and **thorough checking** of the breeding animals before each breeding season with the aim of excluding the chronically infected animals.

There is a common **Code of Practice** (*q.v.*) for the control of CEM in France, Germany, Ireland, Italy and the UK. Stallions and mares should not be mated until it has been confirmed by a "designated" or "approved" laboratory that they are free from CEM. The procedures for the routine swabbing, certification and management of "low risk" mares, "high risk" mares, stallions and teasers and the action to be taken if CEM occurs are clearly documented in the Code.

OTHER BACTERIAL INFECTIONS OF THE REPRODUCTIVE TRACT AND MASTITIS

Pseudomonas

Pseudomonas aeruginosa is a ubiquitous, slender Gram-negative rod that produces a formidable array of virulence factors including proteases, elastases and toxin A, which inhibits protein synthesis.

P. aeruginosa can be found on normal skin and in the mucosa of the upper respiratory tract, alimentary tract and external areas of the reproductive tract in animals. It is also found in water and soil.

P. aeruginosa behaves principally as an opportunistic pathogen in domesticated animals. Its establishment and production of lesions, for example in the equine **cornea**, is usually preceded by some form of local or general **debilitation**, such as might be induced by natural or surgical trauma, burns, natural or induced states of immunosuppression or by prolonged administration of antimicrobial drugs.

Mares that have had difficulty at parturition are susceptible to infection with *P. aeruginosa*. The organism can also be transmitted to mares by an infected stallion at the time of covering. The frequent use of chlorhexidine as an antiseptic at the time of service can lead to a build-up of the numbers of *P. aeruginosa* present in the prepuce of the stallion. Venereal infection with certain serotypes of *P. aeruginosa*, for example the O3H3 group that predominate in the UK, is associated with **metritis** and even abortion (*q.v.*).

The bacteria are very easy to grow and recognize in the laboratory. Recognition is facilitated by the fact that the cells produce: (1) pigments (a greenish fluorescein and bluish-green pyocyanin) which diffuse into the agar and oxidize with time to yellow and brown, and (2) an aminoacetophenone, which smells like the ripe grape. Some strains giving a very mucoid growth on agar are commonly found in the pulmonary lesions in children with cystic fibrosis and have also been recorded in the damaged guttural pouch in a horse.

P. aeruginosa is resistant to many antimicrobial drugs. This resistance can be spontaneous or induced. The induced form can be provided by R factors or chromosomal changes. Antibiotics known to have some activity are gentamicin, tobramycin, amikacin, polymyxin B and colistin (*q.v.*).

Antibodies against the virulence factors of *P. aeruginosa* protect against the effects the organism can have. **Vaccines** are effective against the devastating disease which *P. aeruginosa* produces in young, farmed mink but in racehorses these vaccines diminish the severity and decrease the recovery time from associated corneal ulceration.

Klebsiella

Klebsiella pneumoniae produces disease in the reproductive tract of the mare. The bacterium is a markedly encapsulated, rather coccobacillary rod that can be grown easily in the laboratory. The capsule is easily recognizable in suitably stained smears and is composed of serologically distinct, heat-stable polysaccharides, the existence of which provides the basis for a typing scheme. Some 80 such serotypes are known, but of these very few (types 1, 5 and 7) appear to predominate in the diseased mare.

The bacterium is a member of the enterobacteria but is merely a minor constituent of the gut flora in normal animals. It also occurs in the general environment and can be detected in large numbers in damp wood products such as shavings or sawdust. Some mares harbor strains of *K. pneumoniae* on their urethra or clitoris. Although the stallion can therefore contract and transmit klebsiellae, the bacteria are not usually able to persist in the normal reproductive tract of mares. Hence the stallion is rarely a source of this infection. In mares an invasion of the reproductive tract leads to infertility, metritis and/or abortion (*q.v.*).

Mastitis

Acute mastitis in the lactating mare is observed most frequently when the animal is drying off. One or both glands can be affected. The infected gland is swollen, tender and painful. The infection can be sufficiently severe to produce systemic disturbance. When the changes in the gland are extreme they affect the posture and gait of the mare. The excretion is abnormal in consistency, content and cell numbers.

In the mare **prompt treatment** of mastitis is needed, otherwise there is a risk of chronicity or induration with permanent loss of secretory tissue. The cause of mastitis should be determined by bacteriologic examination of a sample of the affected milk. The specimen should be collected before any intramammary

infusion or parenteral injection of antibiotics is made. If treatment with intramammary infusions is selected, **both teat canals** in the gland should be infused.

The bacteria producing mastitis in the mare are mainly Gram-positive cocci, particularly of the genus *Streptococcus*, including *S. zooepidemicus*, *S. equisimilis* and *S. equi*, although a wide range of bacteria have been implicated.

MAJOR INTERNAL PARASITES OF HORSES

HELMINTH PARASITES

Introduction

Helminth (worm) parasites are ubiquitous in horses. Horse owners are generally aware of the fact that worms are transmitted via infective stages on pasture, and usually assume that regular worming is necessary and effective in controlling these parasites. As a result, veterinary involvement in providing advice on worm control is often not sought until obvious clinical problems arise. However, **anthelmintic resistance** in some of the most important helminth parasites of horses has become widespread. It is now crucial that veterinarians communicate to horse owners and managers of equine establishments that excellent worm control can be achieved by using knowledge of parasite life cycles and good pasture management coupled with strategic dosing only where necessary.

The major helminth parasites of horses are shown in Table 1.1. All grazing horses are likely to be infected with some or all of these worms. In general, low burdens are tolerated well, with the development of clinical disease or subclinical ill-thrift depending on the numbers and species of worm present, which in turn depends on various environmental and epidemiologic factors.

Table 1.1 Major internal parasites of horses

Type of parasite	Species involved	Predilection sites	
		Adults	Larvae
Cyathostomins	About 50 species known, 4 especially common	Large intestine	Intestinal wall
Roundworm	<i>Parascaris equorum</i>	Small intestine	Liver, lungs
Large strongyles	<i>Strongylus</i> spp., <i>Triodontophorus</i>		
Tapeworms	<i>Anoplocephala</i> spp.	Ileocecal junction	Invertebrate intermediate host (forage mites)
Lungworm	<i>Dictyocaulus arnfieldi</i>	Airways	Lung parenchyma
Roundworm	<i>Strongyloides</i> spp.	Small intestine	—
Pinworm	<i>Oxyuris equi</i>	Large intestine	Intestinal wall
Bots	<i>Gasterophilus</i> spp.	Female flies lay eggs on hairs	Stomach
Apicomplexa protozoa	Various, including <i>Sarcocystis</i> , <i>Neospora</i> , <i>Babesia</i>	Various tissues	N/A

Although **mixed infections are the rule**, a number of specific disease syndromes may emerge, for example strongyloidosis due to threadworm infection in young foals, parascariasis due to the roundworm *Parascaris equorum* in older foals and yearlings, and most important in animals of all ages, strongylosis and cyathostominosis due to infection with the large and small strongyles or redworms. A range of drugs are active against these parasites.

Three classes of anthelmintics are available for control and treatment of helminths in horses:

1. Avermectins/moxidectins
2. Pyrantel/morantel
3. Benzimidazoles.

With the rise in benzimidazole resistance (*q.v.*) among the cyathostomins, it is essential that development of further resistance be slowed through **strategic anthelmintic use** together with maximal use of complementary control methods such as **pasture management** and **dung removal**.

Generally, it is advisable to treat horses only when this is indicated by fecal egg counts, to leave a proportion of the population undosed where possible, and to rotate the drug family used annually or twice a year. In many cases anthelmintics are **overused** in horses, and the true potential of grazing management and dung removal for helminth control is not realized.

Strongylosis/cyathostominosis

The term **strongylosis** is used to describe disease caused by infection with the large strongyles (*Strongylus* spp., *Triodontophorus* spp.) and small strongyles (*Cyathostominae*). Equine strongylosis is usually due to a mixed infection with these parasites. Heavy infections, characterized by loss of condition and anemia, are common in horses of all ages, but especially in animals between 1 and 3 yr of age. There are special features associated with infection with the larval stages of small strongyles or cyathostominae, (larval cyathostominosis) and of *Strongylus vulgaris*.

Life cycles—pathogenesis

Equine strongyles comprise the **large strongyles** (three *Strongylus* spp., including *S. vulgaris*), several *Triodontophorus* spp. and over 51 species of the subfamily cyathostominae, also called “small strongyles”. All of these helminths have direct life cycles, all produce typical strongyle eggs, and all develop in a similar way on pasture: eggs hatch to release the first larval stage (L1) which then molts to the second larval stage (L2) and then the infective stage (L3) on pasture. The time taken for development through to the infective stage is dependent on ambient temperature.

In temperate climates, some eggs and larvae **survive over the winter**, serving as an initial source of infection for susceptible animals on pasture in springtime. As temperatures increase over the summer, the time taken for development to infectivity decreases, thus leading to a peak in pasture infectivity in mid-summer. In continental climates, cold temperatures during winter prevent carry-over of infectivity on pastures, and very hot, dry weather in summer may also limit the build-up of infectivity.

The parasitic phase of the life cycle, together with the pathogenesis of infection, differs between the different groups of strongyle parasites. These are dealt with separately here. The same general principles apply to the control of all of these parasites.

The **cyathostomes** or **small strongyles** are now considered to be the most common helminth parasites of horses and the cause of the most **intractable** disease problems. Although over 50 species of the subfamily (in four genera) are recognized as occurring in the horse, perhaps a dozen are commonly found, usually as mixed infections. The adult worms are found in the lumen of the cecum and colon where they feed on plugs of mucosa, leaving small **erosions and hemorrhages** at each feeding site. Adult cyathostomes contribute to the general syndrome of **ill-thrift**, anemia, and the “wormy horse” along with *Strongylus* and *Triodontophorus* spp.

Before reaching the large intestine, ingested infective larvae first burrow into the mucosa, where they may undergo a period of **hypobiosis** (arrested development) for several months or even longer before molting to L4 and L5, and emerging to mature in the lumen. The triggers for larval hypobiosis and for resumption of larval development are not well understood. However, post mortem examination has revealed that most horses have high burdens of hypobiotic larvae in the mucosa of the large intestine.

The synchronous reactivation and re-emergence of larvae into the lumen is important in the pathogenesis of larval cyathostominosis (LC). Cases of LC typically occur sporadically, in late winter or early spring, in yearlings or other young horses after a season at grass. Synchronous larval re-emergence is associated with **intense intestinal inflammatory stimuli**, rapid weight loss, sometimes diarrhea, and a poor prognosis.

The pathogenesis, still incompletely understood in terms of the inflammatory pathways and mediators responsible, is in many ways analogous to ostertagiosis in cattle occurring due to re-emergence of hypobiotic larvae (“type-2 ostertagiosis”), and is therefore also termed a “type-2” disease. Some of the triggers for re-emergence of cyathostomin larvae may include **recent anthelmintic administration**, removing the adult population of worms from the intestine, immunologic or nutritional factors.

Apart from LC occurring during larval re-emergence, the potential of large burdens of hypobiotic larvae in the lumen to interfere with neuromuscular control of intestinal motility, and to predispose to **colic**, is now widely recognized.

Strongylus spp. and *Triodontophorus* spp.

The three *Strongylus* species (*S. vulgaris*, *S. equinus* and *S. edentatus*) have migratory life cycles, with the larvae spending extended periods of time in various predilection sites before returning to mature in the large intestine. This results in relatively long prepatent periods of infection. In addition, the migratory stages of *S. vulgaris* are associated with damage to the **cranial mesenteric artery**, the resting site of predilection for larval stages, or sometimes other visceral arteries.

Larval presence in arteries results in **thrombosis** (*q.v.*), sometimes embolism, and ensuing disruption of the blood supply to the intestine and colic. Unusual but dramatic sequelae can result from long-standing damage due to repeated infections, with **aneurysm** and **fatal internal hemorrhage**.

Adult worms of these three species contribute, through plug feeding, to ill-thrift, anemia and other low-grade signs of helminth infection.

There are several *Triodontophorus* spp. that commonly occur as part of mixed strongyle infections. These worms do not undergo migration within the host, so the pathogenic mechanisms associated with infection are attributable to adult stages only, and are similar to those described above for *Strongylus* spp. One particular species, *Triodontophorus tenuicollis*, tends to feed in groups, thus leaving larger erosions on the mucosa than is the case with other strongyle worms, and may be associated with slightly more severe clinical signs.

A marked trend over recent years has been the decline in prevalence of infection with large strongyles and an increase in the incidence of disease due to the cyathostominae. This can be attributed to the greater ability of the latter to evade the action of modern anthelmintic drugs by hypobiosis and/or acquisition of drug resistance.

Epidemiology

All horses, but particularly those reared on permanent horse pastures, are susceptible to ill-thrift and anemia as a result of large burdens of adult strongyles, but horses under about 3 years of age, together with those of advanced age, more often show obvious clinical signs of infection. Signs may occur at any time of year, although pasture burdens peak in mid to late summer.

Acute cases of **larval cyathostominosis** most often occur in late winter or early spring following a grazing season in which large parasite burdens have been acquired. One animal, or sometimes a group of animals, may be affected. A common factor in many of these cases is a recent history of anthelmintic treatment. As **hypobiotic larvae are not susceptible to anthelmintics**, anthelmintic treatment has the effect of clearing out the adult worm burden, which may in turn remove signals responsible for preventing resumption of larval development. Other predisposing factors may include genetic predisposition, previous infection history and degree of acquired immunity. Individual animals experiencing the most severe clinical signs are those developing the most intense inflammatory and immunologic responses to the stimulus of larval re-emergence.

Clinical pathology

In individual cases of strongylosis, strongyle fecal egg counts are difficult to interpret since the level of egg output gives little indication of the number, species and stage of development of the worms present, either as immature adults in the gut lumen, or as hypobiotic larvae in the mucosa. However, egg counts from a group of animals sharing the same pasture are a very useful tool as a measure of potential pasture contamination, in designing and implementing worm control programs and in monitoring the success of control programs.

Although not specific, most cases of strongylosis and larval cyathostominosis will show evidence of anemia, eosinophilia and neutrophilia on hematologic examination, and serum albumin levels will be low. A hyperglobulinemia involving beta-globulins has been associated with larval infections of both the cyathostomins and *S. vulgaris*, however this is not pathognomonic of recent infection with these parasites.

Post mortem findings

At post mortem there is evidence of anemia and poor body condition associated with the presence of large numbers of different species of strongyles in the lumen of the cecum and colon and in the large intestinal mucosa. Lesions include **hemorrhagic spots or ulcers** caused by the feeding of adult parasites, with inflammation and edema of the mucosa and enlargement of associated lymph nodes.

Very large numbers of coiled, developing cyathostomin larvae may be seen on close inspection of the **mucosa** and there may be numerous **necrotic nodules** resulting from recent larval emergence; these nodules involve extensive areas of the large intestinal mucosa in cases of larval cyathostominosis.

S. vulgaris larvae may be found in association with thrombosis, inflammation and thickening of the **cranial mesenteric artery** and its main branches; infarction and necrosis of parts of the small and large intestine have been seen within a few weeks after experimental infection due to arteritis and thrombosis of small arteries close to the intestinal wall. Patches of subserosal hemorrhage may be seen as a result of the migration of *S. edentatus* larvae in the flanks.

Diagnosis

Strongylosis should always be considered in young horses that have lost condition, particularly if they are **anemic**.

The detection of strongyle eggs in the feces is of limited value in diagnosis as substantial worm burdens may be associated with fecal egg counts of only a few hundred eggs per gram due either to **low egg output** by adult worms or to the presence of many immature parasites. For example, in cases of larval cyathostominosis, fecal egg counts may be **negative** but many bright red larvae may be passed in diarrheic feces or seen on the glove used for rectal examination. In such cases there is also a history of rapid marked weight loss, and a neutrophilia and hypoalbuminemia are generally found on examination of a blood sample.

Treatment

Anthelmintics for use in horses are usually marketed for oral administration either in the feed, for example as a powder or granules, or for direct administration as a paste, gel or suspension. See also Table 10.2, page 593.

Of the three chemical groups of anthelmintics licensed for use in horses, the **pyrantel/morantel** drugs have the advantage of being effective also against tapeworms (*q.v.*) and the **avermectins** have residual activity and associated long egg reappearance times. **Benzimidazoles** have been very widely used in horses over the past 30 years, and resistance to this group is now widespread among the strongyles of horses.

In order to slow down the development of further **drug resistance** within the strongyles, anthelmintics should be used as **infrequently** as possible in horses as is compatible with health. When clinical cases of ill-thrift, anemia or diarrhea occur in individuals or groups of horses, either pyrantel or an avermectin type dose should be given, taking care to calculate the dose rate correctly. Steps should also be taken, by appropriate pasture management and strategic dosing if necessary, to prevent the conditions leading to clinical disease recurring in the future.

Cases of **acute larval cyathostominosis** carry a guarded prognosis. Some success has been achieved by administering daily doses of **fenbendazole** at 7.5 mg/kg BW for several days until the clinical signs have abated. This drug may be effective in killing larvae that are on the point of emerging into the mucosa, hence the necessity of administering daily doses.

It is clear that the clinical signs of this condition are due to an **exaggerated host inflammatory response** to emerging larvae, although much remains to be done to describe the exact mechanisms involved. Although there are few studies on the use of anti-inflammatory drugs in the management of clinical cases, logic suggests that appropriate anti-inflammatory therapy, along with anthelmintics, has a role to play.

Control

Although control programs at different equine establishments will vary according to conditions such as management and availability of grazing, the following measures will dramatically reduce the level of infection:

1. **Collect feces** frequently (up to twice weekly) during the summer and less frequently (every couple of months) in cold weather. Depending on circumstances, this can be done manually or by using specialized “pasture-sweeping” machines. Fecal collection before parasite larvae have migrated out from the fecal pat is extremely effective in reducing pasture contamination and is the **single most important measure** that can be taken to prevent problems from equine strongylosis. It is also cost effective when the reduced anthelmintic dosing requirements are taken into consideration.
2. Implement a **strategic helminth control program** involving representative fecal sampling to assess the need for strategic use of anthelmintics. Generally, helminth burdens are overdispersed, such that most of the worm burden occurs in a minority of the population. This group represents the animals most at risk of clinical disease. Ideally, only this vulnerable group should be treated. Leaving some animals undosed dilutes the selection pressure of anthelmintic use, as some larvae contaminating pastures will not have been exposed to this selection. The intervals between dosing depend on the residual period of the drug used, and the stringency of fecal collection. The chemical group of drug used (see p. 96) should be rotated **annually or biannually**, again to minimize the effect of selection on acquisition of drug resistance by helminth populations.
3. Stress the importance of additional **management factors** such as good stable hygiene and paddock rotation and/or mixed grazing, reserving the least contaminated pastures for nursing mares and their foals. At the end of the grazing season, if the animals are housed, treatment with a compound active against small strongyle larvae in the intestinal mucosa should prevent outbreaks of larval cyathostominosis during late winter or the following spring. A **5-day treatment with fenbendazole** (7.5 mg/kg BW) is one recommended regimen for this purpose. It is also good practice to dose all animals arriving from other establishments, and to isolate them for 72 h, to prevent introduction of anthelmintic resistance.

Parascariasis

Heavy infections with the roundworm *Parascaris equorum* are extremely common in foals and yearlings, the prevalence of infection decreasing with age. The main clinical sign is **unthriftiness** with rare reports of death due to impaction or rupture of the small intestine (*q.v.*).

Life cycle and epidemiology

The large adult parasites (up to 40 cm long) live in the small intestine and produce circular, sticky, typical ascarid eggs that are passed in the feces. These develop to the infective stage, which is the egg containing the L2, in a minimum of 10–14 days, and foals are infected by ingesting these eggs. *P. equorum* larvae migrate through the liver and lungs to their final site in the **small intestine** and the prepatent period is approximately 3 mo.

The important factors in the epidemiology of *P. equorum* are the high egg output of the adult worms and the ability of these eggs to survive for several years in the environment. The sticky outer coat enables the egg to **adhere to stable floors** and fittings and facilitates passive spread of the eggs.

Pathogenesis

Migration of larvae through the liver and lungs results in small, focal hemorrhagic lesions, which in the case of the liver are followed by grossly visible white areas of fibrosis. The major pathogenic effect of these parasites, however, is caused by large numbers of adults in the small intestine, which, although not responsible for gross lesions, compete with the young host for nutrients and cause marked **weight loss** or failure to thrive.

It has been shown experimentally that foals infected with *P. equorum* have **reduced gut motility**, an increase in the ratio of body water to body solids and decreased body pools of albumin.

Clinical findings

In experimental studies in young foals, **coughing** and a white/gray nasal discharge have been observed during the third and fourth week after infection when larvae are making their way, via the trachea, back to the small intestine.

Foals with large numbers of worms in the intestine often eat well and remain alert but, in spite of this, they show marked **unthriftiness** with weight loss, leading in some cases to emaciation. In foals and yearlings fatal cases due to intestinal rupture with subsequent peritonitis have been reported.

Clinical pathology

Parascaris eggs, which are circular with thick shells, are usually present in large numbers in the feces of clinically affected animals and the majority of infected animals also have low serum albumin levels.

Post mortem findings

Apart from the finding of large numbers of worms in the small intestine, which may be associated with some reddening of the mucosa, there may be

few gross lesions. The carcass will probably be emaciated and edematous and there may be small white lesions in the liver as a result of previous larval migration. In the lungs, small subpleural grayish-green lymphocytic nodules that have developed around dead or disintegrating larvae may be seen.

Diagnosis

Parascariasis is a common cause of **unthriftiness** in foals and yearlings. Infection may be confirmed by the finding of typical brown, thick-shelled, spherical eggs in feces, although fecal egg counts may vary from day to day. Anthelmintic treatment of unthrifty young foals in which fecal examination has proved negative may result in the expulsion of large numbers of well-developed but sexually immature parasites.

Treatment

Piperazine and all modern broad-spectrum anthelmintics at the usual recommended dosages are effective against *P. equorum* in the small intestine.

Control

Since it is extremely difficult to remove infective eggs already present on pasture, control measures should be aimed at preventing further contamination. This is achieved by scrupulous anthelmintic dosing of foals. Treatment should begin at **1–2 mo of age** to remove parasites before they start laying eggs, which would otherwise become available to infect foals of the same or succeeding generations. Where possible, mares and foals should avoid **for several years** pastures previously grazed by young animals.

Strongyloidosis

Infection with the threadworm *Strongyloides westeri* is common in foals aged 2 wk to 4 mo but seldom persists in animals >6 mo of age.

Life cycle and epidemiology

Foals are commonly infected by the larvae in their **dams' milk** but infection may also occur by ingestion or from **penetration of the skin** by infective larvae. The prepatent period of *S. westeri* is 8–14 days and eggs can be found in foals' feces before 2 wk of age.

Although animals may be infected from larvae in the environment, the main source of infection for **sucking foals** appears to be the reservoir of larvae in the tissues of the mare. How these larvae are acquired, stored and migrate to the mammary gland is not well understood, but it is possible that in immune animals infective larvae penetrating the skin may be inhibited in development until triggered to migrate to the mammary gland in late pregnancy/early lactation. Successive foals from certain mares appear to suffer heavy infections.

Heavy, clinically significant infections are most likely to be found in animals housed in **unhygienic conditions** or in foals with an underlying immunodeficiency (*q.v.*).

Pathogenesis

Heavy infections may cause enteritis and diarrhea associated with inflammation of the anterior third of the small intestine, with atrophy of the villi and increased numbers of lymphocytes in the lamina propria.

Clinical findings

In severe infections, diarrhea may occur up to 4–6 wk of age. Older foals may have high fecal egg counts without any clinical signs.

Clinical pathology

Although thin-shelled larvated eggs may be found on examination of diarrheic feces from infected foals, the presence of these eggs in some cases may be incidental.

Diagnosis

Diagnosis is based on the occurrence and persistence of yellowish diarrhea in very young foals associated with the presence of large numbers of typical eggs in the feces. Diagnosis may be confirmed retrospectively by a rapid response to suitable anthelmintic treatment.

Treatment

Benzimidazoles or avermectins are recommended for the treatment of clinical infections, at manufacturers' recommended dose rates.

Control

Attempts to treat mares to prevent infection of foals have been largely unsuccessful, daily treatments being required to prevent larvae being passed in the milk.

Where strongyloidosis is a **recurring problem** on a stud, routine anthelmintic treatment of 1–2-wk-old foals with avermectins or pyrantel has been reported to be beneficial. Attention should also be paid to improving environmental conditions.

Lungworm infection

Although larvae of the equine lungworm *Dictyocaulus arnfieldi* are frequently found in fecal samples from **donkeys**, infection is **rarely** associated with signs of respiratory disease in this host.

In horses, on the other hand, lungworm infection is often incriminated as a cause of **chronic coughing**. The true prevalence of infection in the horse is not known since larvae are rarely found in the feces (except in foals and occasionally in pregnant mares).

Life cycle and epidemiology

Infection occurs by ingestion of infective third-stage larvae (L3) on pasture. These larvae then travel from the intestine via the lymphatics and blood to the

lungs where they develop to the adult stage in the **bronchial tree**. Adult females produce larvated eggs, which are passed in the feces, but these hatch almost immediately to first-stage larvae. The prepatent period is a minimum of 2 mo.

The epidemiology of lungworm infection in horses is poorly understood but in the majority of confirmed cases there is a history of previous contact with **donkeys**. In the donkey, patent infections usually establish during the first season at grass and, in the absence of anthelmintic therapy, the majority of animals subsequently remain infected throughout their lives.

Pathogenesis

The presence of worms in the lungs produces valve-type lesions that lead to discrete, 3–5 cm areas of overinflation. Although infection is well tolerated in donkeys, the presence of lungworms in the horse can lead to chronic coughing.

Clinical signs

Despite the prevalence of *D. arnfieldi* in donkeys, clinical signs directly attributable to lungworm infection are rarely seen. In the horse it has been shown that infection of young foals is associated with the development of patent infections in the absence of clinical signs. Infection of horses and ponies >1 yr of age does not usually result in the establishment of patent infections but may be associated with marked clinical signs including coughing, increased respiratory rate and adventitious lung sounds. It is also possible to detect **lungworm larvae** in feces samples from a very small proportion of apparently healthy horses (most often foals and pregnant mares).

Clinical pathology

Laboratory tests are of little value in the diagnosis of lungworm infection in the horse. In very few cases, chronic coughing may be associated with a patent infection with first-stage larvae being found in feces. In contrast, in donkeys, larvae are frequently found in the feces of apparently normal animals.

Post mortem findings

Grossly raised circumscribed areas of **overinflation** are visible if the lungs are examined soon after death but these can gradually disappear and may not be obvious if post mortem examination is delayed.

Microscopically, there is hyperplasia of the bronchial epithelium, an increase in the size and number of goblet cells and infiltration of lymphoid cells around the airways. Often only a few parasites are present coiled up in the lower bronchi and these are difficult to recover.

Diagnosis

Diagnosis is based on history, clinical signs and examination of feces for *D. arnfieldi* larvae, although in the horse patent infections are not common. A modified Baermann technique is used to examine fecal samples for lungworm larvae. It is important to use fresh feces taken from the rectum, otherwise free-living and first-stage strongyle larvae may be present in fairly large numbers and make examination for first-stage *D. arnfieldi* larvae difficult.

Treatment

Clinical trials have indicated that **fenbendazole** at a dose rate of 15–30 mg/kg is successful in the treatment of horses while in a controlled trial in donkeys treatment with **mebendazole paste** at a dose rate of 15–20 mg/kg daily for 5 days was shown to have 75–100% efficiency against parasites in the lungs. However, **ivermectins** at manufacturers' recommended dose rates are probably the treatment of choice.

Control

To reduce the risk of infection in horses, contact with **untreated donkeys** should be avoided. To reduce the overall level of infection in donkeys, regular treatment (every 8 wk) with ivermectin is recommended: fecal samples collected at the time of treatment should be examined to monitor the effectiveness of such a treatment regimen.

***Oxyuris equi* infection**

Infection with the horse pinworm *Oxyuris equi* is relatively common, especially in young animals. The female worms lay eggs around the anus, which causes a **perineal pruritus**. Broken hairs and occasional bare patches on the tail are caused by rubbing in response to the pruritus and on lifting the tail the egg masses are seen as grayish/yellow streaks on the perineum.

Oxyuris is susceptible to all of the modern broad-spectrum anthelmintics (see p. 96) and should be adequately controlled by routine parasite control measures.

TAPEWORM INFECTIONS

Anoplocephala perfoliata is the common tapeworm of horses.

Epidemiology and pathogenesis

Infection is by ingestion of **forage mites** containing the intermediate cysticercoid stage. Occasionally specimens 4–5 cm long and resembling large flukes are found in feces.

A. perfoliata occurs in the small intestine and cecum near the ileocecal valve, and is often seen in association with **erosive changes** in the mucosa. The occurrence of several *A. perfoliata* worms at their predilection site around the ileocecal junction is associated with interference with passage of ingesta through this "bottleneck", and with some cases of spasmodic colic (*q.v.*). Whereas this parasite was formerly regarded as a minor, occasional pathogen, there is now sufficient evidence of its involvement in colic to warrant specific control measures being taken.

Diagnosis

McMaster examination (*q.v.*) or fecal flotation may reveal typical *A. perfoliata* eggs which are distinctive with an internal "**pyriform apparatus**". However, low numbers of eggs may be missed using this method. An ELISA is available for serologic diagnosis and not only detects infected horses but can also estimate the extent of the parasite burden.

Treatment and control

A double dose of pyrantel (13.2 mg/kg BW) is recommended for eliminating *Anoplocephala* burdens. This should be administered **in addition** to other anthelmintic treatment in years in which other chemical groups are used for roundworm control.

BOTS

Infection with horse bots is common, as evidenced by the frequent finding of bot fly (*Gasterophilus* spp.) larvae in the stomach at post mortem examination, and the presence of fly eggs on the hairs of many horses during the later summer and autumn.

In temperate areas bot flies have only one generation per year. The flies are active during July to September and during this period eggs are laid. After hatching, the larvae migrate and develop in the stomach for 9–10 mo. When they mature the following June they are passed out in feces to pupate and develop to the adult stage. In tropical and subtropical areas bot flies can survive throughout the year and infection cycles are continuous.

The pathogenic significance of bot larvae in the stomach is not well understood but the **adult flies** may cause a great deal of annoyance when approaching horses to lay their eggs.

From the life cycle it is obvious that removal of the bots after they have accumulated in the stomach during the late autumn and winter will effectively break the life cycle. Drugs with a high activity against developing bot larvae in the stomach are **ivermectin, dichlorvos and metrifonate**.

OTHER INTERNAL PARASITES OF HORSES

Several less common or less important helminth parasites that may infect horses are the stomach worms *Trichostrongylus axei* and *Habronema* spp., and the liver fluke *Fasciola hepatica*. Horses also harbor the intermediate hydatid cyst stages of the tapeworm *Echinococcus granulosus*.

TRICHOSTRONGYLOSIS

Trichostrongylus axei, a common parasite of ruminants, can infect horses but burdens are usually low. The life cycle is direct, infection occurring by ingestion of L3 from pasture. Following ingestion, larvae invade the gastric mucosa and lesions develop as circular thickened areas several centimeters in diameter. Experimentally infected animals have shown diminished appetite and progressive weight loss but infection is usually asymptomatic. Treatment is rarely called for but *T. axei* is susceptible to most broad-spectrum anthelmintics.

HABRONEMIASIS

Although *Habronema* spp. infections are common they are rarely considered important and are usually discovered only at post mortem examination, sometimes in association with a mild chronic, catarrhal gastritis. One species,

H. (Draschia) megastoma, provokes the formation of **large fibrous nodules** in the stomach, but even these are well tolerated unless they occur close to the pylorus. Treatment against adult worms is rarely called for.

The chief importance of *Habronema* spp. is as a cause of **cutaneous habronemiasis** (*q.v.*) or “summer sores” in warmer climates. **Ivermectin** is the drug of choice for the treatment of skin lesions but several doses may be required depending on the response. Control is almost impossible due to the ubiquity of the fly intermediate hosts but treatment of skin wounds with fly repellents may reduce the incidence of “summer sores”.

FASCIOLIASIS

Most mammals may be infected with *Fasciola hepatica* but infection of horses is perceived as relatively uncommon. However, in spite of infrequent ante mortem diagnosis, **liver flukes** are quite a common **incidental finding** at post mortem examination.

Although eggs of this parasite may be found in the feces of horses and donkeys grazing in known “fluke” areas, clinical signs of infection such as loss of weight, poor performance and anemia are rare. Successful treatment has been reported with rafoxanide, oxcylozanide and triclabendazole. The advent of reliable serologic diagnostic tests will provide a useful tool for investigating the true prevalence and clinical significance of this parasite in horses.

HYDATIDOSIS

Hydatid cysts are often seen at post mortem examination, situated mainly in the liver but occasionally in other organs. They may occur as a few large spherical cysts projecting from the surface, or as many small cysts scattered throughout the parenchyma. Infection appears to be completely tolerated.

Equine hydatidosis is not a public health problem since the subspecies involved, *Echinococcus granulosus equinus*, has an exclusively dog-fox/horse cycle and has never been found in other animals. *E. multilocularis* has occasionally been reported in horses.

ALIMENTARY PROTOZOA

A number of enteric protozoan parasites such as *Cryptosporidium*, *Eimeria* (*Globidium*) *leuckarti*, *Giardia* and *Tritrichomonas* spp. have been reported occasionally as causes of **clinical enteritis** in the horse.

Although *Cryptosporidium* has been incriminated as a cause of diarrhea in immunocompromised foals and in young animals with concurrent viral infections, the true pathogenic significance of this parasite in the horse is poorly understood. At present there are no therapeutic agents with known efficacy against *Cryptosporidium*.

In the case of *Giardia*, *Tritrichomonas* spp. and coccidiosis due to *E. leuckarti*, there are some reports of infection associated with diarrhetic syndromes of varying severity. These are generally considered to be of fairly minor pathogenic significance.

BLOOD PROTOZOA

Several blood protozoa may be responsible for serious infections in horses, especially in the tropics and subtropics, for example tick-transmitted *Babesia* and some *Trypanosoma* species.

Piroplasmosis (babesiosis)

Equine piroplasmosis caused by *Babesia caballi* and *B. equi* (syn. *Theileria equi*) occurs in many parts of the world including Europe, Asia, Africa and the Americas and there are endemic foci of *B. caballi* infection in the southern USA.

These organisms are transmitted by **ticks** of the genera *Dermacentor*, *Hyalomma* and *Rhipicephalus*. The pathogenic effects of different strains of equine *Babesia* are variable and clinical signs include anorexia, fever and anemia; jaundice and hemoglobinuria may accompany *B. equi* infection. Horses raised in endemic areas are often **asymptomatic carriers** due to premunity (*q.v.*) and may only show clinical signs when **stressed**.

Diagnosis is based on clinical signs and the demonstration of parasites in the **red blood cells** in acute cases. A CFT may be used to detect parasite antibodies within 5 days of infection and a negative CFT is required for all horses entering the USA from endemic areas. Molecular tests are now also available.

A number of drugs, including imidocarb, diminazene and buparvaquone, are recommended for the treatment of equine piroplasmosis but for all drugs the manufacturers' doses and instructions should be carefully observed.

Trypanosomosis

Equine trypanosomosis may result from infection with *Trypanosoma congolense*, *T. vivax*, *T. brucei* and *T. evansi*, which are transmitted by tsetse flies and other biting flies. Horses may also suffer from a chronic wasting disease, **dourine**, caused by a venereally transmitted species, *T. equiperdum*. A summary of some of the main features of the diseases caused by trypanosome infection in horses is given in Table 1.2.

Table 1.2 Equine trypanosomosis

Disease (distribution)	Trypanosome species involved	Method of transmission	Major clinical signs
Nagana (Africa; also South America— <i>T. vivax</i>)	<i>T. congolense</i> <i>T. brucei</i> <i>T. vivax</i>	Tsetse transmission. Also mechanical, by biting flies in <i>T. vivax</i>	Acute-chronic disease. Intermittent fever, anemia, weight loss, edema of limbs and genitalia
Surra, mal de caderas (Africa, South America)	<i>T. evansi</i> <i>T. equinum</i>	Mechanical. Biting flies and vampire bats	Often acute. Similar to nagana with progressive paralysis of hindquarters in chronic cases
Dourine (Africa, Asia, South America)	<i>T. equiperdum</i>	Coitus	Genital and ventral edema, progressive emaciation, ascending motor paralysis, in some cases fatal

Diagnosis in most cases depends on clinical signs and the demonstration of **trypanosomes in the blood**. A CFT is necessary in the case of *T. equiperdum* infection. A number of trypanocidal drugs can be used in the horse including **quinapyramine, ethidium and suramin**.

TISSUE PROTOZOA

A number of protozoan parasites occur in the tissues of horses, for example species of the genus *Sarcocystis* in the muscles and *Klossiella equi* in the kidneys. With a couple of notable exceptions, these are of minor pathogenic significance, being incidental findings on routine histopathology.

Equine protozoal myeloencephalitis

Equine protozoal myeloencephalitis (EPM), identified in North America, is characterized by various degrees of gait abnormalities, ataxia, paresis, weakness and asymmetrical hypermetria.

Etiology and life cycle

The organism responsible for most cases of EPM is *Sarcocystis neurona*, which like other members of the Sarcocystidae has an indirect life cycle, using the **opossum** as definitive host and various species of mammals (terrestrial and marine) and birds as intermediate hosts.

The life cycle is typical of the genus *Sarcocystis*, with oocysts or free sporocysts in the feces of the definitive host infecting intermediate hosts by the oral route.

Horses are not as permissive of the intermediate stages of life cycle as other intermediate hosts. Parasite stages in the **brain and spinal cord**, and the host response to them, are responsible for eliciting clinical signs in some animals, although many animals are infected with no apparent clinical consequences.

Epidemiology

Horses may become infected if they graze areas contaminated by **opossum feces**. Other species capable of acting as intermediate hosts and maintaining an infection reservoir include cats and raccoons, as well as some species of birds.

Serologic evidence indicates that up to 50% of horses in the USA have been exposed to the causative agent. Most clinical cases have been described in North America but there are also cases documented in horses imported into various countries from the USA. Recently, cases similar to EPM have been described in horses in France that had never been overseas. The epidemiology and precise etiology of these cases have not yet been established. Recently, *Neospora* spp., in particular *Neospora hughesi*, was implicated in some cases of protozoal encephalitis in horses.

Pathogenesis and clinical signs

Clinical signs are variable depending on the site of the **multifocal necrotic lesions**, which may occur in any part of the **CNS**, but most cases show

weakness, ataxia and muscle wasting, often with a history of a **long-standing vague lameness**.

The fact that many horses are infected without showing clinical signs points to involvement of host immunologic factors in the development of disease. Without treatment, most cases show **progressive deterioration**.

Diagnosis

A major problem in making a specific diagnosis in any disease caused by a *Sarcocystis* spp. is that of specificity. This is because various species of the genus commonly infect most mammals with few or no clinical implications. These share considerable serologic cross-reactivity with those few species that are clinically relevant.

Western blotting, using CSF samples reacted with separated antigens of *S. neurona*, is regarded as a reliable diagnostic test for EPM. The Western blot test is highly sensitive, but not very highly specific. As a result, a negative result can be regarded as ruling out EPM but a positive result may be false. In doubtful cases, examination of paired CSF samples may be necessary. At post mortem examination, immunocytochemical and PCR detection of parasites is also useful in confirming a diagnosis.

Treatment and control

Many cases, especially if diagnosed relatively early, respond well to treatment. Based on clinical experience, **pyrimethamine** combined with **sulfonamides** given over a prolonged period (150–180 days) gives good results, especially with the inclusion of anti-inflammatory drugs such as flunixin meglumine (at 1.1 mg/kg BW). Other effective compounds include **ponazuril** (5 mg/kg BW PO s.i.d. for 28 days) and related drugs.

Preventing opossums, feral cats and wildlife from accessing land grazed by horses is a commonsense control measure.

Neosporosis

Neospora caninum first came to attention as a pathogen of domestic animals in 1988 when it was recorded as being responsible for some cases of neuromuscular signs and ataxia in dogs previously attributed to *Toxoplasma gondii*. In the years since then, the parasite has become recognized as a very important cause of bovine abortion, as well as congenital and other disease in dogs. In 1998, it was established that the dog is the definitive host of *N. caninum*, although an inefficient one, producing only very low oocyst numbers following experimental infection. The existence of another definitive host, such as a wild canid, is still suspected. Infection in cattle may occur via exposure to a point source of infection, such as the feces of infected dogs, but vertical transmission is more important in maintaining infection in herds. Bovine infection is often subclinical, except during pregnancy, when an acute infection or reactivation of a chronic infection can occur, sometimes leading to fetal resorption, abortion, or birth of weak calves. The pathogenic mechanisms involved probably include a combination of direct fetal infection and immunopathology. *Neospora* infection is now recognized as being common in other species including horses.

Epidemiology and pathogenesis

Recent molecular studies have indicated that a *Neospora* parasite distinct from that found in cattle infects horses. This has provisionally been classified as a separate species, *Neospora hughesi*.

There have as yet been only a limited number of studies of *Neospora* infection in horses. At present it is safe to say that it is potentially a cause of **reproductive failure** as well as neonatal problems and neurologic disease, and should be considered as a differential diagnosis in such cases.

Diagnosis

There are several serologic assays available for neosporosis including an indirect fluorescent antibody test (IFAT), direct agglutination and ELISA.

Treatment and control

In dogs, clindamycin is effective in alleviating clinical signs in the early stages of disease. By extension from the situation with toxoplasmosis in sheep, in-feed medication with **monensin** may be effective in preventing maternal infection during pregnancy. However, there are no reliable data to support treatment regimens for neosporosis in horses. The recommendations for the treatment of EPM (*q.v.*) may be followed.

EQUINE IMMUNOLOGY

INTRODUCTION

Advances in immunology and technology have contributed significantly to the understanding of fundamental concepts of disease, to the identification of preventive methods and to the evaluation of treatment responses. Nevertheless, many areas in the field of equine immunology await reagents and technical

capabilities to expand our knowledge of the mechanisms involved in many infectious and non-infectious processes.

The development and characterization of **monoclonal antibodies** for equine molecules and the **decoding of the horse genome** are dependent on a cooperative effort among investigators concerned about the well being of the horse. When available, however, traditional and state of the art techniques can be used to reveal the role of immune cells in the pathogenesis and regulation of diseases. This chapter reviews the major conditions of the horse that directly involve the immune system and indicates the available diagnostic resources for the identification and monitoring of these processes.

A glossary of principal **immunologic terminology** is given in Box 2.1.

Box 2.1 A glossary of immunologic terms

Adjuvant: a substance that enhances the immune response to antigens.

Allele: any one of a number of alternative forms of the same gene occupying a given locus (position) on a chromosome.

Allergen: an antigen that induces IgE-mediated hypersensitivity reactions.

Alloantibody: antibody produced against a protein of an allele from another member of the same species and which can function as an antigen.

Anaphylatoxin: activated complement components (C3a, C5a) that induce mast cell degranulation.

Antibody: protein with specific binding properties produced by plasma cells in response to antigenic exposure.

Antigen: foreign molecule that can induce an immune response.

Antigen-presenting cell (APC): specialized type of cell (dendritic cells, macrophages) that can process and present antigens to lymphocytes.

Antigen processing: breakdown of molecules into peptides that can be presented to lymphocytes via major histocompatibility molecules.

Antigen receptor: the specific antigen-binding receptor on T (T cell receptor) or B (B cell receptor) lymphocytes.

B lymphocyte (B cell): lymphocytes that develop in the bone marrow, finish their maturation and differentiation in the periphery, and become antibody-secreting cells.

Blocking antibody: antibody molecule capable of blocking the interaction of antigen with other molecules.

Cell-mediated immunity: immune response mediated by T cells, often CD8+ T cell cytotoxic response.

Chemotaxis: directional migration of cells toward a concentration gradient of an attractant (chemotactic substance).

Classical pathway: the mechanism of complement activation initiated by antigen–antibody aggregates that induces the activation of C1, C4 and C2 components.

Cluster of differentiation (CD): cell surface molecules (markers) of leukocytes that can be identified by monoclonal antibodies to differentiate cell populations.

Complement: group of serum proteins involved in inflammation, phagocyte activity and lysis of cell membranes; the complement cascade is triggered classically by the interaction of antibody with specific antigen.

Complement receptor: a structure that binds C3 fragments found on phagocytes (neutrophils, monocytes and macrophages) and lymphocytes (B cells).

Coombs test: a test used to detect antibodies or complement on red blood cells using anti-immunoglobulin antibodies.

Cytokines: soluble substances secreted by cells, which have a variety of effects on other cells.

Cytotoxic T cell: lymphocyte (CD8+ T cell) that kills infected cells expressing processed antigen peptides via major histocompatibility class I.

Dendritic cells: cells present in tissues that capture and process antigens, migrate to regional lymph nodes and present processed antigen peptides to T lymphocytes.

Glossary continues on page 115

Box 2.1 A glossary of immunologic terms [continued]

Enzyme-linked immunosorbent assay (ELISA): assay that measures quantitatively the amount of a substance using enzyme-conjugated antibodies and a substrate that produces a colored end-product upon binding of the enzyme.

Epitope: part of the antigen that contacts the antibody or T cell receptor.

Fc receptor: receptor on a cell surface with specific binding affinity for the Fc portion of an antibody molecule.

Flow cytometry: analysis of cell populations in solutions according to their size, granularity and fluorescence of cell markers detected by fluorescent monoclonal antibodies.

Fluorescent antibody: antibody conjugated with fluorescent dye often used in flow cytometric analysis and immunofluorescent assays.

Germinal centers: distinct areas in secondary lymphoid tissues (spleen, lymph node) in which B cells aggregate and go through differentiation and antibody class switching.

Helper T (Th) cells: class of T cells (CD4+ T cells) that help B cells to produce antibody and generate cytotoxic CD8 T cells; helper T cells recognize processed antigen peptide presented via major histocompatibility class II.

Humoral response: immune response mediated by antigen-specific antibodies present in serum and tissues.

Hypersensitivity: state of reactivity to an antigen that is far greater than the antigenic challenge presented.

Idiotype: the combined antigenic determinants (idiotopes) found in the variable region of antibodies.

Immune complex: antigen bound to antibody that may or may not contain complement components.

Immunoglobulins: proteins (antibodies) produced by plasma cells. There are five main types of antibodies: IgA, IgD, IgE, IgG and IgM.

Immunomodulators: substances that enhance or decrease non-specifically the immune response.

Immunosuppression: a mechanism (treatment) for producing a specific state of immunologic unresponsiveness.

Interferons: proteins with antiviral activity, which are involved in signaling between cells.

Interleukins: glycoproteins secreted by a variety of leukocytes, which are involved in signaling between cells.

Isotypes: classes of antibody that differ in the constant region of their heavy chain (Fc portion).

Isotype switching: the shift of a B cell from the secretion of antibody of one isotype (e.g. IgM) to a different isotype (different heavy-chain, e.g. IgG).

Leukotrienes: metabolites of arachidonic acid involved in inflammation.

Lymphokine-activated killer cells: cytotoxic cells generated ex vivo by stimulation with IL-2.

Major histocompatibility complex (MHC): cluster of genes encoding cell surface molecules that are polymorphic (multiple alleles at a particular genetic locus); this polymorphism codes for antigenic differences that can lead to graft rejection between members of a single species; the molecule is also involved in processed antigen peptide presentation to CD8+ T cells (MHC class I) and CD4+ T cells (MHC class II).

Mitogen: substance that stimulates the proliferation of many different clones of lymphocytes (e.g. phytohemagglutinin, PHA; concanavalin A, ConA; pokeweed mitogen, PWM; lipopolysaccharide, LPS).

Monoclonal antibody: antibody that is produced from a single A clone is the progeny of a single cell. In immunology, monoclonal generally describes a preparation of antibody that is monogenous, or cells of a single specificity.

Opsonin: antibody or complement component that coats a foreign particle (opsonization) to enhance phagocytosis by phagocytic cells.

Oxidative (respiratory) burst: increased oxidative metabolism within phagocytic cells stimulated by the phagocytosis of organisms; the reactive oxidative products that originate from this metabolism have killing properties.

Passive immunity: preformed antibody solution (e.g. colostrum, plasma) transferred to an individual.

Phagocytosis: the engulfment of a particle or a microorganism by phagocytes (neutrophils, macrophages); phagocytosis is facilitated by the binding of immunoglobulin- or complement-coated particles to the Fc receptors on the cell surface.

Primary immune response: cellular and humoral response to the first encounter with antigen; in general, this response has a long induction phase.

Protein A: component of the cell wall of certain staphylococci that binds the Fc portion of most IgG antibodies.

Glossary continues on page 116

Box 2.1 A glossary of immunologic terms [continued]

Reticuloendothelial system: network of phagocytes present in the liver and spleen, which remove abnormal circulating cells (e.g. antibody-bound erythrocytes).

Secondary response: cellular and humoral immune response that follows a subsequent encounter with a known antigen; often this response is faster and more specific than the primary response.

T cell: lymphocyte originating in the bone marrow that goes through differentiation and selection in the thymus.

Toxoid: nontoxic derivative of a toxin used as an antigen for the induction of antibodies.

VACCINATION

Vaccination is an important component of disease prevention programs and it is a relevant example of **modulation of the immune system**. The development of an effective vaccine requires detailed knowledge of the organism, the host's natural immune response to it, and risk factors of disease. Therefore, microbiologists, immunologists and epidemiologists work together in the design of vaccination programs. Great effort is dedicated to discovering vaccine elements that stimulate, similar to natural infection, a long-lived protective immunity with humoral and cellular components at the systemic and mucosal levels.

Serious **side effects** to vaccines, including anaphylactic or anaphylactoid reactions, swellings and abscesses at the injection site, laminitis and death, are rare. **Fever and malaise** are however expected, and they are **indicators of response** to the vaccine. In general, the small risk of vaccine side effects is greatly outweighed by the benefits.

All vaccine products must go through safety tests before commercialization. The same requirement is not always true for tests that evaluate **efficacy**. Rarely, there is scientific evidence of efficacy from experimental challenge trials, and the estimation of protection is often taken from clinical and epidemiologic observations. In addition, almost no data are available on the efficacy of multivalent vaccines. Although immunization with different antigens is practical, differences in the risk of exposure (e.g. time of the year, age and group of risk), the duration of immune protection to each antigen, and the quality of the desired immune response may require dissimilar frequencies of vaccine administration.

Types of vaccines

There are two main categories of vaccines:

1. **Dead or inactivated vaccines:** these vaccines contain the whole inactive pathogen or selective antigenic elements of the pathogen; they induce mainly humoral immunity, however DNA vaccines may induce both humoral and cell-mediated immunity.
 - (a) **Chemically inactivated whole pathogen vaccines**—immunogenic and easy to prepare vaccines that require adjuvants and regular boosters
 - (b) **Protein vaccines**—naturally produced protein of organisms that are used as antigens; also require adjuvants

- (c) **Recombinant subunits vaccines**—synthetic production of antigenic peptides using expression systems to retain immunogenicity of the native protein; require the knowledge of a pathogen antigen that is important for immunity and adjuvants
 - (d) **DNA vaccines**—the objective is to mimic natural immune response by the *in vivo* synthesis of antigenic proteins with both MHC class I and MHC class II antigen presentation, hence both cytotoxic and antibody responses.
2. **Live vaccines:** the attenuated organism is able to invade a cell and use its replication machinery. Therefore, the organism is processed by the endogenous pathway for MHC class I presentation to generate cytotoxic T cells (CTLs), and MHC class II presentation to generate long-lasting humoral responses.
- (a) **Modified live vaccines (MLV)** are modified organisms that have attenuated pathogenicity but still replicate in the vaccinated animal; the organism may be attenuated in cell culture by growing it in abnormal conditions, by the creation of temperature-sensitive mutants (random mutants that may reacquire virulence), by using recombinant DNA technology for predicted deletion mutation that cannot be reversed, or by using variant forms of the organism that affect other species.
 - (b) **Recombinant vector vaccines (RVV)** are engineered bacteria or viruses (vaccinia virus) that become carriers (vectors) of selected antigenic peptides from other pathogens. The bacteria or virus infect cells in the host and carry a target peptide that is known to induce a protective response against the organism. A variant of this type of vaccine is a multivalent vaccine in which one modified-live virus of interest carries another virus peptide.

Vaccination programs

A **vaccination program** should be tailored according to the degree of exposure to pathogen, number of animals in the herd, age groups involved, type of activity, horse transit, degree of stress, geographic location, management and hygiene and ventilation of the facilities housing the horses.

Primary and secondary vaccinations should be timed to precede the period of greatest exposure to the organisms. In addition, **all the animals of the herd should be vaccinated at the same time** to minimize replication of the infectious organisms and increase the protection of those animals that respond poorly to the vaccine.

It is possible that **maternally derived antibodies may interfere with antigenic response** and endogenous antibody production in foals. Ideally, vaccination of the foals should be performed after antigen-specific serum maternal antibody levels decline. In general, colostral IgG half-life is 28–35 days; however, specific antibodies may be transferred to the foal in different concentrations, and their catabolism may depend on environmental challenge.

The protocol for the immunization of foals has been revised because of a better understanding of the foal's immune response to distinct vaccines in early life. Nevertheless, vaccination of foals is initiated around 3–6 mo of age,

followed by one to two boosters 3–4 wk apart. In addition, vaccination of mares in **late gestation** against agents that are responsible for disease in early life is recommended in order to confer passive transfer of organism-specific immunoglobulins, e.g. rotavirus (*q.v.*) and *Clostridium botulinum* (*q.v.*).

HYPERSENSITIVITY REACTIONS

Hypersensitivity reactions are **immune responses to previously encountered antigens** with subsequent detrimental effect to the host. The classification of hypersensitivity reactions is based on the type of cells and the immune mediators that promote tissue injury:

TYPES OF REACTION

1. **Type I hypersensitivity reactions** are mediated by antigen-specific IgE, mast cells, basophils and their mediators. Examples are urticaria (*q.v.*), insect-bite hypersensitivity (*q.v.*) and food allergy.
2. **Type II hypersensitivity reactions** involve autoantibodies IgM or IgG against specific (often self) cell surface or extracellular matrix antigens. Subsequently, there is opsonization and phagocytosis of these cells and complement- and/or Fc receptor-mediated cell destruction. Examples include autoimmune hemolytic anemia (*q.v.*), thrombocytopenia (*q.v.*), incompatible blood transfusions, pemphigus foliaceus (*q.v.*) and drug hypersensitivity (*q.v.*).
3. **Type III hypersensitivity reactions** are promoted by the random deposition of immunocomplexes of circulating antigens (self or foreign) and IgM or IgG antibodies in blood vessels, with subsequent complement- and Fc receptor-mediated recruitment and activation of leukocytes and vasculitis. Examples include serum sickness (antisera passive immunization) (*q.v.*), glomerulonephritis (*q.v.*) and purpura hemorrhagica (*q.v.*).
4. **Type IV hypersensitivity reactions** do not involve antibodies and are mediated by sensitized CD4⁺ T cells (Th1 response) and CD8⁺ T cells (direct cytotoxic effect), which induce infiltration of macrophages and inflammation mediated by cytokines. An example is contact dermatitis (*q.v.*).

Homeostasis is widely dependent on a protective and balanced response of the immune system, which involves complex and redundant regulatory mechanisms. Occasionally, the immune system responds to a non-self structure or a danger signal with extreme properties that may lead to disease. In these conditions, selective activation or suppression of specific responses without affecting peripheral immune function becomes necessary.

ANAPHYLAXIS AND ANAPHYLACTOID REACTIONS

Anaphylaxis is a severe form of immediate hypersensitivity that manifests within minutes following exposure to an allergen (e.g. insect bite/sting, drugs

or vaccines, food). The hypersensitivity reaction involves a primary exposure to an antigen, CD4+ T cell cytokine-mediated activation of B cells for the production of IgE, and the binding of IgE to receptors on mast cells and basophils. Upon a successive exposure to the sensitizing antigen, its cross-linking with IgE triggers the release of mediators in cytoplasmic granules. These mediators (histamine, tryptase, leukotriene [LT] C₄, prostaglandin [PG] D₂, tissue necrosis factor [TNF]) **cause early effects** of vascular permeability and dilatation, and **late effects** of inflammation that last approximately 24 h.

The more rapid the onset of clinical signs, the more severe is the event. The release of allergic mediators may lead to mild effects including nasal swelling, urticaria, erythema and pruritus. However, anaphylactic responses may be moderate to severe and lead to **vasculogenic shock** characterized by hypotension (vasodilation, increased vascular permeability, reduced venous return, cardiac arrhythmias, myocardial ischemia), **difficulty in breathing** (increased bronchial smooth muscle tone, increased mucosal secretion, laryngeal edema, pulmonary edema), and **death**. In addition, there may be **gastrointestinal clinical signs** including colic and diarrhea.

Anaphylactoid reactions are anaphylactic-like reactions that do not involve IgE. The degranulation of mast cells and basophils is directly induced by the agent (e.g. drug) and activation of complement cascade components C3a and C5a. Therefore, this type of reaction may happen at the **first time of exposure** to the molecule. Nevertheless, the vasogenic effects, clinical signs and treatment do not differ from the anaphylactic reaction.

Confirmation of anaphylactic and anaphylactoid reactions may be pursued by measuring **serum or plasma tryptase** (peak concentration in 1 h of exposure) or **methyle histamine** in the urine (collect the second urine sample after exposure to antigen).

Anaphylaxis is an **emergency** condition that requires immediate diagnosis and treatment. **Epinephrine** (adrenaline) (0.01 mL/kg BW of a 1 mg/mL solution, IM) should be given by injection without delay. Epinephrine has positive inotropic and chronotropic effects, increases cardiac output, and promotes peripheral vasoconstriction and bronchodilation. **IV fluid therapy** may assist in fighting hypotension but should be used cautiously in the event of pulmonary edema; hence, **colloids** should be considered. **Airway patency** should be assessed and endotracheal intubation or tracheotomy considered in cases of severe angioedema.

After lifesaving measures and epinephrine administration, **antihistamines** (both H₁ and H₂ blockers) and **corticosteroids** (methylprednisolone 20–30 mg/kg BW IV slowly) may be given to further reduce clinical signs. **Bronchodilators** (β₂ adrenergics such as albuterol, clenbuterol, salmeterol) (*q.v.*) and oxygen therapy may also be used in severe cases.

Anaphylactic reactions can be uniphasic, biphasic or protracted. In the **uniphasic reaction**, clinical signs resolve within hours. In the **biphasic reaction**, there is a recurrence of the anaphylactic signs any time between 1 and 30 h after the initial remission. In some cases, the severity of the biphasic reaction is comparable to and often involves the same clinical signs and body systems as the initial reaction. In human patients, delay in the administration of epinephrine is associated with an increase in biphasic reactions and anaphylactic death. It is not clear in human medicine whether steroid therapy

prevents biphasic reactions although its anti-inflammatory properties could counter the delayed inflammatory response of anaphylaxis.

In the **protracted reaction**, profound hypotension may last beyond 24 h despite treatment. It is important to remember that, although rarely used in equine medicine, beta-blockers (e.g. propranolol) and angiotensin converting enzyme (ACE) inhibitors (e.g. enalapril) may **increase the severity** of anaphylaxis by decreasing blood pressure, promoting bronchoconstriction, and **antagonizing the response to epinephrine**. Therefore, in patients with refractory reactions, the dose of epinephrine may have to be repeated IM q 10–20 min, or epinephrine may be given IV (0.01 mL/kg BW of a 0.1 mg/mL solution). Other **beta-adrenergic drugs** (e.g. dopamine 10 µg/kg BW/min IV, isoproterenol 0.05–0.2 µg/kg BW/min IV) may also be used in non-responsive cases.

ALLERGY OR ATOPY

Allergy or atopy is an immediate hypersensitivity response of skin and mucosal membranes mediated by IgE, mast cells and basophils in **genetically susceptible individuals**.

A primary exposure to the allergen is required, in which CD4+ T helper cells and Th2 cytokines induce B cell class switching and the production of high concentrations of allergen-specific IgE. Subsequently, the IgE binds to high-affinity Fc receptors specific for the ϵ heavy chain on mast cells present in tissues or circulating basophils. Upon **successive exposure**, the allergen binds to the cell-associated IgE, and the cross-linking with other IgE molecules and Fc receptors **triggers the release of mediators** present in the cytoplasmic granules.

In addition to IgE-mediated allergy, the release of cytoplasmic granules by mast cells and basophils can be mediated by complement components C3a, C4a or C5a, which are known as **anaphylatoxins**. Elements that may trigger this hypersensitivity response include **exercise, opiates, cyclo-oxygenase inhibitors and IV contrast materials**.

Hypersensitivity diseases in horses may result from exposure to allergens via ingestion (food allergy), inhalation (heaves), injection (drug, insect bite) or percutaneous absorption (contact dermatitis). A familial or hereditary component seems to be involved, and it may be associated with major histocompatibility class I haplotype.

In **urticaria** (*q.v.*), cutaneous wheals of various sizes and shapes, pitting edema and pruritus develop within minutes to hours after exposure to the antigen. Urticaria may not involve an IgE-mediated hypersensitivity response, and **angioedema** secondary to systemic diseases, physical (dermatographism in areas of pressure), temperature-sensitive, cholinergic, and exercise-induced urticarias are possible. A complete history, physical examination and dermatologic testing may help identify the primary cause of the disease. Histopathologic findings in urticaria may include vascular dilation in the superficial and middle dermis and infiltration of inflammatory cells (mononuclear cells, neutrophils, mast cells and eosinophils) in the perivascular regions.

Sweet itch or **insect-bite hypersensitivity** (*q.v.*) is a **seasonally recurrent** hypersensitivity skin reaction to antigens in the saliva of *Culicoides* species characterized by widely distributed pruritic crusting dermatitis. Following antigen

exposure, eosinophils are recruited to the affected skin in response to histamine, platelet-activating factor (PAF) and eotaxin. Eosinophils may contribute to the disease with the release of proteases and inflammatory mediators.

To date, clinical studies have indicated that allergic tests still lack levels of sensitivity and specificity when horses affected by sweet itch are compared to normal horses. Therefore, allergic testing alone should not be used to diagnose this hypersensitivity reaction, and results should be evaluated in combination with the history and clinical manifestation of the disease. **Serologic testing** (ELISA for IgE or radioactive [RAST] or fluorescent allergosorbent [FAST] tests) may be used to aid in the design of a treatment plan. A positive reaction indicates the presence of antigen-specific IgE but alone it does not indicate whether that specific antigen is the cause of the disease. **Intradermal allergy testing** is probably more clinically significant than serology because it tests not only the presence of antigen-specific IgE but also the level of sensitization upon exposure to the allergen.

Acute idiopathic hypersensitivity reactions may be responsive to antihistamines (e.g. **hydroxyzine hydrochloride** 0.5–1 mg/kg BW t.i.d. PO) and corticosteroids (**dexamethasone** 0.05–0.1 mg/kg BW s.i.d. IV or PO; **prednisolone** 1 mg/kg BW s.i.d. or b.i.d. PO).

Management of chronic allergic reactions is based on **minimizing or removing exposure to the allergen**, which is often not possible. Treatment of recurrent allergies may be frustrating and prevent horses from competing due to regulatory drug withdrawals.

Hyposensitization with a vaccine formulated with antigens selected on the basis of history and results of intradermal testing seems to be a long-term treatment option, and response rates vary from 50% to 85%. The chronic administration of low doses of allergen (1 mL of a 20 000 protein nitrogen unit [PNU] of allergen per milliliter of water SC or IM q 21 days) may stimulate the Th1 type response and/or production of IgG “blocking antibody” that anticipates the binding of IgE to the antigen. In addition, hyposensitization may decrease the number of B cells expressing IgE receptor and restore antigen-stimulated IL-4 production to the levels of non-affected individuals.

AUTOIMMUNITY

Autoimmune diseases

Autoimmunity is an immune response against self-molecules. The presence of autoimmunity is common to all individuals and may or may not have an adverse effect on the body. **Autoimmune diseases** are clinical manifestations that involve B lymphocytes (antibodies) or T lymphocytes (CD4+ helper or CD8+ cytotoxic cells) reactive to self-antigens. Auto-reactive B and T cells are controlled by mechanisms of central and peripheral tolerance. However, immune dysfunction involving antigen presentation and co-stimulation, genetic defects (often familial) and environmental factors may lead to failure of autoimmunity control and, consequently, to autoimmune disease.

The failure of the anti-idiotypic control mechanism of antibody production may allow the production of **autoantibodies**. In addition, **molecular mimicry of microbes** and self-epitopes may result in immune responses that overcome

immunologic tolerance and lead to tissue injury. Exposure of auto-antigens present in systems that are **not normally visited by lymphocytes** (e.g. a breakdown of the blood–brain barrier in the central nervous system) or the development of new epitopes on normal proteins may stimulate an immune response.

Viruses, particularly those that infect lymphoid tissues, may be capable of interfering with immunologic control mechanisms. **Exotoxins produced by bacteria** (e.g. *Clostridium* spp.) may promote damage of red cell membranes and the development of antigenic epitopes for the production of autoantibodies. **Penicillin-induced immune-mediated hemolytic anemia** is caused by the strong binding of the drug hapten to the surface of red cells. The complex induces the production and subsequent binding of antibodies. In some cases, autoimmunity is associated with the **aging process** and immune system malfunction, or the effect of **sexual hormones**. The mechanisms that induce tissue injury are those described in hypersensitivity reactions (*q.v.*).

Immune-mediated thrombocytopenia

Thrombocytopenia is a rare condition in horses, and most cases are of unknown cause. In addition to disseminated intravascular coagulopathy and decreased megakaryopoiesis, thrombocytopenia may be associated with autoimmunity. In the latter, it may occur in patients with infectious agents such as equine infectious anemia (*q.v.*) or *Clostridium* spp. (*q.v.*), after administration of drugs (e.g. penicillin, heparin, quinidine, thiazides, digoxin, sulfonamides, erythromycin) or in neoplasia (lymphosarcoma).

Clinical signs include **hemorrhagic diathesis** characterized by **epistaxis**, prolonged bleeding from injection sites, mucosal petechiae, hematomas, occult blood in urine and feces, melena, hemoarthritis, and/or hypHEMA. These findings may be differentiated from vasculitis by the **absence of heat, pain and swelling**. In general, clinical signs are not detectable until platelet counts are $<40\,000/\mu\text{L}$, and spontaneous bleeding may occur when counts are $<20\,000\text{--}10\,000/\mu\text{L}$.

A **coagulation profile** (*q.v.*) often reveals prolonged bleeding time, abnormal clot retraction, slightly prolonged activated coagulation, elevated fibrinogen degradation products (FDP), normal prothrombin time (PT) and normal activated partial thromboplastin time (APTT). Megakaryocytic hyperplasia is an expected response to the platelet destruction in the periphery and, when absent, may indicate immune-mediated destruction of megakaryocytes or myelophthitic disease.

Immune-mediated thrombocytopenia results either from the production and binding of immunoglobulins to platelets or megakaryocyte antigen surface (**primary or idiopathic thrombocytopenia**), or from the binding of immunocomplexes (antibodies against microorganisms, or a drug hapten) to the Fc receptors on platelets (**secondary thrombocytopenia**). In addition, platelet-bound IgM may fix complement. The antibody- or antibody-complement-coated platelets are non-specifically removed from the circulation by the reticuloendothelial system (macrophages in the spleen and liver that phagocytose the platelets via their Fc and complement receptors). The mechanism for autoantibody production may involve auto-reactive B cell clones that are stimulated during an immune response to infectious organisms,

dysfunction in CD4+ T cell regulation of B cell response, antigenic mimicry and altered anti-idiotypic regulation of antibody production.

Thrombocytopenia should be confirmed by performing an automated platelet count (*q.v.*) using a blood sample preserved in citrate anticoagulant, and/or a platelet hand count to rule out pseudothrombocytopenia. **Flow cytometric analysis** of IgG and IgM coated platelets may confirm the diagnosis of an immune-mediated process. The immuno-injury assay that measures anti-platelet activity in plasma of affected horses often renders false negative results. The presence of young platelets in the circulation as an indicator of bone marrow response to thrombocytopenia can be assessed by the staining of blood platelets with thiazole orange and flow cytometric analysis. Physical examination and ancillary diagnostics should be used in an attempt to identify the presence of **bacterial or viral infections and tumors**. A **Coggins test** should be used to diagnose equine infectious anemia (*q.v.*). In confirmed cases, intermittent hemolysis occurs concomitantly with viremic states.

If **drug-induced thrombocytopenia** is suspected, discontinuation of the medication is imperative for remission of the autoimmune response.

Platelet-enriched plasma transfusion may partially replace the loss of platelets to levels that prevent spontaneous bleeding or diathesis. Platelet-enriched plasma is prepared by centrifugation at 200g for 10 min at room temperature of **aseptically collected blood** in plastic bags containing 2.5% sodium citrate. This therapy may be more effective in horses of small size (foals). The shelf life of platelet-enriched plasma is just a few hours before platelet function inactivation.

Immunosuppressive therapy may be attempted with the use of **corticosteroids (dexamethasone 0.1–0.2 mg/kg BW s.i.d. IV)**, which suppress phagocytic function and antibody production. After 4–5 days, an increase in platelet counts may allow progressive reduction of the dexamethasone dose (20% daily) and, potentially, its substitution with **prednisolone** (starting at 1 mg/kg BW b.i.d. PO, with subsequent reduction in dose). Low dose corticosteroid treatment or early discontinuation of therapy may result in persistence or recurrence of disease. Therefore, in many patients, immunosuppressive therapy may last for 30 days.

The use of other **immunosuppressive therapy (vincristine sulfate 0.01 mg/kg BW IV one or two doses a week apart, in combination with dexamethasone; or azathioprine 3 mg/kg BW s.i.d. PO, and subsequent decreasing doses)** is an option in cases refractory to corticosteroid therapy. Immunoglobulin transfer using IV plasma transfusion may assist by interfering with macrophage Fc-receptor clearance of immunoglobulin-coated platelets.

Immune-mediated hemolytic anemia

Immune-mediated hemolytic anemia has been reported in horses **secondary** to neoplasia (lymphosarcoma), bacterial infection (*Clostridium* spp.) or viral (equine infectious anemia) infections, chronic inflammatory diseases and exposure to certain drugs.

Clinical signs are determined by the severity of red cell destruction and include mild depression, icterus, tachycardia and tachypnea. Blood analysis

reveals **progressive anemia** and **indirect hyperbilirubinemia**. Frequently, red cells coated with autoimmune IgG go through extravascular destruction by the reticuloendothelial system in the spleen via Fc receptors. Auto-reactive IgM-coated red cells facilitate complement fixation and red cell removal by the hepatic macrophages via complement receptors. When antibody and complement fixation activity increases, **severe intravascular hemolysis** may result with discoloration of serum and, occasionally, urine. Bone marrow cytology reveals regenerative erythropoiesis.

Diagnosis is confirmed by the detection of red cell auto-agglutination after 1:4 dilution of blood with saline. The presence of antibody on red cells can be evaluated by **Coombs test** (rabbit antiserum against equine IgG and IgM) or direct detection of IgG and IgM antibodies on the cell surface by flow cytometry. Physical examination and ancillary diagnostics should be used in an attempt to identify the presence of bacterial or viral infections and tumors. A **Coggins test** should be used to diagnose equine infectious anemia (*q.v.*). In confirmed cases, intermittent hemolysis occurs concomitantly with viremic states.

Treatment should include the discontinuation of any current therapeutic drug and investigation of potential causes of immune-mediated disease. The overall treatment goal is to **remove the primary cause of disease**. In life-threatening anemia, rapid hemolysis can cause somnolence and dyspnea, packed cell volume (PCV) <12% and low venous pO₂ (PvO₂). In these cases, **blood transfusions** are necessary to stabilize the patient. On the other hand, when red cell lysis is slow, PCV remains >12–15%, and the patient is stable, blood transfusion should be avoided so as not to cause suppression of bone marrow erythropoiesis. In the latter case, frequent monitoring of the patient's condition and PCV will indicate whether blood transfusion has become necessary.

Slow whole blood transfusion (4 mL/kg BW/h) should be performed after blood cross-match between donor and patient, and under close supervision for anaphylactic and anaphylactoid reactions. A horse blood donor can donate up to 20% of total body blood volume (body weight [kg] × 8%). For adult horses (500 kg), 6–8 L of blood may be collected and transfused; proportional doses can be calculated for ponies and foals. Whole blood should be collected using aseptic technique and blood collection sets with anticoagulant (e.g. 2.5% sodium citrate). Blood transfusion should be given by blood administration sets (with filter), which should be replaced every 3–4 L. During transfusion, the patient should be monitored for adverse reactions, which are expressed by tachypnea, restlessness, piloerection and muscle fasciculation. If these clinical signs develop, the blood transfusion should be stopped immediately and anti-anaphylactic treatment considered (epinephrine 0.01 mL/kg BW of a 1 mg/mL solution, IM).

Alternatively, **polymerized bovine hemoglobin** solution (e.g. Oxyglobin, Biopure Corporation, Cambridge, MA) can be used as an emergency treatment to improve hemodynamics and oxygen transport.

Immunosuppressive therapy should be considered in patients with rapid red cell hemolysis. In general, immune-mediated hemolytic anemia in horses is responsive to dexamethasone (0.1–0.2 mg/kg BW s.i.d. IV). The **corticosteroid therapy** should be aggressive until PCV value is >20%. In this case,

the dexamethasone dose can be gradually decreased (20% per day) and slowly substituted by prednisolone (1 mg/kg BW s.i.d. or b.i.d. for a week PO). In refractory cases and when the underlying disease cannot be treated, the use of immunosuppressive therapy is prolonged and tailored to the patient's needs.

Vasculitis

In horses, **vasculitis of the small vessels** is often associated with autoimmunity. Although the skin and mucous membranes are mostly affected, the gastrointestinal, respiratory, renal and muscular systems may also be involved. This immune-mediated condition may be **primary** (type II hypersensitivity) or **secondary** (type III hypersensitivity) to infections caused by *Streptococcus equi*, *Streptococcus zooepidemicus*, equine viral arteritis, equine influenza virus, equine infectious anemia virus, equine herpesvirus 1 and *Anaplasma phagocytophila* (formerly *Ehrlichia equi*). In addition, tumors and drugs may supply antigens for the hypersensitivity response.

Clinical signs include diffuse or localized edema of skin, subcutaneous tissues and/or mucosa, exudation, petechiations and necrosis. The purplish discoloration of the skin and mucous membranes produced by the breakage of small vessels describes the condition known as **purpura hemorrhagica**. In the horse, purpura hemorrhagica is associated with high levels of circulating C3 complement component, immune complexes of IgA and *S. equi* M protein, and low levels of IgG specific for *S. equi* during the acute phase. In the initial phase, edema, heat and pain to the touch are observed in the distal extremities. In severe cases, fibrinoid necrosis of blood vessels may lead to respiratory (dyspnea) and gastrointestinal (colic) lesions. The presence of fever has been associated with poor prognosis.

Diagnosis is based on history, clinical signs and **histopathology of skin biopsies**. In the latter, neutrophilic infiltration of vessels of the skin and subcutaneous tissues is often seen. The presence of immune complexes or antibodies against endothelial cells may be observed by direct fluorescent tests in the initial phase of the lesions. In the case of infection, serology of paired samples and tests for *S. equi* M protein levels may indicate the organism implicated in the disease process.

Treatment should aim at the **removal of the antigenic stimulus** by treating the primary disease (antimicrobials) if possible. The inability to identify or eliminate the antigenic stimulus may lead to systemic vasculitis, debilitation (synovitis, thrombophlebitis, skin necrosis/sloughing) and death. When there is concern about drug-induced vasculitis, it is imperative to **stop the administration of all medications** and to change those that are indispensable. Immunosuppressive therapy can be used to decrease immune and inflammatory responses, although some cases of vasculitis have spontaneous remission. **Corticosteroids** (dexamethasone 0.1–0.2 mg/kg BW s.i.d. IV; prednisolone 1 mg/kg BW s.i.d. or b.i.d. PO) should be used in higher doses in the initial phase of the disease, and the dose decreased or discontinued according to the individual response. Prolonged immunosuppressive therapy is often needed, and premature discontinuation of therapy may result in recurrence of disease.

Heaves or recurrent airway obstruction

Heaves (*q.v.*) is an allergic respiratory disease of horses characterized by **bronchoconstriction** and **mucus production**, leading to exercise intolerance, nasal discharge, chronic cough, respiratory distress at rest, depression and weight loss. Affected horses often present **expiratory effort**, which is noticeable by a prolonged expiratory phase and the formation of a “**heave**” line along the abdominal muscles. At auscultation, expiratory wheezes and tracheal rattles are easily identified. The age of onset is between 9 and 13 yr of age, and horses that are stabled and bedded on **straw** and fed **hay** are at risk.

The hypersensitivity reaction seems to be in response to **inhaled dust** present in hay and straw. In addition, there is evidence for the implication of specific antigens: candidates are molds and endotoxin lipopolysaccharides. Horses pastured in hot, humid climates may present hypersensitivity to molds on grasses and develop a similar syndrome known as **summer-pasture associated heaves**.

When exposed to the triggering factors in the environment, susceptible horses may develop **pulmonary dysfunction** within hours and demonstrate diffuse bronchospasm, low tidal volume, high lung volumes, increased maximal transpulmonary pressures, reduced dynamic compliance, increased pulmonary resistance, and hypoxemia. **Bronchoalveolar lavage fluid** cytology reveals **neutrophilic inflammation** (neutrophil percentage 50–70%) with concomitant reduction in the lymphocyte and macrophage populations. There is an increase in the CD4+ /CD8+ T cell ratio. These changes are often proportional to the clinical parameters. Airway obstruction and neutrophilic inflammation may be reversed within a week after removal from exposure to the insulting factor.

The immuno-pathophysiology of heaves has not been completely determined. In addition, it is not known whether heaves and summer-pasture associated heaves share the same mechanisms of disease. Diffuse bronchospasm seems to be caused by the direct effect of inflammatory mediators and an indirect vagal stimulus on smooth muscle. Nitric oxide (NO) deficiency, histamine and cyclo-oxygenase derived prostaglandins do not seem to play a role in this process because NO levels are increased in horses with heaves, and the use of **anti-histamines and non-steroidal anti-inflammatories does not relieve bronchoconstriction**. Bronchiolitis is characterized by smooth muscle hypertrophy, peribronchial lymphocytic infiltration and IgA-secreting lymphocytes. **Thoracic radiographs** may be useful to rule out other causes of pulmonary disease; in the case of heaves, they reveal peribronchial inflammation, mild interstitial opacity and flattening of the diaphragm (pulmonary overinflation).

Treatment of heaves primarily involves **management changes** to minimize exposure to dust particles, i.e. strict pasture and pelleted feed management. During acute episodes, **corticosteroid therapy** is the most effective treatment to decrease peribronchial smooth muscle contraction and production of mucus, and improve pulmonary function. This effect is mediated by glucocorticoid receptors and affects cytokine and inflammatory mediator transcription. Dexamethasone (0.1 mg/kg BW s.i.d. IV) is indicated for horses with severe respiratory distress. After 3–4 days, maintenance may be accomplished

with prednisolone (1 mg/kg BW PO s.i.d. or b.i.d.). Alternatively, mild cases of heaves may be treated with **aerosolized corticosteroid therapy** (fluticasone propionate, beclometasone dipropionate).

Metered-dose inhaler therapy using a mask or nostril delivery system allows direct delivery of the drug to the lower respiratory tract, which reduces total therapeutic dose and minimizes the exposure of other systems to the drug. Nevertheless, severe respiratory distress may not allow adequate drug delivery due to the strong expiratory phase of respiration and bronchoconstriction. In these cases, the use of parenteral corticosteroids or bronchodilators is recommended before the administration of inhalatory corticosteroids. Important adverse side effects of corticosteroid therapy, including the inhalatory form, are **adrenal suppression and susceptibility to infection**.

Bronchodilators are an important component of the treatment of heaves because they provide immediate improvement of bronchoconstriction and pulmonary function. An inhaled β_2 -adrenergic agonist (short-acting **albuterol** or long-acting **salmeterol**) and anticholinergic bronchodilators (**ipratropium bromide**) may be used individually or in combination depending on the severity of disease and tolerance of the drug. In addition, **clenbuterol**, another β_2 -adrenergic agonist, may be administered PO to manage mild cases.

Pemphigus foliaceus

Pemphigus complex is a group of autoimmune skin disorders characterized by the production of **autoantibodies** directed against the **intercellular cement in the skin**. The inflammatory response disrupts adhesion between cells to cause bulla or pustule formation. The classification of the lesions is based on their distribution: pemphigus vulgaris (persistent thin blisters at mucocutaneous junctions), pemphigus vegetans (thick blisters or pustules in intertriginous areas or folds of skin), **pemphigus foliaceus** (superficial lesions on the face, ears, muzzle and limbs), and pemphigus erythematosus (milder lesions than pemphigus foliaceus with features of lupus erythematosus). **Bullous pemphigoid** has a similar presentation to pemphigus and the lesions involve skin and mucocutaneous junctions. In the horse, pemphigus foliaceus is the most common autoimmune skin disease, and it likely involves the destruction of desmosomes by autoantibodies against a desmosomal glycoprotein.

The **diagnosis** is confirmed by histopathology (acantholysis of keratinocytes, intraepidermal and subcorneal vesicles, non-degenerative neutrophils) and direct immunofluorescence of immunoglobulins deposited in the intercellular cement. Because the lesions are very superficial, fresh blisters should be sampled using excisional biopsy. **Treatment** can be instituted with corticosteroids (dexamethasone 0.1–0.2 mg/kg BW s.i.d. IV) in combination with azathioprine (3 mg/kg BW s.i.d. PO) or gold salts (aurothioglucose 1 mg/kg BW once a week decreasing to once a month IM). **Corticosteroid therapy** should be aggressive until the clinical signs have resolved. The dexamethasone dose can then be gradually decreased (20% per day) and slowly substituted by prednisolone (1 mg/kg BW s.i.d. or b.i.d. for a week PO). In refractory cases, immunosuppressive therapy is prolonged and tailored to the patient's needs.

NEONATAL ISOERYTHROLYSIS

Neonatal isoerythrolysis (NI) is a hemolytic disease that develops within hours to a few days of life and involves the **maternal alloantibodies** absorbed from the colostrum. The alloantibodies are directed against the incompatible antigens on the red cell of the foal. The binding of the antibodies causes extravascular hemolysis, red cell agglutination and complement-mediated intravascular hemolysis.

Clinical signs include depression, weakness, lethargy, tachycardia, tachypnea, icteric or pale mucous membranes, moderate to severe anemia, normal total protein, metabolic acidosis due to poor tissue oxygenation, hyperbilirubinemia, hemoglobulinemia and hemoglobinuria. In severe cases, pigmentary nephropathy, azotemia, tissue inflammation due to hypoxia (central nervous system, gastrointestinal tract, liver), fever and seizures may occur. In addition, kernicterus or bilirubin encephalopathy may lead to severe depression, opisthotonus, rigidity, convulsions and death due to the deposition of unconjugated bilirubin and necrosis of cerebral gray matter.

The **alloantibodies are produced by the dam during gestation** under specific conditions:

1. The foal must have inherited antigenic blood factors from the sire that are not common to those of the dam.
2. If the mare becomes exposed to fetal blood close to parturition, she produces antibodies against these factors.
3. Because peak antibody production is only achieved approximately 9 days after foaling, these antibodies do not reach the colostrum in time to be absorbed by that foal; however, in the **following pregnancy**, the mare will transfer to the colostrum high levels of antibodies against that blood factor.
4. If the foal expresses the incompatible blood factors, the absorbed maternal antibodies will cause **red cell lysis**.

An exception to this sequence of events, and one that leads to the possibility of neonatal isoerythrolysis in the **first pregnancy**, is that the mare had received a blood transfusion from an incompatible blood type that is the same as that of the foal.

There are numerous **blood types** in horses but the most important blood groups associated with neonatal isoerythrolysis are A and Q. The antigens Aa and Qa are responsible for more than 90% of cases; other less important antigens include Ab, Qrs, Qc, Dc, Da, Ka, Pa and Ua. All breeds can be affected with different levels of incidence of disease.

Neonatal isoerythrolysis can be predicted and avoided using appropriate testing, which includes blood factor assays, hemolytic assays, cross-matching and the jaundice foal agglutination test. **Blood factor assays** test for the presence or absence of factors Aa and Qa on the red cells of the dam and sire at any time before breeding. If the dam does not have factor Aa or Qa, she is at risk of producing NI-causing antibodies and needs to be tested for antibodies before foaling.

If the dam is positive for one of the blood groups, there is no risk for that specific blood group. If the sire is negative for both blood groups, there is no

risk for the disease. In addition, the mare's serum can be cross-matched with the sire's red cells: a negative reaction indicates no risk for the foal; a positive reaction indicates a 50% risk of NI, and a cross-matching test should be done at foaling or colostrum withheld.

Hemolytic assays test for antibodies against the blood factors in the mare's serum within 30 days of foaling. Different dilutions of the serum from the mare are mixed with red cells expressing Aa or Qa or Ca (other factors—D, K, P, U and T—may be tested in some laboratories). If antibodies are present in the mare's serum they bind to the red cells (antigen–antibody complex) and, after adding rabbit complement, lysis of red cells is induced. Cell lysis intensity is determined from 0 to 4, and the last dilution of serum that promoted cell lysis is identified. Serum dilutions above 1:16 for Aa and Qa that cause hemolysis in vitro may produce NI; therefore, **withholding colostrum is recommended**. Antibodies to Aa and Qa factors detected at 1:2 serum dilutions require retest before foaling. If antibodies are found against other factors, withholding colostrum is recommended because of the uncertainty of the interpretation of the results. Antibodies against Ca factor do not cause NI but can cause false positive reactions.

Cross-matching at the time of foaling tests for the presence of absorbed colostral antibodies against the blood factors in the foal's serum, or for antibodies in the dam's serum (minor cross-match).

Jaundice foal agglutination tests for NI-causing antibodies in the colostrum against the foal's red cells. In this test, serial dilutions of the dam's colostrum with saline (1 mL of 1:2, 1:4, 1:8, 1:16 and 1:32 dilutions) are mixed with one drop of the foal's whole blood. A 1 mL saline sample is used as a negative control. The mare's blood may be tested under the same conditions as a negative control. The presence of agglutination in the red cells may be observed after centrifugation for 2–3 min at a medium speed and inversion of the tubes. A positive **Coombs' test** is not specific for NI.

Prevention of NI can be accomplished by milking out and discarding the colostrum from the dam for 36 h after birth. The foal should be fed with a safe source of **good quality colostrum or IV plasma**. Meanwhile, the foal should be muzzled and fed milk replacer or another mare's milk using a bottle or nasogastric intubation. To ensure adequate levels of antibodies, the foal's serum should be tested for immunoglobulin G levels.

Treatment decisions should be based on the patient's condition (depression, dyspnea) and blood analysis ($PCV < 12\%$, low venous pO_2), wherein abnormalities are often proportional to the amount of alloantibody absorbed and its affinity to the red cell antigen. **Transfusion of whole blood** from a cross-matched donor (Aa and Qa negative) or washed red cells from the dam can be used. If a cross-match is not available, whole blood from a gelding with no history of previous blood transfusions may be used. Another option until cross-matching or whole blood for transfusion becomes available is the administration of **polymerized bovine hemoglobin** (Oxyglobin, Biopure Corporation, Cambridge, MA). Whole blood transfusion may be necessary in addition to polymerized hemoglobin because its half-life in the circulatory system is short (18–43 h). Rare anaphylactoid reactions to this product have been reported in horses. Calculated fluid therapy may be needed to maintain renal function and to prevent renal disease due to the hemolysis.

The prophylactic or therapeutic value of **Sn-mesoporphyrin**, a heme oxygenase inhibitor that decreases bilirubin production, is still to be determined for its protection against kernicterus in the horse. Immunosuppressive therapy to decrease removal of antibody-coated red cells by the reticuloendothelial system is not indicated for the treatment of NI because of the short presence of maternally derived antibodies against red cells, and the side effects of general immunosuppression in foals.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

Neonatal alloimmune thrombocytopenia (NAIT) may occur in **neonate foals** and mules that ingested colostrum containing alloantibodies against **platelet cell surface antigens**.

Similar to NI, the dam produces antibodies against paternally inherited, incompatible surface molecules on the foal platelets. Megakaryocytic hyperplasia is an expected response to the platelet destruction in the periphery and, when absent, may indicate immune-mediated destruction of megakaryocytes or myelophthistic disease.

Thrombocytopenia develops despite platelet production because the binding of maternally derived antibodies to platelets decreases platelet survival time to a few hours. Antibody-bound platelets are efficiently removed from the circulation by the reticuloendothelial system. Fortunately, this same process favors the clearance of reactive antibodies and shortens their negative effect.

The most common **clinical signs** include petechiation, extensive bleeding from injection sites, hematomas, hemarthrosis and hyphema. The coagulation profile often reveals prolonged bleeding time, abnormal clot retraction, slightly prolonged activated coagulation, elevated fibrinolytic degradation products (FDP), normal prothrombin time (PT) and normal activated partial thromboplastin time (APTT).

Diagnosis is based on the history, clinical signs and presence of antibody-bound platelets in the foal, which can be tested using a direct flow cytometric assay (fluorescent antibodies against horse immunoglobulin [Ig] G, M or A). In addition, confirmation of the diagnosis can be attempted by platelet aggregation and an **immunoradiometric assay** using staphylococcal protein A (SPA) to test for platelet-bindable antibody. In this assay, isolated platelets are incubated with radiolabeled SPA, excess radiolabeled SPA is washed out, and platelet-bound radioactivity is measured in a gamma counter. These techniques may confirm the diagnosis by testing the absence of antibodies on the maternal platelets, circulating antibodies in the foal plasma that bind foal and sire platelets, allotypic differences between dam and foal platelets, and/or the presence of antibodies in the dam's serum and colostrum against the foal and sire platelets.

Differential diagnoses include autoimmune or drug-induced thrombocytopenia (*q.v.*), sepsis, disseminated intravascular hemolysis (*q.v.*), equine infectious anemia (*q.v.*) and myelophthistic disease.

Treatment is based on transfusion of platelet-rich plasma (*q.v.*) from a donor, or washed maternal platelets. For the same reasons described for

neonatal isoerythrolysis (*q.v.*), immunosuppressive therapy is not indicated for the treatment of NAIT.

EQUINE PERINATAL IMMUNOLOGY

EQUINE FETAL IMMUNOLOGY

A significant portion of the development of the equine immune system happens during **fetal life**. Thymic corticomedullary organization of lymphocytes is present as early as 80 days of gestation, and these cells are responsive to mitogenic and allogenic stimulation by 100 days of gestation. Fetal spleen lymphocyte distribution in periarteriolar sheaths and germinal centers, and response to stimulation are present by 200 days of gestation. Peripheral lymph nodes are also populated and responsive to stimulation by this age. The mesenteric lymph nodes and intestinal lamina propria become populated by lymphocytes by 13 wk of gestation. Peripheral blood lymphocytes are detected by 120 days of gestation, and they are responsive to mitogens by 140 days. B lymphocytes are functional during normal gestation despite negligible exposure to organisms. Serum IgM concentration of 4–10 mg/dL may be identified in fetuses older than 185 days of gestation, and values >16 mg/dL in presuckle foals. Serum IgG concentration of 5 mg/dL can be detected at 180 days of gestation, and presuckle foals may show a variable amount of serum IgG. Specific antibody response following in utero vaccination has been detected in equine fetuses as early as 200 days of gestation.

PASSIVE TRANSFER OF MATERNAL IMMUNOGLOBULINS

The **epitheliochorial placentation** of horses does not allow in utero transfer of maternal immunoglobulins to the fetus. Because of lack of immunogenic stimulation in utero, the presuckle foal is essentially **agammaglobulinemic**, although low levels of IgM and IgG can be detected. Immunoglobulins are transferred from the blood to the mammary secretions through selective Fc γ receptors on the surface of epithelial cells. This immunoglobulin transfer to colostrum is intense 2–3 wk before parturition and decreases throughout lactation. The correlation between IgG and IgM concentrations and mare's serum and colostrum, or between immunoglobulin concentrations in the foal's serum and in the mare's colostrum is largely dependent on the time of colostrum and serum sampling.

The rate of mammary secretion of **colostrum** is approximately 300 mL/h in mares, and total colostral volume is 3–7 L. Colostrum contains mainly IgG and IgG(T), intermediate levels of IgM, and less IgA, lactoferrin and complement. It is replaced by milk with low levels of IgG and high levels of IgA **within 12 h** from the time the mammary gland is first suckled by the foal. After parturition, the colostral IgG concentration is 6500–30 000 mg/dL, and decreases significantly beyond 8 h. At foaling, the colostral IgM concentration ranges from 12 to 240 mg/dL, and decreases significantly beyond 6 h. Approximately 20% of total colostral IgG and 14% of total IgM contents are found in the initial 500 mL of colostrum.

Specialized epithelial cells in the small intestine absorb the colostral immunoglobulins via non-selective pinocytosis. The absorbed immunoglobulin reaches the lymph system and later the blood system through the thoracic duct. **Immunoglobulin uptake** peaks within 8 h of parturition and declines with time, regardless of the time of oral intake of macromolecules. The specialized epithelial cells are replaced within 24–36 h by mature cells. If the foal nurses within 2 h of birth, serum IgG levels become detectable at 6 h and peak at 18 h.

Although newborn foals are **immunocompetent at birth**, the primary immune response requires at least 2–3 wk to be established and this window favors bacterial invasion and spreading. Therefore, transfer of maternal antibodies plays an important role in controlling infection during this period. The **persistence of maternal antibody** in the foal is proportional to the amount of immunoglobulin absorbed in the colostrum. Serum IgG concentrations in foals may vary from 500 to 6000 mg/dL after ingestion of colostrum.

Foals suckling colostrum from dams vaccinated within the last month of pregnancy have higher, prolonged serum IgG concentrations compared with foals from non-vaccinated mares. The significance of high immunoglobulin concentration in enhanced protection against environmental pathogens is not known. However, the amount of maternal immunoglobulin absorbed by foals may influence maternal immunoglobulin catabolism and delay the synthesis of neonatal endogenous antibody. The half-lives of colostral IgG and IgM are 26–32 and 5–10 days, respectively. Typically, maternal IgG concentrations decrease and foal endogenous serum IgG concentrations increase around the fourth to sixth week of life. During this transitional period, the total immunoglobulin concentration is often low.

FAILURE IN THE TRANSFER OF MATERNAL IMMUNOGLOBULINS

Failure in the transfer of maternal immunoglobulins is characterized by serum immunoglobulin levels <800 mg/dL in the foal 18–24 h after ingestion of colostrum, and values between 400 and 800 mg/dL are considered partial failure.

There are a few methods available for the **measurement of serum immunoglobulins**, which vary in their sensitivity and specificity; they include glutaraldehyde coagulation, the modified zinc sulfate turbidity test, the latex agglutination test, and the SNAP ELISA test (Idexx Laboratories), which is extensively used in practice with moderate sensitivity and high specificity in comparison to radioimmunoassay tests (RIA).

The **incidence** of total or partial failure of passive transfer in well-managed practices wherein foals are ensured to nurse within 3 h of life is 3–17%. Failure of transfer of maternal antibodies may involve one or more of the following factors:

1. Colostrum with low immunoglobulin concentration
2. Prepartum colostrum loss
3. Ingestion of an inadequate amount of colostrum
4. Delayed ingestion of colostrum
5. Inappropriate immunoglobulin absorption related to prematurity and poor development of the intestinal epithelium.

Of importance is the absence of antibodies in the colostrum against specific pathogens in the environment, which occurs with **mares in transit** to a new environment in the period close to foaling.

Despite the fact that approximately 78% of foals with failure of passive transfer become ill with infectious organisms, a small percentage of such foals do not become sick. It is possible that the innate immune system, along with partial transfer of maternal antibody, is capable of providing immune protection on well-managed farms.

IV plasma transfusion is an efficient means of transferring adequate levels of immunoglobulin to the foal after the absorptive period is gone. In general, 1 L of plasma suffices to provide final serum immunoglobulin levels >800 mg/dL and increase opsonization capacity. Nonetheless, foals with septicemia may require additional doses. Plasma transfusion should be administered using a blood transfusion set at a **slow rate in the initial 15 min** to evaluate for adverse anaphylactoid reactions (piloerection, tachycardia, muscle tremors).

INNATE IMMUNE SYSTEM

Both the innate and adaptive arms of the immune system are complementary in the defense against organisms: they are both involved in the recognition and elimination of pathogens. The **innate immune system** may play an important role in response to pathogen challenge in foals until antigen-specific immunity responses are produced. For example, 2–4-month-old specific-pathogen free (SPF) foals inoculated intranasally with equine herpesvirus 1 developed clinical signs of disease (depression, fever, intermittent cough, nasal discharge) on the second day of inoculation. However, the foals were able to recover from disease before specific immunity was developed. Interferon activity was measured in nasal aspirates and was increased by the second day of the primary viral inoculation. This non-specific response was followed by detection of antigen-specific IgM in serum 6 days post inoculation and virus neutralizing antibody 14 days post inoculation. Interferon levels were very low or absent following secondary inoculation, a time when the humoral specific immune response was developed.

Phagocytic activity is facilitated by the presence of opsonins, which may function via C3 receptors (for complement) or Fc γ receptors (for IgG) on phagocytes. Complement activity in presuckle foals has been reported to be 13% of that in the adult, increasing to 64% by 1 mo of age, and 85% by 5 mo of age. **Complement activity** increases more rapidly during neonatal life compared to fetal life. In addition, foals deprived of colostrum have greater complement activity than foals that absorb adequate amounts of immunoglobulin from colostrum. Immunoglobulins and complement reveal synergistic interaction in phagocytosis and oxidative burst activity. This effect is evident by the benefits of plasma therapy in neonates, which significantly increases the opsonic capacity of foals' serum. The absence of antibodies and complement significantly decreases the ability of neutrophils to phagocytose and kill organisms.

Foal phagocytic function is dependent on the maturation of humoral chemotactic and opsonic factors rather than on the maturity of neutrophil function. For this reason, foals may have decreased neutrophil activity up to

4 mo of age in vivo, characterized by decreased migration, phagocytic and oxidative burst activity compared to adult horses. However, there is comparable or superior efficiency in the in vitro phagocytic capacity of foal and adult neutrophils when pooled-adult sera are used for opsonization, indicating that neonatal foal phagocytes are competent.

When foal phagocytes are opsonized with autologous serum, phagocytosis is much reduced up to 5 mo of age compared with adult serum opsonization. In spite of that, the CD18 receptor expression for complement-opsonized material on phagocytes is higher in neonates when compared with adult horses, which may explain the greater in vitro phagocytic activity of neonate phagocytes compared to adult horses.

ADAPTIVE IMMUNE SYSTEM

Despite the intense development of the immune system during fetal life, the horse's **immune system is naïve** to environmental organisms at birth. The intense **expansion of lymphocyte population** in early life may be a consequence of exposure to environmental antigens. In addition, T cell proliferation may respond to mechanisms of immune development that are independent of antigen contact. Along with the increase in the number of circulating cells, there is an increase in lymph node weight and cell output. Also, there is an increase in the circulation of cells through the gut and the appearance of gut-homing T cells, which are likely driven by antigen. Therefore, postnatal development is accompanied by the increase in size of the total lymphocyte compartment and appearance of primed cells.

Studies in foals indicate an **age-dependent distribution of peripheral lymphocyte subsets**. Foals are born with comparable lymphocyte counts to those of the adult horse. These counts increase 2.5–3 times by the third month of age, and CD8+ cells seem to be the major contributors to the increase in lymphocyte counts. Foals are born with B lymphocyte counts lower than adult values, and total and percent peripheral blood B cells increase from the fourth week to the third month of age. This period coincides with the increase in serum IgM and IgG concentrations and indicates activation of the humoral immune response.

Non-specific mitogens (phytohemagglutinin, PHA and concanavalin A, ConA) are known to induce cell signaling and promote **T cell proliferation**, and are extensively used to evaluate lymphocyte function. Phytohemagglutinin stimulation promotes a substantial response in peripheral blood lymphocytes shortly after birth. In addition, foal lymphocytes respond intensively to mitogens from 3 wk to 4 mo of age, a time that coincides with natural lymphocyte proliferation and activation. Foals also present competent **lymphokine-activated killing (LAK)** cell activity of peripheral blood lymphocytes at birth and early life.

Neonatal foals have fewer cells expressing **major histocompatibility complex (MHC)** class II antigen on T lymphocytes in the first month of life, and the number of cells expressing this activation molecule equates to that of adult horses by 4 mo of age. The age-dependent increase in the numbers of T cells expressing MHC class II molecules in the circulation suggests maturation of this cell population.

MUCOSAL IMMUNITY

Colostrum and lactogenic passive mucosal protection in monogastric animals is associated primarily with **secretory IgA** against enteric organisms. Immunoglobulin A on the mucosal surface impairs bacterial binding to enterocytes, and neutralizes bacterial enterotoxins and enterotropic viruses. The participation of passively transferred leukocytes (lymphocytes and phagocytes) in defense against viruses and bacteria has not been described in the horse.

There is an apparent **age-related maturation** of the immune system of the respiratory tract of the equine neonate. At birth, foals do not present organized **lymphoid tissue** in the lungs, and T lymphocytes and plasma cells are virtually absent in the first week of life. Developed bronchus-associated lymphoid tissue is observed by 12 wk of age. Total bronchoalveolar lavage (BAL) leukocyte counts in foals <3 wk of age are half those found in adult horses. Although B cells in BAL fluid are almost undetectable in the first 4 wk of life, B cell values become comparable to those of adult horses by the second month of age. **Immunoglobulin A**, IgG and IgM plasma cells are present in the lower respiratory tract around 8 wk of age. The reduced number of pulmonary lymphocytes in the early neonatal period compared with values in weanling foals indicates dependence of mucosal immune defense on the expansion of the lymphocyte population. Temporal development of a competent mucosal immune defense is also a possibility. **Alveolar macrophages** have impaired chemotactic function up to 2 mo of age. In addition, these cells have lower phagocytic and killing capability compared to peripheral blood neutrophils from the same animal.

IMMUNODEFICIENCIES

Immunodeficiency is a rare disorder of the immune system that results in failure to build protection against pathogens and, consequently, in predisposition to recurrent infections and death. Immunodeficiencies may be primary or secondary. The etiologies of primary and secondary immunodeficiencies are diverse, and the characteristics and clinical manifestations may vary depending on the cells of the immune system that are affected (Table 2.1).

Table 2.1 Immunodeficiencies described in the horse

Immunodeficiency	Immunologic findings	Genetic defect	Breed and age
Failure of transfer of maternal immunoglobulins	IgG < 800 mg/dL at 24 h after birth	None (poor absorption of colostrum Ig)	All breeds Neonates
Severe combined immunodeficiency (SCID)	Agammaglobulinemia, no serum IgM after 1 mo ¹ T cell lymphopenia, absent B cells Hypoplasia of spleen, thymus and lymph nodes Susceptibility to adenovirus, <i>P. carinii</i> , <i>R. equi</i> , <i>Cryptosporidium</i>	Autosomal recessive trait DNA-dependent protein kinase (DNA-PK) gene VetGen test for carriers and affected animals (see p. 143)	Arab and cross-Arab Birth up to 3 mo

(Continued)

Table 2.1 (Continued)

Immunodeficiency	Immunologic findings	Genetic defect	Breed and age
Fell Pony immunodeficiency syndrome	Normal/ hypogammaglobulinemia ¹ B cell lymphopenia, lack plasma cells <5% MHC class II on lymphocytes Lack secondary lymphoid follicles Normal CD4+ and CD8+ T cell counts and function Severe anemia with erythroid hypoplasia Neuronal chromatolysis in peripheral ganglia Susceptibility to adenovirus and <i>Cryptosporidium</i>	Autosomal recessive trait (?) Unknown	Fell Pony Birth up to 3 mo
X-linked agammaglobulinemia	Agammaglobulinemia ¹ Lack of B and plasma cells Normal T lymphocyte response to mitogens	X-linked trait(?) Bruton's tyrosine kinase (<i>btk</i>) gene(?)	TB, SB, QH Only young males affected
Transient hypogammaglobulinemia	Transient pan- hypogammaglobulinemia ¹ Normal B and T lymphocyte counts	Unknown	Arab, TB Young age
Selective IgM deficiency	Serum IgM deficiency 2× STDV below normal mean Normal IgG, IgA and IgG(T) Normal lymphocyte counts Normal T cell response to mitogens	Unknown Primary or secondary to lymphoma	All breeds Young or >2 yr
Common variable immunodeficiency (CVID)	Pan-hypo- or agammaglobulinemia No B cells or B cell lymphopenia	Unknown	TB, Arab, QH Adult first or second decade of life
Transient T cell deficiency	CD4+ T cell lymphopenia (CD8+ T cells may also be decreased) Susceptibility to <i>P. carinii</i>	Unknown	Paint Birth to 6 mo

¹ Serum immunoglobulin levels are variable until maternally derived antibodies are circulating (up to 2–3 mo of age); because IgM is associated with primary immune response, IgM hypo- or agammaglobulinemia after 1 mo of age suggests humoral deficiency.

CD, cluster of differentiation; Ig, immunoglobulin; MHC, major histocompatibility complex; QH, Quarter Horse; SB, Standardbred; STDV, standard deviation; TB, Thoroughbred; (?), not confirmed in the horse.

Clinical conditions that may indicate an immunodeficiency include:

1. Two or more episodes of pneumonia within 1 yr
2. Two or more episodes of sinus infection within 1 yr
3. Multiple sites of infection (pneumonia + sinusitis)
4. Recurrent pyodermatitis, deep skin or organ abscesses
5. A single episode of meningitis or osteomyelitis
6. Two or more mo on antibiotics with little or no effect
7. Failure to gain weight or grow normally
8. History of primary immunodeficiency in the family.

The most common clinical indication of immunodeficiency is **recurrent infections** with frequent treatment failures. In many cases, the horse does well while on antibiotic therapy. However, when antibiotic therapy is discontinued or bacterial resistance to antibiotic develops, the clinical signs of infection reappear. In addition, autoimmunity and neoplasia may be associated with an immunodeficient state.

CLASSIFICATION OF IMMUNODEFICIENCIES

Primary immunodeficiencies are congenital processes associated with a genetic hereditary defect. Therefore, the manifestation of these disorders is more frequently observed in young than in adult horses but it does not exclude the latter. Inheritance patterns should be evaluated when investigating an immunodeficiency. Importantly, many disorders have X-linked inheritance and manifest in male horses. Single recessive genes may result in autosomal recessive inheritance. Other disorders may not have a clear pattern of inheritance but may be found in several individuals in a family.

Secondary immunodeficiencies may occur at any time in life. These are acquired disruptions in immune function that, similar to primary immunodeficiencies, reduce the ability of the system to fight against opportunistic and/or pathogenic organisms. Conditions that may predispose to secondary immunodeficiencies include immunosuppressive treatment, infectious diseases, infiltrative diseases, metabolic/endocrine diseases, age and malnutrition.

Immunodeficiencies are grouped according to the components of the immune system affected (Box 2.2).

Box 2.2 Groups of immunodeficiencies

1. Antibody immunodeficiency disorders (B cell deficiency)
2. Cytotoxic and helper cell deficiencies (T cell deficiency)
3. Combined B and T cell deficiencies
4. Phagocytic deficiency
5. Complement deficiency

HUMORAL IMMUNODEFICIENCIES

Antibody deficiency is the most commonly diagnosed immunodeficiency in mammals. It is characterized by full or partial **failure of B cell development** and differentiation into plasma cells to produce different immunoglobulin isotypes. As a consequence, all or only selected isotypes of immunoglobulins are decreased or absent. **Recurrent, severe infections** caused by **opportunistic or encapsulated microorganisms** are the clinical manifestations in humoral immunodeficiencies.

Clinical signs include pneumonia, meningitis, osteomyelitis, sinusitis, lymphadenopathy, hepato- or splenomegaly, dermatitis, oral candidiasis and failure to grow. Some of the diseases associated with humoral disorders described in the horse include transient hypogammaglobulinemia of the young, X-linked agammaglobulinemia, common variable immunodeficiency, Fell Pony immunodeficiency syndrome (*q.v.*) and selective IgM deficiency.

Horses with humoral deficiencies may be temporarily managed with **plasma transfusions** (*q.v.*) when serum IgG is <500 mg/dL. Some horses may be managed with continuous **antibiotic therapy** alone. The addition of antifungal drugs (fluconazole 4 mg/kg BW s.i.d. PO) may be necessary in the presence of candidiasis (*q.v.*). These horses should be routinely evaluated for the development of infection, more commonly in the respiratory tract. In addition, vaccination of these horses with modified-live or live vaccines is **contraindicated**.

Agammaglobulinemia

A lack of mature B cells and plasma cells, but normal T cell counts and function has been reported in **young male horses** of different breeds. Horses with this syndrome develop bacterial infections of respiratory, gastrointestinal and tegument systems that are temporarily responsive to antibiotic and plasma therapies.

Agammaglobulinemia in male horses presents many features of the X-linked agammaglobulinemia (XLA) described in male human patients and *xid*-mutant mice. These patients carry a mutation of the *btk* gene on the X chromosome that encodes the Bruton tyrosine kinase. The absence of this protein affects sustained signaling in response to B cell receptor engagement, leading to defects in B cell differentiation and proliferation. Typically, XLA patients present with **recurrent bacterial respiratory infections**, absence of B cells and plasma cells, and hypo- or agammaglobulinemia early in life. Female carriers are healthy, although they may display non-random X chromosome inactivation in their B cells.

Transient hypogammaglobulinemia

Transient hypogammaglobulinemia has been described in foals with delayed production of endogenous antibodies. These foals present **recurrent bacterial and viral infection** when circulating maternally derived antibody levels decrease at around 2 mo of age. Peripheral blood B and T lymphocyte counts and distribution are normal. The T cell response to phytohemagglutinin is

normal in vivo and in vitro. Serum IgG and IgG(T) concentrations are low, and IgM and IgA levels may be normal or decreased. A weak response to immunization may be detected in these horses. Appropriate antibiotic therapy and plasma transfusion often protect foals during the period of abnormal immunoglobulin production.

Selective IgM deficiency

Selective IgM deficiency is a presentation of immunoglobulin abnormality reported in horses of both genders and different breeds. It may occur as a **primary** (young) or a **secondary** (adult) immune disorder, and in both cases this condition may be permanent or transient. In these horses, serum IgM concentrations are more than two standard deviations below the mean normal value of age-matched controls (<60 mg/dL). Serum concentrations for IgG, IgG(T) and IgA are normal, as are peripheral blood lymphocyte counts and responses to mitogens. A genetic basis has not been described, and transient conditions may be secondary to lymphosarcoma, immunosuppressive therapy or stress.

Common variable immunodeficiency

Common variable immunodeficiency (CVID) is a symptomatic antibody deficiency syndrome marked by **recurrent bacterial infection** and **impaired humoral response to vaccination in adult horses**. In the horse, this condition has been characterized by chronic respiratory disease, hypo- or agammaglobulinemia, progressive septicemia, and absence of B cells in the bone marrow, lymph node and spleen. The T cell percentage and distribution can be normal to slightly increased, and the T cell response to mitogens may be normal or decreased. Immunohistochemical analysis of tissue sections may support peripheral blood findings with absence or marked paucity of B cells in bone marrow, spleen and lymph nodes. Both sexes and different breeds (Quarter Horse, Thoroughbred, Arab) are affected, and clinical signs are often observed in the second decade of life.

Classification of CVID has been complex due its variable immunologic and clinical phenotypes. The initial diagnosis is usually made by exclusion of other primary causes of immunodeficiency. A method for classification of this heterogeneous disorder on the basis of in vitro immunologic responses of purified B cells to Sepharose-bound antibodies against surface IgM and interleukin-2 has been developed for human patients.

Different groups of disease can be identified based on the presence or absence of B cells, and B cell responses. In CVID, B cells are usually present in low numbers in the system, and a defect in antibody production may be associated with intrinsic abnormalities in differentiation into plasma cells and isotype switching, or impaired T cell co-stimulation of B cells. Other **unclassified immunodeficiencies** involving B cell lymphopenia or hyporesponsiveness have been reported in horses. In one case, a 10-month-old Arabian filly presenting with recurrent gastrointestinal disease and synovitis was diagnosed with non-detectable serum concentrations of IgM, IgA and IgG(T), but normal concentrations of IgG, decreased response of B cells to lipopolysaccharide stimulation, and normal T cell response to concanavalin A. Another case

involved a 3-month-old Thoroughbred colt with recurrent respiratory disease, normal T and B cell peripheral blood counts, decreased B cell response to lipopolysaccharide, and IgM deficiency. In addition, a 3-year-old Quarter Horse colt with chronic diarrhea has been reported to have hypogammaglobulinemia for IgG, IgA and IgM, B cell lymphopenia, and T cell hyporesponsiveness to mitogen stimulation.

Fell Pony Syndrome

An immunodeficiency condition has been described in Fell Pony foals <3 mo of age. Both genders are affected and clinical signs include **severe anemia**, diarrhea, pneumonia, neutrophilia, lymphopenia and death. In addition, repeated chewing and failure to suckle may result from an ulcerative, pseudomembranous coating of the tongue. This syndrome may be caused by an autosomal recessive gene anomaly, of which two thirds of the population is estimated to be carriers.

Immunologic testing using flow cytometric leukocyte phenotyping reveals a **B cell lymphopenia** and decreased cell surface expression of major histocompatibility complex class II on lymphocytes. The CD4+ and CD8+ T cell distribution in peripheral blood is normal, and these cells are responsive to mitogens phytohemagglutinin and concanavalin A, although the response to pokeweed mitogen may be decreased. Serum immunoglobulin levels are similar to those of healthy foals, yet Igm levels may be decreased. Nevertheless, serum immunoglobulin may reflect maternally derived antibodies at this age. Phagocytosis and oxidative burst activity are intact, and opsonization capacity is proportional to the levels of maternally derived immunoglobulins.

On histopathology, the thymus presents atrophy with no demarcation between cortex and medulla. There is a general **paucity of lymphocytes** and absence of germinal centers in the lymph nodes, spleen and gut-associated lymphoid tissues. In contrast, numerous macrophages and neutrophils are present in the primary and secondary lymphoid tissues. The intestine does not contain plasma cells and may be infected with *Cryptosporidium* spp. (*q.v.*) and/or adenovirus (*q.v.*) organisms. The bone marrow reveals severe red cell hypoplasia and abundant hemosiderophages, megakaryocytes and myeloid precursors. In addition, **peripheral ganglionopathy** is also present in these foals, characterized by neuronal chromatolysis with nuclear pyknosis in the trigeminal, cranial mesenteric and dorsal root ganglia.

SEVERE COMBINED IMMUNODEFICIENCIES

Severe combined immunodeficiency (SCID) is a condition in which both the acquired B (humoral) and T (cellular) cell functions are deficient.

This immunodeficiency occurs in **Arabian horses** that lack activity of the **enzyme DNA-dependent protein kinase (DNA-PK)** that is required for gene rearrangement of the antigen receptor on the B and T lymphocyte cell surface. The DNA-PK enzyme defect results from a deletion mutation of the gene encoding the catalytic subunit. The mode of inheritance of the genetic defect is as an **autosomal recessive trait**. Although foals appear normal at birth, this

condition is fatal unless the immune system can be reconstituted by transplants of immunocompetent tissue. Affected foals are susceptible to bacterial, fungal, viral and protozoal organisms by the time maternally derived antibodies wane.

Clinical signs primarily involve the respiratory and gastrointestinal systems, and infections with adenovirus, *Pneumocystis carinii*, *Rhodococcus equi* and/or *Cryptosporidium parvum* are common. The relevant findings that contribute to the diagnosis of SCID include **lymphopenia** (<1000 cells/ μ L), **marked serum IgM deficiency**, and **hypoplasia of secondary lymphoid tissues**. Ante mortem diagnosis can be determined by the characterization of the defective gene by a polymerase chain reaction (PCR) test (VetGen, Ann Arbor, MI, USA), which is very useful in identifying normal and heterozygous horses for the DNA-PK (catalytic subunit) gene. This valuable information should be acquired **before** making breeding decisions.

CELLULAR IMMUNODEFICIENCIES

In the horse, cellular immunodeficiency is difficult to diagnose unless the number and subpopulation distribution of T cells in the peripheral blood is abnormal. T cell disorders may affect directly the cytotoxic function, or indirectly the B cell function due to the lack of T helper cell signals. Autoimmune or tumoral diseases may be accompanied by T cell immunodeficiencies. Cellular immune disorders may be associated with **intracellular pathogens** (viruses, fungi, protozoa and mycobacteria). Recurrent pyogenic infections are common, and clinical signs are similar to those of humoral immunodeficiencies (*q.v.*). In the horse, a transient CD4⁺ and CD8⁺ T cell deficiency has been described in a 3-month-old Paint filly with ***P. carinii* pneumonia**.

Other cellular immunodeficiencies that are not recognized in the horse but are described in human patients include defects in the expression or function of cell surface activation molecules and their cell signaling components. As is the case in humorally immunodeficient horses, modified-live or live vaccines should not be used.

PHAGOCYTIC IMMUNODEFICIENCIES

Inherited forms of neutrophil dysfunction have not been described in the horse but should be suspected in cases of **recurrent infection** with *Staphylococcus*, *Pseudomonas*, *Serratia*, *Klebsiella* and fungi (*Aspergillus*, *Candida*). Affected patients often present with dermatitis, cutaneous abscesses, cellulitis, periodontal diseases and/or organomegaly. Some of the diseases associated with phagocytic disorders described in other species include leukocyte adhesion deficiency, cyclic neutrophil hematopoiesis, Chediak-Higashi syndrome, Pelger-Huët anomaly and chronic granulomatous disease.

COMPLEMENT COMPONENT IMMUNODEFICIENCIES

Primary diseases of the complement components are rare and have not been described in the horse. Deficiencies of complement components have been

described in human patients and other domestic species. Some of the diseases associated with complement component disorders include:

1. Deficiencies of early components of complement C1q, C1r, C1s, C4 and C2 (systemic lupus erythematosus-like signs, glomerulonephritis)
2. Deficiencies of late components of complement C5, C6, C7, C8 and C9 (recurrent disseminated *Neisseria* spp. infections)
3. Deficiencies of C3 component, factors D, I and H (pyogenic infections)
4. Deficiencies of C1 inhibitor (hereditary angioedema or lymphoproliferative disorders)
5. Properdin deficiency (meningococemia).

DIAGNOSIS OF IMMUNODEFICIENCIES

A full **history** may assist in building a list of potential etiologies:

1. **Young animals** may present inadequate serum immunoglobulin levels due to failure of transfer of maternal immunoglobulins, or inadequate production of immunoglobulins (SCID, Fell Pony syndrome) (*q.v.*), whereas common variable immunodeficiency may affect adult horses in the second decade of life.
2. The **gender** of the horse may indicate hereditary traits: consider X-linked agammaglobulinemia in young males (*q.v.*).
3. Certain **intracellular or opportunistic pathogens** have been associated with disorders in immunodeficient horses: *Pneumocystis carinii* (T cell deficiency), *Candida albicans* (SCID, neutrophil deficiency), *Serratia* spp. (neutrophil deficiency) (*q.v.*).
4. **Immunization history** may suggest cellular immunodeficiency (infection after modified-live or live virus vaccine).
5. **Family history** may indicate an immunodeficiency condition (high incidence of young animal death in one family or autoimmunity).

On **physical examination**, poor growth due to chronic infection is a condition often associated with immunodeficiency. Other findings that may suggest impairment of the immune system include paucity of lymphoid tissues (SCID, Fell Pony syndrome), hepato- or splenomegaly (common variable immunodeficiency), chronic dermatitis and periodontitis (neutrophil dysfunction) (*q.v.*).

Laboratory assays and in vivo diagnostic experiments are useful in confirming and characterizing immunodeficiency conditions. For all tests, the use of **age-matched controls** is advised.

1. **Complete blood cell count** may indicate abnormal production, destruction or dysfunction of a distinct cell population: neutropenia, neutrophilia, lymphopenia, lymphocytosis, anemia and thrombocytopenia.
2. **Peripheral blood and bone marrow cytology** may suggest the presence of abnormal cells (lymphoblasts, large granular neutrophils) and hypoplastic cell deficiencies (myeloid-erythroid ratio, cell morphology and maturation).
3. **Humoral function** may be assessed by serum immunoglobulin isotype levels (radial immunodiffusion, ELISA), in vivo antibody response tests

- (immunization with tetanus toxoid), and number of circulating B cells (lymphocyte phenotyping using flow cytometry).
4. **Cellular function** may be evaluated by the distribution of CD4+ and CD8+ T cells (lymphocyte phenotyping using flow cytometry), antigen skin tests (phytohemagglutinin, tetanus toxoid), in vitro response to mitogens (lymphocyte proliferation assays) and cytotoxic function (chromium release assays).
 5. **Phagocytic function** and recruitment may be tested by flow cytometric assays for phagocytosis and oxidative burst activity, the expression of cell surface CD18 molecule, and chemotaxis assays.
 6. **Complement component levels and function** may be measured by complement component radial immunodiffusion tests, hemolytic complement assays and flow cytometric opsonization assays.
 7. **A genetic test** to identify the SCID carrier state or affected state is commercially available (VetGen, Ann Arbor, MI, USA).

IMMUNOMODULATORS

An immunomodulator or biologic response modifier is a substance that enhances or suppresses immune responses. **Immunostimulants** promote a non-specific activation of the immune system and may amplify different areas of immune defense: phagocytosis and intracellular killing of organisms, antigen presentation, cytotoxic and antiviral activity, cytokine release and antibody production. Once the immunotherapeutic agent is processed by antigen-presenting cells, **endogenous cytokines** become the mediators of the immune response that will resist infections or neoplastic conditions.

Common **side effects** following immunotherapy include reaction at the injection site, fever, lethargy and decreased appetite, probably related to induced endogenous cytokine release. For this reason, it is essential that immunostimulants mediate short-term responses; stimulation of the immune response without harmful inflammation and tissue damage is imperative. The **selection** and use of immunomodulators is still challenged by insufficient information on mechanisms of action in vitro and in vivo, deleterious and unknown side effects, lack of response by some individuals, and extra-label use with over-expectations of efficacy.

PROPIONIBACTERIUM ACNES

Inactivated *Propionibacterium acnes* (Eqstim, Immunovet, Neogen Co., Lansing, MI) has been indicated as prophylactic therapy to **reduce the incidence of transport stress-induced respiratory disease** and as an adjunctive therapy in the treatment of primary and secondary viral and bacterial infections of the respiratory tract of the horse. The recommended dose is 1 mL per 114 kg BW IV, 2–3 doses q 48 or 72 h, 1–2 days **before stress is induced** or as an adjunct to conventional therapy. *P. acnes* is known to induce macrophage activation, to enhance natural killer cell activity and CD8+ T lymphocyte cytotoxic activity, to inhibit tumor growth and to induce non-specific resistance to pathogenic challenge in mice, human patients and domestic animals.

In the horse, a series of three doses 24 h apart, IV, increased the CD4+ T lymphocyte population, non-opsonized phagocytosis and lymphocyte-activated killer (LAK) cell activity in peripheral blood and bronchoalveolar lavage fluid. In the latter, total leukocyte counts decreased and the proportion of macrophages increased.

MYCOBACTERIUM CELL WALL EXTRACT

Mycobacterium extracts are one of the most potent stimulants of macrophage function, resulting in subsequent release of inflammatory cytokines and lymphocyte activation. Equimmune I.V. (Vetrepharm Research Inc., Athens, GA) is an oil-in-water emulsion of purified *Mycobacterium* spp. cell wall extract for the treatment of equine respiratory disease complex (ERDC) (*q.v.*) resulting from viruses and/or bacteria.

In a clinical trial, horses receiving one IV dose of purified *Mycobacterium* spp. cell wall extract recovered from respiratory clinical signs in a shorter period of time compared with the placebo group. The recommended dose is 1.5 mL per animal, IV. It has been approved for use in pregnant mares. Hypersensitivity reactions characterized by formation of multifocal granulomas have been reported with the use of *Mycobacterium* spp. cell wall extract in horses and attenuated bacillus Calmette–Guérin (BCG) in humans.

PARAPOXVIRUS OVIS

Baypamun HK (Bayer AG, Leverkusen, Germany) is the commercially available form of purified and chemically inactivated parapoxvirus ovis strain D 1701 for use in horses and other domestic species. It is indicated for the prophylaxis of **stress-induced respiratory diseases** caused by **transportation, hospitalization and weaning**, for the metaphylaxis and therapy of infectious diseases, and to enhance immunization response. The general recommended dose is 2 mL per animal, IM, 2 or 3 doses 48 h apart, 1–2 days **before the stress** (weaning, transportation and commingling) is induced, immediately after birth or with conventional treatment for respiratory disease. Some limited swelling at the injection site may occur.

The mechanism of action of parapoxviruses in the immune system has been studied in humans and animal models for its activation of natural killer cells, phagocytic activity and release of interferon- α and interleukin-2 (IL-2). To this date, there are very limited in vitro data describing the effects of this immunomodulator in horse cells.

CAPRINE SERUM FRACTION

Caprine Serum Fraction Immunomodulator (Centaur Inc., Overland Park, KS) is a sterile, filtered, purified and standardized fraction goat serum preserved in phenol and thiomersal. The label recommendation is 2 mL IM injections, two applications, 7–10 days apart. Potential side effects are swelling and heat at the site of injection for 48–72 h. This immunomodulator is indicated for adjunctive treatment of **lower respiratory tract disease** in horses. In a clinical trial involving

horses with unspecified lower respiratory tract disease, administration of two IM injections of the Caprine Serum Fraction Immunomodulator promoted a reduction of monocyte and CD8+ T lymphocyte counts in peripheral blood, and total cell counts in bronchoalveolar lavage (BAL) fluid.

INTERFERON (IFN)- α

Type I interferons are produced by the innate immune system in response to the presence of viral organisms. Their antiviral effect is characterized by inhibition of viral protein synthesis, activation of cytolytic activity, increase in MHC class I expression of virus-infected cells, enhanced IFN- γ expression by lymphocytes, macrophage activation and dendritic cell maturation. Oral administration of low doses of IFN- α acts directly on oropharyngeal-associated lymphoid tissues, and has therapeutic benefit in horses with **inflammatory airway disease** and **active training**. In a clinical trial, natural, human IFN- α (50 U PO for 5 consecutive days) reduced airway inflammation, pharyngeal lymphoid hyperplasia, nasal discharge and cough compared with horses receiving placebo. Horses that received oral IFN- α recovered their BAL fluid to a non-inflammatory cytologic profile.

The use of commercially available recombinant IFN- α -2a (Roche Laboratories Inc., Nutley, NJ), which contains only one subtype of IFN- α in contrast to the natural form, failed to reduce virus shedding and respiratory disease in experimental herpesvirus 1 infection in horses. It is not known whether the less protective effect of the immunotherapy regimen used was due to inappropriate dosage or differences in the response to the recombinant form. High doses of IFN- α are more likely to cause side effects due to induced self-destructive inflammatory responses and immunosuppression.

LEVAMISOLE PHOSPHATE

Levamisole phosphate is a synthetic anthelmintic with immunomodulatory properties poorly characterized in vitro and in vivo. However, cell-mediated response and phagocytic activity may improve in immunocompromised individuals after immunotherapy. Extra-label use of levamisole, 2 mg/kg BW q 48 h, PO, in horses as an adjunct for the treatment of **respiratory disease** is based on clinical reports of prevention and treatment of chronic respiratory infections in children and neonate animals.

LEUKOPROLIFERATIVE DISEASES

LYMPHOMAS AND LYMPHOSARCOMAS

Lymphomas and lymphosarcomas are the most common malignant neoplasms of the horse. **Primary** (thymus and bone marrow) or **secondary lymphoid tissues** (lymph node, spleen, gut-associated lymphoid tissue and bronchus-associated lymphoid tissue) may be the origin of the tumoral cells. In contrast to other species, no viral etiology has been associated with the development of lymphoma (*q.v.*) or lymphosarcoma (*q.v.*) in horses. One clone

of lymphocytes may become **malignant**, and the type of cells belonging to this clone (B, T, plasma cells) characterizes the type of tumor and effects in the immune system. Horses of a **young age** may develop the disease, both sexes and all breeds may be affected, and clinical signs vary according to the system affected and stage of disease.

Classification of lymphomas and lymphosarcomas in the horse still relates to their anatomic distribution: generalized, intestinal, mediastinal or cutaneous. More importantly, the classification of **malignant lymphomas** should expand from the knowledge of architectural and cytologic characteristics of neoplastic elements to the investigation of multiple parameters, including morphology, immunophenotype, molecular genetics and clinical features. Therefore, as laboratory reagents for lymphoid lineage and cellular differentiation become available for the equine species, immune profiles for the primary diagnosis, classification, staging and immunotherapy of lymphoid neoplasms may develop. In addition, identification of oncogene and tumor suppressor gene products may aid in the understanding of pathogenic mechanisms of lymphomagenesis. Altogether, this information should improve efficiency in the application of novel treatment options based on the targeting of critical mechanisms of cell proliferation and activation.

Generalized or multicentric lymphomas constitute the most common form. It may be characterized by tumor growth in **several tissues**, including the secondary lymphoid tissues, or by the **systemic infiltration** of tumoral cells. Although neoplastic cells originating from metastasizing tumors can be identified in the blood, development of leukemia is rare. **Peripheral lymphadenopathy** is a common but not exclusive finding because abdominal or thoracic lymph nodes may be affected. In addition to lymphoid organs, tumors and infiltration of tumoral cells have been reported in the eye, lung, nasopharynx, liver, kidney, urinary bladder, liver, heart, brain, spinal cord, ovary and uterus. General clinical signs may include depression, emaciation, fever, anemia, hypoproteinemia, and edema due to impaired lymphatic drainage.

The **intestinal or alimentary** form involves the gastrointestinal tract, more frequently the **small intestine**. Metastases to the mesenteric lymph nodes, liver and spleen have been reported. This type of tumor is more common in horses <5 yr. Therefore, malabsorption of nutrients, weight loss, diarrhea, colic, protein-losing enteropathy, hypoalbuminemia and dependent edema may be the clinical signs suggestive of intestinal lymphoma. In advanced cases, necrotic tumoral masses may develop.

The **mediastinal** form of lymphoma is a primary neoplasm of the **thymus**. This type of tumor is more common in adult horses and often metastasizes to other systems. Clinical signs are consequent to the space-occupying lesion and compression of vessels and lymphatics and can include pleural effusion, edema of the ventral thorax and forelimbs, distended jugular veins, muffled heart sounds, tachycardia, tachypnea, dyspnea, cough, inappetence and weight loss. In addition, dysphagia can be induced by lymphadenopathy in the thoracic and retropharyngeal areas.

The **cutaneous** form of lymphoma may involve the dermis and/or subdermis of young adult horses. The **cutaneous sarcomatous** lesions are multiple, firm and not painful, from 1 to 20 cm in diameter, with a tendency to be distributed in the ventral aspect of the neck, chest, abdomen and perineum.

The lesions may develop slowly or rapidly, remain static or even regress in size. Most of the lesions do not show hair loss, although very large lesions may lose the hair and skin integrity due to trauma or necrosis. This type of tumor is usually of B cell origin, lymphadenopathy is present in half of the cases and metastasis to other systems is rare.

Mycosis fungoides is another form of **cutaneous lymphoma** in which there is **diffuse infiltration** of tumoral T helper lymphocytes in the dermis and subdermis. A variant of this type of tumor includes cutaneous and leukemic Sézary cells, which are malignant cells with a cerebriform appearance. Phenotypic and structural heterogeneity of cutaneous lymphomas is possible. In the horse, there is one report of B cell cutaneous lymphoma with Sézary cells and monoclonal gammopathy.

LEUKEMIAS

Leukemias are rare conditions in the horse and may be of **lymphoid** or **myeloid** (granulocytic, myelomonocytic, monocytic and eosinophilic) cell origin. In horses, myeloid leukemias are rare and the lymphoid leukemias characterized in the literature include the phenotypes B cell/IgM positive, B cell/IgM negative, CD5 positive T cell positive, and CD3 negative/CD4 positive T cell.

In **primary leukemia**, a neoplastic hematopoietic cell line develops in the bone marrow and leukemic cells may invade vascularized organs without forming masses. In **secondary leukemia**, tumoral cells metastasize to the bone marrow. When the bone marrow is diffusely infiltrated by neoplastic cells, the production of the non-tumoral cells may become compromised (myelophthisis).

In addition, leukemias can be classified into **leukemic**, **subleukemic** and **aleukemic** according to the presence and number of circulating tumoral cells. In plasma cell myeloma, there is a malignant proliferation and monoclonal expansion of a single plasma cell lineage in the bone marrow. When diffuse, the cell proliferation promotes bone marrow destruction, osteolysis, myelophthisis and lameness. The monoclonal gammopathy can be diagnosed by serum and/or urine protein electrophoresis, and it is often of IgG isotype. Secondary infections due to lack of diversity in immunoglobulin isotype production may occur.

DIAGNOSIS OF LEUKOPROLIFERATIVE DISEASES

The diagnosis of lymphomas and leukemias is based on the history, physical examination, and characterization of the tumoral cells. A **complete blood cell count** may indicate anemia due to chronic inflammation, myelophthisis, immune-mediated hemolytic processes (Coombs test positive) or, rarely, blood loss (secondary to immune-mediated or myelophthisic thrombocytopenia and tissue damage). Eosinophilia or diffuse eosinophilic infiltration of tissues is rarely seen as a response to paraneoplastic cytokine interleukin-5 (IL-5) and granulocyte-monocyte colony-stimulating factor (GM-CSF) production by certain lymphoma cells. **Hypoalbuminemia** is observed in infiltrative tumors of the gastrointestinal tract that cause malabsorption and/or protein-losing enteropathy.

Diagnosis of **malabsorption** may be made by testing the absorption of D-glucose or D-xylose. The horse should be fasted for 18 h. A 10% solution of D-glucose (1 g/kg BW) or D-xylose (0.5 g/kg BW) is administered via nasogastric tube. Heparinized blood samples are collected before and at 30 min intervals up to 3 h after administration. Plasma glucose or xylose values peak approximately 60–90 min after administration in normal horses. **Hyperglobulinemia** caused by high levels of alpha and beta globulins is associated with inflammation (along with neutrophilia, hyperfibrinogenemia and fever) whereas the presence of monoclonal gamma globulin may indicate plasma myeloma or B cell leukemias.

Blood chemistry may be useful to identify inflammation in organs that may harbor tumoral cells or masses. **Hypercalcemia** is not a consistent finding in lymphomas, yet it can be secondary to the production of parathyroid hormone-like protein by some neoplasms. Tumoral masses and/or infiltrative tumoral cells may not be readily recognized and require thorough testing (radiographs, ultrasound and exploratory surgery). **Cytology** of blood smears, bone marrow, pleural fluid and peritoneal fluid, or histologic examination of biopsies of enlarged lymph nodes or skin may reveal neoplastic cells.

Immunologic testing

To date, **immunologic testing** has been used only occasionally in horses with lymphoma and lymphocytic leukemias due to the limited number of laboratories performing these types of tests. Clinically, patients with cancer should be monitored for **immunodeficiency** because of the direct effect of tumoral cells on the immune system (inhibition of lymphocyte activation/function or antibody production) or because of the effect of immunosuppressive therapy. **Protein electrophoresis** and **serum immunoglobulin quantification** by radial immunodiffusion may characterize hypogammaglobulinemias or monoclonal gammopathies (IgG, IgA or IgM). Suppression of T lymphocyte function by tumors may be evaluated by **lymphocyte proliferation** response to mitogens in vitro.

Phenotyping of the tumoral cells may be accomplished by flow cytometry using a panel of monoclonal antibodies that characterize cell lineages (CD4+ T cell, CD8+ T cell, B cell and other cell surface molecules) in fluid or tissue aspirates.

Additional information about the tumoral cells can be obtained by flow cytometric analysis of **DNA content** to evaluate their ploidy status, and polymerase chain reaction (PCR) to identify clonal expansion of T or B cells by detecting single T cell (TCR) or B cell (BCR) receptor patterns.

Immunohistochemistry and **immunocytochemistry** may also be used for the phenotyping and distribution of tumoral cells in tissues (**biopsy or necropsy** samples) and cell suspensions (tissue or fluid aspirates). Most antibodies available for this type of assay do not work in fixed or paraffin-embedded tissues, therefore it is important to save snap-frozen tissues without preservatives (placed on dry ice or in liquid nitrogen vapor for freezing and maintained at -20°C) and unfixed cytologic smears (dry impress smears preserved at room temperature).

These tests add to the histopathologic and morphologic information about the type of cell involved in the neoplasm. The classification of **myeloid**

leukemias may be difficult, especially if neoplastic cells are poorly differentiated. Therefore, cytochemistry using stains for chemical moieties and cellular products, along with cell morphology and cell counts, forms the basis for the **French–American–British (FAB) classification** of non-lymphoid leukemias. Due to variability in the cell phenotype and activation status of tumoral lymphocytes, this type of information may become fundamental in the development of treatment strategies based on the characteristics of the tumoral cells rather than their anatomic distribution.

TREATMENT OF LEUKOPROLIFERATIVE DISEASES

The treatment of lymphomas and lymphocytic leukemias in horses is often **unrewarding**. Some of the reasons for the failure of treatment are the advanced stage of tumoral development by the time it is perceived clinically, the lack of understanding of the phenotype and activation status of the tumoral cells, and the lack of clinical treatment trials that would support the use of a certain treatment regimen. In addition to supportive therapy, **immunosuppressive therapy** may be attempted with **corticosteroids** (dexamethasone 0.2 mg/kg BW s.i.d. IV or PO for 5 days), followed by maintenance with prednisolone (1–2 mg/kg BW s.i.d. PO).

In some cases, the combination of **chemotherapeutic agents** has been suggested with cytosine arabinoside (200–300 mg/m² q 1–2 wk SC or IM) plus chlorambucil (20 mg/m² q 2 wk PO) or cyclophosphamide (200 mg/m² q 2–3 wk IV) plus prednisolone (1–2 mg/kg BW s.i.d. PO). Remission of the tumor may be observed in 2–4 wk, and the protocol should be used for 2–3 mo, when the treatment interval is increased by a week in each cycle of therapy, to a total of 6–8 mo. Other treatment options include L-asparaginase (10 000–40 000 IU/m² q 2–3 wk) in combination or not with cyclophosphamide and/or prednisolone. In cases of **multiple myeloma**, melphalan (7 mg/m² s.i.d. PO for 5 days, then every 3 wk) has been used.

INTRODUCTION

Nutrition can be defined as the process of feeding and the subsequent digestion and assimilation of food. It is, therefore, of fundamental importance to the well-being of any animal. However, good nutrition will only help a horse to be able to perform optimally; it cannot improve the intrinsic ability of the animal (nor the horse and rider combination). Poor nutrition, on the other hand, may impose limits on an animal's ability to perform. In most instances it is only when an adult horse is asked to exert itself that the result of imbalanced or inadequate nutrition becomes apparent.

Many of the nutrients we now take for granted were only recognized a relatively short time ago. Although in the early nineteenth century it was appreciated that calcium and phosphorus were needed for "hard bone", vitamin B₁₂, for example, was not seen as an essential nutrient until the 1940s and selenium not until the 1950s. The original research into the feeding of horses came mainly from army veterinarians and others involved with cavalry, working and pack horses. Mechanization and the replacement of the horse as a means of transport and a power source resulted in a decrease in equine research. The first **National Research Council (NRC)** report on equine nutrition was published in 1949. The second, in 1961, stated that little new information had been obtained since 1949 and contained many estimates based on extrapolations from ruminants. The next in 1966 was similar. The last one, carried out in 1989, is well overdue for revision. Since then increasing numbers of equine nutrition studies have been carried out, as the popularity of the horse for recreational purposes has increased.

However, many of the equine nutritional practices currently employed have not changed significantly from those followed hundreds of years ago,

although the nature and composition of the basic feedstuffs has changed in some instances. The most significant change in the twentieth century was probably the introduction of **pelleted feeds** around 1920. These became popular in the 1960s when competition, increased knowledge, more ethical companies and government regulations resulted in the evolution of good quality, commercial, compound feeds.

Unfortunately, in many areas of equine nutrition **good scientific information** is still not available. Confusion and controversy often exist, especially where one research paper's findings directly contradict those of another. There are many reasons for this confusion. Much of the research has been carried out in ponies and then applied to the horse but such extrapolations may not always be applicable. In other instances, the data available have been extrapolated from another species such as a ruminant. Largely for financial reasons, most of the nutritional research in horses has been carried out on relatively few animals and has concentrated on the effects of short-term alterations in intake.

The **adaptive changes** that occur over longer periods are therefore not well understood. Differing experimental protocols, basal diets, and exercise regimens may all contribute to the conflicting results. In addition, the normal daily nutrient requirements vary according to several factors, depending on the nutrient involved, and include age, body weight, exercise and environmental conditions. The availability of a particular nutrient may vary not only with the nutrient, its nature in that feedstuff (e.g. of organic or inorganic source) and the presence of other nutrients, but also with the individual animal's **absorptive ability**. Nutrition cannot be considered to be an exact science. Considerably more information on the dietary requirements and digestive physiology of domestic ruminants is available than for the horse, however, and more basic and applied scientific research is needed into most aspects of equine nutrition.

Optimal feeding of horses uses both **art and science**. The science provides the information about the digestive and metabolic processes, the nutrient requirements and the principles behind feeding practices. The art is the ability to convert this theory into practice for the individual horse, its needs, likes and dislikes. In this chapter, a general and, it is hoped, practical guide to equine nutrition is given. Wherever possible, recommendations are based on sound research but interpreted practically. It aims to provide a guideline to follow and to highlight some of the reasons behind the basic rules of feeding. Although, wherever possible, discrepancies between various authors' recommendations have been removed, some remain because in a number of instances "correct" values are simply not known and the best that exists at the present time is a range of acceptable levels.

GUIDE TO TYPICAL FEEDSTUFFS

Domestication and our increasing demand for horses to perform repeatedly have resulted in energy requirements that, for some horses, are above those able to be provided by their more "natural" diet of fresh forage. Cereals provide more net energy than hay, which in turn provides more than twice the

net or usable energy of straw. However, the upper part of the gastrointestinal tract (GIT) has a relatively **small capacity** and the horse has **digestive and metabolic limitations** to high grain, starch and sugar based diets. Large grain meals may overwhelm the digestive capacity of the stomach and small intestine leading to **the rapid fermentation** of the grain carbohydrate in the hindgut. This potentially can result in one of a number of disorders including colic, diarrhea and laminitis.

Therefore, there has been increasing interest in the use of **alternative energy sources** for horses, especially alternative fiber sources, which do not cause such marked disturbances in the hindgut and yet provide more energy than typical forages. In addition, because vegetable oils provide proportionally more net energy than the cereals, yet contain no starch or sugar and may provide other advantages, there is an increasing use of supplementary **vegetable oils**.

Table 3.1 provides figures for the typical composition of some common feedstuffs. Individual samples may vary within a range and, for complete accuracy when evaluating a dietary regimen, **individual analyses** must be undertaken. Pasture and hay analyses vary according to season, soil type, geographic location and other variables such as harvest date. For accuracy, a number of actual representative forage (fresh or preserved) samples must be analyzed when reliable results are required.

The importance of calculating the actual **elemental levels** of the required mineral from the selected source cannot be overemphasized. The **bio-availability** of certain minerals will be affected by many factors such as the levels of any antagonistic minerals present. In addition, there will also be variation in utilization between individual horses.

When assessing the nutrient value of particular feedstuffs, it must be remembered that modern methods of feed production have had two major effects on the composition and feed value of equine rations. First, they have allowed a **wider range of ingredients** to be used as modern production methods destroy many of the harmful substances that might prevent the feedstuff being used in its raw state. Second, they have affected the **nutrient availability and digestibility** of certain traditional and recently introduced feedstuffs. Moreover, there are several methods of preparation or treatment of feedstuffs that have differing effects on palatability, digestibility and stability in storage.

CEREALS, SUGAR BEET AND OIL SEEDS AS FEEDSTUFFS

Major cereals fed to horses

Oats are the traditional cereal fed to horses in work. They contain significantly higher fiber and lower starch levels than most other cereals and the nature of their starch particles helps to promote a high pre-cecal starch digestibility in contrast, for example, to corn and barley. As with all cereals and cereal by-products, oats provide a low level of calcium and a moderate level of phosphorus (which may be bound in phytate compounds, reducing its availability), giving a reversed **calcium to phosphorus ratio** (*q.v.*). Also, in common with most cereals, the level of the essential amino acid lysine is

Table 3.1 Guide to the typical composition of common feedstuffs (assuming 880 g DM/kg), in part derived from the NRC¹

	Crude protein (g/kg)	Crude fiber (g/kg)	Ca (g/kg)	P (g/kg)	DE (MJ/kg)	Mg (g/kg)	Lysine (g/kg)	Starch (g/kg)

relatively low. There are now varieties of oat produced without husks, colloquially often called **naked oats**. They have a better amino acid profile, higher oil levels, and thus considerably higher energy levels than the husked varieties.

Barley has a higher energy level than oats and is generally fed rolled or cooked (cooking increases **pre-cecal starch digestibility**; *q.v.*). However, the amino acid profile, low calcium level, and phytate-bound phosphorus need correcting when barley is the major ingredient in horse rations.

Maize tends to have the lowest crude protein (CP) of the common cereals fed to horses and the highest energy value. In the UK it is generally micronized or steam flaked before feeding but in the USA and mainland Europe it is often simply cracked to open the outer husk.

Wheat has traditionally not been fed to horses. However, with the introduction of efficient cooking methods, the resultant alteration in the structure of the starch has made it a useful high energy feed for inclusion in commercial coarse mixes and home-mixed cereal rations. Large amounts per meal should be avoided, however, as they may lead to a sticky consistency in the stomach which may favor **dysfermentation** (*q.v.*).

Triticale is a hybrid resulting from crossing wheat and rye. In a ground form it should have a feeding value slightly greater than that of barley and evidence indicates that triticale may be better digested by the horse than is wheat. Both rye and triticale are subject to **ergot** infestation (*q.v.*), so clean samples should be sought.

Regardless of how triticale, wheat, barley or maize are mechanically processed, the starch will be less well digested in the small intestine than when cooked grains are fed.

Oil seeds

The **soya bean** is an excellent source of protein in an equine diet, providing good levels of essential amino acids. It must be properly cooked before feeding to help destroy the protease inhibitors as well as potential allergenic, goitrogenic and anticoagulant factors. However, in practice, most soya available in retail outlets has been suitably treated.

Soya is available as an **expelled meal**, with the oil removed; as the **full fat meal**, which has added advantages of providing good levels of essential fatty acids; and as the **full fat flake**, which has usually been micronized. This latter form is the most common to add as a top dressing, as the physical consistency of the meals can be unpalatable to some horses.

Linseed must also be cooked before feeding to destroy the glycoside, which, after soaking, could potentially release **hydrocyanic acid**. Linseed also has a good amino acid profile and in some methods of processing, where the oil is not extracted, also provides good levels of certain key fatty acids.

Vegetable oils

Horses have been shown to be able to digest and utilize high amounts of oil, but for practical purposes approximately 0.75–1 g of oil/kg BW/day may be considered to be the upper limit. Levels of 5–8% in the total diet are more

common in some high performing horses and many performance horses can be fed up to 100 mL/100 kg BW daily in divided doses without any problems provided that it has been introduced gradually, is not rancid, the horse requires such an energy intake, additional vitamin E is provided and the overall diet is re-balanced.

Adding oil to existing feed has the potential to create **multiple** imbalances (including an inadequate vitamin E intake and a calcium imbalance) and therefore could be considered less safe than feeding a diet where the oil has been balanced in relation to all of the essential nutrients in the feed. Any supplemental oil or oil-supplemented feed should be introduced **slowly**.

Supplemental fat or oil diets can be supplied in four main ways:

1. As an **oil supplemented, manufactured diet**. The advantage here is that such diets should be balanced with respect to the protein, vitamin and mineral intake that they provide when fed with forage (and salt as required). This can be a simple, practical and convenient way to feed high oil diets.
2. **High oil supplemental feedstuffs**, such as rice bran, which are also high in fiber and usually low in starch. However, many of the rice brans available have the same disadvantages as wheat bran in that they have a very imbalanced calcium-phosphorus content.
3. **Supplemental animal fat**. Many horses find most animal fats to be unpalatable and these fats seem often to be more likely to cause **digestive upsets**. Their use is not to be recommended.
4. **Supplemental vegetable oils**. The exact type of oil that may be preferred will depend on the individual horse and the nature of the processing to which the oil has been subjected. **Corn oil** and **soy oil** are probably the most commonly used vegetable oils in Europe.

It has been suggested that feeding oil supplemented diets, with appropriate training, can result in a range of effects on a variety of physiologic, metabolic parameters as well as on performance. These include:

1. Increased mobilization of free fatty acids (FFA) and increased speed of mobilization; increased speed of uptake of FFA into muscle—often considered to be rate limiting.
2. A glycogen sparing effect so that fatigue is delayed and performance improved (this could be especially important in endurance activities).
3. Increased high intensity exercise capacity.
4. In horses with a high energy demand, helping to reduce feed volume so that the roughage intake can be maintained (oils have also been suggested to help reduce the extent of bacterial dysfermentations in the stomach and small intestine).
5. Behavioral advantages over high cereal starch diets.

In order to have the potential to obtain metabolic benefits from the feeding of oil or oil supplemented diets, in addition to those associated with its high energy density and lack of starch content, the oil needs to be fed for **several months**.

Linoleic acid and **alpha-linolenic acid** are considered dietary essential fatty acids. However, no evidence of deficiency has been described for the horse and it must be assumed that a normal diet of cereal grains and natural forage, or of pasture herbage, will provide the dietary requirements.

FORAGES AND OTHER FIBER SOURCES

The choice of fiber source is now much wider with the advent of new methods of grass preservation, improved grass and other forage plant species as well as other technological advances. There are two equally important aspects when selecting the most appropriate fiber source:

1. The nutrient levels in the selected forage, and thus the percentage of the horse's total daily nutrient requirements that will be met through the fiber source.
2. The effect that forage may have on other aspects of the horse's health, especially the respiratory system.

Hay

Hay is the most commonly used long fiber source and may be divided into several types.

Meadow hay is generally made from permanent pasture and has a great diversity of species, including several different grasses, herbs and other plants. This hay is often termed "soft", as the diversity of plants results in different rates of growth and stages of maturity at the time of cutting.

Meadow hay will, on average, also provide higher protein (typically 8–12% dry matter [DM]) and digestible energy levels (typically 9–11 MJ/kg DM) than most seed hays. Meadow hays also often have higher mineral levels than seed hay, as they contain a greater proportion of deeper rooting herbaceous species.

Seed hay is produced from specially seeded leys, usually 1–3 yr old, and contains predominantly one or two grass species (often rye grass or timothy). This hay is more uniform and, due to the growth rate and cutting time, is usually fairly mature, with a lower proportion of leafy material and higher proportion of stalk than meadow hay. Typically, seed hay has lower energy (for example approximately 8–10 MJ/kg DM) and protein levels (approximately 4–8% DM) and a lower digestibility than meadow hay. The mineral levels in seed hay also tend to be lower than for meadow hay, although this will depend on the soil upon which the hay was grown.

Legume hay (usually alfalfa or lucerne, clover or sainfoin) has, due to **nitrogen-fixing properties**, higher protein levels than seed or meadow hay. Legume hay may be grown as a pure stand, but can be difficult to dry in cool wet climates as the stalks are very moist and thick so that cutting is often left until later in the season, when temperatures increase. However, by then the hay may have become very mature and stalky, with low energy and digestibility values. An exception to this is alfalfa, which can be cut earlier, barn dried and packaged in a short chopped form in plastic-covered bales. Clover and sainfoin are commonly mixed with grass species such as timothy to make

conventional hay, but care must be taken with the leys, as competition between the species will alter the relative proportions over a number of years.

Barn-dried hay is wilted in the field for 2–3 days when weather conditions are good and loose packed into special buildings; air of a particular temperature and humidity is then blown through the stored grass for 7–10 days before baling. When correctly practiced, this results in hay with a high DM, thus limiting the development of fungal spores.

Sometimes hay is baled with too high a moisture content due to unsuitable weather conditions at cutting time, insufficient turning in the rows, or other factors. A high moisture content will allow the development of large quantities of **fungal spores** (*q.v.*), which can be inhaled by the horse. Hay with a DM $\leq 87\%$ should always be assessed for spore level.

Soaking hay before feeding

The practice of soaking hay with the aim of reducing the number of airborne particles is popular in some areas. It has been reported that soaking a 2.5 kg hay net for 30 min reduces respirable particle numbers by approximately 90%. The water used for soaking must be fresh and increasingly it is recommended that soaking for >30 min may not be advisable due to the potentially negative effect of **prolonged soaking** on the soluble **carbohydrate and nitrogenous content** of hay and the pollutant nature of the effluent. Alternative solutions include the practice of steaming hay or the use of semi-wilted forages, silages or vacuum packed dust-free fodder.

Semi-wilted forages

In an attempt to reduce the level of fungal spores in forage for horses, methods of preserving grass have diversified. “Dust-free” grass and other forage plants such as alfalfa are wilted to approximately 50–60% DM and packaged in semi-permeable plastic, where a mild lactic fermentation occurs owing to the limited amounts of oxygen present. This lactic fermentation stabilizes at approximately pH 4.5–5.5, depending upon the amount of oxygen and substrate available for the microbial fermentation and helps to inhibit the proliferation of fungal spores. (Water activities <0.985 combined with a low pH may help to control in particular the sporulation of *Clostridium botulinum*, *q.v.*).

These forages exert a lower challenge to the horse’s respiratory system and may be a valuable way to provide long fiber to a horse suffering from allergic respiratory disease (*q.v.*).

Damage to packaging allows the influx of oxygen, permitting further microbial activity to occur. This can be identified as a patch of mold, which is limited by the extent of the oxygen diffusion through the hole in the packaging. There may also be an increase in temperature as a result of the microbial activity. Bags in which this has occurred should be discarded.

Silage

Some larger horse keepers now find it economical to use silage. The rapid pH drop, the greater water activity, the decrease in available oxygen and soluble

carbohydrates as fermentation progresses all can help inhibit the development of fungal spores. There are, however, several important factors to be considered before using silage.

First, the DM content is very important to help inhibit **clostridial activity**. Horses also find very low DM material unpalatable, therefore it is recommended that silage for horses should have a DM >35% and preferably >40%.

Second, pH should ideally be <6.0 in order to inhibit undesirable microbial activity. At pH values between 5.0 and 6.0, the DM should exceed 40% as an added inhibitory factor to clostridial activity. Horses may find very low pH material unpalatable, and silage with a pH <4.5 may be rejected by some horses. There are also anecdotal reports that low pH silage may be **extremely unsuitable for donkeys**.

Third, it should be appreciated that if the silage was made to meet the nutrient requirements of dairy cattle the nutrient levels may be unsuitable for horses: for example, lactating dairy cattle require a higher daily protein intake than most horses. Finally, once a “big bale” of silage has been opened it should be used within 2–3 days in order to prevent **secondary microbial activity** from occurring.

Where large amounts of silage or haylage are used, supplementary vitamins D and E are necessary as ensiling destroys vitamin E and vitamin D₂ is not synthesized during the ensiling process. It is always advisable to get professional help when considering producing silage for horse feeding.

Straw

Straw provides a low nutrient level forage, which may be used to provide a portion of the daily forage intake for some horses, although problems with **spores and dust** must be taken into consideration. In addition, due to the high silica and indigestible fiber content there is a risk of **impactions** (*q.v.*) especially in Thoroughbreds and Thoroughbred crosses.

Chemical treatment of straw with **sodium hydroxide** and **ammonia** may increase nutrient value but this requires specialized equipment and expertise and the practice has not gained widespread popularity. Straw may be sprayed with **molasses** to increase its palatability but the nutrient values are still very low. There have been some concerns expressed regarding the various chemicals that may be used in grain production (e.g. to restrict the growth in height and to prolong the vegetative stage). It has been thought, for example, that they may leave unwanted residues on the straw; however, currently there is no evidence to support this concern.

Significant intakes of straw should also be **avoided in young animals**, where the hindgut microflora may not be fully established and the highly indigestible straw may lead to impactions.

Hydroponics

A hydroponic culture is the practice of germinating seeds (usually barley) in water-filled trays in a humidity- and temperature-controlled, enclosed environment.

Correct maintenance of the hydroponic unit is vital to ensure optimal conditions for germination—usually 20/24 h of light and a temperature of

19–20°C. **Routine hygiene** is important to prevent the build-up of mold spores. The barley seeds used should be of the highest quality and must not be treated with mercurial or other seed dressings. The feeding of hydroponic barley is not commonly practiced today.

Soya hulls and sugar beet pulp

It has been suggested that certain fiber sources (sometimes referred to as **highly digestible fibers**) such as sugar beet pulp practically provide more digestible energy to the horse than their traditional crude fiber, protein, fat, etc., analysis would suggest. This is in part because sugar beet pulp contains major fractions of pectins, arabinans and galactans, etc., which are lost during the crude fiber analysis, yet these carbohydrates can be fermented and thereby utilized by the horse. In addition, the fiber or more specifically the non-starch polysaccharide (NSP) in beet pulp is highly digestible over the total tract with a significant proportion being degraded in the small intestine during transit to the hindgut.

Various digestibility studies suggest that not only is sugar beet pulp well fermented in the horse (>60% digestibility of organic matter) but that this degradation occurs to a large extent within the time period that such a feed-stuff would remain within the gut. This explains why sugar beet pulp and a similar feedstuff, **soybean hulls**, are increasingly being used as fiber-based energy sources in modern horse feeds.

In the UK, **sugar beet** is usually molassed and presented as **dehydrated shreds** of compressed pellets. When rehydrated, there is a considerable increase in volume, and thus the practice of soaking sugar beet shreds or pellets in at least twice their dehydrated volume of water is essential before feeding. Small quantities of extruded unmolassed sugar beet in compound mixes need not be soaked before feeding, as the extrusion process has already expanded the material.

METHODS OF FEED PROCESSING

Mechanical rolling, bruising or grinding of cereal grains aims to break open the outer husk, thereby releasing the floury kernel for enzymic digestion. The disadvantages include a greater predisposition for oxidation and an increase in dust. In addition, **mold growth** occurs more readily in grains where the kernel has been broken.

Micronizing cereal grains and vegetable protein seeds is a rapid method of cooking and rolling the grains to gelatinize the starch and improve enzymic digestibility within the small intestine.

Steam flaking of cereal grains is a method of mechanically and biochemically altering the structure of the starch molecules in order to improve digestibility.

Extrusion of cereal grains and vegetable protein seeds involves grinding and increasing the moisture of the cereal grains and “cooking” the resultant slurry at very high temperatures and pressures before forcing the cooked material through a die, where the resultant drop in pressure forces a rapid expansion of the material as air enters the mixture. Typically this process leads to a moisture content of 8–10% (or DM of 90–92%).

Oil extraction and “roasting” of high oil seeds is an industrial process. The resultant oils extracted are then available for use in human or animal feeds, depending upon the degree of refinement.

Grinding and steam pelleting: individual ingredients are ground, mixed, steamed and forced under mechanical pressure.

Coarse mixing combines feedstuffs, often processed by one of the above methods, usually mixing them with a sugary syrup such as molasses or glucose.

FEED STORAGE

Correct storage of feedstuffs is essential to preserve their nutrient value, ensure palatability is retained, and help prevent fungal or bacterial contamination, which may affect the horse's health. In order to help **prevent fungal growth**, feedstuffs should be of the correct moisture level; cereals with a moisture content >16% must be considered suspect. The treatment of high moisture cereal grains with **propionic acid** to act as a mold inhibitor and preservative has been practiced, although the effects of this compound on horses have not been widely studied.

Oxidation is a potential problem in rolled, cracked or bruised cereals. This rancidity will clearly affect palatability and may also affect nutrient availability, especially of certain vitamins. There may also be metabolic implications such as an increased level of peroxides. Storing feed at low humidity and low temperatures will reduce the rate at which oxidation occurs. The importance of maintaining feedstuffs at a suitable temperature, humidity and with adequate ventilation must therefore be strongly emphasized.

Infestation with **mites** is another common cause of feed spoilage. The practice of keeping feeds in galvanized bins can be useful, but care must be taken to ensure the bins are fully emptied and cleaned of all the previous material before a new bag or load is tipped in. In hot weather, high moisture feeds may cause condensation in the galvanized bins, so caution should be exercised.

FEEDSTUFFS ANALYSIS

From time to time it may be necessary to undertake more detailed analyses of specific feedstuffs. Such costly analysis will only be of value if representative samples, especially of pastures or roughage, are taken. Sampling may be required because of a suspected nutritional involvement in a particular disease or disorder where typical, tabulated analyses do not provide the necessary degree of detail or accuracy. Analysis may also be required in order to confirm that dietary ingredients meet the required or designated specification, or to assist with future purchases. If there is any suspicion of a feed related problem the samples should obviously be taken from the feedstuffs that have been fed.

Caution should be exercised as to whether the analyses are given on the fresh **as fed** material, or on a **dry matter basis**. “*Dry matter*” basis refers to the feed or forage after the moisture has been taken out, whereas the term “*as fed*” refers to a feed as it would be fed to a horse. Most concentrate feeds such as

cereals, cubes, pellets, etc., contain approximately 10% moisture with a dry matter content of 88–92% and fresh forage from 20% to 60%. It is important to realize that only the dry matter contains nutrients, so more feed will need to be fed, on an as fed basis, to match requirements if the feed contains more water.

Box 3.1 gives suggestions for routine analyses in order to assess general feed quality and major nutrient levels. In special circumstances, more detailed analyses will be required.

Box 3.1 Suggestions for routine analysis in assessing general feed quality

Cereal grains and by-products, vegetable and animal proteins

1. Dry matter.
2. Crude protein (CP).
3. Digestible crude protein (often based on ruminant data so caution needed with interpretation); or, as a guide,

$$\text{DCP (g/kg DM)} = -27.2 + 0.917 \times \text{CP (g/kg DM)}.$$

4. NDF (and ADF).
5. Ash (as a possible guide to soil contamination).
6. Oil (various methods available, ether extract is usually adequate).
7. Energy (check if given in terms of ruminant ME [metabolizable energy], and conversion coefficients to horse DE should be used—current suggested conversions: divide by 0.9 for high fiber material, divide by 0.85 for low fiber material—very approximate). Many equations are available to estimate DE (i.e. there is no definitive equation) e.g.:

$$\text{DE (MJ/kg DM)} = -3.54 + 0.0209 \times \text{CP} + 0.042 \times \text{Oil} + 0.0001 \times \text{CF} + 0.0185 \times \text{NfE}.$$

8. Micronutrient levels for these ingredients may be obtained from published tables.
9. Certain feedstuffs in the above category contain anti-metabolites in their raw state, and where toxic effects are suspected, analyses for the presence of the anti-metabolites should be made.
10. Results should be interpreted in terms of units per day intake (e.g. g/day protein, or MJ/day DE), rather than percentages as, unless intake quantity is known, the figures are meaningless in terms of effect upon the animal.

Forages (including hay, haylage, silage, straw)

1. The level of fungal contamination in hay should be assessed before purchase.
2. Dry matter.
3. Crude protein.
4. Digestible crude protein (is likely to be based on ruminant data so caution on interpretation).
5. Modified acid detergent (MAD) fiber (other more accurate methods may soon be available). NDF and ADF may also be of value.

Box 3.1 continues on page 164

Box 3.1 Suggestions for routine in assessing general feed quality [continued]

6. Digestibility or D value (based on cattle data, but provides useful comparative data when several samples are assessed).
7. Energy (see under cereal grains).
8. Calcium, phosphorus, magnesium. Other minerals may be assessed as required.

Where forages are the main source of nutrients, further mineral analysis may be advisable. In addition to the above, for silage and haylages:

- (a) pH (see text).
- (b) Ammonia to indicate the nature and suitability of the fermentation.
Ideally $\text{NH}_3\text{-N}$ levels $<3.0\%$ although up to 6.0% are probably acceptable. $>6.0\%$ may affect palatability.

N.B. If abnormally high levels are suspected, nitrate levels should be assessed. Caution should be taken with the interpretation of the nitrate data, as laboratories describe nitrate levels differently.

Pasture and soil

Whilst it may be necessary sometimes to determine the protein and energy levels in pasture, mineral levels are required from both pasture and soil; in the former to ensure any necessary deficiencies are corrected in the concentrate feed, and in the latter to ensure correct fertilizer programs are maintained. Several standard texts on soil analyses and fertilization programs are available.

ADF, acid detergent fiber; NDF, neutral detergent fiber; NfE, nitrogen free extract.

THE DIGESTIVE TRACT

PHYSIOLOGY AND PATHOLOGY OF DIGESTION

The empty alimentary tract accounts for about 5% of the total BW of a horse. The weight of the gut contents varies according to feeding, from 5% (concentrate) to 10% (roughage). In the small intestine, digestion is primarily by the body's own enzymes, while in the voluminous large intestine the feed components are fermented by microorganisms. It is important to appreciate, however, that some fermentation will occur in the stomach and the small intestine. The approximate sizes of the various sections of the gastrointestinal tract are shown in Table 3.2.

Mastication

The duration of feed intake (Table 3.3) depends on the type of feed and the size of the animal. By feeding mainly concentrates, the time taken to ingest the feed and the number of chewing movements are greatly reduced. This may lead to a change in behavioral patterns: for example, animals may bite

Table 3.2 Guide to the size of various parts of the gastrointestinal tract in horses as well as the duration of ingesta passage (500 kg BW)

	Length (m)	Fill (kg/100 kg BW) when feeding		Duration of passage
		Hay	Concentrates	
Esophagus	Up to 1.5	—	—	10–15 s
Stomach	—	2.5	1.8	1–5 h
Small intestine	16–24	2.2	2.2	1.5 h
Cecum	1	3.5	1.5	15–20 h
Colon	6–8	12	6.0	18–24 h
Rectum	0.2–0.3	—	—	1–2
Total		20.2	11.5	35–50 h

Table 3.3 Guide to the duration of feed intake in horses and ponies (min/kg feed)

	Approximate BW (kg)	
	Horse 500	Pony 240
Hay	40	80
Straw	50	—
Milled hay, pelleted	8–10	—
Oats	10	50
Pelleted feed (diameter 4–8 mm)	10	40
Chewing movements/min	80–90	100
Chewing movements/kg hay	3400	—
Chewing movements/kg oats	850	—

and lick objects within their reach. Horses should be fed sufficient amounts of roughage (preferably long fiber or chop) daily in order to help prevent such abnormal behavior.

During chewing, the feed is thoroughly ground by the molar teeth; at the same time the secretion of saliva is stimulated. The **grinding** of whole grains is necessary for their optimal digestion in the small intestine. The intensity of the grinding of the roughage may be important for the passage of digesta through the ileocecal orifice and the large intestine. Short chopped straw or hay (≤ 20 mm) as well as very fine grasses (e.g. wind bent grass [or silky bent-grass], *Agrostis spica-venti*) may be swallowed without intensive chewing and grinding. This increases the **risk of obstructions** as well as increasing the risk of dental enamel points and hooks developing due to restricted chewing movements. The ingestion of lawn mower cuttings increases the risk of colic either due to an obstruction (*q.v.*) or dysfermentation (*q.v.*).

The ground feed is mixed with varying amounts of saliva depending on the duration of the feed intake (Table 3.4). This means that the DM of the boluses swallowed is higher after feeding concentrates than roughage. The occurrence of esophageal obstructions depends not only on the swelling capacity of the feedstuff (for example, dried sugar beet pulp), but also the speed of the feed intake and the size and DM content of the boluses swallowed.

Table 3.4 Principal differences between feeding roughage and concentrate feed

	Roughage	Concentrate feed
Duration of feed intake	Long	Short
Salivation	Heavy	Less intensive
Dry matter of swallowed boluses (%)	<15	>25
Filling of the stomach	Slowly	Quickly
Content of the stomach (temporary)	Moderate	Moderate to high ¹
Dry matter of stomach content (%)	20	30–40
pH reduction in region of pylorus	Normal	Retarded
Microbial activity in stomach and small intestine	Moderate	Moderate to high ¹
Production of organic acids in the large intestine	Continuously	Discontinuously with the risk of low pH in the cecum
Feces dry matter (%)	20	20–45

¹ According to the amount of feed offered per meal.

Stomach and small intestine

The horse has a small, simple stomach, which is suited to the intake of rather small quantities of feed per meal. The cranial region of the stomach is non-glandular and is lined by stratified squamous epithelium similar to the esophagus. As this region fills, bacterial fermentation of the feed starts. This principally involves **lactobacteria**, which convert easily soluble carbohydrates to lactic acid.

Microbial activity and degradation is stopped when the gastric contents reach the fundic gland region and mix with the acid stomach juice containing pepsinogen.

Large quantities of digestive fluids are secreted into the small intestine, in particular from the liver (bile) and the pancreas into the duodenum. The main functions of the pancreatic secretion are to neutralize the acid chyme and to provide proteolytic, amylolytic and lipolytic enzymes. Bile also helps to alkalinize the digesta, and the bile acids are required for emulsification and digestion of lipids.

Although the pancreatic enzyme **amylase** hydrolyses starch to disaccharides and trisaccharides, these have to be further digested by the mucosal enzymes before the resultant hexoses can be absorbed. Mucosal enzymes are also important for protein digestion and absorption.

In the small intestine of the adult horse, the digestive processes (i.e. the enzymatic degradation of proteins, fats, starch and sugar) are similar to those of other monogastric animals. However, the activity of most of the enzymes in the chyme, especially amylase, is lower than in other monogastric animals. The type of feedstuff affects the amount of soluble carbohydrate absorbed as glucose: up to 85% of the starch content of whole oats will be digested by the end of the ileum but only 30% of the starch from whole maize (for heat processed maize grains digestibility increases to approximately 90%).

Adult horses (500 kg BW) secrete >100 L fluid/day into the pre-cecal gut at approximately 70–100 mL/min. The DM content of the small intestine is about 5% so that even indigestible fibrous particles can be easily passed to the

cecum. At the ileocecal junction, the chyme flow is stopped and the contents are discontinuously pressed into the cecum (5–7 times/h; up to 1 L at a time), which means that **obstruction** is a potential risk.

For the commonly fed diets consisting of hay and oats, approximately two thirds of the completely digestible parts of the feed will have been broken down and absorbed by the time the ingesta reaches the large intestine.

Large intestine

The large intestine does not possess mucosal enzymes and does not have active transport mechanisms for hexoses and amino acids. Digestion and absorption of residual carbohydrates and proteins relies instead on microbial action and absorption of the end products of microbial fermentation. The intensity of this process depends on the amount and the temporal influx of fermentable material arriving from the small intestine.

This **bacterial degradation** mainly produces **volatile fatty acids** (VFA), i.e. acetate, propionate and butyrate, plus amino acids, ammonia, sulfides, etc., and, after a high influx of easily fermentable carbohydrates, lactic acid. The rate of VFA absorption increases with decreasing pH. Disturbances of the digestive processes in the large intestine are marked on the one hand by insufficient microbial activity and on the other hand by accelerated degradation rates, particularly in the cecum.

Excluding **damage to the flora** (e.g. by antibiotics or mycotoxins) low microbial activity in the large intestine occurs when animals are fed rations consisting mainly of poorly fermentable components such as straw or late harvested hay. If large amounts of these feeds, which are difficult to break down, are ingested, **obstruction of the colon** (*q.v.*) may occur due to slow and incomplete microbial activity. This will be aggravated by any factor that decreases the rate of the passage of ingesta, such as lack of water, little exercise, parasites, and intake of soil and toxins which influence the flora of the large intestine, as well as gastrointestinal motility. On the other hand, if large amounts of easily fermentable substances that escaped digestion in the small intestine flow into the cecum, **abnormal fermentation in the cecum** may result in digestive disturbances and acidosis. This may happen with large amounts of mixed feed per meal or if carbohydrates such as maize starch or lactose are fed. Disturbances are especially likely if the animal has not adapted to a high grain diet.

Undigested proteins and urea that enter the large intestine are broken down by microbial enzymes. The main end product is ammonia, which is absorbed particularly at alkaline pH. **Microbial protein**, which is synthesized in the large intestine, fundamentally cannot be utilized by the horse. Animals with a high demand for protein (e.g. foals or lactating mares) must therefore be fed high quality protein that can be broken down and absorbed primarily in the pre-cecal section of the gut.

Most water-soluble vitamins as well as the fat-soluble vitamin K are synthesized in the large intestine. The horse appears to be able to utilize these so that oral supply is only necessary under certain circumstances (*q.v.*).

Table 3.5 Guide to the daily intake and turnover of water (L/100 kg BW) and electrolytes (g/100 kg BW)¹

	Intake	Secretion(s) ■ Saliva ■ Gastric juice ■ Secretions into small intestine	Flow from ileum into the cecum	Absorption ■ End of small intestine ■ Hindgut
Water	3–5	20–25	10–14	9–12
Sodium	5	~50	30–42	28–35
Chloride	15	~60	10–14	10–14
Potassium	10	~9	5–7	2–3

¹ Based on Meyer, H., Coenen, M. (2002) *Pferdefütterung (Horse Nutrition)*, 4th ed, Blackwell Scientific Publications, London.

Water and electrolytes

There is a large water and electrolyte turnover in the gastrointestinal tract. While considerable amounts of water, sodium (Na) and chloride (Cl) enter the small intestine via the saliva, stomach juices, pancreatic juice and bile, only about 50% of water, 35% Na and 80% Cl will be absorbed by the end of the ileum. Therefore a large ileocecal flow of water and Na (and to a lesser extent chloride) takes place (Table 3.5), but most of the water and electrolytes that enter the large intestine will be absorbed.

Absorption of calcium (Ca) and magnesium (Mg) mainly takes place in the small intestine, while phosphorus (P) absorption occurs predominantly in the large intestine. Therefore a high P intake disturbs Ca absorption to a greater extent than a high Ca intake affects P absorption.

The large water and electrolyte turnover in the intestine has two consequences:

1. With an **ileus** (*q.v.*) in the small intestine, the intestine will fill up very quickly proximal to the blockage. The liquor may possibly reach back to the stomach while the animal becomes dehydrated.
2. **Diarrhea** (*q.v.*) in adult horses is mainly related to dysfunction of the large intestine because an elevated flow of water from the small intestine can usually be reabsorbed in an intact functional large intestine.

The importance of microbial fermentation in the gut

Several types of microorganisms are present within the gut contents; the exact make-up is influenced by a number of factors including substrates that have been fed in the past and are currently being fed, the passage time, the pH and organic acid composition at the various sites as well as extent of the various interactions with the horse's own digestive secretions (such as the gastric juices), etc. There are marked individual differences in the amount and type of the organisms throughout the GIT but the lowest numbers are found in the fundus region of the stomach.

Normal fermentation in meal-fed horses

Ingesta is propelled quite rapidly through the small intestine in a fluid form in the adult horse, some appearing in the cecum within 45 min and much of it reaching that point within 3 h of eating. Protein that escapes digestion in the small intestine is degraded to ammonia by bacteria in the ileum and to a much larger extent in the large intestine. The carbon skeletons are utilized as energy sources by the bacteria yielding acetic, propionic and butyric VFA as by-products. Starch that escapes digestion in the small intestine and most structural carbohydrates are subjected to fermentation by the large gut bacteria, again yielding VFA.

Bacterial fermentation also produces some longer chain fatty acids, as well as lactic acid. These acids and some of the ammonium ions are absorbed from the large intestine and enter the systemic circulation. Much of the ammonia, however, is reutilized by bacteria in the synthesis of **bacterial protein**, stimulating rapid bacterial growth. The bacterial population therefore ebbs and flows between the surges of ingesta reaching the large intestine.

It is important to note that there is a **fluctuation** in the hindgut bacterial populations in any meal-fed horse. The microflora population within the hindgut does adapt to a certain extent to the type of feed being fed. However, if the dietary fluctuations are too marked, or excessive starch or rapidly fermentable carbohydrates reach the hindgut even in the concentrate adapted horse, this will result in a significant change in the **microbial population**, which may have clinical consequences.

Dysfermentation

As well as obstructions, conditions associated with dysfermentation are the main cause of digestive upsets. Mistakes in feeding technique, selecting incompatible feeds or insufficient preparation of some feeds may induce inappropriate microbial growth and/or dysfermentation (*q.v.*), potentially with severe consequences for the health of the horse.

After ingestion of large meals of starch or sugar, fermentation is more extensive in the first part of the stomach, because the stomach contents have a higher DM content and the mixing of feed and gastric juice is therefore slower. This means that either the normal reduction in pH is delayed or the pH remains >4.5. Large amounts of lactic acid will be produced. The same process can occur with feeds that have a sticky consistency or potentially whenever gastric acid secretion is reduced. A further risk comes from feeds that are contaminated, especially with yeasts, when gas production may be so extensive that there is a risk that a **stomach rupture** (*q.v.*) may occur.

Mistakes in feeding technique and the selection of incompatible feeds may also have consequences in the small intestine. Again, inappropriate microbial fermentation (e.g. of easily digestible starch provided in large amounts) may produce high amounts of organic acids, resulting in a reduction in the pH and disruption of normal digestion. **Spasmodic colic** (*q.v.*) may be the final clinical result. All factors that reduce passage in the small intestine (excitement, stress, parasites, etc.) favor microbial activity and potentially increase the risk of colic.

As described above, large amounts of starch and, to a lesser extent, protein, ingested in a single meal may have an effect on digestion both in the stomach and the small intestine. In addition, significant amounts reach the large intestine, stimulating an almost **explosive growth of microorganisms**. Gas production can exceed the rate at which the methane, hydrogen and carbon dioxide are normally absorbed into the blood and expelled through the lungs so that the lumen of the large intestine becomes **distended**. Moreover, the rapid production of VFA and lactic acid in particular causes a rapid **decrease in pH** of the fluid, increases the permeability of the mucosa and upsets the microbial balance. This favors the growth of organisms that can withstand a lower pH, stimulating more lactic acid production and causing the death of certain bacteria that cannot survive under such conditions, thereby releasing **endotoxins** (non-protein lipopolysaccharide fragments of the cell wall of Gram-negative bacteria) and other compounds. These endotoxins, together with the other unwanted compounds produced as a consequence of this change in the conditions of the hindgut, may be absorbed into the blood and have further adverse effects. The blood flow to the feet, for example, may be particularly sensitive to some of these factors that may in turn trigger the development of **laminitis** (*q.v.*).

The importance of fiber

In addition to functioning as a source of energy, the **fibrous components** of feed have other values. In the **long form** (pieces in excess of 2–3 cm in length), fiber occupies the stabled horse's time in chewing, so that it is less inclined to what are often referred to as "boredom-related" stable vices. The gastric contents have a higher moisture content and are more friable, allowing more immediate penetration of gastric juices, including HCl, and promoting better digestion further down the digestive tract. Also the microbial fermentation of fiber (fed as short or long material) proceeds at a slower pace than does the fermentation of starch or protein. This in turn has two advantages:

1. The ebb and flow of the microbial population of the hindgut, in numbers of organisms and in their species distribution between meals, is less marked than when starch and protein are the principal substrates.
2. By diluting readily fermentable material, wild fluctuations in the pH of the hindgut are prevented and thus the likelihood of acidosis is reduced.

Gastric ulceration

Modern management practices that include meal feeding, low fiber/high concentrate diets, early weaning and intensive training programs help to produce a poorly buffered, acidic environment in the stomach. This has been linked to the high prevalence of **gastrointestinal ulcers** (*q.v.*) particularly in intensively managed horses such as performance horses.

Foals are highly susceptible to ulceration because they start secreting gastrin just after birth before the gastric mucosa has fully developed. In addition, stressful weaning programs may act as an exacerbating factor in the development of gastrointestinal tract ulcers. There is a strong correlation between the

diet fed and the pH of the stomach. Concentrate diets have always been implicated but ensuring that these are fed in small amounts, possibly in combination with forages such as alfalfa hay, may help. A **high forage intake**, which encourages chewing and stimulates salivation, may also be advantageous. Turning out to pasture can be very beneficial for those that are affected. Medical treatment is often required.

NUTRIENT REQUIREMENTS

INTRODUCTION

The principal function of feed is to provide the nutrient requirements of the horse and its symbiotic gastrointestinal microorganisms. Maintenance requirements can be defined as the daily intake that maintains constant body weight (BW) and body composition as well as the health of a healthy adult horse with zero energy retention at a defined level of low activity in comfortable surroundings.

Nutrient requirements are typically stated as an amount per kg of feed or amount per kg BW daily. These amounts are the minimum needed to sustain normal health, production and performance of an average healthy animal. The amounts vary widely amongst horse groups with differing physiologic demands, i.e. growth, age, lactation, physical activity and workload (rider weight and ability, terrain and intensity of activity). They will also be affected by other factors including the environmental conditions. For example, energy requirements increase in animals exposed to very **low temperatures**, particularly where there is considerable air movement, and rain decreases the insulation properties of the coat.

As well as varying according to breed, body composition, stage of training, etc., it is also very important to remember that horses are individuals and differ in their metabolic efficiency (e.g. some horses are “good doers”), temperament, health status (including level of parasitic burden), appetite, likes and dislikes and other variables. It should be noted that there can be a difference between what a horse **can eat** and what it **might need** for maintenance, which in practice means that many mature horses will gain weight if fed free choice hay and not exercised.

Guidelines to requirements only can be provided; these then need to be tailored to the individual circumstances. It is important to note that one of the main reference materials used and referred to are the National Research Council (NRC) requirements, which recommend **minimal** rather than **optimal** requirements.

Imprecision in the assessment of nutrient requirements is compounded by uncertainty in feed analysis. The bioavailability of nutrients also varies between feed sources. The values given in Table 3.6 assume a high bioavailability from the ration.

Requirements can be given in a variety of ways. Two of the most common are per kg DM feed intake, and amounts per day on a dry matter or as fed basis. It is important to check what units are being used. Either can be suitable but obviously the DM intake guidelines rely on horses being fed appropriate amounts of feed for their workload, age, reproductive status, etc.

Table 3.6 Guide to the minimum daily nutrient requirements of horses¹

	Digestible energy (MJ)	Crude protein (g)	Lysine (g)	Ca (g)	P (g)	Mg ² (g)	K (g)

Table 3.7 Guide to the minimum¹ water needs (kg) of horses per kg of feed DM consumed and the water (kg) provided by pasture herbage per kg herbage DM (1 kg water is equivalent to 1 L)

	DM	Water
Water requirements of horses per unit of DM consumed		
Last 90 days of gestation	1	3
First 3 months lactation	1	4
Breeding stallion	1	3
Weaned foal	1	3
Barren mare	1	2
Maintenance		
Grain/hay diet	1	2–3.5
All hay diet	1	3.5–4
Water content of herbage per unit of DM		
Spring growth	1	4
Dry summer	1	2.5
Mild winter	1	3

¹ Quantities of water given assume ideal environmental conditions.

BODY WEIGHT ESTIMATIONS

Many nutrient requirements are proportional to body weight. Unfortunately, judgment by eye can be inaccurate; calibrated weighbridges are the most accurate but are not commonly available. Weigh tapes and estimations based on linear measurements provide an approximation but these can only be taken as a guide or used for monitoring purposes where standardized procedures are followed.

There are a number of equations available such as that to **estimate body weight** in kg (w) from heart girth in cm (hg) and length of the body in cm (l) from the point of the shoulder to the point of buttock for the *adult* horse only:

$$w = [(hg)^2 \times l] / 11\,877$$

This will tend to overestimate the weight, for example, of those horses with reduced gut fill in hard work such as the fit racehorse and is not reliable for the pregnant mare in late gestation or for young, growing animals, etc.

WATER

The requirements for water are given in Table 3.7. The water content of the body should remain within the approximate limits of 68–72% of fat-free mass. Values below this represent a dehydrated state. Water is lost by excretion in urine, feces and sweat, as well as by evaporation from the lungs and in milk. Lactation can increase needs by 50–70% above maintenance.

The requirement for supplementary water is influenced both by the amount of DM consumed and by the moisture content of feeds available. Cereals and hay contain approximately 10% moisture whereas pasture herbage contains 40–80% moisture depending on season and rainfall. These sources affect the supplementary amounts of water required (Tables 3.7 and 3.8). Dry mares (or

Table 3.8 Guide to the minimum¹ supplementary water requirements of mares (liters daily per mare)—refer to Table 3.7 for maintenance levels

Body weight (kg)	200	400	500
Last 90 days of gestation ²			
In stable	13	22	26
On pasture	0	0	0
First 3 months of lactation			
In stable	28	42	50
On pasture	7	11	12

¹ These amounts are minimum. They assume ideal conditions and will be insufficient for mares on parched pasture with environmental temperatures >30°C.

² Needs of the breeding stallion are similar to those of the pregnant mare.

other non-lactating horses) on lush pastures with shade, undertaking no work, can thrive without additional water, although it is always advisable that a clean supply be made available. **Pregnant and lactating mares** should be provided with supplementary water at all times (see Tables 3.7 and 3.8). Foals should have adequate access from around 2 weeks of age. The requirements of the **breeding stallion** are similar to those of the pregnant mare.

Maintenance needs are usually met by providing 2–3.5 L/kg DM intake on a mixed diet of grain and hay in temperate conditions. For all hay diets, 3.5–4.0 L/kg DM may be needed. Environmental temperature has a large effect on the amount consumed. Values of 2 L/kg DM at 18°C and 8 L/kg DM at 38°C have been reported. **Sweating** involves losses in particular of sodium, potassium and chloride in addition to water so that severe sweating also necessitates the replacement of these electrolytes.

Sweat production

Unfortunately, the conversion of chemical energy provided by the feed to mechanical energy in the form of **ATP** that can be used by the muscles is not very efficient, and the “waste” heat that is produced has to be removed from the body. One of the main mechanisms for heat removal is via the **evaporation of sweat**. The amount of sweat produced depends on the environmental conditions, nature of the work (which in turn will depend on the rider’s ability and the terrain) and the animal’s fitness. Under favorable climate conditions, sweat loss can be around 2–5 L/h if the work is a run at a low pace (approximately 2–4 m/s) or in the order of 7–8 L/h in long distance rides at a faster pace or in difficult terrain (Table 3.9).

In hot humid conditions where sweating is partially ineffective, production can be as high as 10–15 L/h. Sweat production seems to decrease only after extreme water loss; although there may be some changes in sweat composition with time, basically sweat production is accompanied by an obligate loss of electrolytes. When the sweat loss is low, much of the loss can be made up by absorption of water contained in the large intestine, but if water losses are greater (3–4% BW) a decrease in circulatory volume as well as **loss of skin elasticity** occurs.

Table 3.9 Sweat production

Work	Amount of sweat (L/100 kg BW) ¹	Average	Average water requirement (L/100 kg BW/day [including maintenance])
Light	0.5–1	0.75	5
Moderate	1–2	1.50	5–7
Heavy	2–5	3.50	7–10
Very heavy	>5	5.00	>10

¹ Depending on duration and intensity of activity and environmental temperature. Rule of thumb: 1 L/100 kg BW/h with light trotting at 18–20°C.

Table 3.10 Guide to the composition of sweat

Electrolyte/element	Amount lost per L sweat	Approximate amount needed to be ingested to replace amount lost per L sweat (g)
Sodium	3.1 g/L	3.45
Potassium	1.6 g/L	2
Chloride	5.3 g/L	5.5
Calcium	0.12 g/L	
Magnesium	0.05 g/L	
Phosphorus	<10 mg/L	
Zinc	11 mg/L	
Iron	5 mg/L	
Copper	0.3 mg/L	
Selenium	Traces	

Horses participating in **endurance rides** over distances of 50–200 km typically lose 3–7% of their body weight during the competition—some horses may lose 10% or more. These losses are only partially compensated for during overnight stops, perhaps due to persistent loss in the GIT content, which takes longer than an overnight period to recover to pre-race levels.

Sweat contains relatively low levels of calcium (approximately 0.12 g/L), magnesium (approximately 0.05 g/L) and phosphate (<0.01 g/L) but relatively high levels of sodium, potassium and chloride as shown in Table 3.10. There are also small amounts of various trace elements, e.g. iron at approximately 4.3 mg/L and Zn at 11.4 mg/L. However, the main electrolytes lost with sweat are **sodium, potassium and chloride**.

ENERGY

Energy is supplied to the horse via its diet, but fundamentally energy is not a nutrient. The chemical energy or gross energy contained within feeds needs to be converted into a form of energy that the cells can use for work or movement (usable or **net energy**). Dietary energy is provided by the four principal dietary energy sources.

1. **Hydrolyzable carbohydrates**, e.g. simple sugars and starch. These can be digested by mammalian enzymes to hexoses that are absorbed from the

small intestine (SI) or, if they “escape” digestion in the SI, are rapidly fermented in the hindgut.

2. **Fermentable fibers:** component of dietary fiber—cellulose, pectins, hemicelluloses, etc. These are not digestible by mammalian enzymes but can be fermented by the microorganisms predominantly located in the hindgut. Speed of fermentation as well as site may play an important role in the energy value to the horse.
3. **Oils/fats,** utilized as fatty acids and glycerol. Despite their more “evolutionary traditional” diet containing relatively low concentrations of oils, horses in general appear to be able to digest and utilize up to 20% of their diet as oil if suitably introduced.
4. **Proteins.** Although much of the constituent amino acids will be utilized in protein synthesis, depending on the dietary level and the balance of the amino acids, a significant proportion of the carbon skeletons of many amino acids are combusted as energy sources or converted into fat or glucose. Not an efficient energy source (see below).

With the exception of feeds that contain a lot of fats or ash, the gross energy content of feeds tends to be similar. Differences arise mainly from differences in digestibility. Hay has a lower digestibility than cereals; it produces much more spare “lost” heat so is much more “internally heating” and is therefore especially useful in winter. In addition, the efficiency of conversion of digestible to usable or net energy differs widely.

Cereals have more net energy than hay, which in turn contains more than twice the net or usable energy of straw. Vegetable oils contain proportionally more net energy than the cereals and 2.25–3 times the amount of digestible energy. Replacing forage with cereals and/or oil decreases the amount of feed the animal has to eat in order to obtain the required amount of energy (important as horses have a finite appetite).

Energy requirements

Critical to feeding any horse for health and vitality is the appropriate and adequate supply of energy, especially during the **training** phases (*q.v.*). If a horse is fed too little energy for its needs it will tend to become **dull and lethargic**, lose weight and/or become clinically ill. If a horse is fed too much energy or inappropriate energy it may become **hyperactive**, gain weight and/or become ill.

Adult horses in particular tend to be fed primarily for energy; the diet is then balanced for protein, vitamins and minerals.

At present, the energy potential of a horse feed is described in two main ways: digestible energy (DE) and net energy (NE). Each of these has been determined in a number of ways over the years. The DE system is the most commonly used in UK, Germany and the USA; the NE system and its variants are gaining popularity in the rest of mainland Europe.

The French (who pioneered the value of the NE system for horses), for example, base their system on the horse feed unit (UFC), a net energy system of values relative to the NE values of barley. Net energy is considered to be

that portion of the feed energy that is actually available for use—be that movement, production of milk, fetal growth, etc. However, the efficiency of conversion of the feed energy to available energy varies according to use: for example, approximately 25% efficiency when converted to kinetic energy, approximately 70% for milk production, but only approximately 20% for fetal growth. Figures that have been derived from one use may therefore not be appropriate for another. It is also important to realize that the DE and NE systems are not easily interchangeable and therefore one system should be used throughout to calculate both requirements and the rations to fulfill such requirements.

Two units of energy are in common use in the horse industry: the SI unit of energy, the joule (J where kilojoule [kJ] = 10^3 J, and the megajoule [MJ] = 10^6 J), a unit of electrical work used predominantly in Europe, and the calorie in the USA (4.184 J approximates to 1 calorie).

Requirements and intake are given either as the amount per kg of DM (zero moisture) or the amount in air-dried feed (assumed to contain 12% moisture). Depending on the system and the country, recommendations are given for estimated metabolic body weight and others for actual body weight. Various equations have been used around the world to predict energy requirements. The NRC (1989), for example, uses for **maintenance** (up to 600 kg BW):

$$\text{Maintenance} = 4.184 \times (1.4 + 0.03 \times \text{Body weight}) \text{ MJ DE/day}$$

An adult horse not doing any work typically requires, very approximately, about 13–15 MJ DE/100 kg body weight. The amount of total feed in the daily ration should be adjusted according to the amount of **work performed** and the **condition** of the individual horse. It is therefore important to monitor body condition and weight regularly. Obese or underweight horses are unlikely to perform optimally, and certain clinical conditions may result in a loss of weight.

As energy is stored by the horse there is no requirement for energy needs to be fully met on a daily basis. Indeed it is unlikely that they will, or should be. The immediate energy requirements are met almost entirely from energy stored as glycogen, fat, circulating glucose and high energy phosphates.

Energy deficiency and excess

A protracted deficiency of dietary energy causes a **loss of depot fat** and of **muscle mass**, whereas excess dietary energy leads to fat deposition at sub-cutaneous abdominal and intra- and inter-muscular sites. Both can result in clinical signs as well as changes in temperament.

PROTEIN

Dietary protein is normally measured as crude protein (CP: nitrogen \times 6.25, for most common feedstuffs). **Digestible crude protein** (DCP) is defined as the proportion of dietary CP that is **apparently** digested. Frequently this is a calculated value rather than a value derived from digestibility studies in horses, and it varies considerably from approximately 40% to 80% of CP. The digestibility appears to vary in relation to the protein content of the feed

(e.g. low protein grass hay will have a lower protein digestibility than high protein alfalfa hay) and to the concentrate–roughage ratio (increasing the concentrate–hay ratio from 1:1 up to 3:1 will tend to increase digestibility; above this range the digestibility may decrease).

Protein sources

Most feedstuffs contain some protein but, as indicated in Table 3.1, there is considerable variability in the amount of protein and amino acids, especially lysine (limiting to the rate of tissue protein synthesis). The oil seed meals are generally good sources of protein whereas cereal grains contain less protein and are also generally poorer in their amino acid profile. Grass hay typically provides less digestible protein than cereals, whereas the protein value of legume roughages depends considerably on the care that has been taken to preserve **plant leaf**.

Dietary protein requirements

Requirements vary in proportion to tissue demands for protein synthesis and are, therefore, much greater during lactation or during growth than for adult working horses. The requirements are set (see Table 3.6) as those that meet the minimum needs of approximately 95% of healthy horses, accepting that individual differences exist. During ill health, such as recovery from trauma and infection, **protein needs increase** considerably.

Again, recommendations vary according to the various systems. The NRC recommends approximately 10 g CP/MJ of DE per day for horses at rest and in work.

Protein deficiency

Insufficient dietary protein causes a **negative nitrogen balance**, loss of protein from tissues, restrictions in milk production of lactating mares and growth failure in foals. There are no specific symptoms of deficiency other than a **gradual loss of muscle and liver mass**, with a decline in blood plasma albumin concentration, failure of suckling foals, or of weaned foals, to grow and some loss of appetite. A protein deficiency is possible especially where poor roughages constitute the majority of the diet, when **energy** will also be limiting. This partly results from a decline in the ability of large intestine microorganisms to degrade dietary fiber when nitrogen intake is severely restricted.

Amino acid balance

A **protein deficiency** implies an amino acid deficiency. Few natural protein sources contain the optimal proportion of dietary essential to non-essential amino acids, and few potential feed proteins contain an ideal distribution of the 10 dietary essential amino acids (based on experimental work on growth in the rat). Thus, in biologic terms, a protein deficiency can be most efficiently rectified by giving initially supplements containing the amino acid(s) that

is/are the principal limiting amino acid to tissue protein synthesis (including growth, milk production, etc.).

In the horse, **lysine** has been established as the first limiting amino acid for most diets. Of the other dietary essential amino acids, only six of the 10 have been demonstrated to change in respect of their blood plasma concentration when a protein deficiency is induced. These are isoleucine, leucine, phenylalanine, threonine, tryptophan and valine. Few of these have been adequately examined, although it is believed that for growing horses **threonine** may be the second limiting amino acid.

The practical solution for supplying additional limiting amino acids is to add **soya bean meal**, or other good quality protein, to the diet. It could then be assumed that the need for the limiting amino acids would be met (providing extensive synthetic sources alone have not been used, see below).

Protein excess

A moderate excess of dietary protein (up to approximately 50% above the requirements of the individual) has no observable adverse effect in healthy horses. More than this may cause a slight reduction in the performance of racehorses and possibly some reduction in appetite. It has been recommended not to feed >2 g DCP/kg BW to exercising horses, especially endurance horses.

Protein, however, is not a nutritionally preferred option as an energy source as it is inefficiently converted to usable energy with proportionally higher amounts of waste energy (heat) produced; the nitrogen must be removed, as excess protein is not stored. Excess protein is degraded in the liver with the formation of urea. This is excreted by the kidneys (urine) and is secreted back into the lumen of the gut. There are potentially higher **ammonia levels** in the stable as the urea in the urine is converted by bacteria in the environment to ammonia.

The process of degradation and excretion of the products requires the expenditure of energy and increases basal water requirements. Where there is loss of either hepatic or renal function, large excesses of dietary protein may cause an accumulation of protein degradation products and even cause **ammonia toxicity**, although under normal circumstances this is unlikely.

Protein excess may result in increased renal losses of Ca and P, although evidence regarding this is conflicting. Despite a link in many horse breeders' minds, there have not been any conclusive studies demonstrating adverse effects of high or low protein intakes on the incidence of **developmental orthopedic disease (DOD)** (*q.v.*) in the horse.

Deficiencies and excesses can also occur where total protein intake is within the normal range, but where dietary amino acid imbalances exist. The most likely situation is when growing horses receive diets providing poor quality proteins deficient in lysine. Another possibility exists where synthetic amino acid supplementation occurs of some amino acids only or in the incorrect proportions.

MINERAL AND TRACE ELEMENTS

The macro- and micro- (or trace) elements required in the diet for normal cellular function can be provided inorganically or organically. **Macroelements**

are required in quantities in the range of several grams per day and include sodium, potassium, chloride, calcium, phosphorus and magnesium. Sulfur is normally considered a macromineral and is provided organically from proteins containing sulfated amino acids such as methionine and cystine. The **electrolytes** (Na, K, Cl, Ca, Mg—substances that exist as positively or negatively charged particles in aqueous solution) principally affect intra- and extracellular ion and acid-base balance. **Microelements** are required in milligrams per day and include iodine, iron, manganese, zinc, selenium, cobalt and copper.

The elements that are most frequently **deficient in natural diets** are calcium, sodium, chloride, copper, zinc, iodine and selenium. Others that could be deficient in some areas of the world include cobalt and chromium. It is also possible that some of these elements could be present in toxic quantities.

Utilization of dietary sources

The availability, i.e. the proportion of an element that can be absorbed (**true digestibility**), differs considerably amongst sources of the same element, and also amongst elements; for example, the availability of common calcium sources may vary from 35% to 60% whereas the extent to which some trace elements are absorbed may be <5% of that consumed. In addition, there may be marked individual variability in the availability from different sources. Thus it is often not possible to give exact values for required dietary content.

Interactions

There are **many interrelationships** amongst the macro- and micronutrients. Few of the possible interactions have been thoroughly investigated in the horse and in practice only a few of the possible interactive effects appear to require practical measures to avoid adverse consequences. For example, while little evidence exists that moderate excesses of dietary Ca have any deleterious effects on P or Zn utilization, an excessive dietary concentration of P with Ca:P ratios ≤ 1.0 may depress calcium absorption and may cause skeletal problems.

Mineral requirements

The minimal maintenance requirements of minerals depend on their endogenous (inevitable) fecal, renal and cutaneous losses and their availability (Table 3.11).

Calcium, phosphorus and magnesium

In adults, the rate of **calcium** absorption seems not to be regulated at the gut wall, so that the amount of calcium absorbed increases proportionately with intake. Renal excretion therefore increases with intake. Calcium absorption appears to be higher in younger than in older animals. It is, however, reduced with high intakes of oxalic acid and phytate. Greater than 0.5% oxalic acid in

Table 3.11 Guide to endogenous mineral losses by horses, average availability and the minimum mineral requirements for maintenance per kg BW/day

	Ca	P	Mg	Na	K	Cl
Endogenous losses (mg/kg BW/day)	30	12	5	18	40	5–10
Assumed availability (%)	60	40	35	90	80	95–100
Requirements for maintenance (mg/kg BW/day)	50	30	15	20	50	80 ¹

The endogenous losses include a safety margin to allow for variations resulting from the type of feed, the individual animal and the amount supplied.

¹ According to influence on acid–base balance.

the feed may reduce calcium absorption when the calcium–oxalate ratio is <0.5 (weight to weight basis). With a ratio ≥ 1 , higher oxalic acid levels (up to 0.87%) may be tolerated. **High phosphorus intake** (especially in the form of phytate) may disturb calcium absorption, especially when the Ca:P ratio is ≤ 1 .

Major natural **sources of calcium** are leafy forages, particularly legumes, while supplementation may be achieved for example with limestone flour, calcium gluconate or dicalcium phosphate.

The greatest requirements for calcium arise in the young foal where bone mineral is being accreted. Inadequate calcium intakes by developing foals are characterized by poor mineralization of the osteoid tissue (*q.v.*). Mares at the peak of lactation use considerable quantities of calcium for **secretion in milk** and therefore their requirements are higher than those of other adult horses. At peak lactation they are usually in negative calcium balance, drawing on **bone calcium reserves**. In working horses, low calcium intake or high oxalate or phosphorus content in feeds can lead to **nutritional secondary hyperparathyroidism** (“big head disease”) (*q.v.*).

Although there is no conclusive evidence that excessive calcium intakes are harmful to skeletal development in the horse, it is considered inadvisable to exceed 3–4 times the requirements as shown in Table 3.12.

Phosphorus absorption, which mainly takes place in the large intestine, is not affected significantly by high calcium intakes. Phytate P of plant origin is less well absorbed than inorganic P, but it may be partially available because there is some phytase activity in the large intestine.

Cereal grains and their by-products are the principal sources of phosphorus. Phosphorus from cereal sources is approximately half to two thirds as available as that in dicalcium phosphate, the common supplementary source.

Protracted and inadequate intake of phosphorus may produce skeletal abnormalities in growing horses similar to those produced by inadequacies of calcium and vitamin D. Deficiency may also cause **abnormal appetite**.

Excessive phosphorus reduces calcium absorption and potentially leads to **nutritional secondary hyperparathyroidism** (*q.v.*). Dietary phosphorus should conform to the amounts indicated in Tables 3.6 and 3.12, and the calcium–phosphorus ratio should lie between 1:1 and 2:1.

Magnesium absorption is slightly higher from organic compounds (e.g. magnesium aspartate) than from inorganic sources (e.g. MgO). No negative effects on absorption have been reported with oxalates. Hay feeding has

Table 3.12 Guide to the mineral and vitamin requirements of horses per kg feed (DM) for a horse of mature weight 500 kg. NB The maximum tolerated is the level at which signs of toxicosis are more likely to occur; this may mean that under certain circumstances unwanted signs may be seen at lower levels. Lower limits, e.g. for selenium, also may be set by relevant legislation

	Maintenance	Pregnancy/lactation	Growing ¹	Maximum tolerated
Typical daily intakes (kg)	8	9–14		
Calcium (g)	2.5	5	6	(15%) ²
Phosphorus (g)	1.5–2.0	3.4	3.5	(10%) ²
Magnesium (g) ³	1.2–1.5	1.5	1.5	(6%) ²
Sodium (g)	1.25	1.5	1.0	12.5
Iron (mg)	40	50	50	750
Manganese (mg)	40	40–60	40–60	750
Copper (mg)	10–15	15–20	15–20	400 ⁴
Zinc (mg)	40	45–80	60–80	500
Selenium (mg)	0.1	0.2–0.3	0.2	2.0 ⁵
Iodine (mg)	0.1	0.2	0.2	4–5 ⁶
Cobalt (mg)	0.1	0.15	0.15–0.2	20
Vitamin A (IU)	2–4000	4–6000	4–5000	20 000
Vitamin D (IU) ⁷	3–600	800	900	2200
Vitamin E (IU)	50–100	80–160	80–160	1000 ⁸
Thiamin (mg)	3	3–5	3–5	3000
Riboflavin (mg)	2–4	2–4	2–4	

¹ Typical allowances for growing horses are 400 g/day DM per individual per mo of age up to weaning. Heavy topped foals may require a smaller intake of energy and protein, but mineral and vitamin allowances should be maintained. After weaning, daily intakes of air-dried feed should be equivalent to 2.5–3.0% BW daily up to around 18 mo depending on breed. If protein and energy allowances are decreased, mineral and vitamin intakes must be maintained. After 18 mo, feed allowances can be reduced if growth rate has become minimal.

² A very approximate guide.

³ Assuming availability of 35%.

⁴ Less may be tolerated by growing horses, particularly if zinc intake is not also elevated.

⁵ European legal limit of 0.5 mg/kg DM ~ 1 mg/100 kg BW.

⁶ In pregnancy advised not more than 1 mg/kg DM.

⁷ Allowances of up to 1500 IU vitamin D have been recommended by some authorities.

⁸ No evidence is currently available that more than this level will produce adverse effects in the horse, see text.

been said to favor calcium and magnesium absorption (in contrast to pure concentrate feeding). Major sources are oil seeds, rice grains, legume forages, sugar beet pulp and sugar beet molasses. Most good quality mixed natural diets contain at least 0.1% magnesium. This will meet the requirements of the majority of horses. Nevertheless many manufacturers provide supplements of magnesium as calcined magnesite (MgO), in commercial feeds. The availability of magnesium in MgO of various origins has been shown to differ for the ruminant, but no equivalent studies have been undertaken for horses.

Muscular tremors and **ataxia** resulting from acute hypomagnesaemia are unlikely to occur in horses given good quality natural feedstuffs, but may occur in horses receiving magnesium-deficient feedstuffs although not proven to date.

No evidence has been produced that excessive intakes of magnesium are harmful, except **sulfates**, which are **purgative**. Although there is a potential risk of magnesium toxicity where dolomite limestone is used, the lack of evidence for this may indicate low availability of magnesium from this source.

Sodium, potassium and chloride

With a low sodium or potassium intake the endogenous losses will be reduced to <10 mg/kg BW/day for sodium and around 5 mg/kg BW/day for potassium. However, this does not appear to be the case for chloride. Low intakes may increase the true absorption rate for sodium and potassium. In horses with diarrhea or dysfermentation in the intestine, the fecal losses and, therefore, the total requirement will increase.

The maintenance requirement of chloride is not only related to the Cl balance but also to the acid-base metabolism. Intakes of <80 mg/kg BW/day may result in lower plasma Cl concentrations (≤ 100 mmol/L), alkaline urine, and a tendency for the development of metabolic alkalosis (*q.v.*).

Sodium and chloride are commonly provided by common salt, milk products and sugar beet molasses. Nutritionally improved straw is also a source. The main sources of potassium are leafy forages, sugar beet molasses and milk products.

The provision of forage and water in the last meal before extended exercise increases the fluid and electrolyte contents of the large intestine, which it is believed can act as a reservoir of these nutrients.

Possible clinical signs associated with deficiencies

Forages are generally rich in potassium, and diets containing adequate forage of good quality are unlikely to be potassium deficient. Acute water and potassium depletion may occur in foals with chronic diarrhea, or in adult horses subjected to extended exercise, especially when being fed low forage intakes and/or in hot weather. In both cases, **water and electrolyte supplements** are required to bring about immediate rectification.

Whereas most good quality rations provide sufficient potassium for normal maintenance, **supplementary sodium** in the form of common salt is generally advised, and is necessary for horses given rations based on cereals and undertaking extended exercise in hot weather. Sodium, potassium and chloride are major constituents of sweat, and depletion of these electrolytes by heavy sweating suppresses thirst and the desire to drink despite dehydration.

Possible clinical signs associated with excess

The horse has little capacity to store water or potassium and excessive dietary intakes are rapidly excreted, although in the case of potassium this assumes that water intake is adequate. Potassium toxicity is unlikely except when given parenterally in excess, when it can cause **cardiac arrest** (*q.v.*) or **hyperkalemic periodic paralysis** (*q.v.*). Sodium toxicity is unlikely under normal circumstances, except where a dehydrated horse is given access to salt water ad libitum.

Micro- (trace-) mineral requirements

Principal sources of microminerals

The adequacy of most natural plant materials as sources of microminerals depends to a large extent upon the soil on which the plants are grown. However,

soil content and plant content, especially for certain trace elements such as selenium, do not always closely correlate. It is common practice to supplement feeds with inorganic sources. These should be prepared by competent organizations, as there is a risk of providing excess. Synthetic sources are the most practical alternative for copper, manganese, zinc and selenium. Seaweed meal or potassium iodide can be used as sources of iodine, although toxic intakes have occurred where users have not been aware of the risks of excess.

The most critical trace elements in typical horse diets are iodine, selenium and copper (see Table 3.12 for information on requirements).

Deficiencies and excesses of microminerals

Signs of **iodine** deficiency and excess are similar, and are observed under practical conditions only in foals. Diets for the dam that provide <0.5 mg or >50 mg iodine per day, with a daily dry feed consumption of 10 kg, are likely to cause goiter. Some reports suggest that even lower intakes may increase the risk of **goiter** (*q.v.*) and therefore it has been recommended that pregnant mares are in fact fed <1 mg iodine/kg DM intake and preferably not >1 mg of iodine per 100 kg BW. Excess iodine is also a possible cause of bony abnormalities in foals. Excesses are commonly caused by feeding large amounts of **seaweed meal** or supplementation with excessive potassium iodide or iodate.

Horses apparently can tolerate high levels of dietary **copper**. Dietary deficiencies of copper, including **copper-deficient pastures**, especially for the dam during gestation, are thought to be a factor in the pathophysiology of certain developmental orthopedic diseases (*q.v.*). It has been suggested that diets containing approximately 20 mg/kg DM may be preferable both for the pregnant and lactating mare as well as the growing foal. Moreover, copper availability in pastures may be adversely influenced by heavy metals.

Zinc deficiency in foals is accompanied by inappetence, reduced growth rate and parakeratosis (especially of the lower limbs). Zinc deficiency and excess have been linked to DOD, although there are limited data to support this assertion. Excessive intake can depress plasma copper concentration.

Manganese is required in the synthesis of chondroitin sulfate and deficiencies in other species have led to abnormalities in **cartilage development**. **Cobalt** is required by intestinal bacteria in the synthesis of vitamin B₁₂ and therefore is likely to be of most importance to breeding mares and growing foals. **Iron** is essential for the synthesis of hemoglobin, myoglobin and the cytochromes. Natural diets containing 50 mg/kg iron should be adequate for growing foals, and therefore a deficiency should not occur where good quality natural diets are given. There is a risk of toxicity (**nutritional siderosis**) where excessive supplementation occurs.

Selenium deficiency is seen particularly in foals of mares grazing **selenium-deficient pastures**. This may lead to nutritionally associated myopathy (**white muscle disease**) (*q.v.*), which occurs in both skeletal and cardiac muscle. Selenium deficiency may also lead to **depressed immune responses** and **lowered thyroid hormone availability**. Diets containing <0.05 mg/kg DM are likely to depress blood glutathione peroxidase (GSH-px) activity below an acceptable limit.

The margin of safety for selenium is relatively narrow and selenosis can occur. While **acute toxicosis (blind staggers)** (*q.v.*) tends to result in blindness, as well as gastrointestinal, cardiovascular and respiratory signs, it is the more chronic form of toxicity (alkali disease) (*q.v.*) that is more common and causes problems for the feet. The signs include **hair loss**, especially in the mane and tail, and **sloughing of the hooves**. This is seen in particular in areas of seleniferous soils/plants and when supplementation is miscalculated. It has also been suggested that moderately high intakes of selenium, which are not toxic enough to cause the signs described above, may affect the frog horn and be a factor in some cases of persistent thrush.

There is a current legal European limitation to the amount of selenium that can be fed to horses (maximum of 0.5 mg/kg diet at 88% DM) which approximates to around 1 mg/100 kg BW as fed.

Horses are more tolerant than are cattle to excess dietary **fluoride** and adults seem to be able to tolerate 50 mg fluoride per kg DM for extended periods of time.

VITAMINS

Introduction

Vitamins are a heterogeneous group of organic substances, essential for life, that have metabolic functions and are not degraded as sources of energy. They are arbitrarily divided into those soluble in fats and fat solvents, and those soluble in water. Most vitamins are represented by more than one compound, which may have different potencies. Certain **pro-vitamins** exist, e.g. β -carotene and 7-dehydrocholesterol, that do not possess vitamin activity but which can be converted into active vitamins by the body.

The ability of the body to store reserves of vitamins varies. For example, enough vitamin A can be stored by the liver to last for 2–6 mo and reserves of vitamin B₁₂ can last for a year through enterohepatic cycling, whereas reserves of thiamin may be sufficient for only 1–2 wk. The healthy horse, however, requires no dietary source of ascorbic acid (vitamin C) as it is synthesized in adequate quantities from glucose in the liver.

Each vitamin may have many functions with differing demands on reserves. It is possible that greater dietary amounts of certain vitamins than are necessary to sustain life may, therefore, have metabolic advantages under certain circumstances.

Vitamin requirements (see Table 3.12)

Similar to other nutrients, vitamin requirements can be affected by a number of factors including age, amount of exercise and reproductive status. However, many are also influenced by the health status of the individual and in particular that of the kidney and the gastrointestinal tract. The need for vitamin supplementation can also depend on external factors such as the type and quality of the diet and the amount of access to sunlight. Today many horses do not have access to good quality green forage all year round and therefore **vitamin supplementation** is often required. Relatively little research has been carried out into the vitamin requirements of the horse, in particular the amounts needed

not just to prevent or correct deficiency symptoms but to promote optimal growth rate, health and performance.

Fat-soluble vitamins: sources and possible clinical signs of deficiency and excess

Vitamin A

The principal source of vitamin A is β -carotene, contained in green herbage and to a lesser extent in carrots, yellow maize and legume seeds. Principal supplementary sources are the partly water-soluble retinyl esters of palmitate and acetate (synthetic). During the winter, herbage contains less pigment and may be deficient in β -carotene. Research has suggested that the use of certain synthetic β -carotenes as the sole source of vitamin A cannot meet vitamin A requirements of horses and is not to be recommended (always check the bioavailability). Heat, light and oxidation can destroy β -carotene content of feed and therefore the content is significantly reduced with storage.

Possible clinical signs associated with deficiency include night blindness, poor growth, excessive lacrimation, reduction in disease resistance and reduced appetite. Clinical signs associated with excess may include bone fragility and malformations, plus there have been suggested teratogenic effects. In adults there is unthriftiness, poor muscle tone, ataxia and loss of hair. Hypervitaminosis A is unlikely to result from the provision of rich sources of β -carotene, such as artificially dried alfalfa, as the horse is thought to be able to reduce the conversion of β -carotene to vitamin A.

Vitamin D

Vitamin D is provided as vitamins D₃, through ultraviolet (UV) irradiation of 7-dehydrocholesterol in the skin, and D₂ through exposure of ergosterol, found in plants, to the action of UV light during desiccation after cutting. It occurs in significant amounts only in naturally cured hays. **Ergosterol** also occurs in other plant forms, e.g. fungi, yeasts, etc. Irradiated yeast is used as a commercial source of vitamin D₂ (**ergocalciferol**). Commercial supplements of vitamin D₃ and D₂ are widely available. **Vitamin D is not believed to be essential for the absorption of calcium in the horse.** Vitamin D may be destroyed by heavy metals and alkaline components of feeds.

The dietary requirement for **vitamin D** is considerably influenced by the extent of exposure to **direct sunlight** and its angle of incidence. In winter there is almost no UV light at latitudes above 50°. The requirement is also influenced by the degree to which dietary minerals (Ca, P and Mg) are balanced and the extent to which the current year's sun-cured hay is given.

Possible clinical signs associated with deficiency include **skeletal abnormalities in foals** and **osteomalacia** (*q.v.*) in adult horses. Potential signs of a deficiency can include a decrease in appetite, food intake and growth rate as well as impaired mineralization of growing bone with a reduction in bone ash content, bone cortical area and bone breaking strength. True 'rickets' and osteomalacia as seen in other species have not been confirmed in foals or adult horses.

Possible clinical signs associated with excess vitamin D include hypercalcemia, hyperphosphatemia, bone resorption, soft tissue calcification, anorexia

and poor performance. When given in large oral doses, vitamin D₃ is approximately twice as toxic as vitamin D₂.

Vitamin E

Vitamin E (α -tocopherol) occurs naturally as several isomers of tocopherol and tocotrienol. The highest potency, as a vitamin, is possessed by the α -isomer of tocopherol. Research has suggested that the d- α form may result in higher plasma concentrations than the equivalent amounts of dl-forms. The richer sources are oils of green plants. Wheat germ oil is the richest source, containing 0.85–1.28 mg/g α -tocopherol. Synthetic supplements of α -tocopherol acetate are widely available. Natural sources are believed to be more bioavailable than the synthetic.

Whether **athletic performance** is improved by high dietary concentrations of α -tocopherol is unproven. However, there is some evidence that exercising animals may benefit from additional supplementation. Large doses accumulate in muscle and liver tissue, and the stability of polyunsaturated fatty acids of tissues is affected by their vitamin E content. Vitamin E is believed to be important for the immune system in general, and intakes of 160 IU/kg DM in gestating mares have been shown to specifically increase the **immunoglobulin concentrations of the colostrum** and subsequently in the suckling foals.

The requirement is currently considered to be between 1.5 and 4.4 mg/kg BW daily and even up to 6 mg/kg BW in the intensively exercising animal. Therefore, levels of 160–250 IU/kg DM feed have been recommended for the performance horse with an additional 100 IU/100 mL of any supplementary oil. This is higher than the level of supplementation of many rations and may be higher than the total vitamin E content, i.e. natural plus supplementary, of some rations. In particular, supplementation needs to be considered carefully for horses in work, gestating mares, sufferers of the **equine rhabdomyolysis syndrome** (*q.v.*), those being fed supplementary oil and those without access to green pasture.

Possible clinical signs of deficiency include vitamin E and selenium responsive myodegeneration “white muscle disease” (*q.v.*)—a common manifestation of vitamin E and/or selenium deficiency in young foals in particular. Possibly more important potential signs of deficiency are **depressed immune status**, poor performance, reduced fertility and fetal death. **Equine motor neuron disease** (*q.v.*) is believed to be caused by a lack of vitamin E, which may predispose the type 1 oxidative neurons to oxidative injury and death. It tends to occur in horses that are either stabled or have access to dirt paddocks and are only fed grass hay with a high grain ration. However, this is not always the case.

Possible clinical signs of excess have not been produced and are likely to require very high intakes. However, it has been suggested that very high doses may interfere with absorption or utilization of other fat-soluble vitamins.

Vitamin K

The horse appears to have **no need for supplementary sources** as the intestinal bacteria seem to synthesize the menaquinones (vitamin K₂), which are absorbed in adequate quantities. If there is chronic use of sulfonamides, or of other antibiotics, in amounts adequate to disrupt this synthesis then supplements may become necessary. Vitamin K status affects **bone metabolism** as

well as **blood coagulation** and it has been suggested that the requirement may increase during times of increased bone metabolism, but there is little work to support this in the horse.

It has been suggested that an increased risk of prolonged bleeding may be seen with the ingestion of certain plants, or if hindgut fermentation is severely depressed, or if liver function is compromised (as vitamin K is converted to its active form in the liver).

The plant form is not thought to be well absorbed and is therefore unlikely to cause toxicity; however, grossly excessive intakes of synthetic vitamin K₃ may be toxic and cause fatal anemia and jaundice. Injectable forms may be toxic and have been suggested to have the potential to result in depression, kidney failure, loss of appetite and laminitis.

Water-soluble vitamins: sources and possible clinical signs of deficiency or excess

Vitamin C (ascorbic acid)

Ascorbic acid is synthesized in adequate amounts by the liver and other tissues from glucose under normal circumstances. It has been suggested that the requirement may increase in times of stress and disease when natural production may not meet demand. Recently it has been shown that ascorbic acid is a key antioxidant in the fluid lining the lungs and that levels are reduced in horses with **recurrent airway obstruction** (RAO; formally known as COPD, or heaves) (*q.v.*) as well as with lung inflammation in general. Additional supplementation may be of value under such circumstances. Synthetic forms are sometimes used as supplements but the efficiency of intestinal absorption is very poor for some forms and their stability through processing varies.

The needs of the healthy horse for ascorbic acid are met by tissue synthesis, but horses that have been subjected to trauma, disease (especially of the respiratory system) or major surgery may require additional supplementation.

Vitamin B₁ (thiamin)

Thiamin is synthesized in the intestinal tract and is present in natural diets. The richest source is brewer's and baker's yeast, containing 150–160 mg/kg. The cereal grains are good sources, thiamin being contained in the scutellum and germ, so that cereal by-products contain 10–15 mg/kg. Synthetic thiamin salts are widely available.

Some feeds may contain insufficient amounts of **thiamin**, and supplementation to bring the dietary concentration to 3 mg/kg air-dried feed has been suggested to increase growth rate in young stock. Amongst exercising horses 4 mg/kg air-dried feed may be insufficient and it may be prudent to ensure that the level is approximately 5 mg/kg air-dried feed.

Signs suggested to be associated with deficiency include a reduced growth rate and appetite, leading to anorexia and loss of weight, ataxia, bradycardia, missing heartbeats, muscular fasciculations and decreased erythrocyte transketolase activity. Bracken fern poisoning (*q.v.*) (bracken contains thiaminase) causes nervousness.

As to excess, there have been unconfirmed reports that parenteral doses ≥ 5 mg/kg BW may have a **tranquilizing** effect.

Biotin

Biotin sources differ in bioavailability. Reasonably good sources include brewer's yeast, oil seed meals (especially rapeseed meal), alfalfa meal and maize grain, although availability in other cereal grains is low. Synthetic supplements are widely used. Biotin is synthesized by gut microorganisms in amounts adequate to supplement the diet for most horses. There is some evidence that certain types of **equine hoof defect** may be aided by biotin supplementation over many months or years. Biotin in wheat, barley, sorghum and bran is said not to be very available due to phytate binding.

Biotin has been identified as a key component of the metabolic pathways of cornification, and in cattle biotin has been shown to be specifically required for the normal production and cornification of hoof horn tissue. A deficiency of biotin, therefore, has often been related to poor skin, poor coat condition and/or poor hoof quality in other species.

Although evidence of biotin deficiency per se has not been published in the horse (and depressed activity of biotin-dependent carboxylase has not been investigated), there is some scientific research to suggest that when supplemental biotin is added to the diet of horses with poor hoof health, an improvement may be seen in some but not all horses. However, other defects do not respond to biotin and require adequate calcium, protein and possibly zinc. As it is not possible by eye to determine which horses have which type of defect, it may be that a **good balanced diet** with additional biotin is the initial route forward for horses with problem hooves.

The amounts of biotin that are recommended to be of value vary: levels of 3–4 mg/100 kg BW/day have been recommended in the literature (for a minimum of 6–9 mo). It is, therefore, important to recognize that biotin is not a panacea for all horses with poor hooves but that it may be worth considering for some.

Currently no recommended upper daily intake limit has been set for biotin but it has been suggested that horses are not given >3 times the levels recommended above.

Folic acid and vitamin B₁₂

Reasonably good sources of folic acid include brewer's yeast (15 mg/kg), green forages (alfalfa meal 1–5 mg/kg), wheat bran (0.8 mg/kg), oilseed meals and whole wheat (0.5 mg/kg). Synthetic supplements are widely available. Vitamin B₁₂ is found only in animal products. For foals, fishmeal, milk products and synthetic supplements are used. The **foal** has the greatest need for dietary sources of **folic acid and vitamin B₁₂** as it does not have a fully functioning hindgut for some time after birth. Some evidence indicates a need for supplementation of horses in training with folic acid.

Synthetic supplements of folic acid providing 20–200 mg daily have been used, but there is little scientific evidence as to their efficacy. Suggested levels for folic acid are 0.55 mg/kg DM feed for adult horses at rest and in light to moderate work, approximately 1.1 mg/kg DM in pregnant and lactating mares, and approximately 1.7 mg/kg DM for those in intensive work and young growing horses with the greatest demands. **Vitamin B₁₂** levels of 5 µg/kg feed as fed for performance horses and 15 µg/kg feed for young growing horses have also been suggested.

Possible clinical signs of folic acid deficiency include **megaloblastic anaemia with macrocytosis**. However, this has not been confirmed for folic acid in the horse. In other species differentiated from vitamin B₁₂ deficiency by the absence of methyl malonyl CoA accumulation but with homocysteine accumulation in the blood.

Signs due to excesses of folic acid and vitamin B₁₂ have not been produced in the horse.

No dietary supplementary requirement appears to exist for other water-soluble vitamins.

PRACTICAL NUTRITION AND PRACTICAL RATION FORMULATION

GENERAL ASPECTS

General information about rations and feeding technique is provided in several specialist books about horse feeding; in this chapter only an overview is given.

Horses are individuals and vary in many of the areas that influence their needs with respect to nutrients and energy. Owners and riders also have individual requirements with respect to the condition of their horse and the nature of the ride, some of which may be influenced by the diet fed. Some horses seem to be “extremely lively” whatever they are fed, others remain stoical, but what might make one horse fat or excitable may be ideal for its stable mate.

Although BW can be a useful guide to requirements, **feed conversion efficiency rates** vary significantly. Daily feed intakes determined as a percentage of BW must be used as a guide only, and adapted to suit the individual's metabolism. Regular monitoring of BW and condition scoring can be a very valuable tool.

Appetite

Horses have a **finite appetite**, which influences what they can be fed in order to meet their energy requirements. This ranges from approximately 1.5% to 3.0% of BW on an as fed basis for most adult horses, although nursing and weaning foals may eat significantly more. On average, most horses eat approximately 2–2.5% BW/day (at 88% dry matter), i.e. 10–12.5 kg for a 500 kg horse (corresponding to approximately 2% of BW on a dry matter basis, i.e. 10 kg DM for 500 kg BW).

Number of meals

Feeding rations based on roughage or silage in the stable causes few problems because the ingestion time is long (see Table 3.4). Feeding roughage twice a day is satisfactory. On the other hand, **horses eat concentrate feed very quickly** (see Table 3.3). To prevent disturbances in the stomach (gas production, ulcers) and/or in the cecum (acidosis) and to have the highest energetic utilization of the feed, horses should, ideally, not be fed >0.5 kg concentrate

feed/100 kg BW/meal. This means that horses (500 kg BW) that need >5 kg concentrate feed/day should be fed three times a day and performance horses with requirements for 8–10 kg concentrate feed/day should be fed four times a day.

When to feed and water

There has been considerable debate over the years about when and what to feed horses before they are exercised or at a competition. Should they be fed or fasted and when should the hay be fed in relation to the grain or exercise? Some studies have concluded that, at least in horses undertaking **event type work**, feeding large amounts of hay along with grain may result in a lowered plasma volume and an **increase in body weight**, which may be detrimental to performance. Recently it has been recommended that grain should be withheld from many types of performance horses for at least 3 h before exercise, but **repeated small quantities of hay** should be fed to ensure proper gastrointestinal tract function and psychological well-being.

After physical activity and sweating, horses should have water (**before feeding**) to restore their water losses. Initially small quantities (not too cold) should be offered soon after intensive exercise and during cooling out. Water may be offered ad libitum to a fully recovered horse. At other times it is not necessary to provide water only before feeding—it should be available constantly.

Protein digestibility may be improved by feeding a small amount of roughage a few hours before feeding concentrates.

Forage: concentrate ratios

Forage (fresh or preserved) should be the **foundation** of any horse's diet, even those in hard work. Many horses and ponies do not require any other core feed, and those animals with maintenance or low energy needs may be satisfied by feeding plenty of forage at 1.5–2% BW. As energy needs increase, hays with higher energy levels and greater digestibilities should be considered. If this is not sufficient then additional feeds will be needed to meet the energy needs. Protein, vitamin and mineral supplements are likely to be needed to supply the essential nutrients not contained in the forage, or the forage and additional energy source(s), especially if manufactured compound feeds are not being fed.

Those horses in little or no work or those that are extremely efficient feed converters may benefit from being fed lower energy containing roughages but care must be taken that this does not increase the risk of impactions (*q.v.*).

For the majority of horses, even those in work, at least 50% of the diet, on a dry matter basis, should be suitable forage (approximately 1 kg DM/100 kg BW). Even fit, very intensively working horses should be fed at least 35%, and preferably 40%, of DM intake as forage. This may be as “long” fiber, such as hay, or may be chopped or ground and pelleted. Under most circumstances it appears to be beneficial to provide a significant part of the fiber intake as either “long” fiber or as a long chop. Depending upon the season and land available for grazing, pasture may provide a significant proportion of the

forage requirements. Forage type should not be changed rapidly and poor quality forage should be avoided.

For accuracy of formulation, and particularly where nutritional problems are suspected, the forage must be **analyzed**. In practical situations where hay is purchased in small quantities, visual assessment of the leaf–stalk ratio coupled with knowledge of the typical analysis for that type of hay may provide a rough guide to nutrient content.

During certain times of the year the fiber levels in grass and other fresh herbage are low, the moisture content high, and the soluble carbohydrate level high. During these periods, restricted access to pasture is necessary for some animals (especially those prone to the **equine rhabdomyolysis syndrome** and **laminitis**) if such a nutrient composition is undesirable (*q.v.*). Where access to pasture is restricted, or animals are being kept on “starvation paddocks” for example, alternative sources of forage of an appropriate nutritional content (plus vitamins and minerals) must be provided to maintain key nutrient intake and to help avoid disorders such as **hyperlipemia** (*q.v.*).

Pasture

It must not be assumed that abundant pasture will meet all nutrient requirements. Pastures over the winter months are generally poorer sources of protein, energy and phosphorus. Moreover, with **wet winter weather** the calcium content can be low. Caution should be exercised where the pasture appears to meet energy, crude protein and fiber requirements (as judged by the animal’s bodily condition) as the mineral and amino acid intakes may in fact be deficient. This is particularly important in brood mares, weanlings and yearlings turned out on abundant pasture. Other minerals, such as copper, zinc, and in some areas manganese and/or selenium, can also be very low.

As well as nutrient deficiencies some further risks should be taken into account, for example very short grass (golf grass) may lead to **ileal obstructions** while **high fructan** contents, especially in spring and harvest, may induce laminitis (*q.v.*).

For horses at risk, such as brood mares, young stock and laminitis cases, **herbage analysis** should ideally be used to provide the necessary data to indicate whether supplementary minerals and amino acids are required. Additional protein and energy from concentrate feed may not, however, be required.

CONCENTRATE FEED DESIGN AND SELECTION

There are two main options when selecting a concentrate regimen:

1. To use a manufactured compound feed (either cubes, coarse mixes or extruded feeds), or
2. To mix “straights” or individual raw materials and mineral and vitamin supplements to the desired specification.

The latter includes the practice of feeding cereals and a cereal “balancer”.

Compound nuts, coarse mixes and extruded feeds

If a compound feed is used, it is vital that it is chosen to meet the requirements of the horse or pony in question. In most cases, these feeds are designed to be fed as virtually the sole concentrate feed, with hay, water and sometimes additional salt or other electrolytes. Additions may therefore cause **significant imbalances**. Owners should be discouraged from adding to the selected compound feed, in particular micronutrient supplements, as minerals and vitamins can be fed in excess. **Reduced performance** and possibly **clinical toxicosis** may result.

Most compound feeds contain a broad-spectrum mineral and vitamin supplement designed to meet the requirements of a normal, healthy horse for which the feed was designed, when fed at the minimum specified level. If higher levels of feed are required, larger amounts of micronutrients will also be consumed. These amounts are unlikely to be toxic, but this depends on their concentration and what other supplements are being fed. It is usually advisable to change to a feed with a higher energy density that is more suitable to that individual's requirements.

When the level of compound feed drops below the required minimum, either a lower energy and protein specification ration should be offered (at the required minimum level), or additional micronutrients should be added to the reduced concentrate intake.

"Straight" rations

Many owners still like to mix their own materials. This is often referred to as "traditional feeding". Unfortunately, much of the "tradition" has been lost or distorted. In addition, the nutrient composition of traditional feedstuffs may have altered as a result of changing agricultural methods. However, it is of course possible to use home mix rations very satisfactorily. Tables 3.6 and 3.12 can be used to help to determine the nutrient requirements of the horse in question. With knowledge of the raw materials, a mixture of these ingredients may then be selected to meet these nutrient requirements. It is likely that a broad-spectrum mineral and vitamin supplement will be required; these are readily available but must be assessed for their efficacy.

Mineral and vitamin supplements

Several mineral and vitamin supplementary feeds are available. The correct dose depends on ration calculation and the requirements of the horse. Most times they are only necessary to complete rations of roughage or roughage and grain. Industrially produced feeds from reputable manufacturers usually contain sufficient amounts of minerals and vitamins (when fed as recommended). Consequently there is normally no need for additive feeding of single minerals or vitamins unless for a specific reason, e.g. biotin and poor hooves.

Specific micronutrient supplements

Many supplements target specific potential deficiency areas or cases where limited research indicates that a higher level of a certain micronutrient may

enhance performance. These supplements include those said to provide higher levels of the antioxidant micronutrients vitamin E and selenium; the so-called “hematonics” which claim to provide elevated levels of the B complex vitamins, and perhaps iron and copper, for their roles in the hemoglobin molecule; or elevated levels of certain microminerals known to be important in musculoskeletal development such as copper, zinc and manganese. Although there may be cases where the use of these supplements is indicated (e.g. biotin for horses with poor hooves, vitamin E and selenium in gestating mares), in most horses they are not necessary.

Items to avoid

Items such as lawn clippings, large amounts of **rapidly fermentable feeds** such as apples, or feeds designed for other types of animals should not be given to horses.

FEEDING THE PERFORMANCE HORSE

The main specific problems in working horses result from their high energy, water and electrolyte demands.

ENERGY

Energy is supplied to the horse via its diet but fundamentally **energy is not a nutrient**. The chemical energy or gross energy contained within feeds needs to be converted into a form of energy that the cells can use for work or movement (usable or **net energy**).

The energy demand, above that of maintenance, required for various physical activities is suggested in Table 3.13. The average estimated requirements for working horses of energy and digestible protein are presented in Table 3.14.

The energy turnover in muscle during maximum exercise is high. According to recent figures, racehorses need 40–60 MJ digestible energy (DE) above maintenance during training or racing. Assuming the maintenance requirement of such animals is similar to that of other animals (see Table 3.14), the total requirement of DE is in the range of 100–130 MJ DE/day. However, individuals can vary considerably in how much energy they require to maintain condition and provide the rider with the type of ride they require, and all diets should be adjusted to the individual.

Tables 3.13 and 3.14 may be useful for estimating the specific energy demands of horses maintaining submaximal speeds over longer distances. For example, horses of 500 kg BW require for maintenance approximately 65 MJ DE; for 1 h walking (including tack and rider of 75 kg: total BW = 575 kg) = 5.75 MJ DE; for 1 h slow trotting, 14.4 MJ DE; for 10 min galloping 14.4 MJ DE, giving a total requirement of approximately 100 MJ DE/day. Cold weather may increase energy needs by 10–15% to maintain warmth. Exercising up hills or under heavy wet or deep soil conditions may also increase energy needs.

Table 3.13 Guide to the energy requirements above maintenance for various activities (kJ DE/kg BW)¹

Activity	Speed (km/h)	Requirements		
		Per km	Per 10 min	Per h
Walking	4	2.5	1.7	10
Slow trotting	10	2.5	4.2	25
Fast trotting/cantering	15	3.4	8.3	50
Galloping	25	6.0	25	—
Top speed	40–50	Up to 40	30 ²	—

¹ Horse and rider.

² Per min.

Table 3.14 Guide to the recommendations for the supply of working horses with digestible energy (DE) and digestible crude protein (DCP). Note that this excludes rider and tack weight. (DCP intake from a ration will be approximately 40–80% of the CP content depending on the diet.)

Degree of work	Additional requirements in % of maintenance requirements (MJ)	Kg body weight					
		200		500		600	
		DE (MJ)	DCP (g)	DE (MJ)	DCP (g)	DE (MJ)	DCP (g)
Maintenance		31.9	160	65	318	72.6	363
Light	Up to 25	38	190	76	380	87	435
Moderate	25–50	44	220	87	435	100	500
Heavy	50–100	56	280	111	555	127	635
Very heavy	~100	64	320	127	635	145	725

The daily DE intake of **3-day event** horses (average 600 kg BW) during intense training (2.9h/day) will be in the range of 150–170 MJ DE, but again many individual animals will not need anywhere near as much energy as this.

When horses work very hard for several days the energy requirements often cannot be covered by the energy ingested because their feed intake may be reduced and requirements are high. Such horses mobilize energy from the **fat stores** in the body. Therefore, before starting **long distance rides**, horses must be in **good condition**.

Recent work has suggested that at least in the more difficult endurance rides, thin horses with a **condition score** (CS) <3 (on a 1–9 scale) might be at a disadvantage because of lower energy reserves, whereas over-conditioned horses could have problems, for example due to the insulating effect of a thicker fat cover.

PROTEIN

If the energy intake or energy stores are adequate, exercising horses need only small amounts of protein above the maintenance requirements. An **additional**

protein supply should, however, be provided to cover the **endogenous fecal nitrogen losses** (which are about 3.6 g N/kg DM intake), the nitrogen loss in sweat (1–1.5 g N/kg sweat) and the building of new muscle mass after a period with low activity (bodybuilding).

In exercising horses, the protein intake (digestible crude protein: DCP) per energy unit (MJ DE) can be the same as in horses at maintenance metabolism, approximately 5 g DCP/MJ DE. With increasing energy demand the proportional increase in protein intake will fulfill requirements and maintain protein stores in muscle and organs and, by keeping the ratio of protein to energy at 5:1, even with a very high energy intake (150 MJ DE/day), an excess of protein does not occur (750 g DCP/day).

In **exercising horses**, especially endurance horses, an intake of >2 g DCP/kg BW/day should be avoided.

WATER AND ELECTROLYTES

As discussed above, sweat contains relatively low levels of calcium (approximately 0.12 g/L), magnesium (approximately 0.05 g/L) and phosphate (<0.01 g/L) but relatively high levels of sodium, potassium and chloride as shown in Table 3.10. There are also small amounts of various trace elements, e.g. iron at approximately 4.3 mg/L and zinc at 11.4 mg/L. However, the **main electrolytes lost** with sweat are sodium, potassium and chloride.

The water and electrolyte requirements of working horses are mainly related to losses in sweat and via the respiratory tract (water). Some figures for sweat production are presented in Table 3.9.

Horses do not reduce their sweat production even with extreme water deficiency. At maintenance level, horses need approximately 4–5 L water/100 kg BW/day (depending on diet and environment; see also Tables 3.7 and 3.8). The amount required increases proportionally with activity and sweat production (Table 3.9).

The total requirement of electrolytes depends on the amount of sweat produced and its composition. The **composition of sweat** does not change even with low intakes of electrolytes. Therefore the electrolyte requirement increases proportionally with higher activity and sweat production (Table 3.15).

Losses of calcium and phosphorus in sweat are small (see Table 3.9). Therefore the requirements of exercising horses are only slightly higher than maintenance (see Table 3.15). After a prolonged period without activity, calcium and phosphorus supply should be increased to approximately 20% above the recommended figures to compensate for the losses from the skeleton during inactivity. An excessive calcium intake (more than three times the recommended figures) should be avoided because the absorption of other nutrients (e.g. zinc, copper and iron) may be reduced. Excessive intakes have to be excreted by the kidney and the large intestine.

The magnesium requirement of performance horses increases because magnesium is lost in sweat (see Table 3.15), although it has been suggested that the magnesium concentration of sweat decreases approximately 30–60 min after the onset of exercise. Higher supplies of magnesium compounds have been recommended to improve performance but this measure is open for discussion.

Table 3.15 Recommendation for the minimum daily mineral requirements of adult working horses¹ (g/day): Based on Tables 3.9 to 3.11

Degree of work ²	200 kg BW				500 kg BW				600 kg BW			
	1	2	3	4	1	2	3	4	1	2	3	4
Calcium ³	10	11	11	12	26	26	28	30	31	32	34	36
Phosphorus ³	6	6	6	6	15	15	15	15	18	18	18	18
Magnesium ⁴	3.2	3.4	3.9	4.3	8	8.5	9.7	11	9.6	10	12	13
Sodium	9.2	14	28	38	23	37	70	96	27	45	84	115
Potassium	13	16	24	30	32	40	60	75	39	48	72	90
Chloride	25	33	55	71	61	81	136	178	73	98	163	213

¹ Assumed sweat production as per Table 3.9, i.e. light work ~0.75 L per 100 kg BW, moderate ~1.5 L per 100 kg BW, heavy ~3.5 L per 100 kg BW, very heavy ~5 L per 100 kg BW.

² 1, light; 2, moderate; 3, heavy; 4, very heavy.

³ In young growing animals (2nd and 3rd year) increase supply by 20–30%. Some workers recommend that phosphorus requirements increase slightly with increasing work loads, with a corresponding increase in Ca intake to maintain a Ca:P ratio of between 1.5:1 and 2:1, see Table 3.6.

⁴ Some recommend slightly higher magnesium intakes for working horses, see Table 3.6.

TRACE ELEMENTS

Iron is important for synthesis of hemoglobin and for replacing iron lost in sweat (see Tables 3.10, 3.12 and 3.16). With most rations, the iron intake of horses is adequate. Suboptimal hemoglobin values are usually not due to marginal iron intake. There are possible risks of inducing problems due to excessive iron given either nutritionally or via injection.

In exercising horses, the requirements for **copper** and **zinc** increase only slightly because only small amounts are excreted with sweat (see Tables 3.10 and 3.16). Because **iodine** requirements increase with heat production, and some iodine is lost in sweat, the supply of exercising horses should be higher than during maintenance.

Traces of **selenium** have been found in sweat and it has been suggested that there may be increased losses via the urine in exercising horses (perhaps dependent on selenium source). The supply of selenium to exercising horses should therefore be higher than for maintenance. Selenium in combination with vitamin E is important for integrity of muscle tissue.

VITAMINS

Fat-soluble vitamins

Vitamin E is important for exercise capacity. The tissue levels of vitamin E should be sufficiently high to prevent production of lipid peroxidation products. To obtain maximal tocopherol contents in various tissues, exercising horses need approximately 4–6 mg α -tocopherol/kg BW/day. Intakes from around 160 IU to 250 IU/kg DM intake are currently typically recommended for performance horses.

Vitamins A and D are not involved in energy turnover in muscle. Intakes higher than those needed for maintenance are therefore not justified (see Table 3.16). Since a moderate excess of vitamins A and D might affect performance negatively, intakes of >5–10 times the maintenance requirement should be avoided.

Table 3.16 Guide to the recommendations for the daily supply of working horses with trace elements and vitamins (based on allowing between 10 and 12.5 kg DM intake for a 500 kg horse)

	Per kg total feed DM	Per kg BW
Trace elements		
Iron	50–70 mg	1.0 mg
Copper	10–20 mg	0.2–0.5 mg
Zinc	40–60 mg	0.8–1.5 mg
Manganese	40–60 mg	0.8–1.5 mg
Cobalt	0.1–0.15 mg	2–4 µg
Selenium	0.2 mg	4–5 µg
Iodine	0.15 mg	3–4 µg
Vitamins		
Vitamin A	4000–6000 IU	80–150 IU
Vitamin D	400–600 IU	8–15 IU
Vitamin E	150–250 mg	3–6 mg
Vitamin B ₁	3–5 mg	0.06–0.125 mg
Biotin ¹	0.05 mg	0.001–0.00125 mg

¹ Note that this not the level that would be recommended for specific hoof support, see text.

Vitamin K is sometimes used to prevent exercise-induced pulmonary hemorrhage. There is no evidence to support this practice.

Water-soluble vitamins

Racehorses, in comparison with other types of horse, appear to be more susceptible to marginal **thiamin** deficiency (*q.v.*). It is thought that this occurs as thiamin is required for energy utilization and the racehorse requires such a large amount of energy. Furthermore, the gut synthesis may be lower in racehorses fed low roughage diets. Thus the recommendation of 3 mg thiamin/kg feed for maintenance may not be adequate for performance horses, and approximately 5 mg/kg air-dried feed has been suggested.

It has been suggested that animals in hard work that go “off feed” may be beneficially treated with a thiamin supplement (e.g. brewer’s yeast); however, this is anecdotal. Stabled racehorses may require a **folate** supplement, but horses on pasture usually do not. Pasture is an excellent source of folate, although weathered pasture may have lower levels. High intakes of biotin (up to 20 mg/day for a 500 kg horse) might only be useful in horses that have a disposition for poor hooves. Doubt must be placed on the practice of giving regular doses of **vitamin B₁₂** to horses before racing.

ANTIOXIDANT SUPPLEMENTATION

Free radicals are independent yet unstable molecules that contain one or more unpaired electrons and are formed as the result of normal body processes. In particular they are formed as a result of aerobic metabolism, therefore their production is increased with exercise, but they may also be created following injury, disease or exposure to certain environmental factors such as allergens, pollutants or radiation.

The phrase “**reactive oxygen species**” (or ROS) (*q.v.*) is often used to describe all those free radicals and other molecules that are capable of causing oxidative damage and contain one or more oxygen atoms. “**Oxidative stress**” occurs when the antioxidant defense system cannot cope with the rate of free radical production. Left uncontrolled, the self-perpetuating “chain reaction” production of free radicals and the consequent damage they cause can lead to alterations in the structure of cell membranes, cell DNA and other cellular components, and cause disruption of normal physiologic processes (some of which may be irreversible), i.e. “**oxidative damage**”.

In recent years, there has been growing awareness of the role of oxidative damage, at least in humans, in both the **aging process** and the development of a number of diseases or conditions such as asthma, cancer, skin disease, arthritis, muscular atrophy, cardiovascular disease, liver disease and autoimmune disease. It is thought that oxidative damage may also be implicated in similar diseases in animals. **Antioxidants**, often referred to as “**free radical scavengers**” (although not all antioxidants act by scavenging free radicals), are the body’s natural defense against oxidative damage. The main dietary antioxidants for the horse are vitamins C, E and β -carotene as well as selenium. It is therefore important to ensure that adequate amounts are provided to all horses, in particular the performance horse.

There is now clear evidence, both in humans and horses, that a mixture of antioxidants (especially from natural sources) may be more beneficial than a single antioxidant in helping to support antioxidant defenses. Feeding of a single antioxidant or unbalanced mixtures of antioxidants may lead to antioxidant depletion, imbalance and a diminished antioxidant capacity; if fed in excessive amounts, some antioxidants may act as pro-oxidants.

FEEDING THE PREGNANT/LACTATING MARE

INTRODUCTION

It is increasingly recognized in the horse, as well as in humans, that nutrition of the mother may have a very important role in the subsequent health of any offspring. The gestation period of the mare commonly lasts 335–345 days but a considerable variation can exist. The pregnant mare should be kept fit throughout pregnancy, but not fat. Even before pregnancy, a lean but healthy barren, or maiden, mare is better where early conception is required. Individuals that are increasing in body weight are thought **more likely to conceive**.

By the seventh month of gestation the fetus will be approximately 17% of its birth weight. The majority of studies have suggested that embryonic development and fetal growth require no additional nutrients throughout the first 8 mo of pregnancy. Feeding a good balanced diet during this period is still very important. However, fetal growth obviously accelerates markedly during the last three months of gestation and this is a **crucial time** in the nutrition of the mare. Nearly half the copper, zinc, and manganese accumulation, for example, occurs in the 10th month.

Postnatally, pre-weaning is the period of most rapid growth (approximately 110 kg gain in the first 3 mo in Thoroughbred foals). Maternal effects (birth

weight, milk yield, etc.) appear to be more important than direct genetic effects during the early postnatal period. However, maternal influence decreases later in life and direct genetic effects become the primary influencing factors for growth.

During early to mid gestation the mare's nutrient needs for maintenance and any change in body condition or her own growth as well as any exercise should be met. Good quality pasture may meet energy and protein needs but it is unlikely to meet all the mineral requirements. Acute malnutrition with maternal weight loss greater than 50 kg has been associated with early embryo loss and it has been suggested that levels of nutrition of either half or double maintenance may have adverse effects on early embryo survival.

Late gestation is a crucial period in the nutrition of the mare. Mares have varying reserves that they can draw on if intakes during pregnancy are inadequate, but at what stage nutritional imbalances might influence the health of the foal or its health as an adult horse is currently unknown. There is an increased risk of inducing **hyperlipemia** (*q.v.*) if a pregnant mare is starved. It is recommended that the intake of feed be gradually increased during the last few weeks of gestation so that there is no sudden change in feed intake when the mare starts to lactate. The dam ideally should be kept in the foaling environment for at least 2 wk prior to foaling so that the antibodies produced and passed to the foal via the colostrum are appropriate.

Birth weight is important because of neonatal viability. In general, the mature number of cells in many tissues will have been achieved by birth or shortly afterwards, so to a large extent mature weight (apart from fat deposition) is determined by birth weight. It depends much more on the size of the mare than upon the size of the stallion or upon the amount of feed given during gestation. The amount of feed given to the mare during the latter part of gestation will, nevertheless, influence the flow of milk in early lactation.

Abundant good quality pasture can meet the energy, protein, calcium and phosphorus needs of **lactation**, even though the minimum dietary protein requirement will have risen to 125 g/kg of dry feed. Increases in milk yield have been obtained by providing a third more than this, but it is unlikely that this is desirable. As many horse pastures contain poor quality herbage species, the yield of good quality forage can be short lived and stocking density may be such that the provision of concentrates and hay is necessary.

Lactating mares will consume large quantities of roughage, but if the quality of this is poor, **milk yield will suffer**. This could be desirable around weaning to encourage the foal in the search of supplementary feeds and more grazing. A deficiency of water, energy, protein, calcium or phosphorus will ultimately bring about a decrease in milk output without altering its composition, so that within limits the foal will remain healthy but small and of slightly abnormal proportions, as for example, physes in the limb extremities may close early.

During lactation the concentrate proportion of the feed required will vary according to the individual and the quality of the feed being provided. A very heavy milker may need 1.75% BW as concentrates (non-forage portion) although more typical may be 0.75–1.25% BW, especially if the mare is being kept on good pasture. Typical feed intakes during lactation are approximately 2–3.0% BW on an as fed basis (approximately 90% DM). According to the NRC, mares produce approximately 3% of their BW as milk for the first 12 wk

of lactation and then an average of 2% BW for the next 12 wk. Other studies have suggested that the rates are higher—at around 4% reducing to 3%. Because of this discrepancy it has been suggested that the energy recommendations of the NRC are approximately 10–12% lower than those actually required.

A guide to the nutrient requirements of the breeding mare is given in Tables 3.6 and 3.12. The requirements of mares of other weights can be approximately gauged by interpolation (or within small limits of extrapolation). If the mare is lactating during the early part of gestation then her requirements during that period will exceed those of later gestation. The most crucial nutrients for mares given traditional diets are sources of energy, protein, copper, vitamin E, selenium, calcium and phosphorus.

ENERGY REQUIREMENTS

The first 8 mo of gestation have no practical impact on nutrient needs over those for maintenance unless the mare is growing, exercising or needs to gain condition. Most of the fetal growth occurs during the last 90 days of gestation. Even so, the nutrient drain incurred to sustain normal fetal growth is much less than that for lactation. Nevertheless, as the fetus occupies an increasing proportion of the mare's abdominal cavity, her **capacity for bulky feeds** declines during the period in which nutrient requirements increase. This may correspond to an increase in the quality of grazing but, if not, mares should be given forage and concentrates of higher quality than hitherto.

In **late pregnancy** some allowance for the energy needs of the fetus is needed. It has been recommended that mares in the 9th, 10th and 11th months of pregnancy (3rd trimester) should receive 1.11, 1.13 and 1.2 times the maintenance requirements respectively (NRC). Certain breeds may require more to maintain condition and optimal fetal development.

For a mare in the first 3 mo of lactation typically producing around 3% BW of milk according to the NRC:

DE MJ/day = Maintenance + allowance for the energy content in milk,
i.e. $[4.184 \times (1.4 + 0.03 \times \text{Body weight})] + [(0.03 \times \text{BW}^* \times 0.792) \times 4.184]$

PROTEIN REQUIREMENTS

The protein requirements of the pregnant mare are relatively low; nevertheless, when grass hays form a major part of the diet, supplementary protein is required as such hays typically contain only 5–7% protein. If they constitute 70% of the diet, then the concentrate should contain 16–17% protein for the latter part of gestation. The protein requirements for milk production are considerably higher, but vary with the potential yield at each stage of lactation (see Table 3.6). Where the intention is to reduce, or limit, milk secretion this is best achieved by restricting the total concentrate intake, rather than by lowering the protein content of that concentration.

The ratio of protein and calcium requirements to energy intake are not identical in pregnancy and lactation to those at maintenance, so one cannot

*NB increase to $0.04 \times \text{BW}$ if the mare is a heavy milker.

just increase the amount of the basal diet to match energy needs. For many mares a compound, manufactured, appropriately fortified feed (complementary feedstuff) specifically designed for the purpose can be advantageous in the last third of pregnancy and during lactation.

The NRC protein requirements are taken as crude protein intake and calculated for **pregnant mares** at a fixed proportion of the energy intake, i.e.:

Requirements g/day ca.10.5 g/MJ DE/day or approximately 1.6–1.75 g of CP per kg BW (dependent on the type of ration being fed)

For the **lactating mare** this is calculated by allowing for the milk protein content and the amount of milk produced (and therefore should vary during the lactating period), but as a guide, in **early lactation** (up to 3 mo) for a 400–900 kg horse producing 3% BW in kg each day of milk (which is taken to contain 2.1% protein) plus allowing for the fact that CP is used for milk production at around 65% efficiency and that a reasonable quality ration is being fed with a protein digestibility of around 55%:

$$\begin{aligned}\text{Protein for lactating mares} &= \text{Digestible protein for maintenance} \\ &\quad + \text{DP for milk production divided by the} \\ &\quad \text{estimated CP digestibility} \\ &= \text{ca. 2.85 g CP per day/kg BW}\end{aligned}$$

For heavy milkers this will increase to around **3.45 g CP per day/kg BW**.

In **late lactation**, with a milk yield of approximately 2% BW and a milk protein content of approximately 1.8%, the requirements will be approximately **2.10 g CP per day/kg BW**.

The digestibilities will vary with the diet, being higher than the estimated CP digestibility of 55% allowed for here if more concentrates are fed or high quality protein feedstuffs are used.

CALCIUM AND PHOSPHORUS REQUIREMENTS

During the last 90 days of gestation, mares kept entirely on reasonably good quality pasture or on high quality conserved forage containing some 30–40% leafy clover, alfalfa or sainfoin **require no other source of calcium** and, if the forage contains 10% protein per unit DM, no supplementary protein. The **phosphorus requirements**, however, amount to approximately 3 g/kg of the total dry diet. Although this would be provided by good pasture, it is frequently not provided by the hay typically given to horses in the UK. This hay normally contains <2 g phosphorus/kg and a supplement may be needed. However, there is a need to ensure that the overall intake of both calcium and phosphorus is adequate; the ratio is ideally between 1.5:1 and 2:1. Table 3.6 gives a guide to requirements. Full tables are available in textbooks but if the data are based on NRC recommendations it is important to remember that these are **minimal** requirements.

During lactation, calcium and phosphorus requirements depend on the actual amount of milk produced and the amount deposited within the milk as well as the availability of the nutrient from the diet. For example, heavy milkers produce approximately 4% BW as milk; moderate milkers approximately 3%, and low or late lactating mares approximately 2%. The amount of calcium

deposited in early and late lactation is approximately 1.2 g and 0.8 g/kg milk respectively. Assuming an absorption efficiency of 50%, this would mean a minimum requirement of **approximately $0.11 \times \text{BW g Ca/day}$** for a moderately milking mare in early lactation. However, 50% may not be valid for all individuals and all diets, therefore it has been recommended that more optimal levels may be approximately $0.14 \times \text{BW g Ca/day}$.

WATER REQUIREMENTS

The requirements of the mare for supplementary water during gestation and lactation are given in Table 3.8.

SUPPLEMENTARY FEED DURING PREGNANCY AND LACTATION

Supplemental vegetable fat or oil in the diet of pregnant and gestating mares can be beneficially used as an energy source, allowing for the fact that it provides no additional protein, vitamins (available vitamin E content is variable) or minerals.

Pasture and forage vary considerably in their nutritional content and yet in most pregnant and lactating horses these provide the bulk of the diet. These should ideally be monitored regularly so that the diet can be appropriately fortified for the individual circumstances.

Recent research has suggested that dietary supplementation of vitamin E (total intake of 160 IU/kg DM) and selenium (total intake approximately 0.2–0.3 mg/kg DM) to the mare during the peri-parturient period may beneficially influence colostrum concentrations of immunoglobulins.

It is also suggested that providing adequate copper supplementation during gestation in particular may be advantageous (approximately 15–20 mg/kg DM intake).

FEEDING THE FOAL AND WEANLING

REQUIREMENTS

Foals of many breeds have the capacity to grow relatively fast, but the rate of growth per 100 kg BW declines continuously from about 2 wk of age. The rate of growth of long bones and of skeletal muscle declines at an even faster rate and an increasing proportion of the gain constitutes fat, which has much higher demands for feed energy. Thus, the dietary requirements for protein, calcium and phosphorus, in particular, decline fairly rapidly as a proportion of the total diet with increasing age (see Tables 3.6, 3.12, 3.17 and 3.18).

By 12 mo of age, Thoroughbred foals reach approximately 60–70% mature weight, 90% mature height and 95% of eventual bone growth. This can be delayed somewhat, without incurring an ultimate reduction, by slightly reducing the rate of feeding. Foals growing at a rapid rate deposit greater quantities of bone, muscle and fat than their slower growing counterparts and therefore need more calcium, phosphorus, lysine, etc.

Table 3.17 Recommended requirements (based on the NRC, 1989)¹ of DE and CP on a daily basis for growing horses (500 kg mature weight) with varying average daily gains (ADG)

	Age (mo)	Body weight (kg)	ADG (kg/day)	DE (MJ)	CP (g)
Weanling	4	175	0.85	60.0 (14.4 Mcal)	720
	6	215	0.65	63.0 (15.0 Mcal)	750
	6	215	0.75	67.0 (16.1 Mcal)	805
	6	215	0.85	72.0 (17.2 Mcal)	860
Yearling	12	325	0.50	79.0 (18.9 Mcal)	851
	12	325	0.65	89.0 (21.3 Mcal)	956

² Higher magnesium levels have been suggested by other workers (see Table 3.10).

³ mg/kg Cu in the feed on a DM basis. Higher copper levels have been recommended by other workers (see Table 3.9 and text). ADG, average daily gain.

Energy

The large intestine of the foal is relatively small and so it depends to a greater extent on digestible starch and sugars as sources of energy. Nevertheless it is prudent to stimulate the development of the large intestine and a mature digestive function. Thus high quality leafy hay may be provided in small and increasing quantities as a stimulant.

It is important to allow for maintenance plus growth **and exercise**, if appropriate, which means, based on the NRC (1989):

DE MJ/day = DE for Maintenance + Allowance for growth: where
X = age in mo and ADG is average daily gain in kg
= 4.184 × ([1.4 + 0.03 BW] + [4.81 + 1.17 – 0.023X²] × ADG)

There is increasing evidence to suggest that the way energy is provided to the growing foal may be important, especially in relation to DOD (*q.v.*).

Replacing traditional diets high in starches and hydrolyzable sugars with ones high in fat and fiber has been suggested to have a number of **potential advantages**. The feeding of appropriately fortified **fat and fiber based diets** may help to reduce the incidence of certain digestive and metabolic disturbances as well as resulting in a reduced risk of DOD.

Protein

Protein requirements for growth in horses depend to a large extent on the amino acid requirements of the foal, the amino acid content of the feed ingredients and the digestibility of these amino acids. **Lysine**, as for the mare, is believed to be the first limiting amino acid in typical horse rations for growth and threonine is believed to be the second. The mare's milk has this quality, as do fishmeal and properly processed soya bean meal.

Minerals

The foal has particularly high requirements for calcium and phosphorus and, to a lesser extent, for magnesium, reflecting its skeletal growth (see Tables 3.6, 3.12 and 3.18).

Vitamins

The absence of a fully functioning hindgut necessitates a dietary source of B vitamins. Supplements of vitamins A, D₃ and E often should also be provided.

COLOSTRUM AND NEONATAL FEEDING

It is essential that the foal receives colostrum during the first 12 h of life, and the **absorption of the immunoglobulins** depends upon it not receiving other sources of food during that time. Where colostrum is not available from the dam the foal should receive it from another source. The first factor to be determined with the sick newborn foal (*q.v.*) is its immune status. If immunoglobulin levels are ≤ 400 mg/dL and the foal is < 12 h old, then provision of equine colostrum should be considered and be administered by stomach tube (approximately 2 L colostrum or until immunoglobulin level reaches 800 mg/dL). If the foal is > 12 h old, septicemic and/or hypothermic, the specialized absorptive cells lining the intestinal tract will have a **decreased absorptive capacity** and consideration should be given to providing **equine plasma** (2–4 L at ≥ 1600 mg globulins/dL) from a suitable donor or plasma bank. Immunoglobulin levels should be **monitored** and plasma administration can be stopped once levels are approximately 800 mg/dL.

Foals have **low energy reserves** and therefore can rapidly become **hypoglycemic** if undernourished. This is especially the case if they are **premature** or compromised by infection. The mare should be kept in contact with the foal when possible, even if it is too sick to nurse, so there is a greater chance of

the dam accepting the foal at a later date. There are two advantages if the dam can be milked:

1. The foal receives equine milk/colostrum from its dam.
2. The mare's milk supply will not dry up.

At birth, much of the large intestine contains the **meconium**, which is normally completely voided within the first 2–3 days of life. Sucking usually sets up a reflex promoting defecation of this material. If this does not occur, the normal passage of colostrum and milk may become blocked. The foal may then go off suck for an extended period and should be given fluid feed by stomach tube or appropriate IV solutions of glucose and an isotonic electrolyte solution.

SUPPLEMENTARY FEED

Normal foals start to nibble hay and concentrates at 10–20 days of age. If the supply of milk or the amount of grass is inadequate, the provision of a creep feed from this time may well enable a normal growth rate to be achieved. A month or so before the intended weaning time the foal should be given increasing amounts of a dry feed to compensate for a decline in pasture quality and in milk production of the dam and to accustom the foal to the dietary regimen it must expect upon weaning. This should reduce weaning stress. Any product should be adequately fortified with minerals, trace elements and vitamins and it should contain high quality protein.

WEANING

Age at weaning does not appear to influence significantly mature height and weight but nutrition around this time can be crucial. More gradual techniques of weaning seem to be beneficial. If foals are not used to eating solid feed before they are weaned they will show a more prolonged decrease in **ADG** post weaning which is often followed by an undesirable compensatory growth spurt. NRC states that 200–230 kg weanlings consume up to 3.5% BW but practical work suggests that intakes of approximately 2.5–2.9% BW are more likely. The NRC recommends 30% hay or forage in the ration regardless of the growth rate. Others suggest varying the forage–concentrate ratio depending on the desired ADG; however, it would be recommended that at least 30% of the ration was forage or forage equivalents.

Weaning (*q.v.*) should entail **reducing the supplementary feed of the mare**, or removing her from high quality pasture some days before weaning. Foals should have **company** subsequent to weaning but should be out of sight and earshot of the dam. As a proportion of the diet, requirements for protein and calcium are high at weaning, owing to rapid growth of muscles and bones and their mineralization (see Tables 3.6, 3.12, 3.18 and 3.19). The requirement for these declines markedly over the first year of life as the skeleton matures and as fat deposition replaces rapid muscle growth. Clean water should always be available to the foal and provided in an accessible manner from around 2 wk of age (see Table 3.7).

Table 3.19 Typical range in pasture composition (northern temperate) (mg or g/kg DM).¹ Note that individual pastures may be lower or higher than these guide ranges: e.g. ranges for copper were reported by MAFF in 1990² for the UK for all grasses as being between 3.0 and 20.2 mg/kg DM with a mean of 6.7 ± 2.6

	May	July–August
Crude protein (g)	170–250 ³	110–180
Crude fiber (g)	190–230	300–330
Calcium (g) ⁴	4–12	3–9
Magnesium (g)	1.4–2.2	1.0–2.4
Phosphorus (g)	2.9–4.0	1.9–3.0
Potassium (g) ⁵	18–22	17–20
Copper (mg)	4–12	4–12
Zinc (mg)	20–60	30–60

¹ Note that this illustrates how pasture alone may not provide all the macro- and micronutrients for horses at different life stages or with different lifestyles, e.g. calcium for the lactating mare and growing foal; sodium for the exercising horse; copper for gestation and growth. In particular, attention needs to be given to mares and foals out on pasture of unknown nutrient composition.

² MAFF (1990) UK Tables of Nutritional Value and Chemical Composition of Feeding Stuffs. Eds D. I. Givencs and A. R. Moss. Rowett Research Services, Aberdeen.

³ A few pastures may have protein levels up to 300 g/kg DM or more, especially if primarily for cattle and not horses.

⁴ Calcium levels may fall below phosphorus levels, giving reverse ratios over the winter and spring months.

⁵ Potassium concentrations can be >35 g/kg DM.

The **yearling's** appetite tends to be approximately 2–3% BW as fed. The maximum non-forage recommended is 60%. On good, lush pastures, only an appropriately **fortified vitamin and mineral supplement** may be required. Levels of approximately 1–1.7 kg complementary concentrate feed per 100 kg BW may, however, be required, especially for foals receiving grass hay based rations and those on poor quality pasture.

The **long yearling's** appetite tends typically to be approximately 2–2.75% BW as fed. It is recommended that the non-forage feed proportion should be a maximum of 50–60% of the total intake, i.e. approximately 1.0–1.35 kg complementary concentrate feed/100 kg BW.

SODIUM, POTASSIUM AND CHLORIDE REQUIREMENTS FOR PREGNANT, LACTATING AND GROWING HORSES

Pregnant, lactating and growing horses probably need approximately 0.1–0.2% of total diet as sodium (on an “as fed” basis). An average of 0.15% may be most useful.

Potassium intakes for the pregnant mare have been given as $0.38 \text{ g} \times \text{MJ}$ intake per day or approximately 0.35% potassium in the total diet at the end of gestation. Early lactating mares require slightly more potassium, depending again on the amount of milk being produced, the level of deposition in the milk and the digestibility, e.g. for early lactation in a moderate milker ($=0.05 \times \text{BW} + (0.03 \times \text{BW} \times 0.7)/0.5$) = **ca. 0.092 BW**. These are minimal requirements from the NRC; more optimal requirements may be approximately 1.3 times these levels.

Recently, it has been recommended that the chloride intakes for pregnancy are 80–82 mg/kg BW/day; early lactation, 89–93 mg/kg BW/day; growth until 6 mo, 93 mg/kg BW/day; and growth 6–12 mo, 85 mg/kg BW/day.

EFFECTS OF DIETARY EXCESSES AND DEFICIENCIES

The young foal has higher requirements for nutrients per unit of feed than other horses.

Excesses

Concern exists that an excess of nutrients, and too rapid a rate of growth, may predispose the foal to **abnormalities in skeletal development**. Present evidence suggests that amounts of dietary protein sufficient for the foal to attain its potential growth rate have no significant adverse effect as long as the remainder of the diet is adequately supplemented. A moderate excess of calcium, trace minerals or vitamins also does not appear to have consistent adverse effects. **Excess dietary phosphorus** can, however, contribute to skeletal problems, and an excessive intake of soluble carbohydrate may contribute to the development of **DOD** (*q.v.*). **High dietary concentrations of soluble carbohydrate should be avoided.**

Deficiencies

The most obvious nutritional deficiencies seen in foals at birth are those of selenium, associated with vitamin E and selenium responsive myopathy, and potentially of copper, associated with **bony abnormalities**. These deficiencies reflect deficiencies in the mare's diet. In foals receiving inadequate milk, or in poorly fed weaned foals, general condition and conformation are adversely affected by an insufficient intake of protein and energy.

FEEDING THE AGED HORSE

INTRODUCTION

There is little reliable published information on nutritional needs specific to the aged horse. Nevertheless, the old horse is generally less able to assimilate feeds than are healthy younger animals. **Badly worn teeth** make it difficult to chew and ingest poor quality roughage, and body weight and condition can be difficult to maintain, especially in winter. Ground roughage contained in high fiber pelleted feeds can make a useful contribution.

Maintenance of normal body weight may require some concentrated feedstuffs. Elderly horses, and especially elderly ponies on good pasture, are subject to **laminitis** and **colic**. Therefore concentrated feedstuffs should be split amongst several daily feeds, and a feed of good roughage should be given, and eaten, before old horses are first introduced to pasture. Pelleted feeds are often helpful in avoiding colic, especially if they contain adequate and appropriate fiber (approximately 15%), 10–20% grain and approximately 12% good quality protein; vitamins and minerals are as required by other adult horses (see Tables 3.6 and 3.12). It is important to ensure that good quality protein is fed and that an adequate calcium and phosphorus intake is maintained.

The inclusion of cooked cereal grains as well as highly digestible fiber sources can be of benefit. Several high fiber pellets are available which, when

moistened and fed as mashes with additional salt and oil if required (and no contraindications), can be used as part or all of the diet of older horses with poor or limited dentition.

PROBIOTICS

Probiotics are **live microbial feed supplements** fed with the aim of improving the intestinal microbial balance. Much more work is needed in this area since the evidence for their use is currently conflicting. Certainly, ***lactobacilli*** have been administered to scouring foals for hundreds of years through the practice of allowing milk to sour in the manger. Similarly, fecal material collected from healthy horses has been used as a drench in cases of diarrhea (*q.v.*), as a way of recolonizing the intestinal flora.

When selecting a probiotic product, it is helpful to choose one that most closely resembles the normal range of flora in the intestine, although the use of selective strains may be beneficial under some circumstances. The product needs to reach its target area of the GIT in sufficient numbers to enable it to function effectively.

In recent years, certain **yeasts** have been included in probiotic preparations for their putative role in improving digestibility of fiber and other nutrients, notably phosphorus—in particular when added to cereal (starch) based rations. The apparent increase in digestibility has been suggested to arise at least in part from the yeasts stimulating the required enzyme-producing bacteria rather than from a direct effect of the yeasts themselves. Yeasts do not appear to be maintained in the established flora, and presumably need to be fed continuously to maintain their effect. Recently a yeast culture has obtained EU registration for use in equine diets and there is some evidence for beneficial effects when fed with high starch diets.

NUTRITION AND MANAGEMENT IN THE FIELD

The horse is less efficient at digesting fiber than domesticated ruminants and it therefore tends to seek out **younger herbage**. The capacity of pastures to maintain horses in good condition will depend on the amount of herbage in the pre-flowering state of growth. Studies that have been undertaken with horses weighing approximately 500 kg show that, with access to good quality pasture for 7 h daily, they can consume an average of 5.5 kg organic DM, sufficient to maintain their body weight. The intake of herbage diminishes with increasing maturity of that herbage and horses therefore eat reduced quantities of less digestible material, rather than more to compensate for its lower digestibility. Consequently the milk production of mares and the growth rate of foals and yearlings decline rapidly as pasture herbage matures to the flowering stage.

One hectare (approximately 2.5 acres) of high quality grassland could provide pasture and hay for 3–4 light horses of approximately 400 kg, or 4–6 ponies. Low quality permanent pasture, however, may support only one horse per hectare, and where rainfall is low many hectares may be required to supply the needs of a single horse throughout the year. Where the annual rainfall is

of the order of 61–64 cm, average quality grassland can produce sufficient growth for 2 horses and, when fertilized, for 3 horses per ha, or when just being used as summer pasture potentially up to double the number.

The productivity and feeding value of all pastures varies considerably with season (see Table 3.19), rainfall, soil fertility and ambient temperature. Pasture grasses that are going to seed, and brown-colored summer or winter (frost-affected) pastures tend to be of low feeding value for horses.

NUTRITIONAL ASPECTS OF METABOLIC DISEASES

INTRODUCTION

A proper assessment of the nutritional status of healthy working or breeding horses is always a difficult matter, but it is far more complex when there is a superimposed medical problem. The relationship of diet to growth and skeletal development of foals and horses, and a series of metabolic problems that commonly affect horses are described below.

DISTURBANCES OF GROWTH AND SKELETAL DEVELOPMENT

The necessity for correct nutrition of foals, weanlings and yearlings cannot be overemphasized, both in terms of productivity and longevity of competitive horses. Despite this necessity, few specific details of nutritional requirements are available and optimal growth rates of young horses have not been precisely established. This may be why problems of overnutrition in young animals appear to be much more prevalent than those associated with undernutrition.

The term **developmental orthopedic disease** (DOD) (*q.v.*) was first coined in 1986 to encompass all orthopedic problems seen in the growing horse and therefore encompasses all general growth disturbances of horses. It is non-specific and the definitions are not uniformly agreed. However, as defined by some, DOD may be taken to include **osteochondrosis** (OC) (*q.v.*), i.e. “a defect in endochondral ossification that can result in a number of different manifestations, depending on the site of the endochondral ossification defect”, one manifestation of which is **osteochondritis dissecans** (OCD) and **subchondral cystic lesions** (SBC) (*q.v.*) of cartilaginous origin; **physitis** (*q.v.*) acquired angular limb deformities; flexural deformities; tarsal collapse; juvenile arthritis or juvenile degenerative joint disease; bony fragments of the palmar/plantar surface of the first phalanx of Standardbred horses (believed to be traumatic lesions); and wobbler disease or cervical vertebral malformation (*q.v.*).

It has been suggested that the clinical signs occur only after a progression of events that begin with a disturbance in the normal development of the cartilage (sometimes referred to as **dyschondroplasia** or DYP) leading to OC. At this point physical (i.e. biomechanical) stresses are superimposed, leading to clinical signs. It is also thought possible that the initial defects or lesions may heal or develop into OCD or SBC.

Due to the **multifactorial nature** of DOD, no single cause is likely to result in expression. Factors that may contribute include genetic predisposition,

biomechanical trauma, and mechanical stress through inappropriate exercise, obesity, rapid growth and inappropriate or imbalanced nutrition. Different combinations may be involved in different cases. Environmental or management factors most likely determine whether expression occurs, i.e. provide the final triggering factor(s).

Various nutrients have been highlighted over the years, in particular energy, calcium, phosphorus, copper and zinc and protein. Many studies have been undertaken and suggested to either support or refute the role of a particular nutrient. However, caution needs to be taken when evaluating and extrapolating from these studies. In a survey in Germany, for example, there was no apparent significant link between the feeding management of foals and the incidence of OC, and no relationship was found between the nutritional status of the mares (in relation to digestible crude protein and digestible energy) and the incidence of OC. However, for a number of reasons (e.g. when stabled, foals were not fed separately from the mares, estimations were used to determine milk and pasture intakes, etc.), the nutritional status of the animals could not be determined accurately.

OVERFEEDING FOALS

Energy

A number of studies have suggested that a high intake of energy may result in an **increased incidence of DOD**. A significant increase in incidence was for example found when diets provided approximately 130% of NRC energy intake (see Tables 3.6 and 3.17). However, it should be noted that there has been concern that the lesions produced by some of these studies are not directly comparable to those found in the field and many field studies have reported foals being fed much higher energy intakes without an apparent increase in clinical incidence. This may be linked perhaps to the background level of predisposition within the individuals, the nature of the energy being provided and the balance of the diet. It has been suggested for example that diets which intrinsically produce high glycemic peaks, or individual horses that respond to certain diets to produce high glycemic peaks (and subsequent effects on insulin and other hormones) may have an increased risk of developing DOD. Such diets have the potential to establish a feeding–fasting cycle, which is a perturbation from the hormonal patterns likely seen in grazing animals. This in turn may adversely influence bone development as the cyclical changes in glucose and/or insulin may influence bone maturation via effects on the somatotrophic axis.

In other species, such as the pig, dog and sheep, evidence of increased **osteochondral lesions** has been found in breeds with **rapid growth rates** compared with the slower growing breeds. Growth rate depends on both genetics and nutrition. A number of studies have linked rapid growth rates (and often, by inference, excessive feed/energy intake—see above) with an increased incidence of DOD. The connection, however, lacks strength because the chain of events between rapid growth and the molecular events that initiate DOD is a long one. Also, the multifactorial nature of this syndrome means that the connection is not always direct; for example, in some animals a rapid growth rate could be a predisposing factor but expression might only

occur when a number of other factors are superimposed (e.g. as a hypothetical example, those foals genetically predisposed to rapid growth whose dams were fed inadequate copper during gestation and who were subsequently fed an unbalanced diet as weanlings).

Rapid growth may affect bone maturation directly or indirectly due to mechanical overload or disturbances in nutritional supply and hormonal balance. These and other factors associated with rapid growth rates therefore may be involved to a greater or lesser extent in individual cases. However, it is generally recommended that rapid growth rates with high energy intakes should be avoided, especially in animals or breeds prone to DOD.

Despite proposals that excessive protein in the diet causes DOD, this has not been confirmed as a causative factor, nor does it appear to have deleterious effects on growth. However, diets with excessive high quality protein are expensive and therefore wasteful. Whether certain diets that contain higher amounts of insulinogenic amino acids are more likely to adversely affect the incidence of DOD is currently unknown.

In a study of Dutch Warmbloods, the incidence of OC in foals fed high intake with high exercise (HH), high intake with low exercise (HL), low intake with high exercise (LH) or low intake with low exercise (LL) was compared. The researchers found that the HL and LH groups had a significantly higher incidence of OC than the HH or LL groups, the highest incidence being found in the HL group. This suggests that it is likely to be a **combination of factors** that influence incidence and that neither low activity nor high intakes will always result in an increased incidence. However, the lowest incidence was in fact seen in the HH group, suggesting that, if matched by intake, appropriate exercise may be of value in reducing the incidence of OC.

The nature and type of exercise that should be taken is still under discussion. However, it has been suggested that **paddock exercise** may be preferable rather than just forced exercise. Several studies have suggested that the time of birth may influence the incidence of particular forms of DOD (positively or negatively) perhaps due to influence of time of year on nature of the pasture, access to land for exercise and the relative hardness of such ground.

Mineral imbalances

Imbalance of mineral homeostasis is another important facet of the pathogenesis of osteochondrosis (*q.v.*). Foals fed excessive amounts of phosphorus (e.g. four times NRC recommendations, with limited exercise) tended to show lesions of dyschondroplasia in one study, although there may be no clinical signs of nutritional **secondary hyperparathyroidism** (*q.v.*) provided adequate calcium levels are fed.

Excessive dietary calcium has been proposed as a cause of **hypercalcitoninism** leading to osteochondrosis and osteosclerosis (*q.v.*) but there is no evidence to support this theory in foals. The levels of calcium recommended by NRC appear to be adequate (see Tables 3.6 and 3.18) and supplementation (e.g. three to four times NRC recommendations) does not appear to be detrimental to the skeletal development of foals. Increasing the calcium-calorie ratio to foals fed excessive energy (e.g. 129% DE and 340% calcium of

NRC recommendations) does not appear to be protective as in one study lesions of dyschondroplasia still developed.

No adverse effects of **magnesium** have been reported in relation to the incidence of DOD. However, little direct work has in fact been done on this in the horse despite the fact that magnesium may compete for copper binding sites and excessive magnesium may inhibit parathyroid hormone (PTH) secretion.

A copper-containing enzyme—**lysyl oxidase**—is involved in the cross-linking of protein chains in elastin and collagen of cartilage. Disruption of these cross-links due to copper deficiency may result in biomechanically weakened cartilage and increase the risk of DOD. A number of studies have suggested a relationship between **copper** and DOD. In discussing the possible inter-relationship it is important to consider that:

1. Milk has a low copper content, which does not fulfill the copper requirements of the suckling foal. Normally the foal is born with high copper concentrations in the liver, which it is thought will compensate for the milk. If the mare does not get sufficient copper during pregnancy (15–20 mg/kg BW/day) then the foal is more likely to be born with low copper reserves in the liver which in turn makes it less likely to be able to compensate for the low intake from the milk.
2. If foals are grazing in an area with low copper values in grass (<5 mg/kg DM) without supplementation, then a copper deficiency may potentially occur.

Feeding high levels of copper does not automatically entail a reduction in the incidence of DOD. In a number of studies it has been suggested that early signs of DOD may resolve, although there may be a time component to this. In fact, recently it has been suggested that rather than low copper being a causative factor, an increased availability of copper may support various degrees of reparation. A study in Holland correlated the liver copper status of mares and foals with OC scores. All animals had the same availability of feed but their estimated intakes of copper ranged from 95 to 153 mg/day and resulted in mean foal liver copper levels of 372 mg/kg at birth. No direct link between liver copper status of mares and foals at birth or radiographic evidence of OC development in foals at 5 or 11 mo was established. However, foals with higher liver copper status at birth showed increased recession of lesions before reaching the threshold age of 8 mo. It could be suggested that a slightly better placental supply and greater liver stores at birth helped in the lesion repair process and that a good copper supply during gestation may be advantageous. This conclusion is supported by work carried out in New Zealand that suggested possible advantages of providing supplements to the gestating mare, although further research on a much larger scale is needed in this area.

In conclusion, more recent work confirms that **copper supplementation** may not be the “magic bullet” suggested by some in the past as far as DOD is concerned. However, reduced copper intake or absorption, especially during gestation, could possibly either be permissive to the development of DOD under certain conditions or reduce the ability to repair lesions.

Horses appear to have a high resistance to **chronic copper toxicity** and it seems they can withstand levels of <800 mg/kg; therefore it seems very unlikely that levels of approximately 20 mg/kg copper in the feed for the mare and foal will have any deleterious effect. No evidence exists that **molybdenum** interferes with copper metabolism in the horse since the persistent, protein-bound thiomolybdates that occur in ruminants have not been identified.

There have been several reports that industrial contamination of grassland with either **zinc** or **cadmium** has resulted in an increased incidence of DOD (sometimes not confirmed histologically) in foals and young stock, suggesting that increased exposure to zinc and possibly cadmium may result in the development of OCD. However, more research is needed to confirm any possible relationship, to determine what the zinc-copper ratio should be and to ascertain what influence this may or may not have on the incidence of DOD.

There has also been some discussion regarding the nature and distribution of lesions caused by chronic **zinc** or **zinc/cadmium toxicosis** and whether such atypical patterns should be considered in the same way as the more **typical** DOD found routinely in the field. It has been suggested that in fact they should be specifically referred to as “zinc induced osteochondrosis” rather than being “combined under the more general term of DOD”.

ROLE OF NUTRITION AND EXERCISE

At present the interrelationship between exercise and feed intake in relation to DOD is far from clear, although there is an indication that there needs to be a balance between these two factors and extremes must be avoided. There also seems to be a “time window” in which the development of lesions may be influenced by both exercise and nutrition either positively or negatively. This may vary with the different joints but is most likely to range from in utero to approximately 9 mo of age.

NUTRITIONAL MANAGEMENT OF FOALS WITH DOD

Foals identified as having lesions of DOD must be carefully managed to prevent any exacerbation and to allow healing to be promoted. Three factors affecting foals with DOD have been identified:

1. **Dietary digestible energy level.** Although few experimental data exist, it appears to be beneficial to decrease the DE level to approximately 85% of that recommended by NRC, with 100% levels of crude protein, calcium, phosphorus and other nutrients. Excessive levels of calcium in combination with high levels of DE have not been effective in protecting foals from osteochondrosis and it is unlikely that high levels of calcium assist in the healing of DOD.
2. **Dietary copper level.** Collagen cross-linking may be enhanced when dietary dry matter (DM) contains higher levels of copper (e.g. 30–45 mg/kg). However, collagen cross-linking is probably adequate at lower levels (e.g. 10 mg/kg). In cases of physitis it has been suggested by some that levels of approximately 30 ppm copper in the dietary DM may be beneficial. Since

horses have a high threshold level for copper toxicity, the level can be increased with relative impunity.

3. **Exercise and feeding.** If a foal is diagnosed with osteochondrosis and/or physitis, then the level of DE fed should be decreased and any joint trauma minimized by confining the foal and allowing only hand-walking exercise. However, the lack of exercise will further decrease the foal's DE requirement and 70–75% NRC DE may then be adequate.

NUTRITIONALLY ASSOCIATED LAMINITIS

Laminitis is the local manifestation of a serious systemic metabolic disturbance (*q.v.*). Laminitis is perhaps most commonly associated with certain feeding and management factors that will increase the likelihood of a potential attack whatever the type or breed of horse. **Grain overload** for example, whether by accident or deliberately induced, increases the risk of developing laminitis.

Administration of a suitably large 85% carbohydrate and 15% **fiber meal** can result in clinical signs of laminitis within 40 h; another potential iatrogenic cause is **constant tube feeding** with a high energy–protein ration. Turning certain ponies out onto **lush pastures** in the spring and autumn/fall is a common triggering factor for the development of laminitis. Currently it is thought that the high levels of water-soluble carbohydrates (which include the simple sugars as well as the more complex storage carbohydrate **fructans**) may be involved in this process. It has recently been shown that giving relatively large amounts of a particular fructan (*q.v.*) can induce laminitis in the horse.

It is thought that, as in other mammals, the horse does not have the necessary enzymes to digest fructans directly within the small intestine. The bulk of the fructans therefore passes into the hindgut where they are readily fermented, in a similar manner to starch that escapes digestion in the small intestine, triggering off abnormal fermentation as discussed above. Under these circumstances any **endotoxins**, together with various other compounds that may be absorbed into the blood, may have further effects, in particular within the feet (not necessarily directly), triggering the development of laminitis. The degree of fermentation within the small intestine when other more rapidly fermentable feeds are fed possibly is also of some importance in this condition.

Reducing fructan intake

The fructan content of grass varies and is largely dependent upon multiple factors including fertilization, light intensity, ambient temperature, stage of growth, residual fructan accumulation from the previous day, and past and present pasture management regimens. It is usually when energy demands upon the plant are high (e.g. during growth) that the fructan concentration is at its lowest (as it is being utilized to provide energy for growth) and vice versa. It is therefore thought that the safest time to turn out the horse may be late at night, bringing it in by no later than mid morning.

Fructan levels tend to be higher in the stem than the leaf due to the role of storage carbohydrate and therefore **grass management** is important. The amount and nature of the fructan stored vary between grasses; for example, timothy and cocksfoot tend to accumulate larger molecules which may be more slowly fermented in the hindgut than the smaller molecules found in perennial rye grass. The fructan content of hay is likely to be lower than that of fresh grass, and is lower still in haylage due to the fermentation process. Overall, the fructan content of grass is likely to be higher during spring, before the development of the flower, when the fructans are being stored.

Current recommendations to help reduce the risk of laminitis due to high fructan intake include:

1. Turn horses out to pasture when fructan levels are likely to be at the lowest, such as late at night to early morning, removing them from the pasture by mid morning.
2. Do not graze horses on pastures that have not been properly managed by regular grazing or cutting. Try to maintain a young leafy sward approximately 4cm high. Mature, stemmy grasses may contain high levels of stored fructans.
3. Avoid or restrict turning out in spring (before flower development) and autumn/fall when fructan levels are accumulating and plants generally contain relatively high levels of water-soluble carbohydrates.
4. Do not allow horses to graze on pastures that have been exposed to low temperatures (e.g. frosts) in warm, bright, sunny weather.
5. Avoid grazing horses on freshly cut stubble, e.g. after hay harvest, as plant stems are the storage organs for fructans.
6. Consider zero grazing (while providing the horse with suitable forage) if it is essential for the horse to ingest minimal levels of fructans.
7. Graze horses on pastures containing species that produce low levels of fructan, e.g. timothy.

Ponies with laminitis

Prevention is preferred: feed in a similar way to that described for equine rhabdomyolysis syndrome (ERS) (*q.v.*) based on forage with minimal cereals, utilizing oil as an energy source if required (providing there are no contraindications because of liver function). Minimize the intake of fructans as outlined above. As soon as signs of laminitis are noted the animal should be **removed immediately** from the pasture and treated medically. The hoof should be **radiographed** for evidence of pedal bone rotation (*q.v.*) and appropriate treatment and support provided. Feed should not be totally restricted as reduced feed intake and stress may promote **hyperlipidemia** (*q.v.*). Pregnant or stressed ponies should probably be fed approximately 80% of their maintenance requirements to decrease the chance of hyperlipidemia.

High levels of carbohydrate in the feed should be avoided; consequently roughage diets are most suitable.

Ponies with laminitis are frequently **obese** and **glucose intolerant**. As a result severe vasoconstriction and local ischemia may exacerbate the laminitis. Due to the pain involved there is an increased output of glucocorticoids, which potentiates the digital vasoconstrictive effects of sympathetic catecholamines in blood vessels and further compromises vasodilatation.

Horses with laminitis

Horses with carbohydrate (i.e. grain) overload and **endotoxemia** (*q.v.*) always have a poor prognosis, which may be further complicated by the onset of laminitis. There is controversy over the feeding of horses suffering laminitis secondary to endotoxemia. Although some veterinarians maintain that the affected horse should be fed minimal amounts of grain and alfalfa, with the predominant ingredient in any diet being grass hay, others suggest that endotoxemic horses with laminitis should be fed in a different manner to obese laminitic ponies, in which feed intake and DE should be dramatically reduced.

Horses suffering laminitis secondary to endotoxic episodes may therefore require a diet providing approximately 100–130% of the normal maintenance rations. This can be incrementally implemented over the course of week. Sick horses that are in a **catabolic state** may benefit from feeding at 130% of maintenance.

Severely affected horses commonly become **potassium depleted**, when renal loss of potassium is assessed using **creatinine clearance** (urinary fractional electrolyte excretion [FE]) ratios. Potassium has a vasodilatory effect and dietary replacement may be beneficial. Grain has a low potassium content, but levels may be boosted by feeding alfalfa hay, molasses or supplemental potassium chloride in the acute stages. Serum electrolyte levels should be monitored every second day. Oat-based diets are also low in sodium and a complete fiber-based pellet/cubed diet may be more rational. If this is not possible a vitamin–mineral supplement may be required. If voluntary feed intake is still low due to pyrexia or painful episodes, then **parenteral nutrition** should be considered.

Horses with **endotoxemia** need to be supported medically (e.g. IV fluid therapy, antibiotics, flunixin meglumine) and may benefit from the vasodilatory effects of acepromazine and also from appropriate foot support.

EQUINE RHABDOMYOLYSIS SYNDROME

The equine rhabdomyolysis syndrome (ERS; also known as **tying up**, **azoturia**, **exertional rhabdomyolysis** etc.) affects primarily the muscles of horses of apparently any age, breed or gender and results in the partial or complete inability to move. Death can result. Recurrent sufferers are likely to have an underlying susceptibility to the condition, which may then be triggered by one or more factors, usually including exercise, resulting in the clinical signs. The underlying predispositions as well as the triggering factors are likely to differ between groups of sufferers, so the measures that are successful in one individual may not be so successful in another.

Two subgroups with specific and different causes have been identified and others will exist. One subgroup involves a disorder in muscle contractility or excitation–contraction coupling and the other involves a defect in carbohydrate storage and/or utilization (**polysaccharide storage myopathy**, PSSM).

There is no single procedure or set of procedures (including diet and management) that can guarantee against further episodes of ERS (*q.v.*). However, appropriate management procedures and nutrition of susceptible animals may help to reduce the likelihood or frequency of future episodes. The actual diet that will be the most beneficial to an individual sufferer will depend on the horse as an individual and what it is being used for (as influences energy needs), as well as its history with respect to tying up.

Nutritional advice for a horse prone to ERS

The major proportion, if not all, of the daily intake of feed should be **forage**—either fresh (pasture) or preserved (hay). If the energy needs of the individual horse can be met by forage alone then it should be fed approximately 100% forage (non-legume based). An appropriate general vitamin and mineral supplement normally is required to ensure adequate overall nutrition.

Horses prone to ERS should not be turned out onto lush, fast growing pastures but prolonged daily periods outside in a **sparse paddock** are often beneficial. If the horse's energy needs cannot be met by forage alone then add in some highly digestible fiber sources such as **soya hulls** or **unmolassed sugar beet pulp** (appropriately prepared). In addition, either a fiber based complementary manufactured feed (i.e. high fiber, low cereal—a *low oat*—feed; these feeds tend to be “low energy” feeds and if the horse requires either more energy then consider adding additional supplementary oil) or **supplementary oil** may be given, remembering to balance protein, vitamins, mineral and trace element intake. It is advisable in all cases to try to ensure that the diet provides a sufficient intake of electrolytes in an adequate and balanced manner. Ensure that **sufficient salt** is given and that an appropriate electrolyte supplement is given following or during prolonged exercise, especially in hot weather to compensate for sweat losses.

The addition of wheat bran to the horse's diet should be avoided wherever possible, and large amounts should always be avoided (unbalanced calcium to phosphorus ratio). Certain animals might have an individual alteration in their ability to utilize or absorb certain electrolytes and may benefit from having their electrolyte status evaluated using the **fractional electrolyte excretion test** (*q.v.*) followed by appropriate supplementation.

Vitamin E and selenium deficiencies or imbalances (*q.v.*) are unlikely to be the cause of ERS but they may be **permissive or contributory**. It is therefore advisable to ensure that all horses, especially those in hard work, are fed adequate vitamin E (at least 160 IU/kg DM) and selenium (approximately 0.2 mg/kg DM). Energy intake should be reduced during periods of decreased exercise and sufferers should not be fed in anticipation of an increase in workload.

HYPERLIPEMIA

Hyperlipidemia and hyperlipemia (*q.v.*) are the terms used respectively for the subclinical and clinical disorders associated with an elevation in blood triglycerides and lipids. Hyperlipemia describes the clinical syndrome characterized by depression, anorexia and hepatic failure and is associated with dramatic elevations in blood lipid and fatty infiltration of the liver and other parenchymatous organs.

The syndromes are generally precipitated by **stress** (i.e. transport, alteration of diet, pregnancy, lactation, change of paddock/stabling and infection). Most hyperlipemic episodes are associated with reduced dietary intake and, in large horses, an azotemic state, whether pre-renal (most common), renal or post-renal, which exacerbates the condition by inhibiting the peripheral removal of lipoproteins. During fasting, the triglycerides of adipose tissue are broken down into free fatty acids and glycerol, which are then released into the blood.

In horses, fatty acids taken up by the liver are oxidized completely to provide energy or are re-esterified to form triglycerides and phospholipids. These either remain in the liver or are released into the plasma as very low density lipoproteins (VLDLs). In horses, ketone formation is limited, therefore lipemia occurs in response to **aphagia** rather than ketosis as in ruminants.

Fat, unconditioned ponies are much more susceptible to hyperlipemia than large horses because of the innate insensitivity of ponies to insulin. Insulin normally potentiates the peripheral removal of VLDLs and decreases the mobilization of adipose tissue lipid. The condition arises when the animal is in negative energy balance because of depression of food intake or digestion and absorption. This may be associated with a scarcity of feed (e.g. in winter in the northern hemisphere and summer in the southern hemisphere) or inciting stresses such as pregnancy, lactation, parasitism and transportation.

Affected ponies appear dull and anorexic and show rapid loss of bodily condition. The mortality rate can be high if treatment is not initiated immediately. An uncommon presentation of hyperlipemia is related to hormonal imbalance due to a **pituitary tumor** (*q.v.*).

The initial treatment regimen involves the reduction of the negative energy balance by improving feed intake. If the animal will not voluntarily increase its intake of palatable feed and pasture, then tube feeding of a slurry of readily utilizable carbohydrates (Table 3.20) or a slurry of a complete pellet must be implemented. An indwelling nasogastric tube is best if the animal will tolerate it. Concurrently, drugs should be used to remove the lipids from the blood. **Insulin and glucose/carbohydrate therapy** (with supportive amino acids) may be used to curtail lipid mobilization and heparin administration may accomplish an acceleration of triglyceride removal from the blood.

Antipyretics and analgesics should be used if the animal is febrile or in pain. The hydration status should also be carefully monitored to avoid pre-renal azotemia (*q.v.*), which greatly exacerbates the hyperlipidemic condition. **Sodium bicarbonate** may be necessary to correct base deficits, which must be assessed by monitoring blood gases and acid-base status. Food intake produces waves of exogenous glycerides which decline so that the delivery of

Table 3.20 Example of a daily tube feeding schedule that has been used for a 200 kg pony with hyperlipemia. The total diet should be divided into four tube feedings per day

Parameter	Day						
	1	2	3	4	5	6	7
Water (L)	8	8	8	8	8	8	8
Dextrose (g)	120	160	200	240	320	320	360
Casein (g) or dehydrated cottage cheese	120	120	180	240	240	300	360
Dehydrated lucerne meal (g)	600	600	600	700	700	800	800
Electrolyte and vitamin mixture (g)	80	80	80	80	80	80	80

dietary glucose is reduced and there is increased movement of free fatty acids from the adipose tissue.

RENAL FAILURE

Although it is preferable to provide adequate nutrition without excessive protein, it is better to maintain energy intake than to over-restrict protein (dietary crude protein should ideally be <10% DM and of **good quality**). Palatable food should be offered with options as it is important to maintain appetite. Good quality grass hay, possibly with 1–2 kg of oats or corn, is one suggestion. Calcium should not be over supplemented; therefore alfalfa should be avoided but, again, if this is the only forage that the animal will eat, it is preferable to starvation.

Vegetable oil can be added (gradually) if weight cannot be maintained and the serum is not lipemic (e.g. up to 100 mL of corn oil in grain twice a day) but it is necessary to watch out for **lipemia** (*q.v.*). The **blood urea nitrogen (BUN) to creatinine ratios** (mg/dL) (*q.v.*) should ideally be maintained at between 10:1 and 15:1 (<10:1 suggests inadequate dietary protein; >15:1 suggests that dietary protein may be excessive and possibly will aggravate the degree of uremia; *q.v.*).

LIVER DYSFUNCTION

The most useful form of treatment for **acute liver damage** (*q.v.*) is good support and feeding. This involves the provision of oral or IV glucose to combat **hypoglycemia**. In acute hepatitis, **fluid therapy** may also be indicated. The value of protein-rich diets to control the faulty production of plasma proteins is controversial. However, some have used amino acids, especially mixtures containing leucine and valine, with apparently good results. B group vitamins are also commonly used.

In less acute cases the aim is to maximize small intestinal starch digestion in order to increase glucose availability. Oats or cooked grains should therefore be considered. It has been recommended that high protein diets (especially high methionine and other aromatic amino acids diets) should be avoided but intake levels of lysine and other key amino acids, including the branched chain amino acids, should be maintained. Micronized or steam flaked corn has a relatively low protein level but a good branched chain amino acid

to aromatic amino acid ratio and a high starch availability. Sugar beet has been suggested as a potential source of branched chain amino acids.

Alfalfa also has a better ratio than grass hay but it has a higher overall protein content so the intake should be restricted to perhaps 0.75% of body weight with supplemental corn to maintain body weight. Also, avoid early cut hay and haylages, clover in pasture, dried grass products, soya bean meal and high protein compound feeds. It is necessary to feed **little and often** to reduce the metabolic load on the liver. A **low fat diet** should be fed wherever possible. It is not known whether providing choline daily is advantageous (it is a methyl donor and may help moderate hyperlipemia) in the horse. However, additional B vitamins and vitamin C have been suggested to be of value.

WASTING CONDITIONS

Protein-losing syndromes

Loss of bodily condition with or without depression of appetite is common in horses and results from many different causes. Significant amounts of plasma proteins may be lost in urine (i.e. protein-losing nephropathy *q.v.*), pleural and peritoneal fluids, and perhaps most commonly from the gastrointestinal tract (protein-losing gastroenteropathy [PLGE]; *q.v.*). Diets should contain high amounts of quality protein to assist in replacement, although in cases of protein-losing nephropathy it is usually best not to increase protein concentration in the diet as it can exacerbate the azotemic condition.

Protein-losing gastroenteropathy

Protein can be lost from the gastrointestinal tract through loss of mucosal integrity or **lymphangiectasia** associated with increased lymphatic pressure. In acute cases a **plasma transfusion** (*q.v.*) is often necessary to provide protein (albeit a low concentration) to improve osmotic pressure transiently and restore vascular volume. The protein requirement is increased in these horses and if total parenteral nutrition is necessary then the maximum percentage of protein energy used in solution should be approximately 12%.

In chronic cases, diets with a high quality (i.e. digestibility, amino acid spectrum and balance) and quantity of protein should be fed (e.g. soya bean meal, sunflower meal, fishmeal, and alfalfa hay as roughage), unless the horse is concurrently azotemic. Anthelmintics should also be administered.

Diarrhea/malabsorption syndromes

Diarrhea (*q.v.*) results from a multitude of different causes including the so-called “**malabsorption syndromes**”. Requirements therefore depend on the cause, and the optimal ration also depends on the likely underlying cause. Frequent small meals are usually preferable, however, and probiotics (*q.v.*) may be worth considering. Horses with **chronic diarrhea** often have PLGE as well, usually because of **decreased mucosal integrity**. They therefore require additional protein. Usually they are also in a state of energy, mineral and vitamin malnutrition.

One possible diet worth considering is ad libitum alfalfa hay, as well as a high protein-energy concentrate, plus a vitamin and mineral supplement.

Horses with **chronic salmonellosis** (*q.v.*) usually have impaired fiber digestion, and a diet with an increased proportion of grain/concentrate may help maintain body weight. In some refractory cases of chronic diarrhea the best solution is to turn the horse out onto **pasture**, which may promote normalization of gastrointestinal flora. In other cases of diarrhea removal from pasture may be of benefit.

If the diarrhea is due primarily to small intestinal dysfunction then little or no grain should be fed. Highly digestible fiber is essential in all cases as the volatile fatty acids produced (together with glutamine and aspartate) are primary energy sources for the enterocytes. Sugar beet pulp is a good source of fiber for horses, especially those with an intact large intestine; immature alfalfa may be better if only the small intestine is intact. Avoid overly mature, poorly digestible, hays. If small intestinal fat digestion is impaired for >1–2 wk the fat-soluble vitamins A, D, E and possibly K should be given parenterally.

If the condition is mainly a large bowel dysfunction grain could be beneficial. However, the exact site and extent of pathology is often difficult to ascertain in the live horse making precise recommendations difficult. It is necessary to start slowly and build up to 50% of the ration if this does not exacerbate the diarrhea. A mineral supplement (particularly if not feeding a legume hay) with added oil (up to 20% if introduced gradually and if small intestinal function is adequate) and water-soluble vitamins may also be indicated. Horses with colitis frequently have severe electrolyte imbalances. **Monitoring** is therefore advisable.

Hyponatremia and hypochloremia (*q.v.*) occur primarily owing to dilution caused by replacement of fluid loss with water. Severe hyponatremia usually occurs in cases of acute salmonellosis. Hypokalemia may occur in horses suffering **colitis** (*q.v.*) because of decreased intake and gastrointestinal loss. These horses are also **acidotic** and require **intensive corrective fluid therapy** (e.g. isotonic bicarbonate [1.2% solution]). The horses should be offered fresh water and a separate electrolyte drink. Feed should be restricted to grass hay for approximately 2 wk in convalescence as the normal cecal and colonic flora are likely to be at decreased levels. Grain/concentrate may then be slowly and incrementally introduced (e.g. 0.5 kg/wk). A vitamin B complex supplement may also be used for 2 wk.

Hyperkalemic periodic paralysis

The aim in hyperkalemic periodic paralysis is to **control potassium intake**, maintaining it at <1% potassium in total diet (and being consistent in feeding amounts and time). Forage is the biggest source of potassium but as forages vary tremendously according to type, region, irrigation, stage of cutting etc., it is recommended that likely sources be **analyzed**. In general, grass type forages have approximately half (0.8–1.7% on a DM basis) the potassium content of the legumes (1.5–3%) and the more mature forages have a lower content than those that were rapidly growing.

Satisfactory diets can be made by mixing unmolassed sugar beet pulp, which is low in potassium, with grass hay and a vitamin–mineral supplement. It is best to avoid lush grass, early harvest hay, legumes, alfalfa and soybean meal and sugar beet molasses.

Disclaimer

Throughout this chapter, all possible care has been taken by the authors to include safe dosages. Where dosages of non-registered products are indicated, the authors cannot take responsibility for possible toxicity.

INTRODUCTION

The horse poses problems to the veterinarian in relation to the administration of therapeutic agents. Anatomically and physiologically horses differ markedly from other domestic species and humans. Consequently, it is **unwise to use extrapolated dosage rates in the horse**. This has been borne out in practice where the disposition, metabolism and excretion of many drugs in the horse have been shown to differ from other species.

Horses have a very large capacity for **oxidative metabolism**. Drugs that are metabolized by this route, such as the sulfide benzimidazole anthelmintics, are rapidly inactivated and consequently require to be given at higher dosage rates than in most other species. Another good example is the non-steroidal anti-inflammatory drug (NSAID) phenylbutazone, which has an **elimination half-life** of 5–8 h in the horse and 37–60 h in the cow. It has also been shown that the excretion of amphetamine, which undergoes extensive oxidative metabolism in the horse, is unaffected by urinary pH, whereas it is excreted unchanged in humans as the parent molecule and is highly influenced by urinary pH.

Toxicity may also manifest both severely and frequently in the horse. This may be specific to individual agents such as the ionophores, which cause **cardiac failure** (*q.v.*), or it may be typical of a whole class of drugs. Antimicrobial drugs have sometimes been associated with a high incidence of **enterocolitis** (*q.v.*) in the horse. Antimicrobial-associated enterocolitis is dependent on the concentration of antimicrobial drug achieved in the large intestine, on the commensal and environmental bacterial population, and possibly also on **stress factors** such as surgery and transport.

The use of horses in competitions also poses problems, as the several authorities which control equestrian sports each have their own regulations regarding the presence of drugs that could potentially affect the performance of the

competitors. Veterinarians must be aware of the regulations and of those drug disposition properties that permit effective use without contravening guidelines.

ANTIMICROBIAL DRUG SELECTION AND DOSAGE

INTRODUCTION

The effective use of antimicrobial drugs in treating systemic bacterial infections depends on the **quantitative susceptibility** of the pathogenic microorganism, and on its relation to the disposition and potential of the drug to produce adverse effects. It follows that the selection of an antimicrobial drug should take into account both the microbiologic (quantitative susceptibility) and pharmacologic (pharmacokinetic) properties of the drug. In addition, consideration must be given to the **location and severity** of the infection as well as to **formulation of the dosage** forms that are suitable for administration to horses, since this will determine the route of administration and dosing rate (dose/dosage interval). Other considerations include the margin of safety of the drug, the convenience of administration of the antimicrobial drug preparation (product) and the cost of the anticipated course of treatment.

The objective of dosage calculations is to maintain plasma concentrations of the antimicrobial drug that are several times the **minimum inhibitory concentration (MIC)** for the pathogenic microorganism for much of the duration of treatment. This is especially true for drugs with a concentration-dependent bactericidal mechanism.

The MIC is an in vitro quantitative measure of susceptibility and potency and may be defined as the drug concentration that, under the test condition, prevents (just inhibits) the visible growth of a certain percentage of the bacterial species, e.g. MIC₉₀. When MIC data are used in conjunction with pharmacokinetic parameters describing drug absorption and disposition, it is possible to calculate “reasonable” dosing rates. Cognizance is not given to the “post-antibiotic effect” whereby microbial growth may be interrupted for some time beyond the period when antimicrobial concentrations exceeded the MIC.

MICROBIOLOGIC CONSIDERATIONS

Approach to therapy

Having diagnosed the presence of bacterial infection, specimens for bacterial culture and susceptibility testing should, wherever possible, be collected before administering an antimicrobial drug. Since there will be some delay in obtaining laboratory results it is important to **initiate therapy** (on an informed empirical basis). The choice of drug can be based on **clinical experience** and examination of stained material (apply **Gram stain** to direct smear).

The laboratory results of **bacterial culture** and MIC determination (when required) give precise data that may be used in selecting the antimicrobial drug, its route of administration and dosing rate for continuation of treatment (specific therapy). The usual dosage regimen for an antimicrobial product is based on providing plasma concentrations of the drug that will be effective against the

majority of susceptible microorganisms and will not cause adverse effects in the horse. The assumption is made that the systemic clearance of the drug is not changed by the disease state, even though this may not always be the case.

Quantitative bacterial susceptibility

The need to determine **quantitative susceptibility** depends on the microorganism isolated, i.e. the causative organism of the infection. The antimicrobial susceptibility of bacteria such as β -hemolytic streptococci, *Rhodococcus* (*Corynebacterium*) *equi* and *Corynebacterium pseudotuberculosis* is usually predictable, whereas it is generally necessary to determine the susceptibility of other pathogenic bacteria, especially coagulase-positive staphylococci and enteric microorganisms (*Escherichia coli*, *Klebsiella*, *Proteus* and *Salmonella* spp.).

Such susceptibility determinations must follow standard laboratory procedures. Quantitative (MIC) data are preferable to qualitative (disk diffusion, Kirby Bauer method) information because of the possibility of tailoring drug dosage to susceptibility of the causative bacterial pathogen.

Location of infection

When selecting the antimicrobial drug with which to commence therapy, knowledge of the pathogenic bacteria that most commonly cause infections at various locations is useful but should be supported by examination of a stained (Gram or Romanowsky-type Wright–Giemsa) direct smear. Bacterial pathogens that have been isolated from various sites of infection are listed in Table 4.1. Because the principal bacterial species isolated from any site of infection may vary with geographic region, specimen collection for bacterial culture **prior** to commencing antimicrobial therapy is of paramount importance.

Drug selection for empirical therapy

The suggested drug of choice and alternative drug for initial treatment of infections caused by various microorganisms are presented in Table 4.2. The information in Table 4.2 should be used in conjunction with direct smear examination for drug selection (empirical therapy) while awaiting the results of bacterial culture and quantitative susceptibility testing (when considered necessary). Selection of the drug to use is influenced by location of the site of infection.

In **mixed infections** with microbiologically diagnosed **anaerobic involvement**, the concurrent use of metronidazole and benzylpenicillin or gentamicin, depending on whether the primary aerobic bacterial pathogen is Gram-positive or Gram-negative, may represent the antimicrobial drug treatment of choice.

The penicillins, cephalosporins (apart from cefadroxil), aminoglycosides and oxytetracycline must be administered parenterally to horses, while trimethoprim–sulfonamide combination preparations, rifampicin, metronidazole and enrofloxacin (to mature horses only) may be administered PO as paste formulations or by nasogastric tube as oral solutions or aqueous suspensions.

Table 4.1 Bacterial pathogens isolated from various sites of infection

Site	Pathogens
Respiratory system	
Upper	<i>Streptococcus</i> spp.
Lower	
Adults	<i>S. zooepidemicus</i> Opportunistic aerobic bacterial pathogens
Older foals	<i>S. zooepidemicus</i> Opportunistic aerobic bacterial pathogens <i>Rhodococcus equi</i>
Neonatal foals	Opportunistic aerobic bacterial pathogens
Pleuropneumonia	Mixed opportunistic aerobic and anaerobic bacterial pathogens
Gastrointestinal tract	
Peritonitis	Mixed opportunistic aerobic (mainly Enterobacteriaceae) and anaerobic (<i>Bacteroides</i> spp.) bacterial pathogens <i>Actinobacillus equuli</i>
Abdominal abscess	<i>S. equi</i> <i>S. zooepidemicus</i> <i>Corynebacterium pseudotuberculosis</i> <i>R. equi</i> (foals)
Liver abscess	β -hemolytic streptococci <i>C. pseudotuberculosis</i> Opportunistic aerobic or anaerobic bacterial pathogens
Cardiovascular system	
Bacterial endocarditis	<i>Streptococcus</i> spp. Opportunistic aerobic bacterial pathogens
Bacterial pericarditis	<i>Streptococcus</i> spp. Mixed opportunistic aerobic and anaerobic bacterial pathogens
Renal system	
Cystitis, pyelonephritis	Opportunistic aerobic bacterial pathogens
Reproductive system	
Bacterial endometritis	<i>S. zooepidemicus</i> <i>Escherichia coli</i> <i>Pseudomonas aeruginosa</i> <i>Klebsiella</i> spp.
Placentitis	<i>S. zooepidemicus</i> <i>E. coli</i> <i>Klebsiella</i> spp.
Mastitis	<i>S. zooepidemicus</i> <i>Staphylococcus</i> spp. Other opportunistic aerobic bacterial pathogens <i>Mycoplasma</i> spp.
Bacterial septicemia (neonatal foals)	<i>E. coli</i> Other opportunistic aerobic bacterial pathogens (mostly Gram-negative)

Opportunistic aerobic bacterial pathogens include *E. coli*, *Klebsiella* spp., *Proteus* spp., *Pasteurella* spp., *Actinobacillus* spp., *Pseudomonas aeruginosa*, *Staphylococcus aureus* and *Streptococcus zooepidemicus*.

Opportunistic anaerobic bacterial pathogens include *Bacteroides* spp., *Fusobacterium* spp. and *Clostridium* spp.

Table 4.2 Empirical antimicrobial selection based on knowledge of bacterial pathogen

Bacterial pathogen	Drug of choice	Alternative drugs
Gram-positive aerobe		
β -Hemolytic <i>Streptococcus</i>	Benzylpenicillin or ampicillin	Cefalotin or ceftiofur
α -Hemolytic <i>Streptococcus</i>	Ampicillin	Cefalotin or ceftiofur
<i>Staphylococcus</i> spp.	Benzylpenicillin	Cefalotin
<i>Staphylococcus aureus</i>	Cefalotin or oxacillin	Trimethoprim–sulfonamide
Penicillinase producing <i>Rhodococcus equi</i>	Erythromycin + rifampicin	
<i>Corynebacterium pseudotuberculosis</i>	Benzylpenicillin	Trimethoprim–sulfonamide
Gram-negative aerobe		
<i>Escherichia coli</i>	Gentamicin	Amikacin or enrofloxacin
<i>Klebsiella</i> spp.		
<i>Proteus</i> spp.		
<i>Actinobacillus</i> spp.	Gentamicin or ceftiofur	Enrofloxacin or trimethoprim–sulfonamide
<i>Pasteurella</i> spp.		
<i>Pseudomonas aeruginosa</i>	Amikacin	Ticarcillin–clavulanate \pm gentamicin

Interpretation of bacterial susceptibility

There are no agreed guidelines for the interpretation of quantitative susceptibility results for equine bacterial pathogens. Suggested interpretative guidelines for MIC breakpoint values are presented (Table 4.3). The categories are:

1. **Susceptible**, in which an infecting organism is inhibited by concentrations achieved in blood or tissue fluid after the recommended dose including oral administration
2. **Moderately susceptible**, when an infecting microorganism is inhibited only by blood concentrations achieved with maximum doses, up to the limit of toxicity
3. **Resistant**, when an organism is resistant to usually achievable concentrations of the antimicrobial drug in blood or tissue fluid.

Even though the spectrum of activity of individual drugs within each antimicrobial class or subclass in the case of β -lactam antibiotics is, in general, similar, the quantitative susceptibility of microorganisms to individual drugs somewhat differs. Tetracyclines may constitute an exception in that variation among individual tetracyclines in clinical efficacy is largely due to differences in **lipid solubility**, which influences tissue concentrations attained.

The MIC (*q.v.*) is the quantitative value normally used to define the in vitro susceptibility of a microorganism. It is used, in conjunction with pharmacokinetic parameters that describe the bioavailability and disposition of antimicrobial agents, to calculate **appropriate dosing rates**. This approach allows appropriate dosage adjustment to be made for organisms of different susceptibilities. It is the basis for calculating optimal dosage. Even though quantitative susceptibility (an in vitro measurement of activity) generally correlates with clinical efficacy, it cannot be guaranteed to predict the response to therapy.

Table 4.3 Suggested guidelines for the interpretation of minimum inhibitory concentration (MIC) ($\mu\text{g/mL}$) of antimicrobial agents based on bacterial isolates of equine origin, apart from fluoroquinolones which relate to isolates of canine origin

Antimicrobial agent	Susceptible	Moderately susceptible	Resistant
Benzylpenicillin	≤ 0.125	0.25–16	> 16
Ampicillin	≤ 1	2–16	> 16
Amoxicillin	≤ 1	2–16	> 16
Gentamicin	≤ 2	4–8	> 8
Amikacin	≤ 4	8–16	> 16
Fluoroquinolones ¹	≤ 1	2–4	> 4
Erythromycin	≤ 0.5	1–4	> 4
Tetracycline	≤ 1	2–4	> 4
Chloramphenicol	≤ 4	8–16	> 16
Trimethoprim–sulfamethoxazole	$\leq 0.5/10$	1/20–2.5/50	$> 3/75$

¹Quantitative susceptibility of bacterial pathogens varies between individual fluoroquinolones.

Furthermore, use of the antimicrobial agent to which a pathogenic microorganism is most susceptible in vitro might not be clinically indicated because of its potential to produce adverse effects.

Usual dosage regimens aim to **maintain plasma concentrations** that are several times the MIC₉₀ for the majority of usually susceptible microorganisms and could be expected to provide effective therapy. At these plasma concentrations, the penicillins, cephalosporins, aminoglycosides, fluoroquinolones, trimethoprim–sulfonamide combinations, rifampicin and metronidazole produce a bactericidal effect, while tetracyclines, sulfonamides (used alone), erythromycin and chloramphenicol produce a bacteriostatic effect on susceptible microorganisms.

Although the terms **bactericidal** and **bacteriostatic** generally apply to the effect produced, they are relative depending on the concentration attained and environmental conditions at the site of infection. For antimicrobial agents that exert a bacteriostatic effect it is especially important that plasma concentrations be maintained **well above** the MIC₉₀ for the pathogenic microorganism throughout the course of therapy. For antimicrobial agents that produce a bactericidal effect the relationship between plasma concentration and bacterial killing depends on whether the mechanism depends on concentration or time.

For drugs with a concentration-dependent killing mechanism (fluoroquinolones and aminoglycosides), it is usual to recommend achievement of C_{max}:MIC ratios of 10 or greater, whereas for time-dependent bacterial killing drugs (β -lactam antibiotics) it is desirable to maintain the plasma concentration between 1 and 4 times the MIC for at least half the inter-dose interval.

Impairment of host defense mechanisms is a variable, not generally taken into account in dosage calculations, which contributes to a discrepancy between expected and actual response to therapy, particularly for bacteriostatic drugs. Inadequacy of the type, quality and quantity of the immunoglobulins, alteration of the cellular immune system, or either a qualitative or, more importantly, a quantitative defect in phagocytic cells may result in therapeutic failure despite the use of otherwise appropriate and effective drugs. The effectiveness of therapy may be influenced by **local factors** at the site of infection. These include pus, the presence of a foreign body, and in the case of abscesses penetrative capacity of the drug and the pH or anaerobic environment within the abscess cavity.

Optimal dosage

Optimal dosage of a drug that produces a bactericidal effect is required in severe infections such as meningitis and endocarditis (*q.v.*), and in immunocompromised patients. Because of variations in the state of host defenses, the post-antibiotic effect or acquisition of **bacterial resistance**, and disease-induced changes in the disposition of an antimicrobial agent, optimal dosage cannot be precisely calculated. Disease conditions that may alter pharmacokinetic parameters include fever, dehydration, hypoalbuminemia (e.g. chronic liver disease), uremia and decreased renal excretion (*q.v.*).

The **pathophysiology** of the disease condition determines the changes in volume of distribution, clearance and, depending on the changes in these two parameters, the half-life of the drug may be altered. At least some of the pharmacokinetic alterations can be accommodated by adjustment of dosage. The ultimate criterion of optimal dosage is the effectiveness of therapy, as indicated by bacteriologic cure.

PHARMACOLOGIC CONSIDERATIONS

The absorption, distribution and elimination processes for antimicrobial drugs are largely governed by their chemical character and by certain physicochemical properties. The majority of antibacterials are weak organic electrolytes, either acids (e.g. penicillins, cephalosporins, sulfonamides) or bases (e.g. aminoglycosides, macrolides, trimethoprim, metronidazole), while fluoroquinolones, tetracyclines and rifampicin are amphoteric compounds and chloramphenicol is a neutral molecule. Lipid solubility and degree of ionization, which is determined by the pK_a of the drug and the pH of the biologic fluid in question, influence the extent of absorption, the pattern of distribution and the principal elimination process (hepatic metabolism and/or renal excretion) for antimicrobial drugs.

Routes of administration

The route of administration of a drug is governed mainly by the formulation of the dosage form (antimicrobial drug preparation). Parenteral preparations of antimicrobial drugs that are formulated as aqueous solutions can be administered either by slow IV injection or IM. Those formulated as aqueous suspensions are designed to provide sustained release (slow absorption), and thereby a prolonged duration of effective plasma concentrations, and should be administered only by IM injection. **Prolonged-release products**, which cause tissue irritation, and drugs in oily vehicles should *never* be administered to horses. This excludes the use in horses of some so-called “large animal parenteral preparations”.

At the present time, few antimicrobial drugs are available as oral dosage forms that are convenient to administer to horses. **Oral paste** preparations that are palatable and of suitable consistency may represent the best type of oral dosage. The addition of an antimicrobial agent to the feed as a powder is an unreliable method of dosing, due to variability in the dose ingested and to the effect of food on the extent of absorption of the drug.

The action of some antimicrobial agents, whether administered orally or parenterally, on the cecal and colonic commensal microorganisms of horses

can cause **serious digestive disturbances**. This adverse effect makes penicillins **unsuitable** for oral administration to horses other than newborn foals and limits the use of macrolides and, under certain circumstances, of tetracyclines. Foals appear to be less susceptible than adult horses to disturbance in the balance of commensal microbial flora in the large intestine. It is likely that the microbial balance is related to the composition of the usual diet.

BIOAVAILABILITY, DISTRIBUTION AND ELIMINATION

Bioavailability is defined as the rate and extent to which a drug enters the systemic circulation unchanged (as parent drug). The bioavailability of a drug is influenced by the route of administration and formulation of the dosage form while the plasma concentration profile is, in addition, influenced by the dose administered. Significant features of the plasma concentration profile include the peak plasma concentration and the time period that plasma concentrations exceed a desired minimum concentration based on MIC₉₀ for commonly isolated susceptible pathogenic bacterial species.

The usual dosage regimen for an antimicrobial drug must take into account **bacterial susceptibility** to the drug and features of bioavailability, extent of distribution and the overall rate of elimination of the drug based on data obtained in clinically healthy animals, representative of the species of interest. The severity of an infection and functional state of the principal organs of drug elimination may require adjustment of the dosage regimen (either size of dose or dosage interval) or the use of an alternative drug.

When the parenteral preparation is a non-irritating aqueous solution of the drug, absorption from IM injection sites is generally rapid, in that the peak plasma concentration (C_{\max}) is attained within 30–60 min, and complete (i.e. systemic availability approaching 100%) is obtained). This situation applies to the 5% parenteral solution of **gentamicin sulfate**. **Ceftiofur**, as reconstituted aqueous solution of the sodium salt, is administered to horses by IM injection. The drug is rapidly and completely absorbed from the injection site and, following entry into the systemic circulation, is converted by ester hydrolysis to desfuroylceftiofur, which has antibacterial activity similar to that of the parent drug. Even though the apparent half-life of ceftiofur is approximately 3 h, the recommended dosage interval is 12 h.

Long-acting parenteral preparations are formulated in a non-aqueous (such as oil or an organic) vehicle or a poorly soluble salt of the drug is formulated as an aqueous suspension. These preparations decrease the rate of drug absorption, which takes place over an extended period. **Oxytetracycline** formulated in polyethylene glycol is the only long-acting preparation of oxytetracycline that is suitable for IM administration to horses. The horse is the **least tolerant** of the domestic animal species to injection site irritation, and drugs in oily vehicles should never be administered parenterally to horses. The commercially available long-acting parenteral preparations of **amoxicillin** and **oxytetracycline**, apart from one recently formulated preparation, are too irritant for IM administration to horses.

When the rate of absorption significantly influences the overall rate of elimination of a drug, **flip-flop pharmacokinetics** apply, allowing the use of a

longer dosage interval than that associated with a conventional (immediate release) preparation of the drug. This applies to **procaine benzylpenicillin**, which is an aqueous suspension. Following the administration of a single dose (20 000 IU/kg) of procaine benzylpenicillin at various IM injection sites and SC, the peak plasma concentration (C_{\max}) and systemic availability (indicated by area under the curve over a 24 h period) of benzylpenicillin were highest when the long-acting preparation was injected IM in the neck region (*m. serratus ventralis cervicis*) and were lowest when it was injected SC.

Because of differences in the blood flow to various skeletal muscles and in absorptive surface area, location of the injection site influences features of the plasma concentration profile. The lateral neck (*m. serratus ventralis cervicis*) at the level of the fifth cervical vertebra, ventral to the funicular part of the ligamentum nuchae and dorsal to the brachiocephalic muscle, appears to be the optimal site in horses for IM injection of long-acting parenteral preparations. The convenience afforded by the extended dosage interval associated with the use of long-acting preparations is somewhat offset by a loss of flexibility in dosage.

Absorption of antimicrobial agents, like other drugs, takes place by passive diffusion. The absorption process is mainly determined by the physicochemical properties of the drug, namely **lipid solubility** and, in the case of weak organic acids and bases, **degree of ionization** at the principal sites of absorption. In horses, drugs are absorbed from the stomach and proximal (upper) small intestine and, in addition, from the colon. The rate and pattern of drug absorption, which are reflected by the plasma concentration profile, are influenced by the **availability** of the drug for absorption. This, in turn, is influenced by the stability and solubility of the drug in gastrointestinal fluid and binding (adsorption) to the fibrous constituents in feed. When the latter is substantial, the colon may be the principal site of absorption, which occurs following microbial digestion of the fiber.

The pattern of absorption may be **biphasic** with an intervening period of approximately 8 h, during which time digesta move from the small intestine to the colon. The temporal relationship between feeding and oral dosing influences not only the pattern but may also affect the extent of absorption (i.e. systemic availability) of the drug. When rifampicin (5 mg/kg) was administered PO to horses 1 h after feeding, systemic availability of the drug was 26% compared with 68% when the dose was given 1 h before feeding.

Wide individual animal variation in systemic availability is a feature of orally administered drugs that are well absorbed from the gastrointestinal tract (GIT). The systemic availability of orally administered **metronidazole** ranges from 58% to 92% in horses and does not appear to be significantly affected by the time of feeding relative to oral administration of the drug. Several antimicrobial agents that are commonly administered orally to other monogastric species, such as phenoxymethylpenicillin, amoxicillin, cefadroxil and ciprofloxacin, are poorly absorbed in adult horses.

Having traversed the gastrointestinal mucosal barrier, drug molecules are conveyed in hepatic portal blood to the liver, where they are subjected to the **"first-pass" effect** prior to entering the systemic circulation. Hepatic first-pass metabolism can substantially decrease the systemic availability of lipid-soluble drugs that undergo microsomal oxidative reactions (e.g. trimethoprim, metronidazole, rifampicin, enrofloxacin). While the metabolites of most antimicrobial

agents are inactive, some, such as desacetyl rifampicin and ciprofloxacin (to which enrofloxacin is converted), have antimicrobial activity at least equal to that of the parent drug. Because the formation of desacetyl rifampicin is capacity-limited, the half-life of rifampicin is dose-related in horses. Certain antimicrobial agents (erythromycin and chloramphenicol) inhibit hepatic microsomal enzyme activity, whereas rifampicin is a potent inducer of hepatic microsomal enzymes. Drug-induced changes in microsomal enzyme activity are generally associated with chronic rather than short-term use of activity-modifying drugs.

The **extent of distribution** of antimicrobial agents, which is more important than the rate of extravascular distribution, is mainly determined by their lipid solubility and is influenced by the degree of ionization in the blood and extent of binding to plasma proteins. Lipid-soluble antimicrobial agents passively diffuse through cell membranes, penetrate cellular barriers, enter most tissues of the body and generally reach infection foci. However, since most bacterial infections occur in **extracellular fluids**, poorly lipid-soluble drugs (β -lactam and aminoglycoside antibiotics) are equally effective as lipid-soluble drugs provided they are not extensively bound to plasma proteins.

A high degree of ionization in the blood, extensive binding to plasma proteins and rapid elimination are factors that limit the concentrations attained in **transcellular fluids** (aqueous humor, synovial fluid and cerebrospinal fluid [CSF]). Elimination by the liver, especially by hepatic microsomal oxidative reactions, requires at least a moderate degree of lipid solubility. Examples of lipophilic antimicrobial agents include erythromycin, clindamycin (contraindicated for use in horses), trimethoprim, enrofloxacin, minocycline, rifampicin, chloramphenicol and metronidazole. Individual tetracyclines differ in lipid solubility, which underlies variation between members of the tetracycline class in their disposition (i.e. distribution and elimination) and clinical efficacy.

Most lipophilic antimicrobial agents are organic bases, some are amphoteric (fluoroquinolones, tetracyclines, rifampicin), and chloramphenicol is a neutral molecule. Even though aminoglycoside antibiotics are weak organic bases, their polar nature accounts for their limited capacity to enter cells and penetrate cellular barriers, and their elimination by renal excretion (glomerular filtration). *Mycoplasma* spp. lack rigid cell walls but **lipid solubility** is a requirement for an antimicrobial agent to be clinically effective because the microorganism is often located intracellularly.

Penicillins and cephalosporins (β -lactam antibiotics) and sulfonamides are organic acids. Because of their high degree of ionization in biologic fluids, the distribution of penicillins is limited in that they attain low intracellular concentrations and do not penetrate well into transcellular fluids. In the presence of **fever** associated with an acute inflammatory reaction, penicillins have **increased capacity** to penetrate cellular barriers (such as the blood–CSF barrier). This may arise through one or more of several mechanisms, including (a) increased blood flow (arteriole dilatation) and (b) reduced extrusion of penicillin from the CSF through disruption of an active efflux pump.

Amoxicillin distributes more widely than benzylpenicillin in extravascular fluids and tissues, presumably due to the higher lipid solubility of amoxicillin. Penicillins, with the exception of nafcillin, are eliminated by renal excretion (glomerular filtration and proximal tubular secretion). Nafcillin and a small fraction of amoxicillin in the systemic circulation are excreted in bile.

The β -lactamase inhibitors (clavulanic acid and sulbactam) do not alter disposition of the penicillins with which they are combined in commercially available dosage forms. β -Lactamase inhibitors enhance the activity of aminobenzylpenicillins (amoxicillin, ampicillin) and ticarcillin.

Individual cephalosporins, particularly those within the second and third generations, differ both qualitatively (spectrum of activity) and quantitatively (MIC for susceptible Gram-negative bacteria) in antimicrobial activity. Distinguishing features of third-generation cephalosporins (cefotaxime, ceftizoxime, ceftriaxone, cefoperazone, ceftazidime), all of which must be administered IV, are their **expanded spectrum** against Gram-negative aerobic bacteria and their ability (with the exception of cefoperazone) to penetrate the blood-brain barrier.

Cephalosporins, like penicillins, are eliminated by **renal excretion** (glomerular filtration and proximal tubular secretion) with the notable exceptions of ceftriaxone and cefoperazone, which are excreted by the liver in bile. Ceftiofur differs from other third-generation cephalosporins in that ceftiofur is administered by IM injection and, following absorption into the systemic circulation, is eliminated by metabolism, initially conversion by an esterase in the kidneys and liver to an active metabolite (desfuroylceftiofur) which undergoes conjugation with endogenous substances (including glutathione) in the liver.

The sulfonamides constitute a series of **weak organic acids** with pK_a values ranging from 5.0 (sulfisoxazole) to 10.4 (sulfanilamide). Weak organic acids exist predominantly in the non-ionized lipid-soluble form in biologic fluids of pH below their pK_a values. Although sulfonamides are seldom administered alone to horses, certain sulfonamides (sulfadiazine, pK_a 6.4; sulfamethoxazole, pK_a 6.0; sulfadoxine, pK_a 6.1) in conjunction with trimethoprim (organic base, pK_a 7.3) formulated as fixed ratio (5:1) combination preparations are widely used. Both parenteral and oral (paste) dosage forms are commercially available.

The sulfonamides and especially **trimethoprim**, which is more lipid-soluble, have good tissue penetrative capacity and they act synergistically to produce broad-spectrum bactericidal effect. The half-lives of sulfadiazine (3.6 h) and sulfamethoxazole (4.8 h) are reasonably close to that of trimethoprim (3.2 h), while the half-life of sulfadoxine (14.2 h) is much longer. Trimethoprim and the sulfonamides with which it is combined are eliminated mainly by hepatic metabolism and a smaller fraction of both drugs in the combinations is excreted unchanged (as parent drug) in the urine. The renal excretion processes involved are glomerular filtration, proximal tubular secretion and pK_a /pH-dependent passive reabsorption of the non-ionized moieties from distal renal tubular fluid.

An estimation of the extent of distribution of a drug is provided by the pharmacokinetic parameter, **volume of distribution**, which quantifies the apparent space in the body available to contain the drug following attainment of pseudodistribution equilibrium. It does not reveal the distribution pattern of a drug, which can be described only by measuring the levels (amount) of drug in the various organs and tissues of the body. Knowledge of the volume of distribution is required for calculating the dose (mg/kg) that must be administered to provide a desired concentration in the plasma. Drug administration by an extravascular route (PO or IM) may require upward adjustment of the dose to compensate for incomplete systemic availability of the drug.

Table 4.4 Process(es) of elimination and pharmacokinetic parameters describing the disposition of antimicrobial agents in horses

Drug	Process(es) of elimination	Half-life (h)	Vd(area) (mL/kg)	Cl _B (mL/min × kg)
Benzylpenicillin	E (r)	0.90	195	2.50
Ampicillin	E (r)	1.20	300	2.89
Amoxicillin	E (r)	1.43	556	4.55
Ticarcillin	E (r)	0.94	250	3.10
Cefazolin	E (r)	0.65	291	5.27
Cefadroxil	E (r)	0.77	462	6.95
Ceftriaxone	E (h)	1.62	650	5.22
Gentamicin	E (r)	2.50	254	1.20
Amikacin	E (r)	1.70	180	1.23
Enrofloxacin	M + E (r)	4.96	2495	5.73
Ciprofloxacin	M	4.71	3900	9.70
Trimethoprim	M + E (r)	3.16	1378	5.03
Sulfadiazine	M + E (r)	3.64	465	1.45
Sulfamethoxazole	M + E (r)	4.80	500	1.20
Sulfadoxine	M + E (r)	14.20	390	0.32
Chloramphenicol	M + E (r)	0.92	700	8.80
Metronidazole	M + E (r)	3.92	660	1.97
Rifampicin	M	6.00	635	1.34
Erythromycin	E (h) + M	1.00	2300	26.6
Oxytetracycline	E (r ± h)	9.60	1500	1.25

E (r), renal excretion; *E (h)*, excretion by the liver in bile; *M*, (hepatic) metabolism.

For drugs that are eliminated both by metabolism and excretion, the principal elimination process is metabolism.

The overall **elimination** of antimicrobial agents obeys **first-order kinetics** when usual doses are administered by IV injection. This implies that 50% of the drug in the body is eliminated (by metabolism and/or excretion) each half-life. Because lipophilic antimicrobial agents are eliminated mainly by the liver (metabolism or biliary excretion) their half-lives vary widely compared with the half-lives of drugs that are eliminated by renal excretion (Table 4.4). Even though oxytetracycline is eliminated by renal excretion, the relatively long half-life of this antibiotic is attributed to **enterohepatic circulation**. An application of half-life is in the selection of an appropriate dosage interval, which may be either approximately equal to or a small multiple of the half-life. This is especially important for antimicrobial agents that produce a bacteriostatic effect (e.g. tetracyclines, chloramphenicol, sulfonamides).

When a drug is administered by an extravascular route, especially as a long-acting preparation injected IM, absorption controls the rate of elimination and allows the use of a longer dosage interval than that associated with a conventional (immediate release) dosage form of the drug (flip-flop pharmacokinetics). Usual dosage intervals do not take into account the “post-antibiotic” effect, which implies a temporally limited suppression of bacterial growth for a variable period (from 1 to 6 h) after susceptible bacteria have been exposed to antimicrobial concentrations above the MIC.

Aminoglycosides and fluoroquinolones induce a post-antibiotic effect on susceptible Gram-negative aerobic bacteria. Because the half-life is a derived (hybrid) parameter, which depends on the relationship between the volume of distribution, determined by the area method, and the systemic clearance of

a drug, its numerical value is influenced by a change in either or both of the physiologically based parameters.

$$t_{1/2} = \frac{0.693 \times V_{d(\text{area})}}{Cl_B}$$

The **systemic clearance** of a drug, which measures the ability of the body to eliminate the drug, represents the sum of the clearances by the various organs (usually the liver and kidneys) that contribute to drug elimination. Systemic clearance is probably the most important pharmacokinetic parameter to consider in designing a dosage regimen with the objective of maintaining a desired average steady-state plasma concentration. The desired average steady-state concentration should be based on the MIC for the causative bacterial pathogen.

$$\text{Dosing rate} = \frac{F \times \text{Dose}}{\text{Dosage interval}} = C_{p(\text{avg})} \times Cl_B$$

where F is the systemic availability of the drug.

This relationship is more applicable to pharmacologic agents for which there is a defined range of therapeutic plasma concentrations but may be applied to antimicrobial agents, especially those that produce a bacteriostatic effect.

A disadvantage of basing a dosage regimen on the average steady-state plasma concentration is that it provides no information regarding the degree of fluctuation in plasma concentrations during the dosage interval. Fluctuation in steady-state plasma concentrations can be avoided only by administering a parenteral solution of the drug by continuous IV infusion. In the treatment of severe Gram-negative infections in neonatal foals (*q.v.*), consideration could be given to administering cefotaxime or ceftazidime (third-generation cephalosporins) by **continuous IV infusion**. These drugs may have high activity against the causative bacterial pathogens, produce a bactericidal effect, are eliminated by renal excretion and have relatively short half-lives (<1.5 h). Usual dosage regimens for antimicrobial agents that may be used in horses are presented in Table 4.5.

CLINICAL APPLICATIONS

Penicillins have several advantages over other classes of antimicrobial agents in the treatment of systemic bacterial infections of horses. They possess high activity against pathogenic bacteria that commonly cause infection in horses, have a uniquely wide margin of safety which applies not only to adult and maturing horses but also to neonatal foals, the incidence of adverse effects following their parenteral administration is low, and the parenteral dosage forms of various penicillins allow optimal therapy to be provided.

More so than with any other class of antimicrobial agent, dosage with penicillins can be tailored to the susceptibility of the pathogenic microorganism. Because of their inability to acquire resistance plasmids, Gram-positive bacteria, with the notable exception of *Staphylococcus aureus*, remain highly susceptible to penicillins, especially **benzylpenicillin**. Penicillins produce a bactericidal

Table 4.5 Usual dosage regimens for antimicrobial agents used in horses

Drug	Route of administration	Dosage regimen	
		Dose (mg/kg)	Interval (h)
Benzylpenicillin sodium	IV, IM	15 000–30 000 IU/kg	6
Benzylpenicillin procaine	IM	25 000 IU/kg	12 (– 24)
Ampicillin sodium	IV, IM	20	8
Oxacillin sodium	IV, IM	25	8–12
Ticarcillin–clavulanate ¹	IV (slowly)	50	8
Cefadroxil ¹	PO	25	8
Cefalotin sodium	IV	20	8
Cefazolin sodium	IV	20	8
Cefoxitin sodium	IV	20	8
Cefotaxime sodium ¹	IV	20–40	8
Ceftiofur sodium	IM	2.5–5	12 (– 24)
Gentamicin sulfate	IM	2–4	8–12
Amikacin sulfate	IM	4–8	8–12
Enrofloxacin ²	IV	5	12
	PO	7.5	12
Trimethoprim–sulfadiazine	IV	4/20	12
	PO	5/25	12
Chloramphenicol sodium succinate ³	IV	25–50	6
Chloramphenicol palmitate ³	PO	50	6
Metronidazole	PO	20	12
Oxytetracycline hydrochloride	IV (slowly)	3–5	12
Rifampicin	PO	5	12
Erythromycin estolate ¹	PO	20–25	8

¹Recommended for use in foals.

²Administer enrofloxacin only to adult horses.

³Use 12 h dosage interval in neonatal foals.

effect on susceptible bacteria by preventing formation of the cell wall through selective inhibition of peptidoglycan synthesis.

Because *Mycoplasma* spp. lack a rigid cell wall, these microorganisms are inherently resistant to penicillins and cephalosporins (β -lactam antibiotics). Intravenous injection of benzylpenicillin or ampicillin, as the soluble sodium salt, rapidly provides effective concentrations at infection sites that are accessible to penicillins. Because of their rapid elimination by renal excretion, the dosage interval is short (6–8 h).

Procaine benzylpenicillin, the long-acting parenteral preparation of benzylpenicillin, should be administered to horses only by IM injection. The procaine in this preparation decreases the rate of absorption of the penicillin and offsets pain at the IM injection site, but inadvertent IV injection of a fraction of the dose would cause central nervous system (CNS) excitement. The peak plasma concentration of benzylpenicillin will vary not only with the dose administered but also with location of the IM injection site. The long-acting preparation allows the use of a 12 h (preferable) or 24 h dosage interval.

Penicillins should not be administered orally to horses because of their low systemic availability, due to poor absorption from the gastrointestinal tract, and the digestive disturbances associated with the imbalance they may cause in commensal microbial flora in the large intestine. In foals up to 4 mo of age, oral administration of amoxicillin or preferably **pivampicillin**, a pro-drug

which following entry into the systemic circulation is converted to ampicillin, may be effective in the treatment of infections caused by susceptible bacterial pathogens. The parenteral combination preparation containing ticarcillin—clavulanic acid, administered by slow IV injection, may be effective in neonatal foals (<7 days of age) for the treatment of infections caused by susceptible Gram-negative aerobic bacteria.

Penicillins produce a time-dependent bactericidal effect on susceptible bacteria. The overall effectiveness of penicillin therapy is influenced both by the height of the peak plasma concentration, which determines the rate of penetration of penicillin to accessible sites of infection, and the aggregate time, though not necessarily continuous, during which effective penicillin concentrations are maintained.

Cefalotin or cefazolin sodium, administered by IV injection at 8 h dosage intervals, may be effective in the treatment of infections caused by Gram-positive cocci including penicillinase-producing *Staphylococcus aureus*, and a single dose administered by IM injection 1 h before surgery may be indicated for prophylaxis in procedures (performed under optimal conditions) where a wound infection rate exceeding 5% is not unusual. The clinical use of cefadroxil (5% oral suspension) is limited to foals up to 1 mo of age. Cefoxitin, a second-generation parenteral cephalosporin, has a wider spectrum of activity than first-generation cephalosporins against Gram-negative aerobic bacteria and many Gram-negative anaerobes, including *Bacteroides fragilis*, are usually susceptible.

In the treatment of infections caused by susceptible bacteria, **cefoxitin sodium** should be administered by IV injection at 8 h dosage intervals. The clinical use of third-generation cephalosporins, with the exception of ceftiofur sodium, is largely limited to treatment of severe infections in neonatal foals. Significant features of third-generation cephalosporins include an expanded spectrum of activity against Gram-negative aerobic bacteria with remarkably high activity against Enterobacteriaceae, and an ability (except cefoperazone) to penetrate the blood–brain barrier. With regard to anaerobic bacteria, *Clostridium* spp. and *Fusobacterium* spp. are susceptible, whereas *Bacteroides* spp. are often resistant.

Ceftiofur sodium, administered by IM injection to adult horses at 12 or 24 h dosage intervals, is an alternative to ampicillin for the treatment of respiratory infections caused by susceptible bacteria. Because ceftiofur has high activity against fastidious Gram-negative aerobic bacteria (*Actinobacillus* spp., *Pasteurella* spp.), it may be used **concurrently with metronidazole** for the treatment of pleuritis and peritonitis (*q.v.*), which are often mixed infections with anaerobic involvement. Stable mutation to derepression of inducible β -lactamases in certain Gram-negative bacterial pathogens is an important mechanism of high-level resistance to β -lactam antimicrobial drugs. Induction of β -lactamases associated with acquired (chromosomal) resistance is caused especially by cefoxitin and third-generation cephalosporins.

Gentamicin and amikacin, which are the most widely used aminoglycoside antibiotics, show similar pharmacokinetic behavior and have a generally similar spectrum of antibacterial activity but differ in that effective plasma concentrations of amikacin are approximately two-fold higher than those of gentamicin; Gram-negative aerobic bacteria that have acquired plasmid-mediated

resistance due to the production of enzymes that inactivate gentamicin may remain susceptible to amikacin. Anaerobic bacteria are inherently resistant, while streptococci have a natural permeability barrier to aminoglycosides.

Synergistic enhancement of bactericidal activity against at least some strains of streptococci may be achieved by the concurrent use of **gentamicin and benzylpenicillin**, and against some strains of *Pseudomonas*, *Proteus*, *Klebsiella* and other Gram-negative rods by the concurrent use of gentamicin and ticarcillin. Since aminoglycosides and fluoroquinolones have concentration-dependent bactericidal activity, both the height of the peak plasma concentration and the area under the inhibitory curve (AUC), which is the more important for aminoglycosides, influence the rate of bacterial killing.

Because of **rapid absorption** of gentamicin and amikacin from IM (and SC) injection sites, their relatively short half-lives and capacity to induce bacterial resistance, fixed doses of these drugs should be administered at 8 h (preferably), or 12 h, dosage intervals. The plasma concentration profile is not influenced by location of the injection site. The dose administered should be such as to ensure that the trough plasma concentration does not exceed 2 µg/mL for amikacin and 1–2 µg/mL for gentamicin.

All aminoglycoside antibiotics are potentially **ototoxic** and **nephrotoxic** (*q.v.*); due to their selective binding to phospholipid (phosphatidylinositol)-rich tissues, particularly of the inner ear and kidney cortex, they can accumulate in the presence of renal impairment. Calculation of dosage adjustment for gentamicin in horses with renal impairment should be based on endogenous creatinine clearance, which is often impractical.

In neonatal foals (up to 5–7 days of age) and in horses with impaired renal function (specifically, decreased glomerular filtration rate), either the dosage interval should be increased to 24 h or an antimicrobial agent of another class (selected on the basis of quantitative bacterial susceptibility) should be used.

The potential of aminoglycosides to cause nephrotoxicity (acute tubular necrosis) is influenced not only by the dosage regimen applied but also by the duration of therapy, and is enhanced in the presence of dehydration or by the concomitant use of a diuretic, especially furosemide. The activity of aminoglycosides on Gram-negative enteric bacteria is markedly influenced by the pH of the environment; they are most active in an alkaline environment. Increased local acidity secondary to tissue damage may account for the failure of an aminoglycoside to exert its bactericidal effect on usually susceptible bacteria at accessible sites of infection.

Fluoroquinolones have excellent activity ($MIC_{90} < 1 \mu\text{g/mL}$) against Enterobacteriaceae and fastidious Gram-negative aerobic bacteria and have good activity (MIC_{90} , 1–4 µg/mL) against *Pseudomonas aeruginosa*, *S. aureus* and other staphylococci, *Streptococcus equi*, and *Mycoplasma* spp. Fluoroquinolones, in common with aminoglycosides, are more active against Enterobacteriaceae and other Gram-negative aerobic bacteria in an alkaline environment and induce a post-antibiotic effect. Anaerobic bacteria are generally resistant. Maximal clinical efficacy of fluoroquinolones against susceptible bacteria may be achieved when the peak plasma concentration (C_{max}) is approximately 10 times the minimum inhibitory concentration (MIC) of the bacterial pathogen and a 12 h dosage interval is used. Both the administered dose and the dosage interval determine the area under the inhibitory plasma concentration-time curve.

Enrofloxacin, the fluoroquinolone that may be administered orally to mature horses (>4 yr old), is converted by *N*-de-ethylation (a hepatic microsomal-mediated oxidative reaction) to **ciprofloxacin**, which has antibacterial activity at least equal to that of the parent drug. The half-life of enrofloxacin in horses is 5.0 h while that of ciprofloxacin, which distributes more widely than enrofloxacin in body fluids and tissues, is 4.7 h. Ciprofloxacin decreases the systemic clearance of concomitantly administered theophylline to an extent that could be of clinical significance. The basis of the interaction could be a decreased rate of hepatic microsomal oxidative metabolism (*N*-demethylation) of theophylline. Because of their potential to cause degeneration of articular cartilage (*q.v.*) in weight-bearing joints (arthropathy), the use of fluoroquinolones is contraindicated in foals and young horses.

Even though fluoroquinolones, in common with several other antimicrobial agents, especially macrolides, lincomycins, the more lipophilic tetracyclines and orally administered penicillins, have the potential to seriously disturb the balance of **commensal microorganisms** in the colon of adult horses, the use of enrofloxacin at the usual dosing rate does not appear to cause the adverse effect.

Trimethoprim-sulfonamide combinations provide effective concentrations of both drugs in most body fluids and tissues and produce a bactericidal effect against a wide variety of equine bacterial pathogens. These combinations, which can be administered either orally or parenterally, are a useful alternative (second choice) to benzylpenicillin in the treatment of bacterial respiratory infections in older foals (>2 mo of age) and yearlings, whereas ceftiofur may be preferred in adult horses. In the treatment of pleuropneumonia (*q.v.*), which is often a mixed infection caused by **opportunistic aerobic bacteria and anaerobes**, trimethoprim-sulfonamide combination may be used in conjunction with metronidazole.

Another clinical indication for the use of trimethoprim-sulfonamide combination is in the treatment of **placentitis** (*q.v.*). An appropriate dosing rate for trimethoprim-sulfonamide combinations is 24 mg/kg administered parenterally or 30 mg/kg administered orally at 12 h dosage intervals. The higher dose level recommended for oral administration is to compensate for incomplete systemic availability, due mainly to **hepatic first-pass metabolism**, of trimethoprim. Oral dosing close to the time of feeding further decreases the systemic availability, or at least the peak plasma concentration, of trimethoprim and sulfonamides. This is probably due to binding of both drugs to fibrous components of feed.

Tetracyclines have a broad spectrum of antimicrobial activity, produce a bacteriostatic effect on susceptible microorganisms, and the tissue concentrations attained by individual tetracyclines are mainly influenced by their lipid solubility which, in turn, determines their clinical efficacy. The acquisition of plasmid-mediated resistance to tetracyclines appears to be due to a decreased ability of bacterial cells to concentrate the antimicrobial agents intracellularly. Because the effect produced by tetracyclines on susceptible bacterial pathogens is bacteriostatic, it is essential that effective plasma concentrations be maintained throughout the course of therapy.

Oxytetracycline is the drug of choice for the treatment of tentatively diagnosed and confirmed cases of **equine monocytic ehrlichiosis (Potomac horse**

fever) caused by *Neorickettsia risticii* (previously *Ehrlichia risticii*) (*q.v.*). Either a conventional (immediate release) preparation of oxytetracycline hydrochloride may be administered by slow IV injection at the usual dosing rate (3–5 mg/kg at 12 h intervals) or the long-acting preparation containing oxytetracycline formulated in polyethylene glycol may be administered by IM injection at a dosing rate of 6.6 mg/kg at 24 h intervals for 5–10 days. Long-acting preparations of oxytetracycline formulated in other vehicles are **unsuitable** for administration to horses because of tissue irritation caused at IM injection sites.

The concurrent use of oxytetracycline and rifampicin is clinically indicated for the treatment of **fistulous withers** caused by *Brucella abortus* or *Actinomyces bovis* (*q.v.*).

The potential especially of the more lipophilic drugs (minocycline, doxycycline) in this antimicrobial class to affect adversely the **commensal bacterial flora** in the cecum and colon limits their clinical use in horses. Under physiologically stressful conditions, such as following surgery, oxytetracycline can induce colitis X (*q.v.*), with sometimes fatal consequences.

Rifampicin is a lipophilic antimicrobial agent that attains effective concentrations in most tissues of the body. It readily diffuses through cell membranes to attain high intracellular (including phagocytes) concentrations and penetrates the blood–brain barrier. Rifampicin produces a bactericidal effect on susceptible Gram-positive aerobic bacteria, and both Gram-positive and Gram-negative anaerobes are susceptible to rifampicin. Because **chromosomal mutation** of bacterial RNA polymerase (the enzyme which rifampicin inhibits) can develop rapidly, rifampicin should *always* be used in conjunction with another antimicrobial agent selected on the basis that the combination will either produce a synergistic antibacterial effect or have enhanced clinical efficacy. Even though rifampicin is well absorbed from the gastrointestinal tract, hepatic first-pass metabolism (*q.v.*) reduces the systemic availability of rifampicin, which is further decreased by the presence of food in the stomach.

Rifampicin is partly eliminated by conversion in the liver to the desacetyl metabolite. This metabolic pathway has a dual significance in that 25-desacetylrifampicin has antibacterial activity similar to that of the parent drug and at doses above the recommended range (5–10 mg/kg) the capacity of this pathway may be exceeded leading to an increase in the half-life. Enterohepatic circulation contributes to the half-life of rifampicin, which is 6.0 h in adult horses.

Rifampicin is a potent inducer of hepatic microsomal enzymes, which may cause an increase in the rate of elimination (decrease in half-life) of various concomitantly used lipid-soluble therapeutic agents. Rifampicin in conjunction with erythromycin is specifically indicated for the treatment of **Rhodococcus equi infection** (pneumonia, lung abscesses) (*q.v.*) in foals aged between 6 and 16 wk. The recommended approach is to treat concomitantly with erythromycin estolate (20–25 mg/kg administered orally at 8 h intervals) and rifampicin (5 mg/kg PO at 12 h intervals) for a minimum duration of 3 wk. Improvement in clinical signs, the return of white blood cell count and plasma fibrinogen concentration to within the normal ranges, and radiographic resolution of pulmonary lesions serve as a useful guide to the duration of therapy.

The advantages of the **erythromycin–rifampicin combination** are that both antimicrobial agents administered orally attain **effective concentrations** at the site of infection, including an ability to **penetrate abscesses**; they appear

to act synergistically, and resistance of the causative bacterial pathogen to rifampicin is avoided.

Coprophagic behavior of some mares housed with their foals undergoing erythromycin–rifampicin treatment leads to ingestion not only of resistant *Clostridium difficile* (*q.v.*) but also of erythromycin excreted by the foals, which could severely disrupt the commensal bacterial flora of the large intestine and result in acute colitis (*q.v.*) in the mares.

Metronidazole is a lipid-soluble organic base that readily diffuses through cell membranes, distributes widely in tissues and body fluids, and penetrates cellular barriers. The drug is well absorbed from the gastrointestinal tract but shows wide variation in systemic availability within the range 60–80% in horses. Metronidazole exerts a bactericidal effect on most Gram-negative and many Gram-positive anaerobic bacteria. *Bacteroides* spp., including *B. fragilis*, *Fusobacterium* spp. and *Clostridium* spp., especially *C. difficile* (*q.v.*), are susceptible. The development of resistance, which could be due to reduced intracellular drug activation, is rare in usually susceptible bacterial species. In addition, metronidazole has high activity against various protozoa (*Trichomonas foetus*, *Giardia lamblia*) (*q.v.*). Both hepatic metabolism and renal excretion are involved in the **elimination of metronidazole**; the half-life is 3.9 h in horses. A dosing rate of 20 mg/kg administered orally (paste formulation) at 12 h dosage intervals is usual.

The use of metronidazole is clinically indicated in the treatment of **mixed aerobic–anaerobic** infections. The approach that should be adopted is to administer metronidazole **concomitantly** with an antimicrobial agent that has bactericidal activity against the **primary** aerobic bacterial pathogen. When the primary aerobe is Gram-negative, gentamicin or enrofloxacin (in adult horses) may be used whereas when the primary aerobe is Gram-positive, benzylpenicillin or ampicillin may be selected. Because the trimethoprim–sulfonamide combination provides a broad spectrum of activity against aerobic bacterial species, with the exception of *Pseudomonas aeruginosa* (*q.v.*), it could be used in conjunction with metronidazole; however, the use of a narrow-spectrum antimicrobial drug, selected on the basis of quantitative susceptibility (MIC for the isolated aerobic bacterial pathogen) and access to the site of infection, would be preferable.

NEONATAL FOALS

The most common pathogenic bacteria that cause infection (septicemia, pneumonia and septic arthritis) in neonatal (from birth to 7 days of age) and young (<1 mo of age) foals include *Escherichia coli*, *Klebsiella pneumoniae* and bacteria of the genus *Actinobacillus*, with the prevalence varying according to the geographic region.

The failure of passive transfer of maternal antibodies is the most significant factor that contributes to the development of neonatal septicemia. β -Hemolytic streptococci are infrequently isolated from septicemic foals but may cause pneumonia and septic arthritis, while *Pseudomonas aeruginosa* can cause septicemia and pneumonia. Approximately 50% of bacterial infections in neonatal foals are **mixed infections** (including *E. coli*).

Blood culture is a valuable, although not invariably certain, technique for making a microbiologic diagnosis of septicemia.

The success of treatment of bacterial infections in **neonatal foals** (*q.v.*) depends upon the prompt initiation of antimicrobial therapy according to an informed empirical approach, continuation with specific therapy based on precise identification of the causative pathogenic microorganism and its quantitative bacterial susceptibility, and the provision of supportive measures.

To avoid overloading **cardiopulmonary function** in neonatal foals, IV infusion of parenteral solutions should always be performed **slowly**. In selecting an antimicrobial agent, consideration should be given to the stage of development of the physiologic processes that affect distribution and elimination of the drug, and the immune status (serum IgG concentration) of the foal. The former is largely dependent on the age, in terms of days after birth, of the neonatal foal, while the latter is related to the ingestion of colostral antibodies. Correction of any deficit in serum immunoglobulins (*q.v.*) should precede and would enhance the effectiveness of therapy.

In neonatal foals, the use of an antimicrobial agent or antimicrobial combination that produces a **bactericidal effect** is preferable. Whenever possible, a parenteral preparation that can be administered IV should be chosen; this ensures that therapy will not be compromised by variations in drug absorption.

Should **gentamicin** be the drug of choice, precautions must be taken to avoid **nephrotoxicity and auditory damage**; dehydrated or fluid-depleted foals are particularly subject to gentamicin toxicity. The dosing rate for gentamicin is 3 mg/kg administered parenterally, usually at 12 h dosage intervals. Should therapy with gentamicin exceed 7 days, it is advisable to measure trough serum concentrations and monitor renal function.

Even though **amikacin** is less nephrotoxic than gentamicin, its use (6 mg/kg administered parenterally at 12 h dosage intervals) should generally be reserved for the treatment of infections in which the bacterial pathogen is susceptible to amikacin but resistant to gentamicin.

Ticarcillin-clavulanate combination has a wide margin of safety and, depending on quantitative susceptibility of the bacterial pathogen isolated, could be used as an alternative to an aminoglycoside antibiotic. A reasonable dosage regimen for ticarcillin-clavulanate combination is to administer 50 mg/kg by IV injection at 8 h dosage intervals for at least 3 days. Even though ticarcillin is active against *Pseudomonas aeruginosa* (*q.v.*), the concurrent use of ticarcillin and gentamicin could be justified in the treatment of severe infections because of their generally synergistic action against some strains of *Pseudomonas*.

Cefoperazone and especially **ceftazidime**, third-generation parenteral cephalosporins, have high activity against *Pseudomonas aeruginosa* and when used concurrently with an aminoglycoside antibiotic a synergistic action is produced. Whereas ceftazidime may penetrate the blood-brain barrier and is eliminated by renal excretion, cefoperazone does not penetrate the blood-brain barrier and is eliminated by the liver in bile. An empirical dosing rate for **ceftazidime** is 25–40 mg/kg administered by IV injection at 8–12 h dosage intervals.

The failure of many antimicrobial agents to attain effective concentrations in CSF and exert a bactericidal effect is a well-recognized problem in the treatment of bacterial meningitis, especially when caused by Enterobacteriaceae.

Either cefotaxime or ceftriaxone may be the antimicrobial agent of choice because each has the ability to penetrate the blood–CSF barrier and has high activity against *E. coli* and *Klebsiella* spp.

The parenteral preparation of **trimethoprim–sulfadiazine**, administered by slow IV injection at a dosing rate of 24 mg/kg at 12 h dosage intervals, is a useful alternative which is far less expensive than a third-generation cephalosporin. The combination has a bactericidal effect on *E. coli*, *Klebsiella* spp. and *Proteus* spp. and is often, although not always, effective in the treatment of **bacterial meningitis** (*q.v.*).

Because **fluconazole** penetrates the blood–CSF barrier and has activity against *Cryptococcus neoformans*, it is the antifungal agent of choice in the treatment of cryptococcal meningitis (*q.v.*). Fluconazole suppresses oral and esophageal candidiasis in immunocompromised foals and may be effective in the treatment of systemic **Candida infections** (*q.v.*). The empirical oral dosage regimen entails the initial administration of 400 mg (total loading dose) followed by maintenance doses of 200 mg at 24 h dosage intervals. Even though fluconazole has lower in vitro activity than itraconazole against *Candida* spp., it is the drug of choice for treatment of systemic *Candida* infections because it causes fewer interactions with therapeutic agents and least inhibition of hepatic microsomal cytochrome P450 enzymes.

Itraconazole may be the drug of choice for the treatment of mycotic pneumonia caused by opportunistic fungi (*Aspergillus* spp., *Candida* spp., *Mucor* spp.) in neonatal foals (*q.v.*).

ANTIFUNGAL AGENTS

Cutaneous mycotic infections caused by dermatophytic fungi (*q.v.*) are usually treated topically in horses and could be treated systemically. Drugs that may be applied topically include natamycin, various imidazole derivatives and nystatin, while systemic treatment is provided by orally administered griseofulvin, ketoconazole or itraconazole.

Topical antifungal preparations should be formulated to provide **penetration and persistence** of the drug at the cutaneous site of the infection. For topical application, there appears to be no clear preference for the use of one imidazole over others.

Superficial infections caused by *Candida* spp. (*q.v.*) may be treated locally by applying nystatin or an imidazole derivative, whereas soft tissue and gastrointestinal candidiasis are treated by administering orally an imidazole derivative. **Systemic mycoses** caused by dimorphic fungi require oral or parenteral therapy with an **imidazole derivative** usually used alone but could be cautiously used in conjunction with **amphotericin**; the drug is administered IV. Because of its narrow therapeutic index, high potential to cause nephrotoxicity, requirements associated with administration and the high activity of some imidazole derivatives against dimorphic fungi, the clinical utility of amphotericin is limited and decreasing. **Itraconazole** is replacing amphotericin as the drug of choice for the treatment of systemic infections caused by dimorphic fungi and systemic aspergillosis, caused by *Aspergillus fumigatus* (*q.v.*).

Natamycin is a polyene antibiotic with fungicidal activity against a variety of filamentous fungi, including dermatophytes (*Microsporum* spp., *Trichophyton* spp.), and against yeasts (*Candida* spp., *Cryptococcus neoformans*) (*q.v.*). A freshly prepared 0.01% aqueous suspension of natamycin, applied topically by spray or sponge on two occasions with a 4-day interval and again 2 wk later, if required, is often effective in the treatment of **ringworm (dermatophytosis)** (*q.v.*).

It is important that all grooming utensils and tackle be thoroughly cleansed and immersed in the natamycin suspension, which should be prepared in plastic or galvanized containers. Natamycin has been used successfully to treat **filamentous fungal keratitis**, especially when caused by *Fusarium* spp. (*q.v.*). A recommended treatment is to apply 1 drop of a 5% aqueous suspension (natamycin ophthalmic) every 1–2 h, decreasing to 6–8 times daily after a few days. If *Aspergillus* is identified mycologically as the causative organism of a **corneal infection**, the drug of choice is **miconazole**. Miconazole is commercially available as a parenteral solution (10 mg/mL) that can be applied locally at short intervals and administered by subconjunctival injection (10 mg s.i.d. for 5 days). Natamycin is not effective against deep mycotic infections of the eye, because of poor penetration to the site of infection.

Nystatin, a polyene macrolide antibiotic that is structurally similar to amphotericin, is used mainly to treat cutaneous yeast infections caused by *Candida* spp., although some *Candida* spp. other than *Candida albicans* may be resistant. For topical application, nystatin is formulated as a cream and an ointment. Nystatin administered as an oral suspension (100 000 units/mL) is not absorbed from the gastrointestinal tract and may be used for the treatment of gastrointestinal candidiasis. However, itraconazole (oral liquid) may be the antifungal agent of choice. In the treatment of mycotic endometritis caused by *Candida* spp. intrauterine nystatin could be considered second choice to clotrimazole, which is administered as an aqueous suspension (500 mg daily for 7–10 days) by **intrauterine infusion**.

The **azole class** of antifungal agents comprises the imidazoles (ketoconazole, miconazole, clotrimazole and enilconazole) and the triazoles (itraconazole and fluconazole). Based on their greater affinity for fungal than for mammalian cytochrome **P450 enzymes**, the triazoles are relatively more selective in action than the imidazoles, which accounts for the lower incidence of drug interactions and side effects associated with their use.

Azole antifungal agents are generally fungistatic against various **filamentous fungi**, which include *Aspergillus* spp. and dermatophytes (*Microsporum* and *Trichophyton* spp.), yeasts (*Cryptococcus neoformans*, *Candida* spp.), and dimorphic fungi (*q.v.*). Individual azoles differ in their activity against fungal species and in their pharmacokinetic properties, both of which contribute to clinical efficacy. The duration of treatment with azole derivatives should be based on both clinical and mycologic response.

The use of clotrimazole is limited to **topical application**. Absorption of ketoconazole and itraconazole, lipophilic drugs, is increased by low gastric pH. **Ketoconazole** is dissolved in **0.2 N hydrochloric acid** prior to administration by nasogastric tube to horses. In the systemic circulation, ketoconazole and itraconazole bind extensively to plasma proteins and undergo elimination by hepatic microsomal oxidative reactions; ketoconazole especially

causes inhibition of the hepatic microsomal cytochrome P450 enzyme system. **Itraconazole** (oral liquid) is the azole of choice in the treatment of **refractory dermatophyte infections** (*q.v.*) because marked binding to keratin occurs, and is the only azole with activity against *Aspergillus* spp.

Guttural pouch mycosis (*q.v.*), which is most commonly caused by *Aspergillus nidulans*, may be treated by administering **itraconazole** orally (5 mg/kg q 12 h) and irrigating the guttural pouch with a parenteral solution of either itraconazole or miconazole once daily. Itraconazole is the preferred azole for the treatment of systemic infection caused by dimorphic fungi.

Fluconazole differs from the other azoles in that it is soluble in water, binds to a low extent to plasma proteins, readily penetrates the blood–CSF barrier, and is eliminated mainly by renal excretion. It has the **widest therapeutic index** of the azoles and the lowest incidence of drug interactions. Fluconazole is the drug of choice in the treatment of cryptococcal meningitis (*Cryptococcus neoformans*) (*q.v.*) and in urinary tract mycoses, usually *Candida* spp. (*q.v.*). The usual dosing rate of fluconazole for the treatment of fungal cystitis, which may also involve opportunistic aerobic bacteria, is 4 mg/kg administered PO q 12 h in conjunction with trimethoprim–sulfadiazine (oral paste formulation); a long duration of treatment is required.

Griseofulvin is a fungistatic lipophilic antibiotic that is administered orally as a paste formulation or as granules added to the feed for the systemic treatment of cutaneous infection caused by dermatophytes (*q.v.*). Its selectivity of action is due to an energy-dependent uptake of the drug by susceptible dermatophytic fungi (*Microsporum* and *Trichophyton* spp.) The absorbed drug distributes via the systemic circulation to the various layers of the epidermis, including the *stratum corneum* where it selectively binds to **keratinocytes** and persists in the newly forming structures that gradually replace the fungal infected structures. This implies that a **long duration** of treatment is invariably required. The suggested dosage for horses is 25 mg/kg of the oral paste or oral granules (which contain 75 mg/g), s.i.d. for 2 wk followed by 12.5 mg/kg s.i.d. for a further 8 wk. The absorption of griseofulvin is increased when the drug is administered with feed. Because griseofulvin induces hepatic microsomal cytochrome P450 activity during the course of treatment, the rate of metabolism of concomitantly administered therapeutic agents that are mainly eliminated by hepatic microsomal-mediated oxidative reactions is increased.

ANTHELMINTICS

INTRODUCTION

In most countries, several anthelmintics are licensed for use in the horse. The main chemical groupings into which they can be classified include probenzimidazoles and benzimidazoles, tetrahydropyrimidines (pyrantel), avermectins and milbemycins and pyrazinoisoquinolones (praziquantel). In some places, the simple heterocycle, piperazine, the organophosphates and morantel are also available, as are a number of products containing more than one active anthelmintic.

MODE OF ACTION

Febantel is a **pro-benzimidazole** with a phenyl guanidine structure, which is hydrolyzed and cyclized into **fenbendazole** and, while the parent compound may have some neurotoxic effect on parasites, it is likely that the principal mode of action is through the activity of the benzimidazole metabolites.

The **benzimidazoles** have been shown to inhibit parasite metabolic enzymes including fumarate reductase. However, at lower concentrations they attach to nematode tubulin, thus disrupting cytoplasmic microtubules with consequent failure of intracellular secretory granule transportation. This latter effect is thought to be the mode of anthelmintic activity common to all members of the group.

Pyrantel and morantel act as a cholinergic agonist at the parasite ganglion and thus stimulate spastic paralysis of parasite musculature. Preparations of pyrantel are formulated as salts (embonate in the UK, pamoate and tartrate in the USA). The embonate and pamoate salts are less water soluble than the tartrate salt, are less well absorbed from the gastrointestinal tract, and are therefore **less toxic** to the host.

Avermectins and milbemycins affect parasites in many ways, but the most likely explanation for their antiparasitic action is that they increase parasite neuronal membrane permeability to chloride ions. This action, which causes paralysis of the parasites, is mediated by a glutamate-gated mechanism which is potentiated by the avermectins and milbemycins.

The precise mechanism of action of **praziquantel** is unknown but it does affect muscular activity in **cestodes** and causes vacuolation and disruption of the parasite tegument.

Piperazine causes hyperpolarization at nematode muscle cell membranes, which results in flaccid paralysis, and it may act as a GABA agonist within the parasite.

The **organophosphates** inhibit cholinesterase enzymes, particularly acetylcholinesterase, which results in a build-up of acetylcholine in ganglia or at neuromuscular junctions. In the host, the organophosphates initially form a reversible complex with acetylcholinesterase but, with time, the complex becomes irreversible and cholinesterase activity will then recur only when the new enzyme is synthesized. In the parasite, inhibition may be reversible or irreversible, depending on the species involved. Reversible inhibition is usually sufficient to facilitate expulsion of the parasite by peristalsis if its predilection site is the gut.

TOXICITY

The **pro-benzimidazoles** and **benzimidazoles** are very safe drugs in the horse. The therapeutic index (i.e. the dose at which toxic signs are first seen/minimum therapeutic dose) for each drug used is >10 and for fenbendazole is ≥ 200 . If toxicity is seen, it is generally first manifest as diarrhea with abdominal discomfort.

Pyrantel has a therapeutic index >6 and the more soluble tartrate salt is slightly more toxic than the embonate or pamoate salts. Toxicity in the horse reflects the likely mode of action of pyrantel on nicotinic receptors, which

results in increased respiratory rate, sweating and incoordination. Consequently some preparations are contraindicated in debilitated animals. The morantel preparations available for horses comprise the tartrate salt, which is highly polar and thus poorly absorbed from the gastrointestinal tract. This confers good safety on this product.

Ivermectin is reported to be safe at up to 10 times the recommended oral dose. However, at very high dose levels (12 mg/kg or 60 times the recommended dose) animals become depressed and ataxic and may display mydriasis and lower lip droop. Where *Onchocerca* spp. (*q.v.*) are prevalent, treatment at the therapeutic dosage rate may result in a hypersensitivity reaction to dead microfilariae with ventral abdominal edema and pruritus. **Ivermectin is not licensed for parenteral administration in the horse and should not be given by injection** since a low but significant incidence of infected injection sites with consequent clostridial myositis (*q.v.*) occurs. Anaphylactoid reactions (*q.v.*) have also been associated with IV administration and attributed to the presence of the excipient polysorbate 80 in the micellar formulation. **Moxidectin** has been shown to be safe at up to three times the therapeutic dose in foals. At higher dosages signs similar to those reported for ivermectin occur.

Piperazine is unlikely to cause toxicity, even at doses as high as 17 times that recommended for therapeutic efficacy.

The **organophosphates** have relatively narrow therapeutic indices, which may depend upon the capacity for enzymatic degradation or inactivation of the drug. Toxicity may also depend upon the formulation, since these drugs are commonly presented in slow release resins that reduce the maximum peak systemic exposure to the drug and thus its toxicity. Of the two organophosphates commonly used in the USA, **trichlorfon** paste and liquid preparations have a narrower therapeutic index of 1 than **dichlorvos resin pellets** which have a therapeutic index of 3.

Acute organophosphorus toxicity is the result of irreversible inhibition of acetylcholinesterase and presents initially as parasympathetic stimulation with diarrhea and colic. Ultimately all muscarinic and nicotinic receptors become stimulated and animals die of asphyxia as respiratory muscles fail to function properly.

PHARMACOKINETICS

There is little information on the pharmacokinetics of many of the anthelmintic drugs used in the horse. Some of the benzimidazoles, avermectins and milbemycins and pyrantel have, however, been investigated. **Fenbendazole** and **oxfendazole** are metabolically interconvertible as a reversible step in the pathway which leads to the formation of a more highly oxidized metabolite, oxfendazole sulfone, which is anthelmintically inactive.

Lower plasma concentrations of fenbendazole and oxfendazole are achieved following administration of fenbendazole than the same dose rate of oxfendazole. This probably reflects the relative insolubility and consequent slow absorption of fenbendazole and its subsequent rapid oxidative metabolism through the oxfendazole intermediate to the sulfone metabolite. If oxfendazole is administered as the parent compound, its rate of absorption exceeds that of its metabolism and therefore higher plasma concentrations are achieved. These

generate higher plasma concentrations of fenbendazole by reductive metabolism than are achieved when fenbendazole is administered as the parent compound. These characteristics of absorption and metabolism possibly explain the very high dosage recommendations for fenbendazole for the treatment of migratory stages of large strongyles and for immature small strongyles. Oxibendazole undergoes extensive **first-pass metabolism** (*q.v.*) and very low concentrations of parent drug are detected in plasma following oral administration.

The comparatively short persistence of benzimidazoles in the plasma of horses compared with ruminant species means that their efficacy may be improved by dosing over a number of consecutive days, since improved efficacy is a feature of prolonged exposure of parasites to benzimidazoles.

Pyrantel can be detected at low concentrations of up to about 0.1 µg/mL in plasma between 1 and 60 h after oral administration of 13.3 mg/kg BW of pyrantel embonate. It is largely excreted unchanged in the feces, in which concentrations >1.0 mg/kg can be detected and in which it is present for approximately 70 h.

Ivermectin has been shown to persist in the tissues and plasma of many species of animal for some time after administration, conferring prophylactic activity against susceptible parasites ingested or otherwise acquired during the period of persistence. In the horse, oral administration of 200 µg/mL of the commercially available paste preparation results in persistence at measurable concentrations >2 ng/mL for 14 days, conferring activity against ingested infected larvae. This accounts for the interdosing interval of 8–10 wk often recommended for this anthelmintic which is derived from the shortest prepatent period of the common equine parasites (6–8 wk for small strongyles) plus the 2 wk period of anthelmintic prophylaxis. **Moxidectin** is highly lipid soluble, and following administration distributes to the lipid compartments of the body from which reservoir it redistributes slowly to the predilection sites of the parasites. It can be detected in horse plasma for at least 80 days following a therapeutic dose and this may account for the suppression of small strongyle egg output for 90 days.

The pharmacokinetics of other anthelmintics used in the horse are less critical since their efficacy is not dependent upon persistence nor do they confer significant prophylactic activity.

SPECTRA OF ACTIVITY

Anthelmintic medication may be indicated for the following common internal parasites of the horse. In the foal, the large ascarid *Parascaris equorum* and the threadworm *Strongyloides westeri* (*q.v.*) which inhabit the small intestine are frequently the cause of unthriftiness and diarrhea, respectively. In adult horses, treatment for the stomach bots *Gasterophilus* spp. (*q.v.*) and the ileal or cecal tapeworm *Anoplocephala perfoliata* (*q.v.*) is often carried out, although the pathogenic significance of these parasites is unclear.

The strongylid worms are, however, pathogenic. These include the large strongyles *Strongylus vulgaris* (*q.v.*), which has a migratory pathway via the cranial mesenteric artery, and *S. edentatus* (*q.v.*), which migrates via the liver and parietal peritoneum, and the small strongyles or cyathostomes (*q.v.*), which

include many species and which invade and develop within the large intestinal mucosa. The predilection site of all the strongylid species is the cecum and colon.

The colon is also the predilection site for the large pinworm *Oxyuris equi* (*q.v.*), which is not pathogenic *per se* but which lays eggs causing perineal irritation.

Lungworm infection in the horse is attributed to *Dictyocaulus arnfieldi* (*q.v.*) and is relatively uncommon, as is infection with the liver fluke *Fasciola hepatica*.

The efficacy of the available anthelmintics against adult stages of most of these parasitic infections is well established. However, larval stages are often less susceptible and there is a paucity of data on anthelmintic efficacy against immature parasites. Parasite resistance to anthelmintic drugs is an emerging concern and is used to describe parasites that are less susceptible to a drug than the original population.

EFFICACY

The following assessment of drug efficacies is for susceptible parasites.

Febantel is >95% effective against adult and larval *P. equorum*, adult large and small strongyles, and adult and larval *O. equi* when used at a dose of 6 mg/kg.

Mebendazole at a dose of 5–10 mg/kg is >95% effective against *P. equorum* and *S. vulgaris* but less so (80%) against *S. edentatus* and the small strongyles. It is highly effective against larval and adult *O. equi* and is effective against *D. arnfieldi* in donkeys if administered at 15–20 mg/kg daily for 5 consecutive days.

The standard recommended dose rates for **fenbendazole** and **oxfendazole** are 7.5 and 10 mg/kg respectively, and both have been shown to be >90% effective against *P. equorum*, large and small strongyles and mature *O. equi*. They are also effective against immature and migrating large strongyle larvae, although the dose of fenbendazole should be increased to 60 mg/kg for these stages. Fenbendazole is effective against *S. westeri* at 50 mg/kg, against immature small strongyles at 30 mg/kg and against *D. arnfieldi* at 15 mg/kg. Administration of fenbendazole and oxfendazole over a number of consecutive days may prove more effective against the more recalcitrant parasites than a single administration.

Fenbendazole has an efficacy claim for the treatment and control of migrating and tissue larval stages of large strongyles and encysted mucosal 3rd and 4th stage small strongyle larvae, when all administered at 7.5 mg/kg BW daily for 5 days.

Oxibendazole is >90% effective against *P. equorum*, large and small strongyles and adult and immature *O. equi* when administered at 10 mg/kg, and has good activity for *S. westeri* at 15 mg/kg. It has also been shown to be effective against small strongyles resistant to other benzimidazole anthelmintics, although these parasites do subsequently appear to develop resistance to oxibendazole rapidly.

Pyrantel is administered at a standard dose of 6.6 mg base/kg BW, which is equal to 19 mg of pyrantel embonate/kg BW. It is >90% effective against *P. equorum*, *S. vulgaris* and small strongyles, but only 65–70% effective against

S. edentatus and adult *O. equi*, respectively. It is recommended for *A. perfoliata* if the dose is increased to 13.2 mg base/kg (38 mg pyrantel embonate/kg).

Ivermectin at 200 µg/kg is >95% effective against *P. equorum*, *S. westeri* and large and small strongyles including arterial (*S. vulgaris*), tissue (*S. edentatus*) and luminal L₄ (cyathostomes) stages. Its activity on mucosal developing L₃ and L₄ has been inconsistent. It is also highly effective against *D. arnfieldi* and *O. equi*. The activity of ivermectin for **arthropods** also makes this an extremely effective drug for both the oral and gastric stages of *Gasterophilus* spp. (*q.v.*).

Moxidectin (400 µg/kg) has similar excellent activity to ivermectin against *P. equorum*, *S. westeri*, adult and arterial/tissue stages of large strongyles and adult luminal L₄ stages of small strongyles. It has been shown to confer between 55% and 84% reduction in mucosal developing L₃ and L₄ stages of small strongyles and has authorized claims for encysted inhibited early L₃ and developing intramucosal L₄ larval stages in some markets. It has an authorized claim for *Gasterophilus* spp. in some markets, although efficacy has been shown to be rather variable (20–99%) against this parasite.

Praziquantel (1 mg/kg) has excellent activity against *A. perfoliata*, the common cestode of horses (*q.v.*), and is exclusively used for this parasite either alone or in combination products designed to extend the spectrum of activity.

Many of the remaining anthelmintics have limitations in their spectra of activity or efficacy and consequently some of the drugs are produced in combinations that complement each other. **Piperazine** is >95% effective for *P. equorum* and for small strongyles at 88 mg/kg but is otherwise poorly effective and is produced in combination with oxfendazole.

The two organophosphates are highly effective against *P. equorum*, *O. equi* and *Gasterophilus* spp. **Dichlorvos** is also >90% effective for *S. vulgaris* and the small strongyles, and >70% effective for *S. edentatus* at a dose rate of 35 mg/kg. The dose of **trichlorfon** has to be increased from 40 to 80 mg/kg to confer activity against large and small strongyles. The organophosphates are marketed alone and in combinations with benzimidazoles.

There are no drugs specifically licensed for the treatment of *F. hepatica* in the horse. However, the benzimidazole **triclabendazole** has been shown to be highly effective at reducing fecal egg output from infected animals when given at 12 mg/kg. The plasma concentrations of triclabendazole and its metabolites achieved following administration at this dose are lower than those achieved in the ruminant and it may be that a higher dose rate is more appropriate in the equine.

STRATEGIC DOSING

Anthelmintic strategies for the horse depend to a large extent on **prevalence and seasonality** of the parasites. In many countries, control is usually based on anthelmintic administration at 4–6 wk intervals to all horses at grass. The persistent activity of **moxidectin** and its activity against immature stages of cyathostomes mean that the dosing interval can be extended to 13 wk.

If treatments are timed to coincide with **highest egg output** then they should be concentrated in the spring when the horses are producing most eggs

and in the autumn/fall when **pasture contamination** with infective strongyle larvae is highest. Suppressive treatment in the spring may lower pasture contamination sufficiently to preclude necessary medication throughout the latter half of the grazing season. In very hot dry climates larval survival during the summer is low.

In the USA, an alfalfa feed preparation containing pyrantel tartrate has been produced to deliver continuous low-level medication to horses for strongyle control.

RESISTANCE

The development of **resistance to anthelmintics** is a well-recognized phenomenon and in horses occurs principally with the **small strongyles**.

In order to minimize the likelihood of resistance developing, **annual rotation** of anthelmintics from different chemical groupings has been advocated. This system means that each generation (assuming one annual generation) of parasites is only exposed to one drug group and subsequent generations are exposed to a different anthelmintic for which they have not had the opportunity to develop resistance. Where this system is adopted it is obvious that some parasites may not be treated for a whole season since the anthelmintics currently available on their own are **not effective** against all species. It may therefore be necessary to include one or more treatments with another drug with a different spectrum of activity.

The factors that increase the likelihood of resistance developing include:

1. More frequent treatment, which increases the selection of parasites with resistant genes.
2. Using anthelmintics with 90–99% efficacy; if efficacy is <90%, sufficient susceptible parasites survive treatment to retain the susceptibility of the population; if >99.9%, there are too few survivors to reproduce effectively.
3. Few parasites existing in refugia (i.e. not exposed to the anthelmintic), for instance free living stages. In droughts, the number of parasites in refugia may be small, thus if treatment is initiated a large proportion of the total population is exposed and thus selection is intense.
4. Using drugs with a long terminal plasma elimination half-life, since parasites are exposed to subtherapeutic concentrations for a prolonged period. However, where drug activity is increased by time of exposure the influence of this parameter is likely to be complex.
5. Dominant rather than recessive mode of inheritance of resistance.

ANALGESIA

INTRODUCTION

While the equine species has been of central importance to the veterinary profession since time immemorial, understanding of behavioral expression of pain in horses remains poor relative to other domestic species. Horses are frequently described as being “very sensitive” to pain, based primarily on

violent behavioral responses to acute painful or frightening stimuli. **Behavioral manifestations** of discomfort (other than those associated with severe acute pain) are less well appreciated. Experimental evidence indicates that domestic animal species, in common with humans, respond to noxious stimuli of similar intensities, and there is no doubt that manifold subtle behavioral indicators of discomfort in horses probably pass unrecognized. Thus it is considered highly likely that pain in horses is **under-diagnosed** and consequently **under-treated**.

ASSESSMENT OF PAIN

Severe pain associated with conditions such as **laminitis** or **colic** is generally easily recognized. However, horses often demonstrate discomfort through more **subtle behavioral indicators** that may include sweating, ears flicked frequently or held back, reluctance to move or increased locomotor activity, restlessness, reduced weight bearing on a limb or a rigid stance, weight shifting, abnormal postures, abdominal guarding, kicking at the abdomen, interrupted feeding patterns, withdrawal to the back of the stable and reduced interest in/interaction with companions, and abnormal postures, particularly head held below the withers. While increased heart and respiratory rates may accompany severe acute pain, they are not reliable physiologic pain indices in other species, in particular where animals are in unfamiliar surroundings or are being assessed by unfamiliar individuals. The presence or absence of one or more of these signs will depend on the location and severity of the pain, e.g. horses with abdominal pain may also paw the ground, roll, stretch and turn their head towards their flanks.

The nature of the pain, as interpreted by clinical signs, may also help in making a diagnosis. In general, the horse exhibiting signs of colic due to an impacted large intestine does not manifest severe signs of pain, whereas a horse suffering with **tympanitic colic** (*q.v.*) will often manifest pain in a more violent manner. In both instances pain arises due to intestinal distension but is manifested by different behaviors. The horse suffering with **spasmodic colic** (*q.v.*) may show intermittent signs of pain with a return to normal behavior in between episodes. These are important observations and influence the diagnosis and subsequent choice of analgesic drug. Thus, there is a need to observe the nature and pattern of pain in the horse, before selecting analgesic drugs for effective pain management.

The assessment of **postsurgical pain** may be difficult due to the superimposed stress of both anesthesia and hospitalization in horses. Knowledge of procedures considered painful in humans is useful in selecting an analgesic agent and, in the absence of evidence to the contrary, it is reasonable to assume that pain will exist in situations in which humans would experience pain.

Orthopedic procedures, commonly carried out in horses, are likely to be associated with severe postoperative pain, in particular as the animal is required to use the affected limb in some manner during recovery. Superficial or body surface surgery, particularly if extensive, also can cause intense discomfort in humans and other animal species, and is likely to do the same in horses. Intra-abdominal surgery can cause a marked degree of postoperative pain, particularly when the animal resumes a standing position.

PHARMACOLOGIC CONTROL OF PAIN

There are many sites along the pathways involved in the transmission of nociceptive/pain information from the periphery to the CNS where activity may be modulated. Drugs that suppress or modulate the animal's response to pain which act centrally in the brain and spinal cord include the opioids, the α_2 -adrenoceptor agonists, ketamine, nitrous oxide, local anesthetics and NSAIDs. Some of these drugs have peripheral sites of activity which contribute to their analgesic efficacy and/or to their side effects, e.g. inflammatory mediators such as bradykinin and the prostaglandins, which are produced in response to tissue damage, activate or sensitize peripheral receptors in the body that respond to noxious stimuli. The NSAIDs act by decreasing the production of some inflammatory mediators in the periphery (*q.v.*) thereby enhancing their significant centrally mediated analgesic activity.

Local anesthetic drugs have both peripheral and central analgesic activity. Peripherally, they block conduction of impulses from the nociceptors along sensory fibers; centrally, their analgesic activity is attributed to antagonism of specific sodium channels involved in central sensitization of nociceptive transmission. Thus such drugs, when used in an appropriate manner, are highly effective.

The **opioids** produce their effects by activation of one or more specific receptors, the μ (mu), κ (kappa) and δ (delta) receptors. Thus they mimic the action of endogenous ligands such as the endorphins, dynorphins and enkephalins. The opioid drugs are probably best classified according to their relative activity at each receptor. They act as pure agonists or pure antagonists, or may fall into the spectrum between and be termed partial antagonists. In addition, a drug may be a partial agonist at one receptor and an antagonist at another. Activation of one, two or all of the opioid receptors produces analgesia. Other pharmacologic effects consequent to opioid receptor activation either centrally or in the periphery may vary considerably according to the particular receptor activated.

Opioids are indicated for the treatment of **moderate to severe pain**. The undesirable side effects of increased locomotor activity and respiratory depression appear to occur less frequently when the drugs are given to horses experiencing pain. Respiratory depression in horses, unlike that seen in humans, is not a major side effect when the drugs are used at clinically recommended doses. It is notable that administration of opioids by extradural (epidural) injection achieves highly effective spinally mediated analgesia while avoiding the systemic side effects described above.

Horses in pain respond to opioids with a decrease in locomotor activity as relief is obtained, however **increased motor activity** occasionally occurs, particularly after repeat administration to control severe pain. This behavioral disturbance can be controlled with a low dose (0.03–0.05 mg/kg IM or IV) of acepromazine or, alternatively, the effect reversed with an opioid antagonist such as **naloxone**, although analgesia will then also be abolished.

Decreased gut motility is a potential side effect of opioid administration, the consequences of which may be relevant depending on the individual animal and its pathology; however, the depression of gut motility associated with opioid administration should be considered in the context of the depressant effect of unrelieved pain and altered behavior and feeding patterns on gastrointestinal motility.

Individual drugs (for recommended doses, see Table 4.6)

Morphine is a controlled drug and is classified as a pure agonist with a high affinity for μ receptors. It produces analgesia in the horse that is relatively **slow in onset** and lasts for up to 4 h, depending on the severity of pain and the dose administered (0.05–0.1 mg/kg, IV). Respiratory depression and gastrointestinal depression are not considered significant at clinically recommended dose rates in conscious horses, although locomotor stimulation can occur at higher doses. Cardiovascular side effects are minimal. Morphine can be given IM, IV or by extradural injection.

Methadone (controlled drug) has been used widely in combination with a tranquilizer drug to produce chemical restraint in the standing horse, and is frequently administered in some countries. In humans, methadone is roughly equipotent with morphine but has a longer duration of action, and in dogs it appears to be a very effective analgesic. It can be administered IM, IV or by extradural injection at doses of 0.05–0.1 mg/kg.

In addition to its pharmacologic properties as an opioid drug, **pethidine** (controlled drug) has anticholinergic activity and consequently is an effective gastrointestinal spasmolytic. It has a selective role in the horse. The short duration of action and lack of potency limit its use as a postoperative analgesic. However, it may be beneficial for short-term analgesia (approximately 1 h) either to allow movement of a horse, where a rapid onset of effect is required, or for the relief of spasmodic abdominal pain. It is best given by the IM route (2 mg/kg). Effective extradural analgesia has also been described

Table 4.6 Drugs and drug doses commonly used for extradural analgesia

Drug	Doses	Onset of action	Duration of analgesia	Side effects (associated with systemic absorption)
Lidocaine	0.22–0.35 mg/kg	5–15 min	60–90 min	Ataxia/recumbency at high doses
Ropivacaine	0.08 mg/kg	5–15 min	2.5–4 h	Questionable quality of analgesia
Xylazine	0.17–0.35 mg/kg	10–30 min	2.5–4 h	Perineal edema, sweating, ataxia
Detomidine	30–60 μ g/kg	10–15 min	2–3 h	Sedation, ataxia
Morphine	0.1–0.15 mg/kg	Slow; 4–8 h	8–18 h	Sedation, ataxia
Pethidine	0.8 mg/kg	5–15 min	4–5 h	Mild sedation and ataxia
Ketamine	0.5–2 mg/kg	5–15 min	30–90 min	Sedation, mild ataxia
Ketamine/morphine	1 mg/kg and 0.1 mg/kg	Poorly defined; slow, up to 4 h	12–18 h	Sedation, mild ataxia
Ketamine/xylazine	1 mg/kg and 0.5 mg/kg	5–15 min	>2 h	Mild sedation, bradycardia
Tramadol	1 mg/kg	30 min	8–12 h	

As a standard, drugs are administered in an injection volume of 4–8 mL for a 500 kg horse to provide analgesia appropriate for perineal surgery. The higher end of the volume range should be used to provide analgesia suitable for hindlimb surgery. If local anesthetic is used, a total injection volume of, 10 mL to adult (500 kg) horses is recommended to avoid paresis/paralysis of motor supply to the hindlimbs. Where analgesic drugs (without addition of local anesthetic agents) are used, a volume of 10–20 mL can be used in adult horses (500 kg) to facilitate cranial migration of the solution.

using pethidine (0.6–0.8 mg/kg). Intravenous administration in conscious horses can precipitate excitement and collapse associated with systemic histamine release and severe hypotension. This is of particular significance in anesthetized animals.

Butorphanol is a partial agonist that is licensed in the UK for use in the horse. Experimental and clinical evidence suggest that it is more effective in the management of mild to moderate visceral pain than in the treatment of somatic pain and other types of severe pain. It is administered IV at doses of 0.03–0.1 mg/kg. When injected at a dose of 0.1 mg/kg, it may precipitate an increase in locomotor activity, observable as “compulsive walking”. Butorphanol is frequently combined with a sedative such as **detomidine** (*q.v.*) for standing sedation. It is not a controlled drug and, unlike morphine, pethidine and methadone, is consequently not subject to such strict controls regarding its purchase, storage and use.

Fentanyl patches for transdermal analgesic administration have been described for treatment of both postsurgical pain and other refractory pain conditions including severe laminitis. Fentanyl is a potent opioid agonist that has been used parenterally in other species, and its use in transdermal patches has been described in dogs and cats. There are as yet no published studies documenting the pharmacokinetic profile and analgesic efficacy of these potentially useful transdermal patches in the horse, and at this stage their use is not recommended in the horse.

None of the other opioid partial agonists is licensed for use in the horse. **Buprenorphine** and **nalbuphine** have been used in neuroleptanalgesic combinations for standing chemical restraint, but their efficacy as analgesics in this species is unknown. **Pentazocine** has been used to treat visceral pain in the horse but can produce excitement and is best avoided.

α_2 -Adrenoceptor agonists provide profound analgesia for both visceral and somatic pain. Xylazine, detomidine and romifidine are licensed as sedatives/analgesics for use in the horse and are among the most effective and potent analgesics available. Medetomidine is currently not licensed in horses, but has been investigated as a potentially useful analgesic agent intraoperatively. At high (sedative) dose rates, these drugs have numerous side effects and cause marked disturbance in **cardiovascular function**—hypertension, hypotension, bradycardia, decreased cardiac output—and a more significant reduction in gut motility than that recorded with opioid agonists. In addition, they are **contraindicated** in the latter stages of pregnancy due to potential stimulatory effects on uterine smooth muscle. Recent evidence suggests that these drugs may be effective analgesic agents at low doses associated with markedly reduced side effects and minimal sedation. They can be administered IM or IV and appear to be effective when administered epidurally to provide perioperative analgesia for surgery of the vagina, tail and vulva, although significant systemic absorption (particularly of medetomidine) occurs so that systemic side effects must be anticipated following extradural injection.

Xylazine is less potent and shorter acting than either detomidine or romifidine and, when used IV at doses from 0.5 to 1.1 mg/kg, will induce profound analgesia (with significant sedation at the higher end of the dose range). While xylazine can be very useful for the **transport** of horses in severe pain, or prior to surgery, **ataxia** may be undesirable. Extradural administration of

xylazine (0.17–0.25 mg/kg in 10 mL 0.9% NaCl) has been reported to produce prolonged perineal analgesia for at least 2.5 h.

The potency of **detomidine** allows its use in small volumes by IM injection, an important factor in severely distressed animals. Detomidine (10–20 µg/kg) provides effective analgesia with marked sedation at 20 µg/kg. It has been effectively administered by both extradural injection (60 µg/kg) and extradural infusion for prolonged perineal analgesia in horses. **Medetomidine** (7 µg/kg bolus/3.5 µg/kg/h infusion) has recently been described as a potential sedative and analgesic agent in the horse. The analgesic efficacy of **romifidine** has not been detailed but as an α_2 -adrenoceptor agonist is likely to have analgesic properties.

Ketamine has analgesic properties in animals and humans. It is most often used in the horse after xylazine or detomidine or romifidine administration to induce general anesthesia. However, its excitatory effects on the CNS limit its use and it should never be administered alone. It may be injected IV (50–100 mg for a 450 kg horse) to provide intraoperative analgesia and has few cardiovascular or respiratory side effects at these low doses in halothane-anesthetized horses. Its use by infusion has also been described in horses anesthetized with either halothane or the IV anesthetic agent propofol. Research in species other than the horse has shown that ketamine administered at significantly lower, non-sedative doses (0.2–0.5 mg/kg, infusions of 0.5–1.0 mg/kg/h) produces effective analgesia without undesirable behavioral side effects.

Ketamine has also been administered by extradural injection (0.5–2 mg/kg) to produce effective **perineal analgesia**; however, some side effects may occur at the higher dose due to systemic absorption of the drug.

Nitrous oxide (N₂O) is an anesthetic gas used as an adjunct to general anesthesia because of its analgesic properties. The analgesic properties have been attributed to stimulation of endogenous opioid release, and α_{2A} -receptor agonism. The limited potency of N₂O in horses necessitates the use of a 40–50% mixture in the inspired gas, therefore increasing the risk of hypoxemia in the recumbent horse. Hypoxia may also occur at the end of anesthesia if the animal is suddenly allowed to breathe air without allowing time to eliminate N₂O from the body. In addition, N₂O can diffuse readily into air-containing gas spaces such as the intestine, displacing nitrogen, thereby increasing the volume of these spaces and possibly inducing abdominal bloat. Despite these disadvantages it is used by some veterinary surgeons, but should only be considered where facilities for monitoring oxygen saturation or arterial oxygen tension are available. It is useful in foals to hasten induction with volatile anesthetic agents.

Local anesthetics

Lidocaine is a short-acting (approximately 1 h) local anesthetic drug, frequently used in horses to provide analgesia for suturing wounds. **Mepivacaine** is intermediate in its duration of action (approximately 1.5–2 h), produces little tissue reaction and is widely used to block specific nerve trunks in the diagnosis of lameness. **Bupivacaine** is long-acting (up to 6 h) and, although not licensed for use in the horse, has obvious potential as a long-acting analgesic to provide intraoperative and postoperative analgesia for surgery of the lower limbs and head. It is more cardiotoxic than lidocaine in humans and dogs, but

its use in horses is not well documented. Ropivacaine, the dextrorotatory isomer of bupivacaine, is not licensed in horses but is associated with a lower degree of cardiotoxicity than bupivacaine and greater selectivity for C-nociceptor fibers, combined with a prolonged duration of action.

There are numerous routes of administration of local anesthetic agents. In addition to **local infiltration** and **splash blocks** of surgical sites, **intra-articular** (IA) injection of local anesthetics provides analgesia during articular surgery. **Epidural injection** with a local anesthetic will provide analgesia of the tail, perineum, rectum and vagina, but care must be taken to avoid overdosage and therefore hindlimb incoordination and ataxia. Local anesthetic preparations of the above named compounds without preservative are marketed for epidural use (*q.v.*). Reported doses of local anesthetics used for effective extradural perineal analgesia with an acceptable degree of hindlimb ataxia are 0.35 mg/kg lidocaine (60–90 min of analgesia), 0.06 mg/kg hyperbaric bupivacaine, and 0.1 mg/kg 0.5% ropivacaine.

Recently, **lidocaine** has been administered by **controlled-rate infusion** (2 mg/kg very slow bolus followed by 50 µg/kg/min IV infusion) to provide effective intraoperative analgesia. Intravenous infusion of lidocaine is believed to produce analgesia through central antagonism of specific sodium channels involved in central sensitization of nociceptive transmission. During colic surgery, it is postulated that IV lidocaine infusion will also produce useful prokinetic effects. Given the potential for cardiotoxicity, it is imperative that cardiovascular performance is closely monitored during lidocaine infusion.

For the use of **non-steroidal anti-inflammatory** drugs as analgesics, see below (*q.v.*).

CLINICAL PAIN AND CHOICE OF ANALGESIC DRUG

Analgesia may be required in horses to control acute or chronic **pain**, or acute exacerbations of chronic conditions. The acute pain associated with colic (*q.v.*) can be particularly difficult to control effectively while chronically painful conditions (e.g. navicular disease) can present long-term therapeutic problems due to drug toxicity. The acutely laminitic pony (*q.v.*) presents as an urgent case with a potential long-term need for analgesics.

Colic

Horses suffering from colic (*q.v.*) may vary widely in their behavior depending on the precipitating cause of their abdominal pain. Mild to moderate pain may respond well to a NSAID such as **flunixin** (1 mg/kg IV), although the implications of using such a long-acting drug make an accurate clinical diagnosis a prerequisite.

Butorphanol (0.05–0.1 mg/kg IV) may produce reasonable but relatively short-lived (2 h) analgesia in these animals. **Pethidine** (2 mg/kg IM) is particularly useful in horses with spasmodic colic due to its antispasmodic action, however its effects, while rapid in onset, are short lived (30–60 min). **Morphine** has a slow onset time and so for a rapid, reliable effect it is recommended that either **xylazine** (0.5–1 mg/kg) or **detomidine** (10–20 µg/kg) be used, although the cardiovascular effects of these agents must be borne in mind.

Should IV injection prove difficult due to **handling problems**, detomidine (20–30 µg/kg) can be administered IM in a small volume. Both drugs have the advantage of being relatively short acting (xylazine 30–45 min, detomidine 45–90 min) and so the horse's condition can be reassessed frequently. The sedative action of these drugs may be useful when animals have to be transported to a surgical center, provided doses at the low end of the quoted range are used. High doses cause ataxia.

Acute laminitis

The provision of analgesia to horses and ponies suffering from acute, sub-acute or chronic laminitis (*q.v.*) is vital and yet there is much controversy over the best choice of drugs. The optimal approach is provision of multimodal analgesia combined with **therapeutic farriery** and non-pharmacologic strategies (rest, careful nutrition, cryotherapy, hosing the feet, deep bedding).

Complete pain relief can be provided by the use of **nerve blocks** (*q.v.*) with a long-acting drug such as **bupivacaine**. However, many equine clinicians consider the complete abolition of pain to be contraindicated, as movement may aggravate the mechanical separation of laminae within the hoof. Parenteral therapy with a NSAID such as **flunixin** appears to afford a good degree of relief lasting up to 12 h. Parenteral therapy can be continued for 2–3 days until the acute phase has subsided, the animal then being maintained on an oral NSAID. Care should be taken to avoid toxicity and the manufacturer's maximum recommended duration of therapy with an NSAID should not be exceeded.

The use of other parenteral analgesics, such as the **opioids**, has not been well documented. The prolonged duration of action of methadone (relative to other opioids) may make it a useful agent in the acute condition, although caution with dosing should be exercised in case of inducing locomotor stimulation. **Fentanyl patches** have recently been described as potentially useful for medium-term therapy for acute/subacute patients. α_2 -Adrenoceptor agonists, which may cause peripheral vasoconstriction, would be detrimental to these animals and in addition would necessitate frequent administration. Vasoactive drugs (acepromazine, isoxsuprine) may indirectly reduce pain but their success remains controversial.

Trauma

Following trauma, individual horses may display variable behavior patterns. An animal displaying **violent behavior** may need to be sedated rapidly to avoid injury to itself and to its handlers. **Xylazine** (0.5 mg/kg, IV), **detomidine** (10 µg/kg IV; 20 µg/kg IM) or romifidine (0.07–0.1 mg/kg, IV; 0.2 mg/kg IM) is useful in providing both sedation and analgesia while the extent and severity of the trauma are assessed. The cardiovascular effects of these drugs must be borne in mind, particularly where hemorrhage has occurred. Combinations of α_2 -agonists and opioids enhance the degree of analgesia and chemical restraint. Useful combinations include **romifidine** (0.07–0.1 mg/kg, IV) with **morphine** (0.12–0.15 mg/kg, IV) or **detomidine** (10 µg/kg, IV) and **butorphanol** (0.02–0.05 mg/kg IV).

If the horse is quiet, an opioid alone may be sufficient to permit close examination or transport of the animal, although doses of these drugs should be carefully chosen in order to avoid stimulating locomotor activity. **Regional anesthesia** (e.g. nerve blocks around the head and limbs, or epidural block) (*q.v.*) may be helpful in permitting examination and care of a wound or traumatized area. The choice of local anesthetic will depend on the desired duration of action.

PERIOPERATIVE ANALGESIA

Preoperative use of analgesic drugs

Routine preemptive and multimodal administration of several types of analgesic drugs (NSAIDs, opioids, α_2 -agonists, local anesthetics, ketamine, nitrous oxide) through various routes of administration (systemic, extradural, local infiltration, intra-articular administration) is recommended in horses suffering from painful conditions (e.g. fractures).

Prior to induction of anesthesia, combination of an opioid analgesic drug with a sedative or tranquilizer will enhance the degree of sedation obtained, thus facilitating induction of anesthesia and reducing anesthetic requirements intraoperatively. **Butorphanol** (0.05 mg/kg IV), **methadone** (0.05–0.1 mg/kg IV) or **morphine** (0.05 mg/kg IV) may be incorporated with the premedicant.

Intraoperative use of analgesic drugs

Judicious use of analgesic drugs **intraoperatively** provides easier control of depth of anesthesia in all species. However, reluctance is often experienced with the application of this concept in horses. Clinical experience with opioids used intraoperatively in the horse suggests that, at the doses recommended, cardiovascular effects and respiratory effects are minimal and there is no effect on the quality of recovery.

Morphine may be administered perioperatively at 0.12–0.15 mg/kg (IV). **Pethidine** may be injected IM (1–2 mg/kg) just after induction of anesthesia (not IV) and has a rapid onset of action (within 10 min), although the clinical effect may last only 1–1.5 h. The analgesic effect of opioids given intraoperatively in horses has proved difficult to quantify since they do not appear significantly to reduce the dose of inhalational agent required to maintain anesthesia.

Ketamine has been used in low doses (0.1–0.5 mg/kg IV) to provide intraoperative analgesia in horses anesthetized with **halothane** (*q.v.*). It has little effect on cardiorespiratory parameters at these doses and rapidly reduces responses to surgical stimuli. The total dose used intraoperatively should remain less than 1 mg/kg, and ketamine should not be used within 30 min of the end of anesthesia to avoid potential excitatory effects during the recovery period.

Local nerve blocks (*q.v.*) are very useful in providing intraoperative analgesia in the horse. Blocks such as the high palmar nerve block, for surgery below the fetlock, reduce the requirement for deep planes of anesthesia and, if **bupivacaine** is used, provide analgesia during the recovery period. Loss of

any motor function appears to be clinically unimportant in influencing the recovery. Intra-articular injection of lidocaine (2 mg/kg) or bupivacaine (1 mg/kg) also provides highly effective analgesia for arthroscopic and other articular procedures.

Injection of lidocaine (20 mL, 2% solution) into the testes or spermatic cord (avoiding the spermatic artery and vein) improves the quality of anesthesia for castration (*q.v.*), as does SC infiltration of lidocaine around the incision site, reducing the requirement for incremental doses of IV anesthetic agents.

EXTRADURAL ANALGESIA (See Table 4.6)

Caudal epidural anesthesia is a relatively simple technique that can be used to facilitate surgery and analgesia of the tail, perineum, rectum, vulva, vagina, urethra and bladder. The technique is best performed in the standing horse.

Many analgesic agents have been effectively administered by **extradural injection** including lidocaine, bupivacaine, ropivacaine, morphine, methadone, pethidine, ketamine, detomidine, xylazine, medetomidine and tramadol. A combination of agents administered extradurally achieves synergistic long-lasting analgesia but may enhance the likelihood of ataxia and recumbency.

The volume of extradural injection depends on body weight and the desired degree of **cranial spread**. A total injection volume of 4–8 mL has been described as adequate for **perineal analgesia** in a 500 kg horse, while 10–15 mL is indicated for further cranial spread, but with greater risk of hindlimb ataxia.

Extradural catheterization (through the caudal extradural space or occasionally through the lumbosacral space into the sacral extradural space) facilitates prolonged highly effective analgesia. Commercial kits for extradural catheterization are widely available; it is recommended that a 17/18 G 7.5 cm **Tuohy needle** be used rather than a spinal needle for greater ease of successful catheterization, followed by insertion of a 19–20 G extradural catheter, advanced usually 2–4 cm (no more than 30 cm) from the cranial tip to achieve effective analgesia. **Strict asepsis** is mandatory.

Potential side effects of extradural catheterization include **sedation** associated with significant systemic absorption of drugs (particularly likely with highly lipophilic drugs such as medetomidine and butorphanol); recumbency associated with relative drug overdose; cardiovascular effects associated with systemic absorption of significant doses of α_2 -agonists; localized sweating and neurotoxicity (not reported clinically). However, risks of these side effects are relatively low and the significant benefits of optimal analgesia associated with extradural analgesia warrant its consideration as a routine means of analgesia provision.

POSTOPERATIVE ANALGESIA

Postoperatively, the same principles of multimodal analgesia apply. An additional dose of an opioid and NSAID drug may be given at the end of surgery to enhance immediate postoperative analgesia with minimal effects on recovery.

It is vital to remember that horses suffering **severe postsurgical pain** are likely to have recoveries of poor quality if their pain is not attenuated. Low doses of **xylazine** (0.1–0.2 mg/kg), **detomidine** (5–8 μ g/kg) or medetomidine

(3 µg/kg) may be used IV or IM at the end of surgery to provide short-term analgesia and sedation during the recovery period.

Of the NSAIDs available for use in the horse, **flunixin** (1 mg/kg IV) and **carprofen** (0.7 mg/kg IV) are useful to control **acute postoperative pain**, although information on their use in this situation is scanty. Unlike many of the other analgesics, they have no observable effects on the CNS and therefore should not adversely affect the recovery period. The efficacy of these drugs as intraoperative analgesics has yet to be quantified. NSAIDs have potential nephrotoxic effects, which could be exacerbated in hypotensive or hypovolemic anesthetized horses, and care should be taken to ensure good hydration.

The local anesthetics are also useful in the postoperative period, but specific nerve blocks must be done before the end of anesthesia.

NON-STEROIDAL ANTI-INFLAMMATORY DRUGS

INTRODUCTION

Microbiologic, chemical or physical injury to tissues causes either necrosis or an inflammatory response. The latter may be defined as the response of the living microcirculation and its contents to injury.

The initial phase of acute inflammation is characterized by the **cardinal signs** of heat, redness, pain, swelling and loss of function; the underlying microcirculatory changes comprise arteriolar vasodilatation, increased microvascular permeability (resulting in local edema) and the extravascular accumulation of leukocytes. These changes are **protective** in that they normally lead to isolation and destruction of the injurious stimulus and, in the resolution phase of acute inflammation, to restoration of normal tissue structure and function. If the stimulus persists, however, the inflammation becomes chronic and tissue destruction and fibrous tissue formation ensue.

These changes are attributable to the release from storage sites or the de novo synthesis of a wide range of chemical mediators and modulators of the inflammatory response. The complexity of the response is reflected in the large numbers of **mediators** involved, their diverse actions and interactions (one mediator modulating, enhancing or suppressing the actions of another), and the fact that each produces only some of the features of the inflammatory reaction. Mediators may be released from resident tissue cells, from infiltrating leukocytes and other blood cells, e.g. platelets, or from precursors in the plasma. A simplified account of the identity and roles of inflammatory mediators is presented in Table 4.7.

Anti-inflammatory drugs are used extensively to **suppress** the pain, erythema, edema and tissue destruction of acute and chronic inflammatory conditions. In general, available drugs at clinical dose rates suppress but do not abolish components of the inflammatory reaction, thereby providing clinical benefit. Their mode of action is often only partially understood, even in the case of well-known and extensively used agents such as corticosteroids and NSAIDs. However, it is believed that all anti-inflammatory drugs act by preventing the release, blocking the synthesis or inhibiting the actions of inflammatory mediators and modulators.

Table 4.7 Mediators and modulators of inflammation

Mediator/modulator	Inflammatory properties
Histamine	A basic amine released from mast cells; produces vasodilatation, increased permeability of small venules and pain
Bradykinin and tachykinins	Small peptides synthesized de novo increase small venule permeability and cause pain
Eicosanoids (prostaglandins [PGs], leukotrienes [LTs], monohydroxyeicosatetraenoic acids [HETES] and lipoxins)	<p>Polyunsaturated fatty acids derived from cell membrane phospholipid by activation of phospholipase A₂.</p> <p>(a) PGE₂: prolonged arteriolar vasodilatation and potentiation of increased vascular permeability and pain induced by other mediators; usually the predominant prostanoid in equine acute inflammatory exudates; possibly chemoattractant for equine leukocytes</p> <p>(b) PGI₂: similar properties to PGE₂ with a shorter duration of action; also inhibits platelet aggregation</p> <p>(c) LTB₄: chemoattractant for polymorphonuclear leukocytes; increases permeability of small venules (weak)</p> <p>(d) LTC₄, LTD₄: increase microvascular permeability; may be important mediators in allergic airways disease, causing bronchoconstriction, bronchial hyperresponsiveness and increased mucus secretion</p> <p>(e) 5-, 12- and 15-HETE: cause vasodilation (weak) and leukocyte migration</p> <p>(f) Lipoxins: stimulate polymorphonuclear leukocytes to generate superoxide radicals and release lysosomal enzymes, also anti-inflammatory actions</p>
Platelet-activating factor (PAF)	Analogue of phosphatidylcholine, derived from cell membrane phospholipid, causing vasodilatation, increased vascular permeability and chemotaxis of polymorphonuclear and mononuclear leukocytes, platelet and neutrophil activation, bronchoconstriction and bronchial hyperresponsiveness
Complement system	Derived from precursor proteins in plasma. Several components (e.g. C3a, C5a) possess pro-inflammatory properties, e.g. vasodilatation, increased vascular permeability, leukocyte chemotaxis and mast cell degranulation
Nitric oxide	Derived from endothelium, macrophages: potent vasodilator, potentially implicated in several components of acute inflammation
Cytokines (e.g. interleukins (IL), tissue necrosis factor [TNF α])	Many mediators possessing either pro- or anti-inflammatory properties released by leukocytes; pro-inflammatory cytokines possess chemotactic activity, mitogenic and pyretic properties; stimulate production of collagenase, stromelysin and PGE ₂ by synovial cells, chondrocytes and dermal fibroblasts (IL-1); involved in arthritides and the pyretic response to infection
Chemokines (e.g. CXCL8, CCL2, CCL5, CCL11)	A super family comprising many mediators with pro-inflammatory or homeostatic properties, controlling the selective recruitment of leukocytes.

ANTI-INFLAMMATORY DRUG CLASSIFICATION

Given the complexity of inflammatory processes, with the involvement of many mediators and the synergistic and antagonistic interactions between them, it is not surprising that those anti-inflammatory drugs with selective activity against a single mediator (e.g. antihistamines) possess only limited clinical efficacy.

Table 4.8 Classification of anti-inflammatory and anti-arthritic drugs

Class	Examples
1. H ₁ receptor antagonists	Chlorphenamine, clemastine, cyproheptadine
2. Glucocorticoids	Prednisolone, dexamethasone, betamethasone, triamcinolone
3. Non-steroidal anti-inflammatory drugs (NSAIDs)	Aspirin, phenylbutazone, flunixin, ketoprofen, carprofen, vedaprofen, nimesulide, meloxicam, eltenac, dipyron, isopyrin
4. 5-lipoxygenase inhibitors	Zileuton
5. Cysteinyl leukotriene receptor antagonists	Montelukast, zafirlukast
6. Dual cyclo-oxygenase/5-lipoxygenase inhibitors	Tepoxalin
7. Platelet-activating factor (PAF) receptor antagonists	Bepafant, lexipafant
8. Phosphodiesterase inhibitors	Theophylline, roflumilast, cilomilast
9. Disease-modifying agents	Penicillamine, levamisole, gold salts
10. Cytotoxic immunosuppressants	Chlorambucil, azathioprine, ciclosporin
11. Free radical scavengers	Copper, orgotein, some NSAIDs
12. Chondroprotective agents	Polysulfated glycosaminoglycan (PSGAG), pentosan polysulfate, hyaluronic acid, possibly some NSAIDs

Table 4.9 Structural classification of NSAIDs

Carboxylic acids		Enolic acids		Sulfonamide derivatives
Subgroup	Examples	Subgroup	Examples	Examples
Salicylates	Acetylsalicylic acid Sodium salicylate	Pyrazolones	Phenylbutazone Dipyron Isopyrin Oxyphenbutazone	Nimesulide
Quinolines	Cinchophen	Oxicams	Meloxicam Piroxicam	
2-Aryl-propionic acids	Carprofen Ibuprofen Ketoprofen Vedaprofen Naproxen			
Anthranilic acids	Flunixin Meclofenamic acid Tolfenamic acid			
Indolines	Indometacin Eltenac Tepoxalin			

Table 4.8 presents a classification of drugs that either possess anti-inflammatory properties or have been used to treat various joint diseases. It is not comprehensive. Many of these agents are used infrequently or not at all in equine medicine (groups 1, 4, 5, 6, 7, 10). This account will therefore deal principally with drugs in groups 3 (NSAIDs), 8 and 11. Group 2 agents (corticosteroids) are dealt with elsewhere (*q.v.*).

Non-steroidal anti-inflammatory drugs are weak organic acids that can be subdivided into three main groups on the basis of chemical structure, carboxylic ($R-COOH$) and enolic ($R-COH$) acids and sulfonamides. Further subdivisions, also on the basis of chemical structure, can be made (Table 4.9). This classification is of limited value to the extent that it does not signify major differences in pharmacologic activity, as most NSAIDs have the same spectrum of therapeutic actions and side effects, regardless of grouping. There are, however, major pharmacokinetic differences and some pharmacodynamic differences between individual drugs.

PHARMACOLOGIC ACTIONS OF NSAIDS

All NSAIDs inhibit **cyclo-oxygenase (COX)**, an enzyme that converts the 20-carbon unsaturated fatty acid, arachidonic acid, to the cyclic endoperoxide prostaglandins (PG), PGG_2 and PGH_2 . Further enzyme action leads to the formation of several **eicosanoids**, some of which, like PGE_2 , are important inflammatory mediators or modulators. Thus, PGE_2 synergizes with mediators such as histamine, bradykinin and platelet-activating factor (PAF) to enhance their pain- and edema-inducing effects. However, recent evidence indicates that COX generates other prostaglandins with anti-inflammatory properties in the resolution phase of acute inflammation.

Inhibition of COX is believed to be the principal mechanism of action of NSAIDs. However, anti-inflammatory and analgesic potency does not always parallel potency as COX inhibitors; **carprofen**, for example, produces only moderate inhibition of this enzyme in the horse and dog at clinical dose rates and may act partially through other mechanisms. In vitro studies on chondrocytes and cartilage explants in both the horse and dog have shown that carprofen stimulates the synthesis and reduces the breakdown of the high molecular weight cartilage matrix molecules, **proteoglycans**. Carprofen also inhibits activation of the transcription factor $NF\kappa B$ and suppresses release of the cytokine, IL-6. It is unclear whether these actions, demonstrated in vitro, contribute to the therapeutic effects of carprofen in vivo.

Moreover, additional actions of NSAIDs on other enzymes in the arachidonic acid pathway (and on unrelated enzymes) have been described. Thus, **phenylbutazone** inhibits a more distal enzyme, endoperoxide isomerase, and scavenges free radicals, and some fenamic acid NSAIDs inhibit some actions of prostaglandins as well as blocking their synthesis. Higher than therapeutic dose levels, and even clinical dose rates of some NSAIDs, may also inhibit 5-lipoxygenase (5-LO) to suppress the synthesis of **leukotrienes** and related compounds. **Tepoxalin** has been introduced into canine medicine on the basis of its dual inhibition of COX and 5-LO.

Recognition that COX exists in at least two and possibly three **isoforms** (COX-1, COX-2 and COX-3) has stimulated major additional interest. COX-1

is a constitutive enzyme, responsible for **housekeeping functions** including blood clotting and protective actions in the GIT and kidney. It may also contribute to the synthesis of prostaglandins at sites of inflammation. COX-2, like COX-1, is constitutive in some tissues, including the kidney and CNS, but it is primarily an **inducible enzyme** formed at sites of tissue damage and it is responsible for most or all of the eicosanoids generated by such damage.

Commencing in 1990, with the discovery of the separate COX-2 and COX-1 isoforms, there has been an intensive search for novel NSAIDs that **selectively inhibit COX-2**. Recent years have witnessed the introduction of several such agents in the “coxib” group, e.g. rofecoxib (now withdrawn), celecoxib, valdecoxib, etoricoxib, into human medicine. The coxibs have moderate to high selectivity for COX-2 inhibition and they have been shown to have similar efficacy but lower toxicity than classical NSAIDs, the majority of which are now recognized to be non-selective COX inhibitors. Two drugs of this class, **deracoxib** and **firocoxib** have been introduced into canine medicine but no coxib has yet been licensed for equine use. The discovery in dog brain of a splice variant of COX-1, COX-3, has added another dimension. It is possible that paracetamol and some of the older drugs used in equine medicine, such as dipyrone and isopyrin, are partially selective for COX-3, and this might explain the relatively high GIT tolerance of paracetamol.

On the basis of limited evidence the following tentative conclusions concerning NSAID selectivity for COX isoforms in the horse may be drawn: phenylbutazone, flunixin, and ketoprofen are non-selective; carprofen and meloxicam are non-selective or possibly slightly preferential for COX-2; and vedaprofen may be COX-1 selective. To what extent such differences in pharmacologic actions at the molecular level contribute to the clinical efficacy and toxicity of NSAIDs is unclear.

Most NSAIDs possess three classes of clinical action at tissue and whole animal levels; a **local anti-inflammatory** and **analgesic** action and **central antipyretic** and **analgesic** effects (Table 4.10). Differences between drugs have been reported for the three types of activity. Thus, **phenylbutazone** is effective as a **peripheral anti-inflammatory agent** but may be a weak central analgesic, whereas other agents in the same subgroup, isopyrin and dipyrone, are effective analgesics but relatively weak anti-inflammatory agents. These differences may be explained by differential activity against COX isoenzymes, as indicated above.

Differences in COX structure may also explain species differences in plasma concentrations of NSAIDs required for efficacy. For example, plasma phenylbutazone concentrations required in humans for the treatment of inflammatory joint diseases are of the order of 100–150 µg/mL, while therapeutic concentrations in the horse are in the range of 10–20 µg/mL. Concentrations regarded as therapeutic in man are lethal to the horse. Similarly, much *higher* plasma concentrations of phenylbutazone in the cow produce much *smaller* effects at both molecular and clinical levels than in the horse, indicating a major difference in potency between these two species.

As well as the anti-inflammatory, analgesic and antipyretic actions of NSAIDs, other properties have been identified and these provide the basis for further therapeutic uses. Thus, their **anti-endotoxemic** and **antithrombotic** actions are well recognized (*q.v.*).

Table 4.10 Pharmacologic actions, therapeutic uses and toxic effects of NSAIDs

Organ/system	
Pharmacologic actions and therapeutic uses	
CNS	Antipyretic: reduction of body temperature in fever but not in normothermic animals Analgesic; relief of pain but activity generally weaker than morphine-like drugs
Peripheral sites	Anti-inflammatory (antiedemic) Analgesic Antithrombotic Anti-endotoxemic
Toxic effects	
Gastrointestinal tract	Irritation and potentially ulcerogenic; possibly leading to blood or plasma loss (enteropathy) and melena
Kidney	Nephropathy: tubular nephritis, renal papillary necrosis or acute renal failure
Liver	Cholestatic and parenchymal toxicity
Blood and cardiovascular system	Small vein phlebopathy; various blood cell dyscrasias including aplastic and hemolytic anemias and agranulocytosis; methemoglobinemia, hypoprothrombinemia and prolongation of bleeding time
Fetus	Possible embryopathic, teratogenic effects if administered during period of organogenesis; delayed gestation at term
Skin	Urticaria, erythema
CNS	Stimulation, muscle tremor, convulsions (at high dose rates)

SIDE EFFECTS AND TOXICITY OF NSAIDs

Eicosanoids produced from the COX arm of the arachidonic acid cascade play important roles in a number of physiologic processes. It is therefore not surprising that a wide range of side effects have been described (see Table 4.10). These may be common and are normally dose related (e.g. effects on the GIT) or they may be idiosyncratic, arising only rarely and not necessarily related to administered dose (e.g. aplastic anemia in human subjects). Other side effects may become apparent only in the presence of predisposing factors; for example, clinical dose rates of most NSAIDs are not normally renotoxic but in the presence of **hypotension** or **hypovolemia**, intrarenal release of the vasodilator prostaglandins PGE₂ and PGI₂ maintains renal blood flow and glomerular filtration rate (renal autoregulation). In these circumstances, blockade of prostaglandin synthesis by NSAIDs can lead to **renal vasoconstriction** and **acute renotoxicity**.

In the horse, phenylbutazone and flunixin, probably acting through the latter mechanism, can produce **renal papillary necrosis** at clinical dose rates when animals are deprived of water, but not in adequately hydrated animals. High doses of NSAIDs may cause **tubular nephritis**. The fluid retention and edema reported with some NSAIDs in humans seems to be uncommon in animals.

To varying degrees, all NSAIDs produce **GIT irritation** and **ulceration** and, in the horse, this has been well described for phenylbutazone, leading to a **plasma protein-losing enteropathy** and, with high doses, hemoconcentration, hypovolemic shock and death. The horse may be particularly susceptible to this action of **phenylbutazone**, as doses only moderately in excess of

recommended dose rates are **ulcerogenic** and lesions can potentially occur throughout the GIT after IV as well as oral dosing.

Intravenous administration of NSAIDs leads to exposure of the GIT mucosa to the drug through its blood supply; with oral dosing exposure may arise in the same way and also through the presence of drug in the lumen of the GIT. The likely cause of toxicity is inhibition of synthesis of the vasodilator local hormone, **prostacyclin** (PGI_2), leading to ischemia and hypoxia and, in the stomach, inhibition of gastroprotection by loss of the action of PGE_2 to decrease parietal cell hydrogen ion and to enhance mucus and bicarbonate ion secretion. Experimentally, administration of both PGE_2 and **misoprostol**, a stable analogue of PGE_2 , protects against the ulcerogenic action of NSAIDs.

Other means of reducing NSAID toxicity have been sought. Slow-release and enteric-coated formulations have been developed and water-soluble forms of aspirin (e.g. the lysine salt) are available but these are rarely used in equine medicine. Also of potential interest regarding efficacy–toxicity ratios is the introduction of both coxibs and **tepoxalin**—this drug interestingly being selective for COX-1 rather than COX-2—into human and canine medicine. The nitroso NSAIDs or CINODs (cyclo-oxygenase inhibiting nitric oxide donors) are also of potential interest; these are derivatives of classical NSAIDs, such as aspirin, indometacin and phenylbutazone, which are non-selective for COX isoforms, that are converted in vivo to the parent compounds and nitric oxide. The latter, either through a local vasodilator action or through inhibition of leukocyte attachment to vascular endothelium, seems to be mucosa protective, leading to improved efficacy–toxicity ratios. No drugs of these classes (coxibs, dual inhibitors and CINODs) are yet available for equine use.

Laboratory animal studies have indicated that a wide range of factors, including species, sex, age, nutritional status and extent of biliary secretion may influence **NSAID ulcerogenicity**, but whether they apply in the horse is unknown. Some studies in the horse have suggested that pony breeds may be more susceptible to GIT damage from phenylbutazone than larger breeds, but this has not been substantiated in other equine studies. Laboratory animal and canine studies suggest that **carprofen**, which produces only moderate COX inhibition in the horse, is much less ulcerogenic than most other NSAIDs and this seems to apply also to the horse, as it has a wider margin of safety than many other NSAIDs in this species. However, dose–effect relationships of NSAIDs for the ulcerogenic action have not been established in the horse; only phenylbutazone has been studied extensively.

Many studies over the last 25 yr have reported on the **toxicity of phenylbutazone** in the horse. Side effects include anorexia, depression, colic, hypoproteinaemia, diarrhea, melena, GIT erosions and ulcers, weight loss, ventral abdominal edema, petechial hemorrhages of mucous membranes, renal papillary necrosis and hepatotoxicity. Such effects, possibly leading to death, may occur with doses in excess of 8.8 mg/kg/day. It is therefore most important to keep the **daily maintenance dose** of this drug at 4.4 mg/kg or less.

Both cholestatic and parenchymal hepatotoxicity have been described in horses receiving phenylbutazone and the latter effect seems to be **dose related**. As most NSAIDs are extensively metabolized in the liver, drug-induced damage to this organ can potentially lead to a vicious cycle of cumulation and

further toxicity. **Blood dyscrasias** have also been reported in horses receiving high doses of phenylbutazone but such changes, as far as is known, are uncommon with clinical dose rates. Clinical dose rates of flunixin and meclofenamate, administered over several days, reduce plasma protein concentration by 15–20% and this may indicate toxicity to the GIT mucosal cells and/or the kidney and/or the liver.

High doses of NSAIDs inhibit platelet aggregation through inhibition of synthesis of the pro-aggregatory eicosanoid, **thromboxane (TX) A₂**, and this may be associated with internal or external hemorrhage through **impaired clotting mechanisms** (*q.v.*). This is particularly likely with **aspirin**, as this drug, alone amongst NSAIDs, inhibits COX-1 **irreversibly** and hence for the lifespan of platelets. This can be advantageous if an anti-aggregatory action is required, as platelets can be targeted by low doses of aspirin while minimizing side effects on other tissues.

In summary, most NSAIDs currently licensed for the horse are non-selective COX inhibitors, or even selective for COX-1. The efficacy–toxicity ratios are low (carprofen seems to be the main exception), and adherence to recommended dose rates is important if side effects are to be minimized.

PHARMACOKINETICS AND ADMINISTRATION OF NSAIDs

Route of administration

The usual route of administration of NSAIDs is oral, but several drugs are available as solutions for IV dosing (phenylbutazone, dipyrone, isopyrin, flunixin). Some of these are used as concentrated solutions (as high as 20%) which are alkaline (sodium salts) and therefore very irritant to tissues when injected **perivascularly**. Flunixin, which is used as the meglumine salt, has been administered IM to horses. Absorption is very rapid and this drug is less irritant than some other NSAIDs, although IM dosing is not recommended in the product literature.

Acid–base conditions

The pH of fluid in the GIT is usually more acid than plasma (pH 7.35–7.40) and in the equine stomach pH may range from 1.5 to 6.5; **pH usually increases after feeding**. Acid gastric pH **promotes the absorption** of NSAIDs by the mechanism of ion trapping because, as weak organic acids, these drugs are less ionized than in plasma and therefore well absorbed. However, in the horse the stomach is small and this limits absorption from this site. Other factors also influence absorption. Low solubility in acidic conditions, of aspirin for example, can cause precipitation in the stomach, which slows absorption and may increase local irritation.

Feed and formulation effects

Diet may be very important in horses, as some NSAIDs **bind to hay** and other feeds (e.g. pony nuts) of high fiber/cellulose content. This has been demonstrated for phenylbutazone, meclofenamate and flunixin, the degree of binding decreasing in that order (99% for phenylbutazone and 70% for flunixin). This

may explain the **considerable delays** and marked inter-animal variations in phenylbutazone absorption that have been reported after oral dosing in horses, with the time to maximal concentrations in plasma delayed for as long as 18 h after administration to animals with free access to feed.

Restricted access to feed reduces, but does not abolish, the delay in absorption of phenylbutazone. Access to feed also delays absorption of orally administered flunixin in horses, but the effect is less pronounced than with phenylbutazone and peak concentrations in plasma are achieved more rapidly with the former drug in circumstances of both free and restricted access to feed. With both drugs, multiple peaks in the plasma concentration time profile occur when horses have free access to feed at the time of dosing. Binding to hay, and subsequent release of the drug by fermentative digestion in the large intestine of the horse, has been proposed as a basis both for the absorption profile and the ulcerogenic effect of phenylbutazone in the distal regions of the gut.

When racemic (rac)-ketoprofen (a 50:50 mixture of the two enantiomers) was formulated in an oil-based product the bioavailability of both enantiomers was <5%, both in the presence and absence of feed, whereas administration of the drug in hard gelatin capsules gave a bioavailability of 50%. An episodic absorption pattern occurs with phenylbutazone (even when administered orally after withholding feed) when the drug is formulated in an oil-based paste.

In spite of these factors, absorption of NSAIDs is generally good, bioavailability of most drugs exceeding 60%, irrespective of feeding schedules. Veterinarians providing advice to owners on the use of NSAIDs in relation to competitive equine sports should, however, be aware of the **delayed and variable absorption patterns** of these drugs. Many national and international racing and eventing authorities have banned the use of these drugs but in some cases drugs are permitted provided plasma concentrations do not exceed certain limits (*q.v.*).

Elimination half-life

Marked inter-drug and inter-species differences in the elimination half-life of NSAIDs have been reported. Selected examples are presented in Table 4.11. Significant differences can also occur with the two enantiomers of a single compound. This may be especially important when the drug product is licensed as the racemic mixture of the two enantiomers (as is the case for **carprofen**, **ketoprofen** and **vedaprofen**), as the enantiomers have major differences in potency, the *S*(+) being more active than the *R*(-) enantiomer in laboratory animal and in vitro studies. Potency ratios (COX-1–COX-2) may be 20:1 or higher.

In the horse, the *S*(+) enantiomer of ketoprofen is cleared more slowly from plasma than the *R*(-) enantiomer, while the opposite applies to carprofen and vedaprofen. In spite of the greater persistence in plasma of the (presumed) less active enantiomer of the latter two compounds, the racemic mixtures have been shown to possess analgesic activity.

Species and breed differences in pharmacokinetics

It is important to recognize that marked **species differences** in NSAID pharmacokinetics exist. Some examples are presented in Table 4.11. In view of

Table 4.11 Elimination half-life ($t_{1/2\beta}$) of NSAIDs (h)

	Horse	Cow	Dog
Aspirin	0.2	—	—
Salicylate	1–3 ¹	0.5	9
Flunixin	2	8	4
Naproxen	5	—	35–74 ²
Meclofenamic acid	1	—	—
Tolfenamic acid	1	—	—
Phenylbutazone	5–8 ³	37–60	3–6 ³
Meloxicam	3	13	12–36

¹ 1 h following administration of salicylate; 3 h following administration of aspirin.

² Breed dependent, longer in mongrels than beagles.

³ Possibly dose dependent, increasing with administered dose.

these differences, pharmacokinetic data generated in one species can **never be transposed** to another.

Related to the phenomenon of species differences in half-life is the observation of **breed differences**. This has been reported for **naproxen**, the half-life in beagles being approximately half that in mongrel dogs (see Table 4.11), but whether similar differences for this or other NSAIDs occur in different breeds of horse is not known.

Metabolite activity

The activity of most NSAIDs is attributable solely or primarily to the parent compounds, but in other cases active metabolites are formed. **Aspirin**, for example, is rapidly de-acetylated to **salicylate** and the half-life of aspirin in the horse is ≤ 10 min. Most of the activity of aspirin (except for the drug's antithrombotic action) is therefore due to **salicylate**. Salicylate elimination half-life was also found to be short in the horse following sodium salicylate administration (1 h) but was longer (3 h) after aspirin administration.

Another example of active metabolite formation is **oxyphenbutazone**, which is formed by hydroxylation of phenylbutazone. In laboratory animal studies, this compound has a similar potency to **phenylbutazone**. If this were applicable to the horse also, oxyphenbutazone would account for 20–25% of the pharmacologic activity of administered phenylbutazone.

Drug dosage

Dose-dependent pharmacokinetics, believed to be attributable to saturation of hepatic metabolizing enzymes, have been demonstrated, or proposed, for certain NSAIDs in some species, and can present difficulties in establishing dosing schedules that are effective and also safe. The relatively **narrow safety margin** of phenylbutazone in the horse may be due, in part, to increased half-life when doses are raised only moderately in excess of those recommended. This drug can normally be used safely over prolonged periods in most horses, provided doses are not increased above recommended levels.

Drug interactions

At least two types of **pharmacokinetic interaction** between NSAIDs are known (and many similar examples would no doubt be revealed by further investigations). When the pyrazolone NSAIDs **isopyrin** and **phenylbutazone** are administered in combination to the horse, the half-life for both drugs is **longer** than when they are administered separately. Administered dosage and duration of treatment with this drug combination product should be carefully controlled, as the metabolic interaction ensures that the drugs will be more than additive in clinical use and this may increase **toxicity** as well as enhancing efficacy.

Reduced plasma clearance of **phenylbutazone** has also been demonstrated in horses receiving **oxyphenbutazone**, **cimetidine** and **chloramphenicol**. The two latter drugs inhibit hepatic mixed function oxidase and therefore suppress or prevent the ring and side chain hydroxylation that normally occurs.

Protein binding

Almost all NSAIDs (aspirin/salicylate is exceptional) are **highly bound to plasma protein** (98% or greater) and this not only reduces urinary excretion and extravascular drug penetration, but also provides a theoretical basis for interaction with other protein-bound drugs of the same or differing classes.

Competition for protein binding sites can raise plasma concentrations of the free, and therefore active, drug. In practice, such interactions are unlikely. An often-quoted example is the use in combination of **phenylbutazone** and **warfarin** in the treatment of navicular disease (*q.v.*). Both drugs are highly bound to plasma protein, and displacement of warfarin by competition with phenylbutazone could lead to high “free” (and active) concentrations of warfarin in plasma, leading to **fatal hemorrhage**. In fact, available evidence suggests that the interaction between these drugs is due to inhibition of warfarin metabolism and not to plasma protein binding competition.

Age

In general, biotransformation is less efficient in young animals (<4 wk of age), and aged animals may also metabolize NSAIDs less effectively than young adults. Limited data in the horse indicate that plasma drug concentrations are higher in old than in young adult ponies following both IV and oral dosing with phenylbutazone. Reduced dosage and/or longer dosing intervals are therefore advisable in both old and very young horses.

Summary of pharmacokinetics

It is clear that many factors may influence NSAID pharmacokinetics and these should be borne in mind with clinical usage, because in some circumstances efficacy or safety may be compromised. Even when basic pharmacokinetic data are available, however, they cannot be used alone to set dosage schedules. This is partly because different plasma concentrations are likely to be needed for different therapeutic (analgesic, anti-inflammatory, antipyretic,

anti-endotoxemic, antithrombotic) responses, and partly because activity is commonly longer for NSAIDs than might be predicted from plasma clearance. It has been shown that phenylbutazone, flunixin, carprofen and vedaprofen (and potentially other NSAIDs highly bound to plasma protein) penetrate readily into, and are slowly cleared from, **inflammatory exudate**.

PHARMACOKINETIC–PHARMACODYNAMIC MODELLING OF NSAIDs

Pharmacokinetic–pharmacodynamic (PK–PD) modelling provides a means of deriving useful data on the action–effect–response relationships of NSAIDs. The principal *action* is inhibition of COX; the *effect* is to reduce the formation of pro-inflammatory prostaglandins; and the *response* is analgesia, antipyresis, etc.

At either or both inflammatory mediator (i.e. effect) and response levels, PK–PD modelling of NSAIDs, including phenylbutazone, flunixin, ketoprofen, vedaprofen and meloxicam, has provided numerical values for key pharmacodynamic parameters, expressing efficacy, potency and sensitivity of NSAID effects and responses. The data on effect have yielded useful insights into mechanism of action, while data on response have provided a major advance in the design of dosage schedules. For example, it is of interest that the **potency** of flunixin is approximately 40 times greater for prostaglandin inhibition than for clinical analgesic response, implying that a very high level of mediator inhibition (possibly 95% or greater) is required to achieve clinical responses. PK–PD modelling has further shown that, in an equine model of joint inflammation, the efficacy of flunixin in suppressing lameness is greater than that of phenylbutazone.

THERAPEUTIC USES OF NSAIDs

Analgesia and anti-inflammatory effects

Suppression of the pain associated with tissue damage is the major use for NSAIDs in equine medicine, including the acute inflammation associated with **traumatic injury**. Major indications of NSAIDs as analgesics also include all forms of **joint disease** and **pre- or postoperative** use.

The hyperalgesia-inducing mediator PGE₂ is present in detectable concentrations in approximately half of all **synovial fluid** samples harvested from horses with several forms of joint disease (the only exception when PGE₂ is not detectable being cases of **osteochoondrosis dissecans** [*q.v.*]).

The relief of signs of **lameness** by NSAIDs is probably explained therefore by inhibition of synthesis of PGE₂ and related compounds. NSAIDs may be administered IV at the commencement of therapy, while maintenance is usually provided by oral administration of powder (admixed with feed) or paste formulations.

In relation to **surgery**, NSAIDs are key drugs as analgesics, to control post-operative pain for all procedures and especially for the severe pain associated with orthopedic procedures. In addition, their potential anti-edematous action may prevent the swelling that can lead to wound breakdown.

The use of NSAIDs in the therapy of joint diseases (the arthritides) (*q.v.*) is based on their analgesic action. The common routes of administration are IV

for initiation of therapy and orally for maintenance. Occasionally, intra-articular (IA) injection has been used, although most parenteral NSAIDs are too irritant for this route to be used.

There is no convincing evidence to suggest that NSAIDs are “disease modifying”, i.e. they do not retard the **underlying pathologic process** of cartilage erosion. Indeed, there is some experimental evidence (the clinical significance of which is unclear) to indicate that some, but not all NSAIDs can **accelerate** the rate of cartilage loss, possibly by inhibiting the synthesis of new cartilage matrix. This has been shown both in tissue culture and in vivo for **salicylate**, but the action is not shared by all NSAIDs and a few, such as **carprofen**, have the opposite action, i.e. they enhance the synthesis of glycosaminoglycan molecules by chondrocytes and cartilage explants in tissue culture in the horse and dog. Also, in the horse, phenylbutazone has been shown to produce a small increase in proteoglycan synthesis in vitro but it reduces cartilage mass in vivo.

Laboratory animal studies have shown that NSAIDs can either retard or prevent fracture healing. This is an important consideration, but its relevance to clinical equine use remains to be determined. In view of these concerns, NSAIDs should not be withheld from animals in pain but they should be used judiciously.

Intravenous administration of solutions of NSAIDs, usually **dipyrone** (metamizole), **flunixin** or **phenylbutazone**, provides rapidly effective analgesia in equine patients with **spasmodic colic** (*q.v.*) and other sources of pain. However, the clinician must remain aware that the suppression of clinical signs by high-efficacy drugs such as flunixin may obscure diagnosis and mask progress of the condition.

Edema

Laboratory animal studies have shown that NSAIDs reduce edematous swelling and can decrease leukocyte infiltration into inflammatory sites. However, high doses are usually required for both effects and it is not clear whether clinically recommended doses of all NSAIDs currently in equine use reduce the swelling associated, for example, with surgery, although such claims have been made. Experimentally, suppression of edema in the horse has been demonstrated for carprofen.

Endotoxemia

NSAIDs such as flunixin and carprofen are used routinely in horses with endotoxemia. **Endotoxic shock** arises when the lipopolysaccharide (endotoxin) component of Gram-negative bacteria gains access to the circulation in cases of **colic** (*q.v.*).

Some of the life-threatening effects of endotoxin on cardiovascular and respiratory systems and some of the metabolic and gastrointestinal changes in the horse are suppressed or abolished by pre-treatment with NSAIDs in experimental circumstances. This presumably reflects the role of eicosanoids (such as PGE₂, PGI₂ and TXA₂) in mediating some of these changes. Treatment with NSAIDs, therefore, represents a rational approach to therapy for endotoxemia. However, their effectiveness in **established shock** (*q.v.*) is likely to be

significantly less than that provided by pre-treatment in experimental animals. It should also be noted that those effects of endotoxemia mediated by eicosanoids are likely to be due to both COX isoforms, so that the classical, non-selective NSAIDs should be more efficacious than the newer COX-2 selective drugs.

Fever

In fever, **endogenous pyrogens** such as interleukin-1 and other cytokines (*q.v.*) release PGE₂, which acts on the anterior hypothalamus to reset the thermoregulatory center. Inhibition of PGE₂ synthesis explains the antipyretic action of NSAIDs in infections associated with fever. Lowering of body temperature provides clinical relief but NSAIDs may sometimes **prolong** the course of viral diseases, since the production of interferons is enhanced when body temperature is raised. NSAIDs are not widely used in horses for their antipyretic action.

Antithrombotic actions

Aspirin irreversibly inhibits platelet COX-1, this action forming the basis for a further use—not shared by other NSAIDs at clinically recommended dose rates—**inhibition of thrombus formation**. The full potential uses of the antithrombotic action of aspirin in equine medicine have yet to be determined but some diseases of unknown etiology, involving thromboembolic and/or vasoconstrictor components, might benefit from the use of low dose aspirin. These diseases include disseminated intravascular coagulation, laminitis and navicular disease (*q.v.*).

CHONDROPROTECTIVE AGENTS

Compounds with unknown and possibly multifactorial mechanisms of action and various tissue extracts that may retard cartilage breakdown and promote new cartilage synthesis have been administered as chondroprotective (disease modifying) agents in veterinary medicine. Two compounds with established activity *in vitro* are **polysulfated glycosaminoglycan (PSGAG)** and **pentosan polysulfate** (*q.v.*). The latter is administered by intra-articular (IA) or IM injection in the therapy of traumatic and degenerative joint disease (*q.v.*) (but not in septic arthritis) in the horse.

PSGAG is a polymer of approximate MW 10000 Da. It is extracted from bovine tracheal tissue and, structurally, it is based on repeating units of hexosamine and hexuronic acid. Chemically, it is a sulfated molecule similar to heparin and the aggregated proteoglycan molecules that form cartilage matrix. **PSGAG binds to cartilage**, exhibiting especial affinity for osteoarthritic cartilage, leading to retardation of cartilage breakdown. Additionally, the synthesis of new matrix is enhanced. In contrast to steroids and NSAIDs, which provide only relief of signs in inflammatory conditions, PSGAG therapy may attenuate the degeneration of cartilage.

Various **pharmacologic actions** of PSGAG have been described, including inhibition of the clotting and complement cascades, inhibition of lipopolysaccharide-induced PGE₂ synthesis, reduced superoxide radical generation, delayed dedifferentiation of cultured chondrocytes, increased synthesis and decreased breakdown of hyaluronic acid, protection of chondrocytes from steroid-induced toxicity and inhibition of many lysosomal and non-lysosomal enzymes such as cathepsins, collagenase and metalloproteinases. Thus, at concentrations achievable in equine joints following IA injection, therapeutic doses of PSGAG inhibit stromelysin, an enzyme that breaks down cartilage matrix. This is the probable basis for the drug's therapeutic effects.

The side effects of chondroprotective agents seem to be minor; however in doses above the therapeutic range they inhibit clotting through their heparin-like actions. In addition, transient synovial effusion and arthralgia have been reported following IA administration of PSGAG in the horse. Aggravation of inflammation may therefore occur in the presence of synovitis, so that PSGAG is used primarily in subjects in which synovitis is slight or absent. Experimentally, PSGAG has been shown to facilitate the growth of a sub-infective dose of *Staphylococcus aureus* in equine carpal joints. Chondroprotective agents should not therefore be administered by the IA route in the presence of joint sepsis (*q.v.*), and some clinicians concomitantly administer an **aminoglycoside antibiotic** such as gentamicin when PSGAG is injected IA into non-infected joints.

Hyaluronic acid is a high molecular weight mucopolysaccharide. It is a normal constituent of connective tissue matrix and synovial fluid, produced by type B synoviocytes and chondrocytes. It accounts for the high viscosity of synovial fluid. In joint injury, the viscosity of synovial fluid decreases as the hyaluronic acid content falls, and depolymerization occurs. In healthy articular cartilage, hyaluronic acid is linked to the aggregated proteoglycan molecules to form the matrix. In the early stages of arthritis (*q.v.*), cartilage degradation occurs with the loss of proteoglycans and hyaluronate; only later is collagen depleted.

Intra-articular and IV administration of sodium hyaluronate have been used in **joint disease** therapy. The mode of action is unknown, but **binding to cartilage proteoglycans** may slow down processes of cartilage degradation and increased synovial fluid viscosity may also be protective. Hyaluronate possesses additional properties, however. It inhibits PGE₂ synthesis, suppresses leukocyte migration, reduces phagocyte activity and decreases the permeability of synovial membranes. Good clinical responses have been claimed following IA injection of sodium hyaluronate. Efficacy seems to be greatest in the presence of **joint inflammation**. Dosing may be repeated at weekly intervals until a satisfactory response is obtained, or no response occurs. It has also been used as supportive therapy in subjects with infective arthritis and tenosynovitis (*q.v.*).

In recent years there has been a marked rise in the use of a range of compounds classified as nutraceuticals. They include glucosamine and chondroitin (*q.v.*) and they provide the **building blocks** for the synthesis of cartilage matrix. The bioavailability of these compounds is likely to be acceptable, although further studies are required. Their effects in controlled clinical trials have yielded some positive results.

GENERAL PROPERTIES OF CORTICOSTEROIDS

The principal steroid hormones secreted by the adrenal cortex (corticosteroids) comprise two classes, **mineralocorticoids** (e.g. aldosterone) and **glucocorticoids** (e.g. cortisol and hydrocortisone).

The physiologic effects of the mineralocorticoids are exerted on water and electrolyte balance in the kidney (*q.v.*) and parts of the gastrointestinal tract, at which sites aldosterone promotes sodium retention and potassium extrusion. Glucocorticoids affect carbohydrate, lipid and protein metabolism and thus all body tissues. The division is not absolute, however, as some glucocorticoids possess weak mineralocorticoid activity and vice versa.

Both endogenous and synthetic glucocorticoids possess anti-inflammatory properties, and the glucocorticoid hormone cortisol is used, usually in creams for topical application, as an anti-inflammatory agent for general skin conditions involving irritation (*q.v.*) but excluding those associated with microbial infection. Most synthetic steroids possess greater glucocorticoid and reduced mineralocorticoid potency relative to cortisol, so that side effects on electrolyte balance (sodium retention and edema) can be avoided or minimized. Relative potencies of several corticosteroids (cortisol = 1) are presented in Table 4.12.

Anti-inflammatory activity parallels glucocorticoid potency, so that in clinical use equi-effective doses of synthetic glucocorticoids will generally produce the same degree of toxicity. It is important to recognize the very **diverse range** of actions of glucocorticoids, as these underlie the several side effects that can occur in medium- to long-term use, although the development of novel glucocorticoids that selectively inhibit the effects of pro-inflammatory transcription factors may result in fewer unwanted side effects. Topical application of conventional steroids may however be associated with thinning of the skin and there may be increased risk of local infection. These actions are summarized in Box 4.1, and the circumstances in which steroids are either contraindicated or must be used with special care are listed in Box 4.2.

Table 4.12 Relative potencies of corticosteroids (cortisol = 1) and biologic half-life values in the horse

Compound	Mineralocorticoid potency	Glucocorticoid and anti-inflammatory potency	Biologic half-life (h)
Cortisol	1	1	8–12
Aldosterone	800	0.2	—
Deoxycorticosterone	40	0	—
Prednisolone	0.8	5	12–36
Prednisone ¹	0.6	4	12–36
Methylprednisolone	0	5	12–36
Triamcinolone	0	5	24–48
Dexamethasone	0	30	36–54
Betamethasone	0	25	36–54
Flumetasone	0	100	36–54

¹ Inactive, converted *in vivo* to prednisolone.

Box 4.1 Corticosteroids: Pharmacologic actions and side effects in the horse

1. Increased storage of glucose as glycogen in liver but decreased uptake and utilization in other tissues, with increased gluconeogenesis leading to hyperglycemia
2. Decreased protein synthesis, increased protein catabolism leading to muscle weakness and wasting (myopathy) and delayed wound healing
3. Increased lipolysis and, at high dose rates, redistribution of body fat
4. Initial polyphagia, polyuria and polydipsia
5. Mineralocorticoid effects with some drugs (hypokalemia, metabolic alkalosis)
6. Decreased absorption from gastrointestinal tract (GIT) of calcium, increased renal excretion of calcium leading to osteoporosis
7. Thinning of skin
8. Normally little effect on GIT integrity but ulceration occurs in subjects with spinal cord trauma
9. Hepatomegaly
10. Depression of cell-mediated immunity, suppression of antibody production leading to increased susceptibility to infection
11. Hematologic effects: neutrophilia, eosinophilia, lymphopenia
12. Steroid-induced arthropathy possible with intra-articular injection of depot formulations
13. Hypoplasia and ultimately atrophy of adrenal zona fasciculata of the adrenal cortex with reduced capacity to secrete cortisol; impairment of response to stress following withdrawal

Box 4.2 Corticosteroids: Contraindications or special care in use

1. Diabetes mellitus
2. Cardiovascular disease
3. Patients with renal insufficiency, disturbances of electrolyte balance, e.g. hypokalemia
4. Presence of infections, especially viral infections; antibacterial cover essential when used in animals with bacterial infections
5. Presence of corneal ulceration, glaucoma, cataracts
6. Late pregnancy—can induce parturition; early pregnancy—possibly teratogenic
7. Patients with compromised immune status
8. Care with joint disease, steroid arthropathy from inappropriate use of long-acting preparations

NB Cushingoid symptoms (muscle wasting, osteoporosis, redistribution of fat) can occur during treatment and problems deriving from adrenal hypoplasia during recovery.

CORTISOL SECRETION

Three mechanisms controlling the secretion of cortisol from the zona fasciculata of the adrenal cortex have been identified. All forms of **stress** increase the secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary and hence cortisol secretion from the adrenal cortex; increased plasma cortisol concentration reduces the secretion of corticotropin releasing factor from the hypothalamus and ACTH from the anterior pituitary leading to reduced cortisol secretion (a **negative feedback** system). There is also a **natural circadian rhythm** of ACTH and hence of cortisol secretion, with plasma concentrations peaking at 08.00 to 10.00 h (in humans, horse and dog) and in the late evening in nocturnal species like the cat.

Superimposed on circadian secretion is an **episodic pattern** of secretion of cortisol in the horse with 10–17 peaks occurring over 24 h. When exogenous steroids are administered, they mimic the action of endogenous cortisol on the negative feedback pathway and this hypothalamus–pituitary–adrenal (HPA) suppressant activity parallels glucocorticoid anti-inflammatory activity.

In the horse, plasma cortisol is suppressed for 24 h with the water-soluble prednisolone succinate, for 3–4 days with dexamethasone alcohol, and up to 21 days with prednisolone acetate. With long-term steroid therapy, the consequence is reduced cortisol secretion, hypoplasia and, potentially, atrophy of the cortex. Detailed equine studies are lacking but experience in the dog and human indicates that some degree of adrenal atrophy occurs after 1 wk of treatment. After 1 yr of therapy in humans, the **pituitary recovery** takes approximately 5 mo but adrenal responsiveness to ACTH recovers more slowly and may take 9–12 mo. When therapy is withdrawn, the adrenal suppressed animal is unable to mount the normal increase in cortisol secretion in response to stress and therefore is **vulnerable** to any stress situation.

Methods of minimizing **steroid-induced HPA suppression** should be considered. Administration of a short-acting steroid at the time of peak plasma cortisol concentration (early morning in the horse) gives the theoretical advantage that drug and endogenous steroid concentrations should decline together to provide a period of low circulating concentrations prior to administration of the next dose. It is also common to recommend administration of steroids on alternate days and, on terminating therapy after medium- to long-term treatment, dosage should be reduced gradually to increase the opportunity for adrenocortical regeneration.

ANTI-INFLAMMATORY ACTIONS OF GLUCOCORTICOIDS

Mechanisms of action

The mechanism of the anti-inflammatory action of steroids is not fully understood, but they do suppress all components and all forms of inflammation. Many studies have shown that glucocorticoids enter cells to combine with cytosolic receptors. The steroid–receptor complex is transported to the cell nucleus, where transduction leads to increased synthesis and release of polypeptides, the **lipocortins**, with anti-inflammatory properties.

One action of endogenous lipocortins is blockade of phospholipase A₂. This enzyme, when activated by all forms of tissue injury, acts on cell membrane

phospholipid to release the 20-carbon unsaturated fatty acid, arachidonic acid. Arachidonic acid may serve as a substrate for the enzymes COX (*q.v.*), which is inhibited by most aspirin-like drugs (NSAIDs), and lipoxygenases (LO) such as 5-LO, 12-LO and 15-LO (which are not inhibited by most NSAIDs). Steroids, by acting more proximally than NSAIDs in the arachidonic acid pathway, may inhibit the synthesis of a **wide range** of putative inflammatory mediators, including prostaglandins via the COX pathway and the leukotrienes LTB₄, LTC₄, LTD₄, LTE₄ and hydroxyeicosatetraenoic (HETE) compounds via inhibition of lipoxygenases.

This proposed mechanism of steroid action is widely accepted but experimental studies in the horse have shown that both clinical and higher dose rates of betamethasone and dexamethasone fail to inhibit the synthesis of 5-LO and COX derived eicosanoids, or do so only moderately and inconsistently. Glucocorticoids inhibit the synthesis of COX-2 at inflammatory sites, reducing prostaglandin synthesis by this additional mechanism. Glucocorticoids also inhibit induction of **nitric oxide synthase**, an enzyme that is expressed by macrophages and other cells after activation by some cytokines or by lipopolysaccharide. **Nitric oxide** is an endogenous vasodilator and may also be a mediator of tissue damage. Corticosteroids also inhibit activation of the transcription factor NFκB, an important cellular response following toll-like receptor activation.

Whatever the modes of action of corticosteroids, the nature and extent of their actions are clear. They are the anti-inflammatory agents par excellence, suppressing most, and probably all, components of acute and chronic inflammatory

Box 4.3 Glucocorticoids: Actions relating to anti-inflammatory properties

1. Decrease vasodilatation (due, in part, to a direct vasoconstrictor effect on small blood vessels)
2. Decrease fluid exudation (inhibit edema formation)
3. Decrease leukocyte accumulation at sites of inflammation (glucocorticoids also increase release of neutrophils and decrease release of mononuclear cells from bone marrow)
4. Decrease microbicidal activity of macrophages and reduce macrophage-induced tissue damage caused by release of enzymes and toxic oxygen metabolites (free radicals, e.g. hydroxyl radical)
5. Decrease fibroblast and chondrocyte activity (less collagen and glycosaminoglycans synthesized)
6. Inhibit osteoblast activity
7. Increase osteoclast activity (via decreased calcium absorption and the resulting increase in parathyroid hormone which activates osteoclasts)
8. Decrease circulating levels of complement components
9. Cause lympholysis in steroid-sensitive species, e.g. rabbit, rat, mouse
10. Decrease production of pro-inflammatory cytokines and chemokines
11. Decrease eicosanoid and PAF production (inhibition of phospholipase A₂)
12. Reduce histamine release from basophils
13. Suppress induction of nitric oxide synthase and COX-2

responses, including wound healing. Actions of steroids which have been established in laboratory animal studies and which may contribute to their anti-inflammatory actions are listed in Box 4.3, but their occurrence in the horse has not been conclusively demonstrated.

PHARMACOKINETICS AND ADMINISTRATION

There is a latent period of 1–5 h after administration before the occurrence of most corticosteroid-induced pharmacologic effects, and the actions then persist for longer than would be predicted from the plasma clearance and half-life. Thus, elimination half-lives of prednisolone and dexamethasone in the horse are relatively short following IV administration (100 and 53 min, respectively), while the biologic half-lives (the times for which single doses produce HPA suppression) (see Table 4.12) are approximately 24 and 48 h, respectively. The fact that plasma concentration and onset and duration of action are out of phase is explained by the **indirect** mechanism of steroid action.

Duration of action of steroids is also influenced by **route of administration**, the form in which drugs are used (parent compounds and water-soluble esters on the one hand and water-insoluble esters on the other) and product formulation (Box 4.4).

Box 4.4 Glucocorticoids: Formulations available for clinical use

- 1. Parent compound (steroid alcohol): tablets for oral administration, aqueous suspensions for IM injection
- 2. Solutions in mixture of water and organic solvents, e.g. propylene glycol (50%) solution for IV or IM injection
- 3. Water-soluble esters: aqueous solution for IV or IM injection:

Succinate

Phosphate

m-Sulfobenzoate

Isonicotinate

}

Short acting
(1–2 days)
- 4. Water or oil-based suspensions of lipid-soluble esters for IM injection: depot, slow release from IM injection site:

Pivalate

Acetate

Propionate

}

Medium acting
(2–14 days)

Dipropionate

Acetonide

Adamantoate

}

Long acting
(≥2 wk)
- 5. Mixture of water-soluble and water-insoluble esters (e.g. Na phosphate + dipropionate) for IM injection
- 6. Ointments, creams, aqueous drops for local application: esters with diphasic polarity (betamethasone-17 valerate) penetrate skin and retained locally
- 7. Dry powder for inhalation (e.g. beclometasone dipropionate and fluticasone dipropionate)

Water-soluble esters, or parent compounds solubilized with organic solvents, may be administered IV or IM, systemic absorption from the latter site being rapid. The insoluble esters are administered IM to provide a **depot** from which absorption occurs over several days or, in some instances, weeks. However, with such products, adrenal suppression and hence hypoplasia may be unavoidable. Moreover, the **control of steroid action** (both therapeutic and side effects), which can be achieved with shorter acting products administered once daily or on alternate days, is lost. Use of these should therefore generally be reserved for occasions when shorter acting products are unsuitable. In addition to ester solubility, and the use of some products containing fixed oils, which further prolong uptake, duration of action may be controlled by the use of aqueous suspensions of varying particle size.

As well as esters of variable aqueous solubility produced by substitution on carbon 18 of the basic steroid structure, other derivatives with esterification in the 17 position such as **betamethasone-17-valerate** and **beclomethasone dipropionate**, which have diphasic polarity, have been used. These compounds are absorbed into, and bound in, the skin; they have low systemic availability and the risk of systemic side effects is therefore greatly reduced.

Although well absorbed orally, steroids are not generally administered to horses by this route; the usual routes for equine use are topical application to the skin and IV, IM and IA injection, although **inhaled steroids** are also used in patients with respiratory disease. The choice of agent depends on the clinician's personal preference. Daily or alternate day dosing with short-acting compounds is preferable but may be less practicable than depot therapy in conditions such as sweet itch (*q.v.*).

CLINICAL USES

Anti-inflammatory steroids are used to treat a wide range of both immune and non-immune inflammatory conditions. **Allergic conditions** (e.g. *Culicoides* hypersensitivity or "sweet itch"; recurrent airway obstruction) and **non-specific eczemas** respond well to therapy.

If animals cannot be removed from the source of antigenic challenge (biting flies of the genus *Culicoides*), **sweet itch** (*q.v.*) may represent one of the few indications for using **depot steroid therapy** with long-acting esters. As the condition is **seasonal**, such therapy can be applied intermittently. In mild cases, a single IM injection of **methylprednisolone acetate** early in the season may result in an animal having reduced signs for the remainder of the biting season. In more severe cases a second injection 3–4 wk later may be required.

Steroids may also be administered to break the itch–scratch or itch–rub cycles in equine **dermatoses** that can lead to self-excoriation. Local allergies also respond to therapy with steroids.

Steroids are commonly used to treat ear conditions (**otitis externa**) in small animals and **inflammatory conditions of the eye** (*q.v.*) in all species. The chronic use of steroids in the eye can cause sloughing of internal membranes and blockade of the canal of Schlemm, leading to reduced drainage, increased intraocular pressure and possibly glaucoma. Inflammatory responses in the eye and the resulting corneal opacity are effectively controlled by topically applied steroids, but these drugs are **contraindicated** if superficial corneal ulceration is present,

as they retard the initial phase of re-epithelialization. Viral infections in the eye have been converted to **fulminating forms** by the use of topical steroids.

In **acute anaphylaxis** (*q.v.*), the onset of action of steroids is too slow to be clinically useful. Steroids have been recommended for all forms of **shock** but the slow onset of action is again disadvantageous. Unfortunately, the very high doses (at least 10 times the anti-inflammatory dose) required in large animal species like the horse make such treatment prohibitively expensive for general use. Moreover, the efficacy of steroids is much less certain in established shock than when given before the onset of shock. In practice, steroids probably have no advantages over **flunixin** in horses with **endotoxic shock**.

In the presence of inflammation caused by **bacterial infection**, steroids should be administered only with appropriate **antibacterial agents**. Suppression of signs is commonly obtained in the early stages. However, steroid usage is controversial because of the **immunosuppression** (*q.v.*) produced by effective doses and hence possible exacerbation of disease.

Steroids should not be used in the presence of **viral infections**. In addition, tissue repair processes are impaired in the later stages of infection and this may be particularly important in parenchymatous tissues like the lung. If steroids are used, effective antibacterial therapy with a bactericidal agent should also be provided.

Steroids are used to treat disorders of the musculoskeletal system such as **traumatic arthritis** and **myositis, bursitis, tendonitis, eosinophilic myositis** and **osteoarthritis** (*q.v.*). Steroids may actually cause an **acute laminitis** (*q.v.*) by unknown mechanisms but possibly through potentiation of vasoconstrictors such as 5-HT and noradrenaline/norepinephrine in the circulation of the hoof. Most clinicians now consider steroids to be **contraindicated** in all forms of laminitis.

Joint disease

For the treatment of inflammation in **joint diseases**, IA injection of steroids, following the withdrawal of an **equal volume** of synovial fluid, is the most effective means of alleviating pain, inflammation and hence lameness.

Cases of **synovitis** and **capsulitis** (e.g. of the fetlock) (*q.v.*) and **acute pastern soreness** or **spavin** (*q.v.*) unaccompanied by bony changes usually respond to a single treatment with a long-acting ester. Administration by the IA route reduces, but does not abolish, the risk of systemic side effects, as rapid absorption can occur from some formulations. Thus combinations of soluble and insoluble esters or long-acting preparations alone, retained locally for several days or longer, have been used. With any IA injection, **aseptic technique** is essential as infection in joints has a poor prognosis and the **immunosuppressant actions** of steroids may exacerbate infection problems, although signs of infection will be masked for a few days by the anti-inflammatory actions.

Steroids suppress synovitis and capsulitis and alleviate stiffness and pain, and this permits **freer joint movement**. Exposure of treated animals to even moderate exercise regimens may exacerbate, through overuse, processes of joint degeneration. **Complete rest** is therefore generally advised following use of IA steroids. Moreover, steroids may interfere with natural repair processes. Laboratory studies have demonstrated steroid inhibition of chondrocyte

metabolism: high doses in vitro increase chondrocyte mortality, while lower doses suppress the synthesis and release from chondrocytes of proteoglycans and hyaluronic acid, both of which are important components of cartilage matrix. Such actions may explain the **steroid-induced arthropathy** (*q.v.*) that has been reported in vivo following IA dosing. However, this may also involve the presence of particulate matter (steroid suspensions) in the joint; experiments with equine chondrocytes and synovial cells have shown that “inert” particulate matter (bone and silica) can greatly increase the synthesis and release of the inflammatory mediator PGE₂. Steroids may also induce osteoporosis and osseous metaplasia (*q.v.*). The latter may be a reaction to the **vehicles** used for long-acting steroids.

A short-lived local inflammatory response, “**post-injection flare**”, is occasionally seen following the injection of microcrystalline steroid suspension into joints, possibly through the “particulate” mechanism with formation of PGE₂ mentioned above. However, the greater concern is with the **reduction** in cartilage strength and thickness with longer term use.

The debate on IA steroid usage centers on the undoubted benefits provided by their anti-inflammatory (and analgesic) actions on the one hand and the depressant effects on **chondrocyte metabolism** on the other. In the early stages of osteoarthritis, chondrocyte metabolism is increased and the catabolism of existing cartilage and synthesis of new cartilage are both increased. The inhibitory effects of steroids on enzymes responsible for the synthesis of new collagen and cartilage matrix may be regarded as deleterious, while their action in inhibiting cartilage-degrading enzymes is presumably beneficial. Given the present state of knowledge it would seem wise to advocate the cautious use of IA steroids, restricting the size of administered dose and number of injections and **avoiding exercise routines** following treatment.

Three types of joint disease in which IA steroids are wholly **contraindicated** are septic arthritis (*q.v.*) (although they have been administered to suppress persisting inflammation once infections have been completely cleared), osteochondrosis dissecans (OCD) (*q.v.*) as increased cartilage flap formation and the stripping of cartilage from bone have been described, and when bony changes are seen radiographically. Intra-articular fractures and luxations (*q.v.*) should be treated by surgery and rest rather than steroid therapy.

Respiratory conditions

A number of non-allergic and allergic respiratory conditions, such as mixed infection pneumonias in calves and **recurrent airway obstruction** (RAO) (*q.v.*) in horses, may be treated with steroids. However, in RAO, bronchodilator therapy with β_2 -agonists such as **clenbuterol** is preferred for treatment of acute episodes, and steroid use is more common in moderate or severe cases.

TOXICOLOGY

GENERAL CONSIDERATIONS

Horses in many countries are kept as individuals or in small groups rather than in large free-ranging herds. Even in small groups they are often treated

as individuals with relatively close attention, for example in relation to feeding, rather than as extensively ranched animals. As the horse is herbivorous and a grazer, most epidemiologic investigations of equine toxicoses focus on food and forage, although other routes of exposure cannot be ignored. The **history** of a toxicosis (numbers of animals affected, feeding practices, farm procedures, etc.) is often the first indicator pointing to the possibility of poisoning. **Availability** of a poison and access to it are prerequisites for a toxicosis to occur; in the majority of cases either ingestion or skin contact has to precede toxicosis. Careful observation at the farm or stable and interrogation of handlers helps to confirm the toxicosis and aids in identifying causes.

A **thorough clinical examination** is essential for successful diagnosis and treatment. Many poisons do not cause pathognomonic signs or lesions. However, **aggregated** signs or syndromes may assist in identifying the likely cause. A careful and methodical post mortem examination may also be required.

Local knowledge of plants or agrochemical usage may be helpful. Knowing when feed was introduced to the horse or the horse was introduced to the food source, such as to a field with plants, can aid in defining causes and sources. A timeline of the course of the disease will help in tracking the nature of the disease. The progress of a disease and morbidity can help to differentiate between spread of an infectious disease and development of toxic disease.

Clinical pathology is often of great help in assisting the clinical assessment. The laboratory diagnosis can further guide the clinician with regard to sampling and interpretation of results, particularly when the cases encountered are sporadic and even idiosyncratic. Further assistance can be sought from referral centers, veterinary investigation laboratories and poison information centers, although the latter two sources cater mainly for agricultural and companion small animals, respectively.

It is important to have a good working knowledge of toxicology and to be sufficiently cognizant of potential toxic compounds encountered in order to recognize particular toxicoses and to provide the necessary conditions for the successful conclusion of treatment. For many toxicants and plant toxicoses there are **no specific antidotes**. In such cases **decontamination treatment** is employed together with symptomatic and supportive therapeutic measures.

Decontamination treatment involves **removing the source** of the poison (or the animal from the source as in changing the pasture) followed by clearing of the gastrointestinal tract with **liquid paraffin** (light mineral oil) at 2–4 L per 500 kg as a laxative. For many toxicants, **activated charcoal** at 2–5 g per kg made into a **sludge** with up to 4 L of water, can be placed in the stomach for 20–30 min **prior to the laxative** in order to adsorb the toxicant before it is expelled by the laxative. In the case of **skin exposure**, decontamination will include cleansing of the skin.

Symptomatic treatment involves treating the presenting signs in order to ameliorate the toxicosis, whether or not there is an antidote. Supportive therapy includes **fluid and electrolyte therapy** and **pain management**. Hastening renal excretion with administration of fluids and diuretics will be beneficial in the treatment of some toxicants and their metabolites.

Finally, it is necessary to bear in mind the possibility of insurance and medico-legal ramifications as well as the need to handle the case and any samples collected in a reliable manner.

Pharmaceuticals and nutraceuticals are not covered in this text, although cases of iatrogenic origin from overdosing, from side effects, from residues or through adverse reactions have been reported. **Herbal medicines** may also cause poisoning and these are often used without full knowledge of their pharmacologic and toxicologic effects.

FEED-RELATED TOXICOSES

Short feed, concentrates

Apart from accidental mixing of feed, toxicoses that occur through ingestion of horse feedstuffs are uncommon. **Mycotoxins** (*q.v.*) produced in food substrates by fungi during storage are more likely to cause problems in ruminants, poultry or pigs, in part because horses are less likely to be given large amounts of poor quality meal. In many countries, mycotoxicoses are considered very rare. **Aflatoxicosis** (*q.v.*), with its widespread effects including liver damage and hemorrhage, is uncommon to rare in horses, as is mycotoxicosis resulting from **trichothecenes** (*q.v.*).

An interesting mycotoxicosis in horses in some parts of the world is **leukoencephalomalacia (LEM)** (*q.v.*), resulting from maize contaminated with *Fusarium moniliforme* or *F. tricinctum*. CNS damage leads to horses exhibiting head pressing, facial paralysis, aimless walking, goose-stepping gait, circling, blindness, swaying backwards and rapid death after onset of signs. Since the neurologic signs are permanent, recovery is unlikely. Another occasionally encountered mycotoxin is slaframine or “**slobber factor**,” a piperidine alkaloid giving parasympathomimetic effects, notably salivation. The source is clover infected with *Rhizoctonia legumicola*. The animal recovers a few days after removal of the offending infected hay.

Ionophores can be highly toxic to horses. Such poisoning has been reported worldwide but is uncommon in those countries where there is limited extent of usage. However, accidental cases can occur when ionophores are mistakenly added to horse rations. Acute cases, or chronic cases with acute manifestations (including sudden death following cardiac damage) do occur. Signs in acute cases include inappetance (more specifically refusal of the concentrate feed), neuromuscular weakness, ataxia, tremors and recumbency, and cardiothoracic signs of tachycardia, dyspnea and hyperpnea. Terminally there may be seizures. In chronic cases there may be circulatory disorders with pitting edema and exercise intolerance. The cardiac signs correlate with streaking in the myocardium, although renal and hepatic lesions are also likely to be present in the carcass at post mortem examination. There being no specific antidote, treatment consists of decontamination therapy (*q.v.*), supportive treatment and rest because of the cardiac damage.

Plant-related

Introduction

Most domesticated animals avoid toxic plants, and horses are no exception. However, change of circumstances (overgrazing, change of land management,

relocation) can lead to an increase in poisoning cases. The following listing is intended to highlight the prominent features of poisoning by the more important plants with a tabular summary of those that are less important (Table 4.13).

Table 4.13 Plants with potential to poison horses

Plant	Toxic principle	Main system(s) affected	Other signs	Comment
Black walnut (<i>Juglans nigra</i>) English walnut (<i>J. regia</i>)	—	Locomotor	Laminitis, colic possible	Laminitis from bedding on shavings with black walnut shavings, unknown from English walnut
Blue-green algae (<i>Microcystis</i> spp.)	Microcystin	Liver, skin	Photosensitization, jaundice, tremors, ataxia	—
Box (<i>Buxus sempervirens</i>)	Buxine and other alkaloids	GIT; CNS	Gastroenteritis, colic Death from respiratory failure	Rare poisoning
Giant hogweed (<i>Heracleum mantegazzianum</i>)	—	Mouth	Stomatitis, hypersalivation	Irritant plant at site of contact
Hawthorn (<i>Crataegus</i> spp.)	Cyanogenic glycoside		Sudden deaths, respiratory signs	Common hedge plant
Hellebores (<i>Helleborus</i> spp.)	Helleborein	CNS; CVS	Tremors, colic, diarrhea, polyuria	Rare in horses in UK
Holly (<i>Ilex</i> spp.)	—	GIT	—	Very rare poisoning
Horseradish (<i>Armoracia rusticana</i>)	Sinigrin	GIT	Gastrointestinal irritancy, colic	Obnoxious plant, so rarely eaten
Horse chestnut (<i>Aesculus</i> spp.)	Aesculin	GIT	Peculiar gait	Not a problem in Britain but reported in USA
Horsetails (<i>Equisetum</i> spp.)	Thiaminase	CNS	Progressive CNS signs, incoordination to seizures, recumbency and death	Treat with thiamine and purgatives Remove source and feed grain
Ivy (<i>Hedera helix</i>)	—	GIT	Irritancy	Rare
Laburnum (<i>Laburnum anagyroides</i>)	Cytisine, anagyridine	CNS	Excitement, incoordination, sweating, convulsions, death	Highly poisonous tree; horses the most susceptible species
Mercury (<i>Mercurialis</i> spp.)	Mercurialine	GIT	Jaundice, salivation, diarrhea, weakness, lethargy, hematuria and coma	Rare since plant is unpleasant to eat

(Continued)

Table 4.13 (Continued)

Plant	Toxic principle	Main system(s) affected	Other signs	Comment
Monkshood (<i>Aconitum napellus</i>)	Aconitine	Respiratory, CNS	GIT irritancy, salivation, colic, weakness, paralysis, death from cardiac or respiratory failure (asphyxiation, aspiration)	Rare woodland plant (so rarer poisonings)
Oleander (<i>Nerium oleander</i>)	Various cardenolides such as oleandroside	CVS	Colic, melena, diarrhea, cardiac arrhythmias, sudden death	Surprisingly, has been suspected in UK although it is a tropical and subtropical plant
Privet (<i>Ligustrum vulgare</i>)	Ligustrine	GIT; renal	Gastroenteritis, colic, incoordination, renal damage	Rare
Rhododendron	Grayanotoxin (andromedotoxin)	GIT	Colic, salivation, variously diarrhea or constipation, staggering, tremors, collapse	Horses with access to gardens or woodland
Robinia, black locust (<i>Robinia pseudoacacia</i>)	Robin, robitin	GIT, CVS, locomotor	Salivation, colic, diarrhea, anorexia, paralysis, laminitis Tachycardia Excitement and seizures	Common municipal tree so potential is present Bark is also toxic
Sweet clover, melilot (<i>Melilotus</i> spp.)	Coumarins in hay/silage	Blood	Hemorrhages	Poisoning in horses is unlikely, especially given that horses are generally fed higher quality, unspoiled hay
Umbellifers Poison hemlock (<i>Conium maculatum</i>)	Coniine, coniceine	CNS, ANS	Mydriasis, weakness, staggering, respiratory arrest	Uncommon poisonings Nicotine-like and curare-like action
Water hemlock, cowbane (<i>Cicuta virosa</i>)	Cicutol, cicutoxin	CNS	Violently toxic plant Mydriasis, colic, violent convulsions	Yellow juice in root contains the toxin Walnut-sized piece of root will kill a horse
Water dropworts (<i>Oenanthe</i> spp.)	Oenantheotoxin	CNS	Sudden deaths, salivation, mydriasis, convulsions	Multiple roots, "dead men's fingers"
White bryony (<i>Bryony dioca</i>)	Various	GIT; respiratory	Purgation, dyspnea, sweating, polyuria	Rare poisoning Hedge plant
Wild mustards, charlock (<i>Sinapis</i> spp.)	Irritant oils, e.g. allyl isothiocyanate at seed stage	GIT	Gastroenteritis including diarrhea, hypersalivation	Rare in horses

ANS, autonomic nervous system; CNS, central nervous system; CVS, cardiovascular system; GIT, gastrointestinal tract.

Yew (*Taxus baccata*)

The yew, or ground hemlock, is a common plant in many countries, often found in hedges and gardens away from anticipated animal access. Yew is **palatable** and is green when other forage is scarce in autumn/fall through to spring; however, a common source of the plant for horses is clippings. There are a number of toxic principles in the plant but the result of ingestion is often sudden death due to taxine. Traces of yew leaves or twigs may be found in the mouth or stomach at post mortem examination. Signs that have been reported include cold extremities, incoordination, a rapid weak pulse, collapse and excitability. In horses that do not succumb, there may be pyrexia or hypothermia, tremors, muscle fasciculations, dyspnea, bradycardia, colic and diarrhea.

As with many plant poisonings there is no specific antidote, but decontamination therapy (*q.v.*) followed by symptomatic treatment (including **atropine** for the autonomic signs) and supportive therapy should be instigated as soon as possible, since **yew toxicosis can be rapid**.

Bracken (*Pteridium aquilinum*)

Bracken is widespread in many countries, particularly on marginal land. The source of poisoning can be dried fronds contaminating straw bedding or, in the spring, the more succulent young “fiddleneck” appearing before vigorous grass growth. The plant causes several syndromes in animals: the affected horse shows signs of **thiamine deficiency** through the action of a thiaminase. Horsetails (*Equisetum* spp.) also contain a thiaminase.

Thiamine deficiency results in “**bracken staggers**” with incoordination and tremors increasing in severity as the toxicosis progresses to recumbency, convulsions and death; in chronic cases there is anorexia and weight loss. If the horse is encountered before recumbency occurs, then administration of **thiamine** at 0.25–1.25 mg/kg, b.i.d. for 7–10 days on a reducing dose basis, should be carried out IM or by slow IV injection.

Oak (*Quercus* spp.)

Several species of oak tree can affect horses, but cases of poisoning are rare. The toxic principle is from the tannin family of chemicals. Precise characterization of the toxins has not been determined. **Acorns** are the main source of toxicity in Britain, although leaves can be toxic; cases associated with leaves have been reported in the USA. Acorns may be more abundant in some years than others, with hot dry summers increasing the yield.

Clinical signs of acorn poisoning include colic, constipation and melena, pale mucous membranes, buccal ulceration, bradycardia, dark-colored urine, hypothermia, weakness and staggering. Renal and hepatic damage occurs with renal nephrosis and perirenal edema. Treatment consists of decontamination therapy (*q.v.*) (mineral oil or saline) and supportive treatment, particularly with IV fluids to maintain urine flow in view of the possible uremia.

Ragwort (*Senecio jacobea*)

Ragwort is notorious as a poisonous plant that affects horses. The toxic principles are pyrrolizidine alkaloids. Other plants of the same genus also contain pyrrolizidine alkaloids and must also be suspect. Unrelated plants containing

pyrrolizidine alkaloids include comfrey (*Symphytum officinale*) and hound's tongue (*Cynoglossum officinale*). *Crotalaria* (*Crotalaria* spp.) occur in warmer climatic zones.

Pyrrolizidine (*q.v.*) alkaloid metabolites, reactive pyrroles, bind to DNA and affect cell division, resulting in megalocytosis and cell necrosis, bile duct hyperplasia, portal fibrosis and **irreversible perivenous and IV fibrosis in the liver**; in chronic stages the liver can attempt recovery with nodules of regenerative tissue between the fibrotic areas.

Signs reported include colic, pallor, jaundice, constipation or diarrhea, wasting and deranged behavior resulting from hepatic encephalopathy; the common terms "hepatic cripples", "sleepy staggers" and "walkabout disease" summarize the conditions most frequently seen. One problem with these plants is the **lag time** between consumption and the appearance of clinical signs; the animal showing signs may not even be in the same locale as the plants or the hay at ingestion time. Owing to the lag time to onset of clinical signs, the disease is often in its **advanced stages** by the time of presentation to the clinician and treatment is therefore unlikely to be of benefit. Symptomatic and supportive treatment should be used, including sedation and fluid therapy. Control of the disease is best accomplished by **control of the plant**.

Nightshades (*Solanum dulcamara*, *S. niger*, *Atropa belladonna*)

Nightshades are widely distributed in many countries but heavy stands of the plants are usually encountered only infrequently. **Deadly nightshade** (*Atropa belladonna*) prefers chalky soils but the solanaceous nightshades can be found in light woodland and in disturbed soils, neither of which are prime horse grazing locations so that poisoning is uncommon. Additionally, the plants are not particularly palatable so are not preferentially eaten by horses, but **careless disposal of weed waste** can provide a source of the plant, leading to toxicosis.

The toxic principles, which include **atropine** from deadly nightshade, produce inhibitory actions on the parasympathetic branch of the autonomic nervous system, effects ranging from colic and diarrhea or constipation, tachycardia, mydriasis, and dry mouth to CNS effects of depression, weakness, incoordination, convulsions and recumbency. Solanine, a glycoalkaloid, is a **GIT irritant**, resulting in salivation and diarrhea (the latter sign is supposed to be prognostically favorable). It can cause hemolysis and acts on the CNS to produce excitement followed by depression, recumbency and coma. Cardiac arrest may occur.

Symptomatic and supportive therapy is indicated, particularly **demulcents** and possibly **atropine** for the salivation caused by solanine. **Plant control** is the best prevention.

Buttercups (*Ranunculus* spp.)

Buttercups occur widely in pastures and contain ranunculin, which hydrolyzes to the irritant protoanemonin. Protoanemonin is a **vesicant** and can cause blistering around the muzzle of horses grazing infested pasture. Severe cases can be painful with salivation, stomatitis and weakness, incoordination and diarrhea with dark feces due to a hemorrhagic gastroenteritis. Severe cases may involve colic and convulsions.

Demulcents are best used for the GIT irritation, with **emollients** being applied to the skin and supportive therapy used for severe cases.

Clovers (*Trifolium* spp.)

Red clover can become infected with *Rhizoctonia* spp., a fungus that produces “**slobber factor**” (*q.v.*), a parasymphomimetic alkaloid, which in turn causes profuse salivation.

Other syndromes can occur with clovers. “Dew poisoning” or “trifoliosis” is a **photosensitization** (*q.v.*) from which recovery occurs soon after removal from the pasture and sun. Lesions occur in fine weather, after a wet season, and appear on pale skin and around the muzzle. **Alsike clover** has been blamed for cases of hepatic failure and of CNS involvement. Alsike hay may allow more ingestion than pasture so changing the hay is necessary, but there is **no specific treatment**. Cyanide and nitrate poisoning are discussed below (*q.v.*), but can occur with heavy swards of clover.

Cyanide, nitrite, oxalate

In addition to the individual plants mentioned above, chemicals produced by plants in general can cause toxicoses in horses. These chemicals, to which ruminants are more susceptible than horses, are cyanide, nitrite and oxalate.

Cyanide poisoning usually arises from ingestion of plants containing cyanogenic glycosides. There are many potential cyanogenic plants, including grasses, from several plant families. Notable amongst these families is the Rosaceae, with cherry laurel and other plants in the same genus (*Prunus*). This family also includes some stone- and pip-containing fruits that are sources of cyanide.

The cyanogenic glycoside is converted to cyanide via nitrile under the influence of plant-derived β -glycosidases. The resulting effects include salivation, urination, defecation, convulsions, nystagmus, dyspnea and sudden death. Since the action of cyanide is to inhibit cellular respiration, a feature of this toxicosis is the dyspneic animal with red mucous membranes. A smell of **bitter almond** from hydrogen cyanide may indicate the presence of cyanide.

If treatment is feasible, there is a two-part antidote consisting of a single IV injection of **sodium nitrite** (10–20 mg/kg) to form methemoglobin and thence cyanmethemoglobin followed by IV **sodium thiosulfate** (500 mg/kg) to assist, with rhodanase, in converting the cyanide to thiocyanate; the thio-sulfate is not as toxic as nitrite and can be repeated because conversion of the glycoside in the GIT is ongoing. Antidotal therapy should be augmented by decontamination therapy (*q.v.*) with activated charcoal and laxatives.

Nitrate poisoning usually results from conversion of nitrates in plants to nitrites under the influence of bacteria. Nitrites in turn convert ferrous hemoglobin to ferric methemoglobin. Nitrates are irritant and cause salivation and abdominal distress while methemoglobin toxicity (to which ruminants are more susceptible) results in dyspnea, cyanosis, bradycardia with weak pulse and death from hypoxia. Blood color changes to red–chocolate–brown, which causes darkening of organs. Treatment consists of the slow IV injection of 10 mg/kg of 4% **methythioninium chloride solution** to convert the methemoglobin to hemoglobin via leukomethylene blue.

Oxalates occur in several plants of two families, the Chenopodiaceae (beets, goosefoot, fat hen) and the Polygonaceae (rhubarb, docks, sorrels), as well as being associated with some mycotoxicoses, ethylene glycol poisoning, and foliaceous houseplants such as dumb cane (*Dieffenbachia* spp.), Swiss cheese

plant (*Monstera deliciosa*) and philodendrons (*Philodendron* spp.). These latter plants are uncommon sources of poisoning in horses, as they are not very palatable, let alone accessible. Oxalates exist in different forms in plants.

Oxalate toxicity is linked to gastrointestinal irritancy, hypocalcemia and nephrotoxicity. There may be salivation, nasal discharge, weakness, tachypnea, collapse and death.

Treatment should be **symptomatic and supportive**, with **calcium administration** for the hypocalcemia as 100–500 mL of the 23% calcium borogluconate in an IV infusion together with fluids (**not bicarbonate**) for renal perfusion. The heart rate of the horse should be monitored during infusion. The animal may be refractory to treatment depending upon oxalate type.

Photosensitization

Primary photosensitization caused by ingestion of photodynamic chemicals can result from ingestion of buckwheat (*Fagopyrum* spp.), St. John's wort (*Hypericum perforatum*) and also some grasses.

Secondary (icterogenic) photosensitization (*q.v.*) occurs following liver damage and the consequent build-up of endogenous photodynamic substances. In cooler climates, some of the severe cases of photosensitization seen in sunnier parts of the world are not encountered but occasional cases may occur and require **symptomatic treatment** for the inflammatory skin lesions.

INDUSTRIAL AND AGROCHEMICAL TOXICOSES

Environmental toxicoses arising from industrial contamination or agrochemical treatment of the environment are not covered in full here in view of the vast number of chemicals used, but some of the possible agents are summarized in Table 4.14. Also presented in Table 4.14 are other chemicals, used as pesticides, which are occasionally encountered as causes of poisoning in animals.

Metals that can rarely cause poisoning include lead, arsenic, mercury, cadmium and zinc. Iron toxicity also occurs (*q.v.*) usually subsequent to overdosing with supplements.

Lead poisoning, which is decreasing in frequency, is more likely to be encountered in other species, but in the horse lead causes neurologic, hematologic and abdominal signs. The abdominal signs include colic, gastroenteritis and signs arising from liver and kidney damage. Neurologic signs may be peripheral, as in laryngeal hemiplegia (*q.v.*) and muscle fasciculations, or of central origin as with ataxia, depression and hyperesthesia. Chronically there may be weight loss and anemia. Associated hematologic changes are the presence of nucleated red blood cells and basophilic stippling.

Treatment of lead poisoning involves chelation therapy with **calcium disodium edetate** at 75 mg/kg/day in two doses as a slow IV infusion. Treatment should be given for 2–3 days, then stopped for 2–3 days, then repeated. Monitoring of blood and urine concentrations is recommended to determine that lead is being excreted. Therapy may have to be repeated if **blood lead** concentration increases >0.35 ppm.

Arsenic (*q.v.*) was once a widely used agrochemical but is less commonly encountered in recent times with modern systems of farming. Arsenic antidotes such as dimercaprol are unlikely to be readily available so **analgesic therapy**

Table 4.14 Potential toxicants in horses

Classification	Toxicant	Signs	Comments
Molluscicide	Metaldehyde	CNS excitation, tremors, later CNS depression	Has been reported in the UK in horses
Anticholinesterases	Organophosphate and carbamates	Autonomic signs, muscarinic predominating	Atropine antidote
Anticoagulants	Coumarin derivatives	Hemorrhagic syndrome	Inappropriate mix in feed Vitamin K ₁ antidote
Metals/metalloids	Lead, arsenic, mercury, cadmium zinc	CNS, gastroenteritis, colic shock, renal, anemia Lead accumulates in bones Cadmium and zinc affect joints and bones Arsenic severe on GIT	Unlikely to cause poisoning in UK in horses Chelation with EDTA for lead and zinc Sodium thiosulfate for arsenic
Herbicides	Paraquat, diquat, glyphosate, phenoxyacetic acid derivatives	Various Paraquat targets lungs	Many types, no antidotes so symptomatic and supportive treatments needed
Caustics	Creosote	Caustic on mucosae, conjunctivae	Neutralize on mucosae with weak alkali; wash eye repeatedly

and decontamination therapy (*q.v.*) together with **oral thiosulfate** (to bind arsenic) and **IV fluid therapy** for shock should be instigated.

Mercury, cadmium and zinc toxicity is even more rare due to modern environmental legislation and with the decline in use of mercury medications, but environmental contamination can still occur occasionally from industrial sources such as mine tailings and smelting plants. If treatment is needed, **penicillamine** may help mercury chelation and thus hasten urinary excretion, but doses to be used are not established in horses. Decontamination and supportive therapy (*q.v.*) are needed. Similarly there are no antidotes for cadmium and zinc; supportive therapy is needed as with most toxicoses.

Pesticides

Pesticides range from insecticides, through molluscicides to rodenticides. Horses are unlikely to be placed where they ingest large quantities from individual baits, but, occasionally, an individual animal may acquire a significant dose because of faulty handling or misplacing of chemicals by farmers or pest control operators.

Many of the previous therapeutic roles of **organophosphate** (OP) and **organochloride** (OC) insecticides have been taken over by the synthetic pyrethroids, which are relatively safe. Large doses of pyrethroids are needed to reach toxic concentrations in the body and accumulation is less important than with the OPs and OCs.

Organophosphates and **carbamates** (including methiocarb) are agrochemicals with **anticholinesterase** actions. The inhibition of acetylcholinesterase is

caused by bonding with the anticholinesterase and results in cholinergic stimulation and cholinergic signs in the animal. Muscarinic cholinergic signs (on the GIT and heart) usually predominate but nicotinic cholinergic symptoms (such as muscle fasciculations) and adrenergic symptoms due to ganglion stimulation can occur and mask the muscarinic signs.

Major signs of OP/OC toxicity include tremors, profuse salivation, diarrhea and recumbency. Diagnosis can be difficult in view of the plethora of agents causing these signs and the wide range of possible signs. Diagnosis may be assisted by observing the **response to atropine**. A low (pre-anesthetic) dose of atropine (0.02 mg/kg IV) will probably not reverse the signs of anticholinesterase poisoning, so if atropinization occurs the signs may not be due to an anticholinesterase.

Definitive diagnosis involves laboratory identification of the insecticide and analysis of **blood acetylcholinesterase activity**. The latter test is less useful for the shorter-acting carbamates; samples need to be frozen and analyzed soon after collection.

Atropine (0.1–0.2 mg/kg; 25% given IV, the remainder SC or IM as needed) is used for the treatment of both organophosphate and carbamate poisoning in order to reverse the muscarinic signs. **Pralidoxime** (Protopam), an antidote for OP poisoning which acts by reversing OP binding to the enzyme, is unlikely to be available early enough in the treatment regimen, because the OPs act first reversibly but then irreversibly due to aging, or stabilization, of the bond with the enzyme. If pralidoxime is available it should be given IV at 20–40 mg/kg and repeated every 4–6 h.

Anticoagulants

Difenacoum is one of the more frequently encountered causes of **rodenticide poisoning** of horses in many countries; other anticoagulants of the same group also causing poisoning include **bromadiolone**, **warfarin**, **chlorophacinone**, **coumatetralyl** and **dicoumarin**.

The coumarin derivatives act to inhibit vitamin K-dependent clotting factors (*q.v.*) by inhibiting vitamin K epoxide reductase. Usually, in subacute to chronic cases there is a lag time before the clinical signs appear, while vitamin K stores become depleted. Clinical signs are a result of hemorrhage; individual signs depend upon the site of the hemorrhages.

Diagnosis is assisted by analysis of prothrombin times (*q.v.*) (early when factor VII, with a short half-life, is decreased) and whole blood clotting times (later when factors II, IX and X are decreased); ingesta and tissue analysis is also of use in making a diagnosis.

Vitamin K₁ (phytonadione) at a dose rate of 1 mg/kg/day SC is antidotal. With newer generation anticoagulants, treatment may need to be continued for days to weeks. Symptomatic treatment may also help and, rarely, blood transfusion (*q.v.*) may be appropriate.

Herbicides

Paraquat and **diquat**, two bipyridyl herbicides, occasionally cause poisoning in horses. Paraquat specifically targets receptors in the lungs and causes fibrosis.

The kidneys are affected by both compounds. With paraquat the horse becomes depressed, dyspneic and icteric, but apparent recoveries confuse the prognostic judgments in some cases. There is no effective treatment for advanced cases. Both compounds cause ulceration of mucous membranes, colic and diarrhea.

Glyphosate (Roundup™) is not very toxic in the horse, but can cause irritation to the eyes and skin following contact with treated herbage. Flushing of the eyes with **isotonic saline** followed by application of **artificial tears** as an emollient provides some relief, as do emollients for the skin.

The **phenoxyacetic acid** derivatives (including **2,4D**, **mecoprop**, **MCPA**, **MCPB**) are likewise not very toxic but can cause a spurt of plant growth that can lead to increase in nitrogenous compounds in the plants and also alter their palatability. Thus a horse may ingest the plant with the increased nitrate or cyanogenic compounds and be exposed to nitrite or cyanide (*q.v.*).

ZOOTOXICOSES

Snakebite

There are three main families of venomous snakes as shown in Table 4.15. Of these, only the Elapidae and Viperidae are important in the USA and Europe.

In the USA the **pit vipers** (*Crotalus* spp. and *Agkistrodon* spp.) of the subfamily Crotalinae are the source of most bites owing to the number of species and their distribution. Coral snakes of the Elapidae are less widespread in the USA. The only venomous snake likely to be encountered by a horse in Britain is the adder or European viper (*Vipera berus*). Its habitat is usually marginal land (moorland and scrub) rather than prime horse grazing.

The vipers, by their relatively docile behavior, leave themselves open to encroachment by an animal walking by or grazing. Often the viper lies by a track to await prey or to sun itself and, upon approach of a non-prey species “freezes”, which either allows it to be trodden on or to think itself cornered. Otherwise most of these snakes are not overly aggressive at a distance. The viper that bites is usually defending itself rather than being aggressive. Nevertheless several bites may be made in one incident. Not all bites involve evenomation.

Bites to the horse are often on the face or the limb extremities and are not noticed until effects of the evenomation become apparent. Horses may be bitten on the limb extremities, but more usually **the head** is struck. Muzzle or

Table 4.15 The principal families of venomous snakes

Family	Subfamily	Example
Viperidae	Azemiopinae	Adder, viper, copperhead, cottonmouth water moccasin, rattlesnakes
	Viperinae (adders, vipers)	
	Crotalinae (pit vipers)	
Elapidae	Elapinae	Cobras, coral snakes, sea snakes, mambas, kraits, Australian death adder, tiger snakes, taipan, brown snakes
	Hydrophinae	
	Laticaudinae	
Colubridae	Colubrinae	Boomslang
	Aparallactinae	
	Homalopsinae	

facial bites may sometimes cause swelling that leads to a life-threatening **occlusion of the nares or trachea**.

The horse is susceptible to viper bites and the bitten horse should be kept in a calm, quiet environment to lessen cardiovascular effects. Preparation should be made for the horse to lie down. The effects of bites include hemorrhages and edema due to the cytotoxic and anticoagulant components of the venom. The cardiovascular effects include **hypotension** and **shock**, which should be treated with **fluid therapy**.

Actions to be taken include hygienic attention to the wounds with **antibiotic therapy** and symptomatic treatment including analgesics. **Tetanus antitoxin** should be administered as for wound treatment. **Antivenin**, while indicated, may not be practicable as it is expensive and should be given within 4 h of the bite. **Corticosteroids are contraindicated**. Observation is required for several days as complications to the wound may occur and the edema around the head may affect respiration. Adder bites are occasionally fatal.

Elapid bites (including coral snakes) tend to cause more local reaction and pain than crotalid or viper bites. There is potential for neurotoxicity including respiratory depression or respiratory paralysis but the small size of the snake and its low volume of venom make severe toxicosis unlikely in the horse.

Other zootoxins

While **insect bites and stings** do occur occasionally in horses, they are rarely of particular individual significance apart from an occasional allergic reaction. **Africanized bees** have entered the USA via South America and have a reputation for rapid-onset, sustained aggression compared with the European honeybee. In severe cases where the horse has disturbed a nest, symptomatic treatment with analgesics and possibly with epinephrine for treating any anaphylaxis, is usually all that is required.

Cantharidin—blister beetles (*Epicauta* spp.) (*q.v.*)—infest fields in the southern USA and may get into alfalfa hay. Contamination of fodder is unknown in hay of British origin but is of significance in alfalfa hay from parts of the USA. Countries importing such hay can request **beetle-free certified** hay. The cantharidin from the beetles irritates the GIT and also the urinary tract leading to colic, ulceration of the GIT with melena, and frequent urination with perineal pruritus. Death is possible. Decontamination therapy (*q.v.*) with activated charcoal and saline purgatives together with supportive fluid and electrolyte therapy may assist in the less severe cases.

Other arthropods such as the **black widow spider** and **recluse spiders** carry very toxic venoms but their habitat rarely coincides with that of the horse. The initial bite incident is often unnoticed. Antivenin is uneconomic; symptomatic and supportive treatment is needed.

DRUGS AND THE COMPETITION HORSE

INTRODUCTION

The horse is the pre-eminent competition animal: no other animal is involved in such a wide range of activities to test its strength and endurance, its control and conformation. With reputations and money at stake, these sports, which are

often underpinned by gambling, are susceptible to drug malpractice. Therefore, most regulatory bodies have devised strict **medication rules** that are designed to maintain integrity by promoting equine welfare and by discouraging the possibility of unfair competition. This presents the owner and veterinary surgeon with a serious dilemma when faced with an animal needing treatment with drugs close to the time of competition: what are the risks of contravening the rules; what is the **clearance time** (*q.v.*) for the intended drug; would it be wiser to withdraw from the contest; and where can advice be found?

Unfortunately, the answers to these questions are often not straightforward and the many autonomous bodies responsible for regulating equine competitions have produced differing proposals for maintaining the integrity of their sport. Philosophically, it is not difficult to accept the need to rule against the use of those drugs that have no legitimate place in equine sports medicine, or against drugs that are known to affect performance, or against drugs that are not licensed for veterinary use. The problems arise with those drugs that are quite properly contained in the veterinary armory, but whose effects on performance can only be speculated upon.

As it is not possible to find convincing information on the influence of drugs on performance, many authorities have ruled that the detection of a foreign substance or its metabolites in the body fluids of the horse is sufficient grounds for disqualification. Essentially, this is the position of the Fédération Equestre Internationale (FEI)*, and of the Jockey Clubs of Ireland, France and the UK (Box 4.5).

These authorities also recognize that positive medication tests can arise by accident from substances that contaminate food, from substances that occur in ordinary diets and from substances that are endogenous to the horse. In order to reduce the number of infringements arising from such accidental sources, the FEI and the Jockey Clubs have taken the logical step of introducing the concept of **threshold levels** (Table 4.16), although there are differences. For example, the FEI does not include arsenic in its list of threshold levels and has lower concentrations for salicylic acid in urine and plasma.

Other bodies have less exacting rules. Many racing jurisdictions in the USA, for example, allow certain therapeutic agents during competition, arguing that such permissive medication is acceptable because it merely restores the horse's normal performance capacity.

As shown in Box 4.5, and unlike the European Jockey Clubs, the FEI allows three drugs—cimetidine and ranitidine (H_2 receptor antagonists) and omeprazole (a proton pump inhibitor)—for the treatment of **gastric ulceration** (*q.v.*). The FEI, again unlike the major European racing jurisdictions, also permits the use of **altrenogest** for the control of estrus in competing animals. However, the three main conditions attached to its use are that it can be used only:

1. In mares
2. At the manufacturer's recommended dose rate, and
3. On completion and submission of the relevant FEI medication form (Form 2).

Under these conditions there is no apparent anabolic or performance enhancing effect.

* See www.horsesport.org

Box 4.5 Annex IV to the FEI Veterinary Regulations (2005)**PROHIBITED SUBSTANCES**

Horses taking part in a competition must be healthy and compete on their inherent merits. The use of a Prohibited Substance might influence a horse's performance or mask an underlying health problem and could falsely affect the outcome of a competition. The list of Prohibited Substances has been compiled to include all categories of pharmacological action.

The following are prohibited substances:

- Substances capable at any time of acting on one or more of the following mammalian body systems:
 - the nervous system
 - the cardiovascular system
 - the respiratory system
 - the digestive system other than certain specified substances
 - for the oral treatment of gastric ulceration (see Note 1)
 - the urinary system
 - the reproductive system (see Note 2)
 - the musculoskeletal system
 - the skin (e.g. hypersensitizing agents)
 - the blood system
 - the immune system, other than those in licensed vaccines against infectious agents
 - the endocrine system
- Antipyretics, analgesics and anti-inflammatory substances
- Cytotoxic substances
- Endocrine secretions and their synthetic counterparts
- Masking agents.

A finding of a prohibited substance means a finding of the substance itself or a metabolite of the substance or an isomer of the substance or an isomer of a metabolite. The finding of any scientific indicator of administration or other exposure to a prohibited substance is also equivalent to the finding of the substance.

With the objective of helping riders, trainers and their veterinary advisers, the FEI may include in its rules examples of prohibited substances.

Note 1: Oral treatment by the histamine H₂-receptor antagonists ranitidine, cimetidine and the proton pump inhibitor omeprazole is permitted and will not necessitate the use of a medication form.

Note 2: Treatment of mares for estrus-related behavioral problems is permitted with the substance altrenogest (Regumate) under the following conditions:

1. It is permitted only for mares with an estrus-related behavioral problem.
2. The dose and duration of treatment must be in accordance with the manufacturers' recommendations.
3. A Medication Form 2 must be completed by a veterinarian and submitted to the Veterinary Delegate/Commission before the start of the event.

Notes 1 and 2 will be reviewed annually by the FEI.

Table 4.16 FEI list of thresholds (2005). Reproduced with permission of the Fédération Equestre Internationale (FEI)

Thresholds can be adopted only for:	
<ul style="list-style-type: none">■ Substances endogenous to the horse■ Substances arising from plants traditionally grazed or harvested as equine feed■ Substances in equine feed arising from contamination during cultivation, processing or treatment, storage or transportation.	
Thresholds shall be recommended by the Medication Advisory Group, after consultation with official analysts and veterinarians, and approved annually by the General Assembly.	
Substances below the following thresholds are not actionable:	
Available carbon dioxide	37 mmol per L in plasma
Dimethyl sulfoxide	15 µg per mL in urine or 1 µg per mL in plasma
Estradiol in male horses (other than geldings)	The mass of free and conjugated 5a-estrane-3b, 17a-diol to the mass of free and conjugated 5(10)-estrane-3b, 17a-diol in urine from male horses at a ratio of 1
Hydrocortisone	1 µg per mL in urine
Salicylic acid	625 µg per mL in urine or 5.4 µg per mL in plasma

A rule which demands that horses must be forensically clean has the benefit of being easy to apply but can result in an animal being disqualified when a trace of an improbable doping agent is detected by a particularly sensitive test. Rules that permit some form of medication make the problem of **clearance times** (*q.v.*) even more acute. Should the rule disqualify horses only if a sample contains a drug exceeding an arbitrary concentration, or should the rule attempt to reflect a level of drug below which there can be no pharmacologic effect? Should the rule simply allow any level of nominated drugs in competing animals, or should it specify that drugs must not be given within a certain time before competition? These are just some of the problems.

Policies designed to ensure compliance create further difficulties. Deterrence is better than detection. Therefore, a form of **sample selection** is required that is adequate to prevent malpractice and which makes economic sense. Furthermore, it can be seen that the law of diminishing returns can apply equally well in the world of forensic analysis: more does not necessarily mean better. In practice not every horse can be tested, nor may it be necessary to subject every sample to all available analyses. Strategic selection of both competitor and analysis can be undertaken in order to create a powerful protective influence in equine sports.

It is important to recognize that regulatory authorities have different approaches to doping and medication control and current rules should always be checked with the organization concerned.

PHARMACEUTICS AND PHARMACOKINETICS

Apart from selection and analytical processes, the factors that govern whether or not a drug administration produces a positive dope test are (1) drug entry into the body, (2) distribution and metabolism, and (3) elimination from the body.

Drug entry and distribution

Any drug that enters the body ultimately finds its way into the circulation, which distributes it to the tissues. The rate at which this occurs depends on

the formulation and dose frequency, the route and site of entry, the ability of the drug molecules to cross membranes and the rate of tissue perfusion. Once distributed, drug molecules are available to bind to specific or non-specific receptors, or become stored or modified prior to elimination.

It is useful to understand the processes that can lead to delayed drug absorption, since the IM, SC and PO administration routes can sometimes give **surprisingly long elimination times**. Such difficulties can often be avoided by giving drugs IV where possible. Other methods of administration may also result in significant concentrations of drugs or their metabolites in biologic samples.

Intramuscular administration

It has been shown experimentally with some drugs that, after IM injection, the rate and extent of absorption are greater from injection sites in the neck than from sites in the brisket or rump. This effect may be due to the extent of movement of muscles, the degree of spread of the injected drug within and between muscles, and blood supply and drainage. Drugs can also be excreted sporadically after IM injection. This may be caused by inadvertent injection into a poorly vascularized area like fatty tissue or intermuscular injection.

Subcutaneous administration

Absorption of drugs from SC sites is usually considered to be slower, and can also give rise to **considerable variability** between animals. Tissue cooling causes vasoconstriction, and this vascular effect can be exploited with local anesthetics that incorporate adrenaline in order to prolong their local action.

Sustained-release preparations

Suspensions, or oil-based formulations, or preparations of drugs with long ester side chains are used for depot therapy. **Procaine benzylpenicillin** is a salt containing one molecule of benzylpenicillin combined with one molecule of the **local anesthetic procaine**; this ensures prolonged absorption but involves a **high risk of infringing the rules** for up to 21 days after injection. Similarly, benzathine benzylpenicillin is a benzylpenicillin salt with very low solubility and even longer elimination time. Products containing benzathine benzylpenicillin are available in many countries but they have been banned from use in food-producing species in all EU countries.

In many countries, public health concerns have resulted in the removal of a veterinarian's right to prescribe **anabolic steroids** for horses, except for the treatment of certain fertility problems. These regulations have thus reduced the dangers of producing positive dope tests from sustained-release and implant preparations of anabolic steroids and testosterone. If their use is detected in a sample taken from a horse after competition, the person responsible for the administration would also be guilty of an offense.

Recent advances in **controlled release** from the injection site have resulted in drugs being incorporated into a biodegradable matrix, similar to oral slow-release anthelmintics available for ruminants. Other preparations involve the use of **pro-drugs** that are hydrolyzed or cleaved by enzymes to form active molecules.

Intra-articular administration

The belief that intra-articular (IA) injection limits drug effects to the joint, and that systemic side effects of the therapy are reduced, is not supported by experimental studies. For instance, after IA injection of an aqueous solution of a corticosteroid, it is possible to demonstrate rapid urinary excretion of the drug, accompanied by a marked reduction in circulating cortisol caused by the feedback process on the HPA axis (*q.v.*).

Inhalation therapy

Drug delivery by **nebulization** is becoming more widespread, especially for prevention or treatment of bronchospasm associated with airway disease. Corticosteroids, β -adrenergic agonists, antimuscarinics and sodium cromoglicate have all been recommended for inhalational administration.

It is the aim of this approach to deposit small amounts of drug at the sites where it is required without causing systemic side effects; nevertheless, rapid absorption does occur from the alveoli, resulting in demonstrable blood and urinary concentrations. At the same time, the nasal mucosa is similarly exposed to the administration. This route of entry, like the buccal route, can be very efficient and any drug thus absorbed is not exposed to the **first-pass hepatic metabolism** (*q.v.*) that may follow gastrointestinal absorption.

Absorption through the skin

The barrier to drug absorption provided by skin is not absolute: drugs can penetrate at rates determined by their lipid solubility. However, water-soluble molecules can also penetrate the underlying dermis if the epidermis has been damaged. Solvents such as **dimethyl sulfoxide (DMSO)**, which possess both high water and lipid solubility, can penetrate skin readily and carry drugs with them. These effects are accompanied by, and partly attributable to local tissue damage, despite the reputation of this agent as an anti-inflammatory agent.

Other apparently harmless skin preparations have given rise to detection of substances such as analgesics, corticosteroids, rubefacients and fly repellents.

Metabolism and elimination

Most drug metabolism is carried out by liver microsomes, although other tissues (kidney, lung, GIT) do contain important detoxifying enzyme systems. The most notable of these is the intestinal mucosa, which plays an important role in protecting the body from orally administered substances.

Usually, those drugs that are water soluble do not need to be metabolized in order to be eliminated and so do not persist in the body. The usual consequence of the metabolizing systems is to convert lipid-soluble drugs into more water-soluble molecules, which favors their excretion. These processes are complicated by the ability of drugs to undergo plasma protein binding or to become sequestered in tissues. Adipose tissue in particular can act as an effective store for lipid-soluble drugs.

Phase I metabolism converts drugs into metabolites that are generally, but not always, inactive. **Phase II reactions** are conjugation reactions in which the drug

or metabolite is coupled via a hydroxy, carboxylic or amino group to a substrate. This produces molecules that are more readily excreted by virtue of their low lipid solubility; in the horse the main conjugates are glucuronides and sulfates.

Some orally administered drugs are metabolized in the intestinal wall or in the liver, and excretion occurs passively or by active secretion into the biliary system. In a few cases first-pass metabolism can almost completely eliminate the drug. Drugs that have undergone biliary secretion may be **reabsorbed** from the intestine to create an **enterohepatic recirculation**. The drug's persistence in the body can be **increased** by this mechanism. Furthermore, in the horse, the commensal cecal bacteria can contribute to this recirculation by hydrolyzing conjugates that have already been excreted via the bile, so allowing the liberated drug to be reabsorbed.

However, the main route for drug and drug metabolite excretion is in the **urine**. Small amounts of some drugs can be lost in expired air and others in external secretions like sweat and saliva, but these routes have limited forensic implications. The elimination of drugs in **hair** is of increasing interest as hair provides a stable environment for both drugs and their metabolites. Recent reports have identified and quantified many drugs in tail and mane hair, in one case (a potentiated sulfonamide) the trimethoprim and sulfonamide being detected three years after dosing.

In renal excretion those drugs that are not bound to plasma proteins are filtered at the glomerulus. Many drugs are weak acids or weak bases, and these may pass into the renal tubules by proximal tubule transport mechanisms. Drugs that are lipid soluble can diffuse across cell membranes from the renal tubules into peritubular capillaries, but such drugs can potentially diffuse also from capillaries into the tubular lumen. The amount of reabsorption of lipid-soluble acidic and basic drugs depends on **urinary pH**, so that the acidification of urine may have a **profound effect** on the rate of drug excretion. A horse that has undergone intense exercise often produces acidic urine, whereas the same horse can produce alkaline urine when out of training.

Other means of altering urinary acidity may also influence drug excretion. However, while urinary drug concentrations may change according to urine pH, the rate of decline of plasma levels is most commonly governed by drug metabolism.

Other biologic factors that create difficulties in predicting **clearance times** (*q.v.*) are the age and sex of the horse, and diurnal and seasonal variations; the use of urinary concentrations of drugs to indicate pharmacologic effects or times of drug administration is fraught with problems. Nevertheless, some good projections have been made (see below). Furthermore, although it is likely that plasma concentrations will be less variable, few drug trials have been conducted with sufficient numbers of horses in order to demonstrate a reliable distribution pattern.

CLEARANCE TIMES

The sources of pharmaceutical and pharmacokinetic variation described above unite to create the considerable uncertainty that surrounds clearance times and half-lives. **Half-life** is the time required for the drug remaining in the body to be reduced by 50% **after equilibrium distribution has been established**.

By knowing a drug's half-life, an estimate of clearance time can be made, for theoretically 99% of the drug will be cleared from the animal's body in seven half-lives.

However, quoting clearance times on the basis of this "99%" value may represent a problem where, through the use of sensitive technologies, detection of the excretion of the remaining 1% is possible. In providing advice to the practicing veterinarian, it may be more appropriate to attempt to establish "**detection times**". However, detection times are also dependent upon the sensitivity of the analytical technique used for their determination and are susceptible to changes in analytical technologies.

For many years within the competition horse industry, forensic laboratories applied **thin layer chromatography (TLC)** as the major screening procedure. This technique is still widely applied in North America but is now supported by the application of **enzyme-linked immunosorbent assays (ELISAs)**.

ELISAs provide a rapid, robust and sensitive approach to detect misuse of the more potent drugs. In forensic laboratories supporting the competition horse industry in Europe, Australia, Hong Kong, other major racing jurisdictions, and also to some extent in North America, there has been a move away from TLC to instrumental drug screening procedures, again supported by ELISAs. These **instrumental drug screening** procedures include gas chromatography (GC), high performance liquid chromatography (HPLC), gas chromatography-mass spectrometry (GC-MS) and liquid chromatography-mass spectrometry (LC-MS). For confirmatory analysis of the drug in the biologic fluid, where identification is required to satisfy legal criteria, mass spectrometric techniques are applied almost exclusively.

Thus, in determining detection periods based upon screening procedures, a wide range of techniques, varying markedly in their sensitivity capabilities, is available to the analytical scientist. Also, detection period data are usually available only for single doses of drugs administered to small numbers of animals. Veterinarians who use detection period data to offer advice on dosing schedules must therefore recognize the limitations of the approach.

The most comprehensive information on the approximate length of time that drugs can be detected in the blood and urine of horses is to be found in the *Race Track Division Schedule of Drugs* issued by Agriculture Canada. The charts produced in this document are the outcome of research into equine drug administrations, and although the analytical methods are not disclosed, they represent valuable guidance for veterinary surgeons involved in treating competition horses.

The Australian Equine Veterinary Association has also produced a booklet, *Detection of Therapeutic Substances in Racing Horses*, which provides detection times for a wide range of drugs based upon the analytical methodologies used in the four Australian racing laboratories. Similar guidelines are produced by the American Association of Equine Practitioners and published as *Guidelines for Drug Detection Times*.

More recently, the European Horserace Scientific Liaison Committee (EHS LC) has produced information on the detection times of a limited number of drugs (*Information for Veterinary Surgeons on Detection Periods of Named Drugs*). These data were generated through a collaboration of various racing laboratories within Europe with the detection times being determined using established

methods for confirmatory analysis for single drug administrations to small numbers of horses. The published detection times represent the longest time the drug was detected by this approach by any of the participating laboratories. For example, the Jockey Club in the United Kingdom has published times for which IM administered corticosteroids produce suppression of urinary cortisol, ranging from 30 h (dexamethasone sodium phosphate, 20 mg dose) to 830 h (triamcinolone acetonide, 30 mg dose). These figures are inevitably subject to inter-animal differences. For triamcinolone acetonide (30 mg) in two Thoroughbreds, times of urinary cortisol suppression were 700 and 830 h (a difference of more than 5 days). The FEI is undertaking similar studies.

For a number of years there has been concern within the competition horse industry regarding the increasing sensitivity of analytical techniques used for drug and medication control. This increasing sensitivity is necessary for the detection of potent illegitimate drugs but also allows more and more prohibited substances to be detected at very low levels. For some therapeutic substances this increase in the **sensitivity of analytical techniques** can allow for the control of **exposure** not associated to any effect. Also there is the realization that most drug infringements are not due to intentional malpractice, but to residues of therapeutic medication or caused by dietary or environmental contaminants. Thus, since the late 1990s, the EHSCL has been driving a major initiative to ensure that the control of substances commonly used for treating racehorses is both fair and effective. Primary factors for consideration in this are the welfare of the horse, the integrity of the horse racing industry and the harmonization of drug testing procedures in Europe.

Central to this initiative is the concept that approaches to controlling such substances should be based upon sound science and a rigorous analysis of pharmacologic and pharmacokinetic properties. To apply these principles, a pharmacokinetic/pharmacodynamic model has been developed by Toutain and Lassourd* to determine the **effective plasma concentration (EPC)** of therapeutic and commonly used drugs in racing. Risk assessment for individual drugs, taking into account their potential threat to the welfare of the horse and the integrity of the industry, then provides for the determination of irrelevant plasma and urinary concentrations (IPC and IUC, respectively). Following discussions at the International Conference of Racing Analysts and Veterinarians, Dubai (2004), it is hoped that this approach will provide the platform for the authorities to provide laboratories with recommended limits of detection for substances commonly used for treating competition horses.

At the outset of this initiative, a working group was formed to consider these various approaches and drive the practical aspects of the initiative. This working group comprised analysts, veterinarians and veterinary pharmacologists representing racing authorities in France, Germany, the UK, Ireland and Italy. It is clear that only through cooperation between the analyst, veterinary pharmacologist, veterinarian and regulatory bodies, and the pooling of expertise and resources on an international basis, can effective solutions be provided to address this challenge.

*Toutain, P.L., Lassourd, V. (2002) Pharmacokinetic/pharmacodynamic approach to assess irrelevant plasma or urine drug concentrations in post competition samples for drug control in the horse, *Equine Veterinary Journal* 34: 242–249.

INTRODUCTION

Diseases of the skin are commonly encountered in equine practice and frequently present diagnostic and therapeutic problems. Many conditions do not have a pathognomonic clinical presentation, with diseases of different etiology having a similar appearance. A **logical and systematic approach** to the investigation of dermatologic disorders is essential in order to reach a definitive diagnosis and initiate appropriate therapy. Failure to do so results in the use of remedies on an empirical basis, which all too often wastes time, money and the owner's patience, as well as having **welfare implications** for the patient.

A thorough history is required and it may be helpful to use a **customized dermatology questionnaire** to assist in this respect. After completing a general examination and detailed dermatologic examination, appropriate samples should be taken for laboratory examination. In many cases this will include collection of surface debris by brushing or scraping, for identification of ectoparasites or for fungal culture; surface adhesive tape strips are useful for collection of surface ectoparasites and identification of microorganisms by cytologic evaluation. Other samples might include bacterial swabs and skin biopsy.

Skin biopsy is essential to differentiate between the many causes of **papular and nodular lesions**. Multiple biopsies should be taken and the use of disposable biopsy punches facilitates this, with the patient sedated and use of local anesthetic. Larger nodules, masses and ulcerated lesions may require the use of excisional biopsy. Correct choice of biopsy site is important in gaining

the most helpful diagnostic information, and no surgical preparation should be performed, apart from clipping, in order to preserve surface pathology. **Full thickness skin** should be removed, excess blood blotted away and the tissue placed on stiff paper or card to prevent distortion during fixation. A complete history and clinical details must be supplied to enable the pathologist to give an informed interpretation of the pathologic features observed in the tissues examined.

Biopsy should not be viewed as a last resort in the investigation of skin disease and should be performed within 3–4 wk of lesions appearing if a definitive diagnosis has not been made already. Early diagnosis allows early introduction of the most appropriate therapy and accurate prognostication for the owner of the horse.

PARASITIC SKIN DISEASES

MANGE

Sarcoptic mange

Etiology

Sarcoptic mange is a now rare disease of horses, notifiable in the UK and in many other countries, caused by the mite *Sarcoptes scabiei*. The disease has been eradicated from the USA and currently is not specifically listed in the US Department of Agriculture list of Reportable Diseases and Conditions, although any confirmed or strongly suspected case should be brought to the attention of State or Federal veterinarians. Current opinion is that the various mites found on different hosts, although phenotypically different and adapted for a particular host, are genotypically identical. **Cross-infestation** among animals and humans is not uncommon.

The female sarcoptic mite lays 40–50 eggs in epidermal burrows tunneled into the skin. These hatch and, after passing through larval and nymphal stages, reach maturity within 2–3 wk.

Infestation is usually transmitted by **direct contact** between animals, but may also be transmitted on **fomites** such as riders' clothing, stable blankets, harness, etc. In temperate regions and under conditions of poor hygiene, mites and eggs may survive away from the host in grease and debris within buildings, vehicles or on tack and grooming equipment for 1–4 wk.

Clinical signs and diagnosis

Initial infestation is asymptomatic, but within 2–4 wk there is evidence of **papule formation** and scaling accompanied by a **very severe pruritus** in sites of infestation, leading to rubbing, biting and the production of self-inflicted skin damage. Lesions spread rapidly, finally involving all areas of the body. The skin becomes increasingly thickened and corrugated with marked hair loss. Rest and feeding patterns are severely disrupted, leading to serious generalized debility, weight loss, weakness and even death.

Infestation is suspected in animals showing the typical history and clinical picture, and particularly when **humans in contact** present with a papular rash

over the exposed areas of the body. Diagnosis may be confirmed by microscopic examination of scale and debris obtained by scraping affected areas, although mites may be difficult to find. Serologic tests for other sarcoptic mange antibody titers in other species may be adaptable for horses.

Treatment and prevention

A **very strict code of hygiene** must be enforced. All infested animals and those suspected of infestation must be isolated; their blankets, harness, grooming material and living accommodation should also be isolated. Animal attendants must change clothing and wash thoroughly before tending other animals.

Ivermectin has been shown to be effective in the treatment of sarcoptic mange. Infested animals may also be treated using lime sulfur, bromociclen, lindane or organophosphorus preparations, where available, used as a dip, spray or wash at 7–10-day intervals on at least three occasions. These preparations may also be used when necessary for treatment of infested buildings, vehicles and equipment after prior cleaning. In advanced cases or when scaling and skin thickening is excessive, it may be necessary to treat over a much longer period of time.

It is essential that infested animals be kept on a high plane of nutrition. Secondary infections such as by *Dermatophilus congolensis* may require concurrent treatment.

In areas where sarcoptic mange is still endemic, all newly acquired horses must be carefully examined and preventive measures taken where deemed necessary.

Psoroptic mange

Etiology

Psoroptic mange mites are **non-burrowing**, living on the skin surface and feeding by puncturing the epidermis, which causes serous exudation, inflammation and scab formation accompanied by irritation. The female mite lays eggs in the surface debris that hatch within 2–3 days and develop to maturity within 11–14 days. Mite activity, and the development of lesions, is greatest during autumn and winter and is probably associated with periods of **higher humidity**. Transmission is by direct or indirect contact.

Several species of psoroptic mite are reported to infest the horse: *Psoroptes equi*, *P. natalensis*, *P. ovis* and *P. cuniculi*. *Psoroptes* mites show little host specificity and appear to be **genetically homogenous** and it is probably best not to assign specific clinical manifestations to any individual species.

Clinical signs and diagnosis

Clinical signs and pruritus associated with infestation vary from asymptomatic to localized ear disease to truncal dermatitis, predominantly involving the **dorsal midline**. Scaling, papules, hair loss and skin thickening are seen, similar to lesions associated with sarcoptic mange, although irritation is usually less severe. Mild cases may present with mane and tail **seborrhea** (*q.v.*). **Psoroptic otocariasis** may cause severe scaling, irritation and

exudation leading to ear twitching, rubbing, head shaking and a lop-eared appearance.

Diagnosis requires the microscopic examination of material obtained from the **underside of scab specimens** and the surface of underlying skin.

Treatment and control

Ivermectin is very effective in the treatment of psoroptic otoacariasis and dermatitis; two doses of 200 µg/kg PO given 14 days apart are recommended. Treatment of psoroptic otoacariasis may be restricted to the use of topical ectoparasiticides to the head, upper neck and ear canals, but as the mites can survive in the coat for several weeks treatment may have to be prolonged. The owner should be advised to check the **ears** routinely for evidence of recurrence. Attention should be paid to the **cleaning and disinfection** of grooming utensils and harness, which frequently play an important role in transmission of infestation.

Chorioptic mange

Etiology

Chorioptic mange is caused by the surface-living mange mite *Chorioptes equi*, which is a phenotypic variant of *C. bovis*. Mites feed on cutaneous scale and debris without either tunneling or puncturing the epidermis. Their presence may, however, induce **localized inflammation**, irritation and hyperkeratotic changes.

Mite eggs are laid and subsequently develop in **skin debris** with the life cycle being completed within 14 days. Reproductive activity is markedly influenced by microclimatic factors, being greatest under conditions of high humidity. Survival time away from the horse is relatively short, but mites and mite eggs can survive on debris within buildings, bedding and on grooming equipment for several weeks, depending on temperature, humidity and hygiene.

Clinical signs and diagnosis

Chorioptes mites have a predilection to infest the skin of the legs from **below the knee and the hock**. Infestation may also occur on the tail and ventral trunk, and occasionally generalized lesions occur. Draft horses and cobs with feathered limbs are predominantly affected. **Pruritus** is very variable, from intense to absent.

Skin lesions may show a marked **seasonal variation**. Characteristic regionalized scaling lesions accompanied by marked irritation, stamping and rubbing are noted during the autumn/fall, winter and early spring, but apparently resolve spontaneously during the late spring and early summer, with a corresponding reduction in mite numbers, only to recur again the following autumn. The skin becomes **grossly thickened** and may become **secondarily infected** with bacterial or yeast organisms.

Chorioptic mange may be suspected on clinical examination and can be confirmed by microscopic examination of scale and debris obtained from active lesions.

Treatment and control

Selenium sulfide shampoo, systemic **ivermectin** and **fipronil spray** have all been shown to be effective in the treatment of chorioptic mange. Flumethrin is licensed for bovine chorioptic mange.

The legs of heavily feathered animals should be **clipped out** and the legs thoroughly washed and skin debris removed to facilitate topical application. Treatment may need to be repeated over a prolonged period before complete resolution occurs in chronic infestation. **In-contact animals** should be treated, since asymptomatic infection may occur.

Transmission often occurs following contact with infested bedding or grooming equipment and it is essential that contact with infested bedding is eliminated and that all grooming equipment is segregated and routinely sterilized.

Demodectic (follicular) mange

Etiology

Two species, *Demodex caballi* (long-bodied, affecting eyelids and muzzle) and *D. equi* (short-bodied, found on the trunk), have been described in the horse. The mites live and complete their life cycle within the **pilosebaceous apparatus**, only spending a relatively short period on the skin surface at any one time. Many animals carry the mite within their skin without any evidence of skin disease or damage. The factors influencing mite activity and numbers in the horse are poorly understood, but inflammation, debility and immune status may all be of importance. Demodicosis has been reported in association with **chronic glucocorticoid therapy**.

Clinical signs and diagnosis

Demodex mites are a not infrequent finding during routine microscopic examination of skin material. On rare occasions, local massive increases in mite numbers may occur and lead to the production of either:

1. A patchy, non-pruritic, scaling reaction accompanied by hair loss and, on occasions, increased pigmentation. Lesions are most frequently noted over the face, neck and/or shoulders; often these lesions appear to be a sequel to insect bites and many resolve spontaneously in time.
2. Multiple, nodular, follicular cysts, which are non-painful and vary in size from a pinhead to a small pea.

Diagnosis may be confirmed either by finding large numbers of mites on microscopic examination of scale or substantiating the presence of mites in the caseous material obtained from opened follicular cysts or in skin biopsies.

Treatment and control

Scaly lesions may be treated topically with **lime sulfur** in oil, **rotenone** in spirit, or **benzyl benzoate**. Amitraz is contraindicated in horses. Nodular lesions are refractory to all treatments, such lesions persisting for many years and causing little discomfort or serious hair loss.

It is important to investigate and eliminate any factors that may have caused local inflammation, or localized or generalized debility.

FORAGE AND OTHER MITE INFESTATIONS

Etiology

Free-living members of the suborder Astigmata, which occur in livestock bedding and stored foods, are often known as **forage mites**. Certain species, including *Tyrophagus* spp., *Glycyphagus* spp. and *Pyemotes* spp., may produce cutaneous disease by inoculation or deposition of irritant or pharmacologically active substances into the skin or by induction of hypersensitivity reactions.

Many species of larval Trombiculidae (**harvest mites**, red bugs or chiggers) are capable of producing skin lesions and irritation in the horse. These include *Trombicula* (formerly *Eutrombicula*) *alfreddugesi*, *T.* (formerly *Neotrombicula*) *autumnalis*, *T.* (formerly *Eutrombicula*) *splendens*, and *T.* (formerly *Eutrombicula*) *sarcina*. The larvae are active for 4–6 wk in the year in late summer and early autumn/fall. Once they have obtained a meal of lymph and disintegrated skin cells they progress to free-living nymphal and adult stages, and the problem is therefore limited.

Clinical signs and diagnosis

The **cutaneous responses** associated with forage mite infestation in the horse are extremely variable and depend on the particular mite, its mode of infestation and the reactivity of the host. Lesions may present as areas of multiple, pinpoint crusted papules; patchy, irritant scaling; papular urticaria or urticarial plaques. Lesions associated with infestations contracted at pasture most frequently involve the heels, legs, brisket, ventral and lateral chest and abdomen, face and lips.

Harvest mites produce variable numbers of **asymmetrical patches** of small, focal weeping lesions over areas of predilection. In early lesions harvest mite larvae may be recognized by their orange/red appearance. Confirmation of diagnosis in older lesions is difficult as larvae feed and vacate their host within a few days.

Horses at pasture can also pick up other pathogenic forage mites. The lesions they produce may be similar to those of harvest mites or may present as localized irritant scaling, papular urticaria or urticarial plaques.

In stabled and yarded horses the distribution of cutaneous lesions associated with forage mite infestation will vary according to the source of that infestation. Infestations associated with **food troughs** and hay nets frequently only involve the face, neck and brisket, while those associated with **bedding** frequently only involve the lower parts of the body.

Mites such as *Trombicula* and *Pyemotes* species, which produce a mainly irritant response rather than an allergic response, induce skin changes on **all in-contact animals and humans**. Other forage mites, such as some *Tyrophagus* species, only produce changes in individual animals. Lesions due to forage mite infestation must be differentiated from papular urticarial reactions caused by biting insects in temperate summers or throughout the year in subtropical and tropical climates. Similar cutaneous responses may be encountered in association with parasitic mites of birds, fleas and bed bugs in housed animals.

Survival of forage mites on the horse is variable. Many vacate their host after feeding but some species, such as *Pyemotes*, often remain in the coat for a much longer period, particularly if the host has a thick coat or heavily feathered legs. In such cases microscopic examination of **coat brushings** or surface adhesive tape strips may confirm diagnosis. In the majority of cases such an approach is unrewarding and steps must be taken to identify the source of infestation and extract the mites from it for microscopic examination. Identification of forage mites is extremely time consuming. There are over 60 000 known species of mite, of which only a relatively small number have so far been confirmed as being capable of causing skin disease in the horse and other animals.

Treatment and control

Infested animals at pasture should be **moved immediately**, either onto another pasture or into a yard or stable. **Palliative treatment** may be required, either as topical steroid or short-acting systemic steroid. **Fipronil spray** has been demonstrated to be effective against trombiculid mites. In the case of harvest mite infestation, animals may usually be returned to the original pasture after 8 wk but, as infestation is likely to remain from year to year, animals should be **removed from the pasture** at the same time the following years. Populations of other forage mites in vegetation tend to show transitory fluctuations related to growth of herbage and microclimatic factors and it is usually safe to return animals to the original pasture after a break of 2 mo.

Survival and multiplication of forage mites within stored hay, straw and cereals is dependent on the microclimatic conditions within bales, stacks or stores. Many are capable of undergoing **massive increase in numbers** when in store over winter and when humidity and temperature are favorable. Frequently such massive increases in number will be confined to one small group of bales within a stack. Infested material must be removed and replaced by material from a different source. If this is done, then the chance of recurrence of symptoms is low. If the infestation is in the bedding then this may be replaced with shavings or the animals turned out to grass.

PEDICULOSIS

Etiology

Two species of **lice** may infest horses and other Equidae: *Haematopinus asini*, a sucking louse, which feeds on blood obtained by puncturing the skin; and *Damalinia equi*, which survives by feeding on scale and skin debris.

Lice are **host specific** and can only survive for a few days, even under optimal conditions of high humidity and cool temperatures, away from their host. The life cycle is completed on the host. The female louse produces eggs that are firmly cemented onto hair shafts. After hatching, larvae undergo three molts and reach maturity within 3 wk.

Louse activity is subject to **seasonal variation** with numbers being greatest during the autumn/fall, winter and early spring.

Clinical signs and diagnosis

The symptoms and cutaneous changes associated with louse infestation in the horse show marked individual variation unrelated to parasite numbers. Many

animals with a comparatively heavy louse burden present with minimal skin changes and irritation, while other animals with very low levels of infestation present with severe pruritus, patchy alopecia, erythema and excoriation.

Louse infestation is common in the horse and should always be suspected in cases of skin irritation. Isolation of lice can be difficult when numbers are low, as adult lice are relatively small and, being either pale pink or gray, merge easily into the coat. A long and careful search of the coat under strong light is often essential to find the parasite. On some occasions its presence is more easily recognized by the identification of eggs or egg cases firmly attached to hairs on the trunk and neck, or the base of the mane and tail.

Treatment and control

Louse infestation may be treated effectively by the use of either dusting powders or washes containing **pyrethrins or synthetic pyrethroids**. Selenium sulfide shampoo and other insecticidal shampoos may also be effective. All dressings should be applied at 7–10-day intervals on **at least three** occasions. **Fipronil spray** has also been shown to be curative. Systemic ivermectin is likely to be effective against sucking, although not necessarily the chewing, lice. Particular attention should be paid to **stable hygiene** as infestation can be transmitted on blankets, rugs and grooming equipment. All animals should be routinely checked for the presence of lice and any infested or potential carrier animal treated accordingly.

FLY-RELATED DERMATOSES

Fly bites and fly worry

Lesions resulting from the bites of tabanids (*Tabanus*, *Haematopota* and *Chrysops* spp.), stable flies (*Stomoxys calcitrans*), and black flies (*Simulium* spp.) are **crusted papules**, which fade within a few days. Mosquito bites result in papules without crusts and also fade in a few hours to days. Considerable “worry” can result from large numbers of biting insects, and large swarms of black flies can kill cattle and horses.

Hypersensitivity reactions to these insects have been postulated but not demonstrated. Face flies (*Musca autumnalis*), head flies (*Hydrotaea irritans*), and house flies (*Musca domestica*) do not bite but feed on moist secretions in wounds or near mucocutaneous junctions.

Diagnosis of the problem is by **fly identification**. Fly bites should be distinguished from other types of cutaneous nodules such as early dermatophytosis, urticaria, equine eosinophilic (collagenolytic) granuloma and sarcoids (*q.v.*).

Treatment and prevention

Most bites, unless very numerous, do not require treatment, but significant “fly worry” should be alleviated. Successful control of the insects involves treatment or elimination of the **breeding grounds** for the insect involved. This is not always possible due to environmental considerations.

Control of stable flies and house flies requires regular removal of manure so that the larvae have nowhere to develop. Regular treatment of the affected

animals with insecticidal agents and repellents, particularly pyrethrins and pyrethroids, and stabling during the feeding times of those insects may be useful.

Myiasis

Etiology

Primary myiasis due to **screwworm infestation** of healthy tissue of wounds, dermatitis lesions, ulcerated neoplasms or granulomas, and mucocutaneous junctions occurs in the Americas (Central and South primarily), Africa and Asia. The genera *Cochliomyia* and *Chrysomyia* are involved. The adult fly deposits eggs in the moist areas. When the larvae hatch, they burrow into the healthy subcutaneous tissue causing liquefaction and enlargement of the lesion. They drop out in 3–6 days to pupate.

Secondary myiasis (blowfly strike) is not common in horses but may occur. The genera involved are *Lucilia*, *Calliphora*, *Phormia*, and *Cordylobia*. These flies lay their eggs in decomposing tissue of wounds and macerated skin lesions as well as in carcasses. Larvae feed on the decomposing matter and secrete enzymes, causing wound enlargement.

Clinical signs and diagnosis

Lesions are similar in primary and secondary myiasis. They are **painful and odoriferous** with exudation. The animal may become septicemic and die.

Diagnosis is by **larval identification**. Larvae should be preserved in 70% alcohol for shipment to a laboratory. It is necessary to differentiate cases occurring in simple wounds from those cases where tumors or granulomas are secondarily invaded.

Treatment and prevention

Treatment includes debridement and cleansing of lesions, use of topical insecticides, systemic antibiotics for septicemic states, and other symptomatic therapy. The avoidance of surgical procedures during the fly season and prompt wound care with bandaging and application of topical insecticides will prevent myiasis.

Hypodermiasis (warbles)

Etiology

Warbles are caused by heel flies, the larval stages of *Hypoderma bovis* and *H. lineatum*, in many countries in the Northern hemisphere, and sometimes *H. silenus* in parts of Europe and Asia. These are primary parasites of ruminants and horses are only sporadically affected.

Warble flies are similar in appearance to bumblebees and fasten their eggs to hairs on the legs and ventrum. After a few days, the larvae hatch and burrow through the skin, migrating through the body via the connective tissues. *H. lineatum* migrates through the submucosa of the esophagus and *H. bovis* migrates in the epidural fat of the spinal canal. Eventually, the larvae migrate to the subcutaneous tissues of the dorsal back where they become

encysted and form breathing pores. After about 2 mo and two molts, they emerge through the hole and fall to the ground to pupate. Warbles do not usually develop properly in the horse, failing to complete their life cycle. Horses kept near cattle are at the greatest risk of developing these cysts.

Clinical signs and diagnosis

Cattle can have large numbers of nodules while the horse, an aberrant host, seldom has more than one or two nodules, usually located on the dorsal back or withers. Lesions of hypodermiasis are easily distinguished from other nodules (dermoid cysts, eosinophilic granulomas, neoplasms) by the presence of the breathing pore. Identification of the larva removed from the cyst is confirmatory.

Treatment and prevention

The best treatment for horses is **careful surgical removal** of the intact larva. Care must be taken to avoid crushing the larva during surgery because leakage of its internal contents can cause an anaphylactic reaction in the horse.

Control of the warble in the primary or other hosts is important. Ivermectin is an effective larvicide for the control of warbles in cattle and its use in horses for regular intestinal parasite control probably prevents many cases from developing. Prior to the availability of ivermectin, organophosphate insecticides were used to control cattle warbles.

HELMINTH-ASSOCIATED DERMATOSES

Habronemiasis

Etiology

A **hypersensitivity reaction** to the migrating nematode larvae of the equine stomach worms *Habronema majus*, *H. muscae* and *Draschia megastoma* is believed to be the cause of habronemiasis, also called “**summer sores**”, seen in North America, Australia, Africa and northern Asia.

Both the stable fly and house fly deposit their own larvae in manure. The larvae then ingest the early stomach worm larvae and in this way serve as intermediate hosts in the life cycle. The adult flies deposit stomach worm larvae wherever they feed, such as in mucocutaneous junctions, in wounds, and other moist areas. Larvae that are ingested by the horse when deposited on or near the mouth and lips complete the life cycle in becoming adults in the stomach. Larvae are able to penetrate damaged or chronically moistened skin to reach the dermal and subcutaneous tissues where they eventually die.

Clinical signs and diagnosis

Few horses with stomach worms will develop the characteristic ulcerative and proliferative, seasonal lesions that may be responsive to glucocorticoid treatment alone. The problem tends to recur in the same animals year after year. The classic lesions are poorly healing wounds, which develop a granulomatous appearance and discharge a small amount of exudate. Lesions also develop around mucocutaneous junctions. Some are crater-like ulcers with

raised margins and can become quite large and extensive. Small hard granules resulting from calcification of larvae are frequently present.

Lesions of **cutaneous habronemiasis** should be distinguished from other bacterial and fungal granulomas, exuberant granulation tissue, and neoplasms (*q.v.*).

Histopathologic examination of **biopsies** is diagnostic, revealing nodular to diffuse eosinophilic dermatitis with mast cells and foci of coagulation necrosis surrounded by palisading granuloma formation. Larvae are found within the necrotic foci in some sections. Rarely, larvae may be identified on microscopic examination of scrapings from the lesions.

Treatment and prevention

Ivermectin, organophosphates and/or glucocorticoids are the most commonly used systemic treatments. One to three treatments with **ivermectin** (200 µg/kg) at 10-day intervals is usually curative but reinfection may occur if control of flies and stomach worms is not instituted. Systemic organophosphate treatment has variable success and is not without risks. **Glucocorticoids** as the sole therapeutic agent are very successful, lending credence to the hypersensitivity theory. Prednisolone or prednisone at 1 mg/kg orally for 7–14 days is recommended. Adjunctive therapy such as surgical reduction of the lesion, good wound care, and use of topical, glucocorticoid-containing ointments may be employed, as the case requires. Ocular inflammation due to habronemiasis should be controlled prior to antiparasitic treatment.

Regular deworming with **ivermectin** eliminates the adult *H. muscae* from the stomach. Stringent sanitation practices prevent flies from breeding in infected manure and carrying the larvae to susceptible horses. Additionally, good wound care and topical fly control is of particular importance for susceptible horses.

Onchocerciasis

Etiology

Cutaneous onchocerciasis in the horse is thought to be caused by a hypersensitivity reaction to the **microfilariae** of *Onchocerca cervicalis* in the dermis. It occurs in many countries of the world. The adult filariid resides in **fibrous nodules** within the **ligamentum nuchae** and produces microfilariae that migrate via the connective tissues to the dermis, especially of the ventrum, neck and face, as well as ocular tissues. Microfilariae in the dermis are ingested by feeding *Culicoides* spp., which serve as intermediate hosts for *Onchocerca cervicalis*.

Clinical signs and diagnosis

Cutaneous onchocerciasis is a **non-seasonal**, variably- to non-pruritic affliction of mature horses. It is characterized by patches of alopecia, scaling, crusting, erythema, ulceration, exudation, and leukoderma on the face, neck, chest and ventrum. Ocular lesions may also be present, including leukoderma of the temporal bulbar conjunctiva.

The major differential diagnosis for cutaneous onchocerciasis includes *Culicoides* hypersensitivity (*q.v.*) and horn fly dermatitis (*q.v.*). Other diseases

to consider include dermatophytosis, pemphigus foliaceus, eosinophilic dermatosis (*q.v.*) and other systemic infectious or immune-mediated dermatoses (*q.v.*).

Diagnosis is based on typical clinical signs, cutaneous biopsy samples revealing dermal inflammatory infiltrates surrounding microfilariae, and a favorable response to treatment with ivermectin. Since many horses carry the *O. cervicalis* microfilaria in the dermis, the presence of microfilariae without the surrounding dermal inflammatory infiltrates is not diagnostic.

Treatment and prevention

The treatment of choice is **ivermectin** at 200 µg/kg PO to kill the microfilariae. If not simultaneously treated with anti-inflammatory doses of **glucocorticoids**, some of these horses will experience exacerbation of clinical signs resulting in ventral edema and increased inflammation during the first few days post administration. The hypersensitivity reaction is especially strong against dead and dying microfilariae and such exacerbations are more common and more severe when levamisole is used as a microfilaricide. Neurologic side effects are also seen with levamisole use. Improvement after ivermectin treatment takes 2–8 wk and is maximal if biting flies are well controlled.

Since ivermectin does not kill the adult worm in the ligamentum nuchae, treatment usually has to be **repeated** at regular intervals (2–12 mo) to prevent recurrence of clinical signs. Residual alopecia, leukoderma and scarring are likely to occur in severely affected regions. Ocular inflammation due to onchocerciasis should be controlled before treatment and monitored for several days afterwards. Regular use of ivermectin for parasite control may prevent this disease.

Parafilariasis

Etiology

Parafilariasis is caused by *Parafilaria multipapillosa*; adult worms live, coiled within nodules, in the subcutis and connective tissues. The nodules discharge a **hemorrhagic exudate** containing eggs and larvae, which are picked up by various flies, acting as vectors or intermediate hosts.

Clinical signs and diagnosis

The condition has been reported in Eastern Europe and the UK and is characterized by non-pruritic, non-painful nodules affecting the neck, shoulders and trunk in the spring and summer. The lesions become hemorrhagic, crust and heal, with spontaneous regression in the autumn and winter.

Larvae (approximately 0.2 mm long) and embryonated eggs are found in smears of exudate, together with large numbers of eosinophils.

Treatment and prevention

Although the condition resolves, many cases show seasonal recurrence for several years. **Avermectins**, which are effective against bovine parafilariasis, should be effective in horses.

Oxyuriasis

Etiology

The pinworm *Oxyuris equi* (q.v.) is a common parasite of the **large bowel** of horses. The female worm lays her eggs on the perineal skin around the anus of infested horses. Eggs fall to the ground and infection occurs by ingestion. The ovipositing behavior of the females, and possibly the substance that cements the eggs to the skin, may cause varying degrees of irritation and pruritus to the host.

Clinical signs and diagnosis

Most infected horses show no clinical signs, but horses experiencing irritation rub at the tail base, causing damage to hairs, hair loss and excoriation. They may also be restless and irritable.

Diagnosis is by identification of characteristic operculate eggs, collected from the perineum by application of clear adhesive tape.

Treatment and prevention

Routine worming is indicated.

Strongyloidosis

The small intestinal parasite *Strongyloides westeri* (q.v.) is acquired by ingestion or percutaneous penetration of larvae. Cutaneous larva migrans is characterized by varying degrees of dermatitis, involving eosinophilic infiltration and necrotic tracts. The damage caused by the larvae may predispose to ulcerative lymphangitis.

Pelodera dermatitis

Etiology

Larval stages of the free-living nematode *Pelodera strongyloides* can invade the skin of domestic animals kept in moist, dirty, unhygienic environments.

Clinical signs and diagnosis

Lesions consisting of papules, pustules, ulcers, crusts, alopecia, scale and erythema may occur on contact areas, usually with moderate pruritus.

Larvae approximately 600 μm long can be identified in deep skin scrapings, and adult and larval nematodes may also be found in bedding and soil. Biopsies reveal numerous eosinophils, folliculitis, furunculosis and nematode segments within follicles and dermal pyogranulomas.

Treatment and prevention

The lesions are self-limiting once exposure to the contaminated environment is prevented, although topical insecticides may hasten resolution. Contaminated bedding should be removed and destroyed. Symptomatic treatment with medicated shampoos to remove crusts and debris may be helpful; treatment of secondary infection may be indicated and glucocorticoids may be required if pruritus is severe.

PROTOZOAL SKIN DISEASES

BESNOITIOSIS

Etiology

Besnoitiosis is an extremely rare dermatosis of Equidae that is caused by protozoans in the genus *Besnoitia*. It is found primarily in southwestern Europe and Africa, but has been diagnosed in burros in the USA. The major carrier of this parasite is not known, but it may be transmitted orally by fecal contamination of feedstuffs, by biting insects or by injection of contaminated blood.

Clinical signs and diagnosis

Early lesions consist of papules, tufted in haired areas, raised in glabrous areas. Focal leukoderma may be present. In severe cases the condition is characterized by alopecia, thickening, scaling and lichenification. The skin of the limbs, ventrum, perineum and genital regions may be affected and nodules may be found in the nasopharyngeal regions, eyelids and sclera.

More common causes of nodular and seborrheic skin conditions should be considered before making a diagnosis of besnoitiosis. Diagnosis is made by identification of parasitic cysts containing bradyzoites within skin biopsy specimens.

Treatment and prevention

There is no specific treatment for besnoitiosis. Bathing with medicated shampoos and antibiotics for cases with secondary infection may be beneficial. Oral potentiated sulfonamides were reported to be effective in a miniature donkey.

BACTERIAL SKIN DISEASES

Equine skin is **highly resistant** to invasion by bacteria. When bacterial skin infection does become established, host defenses are commonly impaired. Pyoderma may be superficial or deep depending on the level of skin affected.

SUPERFICIAL PYODERMAS

Superficial pyodermas are bacterial infections that involve the epidermis and extend into intact hair follicles. They frequently coexist with deep pyodermas and include staphylococcal folliculitis (*q.v.*) and dermatophilosis (*q.v.*).

Dermatophilosis

Etiology

Dermatophilus congolensis, a Gram-positive, non-acid-fast, filamentous, micro-aerophilic actinomycete, is the causative agent. The disease occurs worldwide, but is especially prevalent in tropical countries. In temperate areas the condition is commonly seen during or following periods of **prolonged rainfall**. Certain predisposing factors, for example moisture and cutaneous trauma,

are necessary for infection to become established. The infective agents are zoospores that are highly resistant to desiccation and may remain dormant in crusts for many months until adequate wetting enables reactivation. The organism is **transmissible by insects** for up to 24 h after contact with infected lesions.

Clinical signs and diagnosis

Clinical signs are extremely variable, but lesions are frequently found in one of two sites: dorsal midline and flanks; or distal limbs, especially fetlocks. The muzzle and eyes may also be affected. Non-pigmented areas are particularly susceptible. In Hong Kong, a generalized form of the disease has been reported in horses washed after racing.

The primary lesion is a **follicular papule** but, as this is felt more easily than seen, it may often be missed. Lesions may vary according to the age and general condition of the horse, the environment in which it is kept and the length of hair coat. Lesions are often highly exudative resulting in crust formation. In horses with a long winter coat, groups of hairs may matt together producing the so-called “**paint-brush**” effect. In short-haired horses, lesions are smaller and occur as multifocal papules covered with crusts or scale. Maceration in moist areas of the body may lead to loss of crust and the characteristic appearance may be absent in these regions. Animals are rarely pruritic but may show pronounced discomfort or pain that may render them unable or reluctant to work. Severely affected horses may show depression, lethargy, weight loss, fever and lymphadenopathy.

Dermatophilosis is an important differential diagnosis of grease heel, a condition of the fetlock causing erythema, exudation, alopecia and crust formation (*q.v.*). Differential diagnosis also includes dermatophytosis, staphylococcal folliculitis and pemphigus foliaceus (*q.v.*). Definitive diagnosis is based on history and clinical examination supported by the results of laboratory techniques. **Impression smears** taken from the undersurface of crusts or from the underlying skin surface may be stained with Gram or Giemsa and examined microscopically to show the characteristic branching hyphae made up of packets of coccoid cells. A portion of crust emulsified in saline or sterile water may release the motile zoospores, which can then be seen under high magnification ($\times 250$). Culture, skin biopsy and immunofluorescence techniques may also be employed. The organism requires microaerophilic conditions for laboratory culture and is easily overgrown by secondary invaders and contaminants; it can be difficult to isolate in chronic cases.

Treatment and prevention

If predisposing factors are eliminated, the infection will resolve spontaneously in many cases. The horse should be kept out of the rain and away from wet or muddy pastures. Clipping may be required, and **topical antibacterial agents** such as chlorhexidine, chloroxylenol, iodophors, lime sulfur (2–5%) or potash alum (1%) are recommended. As the crusts loosen, they should be removed and carefully disposed of, either by incineration or by immersing in a suitable disinfectant (e.g. 5% sodium hypochlorite or any of the above products) prior to removal from the premises. Systemic antibiotics are not normally necessary;

when they are indicated, potentiated sulfonamides and penicillins are frequently used and should be continued until lesions have resolved. No long-term immunity is acquired to this disease, and if crust removal is incomplete, the possibility of recurrence is quite high if environmental conditions are suitable.

Pastern folliculitis

Etiology

Coagulase-positive staphylococci are frequently isolated, *Staphylococcus aureus* or *S. hyicus* being commonly implicated. Streptococcal organisms may also be isolated.

Clinical signs and diagnosis

Pastern folliculitis is an **exudative dermatosis** affecting one or more limbs, principally around the caudal aspect of the pastern and fetlock regions. Erythema may accompany papules and pustules, which, if left untreated, may coalesce to form large areas of ulceration, suppuration and crusting. Systemic signs are usually absent.

Differential diagnosis includes chorioptic mange, dermatophytosis, dermatophilosis, horsepox, photosensitization and contact dermatitis (*q.v.*). Pustule contents may be used for smears and for bacterial culture and sensitivity. Skin biopsies for histopathology and for bacterial culture are often required.

Treatment and prevention

Affected areas should be clipped and washed daily with a **topical antibacterial** preparation. Sedation or even general anesthesia may be required. Topical antibacterial preparations containing **mupirocin** or **fusidic acid/sodium fusidate** may be useful. Systemic antibiotics are rarely indicated but may be required in severe or deep infections. Potentiated sulfonamides are commonly used, but resistant organisms may require treatment with drugs such as penicillin, cephalosporins, enrofloxacin, erythromycin and gentamicin. Antibiotic therapy should be continued for 7–10 days beyond resolution of infection and is typically required for 3 wk for superficial pyoderma. Minimizing exposure to moisture and irritant substances should help prevent this condition.

Truncal folliculitis

Etiology

Coagulase-positive staphylococci.

Clinical signs and diagnosis

Folliculitis is common in the horse. There is no age, breed or sex predilection, but most cases occur in spring or early summer when warmer environmental temperatures coincide with shedding, heavy riding and heavy work schedules.

Any part of the horse is susceptible, but the **saddle and girth** areas are most commonly affected. Poorly fitting tack and inadequate grooming are

predisposing factors. Initially, erect hairs may be seen over a follicular papule or pustule that may regress spontaneously or enlarge to form a crusty, exudative lesion. Lesions are rarely pruritic, but may be painful and render the horse unfit for work. The duration of the disease is commonly between 2 and 8 wk. The healing stage is characterized by progressive flattening of the lesion and a gradually expanding area of alopecia and scaling. Recurrence is common in some horses.

The differential diagnosis of folliculitis includes dermatophytosis, dermatophilosis, demodicosis and pemphigus foliaceus (*q.v.*). Samples of pus or exudate from intact pustules or nodules can be used for making impression smears and stained with Gram or Giemsa for light microscopic examination. Whenever possible, **bacterial culture** should be taken from intact pustules or nodules. Cultures taken from ulcerated lesions or exudative surfaces may yield misleading information. Skin biopsies for histopathology and bacterial culture are useful in deriving a definitive diagnosis.

Treatment and prevention

Mild cases may resolve spontaneously, particularly if the horse is rested or if predisposing factors are corrected. Daily washing with **topical antibacterial** agents such as chlorhexidine and iodophors is usually beneficial. In severe cases, systemic therapy may be needed. Selection of an appropriate antibiotic should be based on sensitivity testing, but in the horse procaine benzylpenicillin (22 000 IU/kg b.i.d. IM) given over 7–10 days is often effective.

Proper hygiene and management should avoid infection. In horses with recurrent infections, **antimicrobial shampoos** before and after work have been reported to be of benefit.

DEEP PYODERMAS

Deep pyodermas are serious bacterial infections that involve tissues deeper than the epidermis and hair follicle. Sinus tracts may appear at the skin surface allowing discharge of pus or serum. Treatment is often difficult and prolonged.

Furunculosis

Furunculosis refers to an inflammatory reaction that breaks through the hair follicle into the surrounding dermis. Folliculitis and furunculosis frequently coexist and may reflect different stages of the same inflammatory disease.

Etiology

Usually staphylococci; occasionally streptococci or *Actinomyces pyogenes*.

Clinical signs and diagnosis

Lesions may occur anywhere, but are most common in the **saddle area**. They consist of papules and pustules, which become exudative and crusted and sometimes coalesce to form large edematous nodules and plaques. Clinical examination alone may be insufficient to distinguish folliculitis from furunculosis. The condition is frequently painful and renders the horse unfit for work.

Differential diagnosis includes dermatophytosis, dermatophilosis, demodicosis and pemphigus foliaceus (*q.v.*). Definitive diagnosis requires microscopic examination of smears, fungal culture, skin scrapings and skin biopsies for histopathology and bacterial culture.

Treatment and prevention

Because weeks or months of antibacterial therapy may be required, in vitro sensitivity testing is recommended.

Cellulitis

Cellulitis literally means inflammation of the cells. It is a severe, deep, spreading suppurative infection involving the subcutaneous tissues of the skin. Lesions are poorly defined and affected horses are often febrile and distressed. Anaerobic bacteria may be involved and treatment with systemic antibiotics may need to be prolonged. The prognosis is guarded. See also vasculitis (*q.v.*).

Abscesses

Etiology

Frequently *Streptococcus equi*, *Corynebacterium pseudotuberculosis*, *Clostridium* spp. and staphylococci, also *Rhodococcus equi*.

Clinical signs and diagnosis

Abscesses are circumscribed, subcutaneous accumulations of pus, which may arise through bacterial contamination of skin wounds resulting from surgery, foreign bodies, ectoparasites or other forms of trauma.

Treatment and prevention

Surgical drainage and debridement, flushing or packing with topical antimicrobial agents. Systemic antibiotics based on sensitivity testing may be necessary but should not be given before the abscess matures or points. See also strangles (*q.v.*).

Ulcerative lymphangitis

Etiology

Usually *Corynebacterium pseudotuberculosis* (*q.v.*); other organisms including staphylococci, streptococci, *Rhodococcus equi*, *Pasteurella haemolytica*, *Fusobacterium necrophorum* and *Pseudomonas aeruginosa* are less frequently isolated. Mixed infections occur and the disease may arise from wound contamination when hygiene and management are poor. Transmission by direct contact or by insect vectors is possible.

Clinical signs and diagnosis

Painful, discharging nodules, unilateral or bilateral, may develop, usually on the distal hindlimbs. Horses are frequently **febrile** and the regional lymphatics may show enlargement, hardening and ulceration leading to lameness and

debility. An improvement may be seen after several weeks but new lesions continue to appear for months or even years. In rare cases, the condition may be fatal.

Differential diagnosis includes glanders, sporotrichosis, equine histoplasmosis, actinomycosis, nocardiosis and mycobacterial infections (*q.v.*). Definitive diagnosis is based on history, clinical signs, smears and skin biopsies for culture and histopathology.

Treatment and prevention

In early cases, surgical drainage, hydrotherapy, exercise and high doses of procaine benzylpenicillin (20 000–80 000 IU/kg b.i.d. IM) over a prolonged period may be adequate. In the later stages, the prognosis is always guarded. Autogenous bacterins have been used to treat this disease but they are of doubtful efficacy. Prevention is best achieved by good hygiene and management including early wound treatment and effective insect control.

Fistulous withers

Fistulous withers (*q.v.*) is an inflammatory condition of the **supraspinous bursa** and associated tissue.

Etiology

The etiology is uncertain and may be multifactorial, including *Brucella abortus* and other bacteria (*q.v.*) such as *Streptococcus zooepidemicus* and *Actinomyces bovis*, *Onchocerca cervicalis* and foreign bodies.

Clinical signs and diagnosis

A painful swelling around the withers may be closed (non-fistulated) or open (fistulated). Systemic illness and inflammation at other sites may be present. Radiography may reveal osteomyelitis, periostitis or fractured dorsal spines of thoracic vertebrae (*q.v.*) as well as calcification resulting from dead *Onchocerca cervicalis* worms. Contrast media can be used to determine the extent and direction of tracts in open lesions. Ultrasonography may help to show the extent of tissue damage.

Blood samples should be taken for routine hematology, biochemistry and serology. Neutrophilia and increased fibrinogen may be found. Serology may show a positive titer for *B. abortus*. In closed cases, tissue aspirates are useful for microbiologic culture and cytology, and deep tissue biopsies are indicated for culture and histopathologic examination.

Treatment and prevention

The mode of treatment depends on whether the lesion is open or closed. Closed lesions require treating with an appropriate antibiotic such as a potentiated sulfonamide (15–30 mg/kg b.i.d. PO) for a minimum of 3 wk. The use of non-steroidal anti-inflammatory drugs such as phenylbutazone and flunixin meglumine may be beneficial in reducing inflammation. Running water from a hose over the withers area twice a day or applying heat packs or ice packs

(20 min b.i.d.) will often help to reduce the inflammation. Open lesions may be washed with 0.5–1% povidone-iodine or 0.5% chlorhexidine solutions and also require long-term antibiotic therapy. Topical application of 10% clofazimine has also been used successfully in cases that were negative for *B. abortus*.

Cases that fail to respond to medical therapy may require **surgical excision** and drainage. Debridement of all affected tissues, dissection along drainage tracts and curettage of diseased dorsal spinous processes, or even subtotal osteotomy, are indicated. The surgery required is **radical and aggressive** and prolonged nursing care is needed. Repeat surgery is often required due to a high recurrence rate.

Complete rest from tacking up is essential. The prognosis is poor. The risk to humans from horses infected with *B. abortus* is believed to be small, but brucellosis in horses is covered by the Zoonosis Order of 1989 as a reportable disease in the UK, and is also notifiable in the USA.

Poll evil

Poll evil (*q.v.*) involves inflammation of a bursa between the nuchal ligament and the atlas or axis vertebrae leading to a **discharging lesion** in the poll area.

Etiology

Possible wound contamination by *Brucella* or *Actinomyces bovis*.

Treatment and prevention

Surgical drainage and antibiotics. See fistulous withers (*q.v.*).

ATYPICAL PYODERMAS

Bacterial granuloma (botryomycosis, bacterial pseudomycetoma)

Etiology

Coagulase-positive staphylococci are most commonly isolated. Mixed infections are possible. *Actinobacillus equuli* has also been isolated.

Clinical signs and diagnosis

Bacterial granuloma is frequently associated with wound contamination of **limbs or scrotum**. Lesions are non-pruritic, firm, poorly circumscribed, nodular growths often with draining tracts and ulceration. White or yellowish granules may be present in the purulent discharge.

Differential diagnosis includes other bacterial and fungal granulomas, habronemiasis, exuberant granulation tissue and neoplasia. Definitive diagnosis is based on history, clinical examination, skin biopsy and culture. Microscopic examination of Gram-stained tissue granules may reveal bacteria.

Treatment and prevention

Treatment consists of complete surgical excision and a prolonged course of systemic antibiotics based on in vitro sensitivity testing. Antibiotic therapy alone may be unrewarding due to inadequate penetration within the granuloma.

Actinomycosis

Etiology

Rare granulomas caused by *Nocardia* or *Actinomyces* spp., which may act as wound contaminants. Sometimes seen in **immunocompromised horses**, such as some Arab foals or horses with hyperadrenocorticism (*q.v.*).

Clinical signs and diagnosis

Lesions are variable and include abscesses, ulcers and draining tracts. The face and mammary glands are commonly affected. Diagnosis is confirmed by cytologic examination (sulfur granules), bacterial culture and biopsies for histopathology and special stains. Granules from lesions of actinomycosis should be cultured anaerobically.

Treatment and prevention

Surgical drainage and parenteral penicillin and streptomycin have been reported to be curative. Another reported case resolved after treatment with isoniazid (8 mg/kg PO daily), potentiated sulfonamides (30 mg/kg PO daily) and sodium iodide (66 ng/kg IV every 1–2 wk) for 12 wk.

Actinobacillosis

Etiology

Actinobacillosis (*q.v.*) is a rare, localized, granulomatous or suppurative condition of horses caused by *Actinobacillus lignieresii*. Prior damage to skin is necessary for infection to become established.

Clinical signs and diagnosis

Actinobacillus has been isolated from an **enlarged tongue** of a horse. Differential diagnosis includes other bacterial and fungal granulomatous diseases. Definitive diagnosis requires direct smears, culture and biopsy. Sulfur granules may be squashed on a glass slide and stained to show Gram-negative coccobacilli.

Treatment and prevention

Potentiated sulfonamide and oral iodide for 4 wk was successful in treating one case, and potentiated sulfonamide with rifampicin in another. In cattle, surgical excision and parenteral iodides are often successful.

Glanders

Etiology

Burkholderia mallei, a Gram-negative, facultative aerobic rod. Glanders (*q.v.*) is now rare or non-existent in many parts of the world although it does occur in Eastern Europe, India and parts of the Middle East.

Clinical signs and diagnosis

Acute and chronic forms occur with **nodules or ulcers** forming in the respiratory tract and skin. Distal limbs, including regional lymphatics, are often involved. Gram staining should demonstrate the organism.

Treatment and prevention

Euthanasia must be considered, as this can be a fatal zoonosis. The disease is notifiable in the EU and in the USA.

Cutaneous tuberculosis

Etiology

Mycobacterium avium, *M. intracellulare*.

Clinical signs and diagnosis

Hard, painful lumps with draining tracts on the abdomen and medial thighs.

Treatment and prevention

Treatment is rarely attempted due to the poor prognosis and public health risk associated with this disease. Strict hygiene procedures should be followed when handling horses suspected of having this condition.

Atypical mycobacterial infections

Etiology

Mycobacterium fortuitum, *M. chelonae*, *M. phlei*, *M. xenopi*, *M. smegmatis* are soil and water inhabitants that may act as wound contaminants.

Clinical signs and diagnosis

Painless nodules, sometimes ulcerated, may be seen typically on the legs. Diagnosis requires cytologic examination, culture and histopathology involving Ziehl-Neelsen staining to demonstrate the acid-fast organism.

Treatment and prevention

Surgical resection.

VIRAL SKIN DISEASES

PAPILLOMATOSIS

Etiology

Papillomatosis is caused by a DNA papovavirus; infection is by direct and indirect contact and requires **damaged skin**.

Clinical signs and diagnosis

Foals and yearlings are most commonly affected. There is no breed or sex predilection. Papillomas are usually found on the muzzle around the lips,

nostrils and eyes, but can also appear on the external genitalia or on the distal limbs. Lesions are often multiple and consist of raised, verrucose proliferations of epidermis. Spontaneous remission usually ensues within 6 mo and immunity is lifelong.

Diagnosis is based on history and clinical signs. Biopsy is not usually necessary. The main differential diagnosis is sarcoid (*q.v.*), which should always be considered when lesions do not resolve or when the age or site is atypical.

Treatment and prevention

Therapy is unnecessary owing to the self-limiting nature of the disease. Cryosurgery and topical agents such as podophyllin and dimethyl sulfoxide (DMSO) have been reported to be successful. There is no evidence that the administration of an autogenous wart vaccine is of any benefit in horses. Ensuring optimum hygiene and keeping down the density of foals and yearlings kept together may help prevent this condition.

AURAL PLAQUE (SQUAMOUS PAPILLOMA)

Etiology

A DNA papovavirus.

Clinical signs and diagnosis

Squamous papillomas principally affect the **inner surface of the pinna** and may be unilateral or bilateral. Other sites occasionally affected include the anus and the vulva. There is no age, breed or sex predisposition and the plaques do not resolve. Lesions start as small, smooth depigmented papules and progress to form larger, coalescing hyperkeratotic plaques. Pain and pruritus are not generally associated with this condition. There is no known treatment.

COITAL EXANTHEMA

Etiology

Equine herpesvirus 3 (*q.v.*). Coitus, insect vectors and fomites spread the disease.

Clinical signs and diagnosis

Affected areas include the penis and prepuce of males and the vulva and perineum of mares. The lips, mouth and nostrils may also be involved. The condition is characterized by papules, pustules and vesicles, which may crust over and ulcerate. Lesions may be painful although pruritus is not usually a feature. Normally there is complete healing within 14 days although focal areas of depigmentation may be a permanent sequel. Recurrence is common.

Differential diagnosis includes squamous cell carcinoma, bullous pemphigoid, horsepox and other genital infections (*q.v.*). Diagnosis is based on history, clinical examination, biopsy and virus isolation, preferably from vesicle contents.

Treatment and prevention

Rest from coitus for 4 wk. Topical creams or ointments may be beneficial. Mating with infected animals should be avoided.

HORSEPOX

Etiology

An unclassified poxvirus antigenically related to cowpox virus.

Clinical signs and diagnosis

Three clinical expressions have been described:

1. Oral lesions
2. Pastern and fetlock lesions
3. Vulval lesions.

Vesicles, umbilicated pustules and crusts are found on skin and mucosal surfaces. Mild pyrexia may be a feature. Lameness may accompany limb involvement.

Biopsy reveals ballooning degeneration of epidermal cells, intraepidermal microvesicles and intracytoplasmic inclusion bodies. A perivascular dermal inflammatory infiltrate is present with neutrophil invasion of the epidermis. Demonstration of poxvirus (*q.v.*) by electron microscopy and virus isolation confirm the diagnosis.

Treatment and prevention

Spontaneous recovery occurs within a few weeks. Infection confers long-term immunity.

VIRAL PAPULAR DERMATITIS

Etiology

An unclassified poxvirus, resembling cowpox and vaccinia viruses.

Clinical signs and diagnosis

Small asymptomatic papules progress to form crusty lesions within 7 days and an annular alopecia after about 14 days. Spontaneous remission usually occurs within 4–6 wk.

The differential diagnosis includes folliculitis, dermatophilosis, demodicosis and dermatophytosis. Definitive diagnosis requires viral culture. There is no specific treatment.

EQUINE MOLLUSCUM CONTAGIOSUM

Etiology

A molluscipox virus, with close DNA sequence homology to human molluscum contagiosum. Contagion between horses does not appear to occur and cases may represent an anthroponosis, with horses acquiring infection from humans.

Clinical signs and diagnosis

Lesions are found on the external genitalia, inguinal and axillary regions and on the muzzle. Early lesions appear as smooth, raised, waxy, whitish papules some 1–2 mm in diameter, which develop a central caseous plug. The histologic appearance is diagnostic, with epidermal hyperplasia and swelling of individual keratinocytes that contain large intracytoplasmic inclusions called molluscum bodies. These cells are exfoliated through a crater in the stratum corneum at the center of the lesion. There is no dermal reaction in most cases.

Treatment and prevention

No successful therapy is reported and animals may remain affected for months to years.

VESICULAR STOMATITIS*Etiology*

A vesiculovirus of the Rhabdoviridae that is enzootic in the Americas. Vesicular stomatitis (*q.v.*) has a seasonal incidence and is believed to be transmitted by biting insects. The virus may infect horses, cattle, swine and humans.

Clinical signs

The condition is known as “sore nose” or “sore mouth” and is characterized by vesicles that progress to painful erosions of the muzzle and mouth, feet and occasionally udder or prepuce. The incubation period is 1–3 days.

Diagnosis

Biopsy reveals marked intra- and intercellular epidermal edema and spongiosis with microvesicle formation and necrosis. A superficial and deep perivascular dermal inflammatory reaction is seen with neutrophils predominating.

Treatment

Healing usually occurs within 2 wk, sometimes leaving depigmented areas. Hooves may be sloughed on rare occasions. Mortality is rare and no specific therapy is indicated.

EQUINE VIRAL ARTERITIS*Etiology*

Formerly classified as a togavirus, equine arteritis virus (*q.v.*) is now classified as a member of the genus *Arterivirus*. The causative virus is transmitted by coitus and inhalation. The disease occurs in many parts of the world and is reportable in the UK and USA.

Clinical signs and diagnosis

Edema of the distal limbs, ventrum, prepuce and scrotum and periorbital areas may be seen, with less frequent involvement of the sternum, shoulder,

intermandibular space and udder. Rarely, papular to urticarial lesions are seen on the trunk.

Biopsies reveal a lymphocytic arteritis, with viral antigen demonstrable in affected vessels. Infected animals can be identified by serologic tests.

FUNGAL SKIN DISEASES

DERMATOPHYTOSIS ("RINGWORM")

Etiology

Superficial fungal infection of skin and hair in horses is caused by several species of dermatophytes, including *Trichophyton equinum*, *T. mentagrophytes*, *T. verrucosum*, *Microsporum gypseum*, and *M. canis*. *T. equinum* is by far the most common. Infection occurs by contact with viable spores from infected hair on **infected animals or people**, on contaminated fomites (especially tack and grooming equipment), and in contaminated soil. The incubation period is 1–4 wk.

Clinical signs and diagnosis

Young animals kept in damp, dirty conditions with overcrowding and poor nutrition are most susceptible to infection. Horses under the **stress of training** are also susceptible. Outbreaks are most common in autumn/fall, winter and early spring.

The lesions consist of **patchy alopecia**, **crusting and scaling** with varying degrees of **erythema**. Early lesions may appear urticarial. Some cases exhibit pruritus or pain. Generally, organisms that are less well adapted to the horse cause more inflamed lesions.

The differential diagnosis should include dermatophilosis, bacterial folliculitis, demodicosis, cutaneous onchocerciasis and some allergic or autoimmune conditions (*q.v.*). Preliminary diagnosis is based on history, clinical signs and positive microscopy (**ectothrix spores coating a hair shaft**). However, **fungal culture** with subsequent identification should follow for confirmation of the diagnosis and to establish the source of the infection in order to institute appropriate control measures.

Treatment and prevention

Most dermatophyte infections are **self-limiting** and regress in the individual animal in **2–3 mo**. Herd outbreaks may be prolonged as the fungus gradually spreads to the susceptible animals. In either case, the **zoonotic potential** of the disease cannot be ignored.

The goal of treatment is to prevent spread to other animals and humans. Topical therapy is aimed at elimination of **infected hairs** by clipping wide margins around lesions (when practical), followed by bathing in **chlorhexidine–miconazole shampoo**. Alternative topical therapies are washing with chlorhexidine or povidone-iodine shampoos and, finally, sponging on a **fungicidal dip** such as 100 ppm natamycin, 0.2% enilconazole, 3% captan, 3–5% lime sulfur, 2–3% chlorhexidine, 10% povidone-iodine or a 0.5% solution of

sodium hypochlorite. Published trials using systemic treatment with griseofulvin are flawed. Dosing according to the manufacturer's recommendations with **griseofulvin is of doubtful efficacy**.

Clipped hairs should be properly disposed of to prevent spread of infection. Bathing and dipping should be performed daily for the first week and then weekly thereafter until lesions have cleared. In a herd, affected horses should be **separated** from non-affected animals, which should be handled separately or before handling affected animals. All persons involved with the horses should be warned of the zoonotic potential and instructed in good hygienic practices. The expense of systemic therapy with griseofulvin is rarely warranted in the horse and systemic therapy does not eliminate the need for topical therapy.

Depending on the dermatophyte involved, **other animals** (cats, dogs, cattle) may require simultaneous treatment in order to eliminate the source of infection. Treatment of premises may be necessary such as fogging with enilconazole or spraying with 3% captan, 5% sodium hypochlorite, 5% lime sulfur, 3% cresol, benzalkonium chloride or other fungicidal agent. Stressful and unsanitary conditions should be corrected and horses in training should be rested until recovered. Fomites such as tack and brushes also require disinfection.

MALASSEZIA DERMATITIS

Etiology

A species of lipid-dependent monopolar budding yeast organism closely related to *Malassezia sympodialis* has been isolated from the skin of healthy horses. A non-lipid-dependent species has been isolated from a healthy horse and also in association with a facial dermatitis. Anecdotally, yeast organisms have been identified cytologically and also by culture, in association with intermammary dermatitis and scaling dermatoses elsewhere on the body.

Clinical signs and diagnosis

Pruritic, scaling and alopecic lesions affecting the face of a horse that had been on glucocorticoid therapy have been reported. The pruritus and the lesions resolved with antifungal therapy. Large numbers of yeast organisms have also been identified on cytologic preparations from crusting/scaling lesions on the trunk and distal limbs of horses (anecdotal), with variable pruritus and resolution with antifungal treatment.

Yeast overgrowth in the intermammary region of mares is associated with often copious greasy exudation, variable erythema and inflammation, sometimes with evidence of pruritus in the form of kicking, and rubbing.

Treatment and prevention

Topical antifungal shampoos such as **chlorhexidine-miconazole**, or chloroxylenol (with the antiseborrheic product salicylic acid and sodium thiosulfate), or miconazole shampoo are effective in securing resolution. Lotions or creams containing azole products may also be useful for cases of yeast-associated intermammary dermatitis. Normal grooming practice should involve keeping the intermammary area of mares clean, and the above shampoos would be suitable for this purpose on a prophylactic basis.

SAPROPHYTIC FUNGAL INFECTIONS

Three main syndromes, mycetoma, phaeohyphomycosis and sporotrichosis, can result from infection of cutaneous and subcutaneous tissues by fungal agents that are not primary pathogens but opportunistic invaders.

Eumycotic mycetoma

Etiology

Mycetoma is a **chronic subcutaneous** fungal (eumycotic) or bacterial (actinomycotic) infection characterized by tumefaction, draining tracts and tissue grains. Eumycotic mycetomas are caused by saprophytic fungi that gain tissue access by traumatic implantation. *Curvularia geniculata* (dark granules) and *Pseudoallescheria boydii* (light granules) are the most common fungal agents isolated.

Clinical signs and diagnosis

Nodules or masses with ulceration and drainage are the typical lesions. There may be single or multiple lesions. A history of wounding may be suggestive, but small wounds or punctures may be missed.

Actinomycotic mycetoma, other bacterial or fungal granulomas, neoplasia and cutaneous habronemiasis (*q.v.*) are the major differential diagnoses. Biopsy of the mass for histopathology and culturing from a sterile biopsy sample or grains, which contain the fungal elements, will yield the diagnosis. Identification of the cultured fungus is based on conidia morphology. Histopathology reveals a pyogranulomatous to granulomatous infiltrate surrounding tissue grains consisting of an amorphous matrix surrounding pigmented or non-pigmented fungal hyphae.

Treatment and prevention

Complete surgical excision of eumycotic mycetoma is the treatment of choice. Some of the newer antifungal agents, e.g. **ketoconazole**, may prove useful, although expensive, in some cases where surgical excision is impossible. Good wound care may prevent many cases.

Phaeohyphomycosis

Etiology

Phaeohyphomycosis is caused by darkly pigmented (dematiaceous) fungi that inhabit soil and vegetation and gain access to tissues via traumatic implantation. *Dreschlera spicifera* and *Hormodendrum* spp. have been isolated in lesions from horses.

Clinical signs and diagnosis

Lesions are typically single or multiple dermal nodules with normal overlying skin. Ulceration and drainage may be seen.

Cutaneous habronemiasis, other fungal or bacterial granulomas and neoplasia should be considered in the differential diagnosis (*q.v.*). Diagnosis is

made by biopsy and culture of tissue samples. Biopsies reveal **pyogranulomatous inflammation** surrounding pigmented, septate hyphae and round to oval yeast forms. Conidia produced by the cultured fungus are characteristic for the species.

Treatment and prevention

No single treatment mode is successful for all cases of phaeohyphomycosis. Where possible, surgical excision is the best therapy. Some of the fungi may respond to systemic antifungal agents such as amphotericin, ketoconazole or newer imidazole or triazole agents. Good wound care may prevent many cases.

Sporotrichosis

Etiology

Sporotrichosis is caused by the fungal agent *Sporothrix schenckii*. It is a dimorphic fungus that inhabits soil and vegetation and gains entrance by traumatic implantation.

Clinical signs and diagnosis

The **cutaneolymphatic form** of sporotrichosis is most common in horses. Firm, subcutaneous nodules develop along the lymphatics. The lymphatics may become hard and swollen, resulting in palpable linear cords. Nodules may ulcerate and drain small amounts of pus or blood-tinged fluid.

The differential diagnosis should include the bacterial and fungal causes of lymphangitis (glanders, equine histoplasmosis, ulcerative lymphangitis) and sterile nodular panniculitis (*q.v.*). Diagnosis is made by cytology, biopsy and culture. **Cytologic examination** of smears from exudate or touch preparations of biopsy specimens may reveal characteristic pleomorphic (round to cigar-shaped) budding organisms. Organisms may be difficult to find in cytologic preparations or in biopsy specimens. Culture of exudate and/or sterile tissue samples followed by identification is the most reliable means of diagnosis.

Treatment and prevention

Iodide therapy with sodium or potassium iodide or with the organic iodide, ethylenediamine dihydroiodide (EDDI), is the treatment of choice. Surgical removal of single lesions may be helpful. Sodium iodide is given IV as a 20% solution at a dose of 20–40 mg/kg s.i.d. for 2–5 days, and then PO in sweet feed or molasses once daily. Potassium iodide is given at a dose of 1–2 mg/kg PO once or twice daily for the first week and then at half that dose daily. EDDI is dosed and administered similarly. Regardless of the form, iodide therapy must be continued for a minimum of 4 wk after complete resolution of lesions. Toxic signs of iodism (scaling, alopecia, depression, fever, cough, excessive lacrimation, nasal discharge, anorexia and salivation) may occur. Iodides should not be used in **pregnant mares**.

Amphotericin has been used successfully in a few cases. The newer imidazole or triazole antifungal agents also may be useful, albeit expensive, alternatives to the iodides. Affected animals should be separated from healthy

animals to avoid accidental spread of the disease due to increased environmental contamination.

Zoonotic potential to persons handling infected horses should not be overlooked. Gloves and protective clothing should be worn when dealing with suspected or confirmed cases of sporotrichosis. Disinfectant agents should be used to scrub after handling.

DEEP/SYSTEMIC MYCOSES

The fungi that classically cause systemic mycoses in humans and animals, *Blasotomycetes dermatitidis*, *Coccidioides immitis*, *Cryptococcus neoformans* and *Histoplasma capsulatum*, are rarely causes of disease, especially cutaneous lesions, in horses. There are, however, three diseases that are appropriately considered under this category: zygomycosis, pythiosis and equine histoplasmosis. Zygomycosis and pythiosis were previously termed phycomycosis.

Zygomycosis

Etiology

Zygomycosis is the term applied to syndromes caused by infection with various environmental saprophytes in the class Zygomycetes. *Basidiobolus haptosporus* and *Conidiobolus coronatus* are the most common species causing equine infection.

Clinical signs and diagnosis

Lesions caused by *B. haptosporus* are **solitary, ulcerative granulomas**, which may become quite large and usually occur on the neck, chest and trunk. Pruritus is usually present. Elongated, gritty, whitish-yellow coral-like bodies known as leeches or “kunkers”, which consist of fungal organisms and necrotic host tissue, are variably present but smaller than those seen in pythiosis. The ulcerative granulomas caused by *C. coronatus* are usually found on the external nares and nasal passages. They may be single or multiple and also may contain small kunkers. As the lesions enlarge, nasal discharge and/or dyspnea may occur. Systemic infection is rare.

The differential diagnosis includes exuberant granulation tissue, pythiosis, neoplasia, and other bacterial, fungal or parasitic granulomas (*q.v.*). The nasal form should be distinguished from amyloidosis (*q.v.*). Diagnosis is accomplished by biopsy and culturing. Broad, infrequently septate hyphae within the lesion are suggestive of zygomycosis but culturing is necessary to distinguish it from pythiosis. Tissue samples and/or kunkers are suitable for culturing. Identification is made by fungal morphology.

Treatment and prevention

Where possible, complete **surgical excision** is the treatment of choice. Systemic antifungal therapy is variably successful. Usually a combined approach with surgery, application of topical antifungal preparations to external lesions and systemic therapy is required. One successful topical agent

(**Brown's Phyco Fixer**) includes 7.5 g of ketoconazole and 4.8 g of rifampicin in 400 mL of DMSO and 100 mL of 0.2 M hydrochloric acid. Amphotericin is the systemic antifungal agent of choice, but results are variable and surgical treatment combined with topical therapy usually is still necessary.

Pythiosis

Etiology

Pythium insidiosum, formerly *Hyphomyces destruens*, is the etiologic agent of the condition called **pythiosis**. This condition is seen in swampy, tropical and subtropical locations and has been called "**Florida horse leeches**". The organism is not a true fungus and is classed in the kingdom Protista. It is a plant parasite that resides in stagnant water and releases motile zoospores that are attracted not only to plants but also to hair, especially of horses and some breeds of dogs. Skin wounds, if present, allow the zoospores to invade the subcutaneous tissues.

Clinical signs and diagnosis

The lesions appear similar to those of zygomycosis with granulomatous tumefaction, draining tracts, large kunkers and pruritus (*q.v.*). Rapid enlargement is characteristic. Lesions tend to occur where wounds are common, especially the lower limbs and also the ventral midline where lesions of horn fly dermatitis, *Culicoides* hypersensitivity or cutaneous onchocerciasis occur. The history may include a poor response to routine wound care. Systemic infection is rare.

The differential diagnosis is the same as for zygomycosis. Culture and identification of the organism from the kunkers or from tissue samples is the best method of diagnosis. Such cultures should be submitted to a laboratory experienced in the identification of *Pythium* spp. Biopsies reveal eosinophilic, granulomatous to pyogranulomatous inflammation containing broad, irregularly branching, infrequently septate hyphae. An immunohistochemical stain has been developed for diagnosis of pythiosis on formalin-fixed sections and is available in a few specialized laboratories.

Treatment and prevention

Treatment of pythiosis is similar to that for zygomycosis: **surgical excision** and application of **topical antifungal preparations**. Amphotericin is unlikely to be of benefit since the organism's cell wall does not contain ergosterol. Immunotherapy using preparations of *P. insidiosum* has been successful but is not free from side effects. Development of **sterile arthritis** has been reported. Early lesions respond more favorably to treatment. Very large lesions carry a poorer prognosis and may require multiple surgical excisions before they are controlled.

Restricting access to stagnant ponds and puddles and prevention of wounding will help prevent this disease. Parasitic dermatoses should be controlled and all wounds should receive prompt, consistent treatment. If healing does not progress properly, wounds should be evaluated as early as possible for *Pythium* infection, before the lesion becomes too large to be easily excised.

Histoplasmosis

Etiology

Equine histoplasmosis (**epizootic lymphangitis**) is caused by the organism *Histoplasma farciminosum*, a dimorphic fungus. The disease is seen primarily in Africa, Asia and Eastern Europe. It is spread by wound contamination and biting flies. The organism can survive in the soil for 2–3 mo. There are rare reports of this infection in humans and pigs.

Clinical signs and diagnosis

Unilaterally distributed, **firm nodules** on the face, neck, head, and sometimes the limbs are characteristic early in the course. The nodules become fluctuant, rupture and discharge a purulent exudate, which may contain blood. The ulcerated nodules tend to enlarge and the lymphatics become prominent. Spread to the contralateral side follows after several weeks. Rarely, spontaneous recovery occurs.

The differential diagnosis should include other causes of lymphangitis (glanders, sporotrichosis and ulcerative lymphangitis), other bacterial and fungal infections and sterile nodular panniculitis (*q.v.*). Since the organism is difficult to culture and grows very slowly, **cytologic examination** of exudate or biopsy for histopathologic evaluation is the best means of diagnosis. Yeast-phase organisms are seen primarily within macrophages in these preparations and are indistinguishable from those of *H. capsulatum*, the etiologic agent in histoplasmosis in small animals.

Treatment and prevention

The disease is reportable and managed by strict isolation and slaughter of affected animals. In herds, insect control, prompt wound care and good sanitation practices may help prevent spread of the disease to the non-affected animals. When implementing these measures, it should be remembered that the incubation period can be longer than 2 mo.

CONGENITAL/HEREDITARY SKIN CONDITIONS

Congenital skin conditions are rare in the horse. In many cases their etiology and mode of inheritance is obscure, as is their prognosis. Their treatment is of doubtful value.

HAIR FOLLICLE DEFECTS

Hair follicle dysplasia

Etiology

Dysplasias of black and white hair follicles are recorded more frequently in species other than the horse. The cause of the disorder is unknown.

Clinical signs

Characteristically there are areas of dystrophic, brittle, lusterless hairs where hair growth is persistently poor. In the Appaloosa breed, foals having apparently

normal follicles at birth show progressive loss of black hairs while non-black hair remains normal. There is no treatment.

Hypotrichosis

Etiology and clinical signs

Congenital hypotrichosis has been reported in a blue Percheron foal born with poorly circumscribed patches of alopecia affecting the trunk. Biopsies revealed severe follicular hypoplasia, but adnexal structures were normal. The alopecia was progressive.

Curly coat

Etiology and clinical signs

Curled hair follicles are abnormal in horses. Curliness of the haircoat has been recognized in several breeds, in particular the **Percheron**. The mode of inheritance of the defect is considered to be as an autosomal recessive trait. There is no treatment for this condition.

Mane and tail hair dystrophy

Etiology and clinical signs

This condition is characterized by dystrophic short, brittle, lusterless hairs that readily fracture leaving the affected area stubbly. The cause is unknown.

HYPERELASTOSIS CUTIS OR HEREDITARY EQUINE REGIONAL DERMAL ASTHENIA (HERDA), CUTANEOUS ASTHENIA (DERMATOSPARAXIS, EHLERS–DANLOS SYNDROME)

Etiology

Hyperelastosis cutis comprises a number of **heritable disorders** seen more commonly in the cat and dog than in the horse. In horses, the more profound collagen defects seen in some other species have not been recorded and defects have been confined to localized manifestation of skin hyperextensibility and fragility. Joint hyperextensibility is said to occur in some cases. Autosomal recessive transmission is suspected. The condition has been reported in Quarter Horses, a crossbred Arab and a Haflinger.

Clinical signs

The signs are often mild with localized areas of hyperextensible, mobile skin. This may be readily torn and show evidence of healing with scar formation. The area most commonly affected is the back and thorax.

Diagnosis

Clinical signs of thin, hyperelastic skin in localized areas, thinning of the dermis and scarring. Histologic examination of biopsy material may show abnormal staining affinity to certain connective tissue stains. Electron microscopy may demonstrate abnormal collagen fibrillogenesis.

Treatment

Symptomatic; suture skin tears. Affected animals should not be bred.

EPITHELIOGENESIS IMPERFECTA (APLASIA CUTIS)

Etiology

An inherited, **congenital** condition reported in several breeds of horses. The mode of inheritance is ill defined but thought to be a simple autosomal recessive trait.

Clinical signs

There is an abrupt area of absence of epithelium, particularly of the limbs but sometimes involving the tongue. The condition may be lethal. The differential diagnosis includes skin trauma at foaling.

Treatment

Euthanasia is usually indicated.

JUNCTIONAL EPIDERMOLYSIS BULLOSA

Etiology

A defect in the expression of **laminin-5**, resulting in separation through the lamina densa of the dermoepidermal junction, has been documented in Belgian draft horses and two French draft horse breeds; an ultrastructurally similar defect has been described in American Saddlebreds. In American Saddlebreds the genetic defect has been mapped to chromosome 8, the locus for the *LAMA3* gene, and in the Belgian and French draft horses a defect in the *LAMC2* gene has been identified.

Clinical signs

Transient vesicles or bullae may be seen at or soon after birth. These rupture to form well-demarcated ulcers with exudation and crusting. Lesions typically affect the coronets, mucocutaneous junctions and skin over bony prominences. Hoof wall separation leads to sloughing; corneal lesions and dental dysplasia may be present. Affected foals are unable to feed; they become depressed, cachectic and die of septicemia.

Diagnosis

Biopsies reveal subepidermal clefts with the PAS-positive basement membrane zone attached to the dermal floor.

Treatment and prevention

Euthanasia is indicated. Parents of affected foals should not be used for breeding. The identification and localization of the genetic defects offers the option of a **molecular test** to identify carrier status and better management of breeding strategies.

DENTIGEROUS CYSTS

Etiology

Dentigerous cysts are a developmental anomaly associated with the first branchial pouch and the condition is seen in foals and young horses. The lesion may contain embryonic teeth.

Clinical signs

A bilateral or unilateral fistulous opening is associated with a firm swelling below the base of the ear. There is usually a persistent, milky, **purulent discharge** from the lesion.

Diagnosis

Radiography, exploratory surgery. The differential diagnosis includes foreign body, abscess and tumor.

Treatment

Surgical excision offers a good prognosis.

PIGMENTARY DISORDERS

CONGENITAL/HEREDITARY CONDITIONS

Albinism

True albinism probably does not occur in the horse, as **no albino gene** has yet been identified in this species. Horses with pink skin and white coat blue eyes, are usually the result of a **double dose** of the **cream dilution gene**, found at the albino locus, and are termed Cremellos. Phenotypically white horses can also result from other gene combinations that determine white coat patterns. The coloration is of little clinical significance except that affected animals may be at greater risk of suffering from photodermatitis, phototoxicity or photosensitization.

Lethal white foal disease

Lethal white foal disease results from the **homozygous expression** of the **autosomal dominant** gene which codes for the Frame pattern of coat coloration. Affected individuals have a defect in migration of neural crest cells resulting in absence of melanocytes and lack of myenteric plexuses in the intestinal tract. The defects of the intestinal tract, which include colonic atresia, are not consistent with survival. The condition is associated with a mutation in endothelin receptor B. DNA testing can be used to identify heterozygote carrier status, since phenotypic expression of the Fr gene may be minimal.

ACQUIRED DEPIGMENTATION

Mechanisms of pigment loss are not well understood. They may in some cases be post-inflammatory, autoimmune, neural or toxic.

Leukoderma

Etiology and clinical signs

Depigmentation follows traumatic injury to the skin or an inflammatory condition. Leukoderma is a common finding in horses, particularly in areas of tack damage. Localized depigmentation around the commissures of the lips and tail base may be due to the effect of chemicals contained in rubber tack such as bit guards and crupper straps.

Diagnosis

History of previous skin damage.

Treatment and prognosis

The loss of pigment may be temporary or permanent. There is no effective treatment. Avoidance of physical injury, particularly from ill-fitting tack, is indicated.

Vitiligo

Etiology and clinical signs

Vitiligo is a **disfiguring**, non-pruritic, non-painful, localized loss of pigmentation in focal areas of the skin, most commonly seen in **Arabian horses**. In the Appaloosa breed, the color pattern of the coat develops postnatally by progressive focal depigmentation, i.e. genetic loss of pigment. Some cases may have an autoimmune basis, but many are idiopathic. Breed predispositions indicate a probable genetic basis.

Diagnosis

Typical clinical findings and absence of preceding skin damage.

Treatment and prevention

There is no effective treatment, but occasional horses re-pigment.

Pinky syndrome, Arabian fading syndrome

Etiology

Idiopathic vitiligo of unknown cause.

Clinical signs

There is **progressive depigmentation** of the skin and hair, particularly around the commissures of the lips and muzzle and also the periorbital skin and eyelids; in some cases depigmentation extends to involve the perianal or perivulval area. Areas of loss of skin and hair pigment are non-pruritic, non-painful and non-crusting. Affected animals vary in age, but most are young (1–2 yr old).

Diagnosis

Based on typical history and clinical signs. Lesions should be differentiated from toxic or post-traumatic depigmentation.

Treatment

None proven as effective. Some investigators have supplemented the diet of affected animals with natural carotenoids (e.g. carrots) and considered these to have had a beneficial effect.

Leukotrichia

Loss of pigmentation of hair may follow inflammatory injury or may have an inherited basis.

Spotted leukotrichia

Etiology

A condition of unknown etiology mainly affecting Arab horses, but also seen in other breeds.

Clinical signs and diagnosis

Widespread, numerous, small clumps of white hairs over the rump and dorsum, arising spontaneously, which are non-painful and non-pruritic.

Treatment

Spontaneous resolution may occur. Cases require no treatment.

Reticulated leukotrichia

Etiology

This condition has been reported in Thoroughbreds, Quarter Horses and Standardbreds; it is of uncertain etiology, but is believed to be hereditary.

Clinical signs

A net-like pattern of crusts develops on the dorsum which, when the debris is shed, the hair grows through white.

Diagnosis

Based on history and clinical findings.

Treatment and prevention

Ineffective. Affected animals should not be bred because of the possible inherited nature of the condition.

Hyperesthetic leukotrichia

Etiology

Unknown; only reported in California.

Clinical signs

Multiple or single crusted lesions up to 4 mm diameter appear along the dorsal midline associated with extreme pain, similar to human *Herpes zoster* lesions. After a few weeks white hairs appear. Lesions spontaneously resolve after 1–3 mo. Once lesions have resolved the pain subsides but leukotrichia remains.

Differential diagnosis

Differential diagnoses include reticulated leukotrichia, dermatophilosis, *Culicoides* hypersensitivity and multiple dermoid cysts (*q.v.*) of the dorsal midline.

Treatment

No specific therapy is known.

MECHANICAL DAMAGE

Pressure sores

Etiology and clinical signs

The type, severity and duration of the changes noted following mechanical trauma vary markedly and responses may be further modified by individual variations in skin reactivity. Mild pressure or low grade frictional forces applied repeatedly to an area of skin will stimulate **increased epidermal activity** leading to acanthosis and hyperkeratosis and either callus formation with loss of hair or, in thick coated animals, compression of the callus into the dermis and the production of “corns” or “sit-fasts”.

If greater frictional forces are applied suddenly or in a sustained manner to an area of skin, tearing of dermal and epidermal tissue can result. This leads to the production of an **acute inflammatory reaction**, tissue disruption and the development of erosions or ulcers and exudation. This type of damage is frequently associated with badly fitting, worn or damaged harness and girths.

When a skin area is subjected to sustained and/or prolonged direct pressure, particularly when that skin area lies directly over bone, ischemia and other dermal changes result and the overlying epidermis becomes compromised. Epithelial death and sloughing may occur initially, followed by changes in dermal collagen resulting either in scarring, permanent loss of hair and the production of an atrophic and easily damaged epithelium, or, when damage is slightly less severe, the production of white non-pigmented hair. These types of change are frequently noted in association with **saddle sores**.

Treatment and prevention

The factors responsible for the production of mechanical damage must be identified and eliminated. Specific treatment of skin lesions may not be necessary. **Callosities** may require little treatment and resolve with time.

Corns and “sit-fasts” often respond to conservative treatment depending on their situation. If present on the back it is essential to ensure that the saddle is in good condition and has been properly fitted and that the area is protected with a thick numnah when the animal is ridden. The lesions may be excised or debrided when necessary, but this can result in more extensive, permanent damage and, as most protected lesions resolve in 6–8 mo, it should be considered a last resort.

Frictional sores and early pressure sores should be protected and treated as superficial wounds. Long-standing saddle sores present a difficult problem, as surgical removal is not usually possible and not advised. A conservative approach is recommended, ensuring that the lesions are well protected and further trauma is prevented.

BURNS

Etiology

Burns result from either direct exposure to high temperatures or over-exposure to harmful short wave radiation (atomic, ultraviolet). Similar tissue damage may result from contact with electrical power or chemical agents.

Box 5.1 Classification of burns according to severity

- **First degree burns** present as erythema and superficial edema, accompanied by severe pain. This leads to superficial desquamation followed, in uncomplicated cases, by complete resolution of lesions and no permanent damage.
- **Second degree burns** present with hair loss, superficial blistering and epidermal necrosis accompanied by pain. Healing takes place within 7–10 days, provided secondary infection is prevented. Again, no permanent changes ensue.
- In **third degree burns** there is hair loss accompanied by a severe blistering reaction with loss of the epidermis and dermis but with absence of pain sensation, except at the periphery of lesions. Healing is slow, epithelialization only occurring from the periphery. Scarring often ensues, with loss of hair follicles, sweat and sebaceous glands and development of an atrophic epidermis.
- **Fourth degree burns** present with loss of both the epidermis and dermis, accompanied by necrosis and destruction of deeper tissues. Lesions heal slowly and scarring is a serious problem. Depending on the site and severity of the deep tissue damage, there may be serious impairment of function.

Clinical signs and diagnosis

The changes noted will vary according to the time, degree of exposure and the agent concerned. The presence or severity of the burns associated with electricity is related to the voltage, the area of electrical conductance and the duration of contact.

Thermal, electrical and chemical burns may be classified according to their severity (Box 5.1).

Alternatively, burn injuries may be more simply classified as superficial, involving only the epidermis and upper part of the dermis, or deep.

Treatment

Early assessment of the severity and extent of lesions is essential. Animals seriously burnt in, say, a prairie or stable fire, having widespread superficial burns that involve **over 50% of the body**, may need to be humanely destroyed. Euthanasia may also be indicated in animals with more localized deep burns that could impair future function. The salvage of any animal suffering damage to the foot or coronary band or smoke damage to the lungs and eyes should be seriously questioned.

Burn lesions should be **soaked thoroughly in cold water or ice packs** applied as soon as possible and for at least 30 min. The agents concerned in the production of chemical burns should be identified and may need to be specifically neutralized.

Plasma loss can present a serious problem in second, third and fourth degree burns, requiring fluid therapy with both colloids and crystalloids. It may be necessary to sedate and/or give analgesics in order to carry out wound treatment. Early assessment of burns can be difficult as lesions are frequently covered with charred hair and skin debris. Inserting a needle into the center of the lesion may aid diagnosis, as absence of pain is indicative of a

deep burn. All burns cases should be given a **broad-spectrum systemic antibiotic**. Short-acting steroids may be considered appropriate.

Individual lesions should be gently cleaned and then dressed either with antiseptic or antibiotic ointment. Silver sulfadiazine cream, gentamicin ointment, cetrimide cream and chlorhexidine have been recommended. Debridement of dead tissue enhances wound healing and reduces infection. Dressings reduce fluid loss and contamination, but the size and extent of burns often render this impractical. Leg lesions should be protected using a **non-adhesive dressing** under a protective bandage. Skin grafting (*q.v.*) may be indicated in the management of extensive, deep burns.

Finally, it is essential in severe burns cases that animals are placed on a high plane of nutrition (*q.v.*).

FROSTBITE

Etiology

Chilling in young, weak, undernourished or debilitated animals can result in generalized cooling (hypothermia) and/or focal skin damage (frostbite).

Heat loss, increased when the body is exposed to low environmental temperatures, is increased further when coat cover or other forms of insulation are absent or sparse, the skin and coat are wet and/or the body surface is subjected to cold air movements (wind chill factor). As a defense measure, muscular activity and shivering is used as a means of increasing body heat and piloerection of body hair is employed to trap an increased volume of insulating static air as a blanket within the coat. Vasoconstriction of cutaneous vessels helps to reduce cutaneous heat loss and to conserve central body temperature, but at the expense of reducing still further peripheral tissue temperatures and increasing the likelihood of frostbite.

When the previously described methods of heat production and conservation fail, central body temperature falls to **hypothermia**, typified by the subject becoming moribund, shivering ceasing, respiratory and heart rate falling and blood viscosity increasing. This further increases peripheral vascular resistance. If this process is not arrested and reversed, coma and death follow.

Local cutaneous changes associated with freezing are dependent on the rapidity of the freezing process. As the skin temperature drops, cellular activity also falls. Further slow reduction in temperature results ultimately in the formation of water crystals within dermal and epidermal cells and also the interstitial spaces. Rapid reduction in skin temperature results finally in gel rather than crystalline changes within cells.

In both hypothermia and frostbite, affected areas become **hard and inelastic**. Subsequent thawing causes further serious damage with marked disruption of tissue and cell membranes, particularly of the endothelial linings of capillaries and venules with extravasation of plasma and the production of edema and inflammation accompanied by serious disruption of the local circulation.

The susceptibility of cells to low temperatures and freezing is variable. Melanocyte function is easily destroyed, even by transitory cooling or freezing that fails to produce serious adverse effects in other cells of the dermis and epidermis.

Clinical signs and treatment

Frostbite is most frequently encountered in the very young, debilitated or **undernourished foal** in harsh climatic conditions. Most sufferers show evidence of hypothermia with **low rectal temperatures** (below 32°C), slow pulse and respiratory rates, general depression or coma. In such cases the foal should be **warmed slowly** by placing in warm water or blankets. **Warm glucose solutions** may also be given either IV or by stomach tube.

Frostbite usually affects the **ears and lower leg**. If areas are very cold, and the tissues are hard and inelastic then frostbite should be suspected and immediate attention should be given. Every effort should be made to thaw such areas by immersing in water kept at 42°C. The tissues must not be rubbed or traumatized.

In mild cases of frostbite, recovery may result initially in localized pain and slight local edema which resolves within a few days, leaving apparently normal skin which later may become covered with an area of depigmented hair. In severe cases, local edema becomes marked and, within 3–5 days, well-demarcated areas of hard, black, necrotic tissue become obvious surrounded by a rim of pink, edematous and weeping reactive tissue. The necrotic tissue will finally **slough** to leave an area of pink granulation, which will then slowly heal. Frostbite affecting the ear can result in small, stunted and distorted ear flaps due to damage to underlying cartilage.

In all cases of frostbite, affected areas should be protected and steps taken to control secondary infection.

IRRITANT CONTACT DERMATITIS

Etiology and clinical signs

Contact dermatitis may result when an agent capable of producing physical or chemical damage or of inducing an allergic response comes into direct or repeated contact with the skin surface (see allergic skin diseases *q.v.*).

Physical contact dermatitis is frequently associated with poorly fitting or poorly maintained harness or noted following exercise over coarse terrain or through heavy grit or mud. The severity of the skin changes is influenced by skin resilience, degree of hair protection and time of exposure and mode of application of agent. **Chemical contact dermatitis** results from direct exposure to irritant or corrosive substances.

The severity of the ensuing skin changes is related to the type of agent, its concentration, corrosive capacity and the exposure time. Powerful irritants and corrosives always produce severe cutaneous changes following initial application. Mild irritants or powerful corrosives in very low dilution may produce little change following initial exposure, but when applied continually or repeatedly may induce serious skin changes.

Chemical contact dermatitis in the horse is most frequently encountered following the inappropriate application of skin medicaments, cutaneous exposure to stable disinfectants or in association with cleaning agents used on harness or stable blankets, etc.

Clinical signs and diagnosis

Severe blistering, edema leading to exfoliation, hair loss and the production of weeping sores will be noted following the application of strong corrosives.

Milder agents may cause a low-grade inflammation accompanied by varying degrees of irritation, scaling and hair loss following either initial or repeated challenge. The response is always confined to the vicinity of the contact area and careful study of the sites involved usually gives an indication of the nature of the causative agent.

Treatment and prevention

Further contact with the agent must be avoided. It may be necessary to wash the agent off the skin or take other steps to neutralize its activity. Severe chemical contact reactions may require palliative treatment to allow healing to take place and to control secondary infection.

PHOTODERMATITIS

Cutaneous exposure to **sunlight** can result in dermatosis of varying severity.

Phototoxicity (sunburn)

Sunburn is a photochemical reaction involving the dermis and epidermis, which is produced by direct exposure to powerful ultraviolet (UV) rays contained within the 290–320 nm (UVB) wave bands, causing erythema, inflammation and tissue damage in unprotected, non-pigmented skin. The severity of the cutaneous changes is related to the time and degree of exposure, the skin area and the ambient temperature.

Photosensitization

Photosensitivity is a **severe cutaneous reaction** that follows penetration of the very much weaker UV rays in the range of 320–600 nm (UVA) into an unprotected, non-pigmented dermis and epidermis which contains **photoreactive molecules** derived from either the circulation or topical application. The response may be classified as primary, secondary (hepatogenous), photocontact or photoallergic.

Primary photosensitivity results from photosensitizing agents being deposited directly and usually unchanged into the skin after injection or ingestion. Ingestion and absorption of certain **pasture plants** can cause primary photosensitization as their tissues contain photodynamic compounds such as furocoumarins (bishop's weed, Dutchman's breeches and wild carrot), fagopyrin and photofagopyrin (buckwheat), perloine (perennial rye grass) and hypericin (St. John's wort).

Certain species of **aphid** are also capable of inducing primary photosensitivity when ingested by horses grazing infested pastures, in particular those containing trefoils. Primary photosensitivity has also been noted sporadically in horses grazing pastures containing Swedish clovers, lamb's tongue and certain species of plantain.

Skin changes only are noted in primary photosensitivity in the horse, with the possible exception of that associated with **rye grass** (*q.v.*), which can cause incoordination and a staggering gait with or without cutaneous changes.

Secondary or hepatogenous photosensitivity is the indirect result of **liver dysfunction** or damage and/or biliary stasis, which allows a number of substances that are normally broken down within the liver or eliminated from the body in the bile to become concentrated in the skin and other organs. The most important substance associated with hepatogenous photosensitivity in the horse is **phylloerythrin**, a powerful photosensitizer produced by the breakdown of chlorophyll by **bacterial action** within the bowel.

Liver damage leading to photosensitivity in the horse may be caused by plant and other poisons. The **pyrrolizidine alkaloids** are of particular importance and are present in a number of pasture plants that may be ingested by horses including certain species of heliotrope, ragwort, rattleweed, Salvation Jane (Patterson's curse), fiddleneck and tarweed. Liver damage has also been reported in other species in association with wild heliotrope, panic grass, alecrim, bog asphodel, ganskweed, bush pea and the coal oil bush, but ingestion of these plants is unlikely in the horse.

Liver damage may also occur, under adverse conditions, following the ingestion of alkaloids contained in water contaminated with **blue-green algae** or hepatotoxins associated with plant mold growing on rotting Bermuda grasses, lupins and stored grain. On very rare occasions, photosensitivity can be associated with carcinoma of the liver, lymphosarcoma, serum and anti-serum reactions, liver infection and copper and phosphorus poisoning.

Photocontact reactions result when photodynamic agents come into direct contact with and are then absorbed by non-pigmented skin which is then exposed to sunlight; all animals so exposed show a similar reaction. Certain plants contain essential oils (furocoumarins), which are powerful sensitizers. These include some members of the carrot family, cow parsley, fennels, hogweed and possibly the buttercup family. Contact with certain coal tar products such as acridine, anthracene, phenanthracene pyridine and creosote may also lead to photosensitivity, as may contact with acriflavine, anthraquinone, eosin and acridine dyes, but this is unlikely in the horse.

Photoallergic reactions are very rare and have not been confirmed in the horse. This type of response has been noted following repeated cutaneous exposure to phenothiazines, sulfonamides and halogenated salicylanilides in humans.

Clinical signs and diagnosis

Cutaneous changes associated with primary and secondary photosensitivity involve all areas of non-pigmented or partially pigmented skin and hair. Hair-covered skin may be less severely affected or spared. Lesions present initially as severe inflammation and edema leading to skin splitting, exudation and finally skin necrosis. Dark-colored horses can present with edema and irritation involving the less protected skin of the lips and nose with milder changes involving the coronary bands.

All suspected cases should be subjected to a thorough clinical examination as hepatogenous photosensitivity is invariably accompanied by some evidence of liver dysfunction such as jaundice, weight loss, inappetance, malaise, generalized debility or, on some occasions, neurologic disorder. Examination of blood samples will reveal evidence of raised liver enzymes and phylloerythrin levels.

The diagnosis of photocontact dermatitis in the horse can present difficulties. Lesions involve only limited areas of the lips, nose and legs, and may present as patches or plaques of severe inflammation and edema leading to skin splitting and sloughing which are often confined to relatively small sections of non-pigmented skin areas.

After establishing the presence of photosensitivity, a detailed examination must be made of the history and also of the environment and diet to establish the cause.

Treatment

Affected animals should be placed in a **dark environment**. **Gentian violet dye** may be applied as a light barrier. Antibiotic therapy may be required and judicious use of short-acting systemic steroid therapy or non-steroidal anti-inflammatory agents may be of value in early cases.

Prognosis is good in cases of primary photosensitivity. Healing is usually rapid, but can result in scarring and permanent hair loss. The prognosis in hepatogenous photosensitivity is governed by the type and severity of the liver changes.

SELENIUM TOXICOSIS

Etiology

Selenium is an essential component of the enzyme glutathione peroxidase. While deficiency, with or without low levels of vitamin E, can precipitate symptoms of **muscular dystrophy** (*q.v.*) in rapidly growing foals and occasionally in older horses, excess intake of selenium from plants, cereals or contaminated water is also deleterious and produces symptoms of either acute or chronic toxicity. Naturally occurring selenium toxicity has been reported in localized areas of Australia, Canada, China, Colombia, Ireland, Israel, Mexico, Russia, South Africa and the USA.

Certain alkaline topsoils can contain very high selenium levels. The problem is amplified by low rainfall, which ensures that the element remains and is not leached out into the safety of the subsoil. The problem of toxicity is often worsened by the presence in pasture of so-called “indicator plants”. These include certain species of *Acacia*, *Aster*, *Astragalus*, *Atriplex*, *Camandra*, *Grindelia*, *Gutierrezia*, *Haplopappus*, *Machaeranthera*, *Mentzelia*, *Morinda*, *Neptunia*, *Oonopsis*, *Oxytropis*, *Penstemon*, *Sideronthis* and *Stanleya*, all of which thrive on alkaline, selenium-rich soils. They are also referred to as “accumulators” as they possess the capacity to concentrate selenium within their tissue. Many are unpalatable, but if eaten can cause acute poisoning. When these plants die and decay, they contribute to raising the concentration of selenium in topsoil still further. All plants growing on selenium-rich soils absorb selenium in sufficient amount to cause toxicity. Concentrations above 4 ppm (either in herbage or cereals) should be considered dangerous if fed for any length of time.

Industrial pollution may also lead to increased levels of selenium contamination. An inappropriately high concentration of selenium added to compounded concentrate feeds may also lead to clinical toxicosis.

Clinical signs and diagnosis

If an animal ingests very high concentrations of selenium over a period of a few days, it will become **fatally ill**, showing symptoms of fever, respiratory distress and diarrhea, leading to collapse and death. Ingestion of lower concentrations of selenium over a longer period may result in chronic selenosis (alkali disease or bob-tailed disease).

During the early stages, mane and tail hair is shed and a generalized scaly and patchy alopecia develops accompanied by dullness, depression and emaciation. Lameness often occurs due to swelling of the coronary band which leads to interruption of normal hoof growth and the production of horizontal faults and cracks in the hoof wall, which finally splits and is shed. Neurologic symptoms, including blindness, staggering gait and head-pressing, may be encountered, leading finally to collapse and death.

Diagnosis is based on history of exposure and the presenting symptoms and may be confirmed by blood tests. **Whole blood selenium levels >4 ppm** are considered diagnostic. Selenium levels indicative of toxicosis may also be measured in hair and urine.

The **differential diagnosis** includes chronic arsenic toxicosis, chronic mercury poisoning and toxicosis due to ingestion of plants of the *Leucaena* genus (*q.v.*). Leucaenosis has been reported in Australia, New Zealand, New Guinea, the West Indies and Hawaii.

Treatment and prevention

The source of toxicity must be identified and steps taken to prevent further ingestion, either by removal of animals from contaminated pasture and/or changing the source of cereal feed. Despite taking these steps, further loss of hair may occur over the following week. The feet should be examined carefully for evidence of pathology and radiographed for evidence of laminitis (*q.v.*). Any hoof cracks should be sealed immediately using an epoxy resin and the feet trimmed. All animals should be placed on a high plane of nutrition. Supplementation with sulfur-containing amino acids may be of benefit.

There is **no effective antidote** to selenium poisoning but in the absence of life-threatening symptoms, exclusion of selenium from the diet will bring about a slow recovery.

MERCURY TOXICOSIS

Etiology

Mercury and mercurial compounds have been used widely in the textile, tanning, chemical and plastics industries, wood preservation, stains, paints, electroplating, electric dry cell batteries, gold and silver extraction and as antifungal seed dressings, diuretics, antiseptics and skin blistering agents.

Mercury poisoning usually results from **accidental ingestion**. It can follow inhalation and percutaneous absorption, but this is unlikely in the horse. The type and severity of symptoms associated with mercury poisoning are dependent on the chemical formulation, solubility, relative toxicity and the amount and rate of ingestion and absorption of the individual mercurial. Mercury is a **cumulative poison** that is only slowly eliminated from the body via the kidney and alimentary tract.

Ingestion of relatively large amounts of certain inorganic mercurials (mercuric chloride 8g, mercurous chloride 12–16g, bi-iodide of mercury 6g) can cause an acute corrosive gastroenteritis resulting in straining, diarrhea, and severe colic followed rapidly by collapse and death. Ingestion of slightly smaller amounts of soluble inorganic mercurials, such as mercuric chloride, may produce milder enteric changes, but these compounds are readily absorbed from the bowel into body tissues, targeting the kidney and causing proximal tubular necrosis leading to irreversible renal failure (*q.v.*) within a few days.

Insoluble inorganic mercurials such as mercurous chloride can cause enteric upset, but are not readily absorbed. If retained within the bowel, these compounds can be broken down slowly into mercury and mercuric salts that can then be absorbed and give rise to symptoms of chronic poisoning which include cutaneous signs.

Chronic mercury toxicosis is frequently noted in association with ingestion of very low levels of organic or inorganic mercurial over many months.

Various ethyl, methyl and phenyl organic mercurials have been used as antifungal seed dressings and as diuretics and skin dressings. Organic mercurials may also be produced by the action of bacteria on inorganic mercurial industrial waste causing pollution of water and vegetation and leading to the incorporation of mercury into the food chain.

Ingestion of large amounts of organic mercurial will cause an **acute gastroenteritis** accompanied by colic and diarrhea. Enteric disturbance will not be observed when intake is lower, as may occur when treated grain or seed forms a small or intermittent part of the diet or when an animal has only limited access to contaminated water or vegetation, but such exposure may be sufficient to produce symptoms of chronic poisoning. Organic mercurials are readily absorbed from the bowel and, being lipid soluble, are then taken up preferentially by nervous tissue and fat.

As mercury levels rise in the nervous system, neurologic changes are noted, typified initially by stiffness and tremor, progressing to incoordination, ataxia, hyperesthesia, occasionally reduced vision and/or deafness and finally to coma and death.

Clinical signs and diagnosis

Chronic mercury toxicosis is typified by malaise, loss of weight and appetite and the following **cutaneous changes**: scaling of the skin which may become ulcerated, particularly over the anal and vulval areas and around the lips and gums, accompanied initially by loss of body hair and occasionally by loss of the mane, tail and leg feathers.

The symptoms of mercury poisoning are not pathognomonic, often making initial diagnosis difficult. It is essential that a careful and detailed investigation of the clinical history, environment, feed and all other in-contact animals is undertaken. Acute colic and/or gastroenteritis (*q.v.*) is more frequently associated with infection, other caustic poisons, plant poisons and mycotoxins. Neurologic changes in the horse may also be associated with plant poisons, certain molds and fungi, lead and arsenic (*q.v.*).

Chronic mercurial poisoning may be confused with all other debilitating conditions, many of which can on occasions induce cutaneous changes and

hair loss. Poor coat growth may also be noted in chronic arsenic poisoning. Loss of mane and tail hair can occur in association with chronic selenium poisoning, but hoof changes are not a feature of mercury poisoning. In certain parts of the world ingestion of *Leucaena leucocephala* will also result in the loss of mane and tail hair and cause ridging of the hoof.

When mercury poisoning is suspected, a **urine sample** should be taken and examined for evidence of mercury. High levels of urinary alkaline phosphatase and γ -glutamyl transpeptidase will often be present.

In acute poisoning post mortem examination may reveal evidence of an **acute corrosive gastroenteritis** and pale swollen kidneys and liver. Histologic examination of the kidney will reveal tubular necrosis in acute poisoning, while in chronic poisoning with kidney involvement there may be evidence of a membranous glomerulonephritis. Animals presenting with neurologic symptoms may display histologic evidence of cerebral and cerebellar atrophy with thinning of the granular layer, but no marked changes in the number or morphology of the Purkinje cells.

Post mortem and histologic examination of material obtained from cases of chronic poisoning not displaying evidence of neurologic or nephrotic changes is disappointing, but kidney assay will reveal mercury levels >5 ppm.

It is essential in all cases of suspected chronic mercury poisoning that a **thorough appraisal** is carried out into the feeds, the environment and potential sources of industrial contamination of vegetation and the water supply. All in-contact animals should also be assessed for evidence of poisoning.

Treatment

Treatment of animals presenting with acute gastroenteritis, nephritis and/or neurologic symptoms is unrewarding. In early cases of chronic poisoning identification and elimination of the source of mercurial compound is essential. Oral treatment with **potassium iodide** (4 g s.i.d.) for 10–14 days accompanied by **dimercaprol** (3–5 mg/kg IM) q.i.d. for 2 days then b.i.d. for a further 8–10 days may also be indicated.

ERGOTISM

Etiology

Symptoms of ergotism result from the ingestion of certain alkaloids and other pharmacologically active substances contained in the **plant fungi** *Claviceps purpurea* and *C. paspali*, which are capable of invading and multiplying in the seeds of many grasses and cereals. The organisms overwinter in the ground and germinate in the spring, developing stomata that produce and eject small ascospores.

The ascospores become wind-borne, finally penetrating rapidly developing seed heads where they undergo rapid hyphal proliferation, engulfing the germinal tissue and finally bursting out of the seed head to form hard, elongated, deep purple sclerotia. The sclerotia contain variable amounts of alkaloids and amines including ergotamine, ergometrine, acetylcholine, histamine and tyramine, which can cause changes in many organs such as the CNS, the uterus and the vascular system.

Active growth and spread of infection is noted during the **summer** and is markedly accelerated during or immediately after prolonged periods of wet weather or high humidity. Propagation can also occur in poorly stored hay and grain.

Clinical signs and diagnosis

The type and severity of symptoms associated with ergot poisoning are variable, being related to the concentration of ergot within the diet, the period of ingestion and the alkaloid content, together with the age and species of the animal involved.

Ergot poisoning is now rare and is most often encountered in cattle and sheep, less frequently in the pig and only extremely rarely in the horse. It is not uncommon to encounter ergot poisoning in cattle and sheep out at pasture while horses grazing the same pasture remain clinically unaffected.

Cases of suspected ergot poisoning may present in the horse as hyperesthesia, incoordination and convulsions, which can result in death. Such changes may be mimicked by mycotoxin poisoning (*q.v.*). Ergot poisoning may also result in smooth muscle spasm and endothelial damage to small peripheral arterioles and capillaries, leading to thrombosis and obliteration of small blood vessels. This results in gangrene of the extremities, particularly the lower leg and tips of tail and ears.

Affected animals present with symptoms of lameness with swelling and edema around and above the coronet on all four feet and accompanied by lack of sensation and warmth in the foot. Necrosis and sloughing of the skin and hoof may follow.

Diagnosis rests on the clinical symptoms and identification of ergot either in the forage or concentrate feed.

Treatment and control

There is no treatment for ergotism, but removal of the source of infection will bring about a slow remission of symptoms and changes in mild cases. Pasture contamination can be reduced by mowing affected areas using a high blade setting and removal of cuttings.

WOUNDS

ETIOLOGY AND CLINICAL SIGNS

Skin wounds may be produced by cutting, puncturing or tearing. The injury may involve damage to or loss of epidermal tissue, epidermis and upper dermis, or the whole of the epidermis and dermis and may involve deeper tissues as well as the skin.

The wound healing process is complex and involves the mobilization, reorganization and replacement of cells and tissues and the utilization of many biochemical mechanisms and pathways. The pattern of wound healing is influenced by the area and depth of tissue deficit, the extent of associated tissue damage, the presence or absence of bacterial infection, the physical status of the patient and area of the body involved.

Superficial wounds involving only loss of epidermis or the epidermis and superficial layer of the dermis heal rapidly, provided infection is adequately controlled and further trauma prevented. Healing is usually completed within 10 days and skin function and conformation are unimpaired. **Full thickness skin wounds** heal slowly unless the skin edges can be brought into close apposition. When closure is not possible, healing relies on the mobilization and utilization of three mechanisms: wound contraction, repair and regeneration (*q.v.*).

Wound contraction can reduce the size of a skin deficit on the flank of a horse by 30–50% within 10 days, but this mechanism is less efficient in wounds situated on the lower limbs. Although the causes of poor wound contracture in distal limbs have not been fully elucidated, previous research has suggested poor blood supply, relative hypothermia, decreased venous or lymphatic return, and imbalance of growth factors as possible contributors to delayed healing. In addition, minimal surrounding tissue is available for recruitment to allow primary wound closure and increased motion of the equine distal extremities causes dynamic tension and distraction of wound margins.

WOUND REPAIR

Wound repair is classically divided into distinct phases; these distinctions can enhance understanding and management of wounds, but are somewhat arbitrary. In reality, wound healing is a **dynamic process** during which multiple events occur simultaneously. Classically, the phases of wound healing are described as follows:

1. **Inflammatory phase.** Initially, local hemorrhage supplies red blood cells, white blood cells, platelets and fibrin to the site, forming a fibrocellular clot. Initial **clot formation** limits blood loss, and local vasoconstriction further attenuates hemorrhage. Within 10 min of clot formation, the local vasculature subsequently dilates, allowing more fibrin and clotting factors into the wound, accelerating the inflammatory process. The surface of the clot forms a scab, protecting the wound and providing early appositional strength. Just as importantly, the clot provides scaffolding for migrating white blood cells which begin the debridement phase under the influence of inflammatory mediators such as prostaglandins, serotonin, histamine and complement, as well as proteolytic and lysosomal enzymes.
2. **Debridement phase.** Stimulated by cytokines released from the first wave of white cells that arrived via initial hemorrhage, neutrophils and monocyte/macrophages arrive in increasing numbers by 6 h following injury. Neutrophils and macrophages both initiate and perpetuate debridement, and also act as antigen presenting cells, enhancing recognition of invading organisms. More specifically, neutrophils are recruited by **cytokines** (*q.v.*) such as complement, tumor necrosis factor (TNF- α) and interleukins (especially IL-1 and IL-8). They prevent local infection by phagocytosis of bacteria and foreign material, and themselves produce chemokines that attract other inflammatory cells, stimulating maturation of monocytes to macrophages within 24–48 h of arrival.

Although neutrophils are important, **macrophages** are critical to healthy healing. Healing is markedly prolonged in the absence of macrophages. They

are recruited by cytokines including IL-1 and interferon-gamma (IFN- γ). They remove non-viable tissue, bacteria and foreign material in phagosomes by formation of proteolytic enzymes and generation of free radicals through inducible nitric oxide synthase (iNOS). Release of metalloproteinases from macrophages also contributes to tissue remodeling, and other macrophage-derived mediators such as tissue growth factor- β (TGF β) and interferon-alpha (IFN- α) promote maturation by stimulating angiogenesis and connective tissue synthesis. Along with platelets, macrophages stimulate fibroblast infiltration and wound repair through the production of many factors including platelet-derived growth factor (PDGF), fibronectins and other cytokines.

3. **Repair phase.** Following elimination of local infection, debris, clotted blood and necrotic tissue, the process of **epithelialization** (*q.v.*) can begin. If manual debridement is performed and tissue is re-apposed with sutures, this process may begin within 12–24 h. Otherwise, the repair phase begins within 3–5 days following injury, after formation of healthy **granulation tissue**.

Granulation

Granulation tissue is an extraordinarily vascular complex of fibroblasts and macrophages within a matrix of collagen and fibrin. It is extremely important, as it provides early strength and blood flow to the wound, provides a surface for migration of epithelial cells and fibroblasts, and resists infection.

Fibroblasts are critical for development of healthy granulation tissue and are recruited by **cytokines** (*q.v.*) released from macrophages (especially PDGF, TGF β , and fibroblast growth factor). In the absence of macrophages, fibroblast infiltration is delayed. Fibroblast infiltration is also stimulated by mild acidity and low oxygen tension in healing tissue. Fibroblasts are recruited from mesenchymal cells in the surrounding connective tissue.

After arrival in the wound, fibroblasts begin to produce collagen, fibronectin, proteoglycan, and elastin, called “ground substance”. As more fibroblasts are recruited, they migrate into the wound across the wound surface via lamellipodia that adhere to the developing scaffold of fibronectin-coated fibrin and collagen established during the initial inflammatory phase. The amount of collagen peaks at 2–3 wk post injury, adding significant tensile strength after 5–15 days in a sutured wound. Early type III collagen fibers are replaced with mature type I fibers during this time.

Granulation tissue develops rapidly in horses, with a tendency towards overproduction, often called “**proud flesh**” (see below). Endothelial infiltration occurs following migration of fibroblasts, as existing blood vessels proliferate to form vascular loops. Lymphatic vessels develop more slowly, causing some lymphatic stasis and local edema in the first hours and days following injury.

Epithelialization

Epithelialization begins to occur immediately following formation of a healthy granulation bed (i.e. within 3–5 days), but will occur as early as 12 h after injury in a sutured wound. The **rete pegs** of the epidermis flatten, forcing cells at the wound edges to stretch across the defect.

Increased mitotic activity of basal cells begins early and enhances the rate of epithelialization, but this process occurs slowly, ranging from less than 0.2 mm/day in distal limbs to 0.8–2 mm/day on the flank. Epithelialization of large trunk wounds may take several weeks, while similar lesions on the lower legs may take several months.

During this process, cells begin to enlarge, separate from the basement membrane, and migrate across the wound gap. Epithelial cells secrete collagenases to allow **proliferation under scabs**; the scab will fall off once underlying epithelialization is complete.

Cell migration is guided by **collagen fibers**: basal cells flatten and stretch across the exposed collagen bundles via pseudopodia and microvilli. The cells should migrate across the defect until contact with other epithelial cells attenuates their progress (contact inhibition). Initially, the new epidermis is one cell layer thick, but it gradually thickens with time. Epithelial cells can also migrate down **suture tracts**, potentially leading to a foreign body reaction, or they may become keratinized, leading to sterile abscesses or scarring. The process of epithelialization is attenuated by the presence of fibrin or excessive amounts of other inflammatory products in the wound, by excessive granulation tissue, by overly frequent bandage changes, by topical corticosteroids, and also by antiseptics and ethyl alcohol (see below).

Wound contraction

Wound contraction occurs after suturing, or formation of a healthy granulation bed. Contraction may occur independent of epithelialization, but both processes appear to work in concert to achieve most rapid healing.

Contraction is mediated in particular by special cells called **myofibroblasts**. The cells, present in granulation beds, contain contractile proteins similar to the actin and myosin in smooth muscle. Myofibroblasts effectively anchor themselves to other cells and to collagen fibers in the granulation bed, and then contract, helping to draw the advancing wave of epithelial cells across the defect. This process stretches the existing cell layer, but continued collagen and epithelial cell proliferation restores the skin to normal thickness.

While the initial increase in wound strength is attributable to collagen synthesis in the early stages of healing, the greatest increase in strength occurs between 15 and 20 days post injury during the **maturation phase**. During this time, the number of fibroblasts begins to decrease, as does the concentration of capillaries.

Initially collagen fibers are arranged at random, but this matrix matures and reorganizes (more quickly in a sutured wound) because wound tension causes fibroblasts, collagen fibers and blood vessels to become oriented parallel to wound edges as functionally oriented fibers are strengthened. **Wound strength** may continue to improve with time, but the scar may only provide 80% of normal strength 1 year post trauma. Eventually an avascular, inelastic area of scar tissue is left within the dermis. After **severe trauma**, this tissue is often devoid of sweat and sebaceous glands and hair follicles, overlaid by a thick, friable epidermis that remains prone to traumatic disruption.

Rapid healing is contingent upon minimizing the total duration of each phase of the healing process. The initial inflammatory phase is essentially

unavoidable, but the duration of time that elapses between initial injury and first treatment is critical to successful primary intention healing (suturing). The “golden period” is generally defined as the first 6–8 h after injury. During this time, **bacterial numbers** will reach more than 10^5 organisms/g of tissue, or more if the wound was highly contaminated at the time of the injury. Non-viable tissue will begin to become necrotic, releasing large quantities of **pro-inflammatory cytokines** into the milieu, initiating the inflammatory phase of wound healing.

Thus, **physiologic wound care** involves attention to minimizing the duration of the inflammatory phase by removing debris, contamination, and non-viable tissue, while preserving homeostasis to promote rapid conversion to local repair phase of wound healing. Therefore, whenever possible, debris and other contaminants should be removed from the wound via **lavage** and **debridement** (*q.v.*), and obviously non-viable tissue should also be removed. These steps are critical components of wound care, as they can shorten the time required to return to normal tissue strength and architecture.

TREATMENT OF WOUNDS

Where possible, primary closure with sutures should be performed to re-appose tissue and minimize the need for granulation tissue formation, wound contraction and re-epithelialization.

Wounds that are **heavily contaminated**, chronic or swollen, or those involving synovial structures may best be handled by **delayed primary closure**, before the formation of granulation tissue, usually within 4–5 days of injury. Closure by **secondary intention** can be performed on chronic, severely contaminated or infected wounds after the formation of healthy granulation tissue; this allows optimal wound drainage and promotes gradual debridement of compromised tissue. Wounds with large skin defects on the upper limbs and body may be allowed to heal by second intention. **Skin grafting** (*q.v.*) may be necessary where the deficit exceeds the capability of wound contraction and epithelialization.

Initial assessment of wounds should include determination of more than depth and size of the wound. The possibility of involvement of **sensitive tissues** such as nerves and synovial structures should be definitively established. Wounds associated with blunt or superficial skin trauma may also involve fractures, although these typically produce more severe lameness. However, **bone trauma** is not always detectable during manipulation and palpation, especially when fracture fragments are non-displaced. Therefore, **radiographic evaluation** is indispensable for definitive evaluation of many wounds.

Wounds involving only the epidermis usually require minimal treatment. **Clipping hair** from the surrounding area and gently removing extraneous contaminants by washing the site with sterile physiologic saline solution (or a homemade solution, using one teaspoonful salt, approximately 5 g in 500 mL water) best maintains local homeostasis.

Antiseptic solutions and soaps, alcohol and hydrogen peroxide all **inhibit wound healing** by retarding physiologic inflammatory responses like wound contraction and re-epithelialization (see antiseptic lavage, below). Topical

antibiotic ointments and solutions enhance healing of minor wounds, and can be applied beneath a dressing before bandaging.

Wounds that are larger, deeper or more heavily contaminated, or those involving synovial structures can benefit from **aggressive wound care**, sometimes including antiseptics, joint and tendon sheath lavage and distal limb perfusion (see below).

Whenever possible, clients should be offered the option of general anesthesia as the optimal means for clinicians to assess, decontaminate and repair extensive wounds or those that involve compromise of synovial structures. However, many of these procedures can also be performed in the field under heavy sedation. After establishing that a patient is stable enough to tolerate sedation, administration of α_2 -agonists (xylazine, detomidine) or a combination of α_2 -agonists and opioids can enhance patient comfort and compliance. A sequential approach to wound management in the field includes many of the steps described below.

Systemic antibiotics

It has been shown that the use of **systemic antibiotics** given within 3 h of injury improves wound healing. The status of vaccination against **tetanus** (*q.v.*) must also be ascertained, and boosters given when indicated.

Broad-spectrum systemic antimicrobials should be administered early in the process, preferably immediately following preliminary evaluation of the wound. Although many lacerations may benefit from administration of routine antimicrobials (e.g. **trimethoprim-sulfa** at 30 mg/kg PO b.i.d., **procaine benzylpenicillin** at 22 000 IU/kg IM b.i.d.), heavily contaminated or chronic wounds may require more aggressive medications.

The combination of broad-spectrum antimicrobials with minimal rates of resistance (e.g. combined therapy with β -lactams and aminoglycoside such as **gentamicin** at 6.6 mg/kg IV or IM s.i.d.) is strongly indicated when wounds are contaminated or when compromise of synovial structures is suspected. For long-term medication, or when patients will not tolerate IM injection, several broad-spectrum **orally administered** antibiotics that penetrate deep soft tissue and synovial structures are available (e.g. **chloramphenicol** at 30–50 mg/kg t.i.d. or q.i.d., **doxycycline** at 5–10 mg/kg PO b.i.d.).

Antiseptic lavage

Initial management of most wounds is similar. Prior to shaving or clipping the surrounding hair, application of moist sterile sponges or sterile, water-soluble lubricant gel to the wound bed minimizes iatrogenic contamination of the wound.

Safety razors are convenient, produce very clean wound edges and may be more acceptable to reactive patients. However, razor burn due to skin sensitivity or inadequate soap/lubricant application can potentiate local infection. Even if not grossly evident, **microscopic irritation** of skin surfaces occurs when shaving with a safety razor, and this has been shown to affect rates of infection detrimentally. Clippers do not remove as much hair, and can be difficult to use on skin edges.

Some patients may not tolerate the sound or feeling of electric clippers, but cordless clippers are quiet, convenient and tend not to provoke patient responses. The surrounding skin should be cleansed with **dilute antiseptic**. Hydrogen peroxide and ethyl alcohol are ineffective at killing bacteria and are cytotoxic to epithelial and inflammatory cells. Although iodine and quaternary ammonium-based scrubs are more efficacious at killing bacteria, they are cytotoxic to epithelial and inflammatory cells, and their use is also contraindicated.

Extraordinarily contaminated or chronic wounds may benefit from a **single direct application** of dilute antiseptic solution such as povidone-iodine (0.1% or 10 mL of 10% proprietary Betadine solution in 1 L saline) or chlorhexidine (0.05%, or 5 mL of 10% proprietary Nolvasan solution in 1 L saline). These solutions offer excellent antibacterial activity and can therefore minimize the inflammatory and debridement phases of wound healing, but they have adverse effects on cellular function. Also available are **surfactant-based products** specifically designed to help remove bacteria and debris without adversely affecting the healing milieu (e.g. Constant Clens, Kendall Products), sometimes obviating the need for aggressive mechanical lavage.

In grossly contaminated wounds where some mechanical action is also required, a wound can be lavaged with **warmed sterile isotonic saline** solution delivered under pressure. A 50 mL syringe with an 18G needle delivers a suitable pressure, although pressure bags, fluid pumps, and dedicated wound lavage systems are optimal. Lavage with water alone may cause cell swelling and rupture, but is convenient for wound irrigation and may be less injurious to tissues than antiseptics, especially if followed by lavage using 0.9% saline. Lavage through a metal cannula provides both a focused stream of fluid and a sterile instrument for probing to determine the extent of the wound.

Hemostasis

Although severe bleeding should be attenuated as soon as possible, **mechanical hemostasis** is less likely to potentiate local infection if performed after initial wound lavage. Small skin vessels may spasm following crushing with hemostats, but larger vessels typically require placement of ligatures.

The use of smaller suture material (0, 2-0) means less foreign material is ultimately left in the wound, but transfixation and double ligatures may be required to ensure that hemorrhage is completely controlled. Taper needles are less traumatic to vessels and surrounding connective tissue, and synthetic monofilament materials (e.g. PDS, Monocryl) combine moderate tissue time with decreased risk of iatrogenic infection. These materials are therefore indicated in contaminated wounds.

Local or regional anesthesia

Whenever possible, **regional anesthesia** (*q.v.*) is preferred. Anesthesia via caudal epidural and distal limb nerve blocks can be administered far from affected areas, minimizing complications. Regional anesthesia also tends to produce better pain control while using less total anesthetic solution. When local infiltration around a wound must be used, anesthetic should be

deposited in an aseptic fashion with attention to nerve supply, with most of the injection focused on the dorsal, rostral or proximal wound margins.

Although the toxic dose of **lidocaine** is 10 mg/kg (250 mL of 2% lidocaine in a 500 kg horse), much lower dosages (1.5 mg/kg) can produce signs of toxicity when rapidly absorbed. Subcutaneous injection of 60–90 mL of local anesthetic is generally safe in a 500 kg horse. Local anesthetic may be diluted to 10 mg/mL (1%) in young horses, ponies and miniature horses to minimize the risk of toxicity, although this may decrease duration of desensitization.

For injuries to the distal limb, **local anesthetic infiltration** at the abaxial sesamoids, low or high four point, or peroneal and tibial nerves will typically provide adequate anesthesia to distal regions. Depending on the site of injury, caudal (coccygeal) **epidural administration** of opioids (e.g. **preservative-free morphine** at 0.1–0.3 mg/kg) combined with local anesthetic (2–3 mL of 20% lidocaine in a 500 kg horse) provides excellent analgesia to the perineum and, when diluted into 20 mL (total volume) of sterile saline, migrates rostrally to provide partial anesthesia to pelvic limbs, pelvis, flanks and even to the caudal ventrum.

The **combination of opioid and local anesthetic** is preferred in part because of the difference in durations of action; epidural lidocaine desensitizes within 15 min but lasts only 4–6 h while epidural morphine takes 2–3 h to become effective and minimizes sensitivity for 12–18 h after administration. In cases needing longer-lasting hindlimb or perineal anesthesia, an indwelling epidural catheter may be placed to allow repeat administration.

Debridement/exploration

Aggressive debridement is a critical component of wound care as it minimizes the amount of debris, infection and non-viable tissue that must be removed from the wound by inflammatory cells. In particular, chronic wounds often require extensive debridement, both to remove necrotic tissue, debris and exuberant granulation tissue and to stimulate bleeding and inflammation prior to closure by second intention. Sterile gloves and instruments should be used to minimize contamination.

Complete exploration should also be performed at this stage. Flexible sterile probes can be used to determine the depth of subcutaneous tracts extending from the wound bed. Some deep tracts may require placement of **Penrose drains** prior to suturing to minimize **seroma** or **abscess formation** (*q.v.*) in the deeper layers.

Joint "needle" lavage

During exploration, it is critical to determine whether synovial structures are compromised. Synoviocentesis of joints and tendon sheaths should be performed early to identify the presence or absence of inflammation. Fluid analysis (gross appearance, total white cell count and morphology, and protein concentration as a minimum data base) should be performed on undiluted samples whenever possible. After a sample has been obtained, **injection of sterile saline** to distend joints, tendon sheaths and bursae can help to determine whether joint capsules communicate with wounds.

If saline introduced into the joint leaks via the wound, the joint is considered compromised. Due to the grave implications of long-standing **septic arthritis** or **tenosynovitis**, referral for general anesthesia and arthroscopic evaluation and lavage should be strongly encouraged. If this is not possible, standing needle lavage using **isotonic crystalloid solutions** is warranted to help minimize infection and inflammation in the joint. A single systemic dose of water-soluble, non-irritating antibiotic (e.g. sodium ampicillin, potassium or sodium benzylpenicillin) may be added to the lavage solution.

In addition to allowing drainage via the tract into the wound, additional needles should be placed to ensure **thorough lavage** of the entire synovial structure, including palmar/plantar pouches. While fluid pumps may not be available, infusion using a pressure bag or multiple large syringes may help expedite through-and-through lavage. Following synoviocentesis or joint lavage, intra-articular administration of 500–1000 mg of **amikacin** is strongly indicated.

Distal limb perfusion

Whether administered via IV or intraosseous routes, **distal limb perfusion** is a very effective technique for treating chronic infected wounds or septic joints and tendon sheaths. This procedure may be performed following sedation and regional anesthesia. In the field, it is most practical to place an 18 or 20 G 50 mm/2 inch catheter into the **palmar digital vein** for instillation of antimicrobials. Then, a **proximal tourniquet** should be placed using a pneumatic tourniquet, Vetwrap or, ideally, an Eschmark bandage. The flat rubber Eschmark bandage is applied very tightly, beginning at the hoof and forcing blood and extracellular fluid proximally to a point above the wound. The tourniquet is removed from distal to proximal, leaving the proximal-most band in place above the wound for a maximum of 45 min.

Typically, 1 g of **amikacin** is diluted in 20 mL of sterile crystalloid fluids and slowly infused via the pre-placed intravenous catheter. This procedure can be repeated on a daily basis, although repeated catheterization of palmar digital (or other) veins is challenging.

Antibiotic lavage

Following debridement and before primary closure, a final lavage of the wound bed can be performed using sterile saline with or without fortification with antibiotics. The decision whether to lavage with antibiotics should be based on degree of contamination, chronicity and proximity to sensitive structures. Antibiotics applied topically to wounds should be water soluble and non-irritant. Good choices include **sodium ampicillin**, **potassium benzylpenicillin** or **gentamicin**; typically one systemic dose of these antibiotics is placed in 1–3 L of crystalloids for lavage. As with antiseptic solutions, a pressure-bag attached via sterile IV tubing to a metal cannula allows both lavage and final exploration of deep tracts.

Sutures

Primary wound closure should begin with apposition of deeper tissue layers. Closure of fascial planes enhances cosmetic healing and minimizes scar tissue formation. Where deeper tracts or dead space remain, **drains** should be

placed with their origin in the deepest extent and with egress through the skin via a separate surgical incision.

Non-absorbable monofilament suture (e.g. nylon or other synthetic non-absorbable, size 0) can be placed percutaneously to fix the drain in place while still allowing removal after healing has progressed.

Apposition of dead space using “**walking**” **sutures** is important to minimize the risk of seroma formation. Walking sutures should be placed beginning at the deepest extent, using absorbable suture material. Braided absorbable suture material has relatively increased tissue drag, which can enhance ease of placement; however, braided suture can potentiate infection when contaminated. Subcuticular suture patterns are indicated to re-appose skin margins and minimize tension. **Small diameter absorbable monofilament suture material** is an excellent choice for subcuticular closure.

The skin should be sutured under minimal tension, employing tension-relieving techniques and **stents** where indicated. Placement of **far-near-near-far sutures** using no. 2 nylon or Prolene is an excellent choice when tension is greater, especially on distal extremities. Simple interrupted sutures or skin staples may be placed between the larger tension-relieving sutures to complete re-apposition of skin margins.

Bandages/dressings

When primary closure of wounds is not possible due to chronicity, gross contamination or infection, or wound edge contracture, **bandaging** can help prepare the wound bed for closure by second intention, or may produce excellent results without suturing. Even sutured wounds may benefit from the protection, immobilization and antimicrobial effects of dressings and bandages. Advanced wound care techniques seek to **augment physiologic healing responses** by minimizing infection and fostering normal cellular responses while avoiding the cytotoxic effects of overly frequent antiseptic application and bandage changes.

In general, mild exudate is desirable, as this fluid will contain beneficial inflammatory mediators, thus **enhancing re-epithelialization**. The end result should be more rapid healing with less scar tissue formation. Although traditional materials are less expensive than some of the advanced approaches outlined below, the relatively infrequent re-application (every 3–5 days) and more rapid healing mean that advanced wound care also tends to be cost effective.

Just like the dynamic process of wound healing, different bandages are appropriate for wounds depending on the degree of infection or stage of repair. Some of the more commonly utilized topical therapies and dressings and their intended applications are described below.

Many chronic non-healing wounds will respond to management using some of these materials. The finely tuned balance of growth factors and pro-inflammatory cytokines (*q.v.*) present in acute wounds is often lost in chronic wounds. Therefore, maintaining a moist wound surface rich in endogenous growth factors is one of the primary goals of the methods outlined below. It is also important to consider the fact that **too frequent bandage changes** can inadvertently debride epithelial cells, further prolonging the healing process. Bandages may be changed as infrequently as every 5 days, provided the exudate is not excessive, and infection is not present.

Some wounds become chronic due to excessive **motion of the affected area**. In these situations, splinting and casting is useful to minimize motion, allowing delicate epithelial cells to migrate across the wound surface. However, some very large wounds, especially those on the distal extremities, may require skin grafting (*q.v.*) for complete resolution.

When **excessive granulation tissue** is present, it is best managed by surgical excision and foam dressings with or without a cast, as mentioned above. In these situations, splinting and casting is useful to minimize motion, allowing delicate epithelial cells to migrate across the wound surface. Wounds that have healed with significant fibrosis or with compromise of function may benefit from **reconstructive surgery**. Some very large wounds, especially those on the distal extremities, may require **skin grafting** (*q.v.*) for complete resolution.

Triple antibiotic ointment

These ointments, typically containing neomycin, polymyxin B and bacitracin, are indicated for treating minor superficial infection. Long-term use may prevent fibrosis and scarring. However, severe infection, necrosis and exuberant granulation tissue are not amenable to treatment with these topical antibiotic ointments alone.

Steroid-antibiotic ointment

Classically used to minimize exuberant granulation tissue formation, steroid-antibiotic-based ointments work by inhibiting fibroblast activity. However, they also diminish activity of epithelial cells and can therefore prolong the healing process overall, sometimes resulting in static, non-healing wounds.

Silver sulfadiazine

Ointments containing silver sulfadiazine have excellent antimicrobial activity, especially on superficial infections caused by *Pseudomonas*. These salves also enhance epithelialization in open wounds but inhibit the activity of fibroblasts, therefore minimizing wound contraction, especially in the early phases of healing.

Hypertonic saline dressing

Dressings saturated in hypertonic saline solution (20% solution) are an **excellent first choice** for treating heavily infected or contaminated wounds, especially **chronic wounds**. Pre-made products are available (e.g. Curasalt, Kendall Products), but similar dressings can be made using sterile water and salt (sodium chloride). These dressings are bactericidal and also serve to draw extracellular fluid osmotically from the wound environment, minimizing local swelling and edema. These dressings are typically used as **wet-to-dry dressings**: they are applied moist to the surface of a wound and left in place for 24–48 h. They are dry when removed, thus helping to remove debris and dead cells from the surface of the wound. Repeat application of similar dressings may proceed until all necrotic material and debris is removed from the wound and a healthy granulation bed has begun to develop.

Hydrogel dressing

Hydrogel dressings (e.g. Curafil, Kendall Products) are useful in dry to lightly draining wounds. These gels help to promote autolysis of non-viable tissue when used with an occlusive dressing, and will not become dry, which can be useful in treating some burns (*q.v.*) and abrasions. Hydrogels stimulate macrophages to produce IL-1 and TNF- α , thereby stimulating fibroblasts and angiogenesis. They are therefore best indicated in the early repair phase of healing, when the production of granulation tissue is desired. However, following the development of a healthy granulation bed, it is most appropriate to stop using hydrogel-type dressings.

Calcium alginate dressing

Calcium alginate dressings (e.g. Curasorb, Kendall Products) are most useful in **heavily exudative wounds** where they promote formation of granulation tissue. Therefore, after development of a healthy granulation bed, alginate dressings should not be used, as they can stimulate the development of proud flesh. Although the contribution of the calcium component is poorly understood, calcium generally contributes to cell migration and remodeling during the repair phase. The alginate interacts with sodium present in wounds, creating a gel that provides an optimal moist healing environment. Calcium alginate dressings are very absorbent, holding approximately 20 times the dressing's weight in exudate. They do not adhere to the underlying wound bed, and their removal is therefore not uncomfortable for patients.

Fenestrated foam dressing

Foam wound dressings (e.g. Hydrasorb, Kendall Products) are indicated for use in heavily exudative wounds, including those with drains, because the foam material helps to wick excessive moisture away from the wound bed. Foam is contraindicated in infected wounds, but is excellent over **mature granulation beds** as it will inhibit excessive granulation tissue formation. Unlike topical ointments containing corticosteroids and antibiotics, foam does not inhibit inflammatory cells and epithelial cells, but preferentially minimizes the formation of proud flesh (*q.v.*).

Antimicrobial impregnated gauze dressing

Some antimicrobial-impregnated dressing materials are commercially available. One such product (Kerlix A.M.D., Kendall Products) is impregnated with polyhexamethylene biguanide (PHMB), an antimicrobial comparable to chlorhexidine. However, PHMB is minimally cytotoxic to inflammatory and epithelial cells, while still having excellent ability to minimize bacterial proliferation within the bandage or on the surface of a wound. These bandages can be applied in combination with any of those mentioned above, or they can be used alone. These are ideal materials for packing into large cavity wounds. PHMB-impregnated gauze is best applied wet, and can even be covered with a completely occlusive dressing, although this might not be necessary in heavily exudative wounds.

Skin grafts

Proper preparation of the graft site is an absolute prerequisite for successful skin grafting. Granulation beds must be free of infection and flush with the skin surface. Exuberant granulation beds are ideally **debrided and bandaged** 2–4 days prior to grafting procedures, as excessive bleeding beneath graft material can decrease acceptance of grafted skin. Grafts may be harvested from a variety of sites, using a variety of methods, most of which are best conducted under general anesthesia.

Ideal donor sites include the **cranial pectoral region** as well as the dorsal neck, especially under the mane. All subcutaneous connective tissue and fascia should be surgically removed from the donor skin prior to placement, and all bleeding from the recipient site must be attenuated. It is possible to achieve cosmetic results with smaller, full thickness wounds provided there is good acceptance of full thickness grafts and appropriately orientated hair growth.

Some full thickness grafts, such as pinch and punch grafts, may be collected from a standing sedated horse following local or regional anesthesia. These grafts are collected using a forceps and blade, or a biopsy punch instrument, and are inserted into pre-placed recipient holes in the granulation bed. Strips of full thickness tissue may also be harvested for placement into linear recipient sites, and sutured with 3-0 non-absorbable monofilament.

Because there is limited availability of full thickness donor skin for grafting, larger defects are typically managed using **partial thickness skin** from donor sites. It is difficult or impossible to harvest partial thickness grafts without the use of expensive **mechanized dermatomes**. These grafts must be obtained under general anesthesia, also allowing access to donor sites on the smooth, flat ventrum. Partial thickness grafts may be sectioned into strips to provide more complete coverage of large granulation beds.

Mesh graft expanders are also expensive, but are another means to accomplish coverage of large defects, and are especially good to minimize fluid accumulation beneath the graft in heavily exudative wounds such as burns (*q.v.*).

In **high-motion areas**, such as the dorsal tarsus, **tunnel grafts** maximize successful graft acceptance. This technique involves burying strips of partial thickness skin within tunnels created in a healthy granulation bed. The graft is placed using a 12 cm long cutting needle attached to adhesive tape on the haired side of donor tissue; the needle is passed through the granulation bed to implant the graft. The ends of the graft are sutured into place using 3-0 monofilament. After 7–10 days, the overlying granulation bed is excised, often necessitating a second general anesthetic. Although this technique is technically challenging, it requires less expensive equipment, and often achieves excellent results.

ALLERGIC SKIN DISEASES

URTICARIA AND ANGIOEDEMA

Etiology and clinical signs

Urticaria and angioedema are usually manifestations of **type 1 (immediate) hypersensitivity reactions** (*q.v.*). Antigens that have been implicated include

insect bites and stings, feedstuffs and additives, drugs, vaccines, infectious agents, parasites, topical applications, pollens, dusts, fungal and mold spores. The appearance of an urticarial reaction may be triggered by non-immunologic factors such as heat, cold, exercise, stress and physical pressure (dermatographism), but there is usually an underlying hypersensitivity state.

Urticaria or **hives** is characterized by the presence of **multiple edematous swellings** in the superficial dermis, often widely distributed over the body surface. The overlying epidermis is normal, although the accumulation of fluid in the dermis may result in overlying hairs appearing to stand up from the rest of the haircoat. Angioedematous plaques are larger in size, arise deeper in the dermis and are more often associated with serosanguineous oozing from dependent skin surfaces and subsequent crusting. There may be associated pruritus, although some animals seem unaware of the lesions. Urticaria may occur as a single episode only, or may be chronic with repeated episodes experienced over a period of time.

Diagnosis

The appearance of the clinical signs is typical. However, identification of the underlying cause of the hypersensitivity reaction can be extremely difficult. A thorough history of diet, management regimen and recent drug exposure is essential. A restriction or exclusion diet may be indicated. Alterations in management routine and intradermal skin testing may be employed in efforts to identify the causal allergen.

Treatment

In the acute phase clinical signs can be reversed, often rapidly, by parenteral administration of **glucocorticoids**. In chronic cases all attempts should be made to identify and subsequently avoid the causal allergen. If this is not possible then oral administration of prednisolone at a dose rate of 0.5–1 mg/kg/day should control the condition. Antihistamines may be helpful in preventing the appearance of lesions and also reduce the steroid dose requirements. Hydroxyzine hydrochloride at doses of 200–500 mg b.i.d. to t.i.d. has been reported to be effective.

ATOPIC DERMATITIS

Etiology and clinical signs

Hypersensitivity reactions (*q.v.*) may occur to aeroallergens such as tree, grass and weed pollens, dusts, animal and human danders, free-living mites, fungal and mold spores. The reactions may be **type I (immediate)** and/or **type IV (delayed)** (*q.v.*). Clinical manifestations of hypersensitivity to aeroallergens may affect the skin and respiratory systems, and allergy has also been implicated in some horses that head-shake. Cutaneous signs include marked pruritus with no primary lesions, and chronic urticaria. Secondary lesions due to self-trauma, such as excoriations, hair loss, thickening of the skin and lichenification, may develop. The condition may be seasonal in nature and age of onset is usually between 1 and 4 yr. As in other species, a genetic predisposition to develop allergy is likely.

Diagnosis

Food hypersensitivity and insect or parasitic hypersensitivity reactions should be ruled out. A tentative diagnosis can be made on history, clinical findings and ruling out other differentials. A circulating eosinophilia may be present. **Skin biopsy** often reveals a tissue eosinophilia, increased numbers of mast cells and a superficial perivascular inflammatory infiltrate. Intradermal skin testing may assist in identification of causal allergens. Drugs, stress and other factors may influence skin test results, and positive reactions can be seen in healthy (non-allergic) horses. Intradermal testing is best performed by experienced operatives, using proven allergen kits. Serologic tests are offered but there are few data demonstrating their reliability published.

Treatment and prevention

Avoidance of implicated allergens is the treatment of choice. This may necessitate major changes in management and feeding regimens, but in cases of indoor allergen reactions can be very successful in managing affected animals. **Hyposensitization** has been reported to be helpful.

Pharmacologic agents may be required to control symptoms and would include **antihistamines** and **glucocorticoids**. Hydroxyzine hydrochloride at doses of 200–500 mg b.i.d. to t.i.d. has been used, but other antihistamines may also be helpful. Prednisolone at doses of 0.5–1 mg/kg, initially daily, will control symptoms but should be administered on an alternate day basis long term. **Essential fatty acid supplementation** may be helpful in the management of the condition.

Owners should be warned about the possible inherited basis of atopy in the case of breeding animals.

FOOD ALLERGY

Etiology

Although frequently suspected in horses, food allergy is **extremely rare** in the horse, with only a few anecdotal reports in the literature. In other species adverse responses to ingested allergens may be manifested by changes involving the alimentary tract, respiratory system and/or the skin. Adverse food reactions may be non-immunologic (irritant, pharmacologic, toxic) or immunologic. The latter may involve **type I (anaphylactic)** and/or **type III (immune complexes)** and/or **type IV (cell-mediated)** hypersensitivity responses.

The mechanisms responsible for the initiation of an allergic response (*q.v.*) in an individual, to one particular food allergen, together with localization of the reaction to one body organ, are obscure. Sensitization to a food allergen, normally protein, is precise and specific and, once initiated, is life long.

Clinical signs

Skin responses that might be associated with ingestion of food allergens in the sensitized horse include a **generalized pruritus** with no evidence of macroscopic skin changes, a generalized papular urticaria, edematous plaques with pruritus with or without swellings of the head and vulva, or a generalized pruritus accompanied by inflammation leading to a generalized seborrhea.

Skin changes associated with food allergens are not pathognomonic and it is essential that they be differentiated from the more common skin changes associated with mite infestation and free-flying insects or atopic dermatitis, and also dermographism and drug reactions. It has been suggested that on rare occasions ingestion of food allergens may trigger off enteric changes involving either the small or large intestine and leading to diarrhea and thickening of the bowel wall.

Diagnosis

Diagnosis of food allergy in the horse is protracted as skin tests and serologic tests are unreliable for this purpose. Initially all suspect cases must be placed on an **elimination diet**. As food allergy has not been recorded in association with meadow or ley grass hay or grass, ideally animals should either be turned out to grass or fed only on hay and bedded on hay, shavings, rubber matting, dirt or sand.

If hay and grass alone are inadequate for the nutritional requirements of the horse, it is necessary to supplement the diet with a single cereal such as oats and observe for a period of not less than 4 wk for evidence of improvement. If this is not evident, the cereal should be changed and the animal monitored. Once improvement has been achieved then provocative challenge can be commenced, allowing at least 7–10 days between each new dietary constituent. Alfalfa may offer an adequate plane of nutrition as the sole foodstuff but has been implicated in adverse cutaneous food reactions and so would only be appropriate in a horse that had not previously received this food.

It is important to be aware that **inhalation** of allergens during feeding may result in allergic rhinitis, conjunctivitis, asthma and even cutaneous signs in sensitized animals. Food allergens may initiate such reactions, but they are more frequently encountered in horses sensitized to dust, fungal spores, yeasts or mite debris.

ALLERGIC CONTACT DERMATITIS

Etiology

Allergic contact dermatitis results from a **type IV (cell-mediated)** allergic response to an agent that has been repeatedly applied directly to the skin.

The capacity for agents to induce an allergic hypersensitivity response (*q.v.*) is extremely variable. Certain substances such as **dinitrochlorobenzene** are powerful contact sensitizers possessing the capacity to stimulate allergic responses in a very high percentage of animals within a few weeks. Other substances are immunologically inert and despite continuous or repeated contact rarely, if ever, induce an allergic response.

Most contact sensitizers are haptenic and require to become conjugated either covalently or otherwise to dermal or epidermal proteins before reaching full antigenicity and stimulating a T lymphocyte cell response. Contact allergens may be either very simple substances of low molecular weight (e.g. chrome, nickel, iodine) or be slightly heavier and complex (formaldehyde, oleo-resins and certain synthetic dyes).

Unlike chemical contact reactions, a response is never noted following initial exposure, and continuous or repeated intermittent contact over many months

or several years is often required before an allergic response is induced. Between the time of exposure to the causal allergen and the sudden appearance of skin changes there is a lag phase that varies from 1 to 5 days.

The severity of the skin changes noted in allergic contact dermatitis is unrelated to the volume or concentration of the applied substances. Severe reactions often follow the application of only **molecular amounts** of allergen.

Clinical signs and diagnosis

The lesions of allergic contact dermatitis are **confined to the areas of exposure**. They may present as well-defined areas of hyperemia, scaling and irritation, cutaneous edema, exudation and irritation with varying degrees of hair loss, or pruritus only. If the condition continues undiagnosed and untreated, secondary changes including skin thickening, increased pigmentation, extensive hair loss and secondary infection may occur.

Close study of the skin changes and their distribution will usually give an indication as to the possible allergens responsible. Responses to fabrics are uncommon, but allergic responses to dyes in blankets, rugs and numnahs/saddle pads and reactions to chrome tanning agents in harness may be encountered. Less frequently, reactions to skin washes and dressings and certain plants may occur.

Treatment and prevention

Having identified the source of the allergy, steps should be taken to prevent further contact, as sensitivity, once established, will **persist throughout life**. Even after further contact has been prevented, irritation is likely to persist for some time and it is essential that affected areas be gently but thoroughly washed to remove as much allergen as possible. It may be necessary in some cases to use short-acting systemic steroid therapy.

Confirmation of the diagnosis may be obtained by **patch testing** an area of skin, either with the agent concerned or an extract, and observing the area every 8h for at least 4 days for evidence of local irritation or other skin changes. Convenient test sites include the sides of the face and neck. Unless hair is very short, clipping is advised prior to application of suspect agents. **Skin biopsy** of test sites may be undertaken to demonstrate the typical histopathology of allergic contact dermatitis.

CULICOIDES HYPERSENSITIVITY

Etiology

Type I and type IV hypersensitivity reactions to the bites of *Culicoides* spp. (midges, "no-see-ums") are the cause of the syndrome also known as "sweet itch", "kasen", "Queensland itch", "muck itch", "dhobie itch" or "Sommererkzem" (*q.v.*). In most geographic locations these insects feed primarily at dusk and dawn, less so during the night, and not during the day. Windless conditions with temperatures above 10°C are ideal for their activity. *Culicoides* spp. breed in areas of moist, muddy ground around ponds, marshes, ditches and tidal flats.

Clinical signs and diagnosis

The onset of this problem occurs between 1 and 4 yr of age or between 1 and 4 yr after first exposure to the insects. It is seasonal, occurring in the summer and early autumn. In tropical and subtropical locations the season may last for 9–10 mo of the year. During the **first year**, the condition tends to be mild, worsening each year thereafter as long as exposure to the insects continues.

Pruritus is the major manifestation of this condition and causes the self-inflicted lesions. The classically described disease affects the head, ears, mane, withers, rump and tail. However, some species of the *Culicoides* insect prefer to feed in other areas on the animal, resulting in lesions with a different distribution. Ventrally distributed lesion may also occur involving the intermandibular space, chest, upper forelegs, the ventral abdomen and the inguinal region. The pruritus experienced by hypersensitive horses causes rubbing and self-trauma which results in alopecia, lichenification, crusting, erosions, ulcerations, fissures, wrinkling or corrugation of the skin, and secondary infections.

Diagnosis is based on history and clinical signs. Intradermal skin testing can be useful for confirming the clinical diagnosis, although appropriate antigens may not be available commercially. Biopsy findings of perivascular cuffs of mononuclear cells and eosinophils suggest allergic dermatitis but are not diagnostic for an etiologic agent. The parasitic manges, other insect hypersensitivities and cutaneous onchocerciasis should be ruled out (*q.v.*).

Treatment and prevention

Treatment requires **prevention of further exposure** to the insects and relief of inflammation. Exposure to the insects is eliminated by housing in **insect-proof stables** from late afternoon until well after dawn. Where stabling is not possible, use of insect-proof blankets may offer protection. Daily to twice daily application of insect repellents containing **permethrins** may be useful, but is likely to be ineffective without stabling. Fine-mesh screening or netting, ceiling fans or strategically placed box fans, and automated insecticide misters may aid in situations where the stables cannot be fully enclosed. **Drainage** of ponds, marshes and boggy areas where the *Culicoides* insects breed may be helpful when environmental regulations allow such alterations. Transfer of affected animals to higher, drier pastures or to drier geographic locations often results in complete or near-complete resolution of signs.

Inflammation is treated systemically with **glucocorticoids**. Initial doses of prednisolone or prednisone required to control the severe itch may be as high as 2 mg/kg daily. If insect exposure is not controlled, it is impossible to reduce this induction dose to lower and safer levels. Some relief of pruritus can be achieved by bathing in tar and sulfur-based shampoos. Secondary bacterial infections should be treated appropriately.

Nightly stabling of affected animals should begin from before the onset of the insect season and continue until the insects subside in the fall. A single night's exposure during the insect season can cause itching that may last as long as a month.

This condition has been seen in related animals, suggesting a **genetic predisposition**. Affected animals should be removed from breeding programs.

PEMPHIGUS FOLIACEUS

Etiology

Pemphigus foliaceus is the most common autoimmune skin disease (*q.v.*) of horses. Autoantibodies directed against epidermal cell surface antigens result in loss of intercellular cohesion, acantholysis and the formation of vesicles in the epidermis.

Clinical signs

Skin lesions often begin on the **face or limbs**, but in younger horses commonly become generalized; in older horses the lesions may be restricted to the coronary bands, ergots and chestnuts. The primary lesion is a **pustule or vesicle**, but these are transient and the usual presentation is of a crusting, scaling dermatosis with oozing, annular erosions and alopecia. Lesions are variably **painful or pruritic**. A **Nikolsky sign** may be present (separation of upper epidermis by pressure, indicating poor cellular cohesion). Many horses show concurrent systemic signs.

Diagnosis

Cytologic examination of vesicle or pustule contents reveals acantholytic keratinocytes and non-degenerate neutrophils and/or eosinophils, with an absence of bacteria. Histologic examination of intact primary lesions is diagnostic. The characteristic pathology consists of intragranular to subcorneal intraepidermal vesico-pustules containing acantholytic cells.

Direct immunofluorescence testing reveals diffuse intercellular deposition of immunoglobulin (IgM, IgG) and, usually, complement in the epidermis. However, false negative results may be obtained after administration of glucocorticoids, and false positive results may be seen in other skin diseases.

Treatment

Therapy of pemphigus foliaceus depends upon the use of **immunosuppressive drugs** and permanent therapy is often required. The initial drug of choice is **prednisolone**, at doses of 1 mg/kg s.i.d. by mouth. Improvement should be evident within 7–10 days, and alternate day therapy can be initiated once lesions are controlled, reducing to the lowest possible maintenance dose. An alternative glucocorticoid is dexamethasone, at doses of 0.2 mg/kg PO s.i.d.

If the condition is resistant to corticosteroids or unacceptable doses are required to control lesions, **gold salts** (chrysotherapy), e.g. **sodium aurothiomalate** (Myocrisin, Myochrysine), have been used successfully in the management of equine pemphigus foliaceus, as an adjunct to steroid therapy. Aurothiomalate is given IM, initially in two test doses of 20 and 40 mg 1 wk apart, followed by weekly injections of 1 mg/kg. There is usually a 6–12 wk lag phase before a response is seen. Once the condition is controlled, injections may be given monthly. It may be possible to withdraw concurrent steroid therapy. Adverse reactions are reported in other species, including blood

dyscrasias, proteinuria and skin eruptions, and periodic hematologic examinations and urinalysis are advised. Azathioprine has been used in a few animals but there is little published information available regarding its use.

BULLOUS PEMPHIGOID

Etiology

Bullous pemphigoid is a rare autoimmune skin disorder (*q.v.*) of the horse resulting from autoantibodies directed against basement membrane of skin and/or mucosa. This results in subepidermal cleft formation due to dermoepidermal separation and vesicobullous formation.

Clinical signs

The primary lesions are vesicles or bullae, but these rapidly ulcerate. Lesions may affect oral mucosa, mucocutaneous junctions and skin, particularly in the axillae and inguinal areas. Ulcers, crusts and epidermal collarettes are the usual lesions, with variable pain or pruritus. Systemic signs of anorexia, fever and depression may be present.

Diagnosis

Bullous pemphigoid must be differentiated from viral diseases such as horsepox, herpes coital exanthema and vesicular stomatitis, systemic lupus erythematosus and drug eruptions (*q.v.*). **Skin biopsy** is strongly suggestive or diagnostic, as long as intact vesicles are obtained. Histopathologic findings are subepidermal vacuolation, clefting and vesicle formation with mild to moderate perivascular inflammatory infiltrates. Direct immunofluorescence testing demonstrates linear deposits of immunoglobulin and, usually, complement at the dermoepidermal junction. Correct choice of biopsy site and absence of steroid therapy is important for immunofluorescence testing.

Treatment

High doses of **glucocorticoids** are indicated in the management of bullous pemphigoid. Therapy, if successful, is prolonged, if not permanent. Prednisolone 1 mg/kg PO b.i.d. or dexamethasone 0.2 mg/kg PO s.i.d. is the initial treatment of choice, reducing to the lowest possible maintenance dose on alternate mornings. Chrysotherapy, azathioprine and chlorambucil have been used in the management of bullous pemphigoid in dogs and humans, but reports of successful management of equine cases are lacking.

SYSTEMIC LUPUS ERYTHEMATOSUS

Etiology

Systemic lupus erythematosus (SLE) is a rare multisystemic autoimmune disorder (*q.v.*) of horses. Several factors, including genetic predisposition, viral infections, hormones, ultraviolet light and immune disorders, are involved in the etiology of SLE.

Clinical signs

Cutaneous signs described in the rare reports of equine SLE include symmetrical alopecia, seborrhea, scaling, panniculitis and edema of the extremities. Systemic involvement may include hemolytic anemia, thrombocytopenia, arteritis, proteinuria, fever, depression and weight loss.

Diagnosis

Definitive diagnosis of SLE can be **challenging** and depends on demonstration of multisystemic involvement and the identification of various autoantibodies. A positive antinuclear antibody test and lupus erythematosus cell test supports the diagnosis, but results must be interpreted with care as both false positives and negatives may occur. The dermatohistopathology in SLE can be variable, but an interface dermatitis with hydropic degeneration, single cell necrosis of the basal cell zone, focal thickening of the basement membrane, hyperkeratosis and lymphocytic dermal inflammation are typical features. Direct immunofluorescence testing may reveal linear deposition of immunoglobulins at the basement membrane zone of epidermis and hair follicles.

Treatment

Cases of equine SLE have been treated with **prednisolone** at initial doses of 1 mg/kg PO b.i.d., reducing to the lowest possible maintenance dose on an alternate day basis. However, the response to therapy is unpredictable and the prognosis guarded.

CUTANEOUS (DISCOID) LUPUS ERYTHEMATOSUS

Etiology

Cutaneous, formerly discoid, lupus erythematosus (DLE) is thought to be a benign variant of SLE (*q.v.*) with cutaneous manifestations and no systemic involvement. **Ultraviolet light** seems to be an aggravating factor, with exacerbation of lesions in sunny weather. It is a rare dermatosis of the horse.

Clinical signs

Skin lesions are seen on face, ears and neck, and typically consist of areas of patchy alopecia, erythema, scaling and crusting, sometimes with leukoderma and leukotrichia. Affected horses are well in other respects.

Diagnosis

Histologic examination of skin biopsies reveals hydropic and lichenoid interface dermatitis. Direct immunofluorescence testing reveals deposits of immunoglobulin and/or complement at the dermoepidermal junction. Antinuclear antibody tests and lupus erythematosus cell tests are negative.

Treatment

The management of DLE includes avoidance of sunlight by stabling during daylight hours, use of topical sunscreens and the use of topical corticosteroids

(1% hydrocortisone, 0.1% betamethasone valerate). Refractory cases may require systemic glucocorticoids, prednisolone at initial doses of 1 mg/kg PO once or twice daily (or dexamethasone 0.2 mg/kg PO s.i.d.), reducing to the lowest possible alternate day maintenance dose.

This more benign autoimmune skin disease carries a better prognosis than those described above, but long-term management regimens may be required to keep the condition in remission.

DRUG ERUPTIONS

Etiology

Many classes of drugs can potentially cause a reaction, which may include cutaneous eruptions. Drugs that have been implicated in horses include antibacterial agents, particularly **penicillin** and **sulfonamides**; **phenothiazine tranquilizers**; non-steroidal anti-inflammatory agents, particularly **aspirin** and **phenylbutazone**; **local anesthetics**; **anticonvulsants**; certain **biological products**; and various **topical preparations**. Cutaneous eruptions may follow systemic administration by any route or topical application. Hypersensitivity reactions are thought to be involved in the etiopathology of drug eruptions, but non-immunologic mechanisms such as toxicity, photosensitivity (*q.v.*) and idiosyncratic reactions may also be involved. Drugs may be immunogenic in their own right or may act as haptens that bind to host proteins. Type I, II, III and IV hypersensitivity reactions (*q.v.*) may be involved.

Clinical signs

Drug eruptions can mimic many dermatoses, and no specific type of reaction is seen. Possible manifestations include urticaria, papular dermatitis, generalized dermatitis, vesicular dermatitis and ulcers secondary to vasculitis. Histopathologic findings are similarly varied with perivascular dermatitis, interface dermatitis, intraepidermal and subepidermal vesicular dermatitis all being possible reaction patterns in biopsies. A drug eruption may occur after only short exposure to an offending drug or after years of administration, and may even appear a few days after drug therapy has stopped.

Definitive diagnosis can be difficult. All other possible causes of the skin lesions must be excluded. A high index of suspicion and a detailed history of drug administration are required. Withdrawal of the offending drug should result in resolution of lesions within 10–14 days. It may be difficult to pinpoint the causal agent in animals on several drugs, and intentional re-exposure to the suspected drug to confirm the diagnosis is contraindicated since it may result in fatal anaphylaxis.

Treatment and prevention

All suspected medications should be discontinued, and appropriate supportive measures indicated. Drug eruptions are often poorly responsive to corticosteroids. If concurrent disease requires continued therapy, then unrelated drugs should be substituted. Chemically related compounds should be avoided in the future.

CUTANEOUS VASCULITIS

Etiology

Cutaneous vasculitis (*q.v.*) is an uncommon disorder in horses, thought to involve type I and III (immune complex) hypersensitivity reactions (*q.v.*). In most cases the etiologic agent is unclear. However, cutaneous vasculitides may accompany certain infections, notably **streptococcal infection** (strangles), *Corynebacterium pseudotuberculosis* infection, salmonellosis, equine viral arteritis and equine influenza (*q.v.*). In some cases lesions restricted to white-skinned and white-haired areas implicate photoactive mechanisms.

Clinical signs

The lesions of idiopathic cutaneous vasculitis commonly occur on the distal limbs, lips, pinnae and periocular regions and consist of purpura, edema, erythema, necrosis, ulcers and crusts. Oral involvement may be seen. Lesions may be painful and affected horses may show systemic signs including pyrexia, anorexia, depression and weight loss.

Purpura hemorrhagica (*q.v.*) is the manifestation of the cutaneous vasculitis that may complicate infectious conditions of the horse. Cutaneous lesions consist of edematous, hemorrhagic subcutaneous swellings of the distal limbs, ventrum and head. Exudation, necrosis and sloughing may follow. Petechial and ecchymotic hemorrhages are seen on mucous membranes.

Diagnosis

Cutaneous vasculitides must be differentiated from autoimmune disease, equine viral arteritis, drug eruptions and toxicosis (*q.v.*). The definitive diagnosis is based upon history, physical examination and biopsy. Histopathologic findings consist of neutrophilic (leukocytoclastic), eosinophilic, lymphocytic or mixed vasculitis, often with fibrinoid degeneration. Diagnostic changes are most likely to be found in lesions 8–24 h old. Horses with purpura hemorrhagica may show mild anemia, neutrophilia with left shift, elevated plasma fibrinogen and globulin concentrations. Platelet counts are normal. Direct immunofluorescence testing may demonstrate immunoglobulin and/or complement in vessel walls, but is not essential for diagnosis.

Treatment

Once a diagnosis of vasculitis has been made, attempts must be made to identify and eliminate underlying causal factors. The progress of the disease depends on the extent of damage in each individual case. There may be only a single, short-lived episode or the disease may be chronic or recurrent.

In idiopathic cases many horses will respond to **glucocorticoid** therapy (prednisolone 2 mg/kg/day PO in single or divided doses; dexamethasone 0.2 mg/kg/day). Maintenance alternate day therapy may be needed. In cases of purpura hemorrhagica the prognosis is better if therapy is initiated early and consists of aggressive **appropriate antibiotic therapy** (e.g. penicillin 22 000 IU/kg b.i.d.), control of edema with **diuretics** (e.g. furosemide) and limitation of the hypersensitivity response (glucocorticoids). Hydrotherapy, gentle exercise, massage and bandaging may be beneficial.

Prevention

Avoidance of sunlight is indicated in cases where photoactive factors are implicated. Any other agents that are identified as possible causal factors should similarly be avoided.

ERYTHEMA MULTIFORME

Etiology

The pathogenesis of this cutaneous reaction pattern is not fully understood, although many triggering factors have been recognized. Hypersensitivity reactions are believed to be involved. In the horse, erythema multiforme has been associated with **potentiated sulfonamide therapy** and idiopathic cases are described.

Clinical signs

Erythema multiforme is a rare, acute, self-limiting dermatosis. The skin lesions are urticarial plaques, maculopapular or vesicobullous lesions, which clear centrally and expand peripherally to give annular (doughnut), arciform and polycyclic shapes. These lesions persist for days to weeks. Scaling, crusting and alopecia are not features. The cutaneous lesions are generally asymptomatic.

Diagnosis

Definitive diagnosis is based on typical clinical findings and skin biopsy. The characteristic histopathologic features are a hydropic interface dermatitis, single cell necrosis in the basal epidermis, with or without superficial dermal edema. Massive subepidermal edema and confluent areas of full thickness coagulation necrosis may result in the development of vesicular lesions.

Erythema multiforme is a cutaneous reaction pattern and evaluation for the presence of underlying causes such as a drug reaction, infection and neoplasia is indicated.

Treatment

Any underlying cause identified should receive appropriate management. The cutaneous lesions are usually self-limiting and require no specific therapy, resolving within 3 wk to 3 mo. Avoidance of implicated causal factors is necessary to prevent the condition.

CUTANEOUS AMYLOIDOSIS

Etiology

Secondary or reactive amyloidosis associated with chronic infections rarely produces skin lesions. **Primary amyloidosis** is usually restricted to the skin and/or upper respiratory tract. Cases with simultaneous cutaneous and systemic amyloidosis have been reported rarely. The amyloid fibrils in cutaneous amyloidosis are derived from immunoglobulin light chains. There is usually no known triggering factor.

Clinical signs

Cutaneous amyloidosis is a rare skin disease of horses, characterized by papules, nodules and plaques and most commonly affecting the head, neck

and pectoral region. Lesions are firm, well circumscribed, non-painful and non-pruritic and covered by normal skin. Although in some cases early lesions may appear urticarial and regress initially, they recur and the condition becomes chronic and progressive.

Diagnosis

Histopathologic examination of skin biopsies reveals amorphous, homogeneous hyaline, eosinophilic deposits of amyloid intra- and extracellularly with an accompanying granulomatous dermatitis with numerous multinucleated, histiocytic giant cells. Congo red stain demonstrates amyloid in tissue, with an apple-green appearance when viewed by polarizing microscopy. Other special stains that may be used include crystal violet and thioflavin. Transmission electron microscopy reveals characteristic amyloid fibrils, 6–10 nm thick, twisted but straight and unbranched.

Treatment and prognosis

There is no effective treatment for amyloidosis. Glucocorticoid therapy has been ineffective. However, if there are no respiratory or systemic lesions then horses may survive for prolonged periods. It may be wise to advise against breeding affected animals since there is evidence of inheritance of certain forms of cutaneous amyloidosis in humans.

EQUINE EOSINOPHILIC EXFOLIATIVE DERMATITIS AND STOMATITIS

Etiology

Eosinophilic exfoliative dermatitis and stomatitis (EEDS) is a rare disorder characterized by eosinophilic infiltration of epithelial tissues, predominantly affecting skin and intestinal tract and associated organs. The condition has been reported in Canada, Australia, the USA, Sweden, the UK and France. The etiology is unknown, but hypersensitivity mechanisms and epitheliotropic cell-associated virus and genetic predisposition in Standardbreds have been postulated.

Clinical signs and diagnosis

Skin lesions often appear in the winter in stabled horses of any age, sex or breed. Scaling, crusting, oozing, alopecia and fissures are seen affecting the face and/or coronary bands. Early in the course of the condition oral ulceration is common. There is progression to a generalized exfoliative dermatitis with extensive alopecia, scaling, exudation, crusting and ulceration. Variable pruritus may be encountered. Systemic signs of progressive, severe weight loss become apparent, despite a normal or even increased appetite.

Laboratory findings that may be present include hypoalbuminemia, leukocytosis and mild anemia. Circulating eosinophilia is rare. Dermatohistopathology reveals superficial and deep perivascular dermatitis. The infiltrate is eosinophilic and lymphoplasmacytic. Irregular ortho- and parakeratotic hyperkeratosis with irregular epidermal hyperplasia is seen, together with necrosis of single keratinocytes. Eosinophilic microabscesses and granulomas may also

be features. Eosinophilic inflammation of other epithelial organs is common. Direct immunofluorescence testing has given negative results.

Treatment

There is no known effective treatment. Immunosuppressive doses of glucocorticoids have failed to reverse the condition, which progresses over a period of months, ultimately requiring euthanasia.

EQUINE SARCOIDOSIS/GENERALIZED GRANULOMATOUS DISEASE (GGD)

Etiology

This is an uncommon condition of unknown etiology characterized by granulomatous inflammation of many organ systems with cutaneous involvement. The disease resembles human sarcoidosis.

Clinical signs and diagnosis

Skin lesions are the major presenting sign, with generalized scaling and crusting with varying degrees of alopecia most commonly described. Cutaneous nodules may be present in addition to the exfoliative dermatitis or as the only skin lesions. Peripheral lymphadenopathy may be present. Systemic signs include weight loss, decreased appetite and persistent pyrexia.

Laboratory findings may include leukocytosis, increased fibrinogen, elevated globulins and, in severe cases, mild anemia. Hepatic and renal function tests may be abnormal.

Definitive diagnosis is based on histopathologic examination of skin biopsies. The major feature is the presence of non-caseating granulomas consisting of aggregates of epithelial cells and multinucleated giant cells located in the superficial to mid dermis. Sarcoidal granulomas are also found in many other tissues including lymph nodes, lungs, gastrointestinal tract, liver and spleen. Direct immunofluorescence testing of affected skin has been negative, as have attempts to demonstrate involvement of pathogenic organisms.

Treatment

Although a few horses have undergone spontaneous remission, most cases suffer progressive dermatitis and wasting requiring euthanasia. The administration of high doses of **glucocorticoids** early in the course of the disease may be helpful. Prednisolone should be given at doses of 2 mg/kg PO initially, reducing the daily dose once a response is seen, ultimately to alternate day therapy. However, equine sarcoidosis would appear to be a more severe disease than human sarcoidosis, justifying a guarded to poor prognosis.

NEOPLASTIC SKIN CONDITIONS

Skin tumors account for two thirds of all reported equine neoplasms. As in any species, neoplastic change can occur in any component of the skin but in horses

certain tumor types predominate. In approximate descending order these are sarcoid, squamous cell carcinoma, melanoma, papilloma and others (*q.v.*).

To enable appropriate management, including prognosis and treatment, a **specific diagnosis** should be obtained in all cases. While clinical features may be suggestive in many cases, only histopathologic examination can give a definitive diagnosis. Treatment modalities (*q.v.*) including surgery, cryotherapy, electrocautery, irradiation, chemotherapy and immunotherapy may be used individually or in combination; the tumor type and site will dictate which is most applicable.

SARCOID

Etiology

Equine sarcoids are **locally aggressive, non-metastatic fibroblastic tumors**. The term is often used to encompass fibroma, fibroma-like tumor, neurofibroma and low-grade fibrosarcoma as well. While these other tumors can be distinguished histopathologically, the clinical appearances, behavior and treatment are similar. Equine sarcoid is a **common clinical entity** that may cause loss of use of the horse and also an **esthetic problem**. A viral etiology has been suggested, with bovine papillomavirus DNA detected in many samples. Possible transmission routes may include flies, rubbing posts and shared equipment. A **genetic predisposition** is also suggested.

Clinical signs

Based on gross appearance, sarcoids can be divided into four groups: occult (flat), verrucous (warty), fibroblastic (proud flesh-like) and mixed verrucous–fibroblastic. Some classifications also include nodular (overlying skin normal) and malevolent (invasive and infiltrative) types.

The most common is the **fibroblastic type**, which presents as a firm, mobile nodule up to several centimeters in diameter within the dermis; this form must be differentiated from other tumors including melanoma, fibroma and neurofibroma/sarcoma (*q.v.*) as well as inflammatory conditions including cutaneous habronemiasis and other nodular skin diseases (*q.v.*). This type of sarcoid may become ulcerated and more exuberant in appearance with a hemorrhagic and purulent discharge; in this state it may be mistaken for granulation tissue (*q.v.*) and must also be differentiated from squamous cell carcinoma (*q.v.*).

The second form is the so-called “**verrucose sarcoid**” with a dry, keratinized, warty appearance; this type should be differentiated from squamous papilloma and dermatophytosis (*q.v.*). The third, **mixed form**, is a combination of the fibroblastic and the verrucose types. The **occult form** presents as a thickened plaque-like area of roughened skin with scant hair. The occult and verrucose forms may develop into the fibroblastic sarcoid, especially when subjected to **repeated trauma**. Although in many cases the physical appearance may be typical of an equine sarcoid, a definitive diagnosis requires histopathologic examination and this should be performed before treatment is started.

Sarcoids can affect any breed and either sex, and there is no association with coat color. There may be an increased incidence in young adult horses. The tumor may be solitary but in a third of cases there will be multiple lesions.

Predilection sites include the ventral abdomen, groin and inner aspect of the thigh, the axillae and head, in particular the lip commissures, periorbital tissue and the base of the ears. When sarcoids occur in the groin and axilla it is not uncommon for “**kissing**” lesions to be present on touching skin folds, suggesting transplantation of neoplastic tissue.

Prognosis

The success of treatment depends on a number of factors and this should be explained to the owner at the outset. The location, size and number of lesions are important considerations; sarcoids of the extremities, axilla and groin may be more difficult to treat, while those affecting periocular regions have been found more responsive to treatment. **Recurrence** of sarcoids is a common problem and repeated treatment may be required for complete resolution in some individuals.

Treatment

Simple **surgical excision** has a high failure rate (50%). Recurrence, usually within 6 mo, may be due to incomplete excision or to iatrogenic transplantation at the time of surgery. Electrocautery may help control blood loss but does not significantly increase the success rate.

Cryotherapy (with or without diathermic resection) (*q.v.*) gives the most consistent results with a high success rate (up to 95%), although **repeated treatments** may be required. The procedure may be possible using local anesthesia and sedation but more commonly general anesthesia is required. The size and position of the lesion, the temperament of the horse and the facilities available are factors influencing this decision.

Stimulation of the host immune system can be achieved by the administration of foreign material. For the treatment of equine sarcoids, various preparations of the vaccine strain of *Mycobacterium bovis* **bacillus Calmette–Guérin** (BCG) have been used. In the UK only the live, freeze-dried form is available as human percutaneous BCG vaccine, but cell wall preparations have also been used with greater efficacy and fewer side effects. Reported side effects after administration of live BCG include anaphylaxis and death (rare), fever, diarrhea, laminitis and active granulomas. The tumor becomes edematous and painful following treatment; this progresses to ulceration with a purulent discharge. Regression of the lesion proceeds from the second or third week but may take several months before it is complete.

Unlike cryotherapy, BCG immunotherapy (*q.v.*) is relatively free from significant scarring and therefore is particularly useful for **sarcoids of the eyelids**. The response to therapy can be good with reported success rates ranging from 50% to 75%. However, the potential for significant adverse reactions should always be considered before embarking on BCG immunotherapy.

Immunotherapy with non-viable *Propionibacterium acnes* is available in the USA and good results are claimed.

Many **topical products** have been used in the treatment of sarcoids, including the antimetabolite **5-fluorouracil** and **podophyllin**, an irritant used in management of warts. Bloodroot extracts and other caustic chemicals may induce sloughing of lesions. Good success can be obtained with a topical ointment

available from the University of Liverpool¹, **AW4-LUDES**, which contains a variety of heavy metals and antimetabolic compounds. Imiquimod cream, which stimulates the production of a variety of cytokines including interferons, is also anecdotally of benefit.

Intralesional injections of an emulsion of cisplatin (*q.v.*) in oil and water after surgical debulking (1 mg/cm³ of tissue on four occasions at 2 wk intervals) have given good relapse-free survival rates without side effects.

Radioactive implants (iridium-192 and gold-198) (*q.v.*) have been used with a high success rate (up to 100%) with minimal complications. However, this form of therapy can only be performed on designated premises by a suitably qualified person; the cost of implants may be prohibitive for certain cases.

SQUAMOUS CELL CARCINOMA

Etiology

Although squamous cell carcinoma (SCC) may arise at any site on the skin, it more commonly occurs at **mucocutaneous junctions**. In particular, the conjunctiva, the eyelids, the prepuce, the penis and the vulva appear to be predilection sites (a fuller discussion of these affected sites is given elsewhere). Chronic exposure of poorly pigmented, relatively hairless areas to **UV light** has been implicated in the development of SCC involving the eye and periocular sites, and **smegma** has been associated with SCC of the penis and prepuce.

Clinical signs

Unlike humans and cats, SCC in the horse tends to be a **proliferative** rather than an erosive lesion. The clinical appearance ranges from a sessile nodular mass that has to be differentiated from a sarcoid through to an exuberant cauliflower-like growth with secondary ulceration, hemorrhage and infection. SCC must be differentiated from granulation tissue, sarcoid, cutaneous habronemiasis and other cutaneous tumors (*q.v.*); definitive diagnosis should be by histopathology.

Prognosis and treatment

SCC is a locally invasive tumor. It does not commonly metastasize and then only as far as the draining lymph node; the lungs are rarely involved. SCC of the **prepuce and penis** tends to be more aggressive and metastasis is more common than from other sites. Treatment of SCC may be by radical excision, cryosurgery or radiotherapy (external beam or implant (*q.v.*)). Intralesional **cisplatin** and topical 5-fluorouracil have also been beneficial (*q.v.*).

MELANOMA

Etiology

Melanoma is a common skin neoplasm in horses, especially in **aged grays**. The tumor is rare in animals <6 yr old. Approximately **80% of gray horses >15 years old** have melanotic masses; however, not all are truly neoplastic. In some cases, a disturbance of melanin metabolism occurs and **focal hyperplasia** of melanocytes occurs; this can predispose to malignant transformation.

¹ Contact Professor Derek Knottenbelt (e-mail address: knotty@liv.ac.uk)

Clinical signs

Melanoma can develop at **any site** but areas of predilection include the perineum, vulva, the underside of the dock, the male genitalia, and also the limbs, neck and ear. The tumors can be solitary or multiple, hard or soft nodules in the subcutaneous tissue. The cut surface is typically dark brown or black but the less common amelanotic melanoma is unpigmented. Definitive diagnosis requires histopathology, although needle aspirate cytology can be useful. However, in gray horses the physical appearance alone may be sufficient to make the diagnosis.

Prognosis

Clinically, three growth patterns exist. The most common is a **slow growth** over a period of years without metastasis; the second is a similar initial pattern but with **sudden malignant transformation and metastasis**; and, finally, melanoma can behave in a **malignant** manner from the outset. Metastatic spread is often widespread to all organs of the body. Melanomas in non-gray horses tend to be more aggressive than in grays.

Treatment

Treatment of melanomas, especially advanced cases, can be unrewarding. Local resection of early solitary lesions or masses that are frequently traumatized can be of benefit. Immunotherapy and irradiation are of little value, although a polyvalent allogeneic antigen-supplemented vaccine has been used in horses with multicentric melanomas (*q.v.*). **Cimetidine** (*q.v.*) has been reported to produce partial to complete remission using an initial dose of 2.5 mg/kg t.i.d., reducing to a lower maintenance dose if there is a favorable response. Others believe cimetidine is of little therapeutic benefit.

MAST CELL TUMOR

Etiology and clinical signs

Mast cell tumors are rare in horses and, in fact, may be hyperplastic aggregations rather than true neoplasms. The lesions of up to 20 cm diameter are usually solitary, occurring most commonly on the head and limbs. The mass may vary from well to poorly circumscribed and may be dermal or subcutaneous. Ulceration, alopecia and hyperpigmentation may occur. The masses are usually self-limiting and regress spontaneously; metastasis has not been reported.

Treatment

Surgical excision has a high success rate, and intratumoral (*q.v.*) corticosteroid therapy is useful to control solitary lesions.

CUTANEOUS LYMPHOMA

Etiology and clinical signs

Lymphoma (*q.v.*) in the horse can occur as a cutaneous neoplasm with solitary or multiple dermal or subcutaneous nodules. Concurrent systemic involvement

is usually present with lymphadenopathy, depression and weight loss, although the disease may be restricted to the skin alone, at least initially. The physical appearance of the skin lesions varies from firm nodules with relatively normal overlying skin to ulcerating plaques; lesions can occur at any site on the body. Lymphoma in the horse tends to be progressive and is ultimately fatal. Biopsy is necessary to confirm the diagnosis.

Treatment

No successful treatment has been found. Corticosteroid therapy may give some palliation.

ADNEXAL TUMOR

Benign (adenoma) and malignant (adenocarcinoma) tumors of the sebaceous and sweat glands and the hair follicles are rare in horses.

BASAL CELL TUMOR

Basal cell tumor is a rare condition in the horse. This neoplasm is not known to metastasize or to undergo transformation to its malignant counterpart, squamous cell carcinoma. Wide excision is curative.

KERATOMA

Etiology and clinical signs

Keratoma (*q.v.*), a benign tumor of the keratin-producing cells of the hoof wall, is not a common condition of horses. It may not be a neoplasm but rather may represent a **chronic localized hyperplastic reaction** following injury to the hoof wall or coronet. The mass develops between the hoof and the third phalanx and may cause lameness if it impinges on the underlying sensitive laminae and/or bone; in some individuals it is an incidental finding.

Keratomas appear more frequently to affect the toe region. The mass may cause deformation of the hoof or deviation of the white line. Commonly, however, there are no external signs and the problem can only be localized by selective nerve blocks or radiography. Necrosis of the pedal bone due to the pressure of the mass shows as focal loss of bone.

Treatment

Treatment is by surgical excision. As long as complete removal is achieved, the prognosis is good.

OTHER TUMORS

Other tumors of the skin have been reported but may be considered rare. Treatment should be by wide surgical excision and/or cryotherapy. In the main, prognoses have to be based upon extrapolation from other species and should, at least, be guarded.

CUTANEOUS ENDOCRINOPATHIES

HYPERADRENOCORTICALISM (CUSHING'S SYNDROME)

Etiology

The plasma glucocorticoid concentration is elevated, most commonly due to excessive secretion of adrenocorticotrophic hormone (ACTH) arising from **adenoma of the pars intermedia** of the pituitary gland (*q.v.*). Loss of sensitivity to dopaminergic feedback control from the hypothalamus is postulated. In addition to increased ACTH production from pituitary adenomas, other peptides such as β -endorphins, melanocyte-stimulating hormone and corticotropin-like intermediate lobe peptide may be secreted. There is failure of negative feedback mechanisms and, under the continual drive of ACTH, hyperplasia of the adrenal cortices ensues, with hypersecretion of cortisol and adrenocortical androgens. Occasionally, the disease may arise as a result of **adrenal neoplasia**.

Clinical signs

The disease is common, recorded in 10% of rescued horses in one study. The most striking feature of equine hyperadrenocorticalism is **hirsutism** (*q.v.*), the exact mechanism of which is unclear. Animals show an excessively long, dense and often curly haircoat, with failure of normal shedding. The mane and tail are usually spared. **Hyperhidrosis** is common, possibly due to abnormal hypothalamic thermoregulation as well as the effects of the thick haircoat. The underlying skin may appear relatively normal, although seborrhea may be present. Other cutaneous findings that may be present include infections and xanthomatous nodules. Bulging of the supraorbital fat pads may be present.

Systemic signs of hyperadrenocorticalism (*q.v.*) include **muscle wasting** and **pot-bellied appearance**, laminitis, chronic infections and often marked polydipsia (up to 80L/day) and polyuria. Concurrent diabetes mellitus is quite common. Neurologic signs are present occasionally.

This is a condition of older horses and ponies: the average age at diagnosis is 19 years, and hyperadrenocorticalism is rare in horses <10 years old.

Diagnosis

Hematologic findings may include neutrophilia, lymphopenia and eosinopenia, although total white cell count may be normal unless secondary infection is present. Liver enzymes are usually elevated and hyperglycemia is common. Urinalysis reveals a low specific gravity, often glucosuria and sometimes evidence of urinary tract infection.

Definitive diagnosis depends upon the results of **hormonal assays**. Resting cortisol values may be elevated, but dynamic tests are required to confirm the diagnosis. ACTH stimulation tests and/or dexamethasone suppression tests (*q.v.*) may be employed.

Measurement of plasma ACTH concentration may be used to confirm the diagnosis. Although the test is sensitive, data on specificity are limited, but values >50 pg/mL indicate a probable diagnosis of the condition. Blood samples require special handling since ACTH is very labile.

An increase in plasma cortisol in response to thyrotropin-releasing hormone (TRH) injection (samples taken before and 30 min after injection) is also indicative of hyperadrenocorticalism, but the test has low sensitivity and specificity, particularly in horses with high basal cortisols or those that are unwell for other reasons.

A **combined dexamethasone suppression–TRH stimulation test** has been described which has increased sensitivity and specificity and allows easier interpretation than either test alone. The protocol is as follows:

1. A baseline blood sample is taken, followed by IM injection of 40 µg/kg of dexamethasone.
2. Three hours later a second blood sample is taken and 1 mg of TRH is given IV.
3. Half an hour later a third blood sample is taken.
4. The final sample is taken 22–24 h after the dexamethasone injection.
5. Samples are submitted for cortisol measurement.

In normal horses the baseline cortisol concentration is suppressed by dexamethasone, is unaffected by TRH administration, and remains suppressed the following day. Affected horses may show some initial suppression of basal cortisol 3 h after dexamethasone, but the concentration returns to basal or above after TRH and remains unsuppressed.

Treatment and prognosis

The prognosis for equine hyperadrenocorticalism is poor, **progression** of disease being likely. However, clinical signs can be ameliorated in many horses with treatment. The dopamine agonist **pergolide**, which interferes with peptide secretion by the pituitary tumor, is more effective than cyproheptadine, a serotonin antagonist, which probably interferes with ACTH secretion. A daily dose of pergolide of 1 mg daily for a 500 kg horse (0.002 mg/kg) is cost effective. If the response to treatment is suboptimal the dose can be increased incrementally to a maximum of 0.01 mg/kg PO daily. Anorexia and depression may occur at higher dose rates.

Trilostane, an inhibitor of steroid synthesis now licensed for the treatment of canine hyperadrenocorticalism, has been shown to be effective in improving clinical and laboratory abnormalities in horses with hyperadrenocorticalism, with no side effects observed. A dose of 1 mg/kg once daily in the afternoon or evening has been recommended.

A high plane of nutrition and good standard of care is required by these debilitated animals. The expense of treatment and the nature of the condition often result in owners requesting euthanasia.

HYPOTHYROIDISM

Etiology and clinical signs

Naturally occurring hypothyroidism (*q.v.*) is a rare condition of horses with few confirmed cases described in the literature. Deficiency of, or interference with uptake of, dietary iodine is the usual cause.

Clinical signs of hypothyroidism may be varied and diverse (*q.v.*). Cutaneous signs may include dry, scaling skin, dull haircoat, delayed shedding, alopecia and myxedema, particularly of the face and lower limbs. Histologic examination of skin biopsies reveals orthokeratotic hyperkeratosis, follicular keratosis, sebaceous gland atrophy, telogen hair follicles and dermal mucinosis.

Diagnosis

Basal thyroid hormone measurement is unreliable since many illnesses and concurrent drug therapy may result in low T₄ and T₃ concentrations. Dynamic testing is required to demonstrate hypothyroidism. A dose of 2.5 IU of thyroid-stimulating hormone (TSH) administered IV results in at least a doubling of baseline T₄ concentration 4 h later in normal horses. Since TSH is difficult to obtain and is expensive, the **thyrotropin-releasing hormone (TRH) response test** is likely to be the test employed. Blood samples are taken prior to and 4 h after IV injection of 1 mg TRH (0.5 mg in fit horses). The response in euthyroid horses should be 1.5–2 times the basal concentration, and within the normal range.

Treatment

For dietary-induced hypothyroidism **iodinated casein** at a dose of 5 g/day PO may be administered. Alternatively, supplementation with sodium levothyroxine (T₄) at a dose of 10 mg daily has been reported to be effective.

MISCELLANEOUS SKIN CONDITIONS

EOSINOPHILIC GRANULOMA (NODULAR NECROBIOSIS, COLLAGENOLYTIC GRANULOMA)

Etiology

The etiology is unknown, but is thought to be an **allergic response**. This is the most common nodular skin disease of the horse. There is no sex predilection and it occurs mainly in adult horses. It is rare in heavy horses and Thoroughbreds and more common in riding horses. The condition is seen more commonly in summer than winter months and for this reason **insect hypersensitivity** has been thought to play a role in the cause.

Clinical signs

Multiple, firm, nodular lesions are present located within the dermis, unattached to underlying tissue. No systemic signs have been described. The lesions are usually non-pruritic and, in most cases, non-ulcerating, spherical masses 1–2 cm in diameter. There is no associated hair loss, although the overlying hair may appear raised or tufted. Where lesions are close together coalescence may occur giving plaque-like masses of 10 cm diameter or more. Older lesions may become mineralized and some may show a small central ulceration in which white calcareous material may be seen. Lesions are mainly confined to the trunk, neck and upper limbs and are particularly common in the saddle area.

Diagnosis

Definitive diagnosis is based on history, clinical findings and skin biopsy. Histologic examination shows areas of granulomatous inflammation with fragmentation of collagen fibers, the predominant cell type present being the eosinophil. It has been demonstrated that true collagenolysis is not present, and the disrupted collagen fibers surrounded by eosinophilic material are now termed **collagen flame figures**. No parasites or other microorganisms are found in lesions. Eosinophilic folliculitis or furunculosis may be seen. Long-standing lesions show mineralization. **Differential diagnosis** includes bacterial furunculosis, abscess, mycetoma, urticaria, fibroma, lymphosarcoma, amyloidosis and viral papular dermatitis.

Treatment

Where lesions are numerous and there is no mineralization, oral prednisolone or prednisone at 1 mg/kg s.i.d. for 2–3 wk may be employed. Isolated lesions may be treated with intralesional corticosteroid, methyl prednisolone acetate 5–10 mg/lesion or triamcinolone acetonide 3–5 mg/lesion. Mineralized lesions will not respond to this treatment. Care should be taken to ensure that not more than 20 mg total of triamcinolone acetonide is administered at any one occasion as a precaution against precipitating laminitis.

Prognosis

The prognosis is guarded. Some cases will resolve spontaneously within weeks, but others may persist for many months, permanently mineralized. It is rare for the condition to make the horse unrideable provided adequate padding is used under the saddle.

UNILATERAL PAPULAR DERMATOSIS

Etiology and clinical signs

Unilateral papular dermatosis is a rare nodular skin condition that mainly affects finer skinned breeds with a predisposition for **Quarter Horses**. No age or sex predilection has been established. The condition presents with the sudden appearance of large numbers of papules and nodules on one side of the trunk with no accompanying systemic response, and no pain, pruritus, or hair loss. Lesions appear to be circumscribed, benign and resolve spontaneously within a few months. Occasional recurrences on the same or opposite side of the body are known. The etiology is unknown.

Diagnosis

Clinical signs of unilateral nodular/papular lesions. Skin biopsy reveals eosinophilic folliculitis and furunculosis with no etiologic agents. Cultures are negative. Differential diagnosis includes furunculosis, collagenolytic granulomas and sterile panniculitis.

Prognosis

Guarded to favorable. If spontaneous remission does not occur then oral prednisolone or prednisone at 1 mg/kg PO s.i.d. may be given.

KERATINIZATION DISORDERS

Generalized seborrhea

Etiology

Seborrhea, by definition, implies an excess production of lipid secretion from the sebaceous glands. Although some skin disorders are accompanied by increased greasiness of the skin and coat, the disorders referred to are really of **increased production of skin scale**. Thus the clinical condition of seborrhea characterized by increased epidermal turnover, which may be accompanied by more or less lipid secretion, is a scaling defect. Seborrhea is a clinical sign rather than a specific disease.

Primary seborrhea is rare in horses while **secondary seborrhea** may be a clinical sign accompanying a wide variety of clinical disorders, e.g. ectoparasitism (lice, mites); fungal infection (dermatophyte invasion of surface keratin); bacterial infection; abnormal lipid metabolism (hepatic disease); deficiency diseases (zinc deficiency); autoimmune disease (pemphigus foliaceus); or endoparasitism (chronic strongylosis).

Mane and tail seborrhea

Etiology

Obscure; no predilection by age, breed or sex.

Clinical signs

Excessive accumulations of skin scale within the hair of the mane and tail.

Diagnosis

Elimination of other causes of excess scale formation, see above.

Treatment

Regular bathing in antiseborrheic shampoos containing coal tar, sulfur and salicylic acid. For greasy seborrhea, benzoyl peroxide shampoos are helpful. If the scale is dry, emollients and humectants may be used as rinses or sprays.

Linear keratosis

Etiology

Unknown, but is thought to be a developmental anomaly similar to epidermal nevus of man. The disorder has been reported mainly in the USA where there appears to be a predilection for young (1–5 yr) **Quarter Horses**, **Morgans**, **Standardbreds** and **Percherons**, but it has also been recognized in the UK.

Clinical signs

Unilateral linear lesions, mostly orientated vertically on the neck, thorax, shoulder and extending down the forelimb to the pastern. The length of the lesion may be up to 50 cm with width 0.25–0.75 cm. The surface of the skin is covered in a thick seborrheic mass arising from non-painful, non-pruritic papular

eruptions, the surface of which becomes covered in hyperkeratotic orthokeratotic debris. Once established, the condition appears to be permanent.

Diagnosis

The clinical signs are highly suggestive. Biopsy reveals epidermal hyperplasia and orthokeratotic hyperkeratosis. Differential diagnosis includes dermatophytosis, dermatophytosis, trauma and possible larval migration.

Treatment

There is no specific therapy. Antiseborrheic preparations may be helpful. Topical creams containing vitamin A have been found of some value in controlling the scaling. The value of more potent retinoids in the condition does not appear to have been investigated.

Cannon keratosis ("stud crud")

Etiology

Cannon keratosis is an uncommon chronic dermatosis of the horse affecting the anterior surface of the cannon area of both hindlimbs, with no breed, age or sex predilection. The etiology is obscure. It is likely that the cause is multifactorial, such factors as hygiene, urine splashing, infection and individual susceptibility to repeated wetting all playing a part.

Clinical signs

Non-pruritic, non-painful scaling with matting of hair in crusted plaques on the dorsal surface of the cannon area of both hindlimbs.

Diagnosis

Typical clinical signs, on fine skinned horses. Bacterial and fungal infection must be ruled out. Skin biopsy is not definitively diagnostic, showing chronic inflammatory changes including epidermal hyperplasia with ortho- and parakeratosis and mild, chronic, dermal inflammatory changes. Photoactivated vasculitis, which may have some clinical similarities, needs to be ruled out.

Treatment

Topical antiseborrheic preparations and glucocorticoid creams b.i.d. Cleansing, removal of crusts, dressing with an astringent (potash alum solution) followed by the application of an emollient cream may also be of value. Particular attention should be paid to management.

NODULAR PANNICULITIS

Etiology

Sterile panniculitis, although a well-recognized condition in the dog, is a condition of great rarity and unknown etiology in the horse. Lipid freed into the tissues following damage to adipose tissue acts as a potent inflammatory

agent once it is hydrolyzed to glycerol and free fatty acid and gives rise to further inflammatory reactions.

Clinical signs

Multiple subcutaneous nodules, sometimes extending to form plaques, from a few millimeters to several centimeters in diameter, mainly affecting the trunk. These rupture and drain producing an oily discharge. Varying degrees of pain are associated with the condition and there may be systemic signs of illness.

Diagnosis

Definitive diagnosis is based on the appearance of the lesions, sterile cultures and excisional biopsy. Histologic findings are of lobular to diffuse pyogranulomatous and granulomatous panniculitis. Differential diagnosis includes all causes of nodular skin lesions of the horse, collagenolytic granulomas, bacterial and fungal infections, foreign bodies and traumatic lesions and immunologic and hypersensitivity reactions.

Treatment

1.0–2.0 mg/kg prednisolone or prednisone once daily for 7–14 days. The prognosis is guarded.

ANHIDROSIS (DRY COAT, EQUINE ANHIDROTIC SYNDROME)

Etiology

The physiologic mechanisms of sweating in horses are complex and still not completely understood. Although not fully determined, the **non-sweating syndrome** of horses appears to be associated with a number of factors that precipitate exhaustion of the sweating mechanism, for example temperature and humidity. Horses reared in temperate climates and transported to regions of high humidity and temperature may **fail to acclimatize**. Certain individuals have a poor response to sweat stimulation by adrenalin (epinephrin). Animals involved in **strenuous exercise**, e.g. racing and other competitive events, may become stressed in a hot humid climate.

Clinical signs

In acute cases sweating is much reduced or absent; this is accompanied by respiratory distress, labored breathing, fever, collapse and occasionally death. **Chronic anhidrosis** is characterized by dry lusterless coat, seborrhea and partial alopecia, particularly affecting the face and neck. Horses also show poor exercise tolerance and loss of condition.

Diagnosis

Diagnosis is based on a clinical history of non-sweating. Anhidrotic horses show a very slow sweat response to an **intra-dermal skin test with various dilutions of adrenaline (epinephrin)**. After injection of 0.5 mL of 1:1000 adrenalin (epinephrin) intradermally the response producing sweating is delayed 5 h or longer.

Treatment

Symptomatic and empirical. Application of cold water to reduce body temperature is recommended. Affected horses have been housed in air-conditioned barns but should be removed to a cooler, less humid environment.

HYPERHIDROSIS

Etiology

Factors resulting in hyperhidrosis include high ambient temperature, infection, administration of drugs, excessive muscular exertion, pain, hyperadrenocorticalism and temperament.

Clinical signs

Excessive sweating may be generalized or localized over the neck, base of ears, around the nostrils and thighs. The coat appears dark and wet with sweat. Specific therapy depends upon the cause.

INTRODUCTION

Diseases of the ear, nose and throat occur relatively commonly in the horse. In many cases an accurate diagnosis followed by a specific medical or surgical treatment can result in a successful outcome. Advances in imaging technology such as endoscopy during treadmill exercise, combined with the increasing availability of novel techniques such as gamma scintigraphy and magnetic resonance imaging, have resulted in an improved understanding of the disease processes affecting the region. Dental disease has been included in this chapter because of the relationship of maxillary dental disease to lesions of the nasal passages and paranasal sinuses.

THE NASAL PASSAGES

EXTERNAL NARES

The external nares are the openings to the nasal passages. The comma-shaped **alar cartilages** support the external nares dorsally, medially and ventrally. Lateral dilatation of the nares is achieved by muscular activity that regulates airflow to the nasal passages, larynx and lower airways. The external nares are the major site of upper respiratory resistance to airflow, therefore in the normal horse the distensible nature of the external nares is vital for athletic function. Narrowing or loss of muscular support to the external nares results in collapse of the nares during the inspiratory part of the respiratory cycle. Upper airway obstruction produced by the external nares can be considered to be either **functional** or **static/luminal**.

Trauma

Lacerations of the external nares are not uncommon. They usually heal well because of the abundant blood supply and musculature in this region. If left to heal by secondary intention the resultant scar formation may produce **stenosis**, limiting dilatation of the nares. Accurate anatomic repair with at least two-layer closure is therefore obligatory. Stenotic nares may be corrected using a cosmetic double apposing Z-plasty technique.

Neurogenic disorders

Facial nerve (cranial nerve [CN] 7) **paralysis**, a result of either peripheral (dorsal buccal branch) injury or a more centrally located lesion, will produce failure of nostril dilatation at deep inspiration. If present bilaterally a **functional obstruction** will result which may necessitate a tracheotomy to relieve the dyspnea, or as a long-term salvage procedure, resection of the lateral wall of the nares.

NASAL DIVERTICULUM (FALSE NOSTRIL)

The false nostril is positioned dorsolaterally to the external nares. Its floor and medial wall are formed by the **alar fold**, a rostral soft tissue extension of the

ventral turbinate. Vibration of the alar fold on expiration during exercise is a normal physiologic occurrence that produces the noise recognized as “**high blowing**”.

Abnormal alar folds

Partial airway obstruction may occur if either the alar folds are excessively thick or the external nares are relatively small. An inspiratory vibratory noise is produced and airflow to the nasal passages is restricted by dynamic collapse of the vestibule.

The subjective assessment of the alar folds and their contribution to an upper respiratory noise is difficult, particularly in the absence of visible or palpable abnormality. However, some assistance may be obtained in confirmation by placing a temporary mattress suture through each alar fold to the skin of the external nares, thus obliterating the space within the false nostril. If the previous respiratory noise is eliminated or significantly reduced in volume during a subsequent exercise test, then **bilateral resection** of the alar fold can be recommended to alleviate the horse's condition.

Atheroma/epidermal inclusion cyst

Atheromas present as spherical, non-painful, unilateral swellings of the caudo-dorsal aspect of the nasal diverticulum. Generally, they are a **cosmetic problem** seldom obstructing the nasal passages.

Recognized usually in younger horses, the cyst contains a thick, gray sterile fluid of keratinized and non-keratinized cells produced by aberrant location of epithelial tissue. Local drainage, curettage of the cyst lining and daily irrigation with povidone-iodine may be performed under sedation and regional anesthesia. This technique may be advised on cosmetic considerations, however recurrence can be expected if there is inadequate removal of the cyst lining. Complete dissection of the unpunctured cyst and primary skin closure under general anesthesia gives more reliable results.

NASAL CHAMBERS

The nasal passages have a number of physiologic functions apart from acting as the initial conduit for air to the lower respiratory tract. They warm and moisturize the ambient inspired air, they are involved in thermoregulation, act as a crude filtering system of airway contaminants and debris, and provide a location for olfactory receptors. The mucosa of the nasal chambers is closely adherent to the supporting structures of the dorsal and ventral turbinates and midline nasal septum.

The well-developed blood supply that courses through the submucosa of the nasal passages during exercise undergoes vasoconstriction. This causes the mucosal epithelium to adhere more closely to the underlying cartilage, maximizing the airway diameter and resisting potential collapse. The mucosa becomes engorged during general anesthesia and in association with **Horner's syndrome** (*q.v.*), producing significant upper respiratory obstruction. This is due in the latter case to impairment of sympathetic control to the nasal vasculature.

Trauma

Depression fractures of the rostral nasal and incisive bones, such as might arise from head-on collisions or kicks, will lead to loss of support to the external nares. If left to heal naturally, this may result in **luminal stenosis**. Surgical correction aims to provide support to the airway, preventing stenotic complications.

Foreign bodies

Nasal foreign bodies are uncommon, however inhalation of grass seeds or twigs will produce persistent clinical signs of head shaking, epistaxis and snorting (*q.v.*).

Fungal infection

Mycotic infection (*q.v.*) is sporadic in occurrence and usually opportunistic, dependent either on impaired local resistance or the presence of devitalized tissue. Clinically, a **fetid serosanguineous/mucopurulent and generally unilateral, nasal discharge** is observed; however, in some horses this discharge may be minimal. A diagnosis can be made endoscopically by recognizing **mycotic plaques** and occasionally granulomas on the turbinates and nasal septum. A definitive diagnosis is obtained by **biopsy and culture** of the lesion.

A wide variety of isolates have been reported including *Aspergillus fumigatus*, *Coccidioides immitis*, *Cryptococcus neoformans* and *Rhinosporidium seeberi*.

Treatment involves **topical application** of antifungal agents, e.g. **ketoconazole** or **natamycin**, via an external irrigation system that utilizes the paranasal sinuses as a reservoir. This may be supplemented by using systemic antifungal agents and surgical removal of the plaques and granulomas, which is usually best achieved by use of endoscopic or endometrial biopsy forceps, under direct endoscopic visualization. In some cases the lesions may be self-limiting without treatment.

Ethmoidal hematoma

Ethmoidal hematoma is a progressive, expansile, encapsulated lesion of unknown etiology; there is no histologic evidence of neoplasia even though the lesion may act like a tumor. The lesion usually develops from the ethmoidal region, however paranasal sinus origin is also not uncommon.

The lesion is typically encountered in middle-aged to older horses, presenting with an **intermittent, unilateral, serosanguinous nasal discharge** unrelated to exercise. Depending on the lesion size and position there may be altered nasal airflow and a respiratory noise at exercise may also be detected.

Endoscopic examination reveals a typically yellow-green-brown space-occupying lesion extending rostrally along the nasal meatus. Radiography can be used to delineate the extent of the soft tissue mass and determine the presence of possible secondary lesions. It should be noted that if a lesion is restricted to the paranasal sinus, the only finding may be a trickle of hemorrhage from the sinus ostium in the middle meatus.

Surgical treatment involves resection using a frontomaxillary sinus bone flap approach to the nasal chamber. Access to the ethmoidal region is then through the floor of the frontal sinus and is inevitably a bloody procedure. The lesion may recur following excision depending on the completeness of lesion removal.

The use of a **transendoscopic laser** (Nd:YAG or diode) to ablate the hematoma has provided a much less invasive procedure, but may be less effective in the confined areas of the ethmoidal region. Injecting lesions with a **10% formalin solution** on repeated occasions has also proved effective, although if large volumes are used there is a risk of fatal encephalitis. Such an injecting system can be purchased or made up by attaching a needle to a piece of stiff tubing and carefully inserting it down the biopsy channel of the endoscope. Both the formalin injection and laser techniques can be used for intrasinus lesions, via direct sinus endoscopy.

Neoplasia

Neoplasia of the nasal passages is rare although squamous cell carcinoma, adenocarcinoma, lymphosarcoma, fibrosarcoma and ossifying fibroma (*q.v.*) have all been reported. Presenting signs reflect the presence of an expansile, space-occupying lesion within the nasal passages, i.e. nasal discharge, epistaxis, altered nasal airflow, respiratory noise at exercise and facial swelling/distortion. The degree of local expansion, accessibility and the size of the area involved before recognition determine therapy and prognosis.

Treatment is by lesional excision through a facial flap, but other than for well-encapsulated benign lesions like an ossifying fibroma, the prognosis is very poor.

Nasal amyloidosis

The etiology of this very rare condition is unknown. Following sustained immunologic stimulation (possibly the result of chronic infection), macrophages deposit glycoprotein fibrils in the form of nasal and cutaneous plaques and nodules. These are non-painful and often ulcerate, producing the clinical signs of nasal discharge, epistaxis and reduced exercise tolerance. The plaques can be recognized endoscopically and are distributed throughout the nasal passages. Diagnosis is confirmed by histopathology of biopsy samples. Palliative treatment involves cauterization and surgical resection. Successful therapy is rare and must address the primary cause.

NASAL SEPTUM

The nasal septum extends from the external nares caudally, dividing the nasal passages as far as the ethmoidal region.

Deviation

Congenital deviation of the nasal septum ("wry nose" or rhinocampylus lateralis) occurs in utero, in association with deviation of the premaxillae.

Difficulties in **suckling and prehension** may result from severe deviation. This can be corrected by a radical surgical technique, first sectioning and then realigning the premaxillae using internal and/or external fixation. Finally, the deviated rostral nasal septum is resected. Such surgery is seldom carried out.

Acquired deviation may develop following external trauma or as a consequence of continuous pressure from space-occupying lesions of the nasal passages, e.g. neoplasia or turbinate distension from sinus cyst formation.

Thickening

A rare congenital **cystic degeneration** of the nasal septum may result in nasal septal thickening. Airway obstruction is marked and the thickened septum can be palpated digitally. Treatment involves resection of the affected portion of the septum using embryotomy wire inserted via trephine holes into the sinus and exiting the nasal passages.

Choanal atresia

Choanal atresia is a very rare congenital malformation associated with failure of perforation of the buconasal membrane at the choanae or posterior nares. The condition may be uni- or bilateral. Failure to perform an emergency tracheostomy at birth will result in asphyxiation of a foal with bilateral obstruction.

Nasal polyps

Nasal polyps consist of inflammatory connective tissue attached to either the turbinates, nasal septum or an alveolar socket. They may act as a space-occupying lesion producing the clinical signs of respiratory stertor, exercise intolerance and mucopurulent nasal discharge. Treatment involves resection and cauterization of their origin.

THE PARANASAL SINUSES

The paranasal sinus system consists of the bilaterally paired rostral and caudal maxillary, frontal, ethmoidal and sphenopalatine sinuses. Functionally, the sinus system reduces the weight of the bony covering that supports the skull contents and protects them from external trauma.

The external landmarks of the maxillary and frontal sinuses are readily palpated. A line from the medial canthus of the eye to the nasomaxillary notch marks the dorsal margin of the maxillary sinus and the lateral margin of the frontal sinus. The ventral margin of the maxillary sinus lies parallel and just ventral to the facial crest. The rostral maxillary sinus extends to a line drawn perpendicular to its dorsal margin that intersects the rostral end of the facial crest. The caudal limit of the caudal maxillary sinus is defined by a line bisecting the orbit. The left and right frontal sinuses are divided on the midline by a complete bony septum. The caudal limit of the frontal sinus is represented by a line perpendicular to the midline bisecting the temporomandibular joint.

The most rostral extension of the frontal sinus lies within the dorsal turbinate (the concho-frontal sinus) and is delineated by a transverse line halfway between the medial canthus of the eye and the infraorbital foramen.

The paranasal sinus system is lined by mainly pseudostratified, columnar, ciliated epithelium and goblet cells. **Drainage of the mucus** that is produced by this respiratory lining is assisted by the coordinated beating of cilia toward the caudal maxillary sinus. The frontal, ethmoidal and sphenopalatine sinuses drain and communicate directly with the caudal maxillary sinus. Normally, a complete bony septum overlying cheek teeth four and five divides the rostral and caudal maxillary sinuses. Continuation of this septum divides the nasomaxillary opening through which the whole sinus system drains to the middle nasal meatus.

SINUSITIS

Sinusitis may be divided into **primary (infectious)** or **secondary sinusitis**. The predominant clinical sign of sinusitis is a **unilateral nasal discharge**. Complete obstruction of drainage from the sinuses results in fluid and soft tissue accumulation within the sinuses and turbinates creating internal pressure which may be recognized clinically as facial swelling, reduced airflow at the nostril, respiratory noise at exercise and a dulled resonance and pain on percussion of the sinuses. If the internal sinus pressure causes obstruction of the nasolacrimal duct as it courses through the maxillary sinus, **epiphora** may also be observed. **Neurologic signs** produced by caudal extension of a disease process through the cribriform plate are rare complications of sinusitis.

Diagnosis is confirmed **endoscopically** by recognizing turbinate distension and a discharge emanating from the caudal middle meatus. Radiography is used to determine the extent of sinus involvement and the presence of fluid within the paranasal sinus system, and to evaluate possible **dental involvement**.

Primary sinusitis

Primary sinusitis is a consequence of an **upper respiratory infection** extending to involve the paranasal sinus system, altering the normal mucociliary clearance mechanism and reducing normal drainage. The presence of fluid within the sinus system is demonstrated by a horizontal fluid–gas interface on a standing lateral radiographic image of the paranasal sinuses. Confirmation of the diagnosis and isolation of the etiologic agent can be achieved following **sinucentesis** of the affected sinus. This is most easily achieved via insertion of a Steinmann pin through the facial bone plate into the sinus, and then aspiration via a needle, catheter or swab.

Treatment must be aggressive to prevent secondary complications of inspissation of accumulated pus and bone necrosis. The primary aim of treatment is to re-establish normal drainage to the nasal passages. Systemic broad-spectrum or, ideally, sensitive specific **antibiotic therapy** should be instituted in association with daily **irrigation and lavage** of the sinus. Large volumes of **physiologic sterile saline** should be administered through an ingress balloon catheter (12–16 G French) positioned in the affected sinus through a small

trephine hole. Therapy should be continued for 7–14 days, during which time exercise is encouraged to assist drainage. (Drainage from the nasomaxillary aperture is temporarily improved during exercise as the nasal mucosa undergoes physiologic vasoconstriction.)

Chronic cases often fail to respond to this conservative management and adequate drainage can then only be established surgically, using a facial flap approach.

Secondary sinusitis

Dental

The last four cheek teeth of the maxillary arcade lie within the maxillary sinus. The development of a **periapical abscess** affecting any of these teeth is likely to produce a **secondary sinusitis**. This occurs most commonly in middle-aged horses and most frequently it is the **4th cheek tooth** that is affected. The resulting unilateral nasal discharge that is produced is characteristically **fetid**.

Accurate recognition of dental involvement requires a thorough examination of the oral cavity and **oblique radiographs** highlighting the roots of the suspected dental arcade. Both procedures can be performed in the standing horse, as can gamma scintigraphy, which is exquisitely sensitive in identifying periapical inflammation. The use of computed axial tomography (CAT) scanning or magnetic resonance imaging (MRI) can also provide high quality detail of dental structures and surrounding alveolar bone. However, both of these techniques normally require the horse to be anesthetized.

Treatment involves removing the affected tooth. Nowadays this is best achieved by oral extraction in the **standing horse**. However, the affected tooth may be **repelled** into the oral cavity and sinus contamination with food prevented by **packing the alveolar socket** with dental wax or methyl methacrylate bone cement, providing **postoperative irrigation** and ensuring adequate drainage of the affected sinus.

Two surgical approaches are commonly employed. They differ in the degree of surgical exposure provided and the amount of postoperative management of the alveolar socket that may be performed. **Trephining** directly over the affected tooth root requires accurate localization, using radiographic images and facial structures (facial crest, medial canthus of eye, nasolacrimal duct and other indicators of sinus topography). Postoperatively the alveolar socket may be irrigated daily and the development of granulation tissue monitored. An approach using a **sinus bone flap technique** provides excellent surgical exposure of the affected tooth roots and more confidence in complete removal of all affected dental tissue. Using either technique, postoperative radiographs are mandatory to ensure complete removal of all dental tissue. Thereafter, management consists of **twice-daily lavage** of the sinus using a balloon catheter system placed in the frontal sinus ensuring normal drainage to the nares.

Maintaining the **alveolar plug** in position while the alveolar socket granulates can be difficult and is imperative for successful surgical management. Dietary management has little effect in preventing leakage around the plug and further sinus contamination.

Traumatic sinusitis

Secondary sinusitis may develop following external trauma to the sinus region. Open lacerations and/or depression fractures will produce **epistaxis** and **facial swelling**. Radiography should be used to confirm the presence of fracture fragments, fluid or hematomas within the sinus. Specific attention should be paid to the dental arcade to determine any damage to the tooth roots, the consequence of which may affect the prognosis. However, it is amazing how often such lesions resolve with minimal complication.

Fracture fragments may be removed or, if accurate anatomic reduction and stable fixation can be achieved, they may be retained. The sinus should be lavaged to remove organizing hemorrhage and contaminating organisms. Postoperative irrigation is advised. Open wounds should be treated aggressively to prevent **sinus fistulae** developing. Chronic fistulae can be treated using periosteal flaps, allowing osteogenesis to occur over the defect.

PARANASAL SINUS CYSTS

Paranasal sinus cysts primarily affect the **maxillary sinus** but they may also occur in the **frontal sinus**. They have a true cystic lining that contains a characteristic sterile, amber/yellow fluid formed from blood breakdown products. They may be found at any age but there is a predilection for the younger horse (≤ 1 yr) and older horses (≥ 9 yr).

The clinical signs are a **mucopurulent/serous nasal discharge**, which is usually scanty, facial swelling and reduced airflow at the affected nares. Endoscopy reveals turbinate distension. Radiography demonstrates a contained soft tissue density, which may show areas of mineralization, and tooth root distortion but no evidence of periapical abscessation. Rarely there may be additional bizarre dental structures, or anomalous dental eruption. **Sinucentesis** can be used to confirm the presence of the characteristic amber fluid.

Complete surgical excision is performed by blunt (digital) dissection through an appropriate sinus bone flap, ensuring adequate drainage to the nares and placement of a postoperative irrigation system. The prognosis following surgery is good and recurrence rates are low.

Rarely, more extensive lesions involve multiple sites and can prove extremely difficult or impossible to remove.

NEOPLASIA

Squamous cell carcinoma, adenocarcinoma, osteosarcoma, fibrosarcoma, lymphosarcoma and ameloblastoma (*q.v.*) have all been recognized in the paranasal sinuses of the horse. Although more common in older horses, neoplasia has also been reported in young horses and rarely congenitally. The size and distribution and invasive nature of the majority of lesions at presentation usually preclude successful therapy.

SUTURE PERIOSTITIS

Suture (diastasis) periostitis is a **non-painful bony swelling** over the margins of the paranasal sinuses that is commonly attributed to a traumatic etiology;

however, often there is no history of trauma. These swellings are a **cosmetic problem** only. They are caused by instability at suture lines, usually between the nasal, frontal and maxillary bone plates. Radiography can be used to monitor the periostitis that develops and also rule out the presence of depression fractures, sequestra or neoplasia. The periostitis is self-limiting. It leaves a permanent, residual swelling although this gradually reduces with time.

Similar swellings can be associated with pressure from expansile sinus masses. Such cases always have evidence of soft tissue density within the sinus and treatment should be directed at the primary cause. Sometimes such suture instability may follow facial flap surgery.

DENTITION¹

The horse is particularly well adapted to a herbivorous diet. The efficiency of mastication (*q.v.*) of ingesta is maximized by molarization of the premolar dentition, which has evolved so that they are almost indistinguishable from the true molars.

Narrowing of the interdental space between neighboring teeth also assists in creating a continuous grinding, occlusal surface. Furthermore, naturally occurring ridges and troughs orientated transversely across the occlusal surface of the maxillary and mandibular arcades interdigitate with each other and create a particularly abrasive surface on which ingesta may be ground down.

In order to ensure a continuous grinding surface and to account for continual wear of the dental tissue the horse has developed teeth that have abundant reserve crown and that erupt continuously.

To assist the grinding action, the mandible has a great range of lateral and rostro-caudal movement provided by the incongruous articulation of the temporomandibular joint. Finally, the main muscle of mastication, the masseter muscle, is well developed with a broad area of attachment rostral to the temporomandibular joint; this maximizes the crushing force that is produced at the occlusal surface.

NORMAL DENTAL DEVELOPMENT

The incisors have a simple anatomy with a deep enamel invagination on their wearing surface. This infundibulum is filled with cement. The cheek teeth of the mandible and maxilla are more intricate in their appearance due to marked infoldings of the enamel layer. During embryologic development the tooth germs of the maxillary arcade develop more quickly and consequently at eruption have a more complicated construction than mandibular teeth. The maxillary tooth also has a true infundibulum that produces enamel lakes on the occlusal surface that at eruption are incompletely cement filled. Mandibular teeth have a more rectangular cross-sectional area than the maxillary teeth.

The normal eruption times of the deciduous and permanent teeth are well documented and are set out in Table 6.1.

¹ For a review of equine dental disorders see Dixon, P.M. and Dacre, I. (2005) A review of equine dental disorders. *The Veterinary Journal* 169, 165–187.

Table 6.1 Normal eruption times of deciduous and permanent teeth in the horse

Deciduous dentition		Dental formula			
		i	c	p	
		<u>3</u>	<u>0</u>	<u>3</u>	
		3	0	3	
	Tooth	Eruption time

	Dp 3	Birth–2 wk			
	Dp 4				
Permanent dentition		Dental formula			
		i	c	p	m
		3	1	3/4	3
		3	1	3	3
	Tooth	Eruption time			
Incisors	I 1	2.5 yr			
	I 2	3.5 yr			
	I 3	4.5 yr			
Canines	C	4–5 yr			
Premolars	P 1	5–6 mo			
	P 2	2.5 yr			
	P 3	3 yr			
	P 4	4 yr			
Molars	M 1	9–12 mo			
	M 2	2 yr			
	M 3	3.5–4 yr			

I, i, incisor; C, c, canine; P, p, premolar; M, m, molar; D, deciduous.

The Triadan system

Recently a new system of dental nomenclature has been adopted from the human dental field. Thus each tooth is defined by a 3-digit number. The first digit defines the quadrant, i.e. 1 for upper right, 2 for upper left, 3 for lower left and 4 for lower right.

The teeth are then numbered from central incisor 1 through to 3rd molar as 11; this allows for a wolf tooth on both upper and lower jaws (tooth 5). Thus the upper right canine will be 104 and the lower left 4th premolar will be 308.

Normal eruption

The timing of normal eruption and wear of the incisors is consistent enough to allow accurate estimation of a horse's age. Eruption is a consequence of vascular activity of the tooth roots forcing the tooth along its normal eruption pathway. Non-painful, bony swellings are often recognized overlying the roots of erupting teeth in juvenile horses. Radiography of the dental roots shows evidence of **periapical hyperemia** and **alveolar bone resorption**. These dental germs, particularly in the mandible, are prone to external trauma and injury.

Abnormal eruption

Rotation, displacement or impaction is most commonly seen affecting the third cheek tooth because this is the final permanent tooth to erupt and it has to do so between the second and fourth permanent teeth. Abnormal eruption may also occur as a consequence of external trauma to developing tooth germs.

Displacement or maleruption of the **wolf tooth** (the rudimentary remnant of the permanent first premolar) may occur and be a genuine cause of biting problems, warranting extraction. (Normal eruption of the wolf tooth is unlikely to be clinically significant.)

Pseudopolyodontia (deciduous tooth retention)

Retained deciduous incisors are usually loosely attached and readily removed with dental forceps. If they are more firmly attached and displace the erupting permanent teeth lingually, **sharp dissection** may be required.

Deciduous cheek teeth “dental caps” may remain attached to the surrounding gingiva during eruption of the underlying permanent tooth, disrupting mastication. Their **sharp edges** may lacerate the surrounding soft tissues producing signs of oral **pain and quidding**.

Regular dental rasping will encourage the shedding of dental caps, some of which may require more aggressive treatment. Removal can be undertaken using sedation or, if firmly attached, under a general anesthetic. The technique involves manipulation with dental forceps and elevator to lever the dental remnant from its attachment.

NORMAL WEAR

Anisognathism

At any point, the distance separating the mandibular arcades is 30% narrower than the corresponding maxillary distance. The mandibular arcades are also straighter in their orientation. The maxillary arcade curves outwards to the buccal cavity.

These normal features, in conjunction with the continual lateral and rostro-caudal grinding movements of the mandible, produce characteristic wear of the occlusal surfaces. The wearing surface slopes down towards the buccal cavity creating sharp enamel points on the lingual surface of the mandibular arcade and on the buccal surface of the maxillary arcade. **Large dental “hooks”** may also develop on the rostral and caudal ends of the arcades. Regular (biannual) rasping is usually sufficient to prevent occlusal dental problems.

ABNORMAL WEAR

Shear mouth

Excessive angulation of the occlusal surface results in prominent enamel points preventing lateral movement of the arcades. This condition can be

attributed to either inadequate width of the mandibular arcades or restricted lateral grinding movements of the mandible following temporomandibular trauma or arthropathy.

Wave mouth

Abnormal mastication and/or differential rates of wear between individual teeth results in exaggerated development of the normal troughs and ridges of the occlusal surface. This provides a sigmoid pattern to the dental arcade when viewed laterally. The impaired mastication and quidding that develop in severe cases necessitate leveling of the dental arcade using rasps and chisels under general anesthesia. Motorized rasps may also be used.

Step mouth

Severe differential wear between adjacent teeth or following tooth removal produces marked variation in the height of adjacent teeth. Mastication is markedly impaired, which may result in malnutrition. Treatment aims to level off the step-like profile of the arcade.

Smooth mouth

Smooth mouth is a **geriatric condition** of the horse that develops as teeth are lost or worn down to the gingival surface. Mastication is severely affected as the grinding efficiency of the occlusal surface is severely limited. Poor condition, colic and malnutrition may develop. Smooth mouth may also be seen in young animals if excessive, frequent and improper rasping is performed.

Enamel hypoplasia

Abnormal enamel development will produce excessive dental wear in young or middle-aged horses. The effect of this is to produce a smooth mouth conformation in a non-geriatric horse.

ABNORMAL DEVELOPMENT

Brachygnathism/prognathism

Congenital shortening of the mandible or maxilla results in malocclusion of the incisor arcade and if severe will also involve the cheek teeth. These are inherited conditions, the most common being **mandibular brachygnathism (parrot mouth)**. This terminology describes the relative shorter length of the mandible compared to the maxilla.

An assessment of the presence of mandibular brachygnathism is usually determined at 2 yr of age when the degree of contact of the central incisors is evaluated. The condition is defined by a complete failure of occlusal contact.

Maxillary prognathism (sow mouth) is a less common developmental abnormality with relative shortening of the maxilla compared with the mandible.

Cosmetic surgery to disguise the signs of either condition is of questionable ethical value. However, attempts at restricting mandibular or maxillary elongation by using braces or wires are frequently carried out, particularly in North America. Treatment is usually unnecessary but rasping and/or cutting of overlong teeth may be needed.

Nutritional secondary hyperparathyroidism (big head/miller's disease)

A generalized skeletal disease is found in horses fed a dietary intake of excess phosphorus in relation to calcium. The presenting signs are facial swelling, nasal obstruction, nasal discharge, mandibular distortion and abnormal development of tooth germs. This condition is of historical importance but is rarely seen with modern balanced diets.

Mandibular cysts

Mandibular cysts produce a **unilateral swelling of the mandible** in the young horse. There is no history of trauma and the horizontal ramus is usually affected. The lesion tends to occur rostrally near the mandibular synostosis. Radiographic examination reveals an expansile lesion containing large radiolucent areas. The etiology of this lesion is unknown, but it does not appear to be inherited. Treatment involves vigorous curettage of the cyst lining. Dental development postoperatively is usually unaffected by this treatment.

Polyodontia

Supernumerary teeth usually occur in the incisor arcade and are generally a cosmetic problem only. If there is abnormal wear and trauma to the surrounding soft tissue, the additional teeth may be surgically removed. Supernumerary cheek teeth may also occur medially or at the ends of the cheek teeth arcades. Their presence usually leads to malocclusion, food impaction and periapical abscessation. If this does occur, surgical removal is indicated.

A particular syndrome occurs occasionally, involving the **eruption of a seventh upper cheek tooth**, caudal to the third molar. These two teeth are frequently separated by a wider gap (diastema) than is usual. Food material may penetrate the caudal maxillary sinus causing a severe sinusitis. The extraneous tooth can usually be removed per os and the sinus treated in the usual way via a facial flap approach. It is seldom necessary to place a protective dressing in the alveolus to avoid food penetrating the sinus, other than for the first two or three days.

Oligodontia

The development of a less than normal number of teeth is known as oligodontia. **Pseudo-oligodontia** develops following either external trauma or surgical removal. True congenital oligodontia may result from nutritional secondary

hyperparathyroidism of the foal (see above). Normal tooth germs fail to develop correctly and those teeth that erupt may do so abnormally.

Heterotopic polyodontia (dentigerous cysts)

Abnormally positioned tooth germs of the branchial arch typically produce **cystic swellings of the temporal region** in yearlings. The dental tissue is well developed and contained within a cyst lining of stratified squamous epithelium. A **fistula** is often present on the leading edge of the nearest pinna, producing a characteristic oily discharge. Treatment requires complete removal of the cyst lining as well as the contained dental tissue. Care must be taken in removing the tooth as it may be fused to the underlying cranium.

PERIODONTAL DISEASE

Periodontal disease may affect any tooth and is usually associated with abnormal wear or abnormal dental eruption that allows food material to accumulate between individual teeth.

The clinical signs are **quidding** and **painful mastication**. Inflammation of the gingival sulcus is followed by erosion and enlargement of the gingival recess, the sequel of which is food impaction. The continued inflammation, infection and erosion of the supporting alveolar bone produce gross gingival pocketing, further food retention and weakening of the periodontium. The abnormal wear creates shearing forces that accelerate loosening of the tooth's normally firm attachment to the supporting alveolus. Ultimately the periodontal attachments of the tooth in the socket are compromised, providing a direct route to the periapical region and subsequent development of a suppurative process.

If untreated, periodontal disease will result in **periapical abscessation** with resultant facial swelling, discharging sinuses to the skin, secondary sinusitis, halitosis and loss of the affected tooth. **Regular prophylactic dental care** to maintain normal mastication is advised to prevent onset of periodontal disease.

PERIAPICAL ABSCESSATION

Sepsis of dental radicles may develop from an extension of periodontal disease via hematogenous spread following dental or alveolar bone fracture, or in the maxillary arcade following impaction of food into the infundibulum. The infundibulum of the maxillary tooth is normally only partially filled with cement. At the depth of the infundibulum the cement is hypoplastic and a potential space persists which may become impacted with food.

Fermentation of entrapped ingesta, and resulting **acidic dissolution** of the surrounding enamel and dentine, erodes the surrounding tooth, weakening it and leaving it liable to potential fracture. Secondary dentine is normally produced as a protective response to this "caries" lesion, however continued dissolution may ultimately bridge the dentine and allow infective agents direct access to the root pulp, the consequence of which is **pulpitis**, followed by periapical abscessation.

Periapical abscessation produces halitosis and painful swelling centered over the affected tooth root. If the tooth is present within the maxillary sinus, secondary dental sinusitis and nasal discharge will result.

Radiographic examination of suspected **periapical abscessation** must include oblique radiographs of the affected dental radicles. Markers and probes are useful to accurately determine the affected root. Radiologically, periapical abscessation is characterized by distortion of the dental roots, a radiolucent halo around the affected root, osteitis of the surrounding bone and loss of the normal distinct lamina dura and periodontal membrane.

Treatment involves repulsion of the affected tooth using a **trephine hole** and punch or sinus bone flap technique for those teeth within the maxillary sinus. Periapical infections of the rostral maxillary and mandibular teeth may also be approached using a lateral buccotomy approach. The exposure using a buccotomy approach is good following resection of the lateral alveolar bone and therefore enhancing complete removal of all dental tissue. Postoperative packing is assisted by using an oral plug and ribbon gauze that can be led out to the skin either dorsally or ventrally. This packing can be gradually removed as the socket granulates. Care must be taken when performing the buccotomy approach to avoid the facial artery, vein, nerve and parotid duct.

DENTAL NEOPLASIA

Odontogenic tumors may be of epithelial, mesenchymal or mixed origin. They are usually encountered in younger horses and may be congenital. **Ameloblastomas** are the most common and benign, however the local invasion is extensive and produces facial swelling, dysphagia, halitosis and weight loss.

Treatment is limited by the lesion size on presentation. If resection is inadequate, recurrence is common.

THE NASOPHARYNX

The pharynx is a muscular tube divided in two by a horizontal muscular sheet, the soft palate. The ventral half is continuous with the oral cavity and is called the **oropharynx**. The dorsal half, the **nasopharynx**, is continuous with the nasal passages.

The soft palate, which is subject to complex muscular actions, forms a continuous sheet from the hard palate rostrally to the dorsal pharyngeal roof caudally. There is a hole in this sheet through which the rostral laryngeal cartilages fit during respiration, much like a button in a buttonhole. This junction is an airtight seal that prevents food leakage from the oropharynx into the airway.

On the lateral walls of the nasopharynx the cartilaginous flaps of the guttural pouches are situated. During deglutition, the nasopharynx is closed by elevation of the soft palate, opening of the guttural pouch flaps and rostro-ventral movement of the nasopharyngeal roof. The larynx moves rostrally and closes and food is propelled from the oropharynx into the esophagus by action of the base of the tongue and progressive caudal constriction of the pharyngeal muscular tube. Immediately after this the pharynx and larynx resume their respiratory positions. The whole process lasts <1 s.

There is widespread lymphoid tissue throughout the nasopharynx with a particular concentration in the pharyngeal recess situated dorsally between the cartilage flaps of the guttural pouches. In young horses these lymphoid follicles may become quite large.

PHARYNGEAL DISEASE

Abscesses

A **pharyngeal abscess** may develop after a respiratory tract infection. Typically it forms in the retropharyngeal lymph nodes following infection by *Streptococcus equi equi* but commonly other *Streptococcus* spp. or other bacteria may be involved. In some cases the abscess may rupture into the guttural pouches producing empyema (*q.v.*). An abscess may form lateral to the nasopharynx as well as in a dorsal position and may occur secondary to infection of a localized injury such as penetration of the pharyngeal mucosa by a foreign body.

Affected horses usually have obvious **pharyngeal swelling** and show signs of **upper airway obstruction**. There may be a respiratory noise and, if the obstruction is severe, **dyspnea** may be marked with the horse adopting an “air hunger” position with its head and neck extended. In the acute phase there may be pyrexia and dullness and elevated hematologic and blood biochemical parameters (leukocyte count, serum proteins and fibrinogen) usually indicate a severe inflammatory lesion.

Endoscopic examination of the upper airway will usually reveal marked nasopharyngeal stenosis, or if there is empyema of the guttural pouches a purulent discharge may be noted from one or both ostia. Lateral radiographic views of the pharynx will usually demonstrate an increased area of radiodensity in the retropharyngeal tissues with concomitant narrowing of the nasopharyngeal airway or reduction in size of the guttural pouch air shadow. In some cases radiologic evidence of **guttural pouch empyema** (*q.v.*) may be noted. Rarely there may be evidence of dysphagia, which can be demonstrated by a barium swallow study.

Treatment with broad-spectrum antibiotics and anti-inflammatory drugs may be the only practical course of action unless a superficial abscess can be drained surgically. In severely dyspneic cases surgical drainage may be carried out as an emergency procedure or as an alternative to insertion of a temporary tracheostomy tube. Although *Streptococcus equi equi* is sensitive to penicillin, some clinicians consider that the course of the disease may be prolonged and the resultant immunity poorer if such treatment is followed instead of a more conservative approach of topical compresses and/or abscess drainage. However there is little scientific basis for this view. Treatment of secondary guttural pouch empyema is employed where indicated (*q.v.*)

Foreign bodies

Although horses are considered to be selective grazers, they will occasionally ingest pieces of twig such as blackthorn or hawthorn. This happens usually while grazing at the edge of hedgerow or as a result of ingesting hay that

contains such a twig. Affected horses will show severe discomfort and often **cough paroxysmally**. Usually there is **marked inappetance**. Occasionally there may be **slight epistaxis**.

Upper airway endoscopy may reveal the foreign body typically situated in the piriform recess or it may just be visible appearing under the edge of the soft palate. Rarely, a long twig may be seen extending from the oropharynx across the laryngeal aditus into the cranial esophagus. Twigs trapped in the oropharynx may remain invisible to endoscopy of the nasopharynx. Radiographic views of the pharynx frequently reveal little evidence of such a foreign body.

Removal of pharyngeal foreign bodies can usually be achieved manually via the mouth with the horse under a general anesthetic although it may also be possible in some cases under heavy sedation.

Neoplasia

Tumors of the nasopharynx are rare but **squamous cell carcinoma** (*q.v.*) formation in older horses can produce signs of dyspnea or dysphagia and there is usually severe halitosis. Endoscopic examination of the nasopharynx will usually reveal a soft tissue mass although in some horses the lesion may be confined to the oropharynx and only visible by examination under general anesthesia. A biopsy will confirm the diagnosis. There is no treatment for the condition. **Lymphosarcoma**, **melanoma** or **adenocarcinoma** (*q.v.*) may produce similar clinical signs, and sometimes epistaxis may be noted.

Nasopharyngeal lymphoid hyperplasia

The tonsillar/adenoidal lymphatic tissue of the horse is very widely distributed throughout the nasopharynx and mucosa of the guttural pouch. Lymphoid follicles may be found in large numbers in young horses in all sites but particularly on the nasopharyngeal roof. The dorsal nasopharyngeal recess has a particularly dense concentration of lymphoid tissue, which has been described colloquially as the **pharyngeal tonsil**. Endoscopy is the diagnostic method of choice.

The lymphoid follicles in young horses are often quite prominent; the mucosa may appear reddened and mucus production may be profuse. This lymphatic reaction is usually a response to antigenic challenge (e.g. respiratory viruses or environmental allergens). Clinical signs are usually minimal or those of respiratory viral infection (i.e. mucopurulent nasal discharge, cough and pyrexia). Prominent nasopharyngeal lymphoid follicles may be responsible for mild upper airway obstruction and an abnormal respiratory noise at exercise.

Topical treatment with anti-inflammatory sprays has been advocated although this is not usually necessary or constructive.

Pharyngeal cysts

Pharyngeal cysts in the nasopharyngeal roof, soft palate and particularly subepiglottic tissue (*q.v.*) are occasionally found in young foals, and rarely in

mature horses. Typically, affected foals make an **abnormal respiratory snoring noise** and dysphagia may be noted. The cyst can usually be seen on endoscopic examination of the upper respiratory tract.

Treatment in any site other than subepiglottic may be extremely difficult although there are reports of successful resection of cysts from the edge of the soft palate. Some subepiglottic cysts are associated with epiglottal entrapment (*q.v.*) and in young foals there may be a secondary aspiration pneumonia (*q.v.*), which should be managed appropriately.

Soft palate defects

Midline clefts of the soft palate may be short or involve the whole length of the soft palate. Affected foals usually regurgitate milk down the nose and **secondary aspiration pneumonia** (*q.v.*) may occur. While oral inspection may reveal a cleft of soft or hard palate, a definitive diagnosis can be made by **nasopharyngeal endoscopy**. Asymmetric defects of the soft palate may present a much greater diagnostic challenge as nasal regurgitation of milk often does not occur. In fact, gross dysphagia is sometimes not noted and the major clinical sign may be an abnormal respiratory noise at exercise or exercise intolerance in an older horse.

There is **no satisfactory treatment** for palatal defects and affected horses are not suitable for athletic purposes.

Laryngopalatal dislocation

The normal horse is an obligatory nasal breather and has a unique anatomic relationship by which its larynx fits intimately through a hole in its soft palate. This is temporarily disrupted during swallowing.

If laryngopalatal dislocation occurs at fast exercise, a loud “gurgling” noise is produced and severe respiratory embarrassment results. This respiratory obstruction is usually transient and is corrected by deglutition when the soft palate returns to its respiratory subepiglottic position. Such respiratory obstruction is known colloquially as “**choking up**” or the horse is described as having “**swallowed its tongue**”. Affected horses usually stop dramatically and then swallow and continue, showing few signs when examined after exercise. Typically the problem affects racehorses towards the end of a race. Commonly such horses may be galloping freely without difficulty, only “choking” when the jockey attempts to make the horse accelerate. The condition is less commonly encountered in event horses on the cross-country course or even hunters exercising on heavy land.

The cause of this severe transient respiratory obstruction is often obscure but **stress** may play a role, particularly in the racehorse. The mechanism is unknown but some believe that caudal retraction of the larynx by the sternohyoid and sternothyroid muscle groups is involved. Recent work from North America has proposed that neuritis of the pharyngeal nerves may initiate palatal displacement.

In a proportion of cases, a primary respiratory problem may be recognized (e.g. **laryngeal hemiplegia** or **small airway disease**). In these circumstances treatment should be directed toward management of this primary respiratory

problem. However, in a large number of cases no primary specific respiratory disease is identified.

While some horses may respond to conservative treatment such as ensuring the horse is completely fit, using a dropped noseband to close the horse's mouth, a tongue strap to limit tongue retraction, or a milder bit, in many cases such methods are ineffective. **Surgical resection** of the sternohyoid and sternothyroid muscle groups and/or the edge of soft palate, or cautery of the palate using a firing iron via the mouth or a Nd:YAG laser per nasum may be effective, but in a significant proportion of cases no treatment is useful. The insertion of a **tracheostomy tube** may help some horses but a number of horses must be retired from racing to less arduous pursuits with which the condition does not interfere.

Fourth branchial arch anomaly

Fourth branchial arch anomalies are occasionally encountered. Affected horses may suffer rostral displacement of the palatopharyngeal arch as a consequence of cricopharyngeal muscle aplasia or hypoplasia. This pair of muscles constitutes the proximal esophageal sphincter, and their absence results in **aerophagia** and thus **eructation** and **tympanitic colic**. Affected animals often have maldevelopment of the laryngeal cartilages, which results in the production of an abnormal respiratory noise at exercise.

Endoscopic examination often reveals the palatopharyngeal arch to be displaced rostral to the corniculate processes of the arytenoid cartilages, and in some horses it is possible to look down the esophagus from the nasopharynx because of hypoplasia of its proximal sphincter. The condition may be unilateral, in which case it is usually right-sided. There may be an asymmetry of the rima glottidis that can be confused with a recurrent laryngeal neuropathy.

An **air-filled cranial esophagus** is usually noted on lateral radiographic views of the area. There is no treatment for the respiratory obstruction produced by the anomaly.

Hyoid bone fracture

Fracture of the hyoid bone is a rare condition that is usually associated with a pharyngeal injury or can occasionally occur secondary to an inflammatory or neoplastic disease. The usual clinical signs are dysphagia or pharyngeal discomfort and the diagnosis is made by radiographic or endoscopic means. There is no need to treat the fracture except by short-term use of **anti-inflammatory drugs**. It will usually heal by fibrous union. In the absence of neurologic signs the prognosis is good.

GUTTURAL POUCHES

The guttural pouches are paired **air-filled diverticula of the auditory (Eustachian) tubes** peculiar to Equidae and the hyrax (a tree shrew). They are situated ventral to the cranium and dorsal to the nasopharynx and larynx. Each guttural pouch has an opening into the nasopharynx by means of a

cartilaginous flap that opens during deglutition. The function of the pouches is obscure but they are lined by mucous membrane containing follicular lymphoid tissue similar to the nasopharynx (*q.v.*) that may be hyperplastic in younger animals.

Each pouch is divided by the stylohyoid bone in the caudal part, producing a smaller lateral and larger medial compartment. The pouches share a common medial septum. The wall of the lateral compartment is closely associated to the maxillary artery (branch of external carotid), the facial nerve (CN 7) and the parotid salivary gland. Cranial nerves 9, 10, 11 and 12, along with the sympathetic nerves and cranial cervical ganglia, are closely associated in a fold of mucous membrane with the internal carotid artery in the caudal wall and roof of the medial compartment. The retropharyngeal lymph nodes lie ventral and caudal to the pouches. Each pouch is directly connected to the middle ear (*q.v.*).

DISEASES OF THE GUTTURAL POUCHES

Empyema

Following some bacterial respiratory infections a retropharyngeal lymphadenopathy and abscess formation may occur. Classically, such a **pharyngeal abscess** is associated with infection by *Streptococcus equi equi* but any bacterium may be involved. The abscess may rupture into one or both guttural pouches producing **empyema**.

Affected horses may be dull and/or pyrexia, and often there is swelling caudal to the vertical ramus of the mandible. A purulent nasal discharge is common and may be bilateral or predominantly unilateral. The discharge may be fetid. Rarely there may be no nasal discharge, typically because there has been **inspissation** of purulent material within the pouch. In such cases **pharyngeal swelling** may be marked and there may be dyspnea and even dysphagia, although this latter sign is uncommon. Dyspnea is the result of nasopharyngeal obstruction, and dysphagia may follow pharyngeal obstruction or pharyngeal neuritis (*q.v.*).

Endoscopic examination of the nasopharynx will usually reveal a **purulent discharge** from the ostium of one or both guttural pouches and there may be evidence of marked **nasopharyngeal obstruction**, particularly when both pouches are involved. **Endoscopic inspection** of both guttural pouches should be carried out to assess the extent of the infection. However, if the pouch is full of purulent material it may be difficult to insert the endoscope and it may also be difficult to visualize the normal anatomy. In chronic cases the purulent material may have become inspissated forming so-called “**chondroids**”, which are balls of dried pus. In some chronic cases the normally thin translucent mucosa of the guttural pouch becomes very thickened and inflamed.

Standing lateral radiographic views of the pharynx will show loss of the normal radiolucent guttural pouch air shadow. Fluid levels may be noted; these may be multiple if both pouches are involved. Irregular increased radiodensity in the guttural pouch area may be present if the purulent material has become inspissated or formed chondroids.

The **treatment** of guttural pouch empyema depends on the clinical severity of the case. If there is dyspnea it may be necessary to insert a temporary

tracheostomy tube or to carry out **emergency drainage** of purulent material with the horse standing. In mild cases it may only be necessary to treat the horse with an appropriate antibiotic as determined by bacterial culture of nasal or nasopharyngeal swabs. In most cases the use of **antibiotics** should be augmented by **lavage of the pouch** using an indwelling balloon catheter. Such lavage using saline, tap water or even a 0.5% solution of **povidone-iodine** or **hydrogen peroxide** should be carried out twice daily until the nasal discharge has resolved. Concentrated solutions of such irritant chemicals may induce neuritis of the adjacent cranial nerves.

If chondroid formation has occurred, it may be necessary to **drain the pouch surgically** via Viborg's triangle (defined by the caudal border of the mandible, the linguofacial vein and the tendon of the sternomandibularis muscle) or a modified laryngoplasty approach (*q.v.*). Such surgery is usually carried out under general anesthesia and care must be taken to avoid the pharyngeal nerves. Usually the wound is left to heal by second intention. It is preferable to avoid surgical drainage if at all possible.

The prognosis for guttural pouch empyema is good provided irreversible pharyngeal nerve damage has not occurred, and that appropriate lavage or surgical drainage and removal of chondroids has been instituted.

Tympany

Air-filled distension of one or both guttural pouches is an uncommon condition usually seen in foals although, rarely, older animals may be affected. It is said to be more common in Arabians and Thoroughbreds in the UK. Affected foals typically have a "**bullfrog**" appearance with marked pharyngeal distension. Although the condition is most commonly unilateral the swelling may appear bilateral because the common medial septum and the soft tissues of the pharynx are flexible. The distension may be intermittent. Affected foals usually make a **snoring respiratory noise, particularly when suckling**, but in bilateral cases dyspnea may be severe.

The etiology of the condition is uncertain, although a ball-valve effect of the mucous membrane fold associated with the cartilaginous flap of the guttural pouch has been suggested. Endoscopic examination of the nasopharynx may be helpful in determining whether the condition is unilateral or bilateral. The nasopharyngeal roof sags asymmetrically in unilateral cases and there may be severe symmetrical collapse of the nasopharyngeal roof in bilateral cases.

The most useful diagnostic aid is a standing lateral radiographic view of the pharynx, which will demonstrate a massively enlarged guttural pouch air shadow. It should also be possible, by assessing the contours of this shadow, to decide whether the condition is unilateral or bilateral.

In unilateral cases the condition may be treated by **fenestration of the common medial septum**. This can be achieved in the standing horse under endoscopic control using a laser or diathermy but is more commonly carried out under general anesthesia via a Viborg's triangle or modified laryngoplasty approach. This technique is obviously ineffective in bilateral cases.

A second surgical method, useful for bilateral cases, involves **ventral enlargement of the nasopharyngeal ostium** of the guttural pouch using a

hooded blade, again via a Viborg's triangle approach, or using a Nd:YAG laser, under endoscopic control.

The third, least invasive and the preferred method is the enlargement of the guttural pouch ostium by **chronic catheterization** using an indwelling balloon catheter. This results in damage and necrosis to the cartilaginous flap, producing a permanently open ostium. Although the catheter must be left in place for 4–6 wk this method can be used in bilateral cases and obviates the need for a general anesthetic.

The most common complication of chronic catheterization is the premature removal of the catheter by the patient, in which case the catheter must be reinserted. Complications of the first two techniques usually arise from iatrogenic damage to the pharyngeal nerves resulting in **dysphagia** (*q.v.*) and **gangrenous aspiration pneumonia**. Occasionally guttural pouch tympany can be complicated by secondary infection and empyema, which can usually be treated effectively by lavage and antibiotic therapy.

The prognosis for resolution of guttural pouch tympany using the above techniques is good provided iatrogenic pharyngeal nerve damage can be avoided and that bilateral cases are recognized and treated appropriately.

Mycosis

Mycotic plaques associated with the guttural pouch mucosa are not rare and typically affect the roof of the medial compartment adjacent to the internal carotid artery and the cranial and sympathetic nerves. Rarely the lesion may be found on the lateral wall of the lateral compartment, associated with the maxillary artery. The fungal lesions appear to develop at these sites in association with **arterial aneurysms** (*q.v.*) although the cause of aneurysm formation is unknown. A variety of fungal and bacterial species have been identified in association with the lesion including *Aspergillus* spp., *Nocardia* spp. and *Pseudomonas* spp.

The most common clinical sign is **epistaxis**, which is usually **bilateral**, is not associated with exercise and may be massive. Such nasal hemorrhage is fatal in a significant proportion of cases if the lesion remains untreated. There is often a foul smelling nasal discharge. Other clinical signs are related to cranial or sympathetic nerve damage, the most common of which is **pharyngeal hemiplegia** resulting in **dysphagia**. Other clinical signs include facial, laryngeal and lingual hemiplegia and signs of sympathetic nerve damage such as patchy sweating, colic or **Horner's syndrome** (*q.v.*). A useful additional clinical sign in these cases is parotid pain, although its severity is variable.

Endoscopic examination of the upper respiratory tract is the diagnostic technique of choice, although visualization may be difficult in horses that have had recent severe hemorrhage. In such cases there may be considerable bleeding in the nasopharynx; however, a characteristic sanguineous discharge from a guttural pouch ostium is usually discernible.

The endoscope should be passed into the pouch with care to avoid disturbing a clot over the artery and consequent hemorrhage. The endoscope is best inserted by passing a biopsy forceps through the biopsy channel of the instrument to open the flap. Sometimes the pouch is full of blood or a **hematoma** making visibility impossible. However, if a clear view can be obtained, a

mycotic plaque is usually easy to see over the roof of the medial compartment; in some horses the lesion may be quite extensive and spread over much of the medial compartment, even extending through the common medial septum to the other pouch. Primary bilateral lesions are extremely rare and lesions affecting the maxillary artery in the lateral compartment are also uncommon. Other endoscopic features may include **pharyngeal or laryngeal hemiplegia** (*q.v.*) and food is often seen in the nasopharynx, larynx and trachea in horses with dysphagia.

Plain radiography is not usually of much value in cases of guttural pouch mycosis. However, lateral radiographic views of the pharynx or a similar view using image intensification after oral administration of a **barium sulfate** suspension may be of great value in determining the presence of pharyngeal paralysis.

Another radiographic technique that is useful in cases of mycosis is obtaining lateral views of the chest in horses with **gangrenous aspiration pneumonia**. Carotid angiography under general anesthesia may also be valuable to determine the presence of **arterial aneurysms** and anomalies. Angiography may be particularly helpful for the inexperienced surgeon in elucidating the arterial anatomy of the carotid tree, which may be variable. However, it is time consuming and unnecessarily prolongs anesthetic time in a potentially poor risk patient and is therefore performed infrequently.

In horses with **epistaxis** (*q.v.*) there is a major risk of **fatal hemorrhage**; the aim of treatment is to prevent this. Although such horses occasionally will recover spontaneously, presumably following thrombosis of the internal carotid artery, **surgical ligation** of the artery via a hyovertebrotoomy approach is the treatment of choice. Although simple proximal ligation has been shown to be effective there is a risk of retrograde hemorrhage via the circle of Willis, and most surgeons usually opt to occlude the artery distally. As the artery distal to the typical site of leakage is inaccessible the most satisfactory method of occluding it is by the insertion of an intra-arterial balloon catheter from a proximal site to beyond the leak. This is combined with proximal ligation.

In any horse with pharyngeal paralysis there is a risk of **aspiration pneumonia** (*q.v.*).

Some horses appear to recover from pharyngeal hemiplegia, presumably because the neuritis may be reversible or because the horse adapts to an altered method of deglutition.

Antifungal medication of the plaque via an indwelling catheter may be helpful in resolving the lesion but is of secondary importance to depriving the plaque of its blood supply. A weak solution of approximately 250 mL **nata-mycin** is injected via a catheter syringe and an indwelling balloon catheter into the pouch. Alternatively a smaller volume may be nebulized into the pouch via the catheter. These treatments are seldom carried out these days other than at the time of surgery, unless neurologic signs are present. However, in horses showing no signs of hemorrhage, medical treatment alone is indicated.

Neoplasia

In gray horses, melanin deposition submucosally in the guttural pouches is quite common and the development of **melanomas** (*q.v.*) is not uncommon.

Such lesions seldom develop to produce clinical signs although pharyngeal obstruction may eventually result if the lesion enlarges. Rarely the guttural pouch may become a site for development of other tumors such as a squamous cell carcinoma (*q.v.*). However, these tumors usually arise primarily in the nasopharynx adjacent to the pouch (*q.v.*).

Allergic parotiditis

Allergic parotiditis is confused frequently with diseases producing guttural pouch distension. The problem occurs only **at grass** and affected horses show a bilateral enlargement of the parotid salivary glands, which may occur to a marked degree. In the most severe cases, **facial edema** develops because of impaired facial venous drainage as a result of parotid gland enlargement. The condition rarely produces respiratory obstruction.

The most striking feature of the condition is the **rapid recovery** when affected horses are brought indoors. Several horses may be affected in one field, and some fields appear more likely to induce the condition than others. Samples of blood collected at the time may show an eosinophilia. It has been assumed that the problem is caused by an **allergy** to some factor in the outdoor environment, possibly some ingested plant material. Treatment is not usually indicated and affected horses may be returned to the same pasture eventually without developing the condition.

THE LARYNX

The equine larynx consists of five cartilages (the epiglottis, paired arytenoid, thyroid and cricoid cartilages). The **rima glottidis** (arytenoid cartilages and vocal cords) of the larynx acts like a biological valve. When fully abducted it permits an adequate flow of air to the lungs at fast exercise and when fully adducted it helps prevent aspiration of food during deglutition.

During quiet respiration the rima glottidis adopts an intermediate position. Movements of the rima glottidis are controlled by muscular action from the vagus (CN 10). The only abductor muscle is the cricoarytenoid dorsalis, innervated by the **recurrent laryngeal nerves**; the other muscles all produce adduction. The only muscle innervated by the cranial laryngeal nerve is the cricothyroid muscle.

On each side of the larynx is a pair of folds (vestibular and vocal) composed of muscle and the covering mucous membrane. The lateral ventricle is a small mucous membrane outpouching situated between these folds on each side. These structures have a role in vocalization. The subepiglottic mucosa is loosely attached to the oral surface of the epiglottis. This permits dorsocaudal movement of the cartilage during deglutition.

The rostral laryngeal cartilages fit snugly through a hole in the soft palate. During deglutition this relationship is disrupted when the soft palate is elevated and the larynx moves rostrally. At this movement the epiglottis is tipped dorsocaudally and the glottis is closed, preventing food entering the lower airway.

DISEASES OF THE LARYNX

Recurrent laryngeal neuropathy

The most important laryngeal disease is paralysis, which usually presents as **left-sided laryngeal hemiplegia** or hemiparesis. The cause of this disease is unknown but a “dying-back phenomenon” is noted histologically in the left recurrent laryngeal nerve. The routes of the left and right nerves are different in the horse, the left being much longer and traveling around the aortic arch before supplying the larynx. It is generally considered that it is the length and route of the nerve that is responsible for the disease. The idiopathic disease probably has a heritable component, which is complex in nature.

The disease is characteristically found in larger male horses but may occur in females and smaller horses or ponies. The disease occurs on the right side in a small proportion of cases. However, many cases that appear right-sided have a branchial arch anomaly (*q.v.*). Bilateral paralysis is extremely rare.

Laryngeal hemiplegia can follow a **specific cause** (e.g. accidental perivascular injection of irritant chemicals around the jugular vein, mediastinal mass, guttural pouch mycosis or lead poisoning) but occurs most commonly in its **idiopathic form**.

The clinical signs of the disease are an **inspiratory musical “whistle”** or harsher “roar” in more severe cases. Respiratory tract obstruction may occur, depending on the severity of the disease and the occupation of the horse. The disease is more likely to produce dyspnea when affected animals are required to gallop for an extended distance. It should be noted that a small reduction in laryngeal airway diameter produces a relatively large increase in airway resistance. After exercise, **gentle palpation** of the larynx may reveal **fremitus**. There is often obvious atrophy of the left dorsal cricoarytenoid muscle and on careful palpation of the area it is possible to feel the muscular process of the left arytenoid more easily than the right because it is denuded of its associated muscle. After exercise, pressure on the right arytenoid cartilage (the arytenoid depression test) may further narrow the rima glottidis in an affected horse and exacerbate the abnormal respiratory noise.

There is **no cure** for laryngeal hemiplegia and in many mild cases there is no need for treatment. Simply making the horse become fitter will often reduce the noise. In many instances the degree of respiratory obstruction is not severe enough to impair performance. However, the disease can be **progressive** and the paralysis may worsen with time.

Traditional treatment for the disease involves left **ventriculectomy** with or without **cordectomy** via a **cricothyroid laryngotomy**, or using a Nd:YAG or diode laser under endoscopic control.

However, in severely affected horses that are required to perform athletically this procedure is often ineffective. In such horses a **ventriculectomy** is usually combined with a **laryngoplasty** (tieback procedure) in which the collapsed left side of the larynx is **fixed in abduction** by the insertion of retrolaryngeal sutures. The **surgical approach** is ventral to the linguofacial vein. The suture(s) is inserted from the caudal border of the cricoid cartilage to the muscular process of the left arytenoid cartilage under the pharyngeal musculature. When tightened and tied, the sutures mimic contraction of the defunct left dorsal cricoarytenoid muscle.

The most serious complication of this operation is the induction of **severe dysphagia** in a small percentage of cases. Aspiration of food material results from failure of laryngeal protection during deglutition. While a postoperative cough and subtle dysphagia may occur more frequently, such cases can often be managed by dietary adjustment or the horse may be able to adapt to it. Most owners are prepared to accept this because of the improvement in exercise tolerance. If the problem cannot be managed, removal of the implants is indicated.

Laryngoplasty may not improve the laryngeal airflow adequately in some cases, particularly when horses are required to perform at the highest level in flat racing.

Epiglottal entrapment

Dorsal displacement of the subepiglottic mucous membrane over the epiglottis produces **epiglottal entrapment**. The condition may be persistent or transient. A significant proportion of cases are asymptomatic but the mucous membrane pouch produced can be responsible for abnormal respiratory noises at fast exercise or even slower paces. The noise is usually harsh and inspiratory but a fluttering or gurgling expiratory noise may be produced in some horses.

The condition may induce **laryngopalatal dislocation** during galloping. It is common to see **ulceration** of the entrapping mucous membrane in those horses producing abnormal respiratory noises. This may be related to laryngopalatal dislocation or to pressure from the underlying epiglottic tip. The condition in its persistent form can be diagnosed easily by endoscopy. In transient cases it can be much more difficult to identify. Stimulating swallowing during endoscopy can induce the condition although in some cases entrapment may last only a second or so. It has been suggested that endoscopy during treadmill exercise may be helpful in such cases.

The etiology of the condition remains obscure although it can occur in horses with **epiglottal hypoplasia** (*q.v.*) or with a **subepiglottal cyst** (*q.v.*) or mass.

Treatment of horses making a respiratory noise is either by **ablation** of the entrapping mucous membranes via a **cricothyroid laryngotomy**, or by splitting the tissue with a hook knife per nasum, or using a Nd:YAG or diode laser, under endoscopic visualization in the standing horse. Transient cases may be most easily treated by the first technique. In some horses speculative resection of the subepiglottic mucosa may be the only option.

Epiglottal hypoplasia

The epiglottis appears extremely varied in size and shape in the normal horse. Normally, epiglottic size is assessed endoscopically but more accurate measurement can be made from a lateral radiographic view of the area. Gross hypoplasia is extremely rare but has been reported, particularly in the Standardbred. Secondary epiglottal entrapment or laryngopalatal dislocation is the usual consequence.

Traditionally there has been no effective treatment for the condition, although some clinicians have been successful in mild cases using

subepiglottal augmentation, increasing epiglottal bulk by submucosal injection of Teflon or a similar polymer.

Arytenoid chondritis

Arytenoid chondritis has been recognized with increased frequency in recent years. The cause is usually unknown although some cases follow surgical or accidental insult to the laryngeal cartilages. Typically there is swelling and distortion of the **arytenoid cartilage**. If the condition is unilateral there is usually an abnormal respiratory noise at exercise and exercise intolerance in some horses.

The condition may be bilateral with consequent severe laryngeal obstruction. There may be a discharging sinus from the affected arytenoid and “kissing” ulceration of the contralateral arytenoid cartilage is common. Characteristically, even in subtle cases there is swelling of the medial face of the arytenoid cartilage and usually there is gross interference with movement (abduction or adduction) of the affected side of the larynx. Although an endoscopic diagnosis is usually straightforward, care must be taken to differentiate the more subtle cases from laryngeal hemiplegia (*q.v.*). Both left and right sides appear to be involved with similar frequency.

Treatment is by partial or subtotal **arytenoidectomy** via a cricothyroid laryngotomy under general anesthesia. The latter method has been associated with postoperative dysphagia. In the mildest cases there may be little obstruction to the glottis. Laser ablation may be effective when the arytenoid enlargement mainly consists of granulation tissue. In severe cases a **tracheostomy** may be the most practical method of case management.

Laryngeal granuloma

A granuloma associated with the larynx is almost always the **sequel to previous surgery** or to an accident but may be associated with chondritis (*q.v.*). Removal of the granuloma in uncomplicated cases is usually effective, particularly when the granuloma is a sequel to ventriculectomy and is attached to the vocal cord. The condition has been reported in the UK associated with an exotic disease, **rhinosporidiosis**.

Subepiglottic cysts

Congenital pharyngeal cysts in a variety of sites occur rarely in young foals (*q.v.*), producing respiratory obstruction and sometimes dysphagia. The predilection site is the loosely attached subepiglottic mucosa. Small cysts may be asymptomatic but in the majority of cases there is an associated snoring or gurgling noise that may be most obvious during suckling or feeding. With large cysts there may be marked respiratory obstruction.

It is not uncommon for such cysts to be associated with **epiglottal entrapment** (*q.v.*). An endoscopic diagnosis is usually readily made although lateral radiographic views of the pharynx, especially after the oral administration of barium sulfate, may be helpful in confirming the condition.

Treatment is by radical excision of the cyst via a cricothyroid laryngotomy incision. The subepiglottic mucosa should also be resected if there is

concomitant epiglottal entrapment. In most cases excision is effective, but the lesion may be very rostral in a small number of cases requiring removal per os using a snare under endoscopic control.

Neoplasia

Laryngeal tumors are extremely rare in the horse although cases of **lymphosarcoma** and **squamous cell carcinoma** (*q.v.*) have been reported. Surgical resection appears to carry a poor prognosis.

THE EAR

The equine pinna is erect and able to rotate about its long axis under muscular control. The horizontal and vertical canals are relatively inflexible which makes examination of the tympanic membrane extremely difficult in the conscious horse. Typically a thick, dark waxy material is present in the normal ear, representing a secretion from the ceruminous glands. The middle ear and the auditory tube are connected with the guttural pouches. The middle and inner ears are contained within the petrous temporal bone.

DISEASES OF THE EAR

Deafness

Deafness is thought to be uncommon in the horse but is extremely difficult to assess. It may be congenital or result from inflammatory changes in the inner or middle ears or guttural pouches.

Epidermal hyperplasia

Raised white plaques are found quite commonly on the inside of the equine pinna. Histologic examination reveals epidermal hyperplasia. The plaques are asymptomatic but may appear unsightly and are of more concern to the owner than the horse. There is no effective treatment for the condition.

Ear mites

Psoroptic mites (*q.v.*) have been reported as an incidental finding in the horse. However they can be associated with otitis externa and severe aural irritation or even head shaking (*q.v.*). Treatment, if necessary, is with eardrops containing gamma benzene hexachloride.

Otitis externa

Although a dark, waxy material is present in the external ear canal of the normal horse, otitis externa is rare. Clinical signs of aural discharge, head shaking, ear-rubbing or even an aural hematoma have been seen. Otitis has been associated with **ear mite** infestation (*q.v.*), **neoplasia** of the ear canal, a **foreign**

body in the external ear canal or **iatrogenic** causes such as attempted treatment of epidermal hyperplasia with ointments or local abrasion.

Treatment of the primary cause of the problem is usually effective and proprietary ointments or eardrops containing mixtures of antibiotics, gamma benzene hexachloride and corticosteroids plus parenteral non-steroidal anti-inflammatory drugs are usually helpful. General anesthesia may be necessary to carry out this treatment effectively and aural lavage may also be of value.

Aural hematoma

Aural hematoma is rare but usually results from direct **trauma** or **self-mutilation** by the horse because of **otitis externa**. The lesion is best treated as in the dog or cat, by surgical drainage under general anesthesia combined with treatment of any underlying otitis externa.

Aural neoplasia

Tumors of the ear canal are rare in the horse although **papilloma**, **melanoma** and **squamous cell carcinoma** (*q.v.*) have been reported. Usually there is an aural discharge and obvious ear shyness or irritation. Diagnosis is usually by biopsy following auroscopy. The treatment involves local excision of the neoplastic tissue. A lateral ear canal wall resection, as used in the dog, has been employed to give better surgical exposure in cases of squamous cell carcinoma. The prognosis for any lesion other than a papilloma is very guarded.

Sarcoids (*q.v.*) affecting the pinna have been reported and are usually managed by resection and/or cryotherapy or laser treatment of the lesions or by the intralesional injection of BCG (Bacille Calmette–Guérin).

The parotid gland adjacent to the ear is an extremely common site for **melanoma** (*q.v.*) development although the lesion seldom involves the ear itself.

Dentigerous cysts

The development of aberrant embryonic epidermal tissue around the base of the ear is usually associated with a swelling and a sinus discharging sebaceous material near the rostral edge of the pinna. Contrast radiography may be of value in defining a **dentigerous cyst** (*q.v.*), which is often associated with single or multiple aberrant teeth attached to the petrous or squamous temporal bones. Oblique radiographic views should be obtained in each case to identify such structures.

Surgical excision of the cyst and associated teeth should be carried out under general anesthesia. Care must be taken in removing the teeth as these are usually solidly embedded in the bone and excessive force may result in skull fracture or intracranial hemorrhage.

Peripheral vestibular disease

Inflammatory changes involving the vestibular system occur infrequently in adult horses. The etiology in many cases is obscure but may follow an ascending

infection from the **guttural pouch** or a descending infection from the **external ear**. Affected horses are usually ataxic with a head tilt or nystagmus and sometimes show signs of other deficits (CN 5 or 7). Diagnosis is based on a neurologic examination and recognition or elimination of possible causes of similar signs such as guttural pouch disease or a fractured skull.

Some cases are associated with an **arthropathy** of the **hyoid apparatus**. Radiographic examination of such cases will usually reveal new bone formation affecting the proximal hyoid bones.

Treatment is by the prolonged administration of **parenteral corticosteroids** (prednisolone is probably best, the recommended daily dose being 1 mg/kg PO and reduced by 50% 1 wk before complete cessation of treatment). Non-steroidal anti-inflammatory drugs may also be helpful. This regimen must be allied to treatment of the primary condition in those cases where this can be identified. The prognosis appears to be variable but many cases will respond to prolonged medication. However, in some horses resection of a portion of the stylohyoid bone is required to resolve the condition.

Head shaking

Head shaking (*q.v.*) may be a clinical sign of a variety of diseases (e.g. **guttural pouch** or **paranasal sinus** lesions). However, there is a well-recognized syndrome that typically involves involuntary rapid dorsoventral head movements at ridden exercise. This dramatic behavioral problem (*q.v.*) is most commonly seen in the warmer months of the year in horses used for general riding purposes but more especially if they are being schooled for more sophisticated disciplines such as dressage. Occasionally, affected horses will try to rub the nose on a foreleg or the ground at the canter. In many cases the horse is either unrideable or extremely dangerous to ride. Usually no clinical, endoscopic or radiologic lesion can be identified to explain the dramatic behavior. The condition is often intermittent and may be weather related.

No specific diagnosis can usually be made and although some horses recover spontaneously, in many cases the problem is persistent. Bilateral infraorbital neurectomy has been found to be effective in a proportion of cases although the reason for its efficacy is unclear. Similarly destruction of the ethmoidal nerve by injection of 10% phenol in almond oil using a long spinal needle has also shown to be effective in a small number of cases, although the improvement may be temporary or incomplete.

In some cases the symptoms may be relieved by the use of muslin gauze attached to the noseband and covering the external nares. Medical management of head shaking horses is usually ineffective although **fluphenazine** has been used.

Chapter 7

The lower respiratory tract

INTRODUCTION

The horse is unique among domestic animals in the demands that are placed on its respiratory system. The cantering and galloping horse has locomotor and respiratory cycles locked in a one-to-one phase. A galloping horse will take over 150 breaths per min (bpm), having <0.5 s to inhale and exhale 12–15 L of air. Minor degrees of respiratory disease in the form of small

increases in mucopus in the airways or minor degrees of airway spasm will quickly take their toll on athletic performance, although horses with minor lower respiratory tract problems may not show overt signs of disease at rest.

Diagnosis has been made easier with the use of the **fiberoptic endoscope and more recently with the videoendoscope**. The covert respiratory problems of the relatively young equine athlete may be precursors of more overt problems later in life in the form of **recurrent airway obstruction (RAO)**, previously known as chronic obstructive pulmonary disease (COPD). Therefore, the diagnosis, treatment and prevention of respiratory problems in young horses have both short- and long-term benefits.

Considerable emphasis has been placed on **environmental factors**. Air quality of stables can affect the incidence and severity of a range of lower respiratory tract problems and in many instances is a valuable adjunct to pharmacologic intervention. The old adage of prevention being better than cure cannot be overemphasized in terms of the respiratory well-being of the stabled horse.

This chapter will review the diagnostic approaches useful in assessing lower respiratory tract disease, therapeutic approaches to some more commonly seen problems and the air hygiene of stables. Exercise-induced pulmonary hemorrhage has been associated with a wide range of equine athletic events and this condition is dealt with separately for this reason.

DIAGNOSTIC APPROACHES TO LOWER RESPIRATORY TRACT DISEASES

INTRODUCTION

The understanding of equine pulmonary disease has greatly increased during the past 25 years due to major advances in veterinary virology, pulmonary pathology, pulmonary function assessments and respiratory endoscopy. The development and application of a wide range of ancillary diagnostic techniques can now enable us to diagnose accurately and monitor objectively pulmonary disease in the horse. Practitioners can readily utilize many of these techniques and their use will greatly enhance the quality of veterinary practice.

CLINICAL EXAMINATION

With gross pulmonary diseases, such as **bacterial pneumonia** in foals (*q.v.*) or advanced **recurrent airway obstruction (RAO)** (*q.v.*) in adult horses, clinical signs of pulmonary disease will be obvious, possibly even on cursory examination.

Clinical signs can include coughing, which may be in bouts (paroxysmal) and which may expectorate large volumes of abnormal **respiratory secretions (RS)** via the oral cavity. Other obvious clinical signs can include bilateral nasal discharge, grossly elevated respiratory rate (i.e. ≥ 25 per min in an adult horse), increased respiratory effort (**hyperpnea**) and poor exercise tolerance or even weakness, with severe hypoxemia. Pyrexia and depression may occur in

infectious respiratory diseases and percussion of the ventral chest will reveal dullness in cases of pleural effusion. Cases with such near-pathognomonic signs of pulmonary disease will present no diagnostic challenge.

Additionally, the history and epidemiologic factors such as age, colostral or vaccination status, numbers of animals involved, transport history, history of contact with donkeys and knowledge of the type of forage, bedding and housing used, may enable a specific type of pulmonary disease to be diagnosed.

Limitations of clinical pulmonary examinations

The above examples of gross pulmonary disease are exceptional and in the majority of cases of equine pulmonary disease the clinical signs will not be pathognomonic. Many, if not most, horses with pulmonary disease do not have a nasal discharge, as all excessive RS produced in the lungs are swallowed.

Many horses with pulmonary disease will not have sufficient change in pulmonary function to increase significantly their respiratory rate or effort to an extent that will be clinically apparent and clearly differentiable from changes due to individual variation, breed differences or physiologic changes induced by clinical examination. While many horses with pulmonary disease have insufficient pulmonary inflammation or loss of pulmonary function to enable a clinical diagnosis to be made clearly, they may have sufficient loss to cause a **reduction in exercise performance**, especially in high performance animals such as racehorses.

Auscultation of chest sounds is a very subjective and unreliable procedure in horses with mild or even moderate pulmonary disease, with little agreement between different clinicians in such cases. **Tracheal auscultation** after nasal occlusion or use of a **rebreathing bag** renders auscultation more accurate.

The presence of **coughing** is probably the most reliable clinical indicator of pulmonary disease in the horse. Yet this sign is sometimes inexplicably absent in horses with significant pulmonary disease, even when excessive RS production is present.

Clinical diagnosis of pulmonary disease can thus be unreliable.

ANCILLARY DIAGNOSTIC AIDS

Ancillary diagnostic tests can be used: (1) to confirm the presence of pulmonary disease where clinical signs suggest, but cannot confirm, pulmonary disease; and (2) to examine for the presence of pulmonary disease in horses showing poor exercise performance, without any overt clinical signs of pulmonary disease.

In instances where pulmonary disease has already been diagnosed, diagnostic tests can be used: (1) to identify precisely the specific pulmonary disorder involved; and (2) to assess objectively the degree of pulmonary dysfunction present so that the progress of the disease and/or response to therapy can be monitored.

ENDOSCOPY

Endoscopy is probably the most useful and easily performed diagnostic technique available for equine pulmonary disease investigation. The horse has an **insensitive upper respiratory tract** that readily allows the passage of an endoscope into the trachea. This procedure (**tracheoscopy**) is usually termed bronchoscopy. In the absence of respiratory disease, the equine trachea will contain no endoscopically visible or just tiny flecks of RS.

Most equine pulmonary disorders are associated with increased production of RS, which are usually **mucopurulent** in nature. Purulent RS occur with bacterial pneumonias and secondary bacterial infections. The overproduction of RS is often accompanied by a reduction in the mucociliary clearance mechanisms, and both factors result in an accumulation of RS in the horizontal (thoracic) trachea.

Excessive tracheal RS can be **graded** from 1 to 5 based on **volume**. The endoscopic presence of a pool of RS in the trachea is a most sensitive indicator of the presence of pulmonary disease. In younger horses, excessive RS usually result from viral infections or their sequelae but in older animals are usually due to RAO (*q.v.*). Some animals can perform to a high athletic level despite the presence of grade 1 or 2 tracheal RS. This suggests that, in these animals, insufficient small airways are involved to significantly affect airflow, even during exercise.

Tracheal mucosal inflammation is usually absent in chronic pulmonary diseases unless coughing is present, but bronchial mucosal inflammation will be commonly seen. **Mucosal inflammation** can be recognized as a blunting of the carina and bronchial divisions, along with redness and possibly the presence of prominent mucosal vasculature.

After spraying a few milliliters of local anesthetic (e.g. 0.2% lidocaine) on the carina, it is possible to advance the endoscope to examine the main bronchi. With pulmonary abscessation (*q.v.*) or exercise-induced pulmonary hemorrhage (EIPH) (*q.v.*), it may even be possible to localize the source of pus or blood to a particular lung segment. Rarely a tracheobronchial foreign body may be present and can be removed. With anterior thoracic masses such as mediastinal lymphosarcoma (*q.v.*) or abscessation, a collapsed mainstem bronchus may be observed. In dyspneic horses, a dynamic collapse of the intrathoracic tracheal and bronchial walls may be seen during expiration. With obstructed pulmonary venous return, e.g. with cardiac disease or anterior thoracic masses, prominent veins will be seen on the lateral tracheal wall.

Pleuroscopy, i.e. the insertion of an endoscope through a surgical incision in the chest wall, after drainage of pleural fluid, may be of diagnostic value in horses with pleural effusion. **Ultrasonography** is, however, a less invasive and generally more useful technique for such investigations.

BACTERIOLOGIC EXAMINATIONS

Nasal or nasopharyngeal swabs

If a profuse **bilateral nasal discharge** is present, particularly in the presence of a cough and bilateral submandibular lymphadenitis, this is suggestive of

infectious pulmonary disease. Such nasal discharges will often contain RS from the lower respiratory tract, but also contain variable numbers of upper respiratory tract (URT) bacteria.

Culture of nasal discharge is unreliable in the diagnosis of pulmonary bacterial infections, but is of value in the diagnosis of **strangles** (*q.v.*), a primary URT infection, although culture or polymerase chain reaction (PCR) analysis of guttural pouch lavage fluid is a much more sensitive method of strangles diagnosis. With **chronic unilateral nasal discharges**, which indicate a unilateral URT infection, nasal bacteriology is frequently worthless, as the recovered bacteria are usually secondary to sinusitis or to mycoses of the nasal cavity or guttural pouches. However, the recovery of pure and heavy fungal growths can suggest a URT mycosis (*q.v.*).

Transendoscopic tracheal aspirates

Cultures of RS, aspirated directly from the trachea using a bronchoscope, are more useful than nasal or nasopharyngeal swabs. However, they usually still have bacterial contamination from the URT and/or from the endoscope, even if the greatest care is taken during the nasal, nasopharyngeal and laryngeal passage of the endoscope.

URT contamination can be reduced by sealing the distal end of a sterile transendoscopic catheter with a plug of **sterile agar**, prior to inserting the sterilized endoscope into the trachea. Before RS collection, this plug is flushed out into the trachea, where it is harmless. More complex techniques such as telescopic sheathed catheters and endoscope sheaths have been developed to overcome URT contamination of tracheal aspirates. Contamination of RS by saliva can be reduced by starving the animal for 30 min prior to bronchoscopy and by rapid sample collection.

Direct transendoscopic aspiration of RS from the trachea is more desirable than a tracheal wash as it allows quantitative bacteriology to be performed. Enumeration of the **numbers** of bacteria present is also very important in assessing the significance of recoveries. Isolates $\geq 10^6$ colony forming units (CFU)/mL RS are usually significant, particularly if a single type of a potentially pathogenic bacterium is present. Isolates $\leq 10^4$ CFU/mL are usually insignificant, especially when a mixed growth is obtained. However, it is essential that **anaerobic** as well as **aerobic** cultures be performed.

Transtracheal aspirates

Transtracheal aspirates constitute the most accurate technique for obtaining pulmonary RS samples for bacteriologic culture. After local anesthesia has been performed on a clipped and prepared distal midline cervical site, a 12–14 G needle or cannula is inserted into the trachea. A sterile catheter is then aseptically inserted through the needle and directed caudally along the floor of the trachea to the thoracic inlet, where RS usually accumulates in the diseased animal.

If RS cannot be directly aspirated after repeated attempts, **20–50 mL sterile saline** can be flushed down the catheter and the resultant “tracheal wash” aspirated. This latter step will, however, preclude quantification of isolates.

Occasionally a **subcutaneous abscess** or **emphysema** (*q.v.*) will develop after tracheal puncture.

Bronchoalveolar lavage fluid (BALF)

Because of inevitable URT contamination and large and variable sample dilution during BALF collection (*q.v.*), cultures of BALF are of limited diagnostic value. With pulmonary abscessation, **transendoscopic** bronchoalveolar lavage of the affected bronchus may be useful.

Pleural fluid

Bacterial pulmonary infections in adult horses are uncommon in the UK, in contrast to the USA where the **pleurisy/pulmonary abscessation syndrome** is common. Such infections are often accompanied by a **massive pleural effusion** that may contain the causative bacteria, which (paradoxically for lung infections) are often **anaerobes**. After routine skin preparation, an 18 G needle is inserted in a caudal intercostal space between the 7th and 10th ribs in the ventral chest. **Thoracocentesis** can confirm the **presence** of and the nature of pleural effusion and can allow the collection of samples for culture and cytology. Concurrent tracheal secretion bacteriology should also be performed in these cases.

VIROLOGIC EXAMINATIONS

Virus isolation is useful only during the **very early febrile stages** of respiratory infections. Nasal or nasopharyngeal swabs should immediately be placed in virus transport medium, cooled and transported within 24 h to a specialized laboratory. If an equine herpesvirus infection (*q.v.*) is suspected, a blood culture is also worthwhile. Because of the short duration of virus shedding and the fragility of such isolates, even with good collection, transport and laboratory techniques, many viral cultures will be negative.

Many immunologic techniques are being developed worldwide that can give rapid diagnosis of viral infections, including an ELISA test for **equine influenza** (*q.v.*) that can give a diagnosis within 24 h, PCR tests for tissue samples for **equine herpesvirus** (*q.v.*), and PCR tests for tissue and semen samples for equine viral arteritis (*q.v.*) that can give results within a couple of days.

Retrospective diagnosis of viral respiratory infections can be obtained by **virus serology**. An initial sample should be taken as early as possible during the course of the disease and a second 2 wk later. The information from such virologic studies may not be available rapidly enough to help the clinical management of individual cases but it can give invaluable information for the development of effective vaccine strategies.

RESPIRATORY TRACT SECRETION CYTOLOGY

RS cytology is a most useful ancillary diagnostic technique, particularly with chronic pulmonary diseases. RS cytology can be performed on tracheal RS or preferably on BALF samples. With pleural effusions, cytology may be used

to diagnose **thoracic neoplasia**, which is commonly due to mediastinal lymphosarcoma (*q.v.*).

Tracheal RS cytology

Tracheal samples are usually collected with a transendoscopic catheter but can also be collected by transtracheal aspiration. Tracheal RS slide preparations usually contain dense mucus clumps, which make cytologic assessment more difficult than BALF cytology. Additionally, tracheal RS cytology does not correlate well with pulmonary histopathology, in contrast to BALF cytology. It appears that different cell populations exist in the trachea and the smaller bronchioles, the latter being the primary site of equine pulmonary disease.

Normal tracheal RS cytology

Tracheal RS cytology from horses without pulmonary disease reveals mainly ciliated epithelial cells and macrophages, with $\leq 20\%$ neutrophils in animals kept inside and $\leq 5\%$ neutrophils in animals kept outdoors; a few cuboidal epithelial cells and lymphocytes and an occasional eosinophil, mast cell and goblet cell may also be found. If stratified squamous epithelial cells are found in tracheal RS preparations, this indicates **salivary or URT contamination** and such samples should be discarded.

BALF cytology

BALF cytology is easier to examine, enumerate and interpret than tracheal RS cytology. BALF cytology also correlates very well with pulmonary histopathology. The areas lavaged during bronchoalveolar lavage are primarily the distal smaller airways and alveoli. With localized pulmonary disease such as **pulmonary abscessation** (*q.v.*), it is possible to lavage a normal area and so obtain misleading results. BALF cytology is currently considered to be the most sensitive diagnostic technique for the diagnosis of RAO (Table 7.1).

For **transendoscopic BALF collection**, a minimum endoscope working length of 180 cm is required in an adult Thoroughbred, but a 300 cm endoscope is required for BAL of the diaphragmatic lobe. Having entered a main bronchus, the endoscope is then advanced into a secondary or tertiary bronchus until it is wedged. The accessory lobe bronchus, off the right mainstem bronchus, is a convenient site in Thoroughbreds, especially when using a 180 cm endoscope.

Table 7.1 Normal BALF cytology

Neutrophils	<5%
Macrophages (with some containing hemosiderin in horses in hard work)	30–90%
Lymphocytes	30–60%
Eosinophils	<2%
Mast cells	<10%
Epithelial cells	<5%

BALF samples may also be obtained with a proprietary BAL catheter or even with a foal stomach tube. BAL catheters tend to lavage the caudal diaphragmatic areas and so are useful in examinations for EIPH. Unlike transendoscopic BAL, BAL catheters do not permit a specific lung area to be lavaged.

Following wedging, **250 mL lukewarm saline** is quickly infused into the lung and immediately aspirated, approximately 50% usually being recovered. Cytology is best performed on a cytocentrifuge preparation.

BALF cytology in pulmonary disease

Neutrophilia, i.e. the presence of $\geq 5\%$ neutrophils in BALF, can occur: (1) permanently in symptomatic RAO, inflammatory airway disease (IAD) (*q.v.*) or summer pasture obstructive pulmonary disease affected horses; (2) for some weeks with viral respiratory infections; and (3) along with high numbers of intracellular bacteria and possibly with toxic neutrophils in bacterial pulmonary infections.

Eosinophilia, i.e. the presence of $\geq 3\%$ eosinophils in BALF, can occur: (1) with eosinophilic interstitial pulmonary diseases (*q.v.*); (2) transiently at pasture (due possibly to *Parascaris* migration [*q.v.*]); and (3) in lungworm (*q.v.*) infection.

If the majority of BALF macrophages in horses performing hard work contain hemosiderin, this may indicate that clinically significant EIPH is present. Nearly all horses in hard work have some hemosiderophages in their RS.

PULMONARY FUNCTION EXAMINATIONS

If sufficient pulmonary tissue is diseased, there may be some measurable decrease in lung function. **Pulmonary function measurements** are primarily of value in the diagnosis and monitoring of severe pulmonary disease. Because of the absence of patient cooperation in veterinary medicine, in contrast to human medicine where measurements such as forced expiratory volume are standard tests, lung function tests must be performed at rest, unless treadmill facilities are available. Unless trained, many horses object to face masks and/or pneumotachographs and may react to their presence by breath holding or hyperventilating, both of which will invalidate results. The use of sedation to facilitate pulmonary function measurement can also influence results.

There are **large reserves in lung function**, especially in the smaller airways, where it is estimated that most of the bronchioles must be obstructed before any detectable change in lung function occurs. Consequently, lung function examinations, especially at rest, are **very insensitive** with small airway disease, and will frequently show no abnormalities, even in the presence of moderate bronchiolar disease.

Significant but unexplained short- and long-term variations in pulmonary function values have been found even in normal trained horses examined under ideal conditions. **Pneumotachography**, which is required to derive dynamic compliance or pulmonary resistance values, requires expensive

equipment and expertise for accurate calibration, recording and interpretation of results.

These factors combine to restrict the usefulness of many equine pulmonary function examinations to group studies, using trained experimental animals. Arterial blood gas analysis (normal PaO_2 85–100 mmHg) and maximal intrathoracic pressure measurements (normal $d_{\text{max}}P_{\text{pl}}$ 1–4 mmHg), if obtained in the relaxed, unsedated horse, are useful examinations that can objectively quantify lung dysfunction. However, they rarely enable pulmonary disease that is not clinically apparent to be diagnosed. Additionally, even when pulmonary function tests indicate dysfunction, they give no indication of etiology.

THORACIC RADIOGRAPHY

Thoracic radiography is of great value for the diagnosis and monitoring of pulmonary disease in foals such as **neonatal or *Rhodococcus pneumoniae* (q.v.)**. In adult horses, due to their large chest mass, thoracic radiography is of limited value.

The majority of adult equine pulmonary diseases, including viral infections, RAO, interstitial diseases and low grade EIPH, result in **diffuse parenchymal lesions** that will not be consistently detected radiographically unless very severe disease is present. Additionally, even minor variations in thoracic radiographic technique in adult horses can cause large perceived differences in chest films. However, major lesions, especially if focal, including severe EIPH, large abscesses or pneumonic lesions, pleural effusions, pneumothorax and diaphragmatic hernias, can be usefully assessed radiographically.

THORACIC ULTRASONOGRAPHY

Ultrasound waves cannot pass through air, limiting the use of ultrasonography in pulmonary investigations to those lesions that extend to the periphery of the lung. However, in cases of pleural effusion and subpleural masses, e.g. abscessation, it is the diagnostic technique of choice.

Ultrasonography can **non-invasively** detect and measure the extent of pleural effusions and can also outline **pleural adhesions** and the presence of particulate matter in these effusions. Most equine pleural effusions are caused by subpleural abscessation. Ultrasonography may detect these abscesses as echoic areas in the peripheral lung field and may even permit ultrasound-guided drainage.

PHARMACOLOGIC APPROACHES TO TREATMENT OF LOWER RESPIRATORY TRACT DISEASES

INTRODUCTION

Viral, hypersensitive and bacterial lower respiratory tract (LRT) diseases generally induce common pathophysiologic changes in the lower respiratory

tract. **Inflammation** is central to these changes and leads to failure in mucociliary clearance, impaired airway and pulmonary defenses and increased susceptibility to airborne environmental irritants (including dusts and noxious gases), allergens, opportunist agents, viral and bacterial pathogens and endotoxin (Gram-negative bacterial lipopolysaccharide and lipo-oligosaccharide).

The pathogenesis of allergic LRT disease is further complicated because many horses progress from *specific* reactivity to allergens to *non-specific* hyper-reactivity to a variety of airborne irritants. Maintenance or exacerbation of clinical signs then occurs without exposure to the initiating allergen(s).

The central role of **stable air hygiene** in LRT disease pathogenesis, especially allergic LRT disease, means that pharmacologic approaches represent only one aspect of management. The most important components of successful therapeutic regimens are twofold: (1) **environmental changes** to improve stable air hygiene, and (2) **rest** if severe disease is present. Irrespective of the initial cause of respiratory disease, inhaled environmental challenge must be minimized. The importance of stable air hygiene and its influence on airway and pulmonary function is discussed below. Exercising horses with LRT disease leads to delayed recovery or worsening of the condition, possibly with permanent impairment of pulmonary function, and will occur despite any pharmacologic precautions that are taken to attempt to keep the horse in exercise.

Exercise exacerbates airway and pulmonary inflammation by a variety of mechanisms, principally involving mechanical damage by large tidal flows and high respiratory rates. The stress of exercise also significantly impairs pulmonary defense mechanisms by further compromising mucociliary clearance and decreasing the phagocytic and cytotoxic activity of pulmonary macrophages and lymphocytes.

Common pitfalls in therapy and management regimens include inability or unwillingness of the owner to improve the **air hygiene** of adjacent and communicating airspaces; placing too much reliance on the beneficial effect of soaking hay rather than considering silage/haylage as alternatives; turning out to pasture but using hay and straw in the field shelter; using paper or shavings in stables but as deep litter that allows heavy fungal and mold build-up; failure to use appropriate combinations and doses of drugs, and not choosing the most effective delivery route.

RECURRENT AIRWAY OBSTRUCTION

Recurrent airway obstruction (RAO), also known as heaves and chronic obstructive pulmonary disease (COPD), is one of the most common causes of respiratory disease. However, despite an improved understanding of the etiopathogenesis of RAO and the availability of effective drugs for its therapy, management and prevention, regimens may fail to provide satisfactory control. There are several reasons for the apparent failure of these regimens.

First, although there has usually been an attempt to improve stable air hygiene, environmental improvements are often incompletely carried out so that horses are subjected to continual or intermittently high levels of **airborne antigen** and **irritant challenge**.

Second, there is frequently confusion over which therapies to use, and often a logical therapy sequence is not followed. Bacterial infections are uncommon in symptomatic RAO horses and antibiotics are of little value in most cases. Many drugs are administered at insufficient doses, for insufficient time or by inappropriate routes to produce a significant clinical effect.

Third, partially controlled, long-term symptomatic horses develop a number of more slowly reversible pathophysiologic changes and are less responsive to therapy, thus requiring more determined management.

The pharmacologic management of RAO cases can be divided into three headings:

1. Routine management
2. Prophylaxis and maintenance
3. Crisis management.

Routine management of RAO cases

Therapy for routine RAO cases (i.e. mild to moderately dyspneic and tachypneic horses that are not in crisis) can be represented as a simple tiered pyramid (Figure 7.1). Therapy starts at tier one and if symptoms fail to improve, deteriorate or become more persistent, then tiers two and three are added in turn until satisfactory control is achieved. Once symptoms are controlled and the horse is stabilized, then tiers can be removed from the regimen and the pyramid descended.

Bronchoconstriction and mucus accumulation

Bronchoconstriction and mucus accumulation are central pathophysiologic changes in the development of RAO and are driven by **inflammation**. The critical point of control for RAO cases, therefore, is to block the inflammatory cascade that results in bronchoconstriction and mucus accumulation. While bronchodilators and mucolytics provide symptomatic control of the *effects* of inflammation, these drugs do not control the inflammatory cascade that *causes* these changes.

In some countries, **bronchodilators**, sometimes in combination with mucolytics, have traditionally formed the sole therapeutic approach to RAO. This

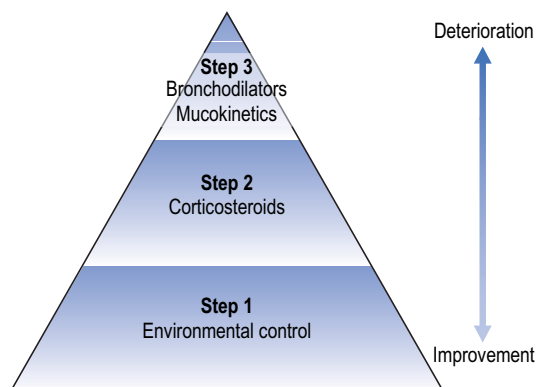

Figure 7.1 RAO therapy objectives (adapted from British Thoracic Society Guidelines).

approach is no longer valid and therapy must control airway inflammation by removing the source of pulmonary allergens and irritants by environmental control, possibly by using **corticosteroids to speed up remission, especially when environmental control is suboptimal**, and then, in cases where there are moderate to severe clinical signs, provide symptomatic relief of bronchoconstriction and mucus hypersecretion using **bronchodilators and mucolytics** (*q.v.*).

Step 1: Environmental management

Environmental management is the first and most important component of RAO therapy. The relationship between **stable air hygiene** and RAO is discussed elsewhere (*q.v.*). If adequate environmental improvements are not made, then any therapeutic regimen implemented is unlikely to succeed. **Drug treatments will not compensate for poor air hygiene** and all efforts must be made to impress the pivotal role that environmental management plays in successful disease control.

Drug treatment in the face of inadequate air hygiene improvements will result in temporary, usually partial, symptomatic relief with return of symptoms as soon as therapy ceases. Wherever possible, horses with RAO should be **turned out to pasture** and kept at pasture year-round. Turnout provides the optimum clean air environment; stable air, whatever stable and management modifications are made, will always have poor hygiene in comparison.

Step 2: Block inflammation using corticosteroids

Corticosteroids are highly effective for reduction of airway and pulmonary inflammation but there is a delay of several (3–7) days before clinical signs improve. Horses with mild disease can be managed with corticosteroids alone. Horses with moderate disease, however, should be treated with corticosteroids and bronchodilators/mucolytics to give rapid symptomatic relief.

(a) Systemic corticosteroids. Systemically administered corticosteroids are convenient and cost effective but do carry a slight risk of laminitis, adrenocortical depression and possibly iatrogenic Cushing's syndrome (*q.v.*). However, the traditionally held fears of the risks of laminitis induction by corticosteroid administration appear to be exaggerated, and judicious use reduces these risks to a minimum. Nevertheless, careful thought should be given before administering corticosteroids to animals with a history of laminitis or with Cushing's syndrome. **Dexamethasone** (0.1 mg/kg IV s.i.d.) is highly effective and is regarded as the "gold standard" corticosteroid therapy for RAO.

Clinical signs, airway neutrophilia and pulmonary function, generally improve from day 3 of treatment and are well controlled by day 6–8. In most cases 7–10 days of treatment is sufficient to control clinical signs. **Prednisolone** (0.5–1 mg/kg PO s.i.d.) is widely used and does provide adequate control of clinical signs within 4–7 days of treatment. Improvements in airway neutrophilia and pulmonary function are less consistent than with dexamethasone, which may be due to the shorter duration of prednisolone's anti-inflammatory effect.

Long acting corticosteroid preparations (e.g. **triamcinolone acetonide** 0.1 mg/kg IV single dose and dexamethasone isonicotinate 0.04 mg/kg IM q 72 h) also provide effective control but result in marked adrenocortical suppression (*q.v.*) and, presumably, increased risk of corticosteroid-associated side effects.

- (b) **Inhaled corticosteroids.** **Inhalation** is a highly effective alternative route for corticosteroid administration that reduces drug dose and the risk of side effects by delivering drug directly to the respiratory tract. This method is more expensive than systemic treatment and does require patient compliance.

Nebulization using jet or ultrasonic units has largely been superseded by the use of **metered dose inhalers** (MDIs). MDIs are quicker and simpler to use than nebulizers and are better tolerated by the horse. There are three equine devices that can be used with MDIs: Equine Aeromask (www.genitrix.co.uk), Equine Haler (www.equinehaler.com) and 3M Equine Inhaler (Boehringer Ingelheim Vetmedica).

Fluticasone (1000–2000 mg b.i.d.) is the most potent (and expensive) corticosteroid MDI. **Beclometasone** (1500–3000 µg b.i.d.) also provides effective symptom control and improves pulmonary function from 24 h of administration. It should be remembered that inhalation reduces, but does not eliminate, the risk of side effects. Corticosteroid inhalation depresses serum cortisol concentrations although adrenal responsiveness to exogenous ACTH administration appears to be less affected. The clinical significance of these observations is not clear but it is sensible to monitor horses treated with inhaled corticosteroids for corticosteroid-associated side effects (*q.v.*).

Step 3: Symptomatic control using bronchodilators and mucolytics

Airway diameter is determined by bronchial wall smooth muscle tone and is a balance between β_2 -adrenoceptor-mediated bronchodilatation and muscarinic cholinergic-mediated bronchoconstriction.

- (a) **Systemic bronchodilators.** The selective β_2 -agonist **clenbuterol** is the most widely utilized bronchodilator for RAO therapy and is initially administered at the rate of 0.8 µg/kg PO b.i.d. or IV. It has minimal α - and β_1 -agonist activity and so is relatively free from the unwanted cardiac and peripheral circulatory effects produced by non-selective agonists (e.g. isoprenaline), although transient patchy sweating and muscle tremors may be seen at higher oral doses and following IV injection. There is rapid (within 5–7 days of administration) **tolerance to β_2 -agonists** when administered on their own but this effect is reduced when they are co-administered with corticosteroids; this is a further reason why sole therapy with β_2 -agonists should not be employed.

Clenbuterol has a more clinically useful duration of action than some other β_2 -agonists (e.g. terbutaline and isoproterenol) and requires twice daily administration only. Oral administration provides effective control of symptomatic RAO horses. Clenbuterol can be administered IV to relieve **acute bronchospasm** and produces clinical improvement within 30 min of injection. A further useful property of clenbuterol is that it

improves **mucus removal** from the respiratory tract by stimulating mucociliary clearance.

If the response to the initial dose ($0.8 \mu\text{g}/\text{kg}$ b.i.d.) is disappointing, then the dose can be increased by $0.8 \mu\text{g}/\text{kg}$ b.i.d. increments at 3-day intervals (i.e. 0.16, 0.24 up to a maximum of $0.32 \mu\text{g}/\text{kg}$ b.i.d.) until satisfactory response is obtained. Therapy should be maintained at least until clinical improvement is apparent (usually 2–3 wk).

Parasympatholytic anticholinergics produce bronchodilatation by decreasing parasympathetic tone in airway smooth muscle. Parenteral atropine is an effective bronchodilator in RAO-affected horses but has a short duration of action.

Even at low doses of $0.02 \text{ mg}/\text{kg}$, atropine has widespread systemic side effects including mydriasis, tachycardia, increased viscosity of respiratory secretions, reduced gut motility and colic, which make it unsuitable for clinical, use.

The phosphodiesterase inhibiting xanthene derivatives theophylline, aminophylline and etamiphyllin (etamiphylline) (all methylxanthines) are moderately effective bronchodilators, but their effect is less profound than that of β_2 -agonists and they have a narrower therapeutic index. Xanthines can be administered orally or IV but have a short duration of clinical action of between 2 and 4 h, and side effects, which include tachycardia and sweating, are frequently seen due to their narrow therapeutic margin.

(b) Inhaled bronchodilators. The long acting β -adrenergic sympathomimetic **salmeterol** and the atropinic ipratropium bromide require just twice daily administration by MDI using the delivery devices listed above and are therefore potentially practical alternatives to the use of systemic clenbuterol. Inhaled clenbuterol has a short duration of effect (3–6 h), thus requiring q.i.d. administration, making it less practical and cost effective than salmeterol.

(c) Mucokinetic drugs. Mucus of increased viscosity and quantity rapidly accumulates in symptomatic RAO horses and its removal is an important component of therapy. This can be partly achieved by improving mucociliary clearance by augmenting ciliary activity via β_2 -agonists. The mucolytic drug **dembrexine** ($0.3 \text{ mg}/\text{kg}$ PO b.i.d.) is frequently used in combination with β_2 -agonists and this combination provides **effective mucus removal**.

There are a variety of other potential methods of achieving mucokinesis although these have limited application in the field. Sterile water, sterile saline, acetyl cysteine and propylene glycol can be delivered by nebulizer although this is not a convenient method for delivery of large volumes and the technique may induce bronchoconstriction. Large volume administration of sterile saline IV appears to offer few advantages, is expensive and risks cardiac overload and pulmonary edema.

Prophylaxis and maintenance of RAO cases

If exposure to environmental challenge cannot be avoided or symptomatic episodes continue due to constraints on environmental improvements, then

prophylactic therapy or low dose maintenance therapy should be considered. Prophylaxis can be achieved with the mast cell stabilizer **sodium cromoglicate** administered by jet or ultrasonic **nebulizer** or by **MDI**.

Sodium cromoglicate can be given (80 mg/day administered by nebulizer or 200 µg/day by MDI) when the horse is in asymptomatic remission and may provide protection for some time after therapy ceases. In humans, sodium cromoglicate is extensively used to control childhood asthma although inhaled steroids are the more usual approach in adults. Its use in horses has so far been somewhat disappointing although this may reflect historical dosing regimen and delivery apparatus deficiencies.

An alternative approach is to control inflammation using low dose maintenance therapy with **inhaled corticosteroids**, typically 25% of the therapeutic dose, although this varies from horse to horse depending on the level of environmental challenge. Systemic corticosteroids are less suitable for long-term maintenance because, even at reduced doses, systemic side effects will occur.

Crisis management

RAO horses in crisis require **prompt and aggressive management**. The most effective means of achieving rapid and profound bronchodilation is by administration of atropine or, less effectively, of short acting inhaled β-adrenergic sympathomimetics by MDI (or nebulizer). Inhaled **clenbuterol** (0.3–0.6 mg q 1–2 h) or **salbutamol** (360 µg q 30–60 min) are the most suitable choices; the longer acting bronchodilators salmeterol and ipratropium bromide are less suitable because of their delayed onset of action.

If it is not possible to administer bronchodilators by inhalation, IV clenbuterol (0.8 µg/kg) is also suitable although the speed of onset is slower and the maximum effect achieved less than when it is administered by inhalation. Atropine (0.01 mg/kg IV) is a potent bronchodilator and can be used as a single dose for rescue but systemic administration does result in marked systemic effects. Corticosteroids, either by inhalation or systemically, should not be used as front line therapy for horses in crisis because their speed of onset is too low.

Pulmonary ventilation and distribution of inhaled drugs is poor in horses with severe LRT disease and therefore inhaled corticosteroids do not reach the lower airway in sufficient concentration. Corticosteroids can, however, be used to supplement bronchodilator therapy and have the advantage of reducing tolerance to the bronchodilator.

SUMMER PASTURE ASSOCIATED OBSTRUCTIVE PULMONARY DISEASE

The pathogenesis of **summer pasture associated obstructive pulmonary disease (SPAOPD)** is similar to that of RAO (*q.v.*) but the inciting allergens appear to be pollens rather than constituents of stable dust.

Many apparent SPAOPD cases are, in fact, long-term, out-of-control RAO horses that have progressed to a state of non-specific hyperresponsiveness and have such extensive accumulated pathology that there is no longer clinical

improvement, but rather worsening, on turnout. Primary SPAOPD cases present in the **summer months** with clinical signs resembling RAO, although generally they exhibit moderate to severe clinical signs.

Initial therapy of SPAOPD is the same as for moderate to severe RAO (*q.v.*) detailed above using **inhaled bronchodilators** supplemented with **systemic corticosteroids**. Maintenance management is more difficult than for RAO because it is difficult to avoid pollens, although stabling in a scrupulously clean stable air environment may help. Most SPAOPD horses therefore require low dose maintenance therapy with inhaled corticosteroids over the pollen season. In subsequent years **inhaled sodium cromoglicate** can be a useful aid in reducing the severity of clinical signs in response to pollen challenge.

INFLAMMATORY AIRWAY DISEASE

Inflammatory airway disease (IAD) is common in young Thoroughbreds and Standardbreds in training and is probably underdiagnosed in other types of horse.

Clinically, horses affected with IAD are not systemically unwell. The presentation of IAD is variable: it may manifest as **poor performance** or prolonged recovery after exercise or as **more overt respiratory disease** with coughing and nasal discharge. Some horses may also have **subclinical IAD**.

The etiology of IAD is uncertain and probably involves many factors. Bacteria (*Streptococcus zooepidemicus*, *S. pneumoniae*, *S. equisimilis*; *Actinobacillus* spp.; *Klebsiella* spp.) (*q.v.*), respirable endotoxin, viral infection, mycoplasmas, allergens, respirable particulate matter (dusts) and air quality may be involved in causing IAD.

Diagnostically, hematology, blood biochemistry and fibrinogen levels are within normal limits. Airway cytology is less consistent than that for RAO (*q.v.*). **Tracheal aspirates** in horses with IAD contain >20% neutrophils and increased mucus while **bronchoalveolar fluid** has an increased percentage of neutrophils, mast cells or eosinophils.

The **uncertain etiology** of IAD makes rational therapy difficult. In all cases environmental changes should be made as for RAO horses (*q.v.*). Horses with convincing bacterial infection (based on **quantitative bacteriology** of airway lavage samples) are treated with antibiotics (usually penicillin and gentamicin \pm metronidazole) although the choice should be driven by the results of bacterial culture and antibiotic sensitivity testing. Airway neutrophilia (in the absence of a bacterial infection) can be managed with **corticosteroids** following the protocols described for RAO (*q.v.*).

Inhaled sodium cromoglicate can be used as adjunct or sole therapy for horses with **increased airway mast cells**. Horses with a mixed inflammatory response are often treated with **immunostimulants** (*q.v.*), although few are licensed for equine use. Popular immunostimulants in the USA include inactivated *Propionibacterium acnes* (EqStim) and mycobacterial cell wall extracts (Equimune). These agents are proposed to act by non-specific upregulation of macrophage and natural killer cell activity and lymphoproliferative responses.

The anthelmintic **levamisole** (*q.v.*) is also empirically used and is believed to upregulate lymphoproliferative responses. There has also been interest in the use of cytokines as immunostimulants. Recombinant human interferon- α

appears to reduce clinical signs in some IAD horses, possibly by increasing lymphoproliferation, T lymphocyte cytotoxicity and macrophage activity.

LOWER RESPIRATORY TRACT INFECTIONS

Bacterial infections

In neonatal foals, common Gram-negative bacteria isolated include *Pasteurella* spp., *Actinobacillus* spp., *E. coli*, *Klebsiella* spp., *Pseudomonas* spp. and *Bordetella bronchiseptica* (*q.v.*). These are often resistant to commonly used antibiotics.

In foals, *Rhodococcus equi* is a common LRT pathogen in certain regions and is frequently isolated along with other bacteria.

In adult horses, **bacterial infections** of the lung (e.g. pneumonia and pulmonary abscess) and the pleura (e.g. pleuritis and pleuropneumonia) can occur as sequelae to prolonged travel or esophageal obstruction (choke) and occasionally following viral infections and RAO (*q.v.*). *Rhodococcus equi* (*q.v.*) can occur as an endemic disease on certain studs. A wide range of Gram-positive and Gram-negative bacteria can be isolated from horses and foals with LRT bacterial disease.

In adults, the streptococci (*q.v.*), especially *Streptococcus zooepidemicus*, are the most prevalent Gram-positive isolates (others include *S. pneumoniae*, *S. equisimilis*, *S. equi*) although other Gram-positive organisms isolated include coagulase positive *Staphylococcus* spp. (including *S. aureus*) and *Enterococcus* spp. However, the presence of bacteria in the airway does not necessarily indicate infection since **resident bacteria** are recovered from the airways of the majority (75%) of normal horses, some of which (10%) are regarded as pathogens (Box 7.1).

Box 7.1 Interpretation of bacterial isolates from tracheal lavage samples

Bacteria regarded as opportunist invaders (commonly isolated from the normal airway but capable of establishing infections):

- Coagulase-negative *Staphylococcus* spp.
- α -Hemolytic streptococci
- *Escherichia coli*
- *Bacteroides fragilis*
- *B. oralis*
- *Enterobacter* spp.

Bacteria regarded as potential pathogens (but may be present in 10% of normal horses):

- *Streptococcus zooepidemicus*
- *Strep. pneumoniae*
- *Pasteurella haemolytica*
- *P. pneumotropica*
- *Klebsiella pneumoniae*
- *Pseudomonas aeruginosa*

It is important that **quantitative bacteriology** to estimate the numbers of bacteria in the airway is carried out to allow more accurate interpretation.

A further complication is that increased numbers of environmental opportunist bacteria (often Gram-negative) that are not involved with the disease process can be recovered from the airway of horses with LRT disease. This is because viral upper respiratory tract infections and most LRT conditions lead to impairment or loss of the **mucociliary escalator** and so the large numbers of bacteria that are inhaled through the equine larynx every day are not removed from the airway. Thus, tracheal lavage results must be interpreted **with caution** and significance can only be attached to bacterial isolates if clinical signs and further investigations (hematology, radiography and ultrasonography) are suggestive of LRT infection. In contrast, **BAL samples** from normal horses are sterile or may contain small numbers of bacteria of low pathogenicity.

Antibiotics are commonly administered to adult horses with respiratory disease but in almost all cases they are not indicated and do not influence the course of the disease. Rest and environmental control are the most appropriate therapy for viral infections. **β_2 -Agonists** are a useful adjunct since they promote mucociliary clearance and this effect is enhanced by concurrent administration of a mucolytic drug such as **dembrexine**. β_2 -Agonists also control the bronchoconstriction induced by post-viral non-specific airway hyperreactivity.

If antibiotics are employed in the therapy of LRT disease, their use and selection must be based rationally on cytology and bacteriology results from samples obtained by tracheal and bronchoalveolar lavage, and thoracocentesis.

Antibiotic selection

Although the choice of antibiotic for longer term therapy must be based on bacteriology and sensitivity results, it is possible to make rational choices for antibiotic selection before the results of bacteriology and sensitivity on airway or pleural aspirates are known.

Most ($\geq 50\%$) LRT infections of adult horses involve a mixed Gram-positive and Gram-negative bacterial infection. In approximately 25% of cases, anaerobic bacteria are isolated as well. The principal bacterial species involved are *Streptococcus zooepidemicus* (60% of cases), *Escherichia coli* and *Pasteurella* spp. (36–40% of cases) and *Bacteroides* spp. (Table 7.2).

The selected antibiotic (Table 7.3) should be given for a minimum of 7 days, but therapy should continue for 5 days after clinical remission occurs.

Gram-positive bacteria

Penicillin remains the antibiotic of choice for the streptococci, although penicillin resistance (*q.v.*) is now recognized in an increasing number of *Strep. zooepidemicus* isolates (up to 30% of isolates in some surveys). **Sodium benzylpenicillin** (22 000 units/kg IV) is rapidly eliminated and consequently must be administered every 6 h (*q.i.d.*). This necessitates IV injection since long-term IM injections at this frequency cause significant injection site reactions. Although this may be a short-term option in practice, it is not suitable for longer term therapy unless the horse can be hospitalized.

Table 7.2 Frequency of isolation of bacteria from pneumonia or pleuropneumonia cases (USA and UK)

Bacterium	Isolation frequency (%)
Aerobes	
<i>Strep. zooepidemicus</i>	60
<i>Pasteurella</i> spp.	40
<i>Escherichia coli</i>	36
<i>Enterobacter</i> spp.	26
<i>Klebsiella</i> spp.	18
<i>Pseudomonas</i>	14
Anaerobes	
<i>Bacteroides</i> spp.	42
<i>Clostridium</i> spp.	28
<i>Fusobacterium</i>	20

Table 7.3 Antibiotics for use in lower respiratory tract infectious disease

Antibiotic	Dose	Route	Frequency ¹
Amikacin	7 mg/kg	IV	t.i.d.
Ampicillin	7.5–10 mg/kg	IM	s.i.d.
Ceftiofur	2 mg/kg	IM	s.i.d.
Enrofloxacin	7.5 mg/kg	PO, IV	s.i.d.
Gentamicin	6.6 mg/kg	IV, IM	s.i.d.
Metronidazole	20 mg/kg	PO	b.i.d.
Oxytetracycline	5.0 mg/kg	IV	s.i.d.
Procaine benzylpenicillin	12 mg/kg	IM	s.i.d.
Sodium benzylpenicillin	22 000 IU/kg	IV	q.i.d.
Rifampicin	5 (10) mg/kg	PO	b.i.d. (s.i.d.)
Trimethoprim–sulfonamide	15 mg/kg	PO	b.i.d.

¹ Manufacturer's recommendations; in field settings, at their own discretion, practitioners may increase the frequency of use of some antibiotics, e.g. procaine penicillin.

Procaine benzylpenicillin is cleared more slowly but achieves much lower plasma concentrations. The manufacturers' recommended doses (12 mg/kg s.i.d.) are inadequate to produce effective respiratory tract concentrations. Higher doses of 24 mg/kg IM b.i.d. are required to achieve adequate concentrations in the respiratory tract, necessitating excessively large injection volumes. This, coupled with the lower plasma levels achieved, means that procaine benzylpenicillin is not a viable alternative and is likely only to be effective against highly sensitive Gram-positive bacteria. These problems are shared by ampicillin. The cephalosporin **ceftiofur** (2 mg/kg IM s.i.d.) and the fluoroquinolone **enrofloxacin** (7.5 mg/kg PO IV s.i.d.) are more expensive than penicillin but are bacteriologically and clinically effective with a broader spectrum of activity than penicillin.

Benzathine benzylpenicillin (a "long-acting" formulation) is poorly absorbed in horses, failing to achieve adequate tissue levels, and should not be used for treatment of respiratory disease.

Gram-negative bacteria

Approximately 90% of Gram-negative respiratory isolates are sensitive to the aminoglycosides **gentamicin** and **amikacin**. Currently, gentamicin is more frequently used, although amikacin may be less nephrotoxic than gentamicin. Gentamicin is now generally administered at a dose of 6.6 mg/kg IV IM s.i.d. rather than the previous regimen of 2.2 or 4.4 mg/kg IV or IM t.i.d. or b.i.d. Care must be taken to monitor renal function in compromised horses that may have hypovolemia or endotoxemia.

Anaerobic bacteria

Anaerobes (*Bacteroides* spp. and *Fusobacterium* spp.) are frequently recovered from horses with LRT infections and they appear to be important since their isolation from pleuropneumonia cases is associated with a poor prognosis. Most anaerobes except the β -lactamase-producing *Bacteroides fragilis* are sensitive to penicillin. However, **metronidazole** is the first choice antibiotic because *Bacteroides* spp. are the most frequent anaerobic isolates from pleuropneumonia cases. Clinical cure rates have been reported to be increased when metronidazole is added to the therapeutic regimen. Metronidazole is administered at 20 mg/kg PO b.i.d. (or q.i.d. for more severe infections).

Alternative strategies

Although the sodium benzylpenicillin/gentamicin regimen outlined above is highly effective and provides a potent, broad-spectrum bactericidal effect, it is expensive and the IV route of administration can present practical difficulties in a non-hospital setting. A variety of alternative antibiotics provide possible alternatives. For systemic delivery, **oxytetracycline**, **ceftiofur** and **enrofloxacin** are all sensible alternatives.

The **potentiated sulfonamides**, trimethoprim and sulfonamide (TMP/S) combinations, are a reasonable alternative to benzylpenicillin/gentamicin regimens and offer a number of potential advantages, including oral administration, although absorption following oral delivery may be less predictable than following systemic administration. They distribute well to the respiratory tract, achieving therapeutic concentrations in the lung and bronchial secretions. They are bactericidal, have a broad spectrum of activity including anaerobes, can be administered both by IV injection and orally at the rate of 30 mg/kg and only need to be given twice daily. Where it may not be possible to achieve the frequent administration required for the penicillins, TMP/S combinations may be the most appropriate first choice antibiotic and should be used along with metronidazole if anaerobic infection is suspected.

Because TMP/S combinations can be administered orally, they are frequently used for longer term therapy. Sulfonamides are absorbed well from the gastrointestinal tract. In contrast, the absorption of trimethoprim is variable since it is degraded by gut flora and its absorption is significantly reduced if it is administered in feed (instead of as a paste independently of feeding). However, it seems that, despite this, adequate trimethoprim-sulfonamide ratios are achieved in the respiratory tract following administration in feed.

Lower respiratory tract infections in foals

LRT bacterial infections are more common in foals than in adults and may occur in association with failure in passive transfer, septicemia, viral upper respiratory infections, stress and specific pathogens, e.g. *Rhodococcus equi* (*q.v.*).

Respiratory and generalized infections in foals should be taken seriously and antibiotics should be used to prevent secondary bacterial infections developing.

A similar range of bacteria are isolated from foals as from adults, although in the first week of life Gram-negative infections (*E. coli*, *Klebsiella* spp., *Actinobacillus* spp.) predominate.

Sodium benzylpenicillin (22 000 units/kg IV q.i.d.) and **gentamicin** (2 mg/kg IM or IV b.i.d.) used in combination with **metronidazole** (20 mg/kg PO b.i.d.) are suitable for treatment of foals but similar administration difficulties may be encountered as for adults.

The nephrotoxicity of gentamicin may present a significant barrier to its use unless renal function (*q.v.*) is monitored frequently since foals with pneumonias may be dehydrated. Compromised renal function is most accurately monitored by urinalysis for proteinuria and falling specific gravity, and by examination of urinary sediment for casts. Serum creatinine is not a sensitive indicator of renal toxicity since glomerular filtration must be decreased by 75% for serum creatinine to become elevated. **Amikacin** (7 mg/kg IV or IM t.i.d.) may be less nephrotoxic than gentamicin but renal function must still be carefully monitored.

Ampicillin trihydrate can be administered orally (10–20 mg/kg b.i.d.) to foals but is poorly absorbed, achieving low concentrations in the respiratory tract. It is thus only suitable against highly sensitive streptococci and so is of little value in LRT infections.

In view of these difficulties, **potentiated sulfonamides** (30 mg/kg IV or PO b.i.d.) are a good alternative choice of antibiotic and may be the most appropriate first choice in field situations.

Rhodococcus equi

Rhodococcus equi (*q.v.*) is an intracellular organism that causes a **chronic bronchopneumonia** with multiple lung parenchymal abscesses and presents particular therapeutic difficulties. *R. equi* has a **narrow antibiotic sensitivity** and this, combined with **distribution problems** to the affected lung regions, means that the response to most antibiotics is disappointing.

R. equi has 100% sensitivity to a combination of **rifampicin** (5 or 10 mg/kg PO b.i.d. or s.i.d.) and **erythromycin** (25 mg/kg PO b.i.d. or t.i.d.) and this combination is the current treatment of choice. Both drugs distribute well to the lung, pleura and bronchial secretions. Rifampicin is not used alone because of the rapid appearance of resistance. Alternative macrolides (**azithromycin** and **clarithromycin**) have been proposed as alternatives to erythromycin because they have greater bioavailability and decreased side effects in people. In vitro antibiotic sensitivity testing suggests that clarithromycin might be the better choice clinically because its minimum inhibitory concentration (MIC) is 10 times less than that of azithromycin. The potentiated sulfonamides appear to have reasonable activity against *R. equi* and offer an alternative to rifampicin and erythromycin.

Treatment must be continued until **radiographic changes** are no longer present or for 7 days after clinical signs become inapparent. This usually means a regimen of 4–9 wk.

Supportive therapy for lower respiratory tract infections in foals and adults

β_2 -Agonists and mucolytics may be useful although in severe pneumonias bronchodilatation may worsen ventilation–perfusion failure by diverting blood flow away from well-ventilated regions.

Corticosteroids should be avoided unless life-threatening pulmonary inflammation is present, in which case short-term or single treatment prednisolone or dexamethasone should be used. NSAIDs, e.g. **flunixin**, may help to decrease pyrexia and improve demeanor and appetite but must be used with care, especially in foals, since they can produce gastric ulceration and are nephrotoxic in dehydrated foals.

Parasitic lung disease

Dictyocaulus arnfieldi (q.v.), and migrating larvae of *Parascaris equorum* (q.v.) in younger horses, have historically caused clinical disease associated with bronchitis and bronchiolitis, but due to the use of modern anthelmintics rarely occur at present. **Ivermectin** given orally at a single dose of 0.2 mg/kg is the current treatment of choice and is highly effective against adult *D. arnfieldi* and migrating larvae of *P. equorum*.

There appears to be little advantage in administering ivermectin by the **unlicensed** injectable routes in horses except that plasma levels may be maintained for longer periods. **Mebendazole** at 20 mg/kg PO daily for 5 days (twice the normal dose rate) is also effective against *D. arnfieldi* and *P. equorum* but has a reduced efficacy (75–100%) compared with ivermectin.

AIR HYGIENE OF STABLES

INTRODUCTION

The stabled horse is exposed to a wide range of potential respiratory pathogens. Whether or not the horse succumbs to disease depends upon the pathogenicity of the agent, the level of challenge of pathogen and the horse's susceptibility to disease. The latter two factors are affected by the **air hygiene** of stables, with stable design and management practices being important considerations.

Air hygiene of stables can affect the incidence of cases of respiratory disease in stabled horses as well as the duration and severity of these episodes in individual horses. This occurs in racehorse stables where young horses have been suffering from infectious respiratory disease. **Improved air quality** confers benefits in the time it takes horses to recover and return to full work.

The respiratory pathogens to which stabled horses are exposed include mold spores, noxious gases, parasites, dust mites, plant material, airborne

mycotoxins (including glucans) and endotoxins and infectious agents such as bacteria and viruses. These agents are pathogenic because they possess one or more of the following properties: infectious, allergic, irritant, toxic or mechanically destructive (e.g. migrating parasites). Other than individual pathogens possessing multiple pathogenic abilities, there are interactions between pathogens; for example, irritation caused by a noxious gas can increase the host's susceptibility to infections.

The **environmental prevention** of respiratory disease depends on maintaining pathogen levels below the horse's threshold limiting values for disease. These limits are unknown for horses and, since responses to many inhaled pathogens are graded, it is best to minimize the levels of challenge at all times.

The levels of airborne contaminants depend on their rates of release into the air and their rates of clearance from the air. Release rates and therefore the horse's exposure levels to airborne pathogens can be decreased by paying attention to the selection and management of forage and bedding materials. Clearance rates of airborne pollutants are primarily influenced by **ventilation** or **air change rates** (*q.v.*).

VENTILATION

Paying attention to the ventilation of a stable will lead to decreased levels of airborne contaminants, a decreased likelihood of condensation, and a decreased likelihood of molding of bedding material in situ. The "**open air factor**" is a potent killer of airborne bacteria and viruses.

A target of **six to eight air changes per hour** is ideal in designing new stables or altering existing ones. In most stables, this can be achieved by natural ventilation. There are three forces of natural ventilation:

1. **The stack effect** (rising warm air)
2. **Aspiration** (i.e. wind blowing across the roof of a building sucking air out)
3. **Perflation** (i.e. air blown from side to side and end to end of the building).

The ventilation of a building is best tested in **still air** conditions, i.e. when the only driving force for ventilation is warm air rising off the horse. Thus, theoretical considerations of providing ventilation should be based on the assumption that windless conditions prevail. However, such conditions are rarely maintained for long periods of time and consideration should be made for placing baffles or Netlon over openings in exposed walls to decrease the risk of draughts.

Guidelines for the size of inlets and outlets for some typical stables are presented in Table 7.4. These openings should be well distributed to ensure proper mixing of air. This is especially important for barns. Most box stalls should have inlets in the back and front walls in addition to the stable door that may be shut in poor weather conditions. Boxes with peaked roofs should have a capped chimney or covered ridge to act as an outlet for warm "stale" air.

Table 7.4 shows the benefit of **insulating stables**; by maintaining a slightly greater temperature difference between the inside and the outside of the stable, smaller openings can be used to provide adequate natural ventilation.

Table 7.4 Guidelines for minimum inlet and outlet areas per horse for box stalls and barns (meters)

	Outlet area	Inlet area

MOLD SPORES

Horses in the best-ventilated stables can be exposed to extremely high challenges of **mold spores** from their feed, especially hay, and their bedding, especially straw. These spores cause overt symptoms of respiratory disease in older horses in the form of RAO or heaves and covert respiratory problems such as IAD (*q.v.*), especially in young equine athletes. These covert problems may only be manifest with **poor athletic performance** with no obvious clinical signs when the horse is at rest. Endoscopic examinations are critical in diagnosis.

Forage

Hay is the **single most common source of fungal spores** for the horse (see Table 7.5). Up to 75% of traditionally produced English hay fed to horses has significant mold contamination. The soaking of hay is a time-proven method of minimizing the horse’s exposure to fungal spores. However, **feeding soaked, poor quality hay to horses cannot be condoned**. As hay that falls to the floor dries, the spores can again become airborne to be inhaled by the horse or to “seed” clean bedding. Furthermore, even though the spores are not inhaled from soaked hay, they are still ingested along with any

mycotoxins present. These toxins can have subclinical effects on performance horses.

Silage and haylages are increasingly being successfully used as alternatives to hay. There have been a small number of deaths due to **botulism** (*q.v.*) associated primarily with big-bale silage. In this context, silage that smells of ammonia or contains dirt should be avoided. When opened, bags of silage or haylage can mold quickly within a matter of days. Opened bags should be used within 2–3 days and damaged bags discarded.

Treated chaffed hay and straw and complete cubed diets also offer alternatives to feeding hay. These products are convenient and are usually effective in minimizing respiratory disease but they do not always offer value for money.

Beddings

Even the cleanest of straws contains significantly more small, respirable fungal spores than alternative beddings such as wood shavings, paper, peat or the new synthetic beddings (see Table 7.6). However, in **poorly ventilated stables** or where deep litter is allowed to develop, significant molding of the plant-based beddings can occur. Deep litter management systems have the added disadvantage of allowing build-up of **noxious gases** such as ammonia, infectious bacteria and the larvae of gastrointestinal parasites.

Feed and bedding storage

Horses can be exposed to significant organic respirable **dust challenges** from feed and bedding storage facilities, especially molds and endotoxins. Haylofts or grain silos are common problem areas for dust generation. Muck heaps in close proximity to stables can also be a significant source of mold spores as well as vermin. Soiled bedding material and manure are best placed in a trailer and removed from close proximity to the stable every 2 or 3 days.

INFECTIOUS AGENTS

Highly infectious agents such as the **equine herpes and influenza viruses** (*q.v.*) are difficult to control by housing and management. Many of these viruses can also be endemic in the horse population and the movement of horses to and from competitive events ensures effective national and international dissemination. Asymptomatic “carriers” exist, and horses can shed bacteria and viruses before they show symptoms of disease. Moreover, it should be remembered that respiratory tract infections can be spread by means other than aerosol dispersal such that, while stable design and management practices are unlikely to affect the incidence of highly contagious respiratory disease, there is clear evidence that attention to the air will help horses recover from such problems. **Sound air hygiene practices** will also decrease the likelihood of low-grade, less contagious infections.

The source for most infectious agents within stables is the **horses themselves**. Most infectious agents only survive a short time once aerosolized. One important exception is the actinomycete *Rhodococcus equi* (*q.v.*). This organism causes severe **bronchopneumonia** in foals. It proliferates in fecal material and soil, and foals are exposed via the aerosol route, especially in dusty conditions. The problem is seen in barns, where the organism proliferates in bedding material, and in fields, especially in warm weather conditions. To avoid this problem, **deep litter management** should be avoided in barns and special attention should be given to the cleaning out of feces.

NOXIOUS GASES

Ammonia is the most commonly encountered noxious gas in horse stables. **Hydrogen sulfide** is also sometimes encountered. The threshold limiting value for ammonia for humans is 5 ppm and for hydrogen sulfide is 20 ppm. Draeger tubes (Oraeger) offer a simple method of assessing the levels of these gases in the field. Problems with noxious gases in stables usually arise because of poor drainage, deep litter management and poor ventilation.

MECHANICAL GADGETRY

A wide range of equipment is increasingly being advocated to improve the air quality of stables. This includes complete mechanical ventilation systems, air filter systems, disinfectant spray systems and ionizers. Owners should be encouraged to improve **natural ventilation** and avoid management practices such as using straw and hay before “investing” in gadgetry.

Most stables and barns can be adequately ventilated without mechanical assistance although fans may be of use in large barns. If mechanical systems are in use, they should be capable of providing **at least six to eight air changes per hour**. Filter systems designed for household and hotel use are usually not of benefit in stables because of their volumetric capacity and the failure of owners to keep filters clean. There is no evidence that justifies the use of ionizers in well-ventilated stables. Equally, spray disinfectant systems that can be of benefit in heavily stocked, poorly ventilated livestock housing are unlikely to be cost effective in a well-ventilated stable.

INTRODUCTION

Exercise-induced pulmonary hemorrhage (EIPH) (*q.v.*) is defined as the presence of blood in the tracheobronchial tree following athletic exertion. The diagnosis is based on an endoscopic examination. A **grading system** has been established to describe EIPH, categories being based on the thickness of the **streak of blood** in the horse's trachea (Box 7.2).

Surveys of horses have shown that a high percentage of horses that **gallop** suffer EIPH. The incidence is highest in Thoroughbred racehorses with up to 75% of competitors affected. Similar studies of Standardbreds show a lower incidence (approximately 30%). This may relate to the type and level of exertion as well as the different breathing patterns of horses involved in these two types of racing.

Repeated examinations on groups of racehorses show that practically **all racehorses** suffer EIPH. This has been confirmed with "lung wash" studies which show the presence of hemosiderophages coinciding with the beginning of fast work. Repeated examinations on individual horses have also shown that the appearance of blood within the tracheobronchial tree after strenuous exercise is not consistent. A positive diagnosis on one day may be followed by a negative the next. Furthermore, horses with the most severe grade of hemorrhage do not appear to be more likely to bleed subsequently than horses with the less severe grades.

A recent prospective cross-sectional study of Thoroughbred horses competing in flat races in metropolitan Victoria, Australia, has shown that both the presence of EIPH and its severity were **significantly associated with performance**. Horses with EIPH (of grades 2 or higher) were 4.0 times less likely to win, 1.8 times less likely to finish in the top three places and finished 1.8 m further behind the winner than did unaffected horses. The severity of EIPH was significantly associated with reduced probability of winning, reduced

Box 7.2 Grading of exercise-induced pulmonary hemorrhage

- Grade 0: No blood detected in the pharynx, larynx, trachea, or mainstem bronchi visible from the tracheal bifurcation
- Grade 1: Presence of one or more flecks of blood or <2 short (less than one fourth the length of the trachea) narrow ($<10\%$ of the tracheal surface area) streams of blood in the trachea or mainstem bronchi visible from the tracheal bifurcation
- Grade 2: One long stream of blood (more than half the length of the trachea) or >2 short streams occupying less than one third of the tracheal circumference
- Grade 3: Multiple, distinct streams of blood covering more than one third of the tracheal circumference and no blood pooling at the thoracic inlet
- Grade 4: Multiple, coalescing streams of blood covering $>90\%$ of the tracheal surface with blood pooling at the thoracic inlet

probability of finishing in the top three places, finishing a greater length behind the winner and a lower likelihood of being in the top 10% of money earned.

PATHOPHYSIOLOGY

It is now widely accepted that the hemorrhage observed in the tracheobronchial tree of horses following competitive events mainly arises from the **dorsocaudal region** of the lung. Post mortem studies have identified a systemic neovascularization in this region of the lungs in retired racehorses. Histologic evidence of airway disease and increased amounts of mucus were also observed in these areas.

Given that **EIPH occurs in most horses** from a young age, a cause and effect relationship cannot be deduced from the post mortem findings in retired horses. Endoscopic surveys have not been able to establish a relationship between the presence of mucopus in the tracheobronchial tree and EIPH. It is also noteworthy that the presence of mucopus in horses' airways has been correlated with poor athletic performance. However, small airway disease should be avoided since, even if it is not essential for EIPH to occur, it appears likely to increase the risk of occurrence.

No association has been found between abnormalities of the upper respiratory tract and the occurrence of EIPH. The most recent theory of the hemorrhage in the dorsocaudal lung is that **biomechanical "stresses"** or the transition of shock waves during locomotion to this area of lung lead to the rupture of alveolar capillaries.

DIAGNOSIS

Only a small percentage of horses with EIPH will show **epistaxis** (*q.v.*). Most studies reveal that only 1–2% of horses involved in racing suffer epistaxis although 75% of horses have blood present in the tracheobronchial tree.

While a clear effect on **racing performance** and EIPH has been demonstrated, a thorough clinical examination of all body systems should be carried out on horses suffering poor performance, even when a positive diagnosis of EIPH is made. Radiologic examinations show that a small number of cases ($\leq 5\%$) have a typical radio-opaque lesion in the dorsal caudal region of the diaphragmatic lobes. This change will normally clear within a week. It may be worth noting that horses in which this radiologic change is persistent appear to be the most problematic to treat in practice.

Tracheal washes or bronchoalveolar lavages are worthwhile as cytologic and microbiologic examination of these samples will identify small airway inflammation and/or infectious disease. The site of pulmonary hemorrhage represents an ideal medium for secondary infection to occur.

THERAPY

None of a wide range of therapeutic regimens for EIPH withstands close scrutiny. Early approaches to treating epistaxis assumed that a coagulation defect was the underlying problem and that this could be addressed by using

agents such as estrogens, vitamin K, hesperidin or citrus bioflavonoids. Controlled studies have shown all of these to be ineffective. Similarly, studies using bronchodilators have not shown efficacy in preventing EIPH. However, bronchodilators and mucolytics will be of use in treating small airway problems in such horses. Antibiotics will also be of benefit if infection exists. Care should be taken in using corticosteroids in horses suffering EIPH as this approach could increase the risk of secondary infections developing at the site of hemorrhage.

FUROSEMIDE

Despite the wide use of furosemide (1 mg/kg IV 4h prior to exercise or racing), there has been a lack of definitive studies that clearly show a beneficial effect in either the prophylaxis or treatment of EIPH. The pharmacologic basis for the use of furosemide in treating EIPH is to decrease pulmonary artery pressure during exercise. Other effects of furosemide that may improve performance have been identified; these include a significant improvement in **lung function** of horses suffering acute attacks of airway obstruction. Another potential explanation of the performance-enhancing effect of furosemide is that it may be little more than a consequence of the reduction of the horse's body weight.

Several studies have failed to show that furosemide affects the **incidence** of EIPH. Likewise, there are no clear benefits in terms of the effect of furosemide on the grades of severity of episodes of EIPH as assessed endoscopically. Data have been generated that show a decrease in the concentration of red cells in the BALF of treated horses. Competitive athletes may have other costs to pay with the use of furosemide including effects on intracellular and extracellular electrolyte levels and thermoregulation.

In summary, careful consideration should be given in assessing the significance of EIPH in individual cases. Full and careful examination should be carried out on all body systems, including the respiratory tract, of a horse with "loss of performance". The latter should include an endoscopic examination and BAL or tracheal wash. Therapeutic regimens should be based on those and other clinical findings.

INTRODUCTION

In horses, the prevalence of cardiovascular disease is low although it can cause **poor performance** (*q.v.*) or cardiac failure and is frequently implicated in sudden death. Cardiovascular diseases can be classified on anatomic, pathologic or functional criteria. A functional approach serves the clinician well as it defines clinical manifestations and, often, appropriate management. A functional classification of equine heart disease is listed in Table 8.1.

Volume overload is the most common type of **heart failure** in the horse and occurs when valvular regurgitation or an intra- or extra-cardiac shunt leads to one or both ventricles receiving excessive quantities of blood. There is activation of the autonomic nervous system and the renin–angiotensin–adrenergic system, progressive ventricular dilatation and, in response, ventricular hypertrophy. Ultimately cardiac dysfunction and irreversible changes within the myocardium ensue.

Table 8.1 Equine heart disease

Problem	Etiology
Volume overload	Acquired valvular disease (degenerative or inflammatory) Congenital defects (intra- or extra-cardiac shunts, valvular malformations)
Pressure overload	Congenital valvular defects (stenosis)
Myocardial failure	Primary myocardial disease (toxic, nutritional, viral, immune-mediated) Secondary myocardial disease (toxic, drug-induced, hypoxia, endotoxemia, septicemia, electrolyte or metabolic disturbances)
Arrhythmias	Primary myocardial disease (toxic, nutritional, viral, immune-mediated) Secondary myocardial disease (toxic, drug-induced, hypoxia, endotoxemia, septicemia, electrolyte or metabolic disturbances)
Diastolic failure	Pericardial disease (effusive or constrictive)

Pressure overload occurs when there is an anatomic or physiologic obstruction impeding ventricular ejection. In response to increased afterload, the myocardial cells in the affected ventricle increase in diameter as myofibrils are laid down in parallel within them. **Myocardial failure** occurs as cellular function deteriorates. Lesions resulting in pressure overload such as aortic or pulmonic stenosis are uncommon in horses and this form of heart failure is rare.

Both volume and pressure overload ultimately lead to failure of the affected ventricle. Accumulation of fluid and congestion in the vascular compartments develops “upstream” to the affected ventricle. **Left-sided heart failure** leads to congestion in the pulmonary circulation, pulmonary edema and respiratory signs (Box 8.1). **Right-sided heart failure** leads to fluid accumulation in the systemic circulation, signs of venous distension and ventral edema. There can be effusions in the pleural and peritoneal cavities and, rarely, bowel edema and diarrhea (Box 8.1). Usually, failure of one ventricle will lead to failure of the other, so that **biventricular failure** ensues and the clinical presentation includes both left- and right-sided signs (Box 8.1).

Primary myocardial (pump) failure implies that there is a primary defect in myocardial contractility leading to a reduction in stroke volume. The low cardiac output reduces perfusion and can lead to **multiple organ dysfunction** (see Box 8.1). This is seen in association with severe cardiomyopathies. Clinical signs produced by low cardiac output will also occur as myocardial failure develops in volume or pressure overload. Where the venous return is severely compromised, e.g. by **effusive pericarditis** (*q.v.*), low output heart failure also occurs.

CLINICAL EVALUATION OF THE CARDIOVASCULAR SYSTEM

THE CIRCULATORY SYSTEM

Physical examination including visual inspection and palpation provides a useful guide to **hydration status**, circulating volume and the efficiency of

Box 8.1 Clinical signs associated with cardiac diseases in the horse**Left-sided heart failure***

- Exercise intolerance

**Biventricular failure produces a combination of right- and left-sided signs.*

perfusion. The skin turgor, venous filling and moistness of the mucous membranes reflect total body water, while the color of the membranes, the capillary refill time, the temperature of the extremities and the pulse volume are indicators of circulating volume and perfusion.

The **arterial pulses** are palpable at the facial, submandibular, carotid, radial, digital, saphenous and coccygeal arteries. The normal arterial pulse has a symmetrical profile. The rate, volume and quality should be assessed by palpation. A pulsation can be seen and felt in the jugular vein in the distal third of the neck in normal horses.

THE HEART

The horse has four **heart sounds**, although in some horses only two or three may be audible.

The **first heart sound** occurs when the left and right atrioventricular valves close at the onset of mechanical systole. It is a loud and low-pitched sound, audible throughout the cardiac silhouette, on both sides of the thorax. Its point of maximal intensity is over the left apex and it is followed immediately by the arterial pulse. Splitting of the first heart sound occurs uncommonly in normal horses.

The **second heart sound** is coincident with closure of the semilunar valves and reversal of blood flow in the great arteries at the conclusion of ventricular systole. The aortic and pulmonic valves may not close synchronously and physiologic splitting of the second heart sound is often found.

The **third heart sound** is not present in every horse. It is associated with termination of rapid ventricular filling, and it is usually heard best around the left atrioventricular (AV) valve area.

The **fourth, or atrial, sound** is almost always audible. It is produced by atrial systole with flow of blood from the atrium to the ventricle. It is usually heard best dorsally over the heart base on the left side. The fourth heart sound occurs immediately before the first heart sound so that it can be mistaken for splitting of the first sound.

The horse's heart is almost totally located under the muscles of the shoulder in the third, fourth and fifth intercostal spaces. The **left AV valve** is auscultated in the left fifth intercostal space, at the caudal border of the triceps muscle and midway between the points of the shoulder and the elbow; sounds associated with the aortic valve are heard in the left fourth intercostal space deep to the triceps muscle just ventral to the point of the shoulder; and sounds associated with the pulmonic valve are in the left third intercostal space at the level of the point of the elbow and deep to the triceps muscle. In the right hemithorax, the **right AV valve** is auscultated in the fourth intercostal space at the midpoint between the shoulder and the sternum.

CARDIAC MURMURS

Cardiac murmurs are found in **up to 80% of normal Thoroughbreds**, and are also frequently auscultated in other breeds of horses and ponies. They are prolonged sounds occurring during periods of the cardiac cycle that are usually silent. Murmurs arise when normal laminar flow is disrupted. **Physiologic (functional) murmurs** are present where there is no cardiac pathology, particularly associated with left ventricular ejection. Although often found in normal horses, they also occur if blood viscosity is lowered in anemia or hypoproteinemia. However, because cardiac murmurs can accompany congenital cardiac disease or valvular insufficiency, it is important that physiologic murmurs are distinguished from pathologic murmurs.

The criteria used to describe murmurs are described in Box 8.2. If all five characteristics of a murmur are considered carefully, the clinician is usually able to formulate a differential diagnosis and differentiate those murmurs that are physiologic (functional) from those that indicate that there is cardiac pathology and justify further diagnostic evaluation.

Functional murmurs are quieter (grade 3 or less), soft and localized, do not have precordial thrills and do not obscure the heart sounds. Functional murmurs in **systole** caused by ventricular ejection are localized to the heart base in the third or fourth intercostal space; they are usually grade 3 or less and have a soft, blowing quality. Functional **diastolic murmurs** occur in early or mid diastole, are frequently musical or squeaky, and are auscultated over the left heart base or left AV valve area. The characteristics of functional murmurs and those associated with a variety of forms of cardiac pathology are compared in Table 8.2.

Box 8.2 Parameters used to describe and classify cardiac murmurs in the horse

1. Timing

Systolic: Between the first and second heart sounds

Diastolic: Between the second and first heart sounds

Pan: Obscuring the heart sounds

Holo: Begins/ends immediately after/before the heart sounds

Early or mid: Distinct from the heart sounds

2. Intensity

Grade 1: A soft murmur audible only after careful auscultation in a localized area of the thorax

Grade 2: A soft murmur that is clearly audible after a few seconds of auscultation

Grade 3: A moderately loud murmur that is audible over a wide area of the thorax, with no precordial thrill

Grade 4: A loud murmur that is immediately audible and heard over a wide area of the thorax, with no precordial thrill

Grade 5: The loudest murmur that becomes inaudible when the stethoscope is removed from direct contact with the thorax, which is always accompanied by a precordial thrill

Grade 6: A loud murmur that can still be heard when the stethoscope is removed from direct contact with the thoracic wall and is always accompanied by a precordial thrill

3. Quality

Frequency, e.g. harsh, coarse, soft, musical or honking

Shape, e.g. band-shaped, crescendo–decrescendo, decrescendo or machinery

4. Point of maximal intensity

Left AV valve: Left fifth intercostal space, midway between the levels of the points of the shoulder and elbow

Aortic valve: Left fourth intercostal space, at the level of the point of the shoulder

Pulmonic valve: Left third intercostal space, at the level of the point of the elbow

Right AV valve: Right fourth intercostal space, midway between the levels of the point of the shoulder and elbow

5. Radiation

Dorsal, caudo-dorsal, etc.: The direction of radiation corresponds to the direction of turbulent blood flow

Note: The caudal border of the triceps muscle overlies the fifth intercostal space.

Table 8.2 Cardiac murmurs and their causes

	Timing	Location	
		Point of maximal intensity ¹	Radiation
Physiologic			
Aortic ejection	Mid/holo systolic	LIC4	Localized
Diastole squeak	Early diastolic	L or RIC4	Localized
Valvular insufficiency			
Left AV valvular regurgitation	Holo/pan systolic	LIC5	Caudodorsally
Aortic regurgitation	Early, mid, holo or pan diastolic	LIC4	Ventrally
Pulmonic regurgitation	Early, mid, holo or pan diastolic	LIC3	Ventrally
Right AV valvular regurgitation	Holo/pan systolic	RIC4	Cranially
Congenital defects			
Ventricular septal defect (VSD)	(1) Pan/holo systolic	RIC4	Widespread
with functional pulmonic stenosis ²	(2) Pan/holo systolic	LIC3	Widespread
Patent ductus arteriosus	Continuous or pan/holo systolic	LIC3 or 4	Localized
	Grade	Quality	
		Frequency	Shape

² VSD is frequently also accompanied by aortic regurgitation with an additional, diastolic murmur.

DIAGNOSTIC AIDS IN EQUINE CARDIOLOGY

There are a wide variety of diagnostic aids available for use in the evaluation of equine cardiovascular disease. The selection of appropriate diagnostic procedures depends on the clinical presentation and the differential diagnosis. Table 8.3 summarizes some of the diagnostic techniques that are used in equine cardiology. **Echocardiography** is the principal means of evaluation of horses with cardiac murmurs where valvular pathology or congenital cardiac diseases are suspected. Normal values for various M mode echocardiographic parameters are listed in Table 8.4.

Electrocardiography, including radiotelemetric and ambulatory electrocardiography, is the principal means of investigation of arrhythmias. Non-specific

Table 8.3 Summary of diagnostic techniques in equine cardiology

Clinical presentation: Cardiac murmurs	
2-Dimensional and M mode echocardiography	Identification of specific anatomic lesions; assessment of cardiac size, dilation, hypertrophy and ventricular contractility; regurgitant jets may cause abnormal valvular motion
Doppler echocardiography	Identification of regurgitant jets or intracardiac shunts; mapping of their extent and location; calculation of pressure gradients between chambers
Angiography	Demonstration of intracardiac shunts in foals
Phonocardiography	Confirmation and characterization of murmurs
Cardiac catheterization	Identification of pressure and PO ₂ changes localizes lesions and determines hemodynamic effects of shunts or valvular regurgitation
Clinical presentation: Arrhythmias	
Electrocardiography (ECG)	Identification and localization of arrhythmias and conduction abnormalities
Radiotelemetric ECG	Identification of arrhythmias during exercise
24 h ambulatory ECG	Documentation of the frequency of occurrence of arrhythmias at rest and during exercise
Cardiac troponins, LDH and CK isoenzymes	Confirmation of the presence of acute myocardial necrosis
Echocardiography	Identification of ventricular dilation, reduced ventricular function and concurrent valvular disease
Non-specific aids	
Radiography	Subjective assessment of cardiac size and demonstration of pulmonary edema
Hematology, biochemistry, blood culture and serology	Elucidation of the underlying cause of valvular or myocardial pathology. Determination of the multisystemic effects of cardiac dysfunction

Modified with permission from Marr, C.M. (1990) Ancillary aids in equine cardiology, *Equine Veterinary Education* 2: 18–21.

Table 8.4 Normal M mode echocardiographic values for adult horses

	Range (mean)
Right ventricle: diastole	32–52 (38.6) mm
Ventricular septal thickness: diastole	19–43 (30.6) mm
Ventricular septal thickness: systole	35–62 (48.1) mm
Left ventricular internal dimension: diastole	80–130 (110.6) mm
Left ventricular internal dimension: systole	43–79 (61.1) mm
Left ventricular wall thickness: diastole	20–40 (29.2) mm
Left ventricular wall thickness: systole	32–56 (44.5) mm
Left ventricular fractional shortening	32–55 (44.1) % ¹
Septal-left AV valve E point separation	<10 mm
Left auricular dimension	35–75 (56.4) mm
Aortic root dimension	55–90 (73.1) mm
Left ventricular ejection time	<0.45 s ²

¹ The left ventricular fractional shortening is normally $\leq 40\%$ at heart rates of less than 50 bpm.

² At heart rates of less than 50 bpm.

aids are used to investigate the etiology of certain cardiac diseases and to assess the other body systems that may be affected secondary to cardiac disease.

MYOCARDIAL DISEASE

There are few known causes of primary myocardial disease (cardiomyopathy) in the horse. The **ionophore antibiotics** (monensin, salinomycin), common additives in cattle and poultry feed, produce **myocardial necrosis** in the horse. Other proposed etiologies include viral and immune-mediated myocarditis. Nutritional deficiencies are common causes of cardiomyopathy in other species and, in the horse, vitamin E–selenium deficiency produces **cardiomyopathy** as well as **skeletal muscle disease** (white muscle disease) (*q.v.*).

Myocardial dysfunction is often secondary, resulting from extracardiac systemic disease or drug reactions. Significant reductions in myocardial contractility have been noted in horses with lymphosarcoma (*q.v.*) (without cardiac infiltration), electrolyte disturbances, severe metabolic derangements, endotoxemia and septicemia.

Myocardial disease is characterized by cardiac arrhythmias and/or ventricular dysfunction with ventricular dilatation and reduced myocardial contractility. The presenting signs depend on the severity of myocardial dysfunction and range from varying degrees of **exercise intolerance** to signs of congestive or low output heart failure in severe cases (see Box 8.1).

The **diagnostic procedures** that are useful in investigation of myocardial disease are listed in Table 8.3. Echocardiography is used to assess ventricular function while electrocardiography is used to categorize arrhythmias and can reveal S-T segment changes or changes in the duration of complexes. Prolongation of ECG intervals may be associated with **primary myocardial disease**, however this should alert the clinician to the possibility of electrolyte or metabolic imbalances.

Measurement of serum concentrations of **cardiac troponins** and CK-MB and HBDH (cardiac isoenzymes of creatinine kinase [CK] and lactate dehydrogenase [LDH], respectively) can be helpful as increases indicate active or recent myocardial damage. However, normal results have been found in horses with significant myocardial necrosis and in chronic myocardial disease. In addition, concurrent damage to other organ systems must be taken into consideration because CK-MB and HBDH are not cardiac-specific in the horse.

Feed analysis for ionophore antibiotics, assessment of acute and convalescent viral titers (e.g. influenza, herpesvirus [*q.v.*]) or virus isolation is appropriate for determining the etiology of myocarditis in individual cases. Myocardial biopsy has not been attempted successfully in the horse.

Appropriate **therapy** depends on the presence and significance of any arrhythmias, and the degree of myocardial dysfunction. Certainly, any **electrolyte or metabolic imbalances**, or systemic disease should be corrected or excluded as a cause of myocardial disease (*q.v.* arrhythmias for further details of management of those horses with clinically significant arrhythmias).

Therapy for myocardial dysfunction includes rest, diuretics (**furosemide**) and, if the horse is showing signs of heart failure, positive inotropic agents such as **digoxin** or, in emergency situations, **dobutamine**. Digoxin is contraindicated in ionophore poisoning. Activated charcoal or mineral oil may be beneficial in horses that are known to have ingested ionophore very recently.

The **prognosis** for myocardial disease varies, and is based on the severity of the myocardial insult, the extent of irreversible changes and the degree of ventricular dilatation. Although horses with arrhythmias are often tentatively diagnosed as suffering from “myocarditis” or “myocardial disease”, these horses can have very **localized inflammation** of the conducting tissue alone. Horses with a pathologic arrhythmia as the only abnormality have a better prognosis than those with accompanying myocardial dysfunction and ventricular dilatation. Thus, **echocardiographic assessment** of ventricular function is the most accurate means of formulating a prognosis.

Horses with recent onset of myocardial dysfunction, including those with ionophore poisoning, may recover completely and return to their previous level of performance. However, if the damage is extensive, irreversible **myocardial fibrosis** will ensue. These horses may survive the cardiac disease, but their **athletic capability** can be markedly reduced. In other cases, cardiac dilatation progresses over weeks to years and the animal eventually dies of congestive heart failure.

CARDIAC ARRHYTHMIAS

Cardiac arrhythmias are common in horses, both at rest and during exercise. They are often physiologic in nature, produced by normal neurohumoral mechanisms as a means of regulating the heart rate and modifying blood pressure. However, arrhythmias can also be pathologic, signifying **myocardial disease**. The equine clinician is frequently required to determine the significance of arrhythmias. A methodical approach allows precise characterization of the rhythm disturbance and its origin and thus provides the basis for assessment of the importance of the arrhythmia.

Diagnosis of arrhythmias

Careful **cardiac auscultation** will enable the detection of most cardiac arrhythmias in the horse and in some instances a tentative diagnosis can be made from auscultation alone. However, an **ECG** is required to diagnose definitively the type of arrhythmia present, and should always be performed if a pathologic arrhythmia is suspected (see Table 8.3). The base-apex lead is used routinely in the horse for assessment of the heart rate and rhythm because movement artifacts are minimized and waveforms are easily visualized.

For the base-apex lead placement is as follows:

1. The negative (“right arm”) electrode is sited dorsal to the right scapula, or in the right jugular groove, two thirds of the way down the neck.

Table 8.5 Normal interval durations in the equine ECG (lead II)

Interval	Duration
P-R	0.22–0.56 s
QRS	0.08–0.17 s
Q-T	0.32–0.64 s

2. The positive (“left arm”) electrode is sited over the cardiac apex (just above the point of the elbow in the sixth intercostal space on the left side).
3. The ground (“right leg”) electrode is sited anywhere on the body, remote from the heart.

Multiple leads can be necessary for the accurate diagnosis of some complex arrhythmias and the standard limb leads used in other species are adequate in the horse. PR, QRS and QT interval determinations are most commonly calculated from lead II (Table 8.5).

ECGs can be obtained during exercise using radiotelemetry or digital ambulatory systems. These techniques are particularly valuable in the horse because arrhythmias that are not present at rest can occur during **exercise**. Equally, arrhythmias that are present at resting heart rates can disappear during exercise. Twenty-four hour ambulatory (Holter) ECG monitoring is a method by which an ECG is recorded **continuously** on magnetic tape or using digital recorders, for prolonged periods. It allows a more accurate assessment of the frequency of occurrence of arrhythmias, and the horse can be left unattended, removing environmental influences that induce or abolish arrhythmias by modification of autonomic tone.

Physiologic arrhythmias

Physiologic arrhythmias are extremely common in normal horses. These are **bradyarrhythmias** associated with parasympathetic activity and occur at resting heart rates, generally <40bpm. Reduction of vagal tone with exercise, excitement or vagolytic drugs (e.g. **atropine sulfate** or **glycopyrrolate**, see Table 8.6) will remove these arrhythmias. These arrhythmias are not indicative of cardiac disease unless the arrhythmia persists at high heart rates or the animal exhibits syncope during the arrhythmia. Table 8.7 lists and describes the physiologic arrhythmias.

First and second degree atrioventricular block are the most common. Second degree atrioventricular block may occur as often as one beat in three. Generally beats are dropped singly, but occasionally, in normal horses, two beats may be dropped in succession. The other bradyarrhythmias are seen sporadically in normal horses.

Pathologic arrhythmias

Pathologic arrhythmias can be associated with primary or secondary myocardial disease, non-cardiac systemic disease, toxins such as monensin, hypoxia,

Table 8.6 Dosages of drugs used for management of cardiac arrhythmias in the horse

Drug	Dose
Atropine	IV: 0.005–0.01 mg/kg
Digoxin	IV: 0.002 mg/kg b.i.d. PO: 0.01 mg/kg b.i.d.
Glycopyrrolate	IV: 0.005–0.01 mg/kg
Lidocaine	IV: 0.5 mg/kg IV bolus every 5 min to 2.0–4.0 mg/kg total
Magnesium sulfate	IV: 2.2–5.5 mg/kg every 5 min to 55 mg/kg total
Procainamide	IV: 1 mg/kg/min to 20 mg/kg total PO: 25–35 mg/kg t.i.d.
Propranolol	PO: 0.38–0.78 mg/kg t.i.d. IV: 0.05–0.16 mg/kg b.i.d.
Phenytoin	PO: 10–22 mg/kg b.i.d.
Quinidine	PO: 22 mg/kg every 2–6 h (quinidine sulfate) IV: 2.2 mg/kg bolus every 10 min to 8–10 mg/kg total IV drip: 0.064% solution, ¹ 0.7–3 mg/kg/h (1.2–2 L/h/450 kg) (quinidine gluconate)

¹ A 0.064% solution of quinidine gluconate may be made by mixing 3.2 g of quinidine gluconate (four 800 mg vials) in 5 L of isotonic IV fluids.

Table 8.7 Physiologic arrhythmias in the horse

Arrhythmia	Auscultation	ECG
First degree AV block ¹	Low to normal resting heart rate; regular rhythm	Prolonged (>0.5 s) P-R interval
Second degree AV block	Low to normal resting heart rate; regular rhythm with occasional pauses; isolated 4th heart sound during pauses	Occasional P waves not followed by a QRS-T Mobitz type I (Wenckebach): progressive lengthening of P-R intervals preceding the dropped beat Mobitz type II: constant P-R interval
Wandering atrial pacemaker ¹	Low to normal resting heart rate; regular or slightly irregular rhythm	Variable P wave morphology; constant or variable P-P intervals
Sinus arrhythmia	Low to normal resting heart rate; slightly irregular rhythm ± associated with respiration	Variable P-P and P-R intervals
Sinoatrial block ¹	Low to normal resting heart rate; regular rhythm with pauses	Absence of P waves during pauses of less than or equal to two P-P intervals
Sinoatrial arrest	Low to normal resting heart rate; regular rhythm with long pauses	Absence of P waves for greater than two P-P intervals

¹ May occur in association with other physiologic arrhythmias.

and metabolic or electrolyte imbalances. A history of, or concurrent, **respiratory viral infection** or fever may be indicative of viral myocarditis. However, the underlying cause of the arrhythmias is often not apparent.

Arrhythmias induced by **exercise**, particularly those immediately after exercise as the heart begins to slow down, are thought to be the result of **autonomic imbalance**. Circulating catecholamines and other hormones released in large quantities during exercise may promote electrophysiologic instability and result in rhythm disturbances during or after exercise.

Exercise-induced arrhythmias can be of no clinical significance, particularly isolated infrequent premature beats occurring during the recovery phase. Exercise-induced arrhythmias have been associated with dynamic upper airway lesions and therefore this possibility should be considered if exercise-induced arrhythmias are noted. Sustained or paroxysmal tachyarrhythmias compromise cardiac function and result in poor performance.

The importance of arrhythmias in the etiology of **sudden death during exercise** is unknown. There is no concrete evidence, but there is considerable speculation that arrhythmias are a major cause. Auscultatory findings indicative of pathologic arrhythmias include premature beats, erratic rhythms, inappropriate tachycardia, and inappropriate or symptomatic bradycardia.

Arrhythmias can arise from any location within the heart. They are classified according to their origin as **supraventricular** (originating in the sinoatrial node, atrial myocardium, the atrioventricular node or junctional conduction tissue), or **ventricular**. An ECG is necessary to differentiate supraventricular and ventricular arrhythmias. Table 8.8 describes the auscultatory and electrocardiographic findings in the pathologic arrhythmias that are seen frequently in horses.

Supraventricular tachyarrhythmias

Supraventricular premature depolarizations

Supraventricular premature depolarizations (SVPDs) are unlikely to affect performance unless they occur frequently during exercise. Isolated SVPDs immediately after exercise during the heart rate recovery phase are not usually clinically significant. If these are documented with radiotelemetric ECG, it is usually possible to offer a good prognosis provided they are not occurring during exercise or very frequently. However, in some horses SVPDs may reflect the presence of **atrial myocardial disease**, which itself can predispose the horse to the development of atrial fibrillation. The presence of underlying electrolyte or metabolic imbalances or systemic diseases should be investigated and, where possible, corrected.

Rest (stall rest with turnout in a small paddock) for 1–2 mo can result in resolution in some cases. **Corticosteroids** (for example prednisolone and dexamethasone) are indicated if an immune-mediated post-viral myocarditis is suspected; however, they are **contraindicated in the presence of active viral infection** due to their potential for immunosuppression. Prednisolone and dexamethasone are given in decreasing dosage regimens, starting at 1 mg/kg and 0.1 mg/kg, respectively. Prednisolone is often used on alternate days whereas dexamethasone can be given at 2–4-day intervals. Clear evidence to favor one specific drug or dosage regimen is currently lacking.

Table 8.8 Supraventricular and ventricular arrhythmias in the horse

Arrhythmia	Auscultation	ECG
Atrial premature complexes	Premature beat \pm compensatory pause	Premature P wave; may or may not be followed by a normal QRS-T
Supraventricular tachycardia	Inappropriately rapid regular rhythm; paroxysmal or sustained; abrupt onset and offset; irregularly irregular if accompanied by variable first and second degree AV block	Atrial: rapid atrial rate P waves may or may not differ from sinus P waves constant, normal QRS-T morphology \pm variable first and second degree AV block Junctional: rapid succession of normal QRS-Ts unassociated with sinus P waves
Atrial fibrillation	Normal resting heart rate (elevated if myocardial dysfunction or congestive heart failure is present); irregularly irregular rhythm; variable intensity heart sounds	Irregular R-R intervals; absence of "P" waves; "f" fibrillation waves
Pre-excitation	Normal	Shortened P-R interval \pm abnormal QRS configuration
Advanced second or third degree AV block	Very low to normal resting heart rate; little to no increase in heart rate with excitement/exercise/atropine Third degree and repetitive second degree: regular rhythm Second degree: slightly irregular	Second degree: frequent P waves not followed by QRS-T occasional conduction Third degree: no evidence of conduction (AV dissociation) junctional or ventricular escape rhythm (third degree and second degree)
Ventricular premature contractions	Premature beat \pm compensatory pause	Premature QRS-T not preceded by a P wave; VPC differs in morphology from sinus QRS; T wave of VPC oriented in opposite direction of its QRS; \pm increased duration of the premature QRS
Accelerated idioventricular rhythm	Normal to slightly elevated heart rate \pm regular rhythm	"Slow" ventricular tachycardia ($\leq 50/\text{min}$) (see ventricular tachycardia)
Ventricular tachycardia	Rapid inappropriate rate \pm regular rhythm	Four or more successive VPCs Uniform VT: single VPC morphology Multiform VT: more than one VPC morphology

Digoxin and **phenytoin** may be successful in suppressing SVPDs (see Table 8.6), but this is not usually necessary unless there is a rapid ventricular response rate and the arrhythmia is accompanied by signs of low cardiac output (see Box 8.1).

Unfortunately, the SVPDs usually **recur** following discontinuation of the anti-arrhythmic agent. Twenty-four hour ambulatory and radiotelemetric ECG recordings obtained before and after treatment are useful to assess the response to treatment.

Supraventricular tachycardia

Supraventricular tachycardia (SVT) can originate in either an ectopic atrial focus (**atrial tachycardia**) or the AV junction (**junctional tachycardia**). Differentiation from sinus tachycardia may be difficult, but is based on the following:

1. With SVT the heart rate is inappropriately high for the horse's clinical condition, whereas with sinus tachycardia the cause is often evident, for example exercise, excitement, pain, systemic disease, or compromised hemodynamic status.
2. With SVT the onset and offset of tachycardia is often abrupt, while the onset and offset of sinus tachycardia is somewhat gradual.
3. Vagal maneuvers: AVT may be suppressed with vagal stimulation, while sinus tachycardia persists.

Anti-arrhythmics are used in the treatment of supraventricular tachycardia only if the ventricular rate is high and/or there are signs of low output cardiac failure (see Box 8.1). **Digoxin** is used to slow the ventricular response rate (see Table 8.6). **Quinidine** (sulfate or gluconate) and **procainamide** can be used as specific anti-arrhythmics in SVT (see Table 8.6).

Atrial fibrillation

Atrial fibrillation (AF) is the most common, and the most clinically significant, pathologic arrhythmia in the horse. It can occur in the absence of myocardial pathology, in association with atrial myocardial disease (myocarditis), or in the presence of **atrial enlargement** due to acquired valvular or congenital cardiac disease.

The clinical signs vary, depending on the **athletic use** of the horse and the presence or absence of **underlying heart disease**. Racehorses often exhibit a marked reduction in performance and, on occasion, have marked exercise-induced pulmonary hemorrhage (*q.v.*) or appear to tie up (*q.v.*). Horses used for less demanding sports may be asymptomatic.

Congestive heart failure (*q.v.*) is often accompanied by AF, in which case the clinical signs (increased resting heart rate, severe exercise intolerance, pulmonary edema and/or ventral edema, see Box 8.1) reflect the congestive heart failure rather than the AF. **AF is a consequence of, and not a cause of, congestive cardiac failure.** Negative prognostic indicators for horses with AF are presented in Box 8.3. The prognosis for successful treatment of AF is good if there is no underlying heart disease, but extremely poor if congestive heart failure is present.

The recommended **treatment** for AF is dependent on the presence or absence of **underlying heart disease** and the **athletic performance required** of the horse. In some horses in which AF is detected as an incidental finding, which are asymptomatic and performing to their owners' expectations and in which the history suggests that the AF may have been present for some time, it is not necessary to treat the horse unless the owner so wishes. These horses are unlikely to collapse or otherwise represent a danger to their riders. In horses with congestive heart failure and AF, therapy should be aimed at reducing

Box 8.3 Negative prognostic indicators for horses with atrial fibrillation

1. Increased resting heart rate (>60 bpm)
2. Grade III or louder murmurs of left or right atrioventricular valvular insufficiency, particularly if atrial dilatation is detected on echocardiographic examination
3. Prolonged (>6–12 mo) duration of AF (the duration may be inferred from the horse's performance history). Horses with prolonged duration of AF require larger quantities of quinidine sulfate to effect conversion, and are at greater risk of recurrence
4. Development of atrial tachycardia with variable first and second degree block during the course of treatment
5. Supraventricular premature depolarizations (SVPDs) following conversion to sinus rhythm (this may indicate underlying atrial myocardial disease, or the SVPDs may result in atrial fibrillation)

congestion with **furosemide** and slowing the ventricular rate with **digoxin** (see Table 8.6) (see congestive heart failure [*q.v.*]). **Quinidine sulfate is contraindicated** in these horses.

In horses with **symptomatic AF but no underlying heart disease**, quinidine sulfate is the drug of choice. Quinidine prolongs the effective refractory period of the atrial myocardium, suppressing the fibrillation waves and allowing sinus rhythm to be restored. The standard protocol for the use of quinidine sulfate is given in Box 8.4.

The **adverse effects** of quinidine include depression and anorexia, diarrhea and abdominal pain. Occasionally, some horses have idiosyncratic reactions, which may include ataxia, sudden death, nasal mucosal edema and urticaria. Quinidine has profound hypotensive and positive chronotropic effects, and horses should not be stressed or moved out of their stalls during treatment. Quinidine also has pro-arrhythmic effects.

Continuous **ECG monitoring** is advisable in order to detect severe arrhythmias during treatment of AF. If persistent **ventricular tachycardia** occurs, magnesium sulfate is the drug of first choice while **propranolol** can also be useful (see Table 8.6). Procainamide should be avoided as it is similar in action to quinidine.

Supraventricular tachycardia with variable first and second degree heart block is frequently seen during treatment with quinidine sulfate and is a poor prognostic indicator. Severe supraventricular tachycardia (200–300 bpm) has been observed in some horses undergoing treatment with quinidine for atrial fibrillation. This arrhythmia, in combination with the hypotensive effects of quinidine, could result in death. If SVT occurs, the measures listed in Box 8.5 should be undertaken.

In most cases, once sinus rhythm has been restored, the horse can resume training immediately unless **active myocardial disease** is suspected, significant adverse effects of quinidine were noted during treatment, or there was a recent history of pronounced **exercise-induced pulmonary hemorrhage** (*q.v.*)

Box 8.4 Treatment regimen for atrial fibrillation using quinidine sulfate

1. Monitor the ECG continuously during treatment if possible
2. Do not move the horse from its stall during treatment
3. 22 mg/kg (10 g/450 kg) quinidine sulfate via stomach tube q 2 h*
4. Obtain ECG prior to each dose and assess for widening of QRS by more than 25% of pre-treatment value; discontinue quinidine if this occurs as quinidine concentrations are likely to be in the toxic range
5. Discontinue if toxicity develops (prolongation of the QRS by 25% of pre-treatment duration, diarrhea, ataxia, nasal mucosal edema or significant tachycardia)
6. If sinus rhythm is not restored after 5–6 treatments have been given, options include:
 - (a) Continue the administration of quinidine, changing to 6 h dosing interval (one half-life of quinidine) to attain a constant plasma quinidine concentration until sinus rhythm is restored or signs of toxicity appear
 - (b) Monitor serum quinidine concentrations to ensure that therapeutic levels are being achieved
 - (c) Digitalization should be strongly considered in horses with supraventricular tachycardia (ventricular rate of 100 per min). Anecdotally, digitalization has also been beneficial in horses that appear to be refractory to quinidine alone. Although digoxin toxicity can occur when quinidine and digoxin are administered together, short-term simultaneous drug administration appears to be safe

**Previously a test dose was recommended, however the majority of quinidine's toxic effects are dose dependent and the first dose in this regimen serves as a test dose for idiopathic anaphylactic reactions.*

Box 8.5 Protocol for the emergency treatment of rapid supraventricular tachycardia induced by quinidine sulfate

1. Digoxin (0.002 mg/kg IV) to slow ventricular response rate
2. Intravenous fluids (large volumes of isotonic fluids, or 4 mL/kg of hypertonic saline) to increase blood pressure
3. Bicarbonate (1 mg/kg IV) to increase protein binding of quinidine and decrease the concentration of free drug
4. Phenylephrine (10 mg in 500 mL of 0.9% saline) in a fast drip to effect vasoconstriction and increase blood pressure
5. Activated charcoal or oil to limit further absorption of quinidine from gastrointestinal tract

or myositis associated with AF. In such cases, an additional period of rest may be warranted. After the horse returns to training, the heart rhythm should be monitored periodically to ensure that AF has not recurred. Most owners can be taught to do this regularly.

Ventricular tachyarrhythmias

Ventricular premature depolarizations

Ventricular premature depolarizations (VPDs) are seen in the same clinical circumstances as those described for SVPDs. Isolated VPDs can be detected after exercise as the heart rate slows, and if they can be shown to be isolated and infrequent they can be considered to be insignificant. Similarly, the treatment for VPDs is that also recommended for SVPDs (stall rest, corticosteroids). VPDs should be more aggressively managed if they are multiform, frequent or the coupling interval is very short (R-on-T phenomenon).

Accelerated idioventricular rhythm

Accelerated idioventricular rhythm is defined as four or more successive VPDs occurring at intervals similar to the sinus R-R interval (i.e. a **sustained accelerated idioventricular rhythm** would occur at a rate of 30–50 bpm). This arrhythmia is seen most often in the presence of non-cardiac disease, particularly gastrointestinal disease. In the majority of horses, the arrhythmia will resolve without specific anti-arrhythmic therapy.

Ventricular tachycardia

Ventricular tachycardia (VT) is defined as four or more successive VPDs occurring at a rapid rate (≥ 50 /min). Again, this arrhythmia is most frequently seen in association with non-cardiac disease, particularly gastrointestinal disorders. In addition to the correction of any underlying disorders, anti-arrhythmic therapy should be considered if the rate is rapid (≥ 100 /min), multiform VPDs are present, or very short coupling intervals (R-on-T phenomenon) are noted. In some instances, the arrhythmia needs to be treated even if none of these criteria applies: a systemically ill horse, particularly one that is hypovolemic, will be much less able to tolerate ventricular tachycardia than an otherwise healthy horse, and signs of low output failure may be present (see Box 8.1).

Evidence on the efficacy and safety of anti-arrhythmic agents in horses is lacking. **Procainamide**, **lidocaine** or **quinidine** may be selected for the initial treatment of VT (see Table 8.6). However, the clinician should be familiar with the following disadvantages:

1. **Lidocaine:** CNS excitability—use with caution; may be preferred over quinidine in an emergency situation or in horses with myocardial dysfunction.
2. **Quinidine:** Hypotension—hypotensive effects may be minimized by administration as a drip, however therapeutic concentrations may not be achieved for several hours.

Magnesium sulfate, **phenytoin** and **propranolol** have been used successfully for the treatment of VT in some horses (see Table 8.6).

Conduction disorders

Pre-excitation

Pre-excitation is a conduction abnormality that has been reported infrequently (**Wolff–Parkinson–White syndrome**), usually as an incidental ECG finding,

without a documented adverse effect on performance. Affected horses can present with SVT that is responsive to therapy with procainamide. However, further episodes may occur due to the presence of an aberrant pathway between the atria and ventricles.

Advanced second degree and third degree atrioventricular block

These are uncommon arrhythmias in the horse and are caused by inflammation or fibrosis at the atrioventricular node. Corticosteroids may be of benefit in the short term. However, cardiac pacemaker implantation is the definitive treatment for pathologic atrioventricular blocks. Vagolytic drugs (**atropine sulfate** 0.01 mg/kg IV, **glycopyrrolate** 0.005 mg/kg IV, see Table 8.6) or β 1-adrenergic drugs (**dobutamine** 0.5–5 μ g/kg/min IV) are indicated if advanced atrioventricular blocks develop under anesthesia.

CONGENITAL CARDIAC DISEASES

Many congenital cardiac diseases have been reported in horses (Box 8.6); however, the majority of these are **extremely uncommon**, and single case reports or small series are often all that are described in the literature. Complex cardiovascular defects usually become apparent within a short period after birth. Foals may be presented with stunting, weakness, lethargy and signs of congestive heart failure (see Box 8.1). Anatomic defects result in disturbances of blood flow, and thus cardiac murmurs are present. The characteristics of these murmurs depend on the specific defect (or defects) present.

Echocardiographic examination is the technique of choice for the evaluation of congenital defects (see Table 8.3). A segmental approach to examination is

Box 8.6 Congenital cardiac defects in the horse

Intracardiac defects

- Ventricular septal defect
- Atrial septal defect
- Atresia of the right atrioventricular orifice
- Tetralogy of Fallot
- Hypoplastic left ventricle
- Common ventricle
- Semilunar valvular anomalies

Extracardiac defects

- Patent ductus arteriosus
- Persistent truncus arteriosus
- Transposition of the great vessels
- Sinus of Valsalva aneurysm
- Coarctation of the aorta
- Persistent right aortic arch
- Miscellaneous anomalies of the great vessels and their branches

necessary. Each cardiac structure is identified separately and its relative position to other structures is assessed. Doppler echocardiography is used to confirm the existence of aberrant blood flow (intra- or extra-cardiac shunts). Angiography may be used as a diagnostic aid in foals and small weanlings, but body size usually precludes its use in older animals. Cardiac catheterization can be helpful in some cases.

VENTRICULAR SEPTAL DEFECT

Ventricular septal defect (VSD) is the most common congenital cardiac disease in the horse. It is usually located in the non-muscular septum, immediately beneath the aortic valve. Occasionally, defects occur in the muscular septum. The shunt through the VSD is from left to right; however, it causes left ventricular volume overload as the extra blood enters the right ventricular outflow tract, over-perfuses the pulmonary circulation and then enters the left heart. Increased right ventricular pressure may be present with large shunts.

The hemodynamic effects and clinical significance of VSDs are dependent on their size. Large defects produce signs of left-sided and, ultimately, biventricular failure (see Box 8.1). More typically, horses with a VSD show signs of **poor performance** or **exercise intolerance** associated with smaller defects. The signs generally become apparent in 2 or 3 yr old horses beginning training. If the defect is extremely small (≤ 2 cm diameter) there may be little or no effect on athletic capability. The prognosis for continuing performance at the same level is good and life expectancy is unaffected. In ponies, it is helpful to compare the size of the VSD with that of the aortic root: a small VSD, $\leq \{1/3\}$ the diameter of the aortic root warrants a favorable prognosis.

The pattern of blood flow accounts for the typical murmurs associated with VSDs (see Table 8.2). The intracardiac shunt within the VSD produces a systolic murmur that is loudest on the right side. This is frequently accompanied by a systolic murmur on the left side over the pulmonic valve because the extra right ventricular ejection produces a relative pulmonic stenosis. The location of the VSD beneath the aortic valve may compromise the right coronary cusp, which prolapses into the VSD. There is, therefore, often aortic regurgitation and a diastolic murmur.

Echocardiography is the method of choice for the diagnosis of VSDs, which are readily visualized in the horse. The prognosis is also based on echocardiographic findings: the diameter of the VSD can be measured and signs of left ventricular volume overload or right ventricular pressure overload can be detected. In many cases the horse can be allowed to continue work.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus generally closes within the first four days of life, and is considered abnormal if patency persists beyond 1 wk of age. Patent ductus arteriosus (PDA) is **uncommon** in horses. When it does occur, the shunt is from left to right from the descending aorta to the pulmonary artery. As in VSD, the increased blood flow to the lungs returns to the left side of the heart

and leads to left ventricular volume overload. Blood flow in the PDA is continuous, thus there may be a continuous “machinery” murmur (see Table 8.2). However, often the murmur is heard in systole only, particularly as pulmonary hypertension increases and the diastolic component of the shunt decreases. The arterial pulses are usually bounding in quality (water hammer) due to the rapid fall in diastolic pressure as blood leaves the left side via the shunt.

Horses with PDA may be presented within the first year of life with stunting, ill-thrift and signs of left-sided or congestive heart failure (see Box 8.1). However, PDA has been detected as an incidental finding on post mortem examination. The diagnosis of PDA can be difficult. It cannot be visualized easily with echocardiography because the lung often obscures the descending aorta. Retrograde blood flow in the pulmonary artery may be apparent on Doppler echocardiographic examination. Cardiac catheterization may be of benefit. Surgical closure of PDA has not been reported in horses. Short-term management of congestive heart failure with digoxin, furosemide and vasodilators may be instituted in some cases (see congestive heart failure [*q.v.*]).

ACQUIRED VALVULAR HEART DISEASES

Valvular lesions are the most common pathologic cause of cardiac murmurs in the horse. They are usually acquired and degenerative or inflammatory in nature. **Valvular stenosis**, which is common in other species, is extremely uncommon in the horse, although reports of congenital valvular malformations have appeared in the literature. Inflammation of the endocardium is most frequently associated with bacterial infection (**bacterial endocarditis** [*q.v.*]). In this disease, the lesions may not be confined to the valves, and may also affect the mural endocardium and the myocardium.

Rupture of the chordae tendineae of the left or right AV valve may occur spontaneously or following degenerative or inflammatory changes in the chordae. The right accessory leaflet of the left AV valve is affected most commonly, but any leaflet may be affected. Rupture of the chordae tendineae produces acute regurgitation, which is usually severe, leading to left- or right-sided heart failure, depending on which valve is affected. Tearing of a semilunar valve cusp can also occur spontaneously and this also results in acute severe valvular insufficiency.

DEGENERATIVE VALVULAR DISEASE

Degenerative lesions include generalized or nodular **fibrosis** and distortion of the **valve cusps**. The precise etiology and pathogenesis of degenerative valvular lesions in the horse is unknown. They are detected most often in middle-aged or older horses but can be seen in horses of any age.

The clinical presentation and prognosis in degenerative valvular heart disease varies according to which particular valve is involved. Careful auscultation allows the identification of murmurs and their characterization. On this basis a differential diagnosis and, frequently, a tentative diagnosis can be formed. The characteristics of physiologic murmurs, and the murmurs typical of each type of valvular insufficiency are listed in Table 8.2.

Table 8.9 Echocardiographic findings in acquired valvular heart disease in the horse

Left ventricular volume overload	
B mode	Globoid, enlarged LV; hyperkinetic LV
M mode	Increased LVD, LVS, FS% and SEP; "swinging" septal motion
Pulmonary hypertension	
B mode	Pulmonary artery dilatation ¹
Right ventricular volume overload	
B mode	Globoid, enlarged RV
M mode	Paradoxical septal motion
Left atrioventricular valvular insufficiency	
B mode	LAV valve thickening or nodules; flail cusp (ruptured chordae tendineae); valvular prolapse; ² LA enlargement; signs of LV volume overload; pulmonary artery dilatation ¹
M mode	Valve thickening; signs of LV volume overload
Doppler	Regurgitant (high speed, turbulent retrograde) blood flow in the LA
Right atrioventricular valvular insufficiency	
B mode	RAV valve thickening or nodules; flail cusp (ruptured chordae tendineae); valvular prolapse; ² RA enlargement
M mode	Signs of RV volume overload
Doppler	Regurgitant (high speed, turbulent retrograde) blood flow in the RA
Aortic valvular insufficiency	
B mode	Valve thickening or nodules; flail valve (torn cusp); valvular prolapse; ² signs of LV volume overload
M mode	Diastolic vibrations on the LAV valve; early diastolic closure of the LAV valve; aortic valve thickening; signs of LV volume overload
Doppler	Regurgitant (high speed, turbulent retrograde) blood flow in the LV
Pulmonic valvular insufficiency	
B mode	Valve thickening or nodules; signs of RV volume overload
M mode	Signs of RV volume overload
Doppler	Retrograde (high speed, turbulent, retrograde) blood flow in RV

¹ Pulmonary artery dilatation is a poor prognostic indicator as pulmonary artery rupture and sudden death may follow.

² Valvular prolapse is a common echocardiographic finding but usually it is not accompanied by significant regurgitation.

LV, left ventricle; LVD, diameter of the left ventricular lumen in diastole; LVS, diameter of the left ventricular lumen in systole; FS%, fractional shortening;

$$\frac{LVD - LVS}{LVD} \times 100$$

SEP, maximal excursion in diastole of the distance between the interventricular septum and the mitral E point; RV, right ventricle; LAV, left atrioventricular valve; LA, left atrium; RAV, right atrioventricular valve; RA, right atrium.

Echocardiographic examination allows confirmation of regurgitation and assessment of the hemodynamic effects of lesions (see Table 8.3). The echocardiographic changes that may be associated with valvular lesions are listed in Table 8.9.

BACTERIAL ENDOCARDITIS

Bacterial endocarditis is an important cause of **fever of unknown origin**. The specific cardiovascular signs depend on which valve or valves are involved

(see Box 8.1 and Table 8.2). The signs are accompanied by depression and occasionally shifting leg lameness and limb swelling. Hyperfibrinogenemia and neutrophilia reflect the inflammatory response.

Streptococcus spp., *Actinobacillus equuli*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Rhodococcus equi*, *Erysipelothrix rhusiopathiae* and *Candida parapsilosis* have all been reported as causes of bacterial endocarditis. Blood culture is helpful as antimicrobial sensitivity can be established, but a negative blood culture does not exclude the diagnosis of bacterial endocarditis. Broad-spectrum antibiotics (e.g. **benzylpenicillin sodium** 20 000–40 000 IU/kg IV q.i.d. and **gentamicin** 6.6 mg/kg IV s.i.d.) should be administered, pending blood culture results. The long-term prognosis depends on the degree of residual damage to the valve and the associated valvular regurgitation.

CLINICAL FINDINGS IN VALVULAR DISEASE

Left atrioventricular valvular insufficiency

The left AV valve is the second most common site for valvular pathology in the horse. However, left AV valvular insufficiency is the most important form of acquired valvular heart disease, as it carries a **poor prognosis**. Thus, echocardiographic examination should be considered in all horses with murmurs associated with the left AV valve.

The clinical presentation is dependent on the severity of regurgitation and the speed of progression of the lesion (see Box 8.1 and Table 8.2). **Atrial fibrillation** (*q.v.*) often accompanies moderate or severe left AV valvular regurgitation. Pulmonary hypertension produces pulmonary edema and signs of respiratory dysfunction, and fatal rupture of the pulmonary artery may occur. Periodic echocardiographic assessment is the best means of determining the speed of progression of valvular lesions to provide an accurate prognosis.

Right atrioventricular valvular insufficiency

Right AV valvular insufficiency is present in many **normal horses** in the absence of valvular pathology (see Table 8.2). Consequently, right AV murmurs associated with mild or moderate valvular regurgitation are often detected in horses showing no clinical signs, and these horses generally have no associated performance problems. These horses often have loud grade 3 or 4–6 holosystolic murmurs audible in the right fourth intercostal space.

Clinical signs of right AV valvular insufficiency, if they do occur, are most often seen accompanying **congestive heart failure** (*q.v.*). Rarely, horses are presented with signs of right-sided heart failure following rupture of the chordae tendineae or other right AV valvular lesions (see Box 8.1). Murmurs of right AV valvular insufficiency that are grade 4–6 or greater and/or the presence of an increased jugular pulse indicating severe right AV valvular regurgitation should prompt **further diagnostic evaluation**.

Aortic insufficiency

Degenerative lesions are frequently found on the aortic valve, particularly in middle-aged or older horses. The murmur of aortic insufficiency is a common

incidental finding in these horses (see Table 8.2). The horse can tolerate aortic insufficiency very well and it rarely produces signs of cardiac failure. Hemodynamically significant **aortic insufficiency** produces bounding or tapping pulses, indicating left ventricular volume overload with a rapid fall in diastolic pressure. If these are detected, further diagnostic evaluation is warranted. In the majority of horses, aortic insufficiency progresses slowly and aortic insufficiency alone rarely results in poor performance or cardiac failure.

Left ventricular dilatation secondary to aortic insufficiency can eventually progress to the stage where the left AV valve annulus becomes stretched, with **left AV valvular insufficiency** and more severe clinical signs. The clinician should be alert to this possibility and should evaluate the left AV valve area carefully in horses with murmurs of aortic insufficiency.

Horses with aortic insufficiency and concurrent ventricular arrhythmias appear to be more likely to have **progressive heart disease**, therefore ambulatory and exercising ECG studies are helpful in identifying these individuals.

Pulmonic insufficiency

The pulmonic valve is an uncommon site for valvular pathology. Horses with severe pulmonic insufficiency have a diastolic murmur (see Table 8.2) and signs of right-sided heart failure (see Box 8.1).

TREATMENT OF CONGESTIVE CARDIAC FAILURE

Long-term management of horses with congestive heart failure is rarely necessary. However, short- or mid-term management may be appropriate. Drugs used for the treatment of congestive heart failure are listed in Table 8.10. Regardless of the underlying cause, the goals of therapy in cardiac failure are to **reduce congestion** and to **increase cardiac output**. Diuretics, principally **furosemide**, are used to decrease fluid accumulation, and a **salt-restricted diet** may be beneficial.

Digoxin is used in the hope of increasing cardiac output. Its negative chronotropic effect allows more efficient diastolic filling and consequently increases stroke volume. Digoxin also increases cardiac contractility.

Vasodilators are widely used in the management of cardiac failure in other species. Their efficacy in horses has yet to be evaluated. Angiotensin-converting enzyme inhibitors such as **enalapril** (*q.v.*) are widely used in other species and have been shown to be safe in normal horses (see Table 8.10). They are being

Table 8.10 Drugs used for the management of congestive heart failure in horses

Drug	Dose
Acepromazine	0.04–0.1 mg/kg b.i.d. or t.i.d.
Digoxin	0.01 mg/kg IV b.i.d.
Enalapril	0.5 mg/kg PO b.i.d.
Promazine	0.4–1 mg/kg PO b.i.d. or t.i.d.
Nitroglycerin ointment	Not known

used increasingly in the treatment of horses with congestive heart failure. **Acepromazine, promazine (arterial) and nitroglycerin ointment** (venous) may potentially be used as vasodilators (see Table 8.9). Again, there is no information on their efficacy in congestive heart failure.

DETERMINATION OF THE PROGNOSIS IN VALVULAR DISEASE

The prognosis in equine valvular disease is dependent on its site and the precise type of pathology involved, the speed of onset of the lesion and severity of the regurgitant fraction, the degree of associated ventricular volume overload and the presence of complications and sequelae such as pulmonary hypertension, pulmonary artery dilatation and atrial fibrillation (*q.v.*). Left AV valvular insufficiency is more likely to limit performance and shorten life expectancy than aortic or right AV valvular insufficiency.

Degenerative lesions that are slowly progressive are less significant than acute, severe lesions such as ruptured chordae tendineae, torn semilunar cusp and bacterial endocarditis (*q.v.*). The rate of progression of lesions can be determined most accurately by repeated echocardiographic evaluation. Thus a **precise diagnosis** and **detailed cardiovascular work-up** are required for the purposes of forming a prognosis and assessing the horse's safety for riding or insurance purposes (*q.v.*). It should be noted that although valvular insufficiencies can be fatal they are not likely to result in sudden death without preceding signs of congestive heart failure.

PERICARDIAL DISEASES

Pericarditis is categorized as effusive or constrictive, and also on the basis of its fluid characteristics, which may be fibrinous, septic, inflammatory or hemorrhagic. The etiologies of pericardial disease include bacterial or viral infections, penetrating wounds and, rarely, neoplasia. However, the majority of cases appear to be **idiopathic**. Increased numbers of pericarditis cases have been documented to occur during outbreaks of **mare reproductive loss syndrome**, a syndrome of fetal loss that has been linked to exposure to the Eastern Tent caterpillar (*q.v.*), but the precise mechanism by which pericarditis is induced in the syndrome is unknown.

EFFUSIVE PERICARDITIS

Effusive fibrinous pericarditis is the most common pericardial disease seen in horses. The hemodynamic effects of the pericardial effusion depend on the rate and amount of fluid accumulation and the physical characteristics (stretch) of the pericardium. When the pericardial effusion increases, the pressure within the pericardial sac can rise to equal the right atrial and ventricular diastolic pressures. Consequently, ventricular diastolic filling is impaired and in turn stroke volume declines (**cardiac tamponade**).

The clinical signs reflect right-sided, low output heart failure and include lethargy and weakness, jugular venous pulsations or distension, ventral

edema, weak arterial pulses and dyspnea (see Box 8.1). Typically, auscultation reveals tachycardia with muffled heart sounds. However, pleural effusion and obesity can also produce muffled heart sounds. In **fibrinous pericarditis**, pericardial friction rubs can be detected, although rubs are often absent in cases of effusive fibrinous pericarditis.

Echocardiography is used to confirm the diagnosis of pericardial disease and to characterize the pericardial fluid. The electrocardiogram may reveal diminished QRS voltage; however, this finding is not specific for pericardial effusion as it may also be seen in obese animals and in animals with pleural effusion. Electrical alternans (cyclical variation in the QRS configuration due to cardiac movement) is occasionally seen. This is most easily detected in one of the limb leads rather than the base-apex lead. Radiographs reveal an enlarged cardiac silhouette. However, if a **pleural effusion** accompanies the **pericardial effusion** this will obscure the cardiac silhouette. Ideally, a sample of **pericardial fluid** should be obtained (Box 8.7). The nucleated cell count, protein content, cytologic evaluation and bacterial culture are of value in determining the etiology and in selecting a therapeutic regimen.

In recent years, reports have indicated that, if effusive fibrinous pericarditis is treated early and aggressively, the prognosis for return to previous athletic performance is good. **Pericardiocentesis** is the procedure of choice for the treatment of horses with effusive pericarditis. The indications include clinical signs of right-side heart failure, cardiac tamponade, and echocardiographic evidence of right atrial collapse. A technique for pericardiocentesis is described in Box 8.7. Removal of the pericardial effusion produces a rapid improvement in the horse's clinical status because cardiac tamponade is reduced and right

Box 8.7 Technique for pericardiocentesis

Location

Left 4–6 intercostal spaces, 6 cm ventral to point of shoulder. Selection of site is facilitated by the use of diagnostic ultrasound.

Sedation

May not be necessary, depending on the horse's clinical status. If necessary, use with caution; these drugs may exacerbate cardiovascular compromise.

ECG monitoring

Have appropriate doses of procainamide, quinidine or lidocaine at hand. If ventricular arrhythmias occur, the needle should be retracted; if this fails, anti-arrhythmic drugs may be necessary.

Site preparation

Clip; surgical scrub; infiltration of lidocaine in skin, subcutaneous layers and intercostal muscles; stab incision.

Catheter selection

Over-the-needle IV catheters (14 G, 13 cm), or chest drains (16 to 20 French) (withdraw trocar once pericardial sac has been penetrated).

ventricular function improves. Potential complications include laceration of a coronary artery or intercostal artery, fatal ventricular arrhythmias and cardiac puncture.

Specific treatment of effusive pericarditis depends upon the suspected etiology. **Broad-spectrum antimicrobials** (for example **benzylpenicillin sodium** 20 000–40 000 IU/kg IV q.i.d. and **gentamicin** 6.6 mg/kg IV s.i.d.) are indicated in septic pericarditis or in those cases in which pericardial disease occurs in conjunction with a systemic septic process such as pleuropneumonia. Non-steroidal anti-inflammatory drugs (for example flunixin meglumine 1.1 mg/kg IV b.i.d.) may be of additional benefit.

Corticosteroids appear to be very useful in horses with idiopathic effusive fibrinous pericarditis but should be avoided when a bacterial or viral etiology is suspected due to their potential for immunosuppression. Prednisolone and dexamethasone are given in decreasing dosage regimens, starting at 1 mg/kg and 0.1 mg/kg, respectively. Prednisolone is often used on alternate days whereas dexamethasone can be given at 2–4-day intervals. Clear evidence to favor one specific drug or dosage regimen is currently lacking.

An indwelling **pericardial drain** may be necessary for cases in which the effusion is septic and/or recurrent. A catheter or drain (e.g. 16 to 20 French chest drain) may be inserted as described in Box 8.7. This can be sutured in place and sealed with a one-way stopcock. An indwelling catheter allows for twice daily lavage of the pericardial sac, with instillation of antimicrobials.

CONSTRICTIVE PERICARDITIS

Constrictive pericarditis is very rare in the horse. It can be idiopathic or, more commonly, a sequel to effusive and/or fibrinous pericarditis. In this condition, inflammation and fibrosis thicken the pericardium and it becomes **inelastic**.

The clinical signs in constrictive pericarditis are similar to those described above for effusive pericarditis (*q.v.*), although **pericardial friction rubs** may be present. Differentiation of constrictive pericarditis from pericardial effusion can be difficult, even with echocardiography. In some cases of constrictive pericarditis there is no effusion but echocardiography reveals a thickened pericardium, measuring approximately 5–7 mm. However, constrictive pericarditis can be accompanied by a fibrinous effusion.

Compression of the right atrium confirms the presence of **cardiac tamponade**. Cardiac catheterization is the best means of differentiating effusive from constrictive pericarditis. In constrictive pericarditis, ventricular filling is limited to early diastole, with abrupt cessation of filling in mid diastole. In contrast, effusive pericarditis interferes with ventricular filling throughout diastole.

Treatment of constrictive pericarditis requires the **surgical resection** of the affected pericardium. **Partial pericardectomy** has been attempted in the horse with limited success. The prognosis is guarded as partial pericardectomy may not be sufficient to improve the horse's hemodynamic status, involvement of the epicardium may result in further restrictive pathology,

and extension of the inflammatory process may produce myocardial atrophy or fibrosis.

VASCULAR DISEASES

JUGULAR THROMBOSIS

Jugular thrombosis can be septic or non-septic. It occurs most frequently as a sequel to **vessel trauma** by IV catheterization or injection, particularly in endotoxemic (*q.v.*) horses or when inadvertent perivascular infiltration of irritant substances occurs. It may also be seen in horses with coagulopathies, notably **disseminated intravascular coagulation** (*q.v.*).

The thrombosed vein is swollen and firm and is hot and painful on palpation if it is infected. In chronic cases it may feel cord-like. In septic thrombosis the horse may be febrile. There are varying degrees of occlusion. **Acute complete obstruction** of venous drainage leads to swelling of the facial structures of the affected side, particularly the cheek and supraorbital fossa. If occlusion is **bilateral**, the swelling can be sufficient to cause obstruction of the airways, stertorous breathing and dyspnea. There may be distension of the superficial veins of the head in horses with long-standing jugular occlusion.

The diagnosis of jugular thrombosis is based on the clinical findings. However, it is important to differentiate septic from non-septic thrombosis. Neutrophilia and hyperfibrinogenemia are present in **septic thrombosis**. The definitive diagnosis of infection is provided by aspiration and culture and allows antimicrobial sensitivity to be performed. **Ultrasonographic examination** is useful for the identification of fluid pockets within a thrombus, which is strongly suggestive of sepsis and is a guide to the best site of aspiration. Gas echoes within a thrombus suggest **anaerobic infection**.

The goals of therapy are to eradicate infection, reduce local swelling, and minimize the effects of venous occlusion. The choice of antimicrobials should be based on the results of bacterial culture and sensitivity. Broad-spectrum antimicrobial treatment should be provided pending these results. Surveys have shown that **penicillin–gentamicin** and **penicillin–amikacin** combinations (benzylpenicillin sodium 20 000–40 000 IU/kg IV q.i.d., gentamicin 6.6 mg/kg IV s.i.d., amikacin 3.5 mg/kg IV q.i.d.) are most successful. **Metronidazole** (15 mg/kg PO q.i.d.) should be administered if anaerobic infection is suspected. Additional measures include aspirin (15 mg/kg PO every other day) and other **non-steroidal anti-inflammatory drugs**, hot packs, poultices and topical anti-inflammatory ointments containing dimethyl sulfoxide to reduce local swelling. The head should be raised and cross-tied if extensive head swelling occurs. **Emergency tracheostomy** may be necessary with severe dyspnea in acute, bilateral jugular thrombosis.

In **septic jugular thrombosis** the prognosis is variable. Potential complications include embolic pneumonia and endocarditis. In **non-septic thrombosis**, the prognosis is better and the affected vein will often recanalize in time. However, long-standing jugular thrombosis has been associated with exercise intolerance. A surgical procedure to replace the occluded vein with a vascular graft has been successfully performed.

AORTO-ILIAC THROMBOSIS

Aorto-iliac thrombosis is an **acquired progressive disorder** affecting the aortic quadrification and its branches. The etiology is unknown. Although some authors have suggested that migrating parasites may be contributory, there is little substantial evidence to support this. Its clinical presentation is related to disruption of blood supply to the hindlimbs. Affected horses show **vague hindlimb lameness**, which is exacerbated by exercise. The digital pulses in the affected limb may be weak or absent and the limb is cooler than the contralateral one.

Successful treatment has been reported using anthelmintics (**ivermectin** 0.2 mg/kg PO) and non-steroidal anti-inflammatory drugs (e.g. **phenylbutazone** 2–4.4 mg/kg PO or IV s.i.d. or b.i.d.). **Aspirin** (15 mg/kg PO every other day) may be beneficial as it inhibits the local vasoconstriction induced by release of thromboxane from platelets within the thrombus. Some horses will recover if they are kept in work, which is believed to promote the development of a collateral circulation. However, the prognosis in aorto-iliac thrombosis is guarded.

AORTIC ANEURYSMS

Aortic aneurysms can involve either the thoracic or abdominal portions of the aorta. In many anatomic locations, the diagnosis of aortic aneurysms is difficult and they are usually first discovered at post mortem examination, following rupture and fatal hemorrhage. However, **sinus of Valsalva aneurysm** has been detected echocardiographically and aneurysms of the terminal aorta may be palpable per rectum. Erosion of an intra-abdominal aneurysm through the **ureter** leading to **hematuria** (*q.v.*) has been reported. The prognosis for aortic aneurysm is guarded regardless of the site as fatal hemorrhage is likely to occur at any time.

VASCULAR RUPTURE

Rupture of major blood vessels is the **most common cause of sudden death** in horses, particularly those that die during exercise. Major vessels can be traumatized or lacerated by long bone fractures, but in most cases the ruptures occur **spontaneously** and unexpectedly. Aneurysms, vessel wall damage and medial necrosis (*q.v.*) can predispose the vessel to rupture. Rupture of a wide variety of blood vessels has been reported, but **severe pulmonary hemorrhage** has been recognized most frequently in horses that die during exercise.

Aortic ring rupture is associated with sudden death during **breeding** in middle-aged or older breeding stallions. The pathogenesis is unknown, although **acquired medial necrosis** or **congenital sinus of Valsalva aneurysms** may be predisposing factors (*q.v.*). The aorta may rupture either into the right ventricle, causing **acute right-sided heart failure**, or produce a **subendocardial hematoma** within the interventricular septum, disrupting the conduction system and leading to **ventricular arrhythmias**. If the horse survives the initial crisis, it may present with signs of distress, thoracic pain, a rumbling continuous

murmur loudest on the right hemithorax and rapid heart rate due to ventricular tachycardia.

In middle-aged, multiparous mares, rupture of the **middle uterine artery** or its branches occurs in **late pregnancy** or the weeks **immediately after foaling**. These mares may be found suddenly dead, or be presented with signs of hemorrhagic shock and collapse. Location of the ruptured vessel at exploratory laparotomy is unlikely to be successful, thus surgery is not recommended. Supportive therapy, including blood transfusion, is indicated. The prognosis for life is guarded; some mares can recover, although their future breeding potential may be jeopardized.

INTRODUCTION

Diseases of the hemolymphatic system are generally due to abnormal quantity and/or function of the normal cellular and humoral components of blood. In order to understand fully hemolymphatic diseases, a basic knowledge of normal blood production (hematopoiesis) and the hemostatic mechanism is necessary.

HEMATOPOIESIS

During postnatal life, hematopoiesis occurs in the **bone marrow**. Maturation is attended by recession of hematopoiesis from the shafts of the long bones and

the replacement of red marrow by resting yellow marrow; however, active hematopoiesis continues throughout life in the epiphyses of long bones and in the flat bones of the skull, vertebrae, sternum, ribs and pelvis. Transition from yellow to red marrow can occur in response to increasing demand for erythrocytes via the glycoprotein hormone **erythropoietin** (*q.v.*).

The bone marrow is composed of differentiated blood cells and their recognizable precursors, undifferentiated progenitor cells, reticular cells, reticular fibers, endothelium-lined sinusoids and adipocytes. Hematopoiesis occurs in the **intrasinusoidal spaces**. All blood cells originate from a population of lymphoid-appearing cells, termed **pluripotent stem cells**, which give rise to committed progenitors of the lymphoid and myeloid series. Pluripotent stem cells (PPSC) are capable of slow self-renewal, whereas the committed progenitor cells differentiate into later stages and their absolute marrow numbers depend upon influx from the PPSC pool.

The amplification and differentiation of hematopoietic progenitors are regulated by polypeptide growth factors called **colony-stimulating factors**. Horse colony-stimulating factors have not been characterized but they are presumed to function similar to those described in humans.

Erythropoietin (Ep) is the most important erythropoietic growth factor. It is produced almost exclusively by the **kidneys** in response to **tissue hypoxia**. Committed erythroid stem cells become progressively more sensitive to Ep stimulation as they mature.

Under homeostatic conditions, marrow production of blood cells approximates the rate of cell destruction. The lifespans of equine erythrocytes and platelets are approximately 155 days and 7 days, respectively, and the circulating half-life of granulocytes is about 10.5 h. Increased use or peripheral loss of marrow-derived blood cells results in production amplification of the necessary component(s). **Complete marrow failure** initially causes enhanced susceptibility to infection due to the loss of granulocytes. Petechial hemorrhages and bleeding secondary to thrombocytopenia follow. Finally pallor and signs of anemia occur.

The **lymphoid stem cell** also arises from the PPSC, but lymphocyte precursor maturation and differentiation are considerably more complex than those of the other hematopoietic cells. Some of the developing lymphocytes are seeded into the thymus, where their maturation into T cells occurs. In mammals, B lymphocyte maturation proceeds in the bone marrow.

Although functionally distinct, T and B lymphocytes (*q.v.*) have a similar morphologic appearance. Circulating lymphocytes, most of which are T cells, are in transit to and from the secondary lymphoid organs where most lymphocyte interactions with antigenic challenge occur. The **spleen** constitutes the largest single mass of lymphocytes in the body. Lymphoid accumulations also occur in great abundance in **lymph nodes** and **near mucosal surfaces**.

The spleen functions only briefly in hematopoiesis during fetal life, but retains this potential into adult life. The unique architecture of the spleen and its fixed phagocytic cells bestow the important function of **filtering** from the blood aged or damaged cells, particulate debris and microorganisms. Hemoglobin from senescent erythrocytes is degraded and iron is stored within phagocytes until it is subsequently released into the plasma for reutilization during erythropoiesis. Splenic macrophages also perform a "pitting function"

by removing inclusions such as **Heinz bodies** (denatured hemoglobin) or intra-erythrocyte parasites from erythrocytes.

In horses, the spleen serves as an important **reservoir** for erythrocytes. Adrenaline-responsive smooth muscle in the equine splenic capsule causes the **packed cell volume** (PCV) to increase during exercise or excitement by as much as 40%. Normalization of red blood cell (RBC) parameters after a period of excitement may require up to 1 h in physically fit horses. The spleen also serves as a **dynamic reservoir of platelets** such that, at any point in time, up to one third of the total blood platelets are retained in the spleen.

HEMOSTASIS

Hemostasis is a complex series of events that functions to arrest bleeding from damaged blood vessels and to maintain blood flow to all body tissues. The processes of coagulation and fibrinolysis, with their respective inhibitors, constitute hemostasis.

Coagulation

The cooperation of platelets and blood procoagulant proteins with the blood vessel wall provides the basis for coagulation, which culminates in the formation of **fibrin**. Immediately after injury, reflex vasoconstriction limits blood loss and the **vessel wall** provides a scaffold for fibrin clot formation. Endothelial cells release substances that activate or inhibit components of coagulation and fibrinolysis.

Platelets interact with a discontinuous vascular surface to form a plug that provides **primary hemostasis**. Platelets adhere to subendothelial collagen and then undergo activation, aggregation and the release reaction. An initial platelet release of adenosine 5'-diphosphate (ADP) into the extracellular environment in response to adhesion promotes **primary aggregation**.

Secondary irreversible aggregation is a consequence of thromboxane (TXA₂) formation and secretion of platelet granule constituents. The phospholipid (PL) necessary at numerous steps during subsequent interaction of coagulant proteins is supplied by platelet factor 3. During and after platelet plug formation the platelet surface protects coagulant proteins from plasma anticoagulants and localizes clot formation. Platelets also prevent spontaneous hemorrhage into the skin and mucous membranes by maintaining "**vascular integrity**".

Coagulation proteins (or coagulation factors) circulate in the peripheral blood as inactive enzymes (**zymogens**). The coagulation "cascade" is a self-amplifying series of proteolytic events in which a zymogen is transformed to a proteinase that effects the subsequent zymogen–proteinase transition. There are two mechanisms by which activated factor X is formed, then coagulation proceeds through thrombin and fibrin production via a single common path.

In the extrinsic pathway, factor Xa is formed via the action of **tissue factor** (TF), which accesses the circulation via inflammation or tissue necrosis. Fibroblasts in the blood vessel adventitia express surface TF constitutively,

while vascular endothelial cells, tissue macrophages and blood monocytes are activated to produce TF by agonists such as **endotoxin** (*q.v.*).

The intrinsic pathway to factor Xa production is initiated when blood is exposed to a **negatively charged surface** such as the platelet plug and/or subendothelial collagen. Through association of the plasma protein factor XII (Hageman factor), prekallikrein and high molecular weight kininogen (HMWK), factor XIIa is formed which perpetuates the intrinsic cascade. Factor VIII generally circulates bound to von Willebrand factor (vWF) in an inactive form, but acquires procoagulant cofactor properties through limited proteolysis by thrombin or factor Xa.

Factor Xa forms a prothrombinase complex with factor Va, PL and Ca^{2+} , which cleaves prothrombin to thrombin. Thrombin dissolves from the PL surface and cleaves fibrinogen to yield fibrin monomers, which spontaneously polymerize. Thrombin activates factor XIII, which crosslinks fibrin and increases the clot's resistance to fibrinolysis.

Plasma **anticoagulant proteins** localize coagulation to the site of injury and thereby protect against **generalized thromboses**. One major anticoagulant mechanism involves antithrombin III (AT III), which accounts for approximately 75% of thrombin-inhibiting activity in plasma. AT III can also neutralize factors Xa, IXa, XIa and XIIa as well as kallikrein and plasmin. **Heparin** produces a conformational change in AT III that results in a 2000-fold acceleration of the latter's inhibitory action.

The second major plasma anticoagulant mechanism is provided by protein C, a liver-derived **vitamin K-dependent** protein that circulates as a zymogen. When thrombin is complexed to endothelial cell thrombomodulin, it activates protein C rather than its other substrates. Activated protein C (APC) cleaves and inactivates factors Va and VIIIa in the presence of Ca^{2+} and PL. This action by APC requires another vitamin K-dependent cofactor, protein S.

Fibrinolysis

Fibrinolysis is activated simultaneously with coagulation and functions to prevent tissue ischemia by the continued presence of fibrin clots. The key **fibrinolytic protein**, plasmin, is formed from circulating plasminogen by the action of several plasminogen activators. The tissue plasminogen activator (tPA) is synthesized primarily by endothelial cells, and both tPA and plasminogen have a high avidity for fibrin. Stasis upstream from an occluded vessel is the primary stimulus for tPA release, and the additional uptake of tPA by the clot tips the balance of hemostasis toward fibrinolysis.

To ensure localization of plasmin activities to the fibrin clot, there is an efficient array of plasma **antifibrinolytic proteins**. Plasminogen activator inhibitor (PAI) rapidly binds and inactivates physiologic concentrations of tPA. Endothelial cells are the primary source of this PAI, although the release of PAI from platelets during coagulation may play an important role in prevention of premature clot lysis.

The inhibition of plasmin activity in the blood is instantaneously carried out by α_2 -antiplasmin (AP). During coagulation, AP competes with plasminogen for binding to fibrin, preventing spontaneous lysis of a normal clot.

ANEMIA

Anemia can be functionally defined as **decreased oxygen-carrying capacity of the blood**. Anemia occurs when the PCV is reduced below that which is considered normal for the horse's age, breed and use. However, the PCV must be ≤ 0.30 L/L before an individual can be classed as anemic.

Anemia develops due to one or more of three pathophysiologic mechanisms:

1. Blood loss
2. Increased RBC destruction (hemolysis)
3. Decreased RBC production.

The bone marrow responds to blood loss and hemolysis by increased **erythropoiesis** (*q.v.*), thus the anemia is regenerative. A **non-regenerative anemia** ensues when the bone marrow does not replace senescent erythrocytes at a normal rate. A bone marrow examination (*q.v.*) is necessary to characterize accurately anemia in horses since peripheral signs of regeneration such as reticulocytosis and polychromasia rarely occur.

Clinical signs of anemia are due to reduced tissue oxygenation and include reduced exercise tolerance, depression, weakness, tachycardia, tachypnea and mucosal pallor. Signs are manifested at a higher RBC mass when anemia develops rapidly since a gradual onset of anemia allows physiologic compensation. A low-grade systolic murmur can sometimes be auscultated when the PCV drops below 0.15–0.18 L/L. Fever, icterus and/or pigmenturia often accompany hemolysis. Epistaxis, hematuria or melena may signal chronic blood loss. Anorexia, lethargy and weight loss suggest an underlying disease process.

LABORATORY EVALUATION

The initial laboratory assessment of anemia includes a **complete blood count (CBC)**, **total plasma protein (TPP)** and **plasma fibrinogen**. There are several unique features of the equine erythron that must be considered during evaluation of the CBC. A horse's PCV cannot be accurately assessed during or after exercise, excitement or endotoxemia since these produce splenic contraction. Splenic contraction in response to **acute hemorrhage** (*q.v.*) also precludes evaluation of the severity of blood loss for the first 12–24 h. Small nuclear remnants called **Howell-Jolly bodies** are occasionally found in erythrocytes of normal horses and do not indicate increased erythropoiesis.

Characterization of anemia as non-regenerative in a horse is most accurately done by **bone marrow examination**. Aspirates to characterize marrow erythropoiesis are most easily obtained from the **sternum** using an 89 mm, 18 G disposable spinal needle. Thin smears should be rapidly air dried, then stained with a modified Romanowsky (Wright) stain. The normal **myeloid-erythroid ratio (M/E)** ranges from 0.5 to 1.5 in horses, thus an $M/E \leq 0.5$ classifies anemia as regenerative.

Equine erythrocytes are small (5–6 μm) and tend to adhere to each other to form a "stack" like coins (**rouleaux**). Marked rouleaux may be confused with autoagglutination, and this tendency for natural aggregation leads to rapid

erythrocyte sedimentation from plasma. Equine plasma is normally quite yellow compared with that of other animals, due to the combined effects of blood carotenoids from green feed and the greater concentration of bilirubin. Fasting causes a marked increase in equine serum bilirubin and can result in **clinical icterus** (*q.v.*). There is no definitive explanation for **fasting-induced hyperbilirubinemia** in horses, but a net decrease in and/or competition for hepatic binding proteins (particularly ligandin) have been proposed. In consideration of hemolytic disease as a cause for icterus in horses, the influence of fasting must be determined.

Red cell morphology should always be evaluated as a routine part of the CBC. Precipitates of oxidized hemoglobin (**Heinz bodies**), parasites, or abnormal cell shape may aid in defining the cause of anemia. The RBC indices are not highly useful in horses since peripheral erythrocytes are nearly always mature. Hemolysis, *in vivo* or *in vitro*, causes an increased mean corpuscular hemoglobin (MCH) due to the presence of free plasma hemoglobin.

The **leukogram** and **plasma fibrinogen** are insensitive indicators of chronic inflammatory disease, which may be the cause of anemia. Chronic inflammation may be attended by a normal or only mildly elevated white blood cell (WBC) count in horses, while an intense erythropoietic response to anemia may result in neutrophilia. Both may cause a left shift.

Hyperfibrinogenemia is more indicative of the presence of inflammatory disease than the WBC count in up to 50% of affected horses. The TPP is useful in evaluation of hydration status, and may provide a clue to the cause for anemia. Reduced PCV in the presence of increased TPP, which may be due to hemoconcentration, suggests that the anemia is actually more severe than the PCV indicates. Mild anemia may be masked by dehydration in addition to splenic contraction. An increase in TPP due to **hypergammaglobulinemia** sometimes accompanies chronic infection. Reduction of both the TPP and the PCV is suggestive of **chronic blood loss**.

Generally, history, physical examination and baseline laboratory data allow categorization of the anemia as due to blood loss, hemolysis or inadequate erythropoiesis. Additional laboratory tests can then address the suspected cause for anemia. When more than one mechanism of anemia is suspected, a bone marrow examination (*q.v.*) is necessary to determine the presence or absence of erythroid regeneration.

Treatment

Identification and elimination of the cause, provision of nursing care, ensuring adequate tissue perfusion and minimizing stress are the basis for therapy of anemia in horses. **Blood transfusion** (*q.v.*) should be reserved for those instances in which oxygen delivery to tissues is inadequate to support life.

BLOOD LOSS ANEMIA

The clinical and laboratory findings of blood loss are largely determined by whether this occurs acutely, chronically, externally or internally. Common causes for **acute blood loss** in horses include trauma to the limbs,

post-castration hemorrhage, rupture of a uterine artery at parturition or erosion of the carotid artery by guttural pouch mycosis (*q.v.*). Hypovolemic shock (*q.v.*), characterized by tachycardia, tachypnea, hypothermia, pale and dry mucous membranes, prolonged capillary refill time, cold extremities and muscle weakness, generally develops when blood volume is reduced by more than 30%. Compensatory mechanisms are triggered immediately in an attempt to maintain circulating blood volume.

The spleen masks the extent of blood loss for several hours post hemorrhage by injection of a concentrated mass of stored erythrocytes into the circulation. Catecholamines induce vasoconstriction and increase cardiac output. Plasma volume is expanded by fluid resorption and retention in the vascular system, which continues at a decreasing rate for up to 72 h. A decline in the TPP can be measured within 4–6 h of the insult, but a reduction of the PCV is usually not appreciated until 12–24 h post hemorrhage.

Diagnosis of acute blood loss is based on history of recent hemorrhage, clinical signs and eventual development of anemia accompanied by hypoproteinemia. Hemothorax or hemoperitoneum (*q.v.*) must be documented by ultrasound examination or paracentesis and cytologic evidence of erythrophagocytosis

Treatment aims for acute blood loss are stopping the source of hemorrhage and maintaining circulatory blood volume. Rapid IV administration of **large volumes** (40–80 mL/kg) of sodium-containing isotonic crystalloid solution is necessary to control **hypovolemic shock** (*q.v.*). Preliminary data in horses suggest that smaller volumes of hypertonic saline (4–5 mL/kg 7.5% sodium chloride) may effectively reduce the pathophysiologic sequelae of experimental hemorrhagic shock; however, clinical studies are necessary to evaluate fully this therapy in horses. Hypertonic saline in the face of ongoing hemorrhage may be contraindicated.

Blood transfusion (*q.v.*) is indicated only when the erythrocyte mass is insufficient to maintain adequate tissue oxygenation. This occurs at a higher PCV if anemia develops rapidly. A PCV ≤ 0.20 L/L indicates that all erythrocyte reserves have been depleted; however, blood transfusion is unnecessary if the PCV stabilizes at 0.12–0.15 L/L. Relative renal hypoxia causes erythropoietin production that subsequently stimulates the bone marrow to begin replenishing erythrocytes within 4–6 days. The adult equine diet includes an excess of all necessary nutrients for erythropoiesis. Milk may contain insufficient iron. In general, iron-deficient states are extremely uncommon in horses and usually associated with chronic external blood loss. Anemia due to blood loss generally resolves within 4–12 wk.

Slow **chronic blood loss** allows the bone marrow to regenerate erythrocytes as they are lost. Anemia only develops once the rate of erythropoiesis is exceeded by the rate of hemorrhage. Gradual tissue hypoxia allows physiologic adaptation, thus clinical signs of anemia are generally masked until the PCV drops to ≤ 0.15 L/L.

Causes of chronic gastrointestinal blood loss include: parasitism (particularly large strongylosis); gastric or duodenal ulcers; non-steroidal anti-inflammatory drug (NSAID) toxicosis; and neoplasia (particularly gastric squamous cell carcinoma) (*q.v.*). Melena is rare. Because chemical tests for fecal occult blood are not highly specific, diagnosis of chronic gastrointestinal blood

loss should be supported by a high index of clinical suspicion and ruling out other sources of hemorrhage.

Blood loss from the **upper respiratory tract** is usually identified by **epistaxis** (*q.v.*). Guttural pouch mycosis, ethmoidal hematoma, fungal rhinitis and neoplasia (*q.v.*) are the most common causes for upper respiratory tract blood loss. Pulmonary bleeding subsequent to severe pneumonia, lung abscess or neoplasia is often occult and only recognized by finding **hemosiderin-laden macrophages** on cytology of a tracheal aspirate or bronchoalveolar lavage specimen (*q.v.*). Exercise-induced pulmonary hemorrhage does not result in anemia. Urogenital neoplasia or vascular anomalies (*q.v.*) may rarely induce chronic blood loss anemia via hematuria, which may be microscopic.

Blood loss anemia can develop due to **hemostatic dysfunction**. Severe coagulation factor deficiencies such as warfarin toxicosis, hemophilia A and other heritable coagulopathies (*q.v.*) generally induce clinically recognizable hemorrhage into joints or other body cavities. **Acute hemorrhage** may follow trauma or surgery. Thrombocytopenia and/or more complex coagulation disorders such as disseminated intravascular coagulation (DIC) (*q.v.*) may be associated with chronic anemia due to mucosal petechial and ecchymotic hemorrhages, epistaxis and occult blood loss from the bowel and urinary tract.

Treatment of chronic blood loss anemia includes identification and treatment of the primary disease process. Chronic external blood loss may lead to iron deficiency (*q.v.*) especially in foals, which have comparatively low body iron stores.

HEMOLYTIC ANEMIA

Hemolytic anemia is associated with **erythrocyte destruction** that exceeds the rate of normal bone marrow erythropoiesis. Intravascular hemolysis occurs in some disease processes, but hemolytic anemia is usually due to extravascular erythrocyte destruction and shortened intravascular lifespan.

Clinical manifestations of hemolysis vary with the rate of development and severity of anemia, as well as the underlying disease process. Clear hematologic evidence of anemia exists when **icterus** is caused by hemolysis. Acute intravascular hemolysis produces hemoglobinemia and hemoglobinuria, manifested as pink plasma and reddish-brown urine, respectively (*q.v.*). Constant or intermittent fever is not uncommon due to underlying infections or active erythrocyte destruction.

There are numerous causes and mechanisms for hemolytic anemia (Table 9.1), which is regenerative anemia without hypoproteinemia. Intensified erythropoiesis is often associated with neutrophilia and regenerative left shift. Total and indirect bilirubin concentrations may be elevated. Other laboratory findings are determined by the cause of the anemia (Table 9.1). In addition to a CBC, TPP and serum bilirubin, the diagnostic evaluation of suspected hemolytic anemia should include thorough blood smear examination, urinalysis, Coombs test and Coggins test (*q.v.*).

Treatment of hemolytic anemia is aimed at the **primary disease process** whenever possible. Massive hemolysis may warrant transfusion with blood, packed red cells or polymerized hemoglobin (*q.v.*).

Table 9.1 Causes of hemolytic anemia

Causes	Diagnosis
Immune-mediated	
Neonatal isoerythrolysis	Hemolytic cross-match
Equine infectious anemia	Coggins test
Autoimmune hemolytic anemia	Coombs test
Secondary immune-mediated anemia (drugs, infection, neoplasia)	History, signs, Coombs test
Incompatible blood transfusion	History, cross-match
Oxidant-induced	
Phenothiazine toxicosis	History, Heinz bodies on blood smear
Onion toxicosis	History, odor, Heinz bodies on blood smear
Red maple leaf toxicosis	History, methemoglobinemia, Heinz bodies on blood smear
Parasitic	
Babesiosis (equine piroplasmosis)	Complement fixation (CF) test
Microangiopathic	
Disseminated intravascular coagulation	Thrombocytopenia and prolonged prothrombin time and/or activated partial thromboplastin time
Acute hepatic failure?	Liver enzymes, biopsy

IMMUNE-MEDIATED HEMOLYTIC ANEMIA

Antibodies bound to the surface of erythrocytes result in hemolysis. Erythrocytes coated with immunoglobulins or immune complexes are generally removed from the circulation by tissue-fixed macrophages in the spleen, liver and bone marrow (mononuclear phagocyte system, MPS). **Complement-mediated intravascular hemolysis** may occur if sensitizing antibodies are IgM or complement-activating IgG. Immune-mediated hemolysis may be primary (e.g. neonatal isoerythrolysis, transfusion reactions, *q.v.*) or secondary to infections, drugs or neoplasia.

Neonatal isoerythrolysis

Neonatal isoerythrolysis (NI) (*q.v.*) is a hemolytic syndrome in newborn foals mediated by maternal antibodies against foal erythrocytes (alloantibodies) absorbed from the colostrum. The disease most often affects foals of multiparous dams.

Clinical signs and laboratory findings

Foals with NI are born clinically normal but subsequently develop depression, weakness and a reduced suckle response at 12–72 h. The rate and severity of disease are determined by the quantity and activity of absorbed alloantibodies. Affected foals have tachycardia, tachypnea and dyspnea. The oral mucosae are initially pale, then, in foals that survive 24–48 h, become icteric. Hemoglobinuria is rare. Cerebral hypoxia may induce seizures as a preterminal event. Laboratory findings include anemia and hyperbilirubinemia.

Metabolic acidosis and azotemia eventually develop due to tissue hypoxia and the nephrotoxic effects of hemoglobin.

Etiology and pathology

In development of natural NI, the foal inherits from the sire and expresses an **erythrocyte antigen** (alloantigen) (*q.v.*) that is not possessed by the dam. **Blood group incompatibility** between the foal and dam is common but most alloantigens are weak immunogens under the conditions of exposure through parturition or placental leakage. However, factors Aa of the A system and Qa of the Q system are **highly immunogenic**, and antibodies to these induce approximately 90% cases of NI. Mares that are negative for Aa and/or Qa (approximately 19% and 17% of Thoroughbred and Standardbred mares, respectively) are at greatest risk of producing a foal with NI. There are reports of other inducing antigens, including Ab, Qb, Qrs, Qc, Db, Dq, Dc, Da, Ka, Pa and Ua.

Not all mares become sensitized to the incompatible alloantigen of their foals. This generally requires **transplacental hemorrhage** during a previous pregnancy with a foal possessing the same incompatible blood factor. An **anamnesic response** is usually necessary to induce a pathogenic quantity of alloantibodies. Ten per cent of Thoroughbred mares and 20% of Standardbred mares have “natural” antibodies to the Ca blood group antigen. Data suggest that these “natural” antibodies may suppress an immune response to other alloantigens since Aa-negative mares that have anti-Ca antibodies often do not produce antibodies to Aa of their foal’s erythrocytes if the latter also contain Ca antigen. Natural alloantibodies have not been associated with NI in horses.

Alloantibodies of sensitized mares are concentrated in the colostrum during the last month of gestation. The foal is normal at birth, since the mare’s complex epitheliochorial placentation does not allow in utero antibody transfer. Thus the final criterion for foal development of NI is **ingestion of colostrum** containing alloantibodies specific for foal alloantigens in the first 24 h of life. Ig-coated foal erythrocytes are rapidly removed from circulation by the MPS or lysed intravascularly via complement. Alloantibodies to Aa are potent hemolysins and generally cause a more severe clinical syndrome than other alloantibodies. Primiparous mares may be predisposed to NI by blood transfusion or other exposure to equine blood products.

Diagnosis

Lethargy, anemia and icterus during the first four days of life suggest the diagnosis of NI. Blood loss anemia is attended by pallor, and icterus due to sepsis or liver dysfunction is not associated with anemia. The definitive diagnosis of NI is based upon **demonstration of alloantibodies** in the dam’s serum or colostrum that are directed against foal erythrocytes. The hemolytic crossmatch between washed foal erythrocytes and mare serum with an exogenous source of absorbed complement (usually from rabbits) is the most reliable diagnostic test for NI. A number of qualified laboratories routinely perform this diagnostic service. Because some equine alloantibodies act only as hemolysins, agglutination tests may be falsely negative. The jaundiced foal agglutination (JFA) test between colostrum and EDTA-anticoagulated foal blood is a rapid screen for anti-red blood cell antibodies. False negatives may occur; however, if positive, this test may be used to determine when the colostrum is safe for the foal to nurse.

Treatment

The dam's milk must be withheld during the first 24 h of life and the foal should be fed from an **alternate milk source**. A minimum volume of milk equivalent to 1% of the foal's body weight should be fed every 2 h (e.g. a 50 kg foal should receive 500 mL of mare milk replacer q 2 h). The dam's udder should be **stripped** regularly (<q 4 h) and the milk discarded. In most instances, NI is not apparent until the foal is >24 h of age when colostral antibodies have been depleted and/or the intestinal absorptive capacity for Ig has diminished. Withholding milk at this point is of minimal benefit.

Supportive care is paramount. Affected foals should not be stressed and exercise must be restricted to a box stall. IV fluids may be indicated to minimize the nephrotoxic effects of hemoglobin as well as to correct any fluid deficits and electrolyte/acid-base imbalances. Antimicrobials may be necessary to prevent secondary infections.

When a foal's PCV drops to ≤ 0.12 L/L, **blood transfusion** (*q.v.*) is warranted to prevent life-threatening cerebral hypoxia. Severe weakness, tachypnea and tachycardia indicate the need for transfusion, even at higher PCVs. Although erythrocytes from the dam are compatible with the foal, they must be **washed free of plasma** in order to prevent administration of additional harmful alloantibodies. Repeated centrifugation with replacement of plasma by saline is necessary to ensure clean packed RBCs. Since most field conditions do not allow safe utilization of dam erythrocytes, **blood-typed individuals** negative for Aa and Qa and free of alloantibodies are optimal donors.

The odds of finding a donor without Aa and/or Qa are higher in Quarter Horses, Morgans and Standardbreds than in Thoroughbreds and Arabians. If an untested donor must be used, a **gelding** with no prior history of blood transfusion is best. Two to four liters of blood or 1–2 L of packed erythrocytes should be given over a 2–4 h period. These allogeneic cells have a very short lifespan and represent a burden to the neonatal MPS that may increase susceptibility to infection. In addition, these cells sensitize the foal to future transfusion reactions. Potential harm must be measured against the benefit in each particular situation.

Recently, bovine polymerized hemoglobin (Oxyglobin) has been used to save foals suffering from severe hypoxemia, prior to identification of an appropriate red cell donor. This ultrapurified hemoglobin improves oxygen-carrying capacity of the blood, but the half-life is likely to be <48 h. The recommended dose is 7.5 mL/kg (3×125 mL bags for a 50 kg foal).

Prognosis and prevention

The prognosis for NI in foals depends on the quantity and activity of absorbed antibodies and is indirectly proportional to the rate of onset of signs. Like most diseases, NI is much more effectively prevented than treated. Foals from any mare that previously produced a foal with NI should be provided with an alternate colostral source unless the sire has known blood type compatibility with the dam. Mares at risk of producing affected foals (negative for Aa and Qa alloantigens) may be identified by **blood typing** (*q.v.*). Stallions negative for Aa/Qa and suitable on the basis of other criteria may be difficult to identify. It is most reasonable to breed "at-risk" mares as desired then to screen their

serum in **the last month of pregnancy** for the presence of alloantibodies. If alloantibodies (other than those to Ca) are detected, dam colostrum should be withheld and the foal provided with an alternative colostrum source. The JFA test has been used to determine when it is safe for the foal to nurse.

Autoimmune hemolytic anemia

Autoimmune hemolytic anemia (AIHA) (*q.v.*) occurs when an individual forms antibodies that bind to its own erythrocytes. **Primary AIHA** is an idiopathic process wherein there is failure to recognize erythrocytes as self. AIHA may arise secondary to infections, drugs or neoplasia and is then referred to as **immune-mediated hemolytic disease**. Both types result in MPS destruction of erythrocytes with or without intravascular hemolysis. AIHA is uncommon in horses but can affect any age, sex or breed.

Clinical signs and laboratory findings

Affected horses have variably severe depression and/or exercise intolerance. Tachypnea and tachycardia are generally present and worsen with exercise. Fever depends on the severity of hemolysis as well as any concomitant disease. Mucous membranes may be moderately icteric. Pigmenturia is uncommon.

Rarely in AIHA, erythrocytes in a blood sample grossly agglutinate. Immune-mediated erythrocyte aggregation persists when the anticoagulated blood is diluted 1:2 in isotonic saline, whereas false autoagglutination due to severe inflammatory disease is easily dispersed. Since equine erythrocytes are small, spherocytosis is rare. Neutrophilic leukocytosis is common subsequent to bone marrow regeneration. **Intravascular hemolysis** causes pink plasma, increased MCH and pigmenturia. **Indirect hyperbilirubinemia** is common.

Etiology and pathogenesis

True autoimmunity results when B lymphocyte cell clones become abnormally reactive and fail to recognize “self”. Dysfunction of T suppressor cells or increased activity of helper T cells may have a role. **Secondary AIHA** is often caused by immune complexes that bind to erythrocyte membranes and mediate extravascular hemolysis. In other situations the erythrocyte membrane is altered by the primary disease process and is then no longer recognized as “self”. Finally, antigenic stimulation of the immune system may result in antibodies that cross-react with normal erythrocytes. Secondary AIHA has been described in horses with equine infectious anemia (EIA), *Clostridium perfringens* infection, injection site abscesses, lymphosarcoma, other internal neoplasia, protein-losing enteropathy, purpura hemorrhagica, and penicillin therapy (*q.v.*).

Diagnosis

Definitive diagnosis of AIHA is based upon demonstration of patient antibodies that react with their erythrocytes. Autoagglutination is diagnostic of AIHA provided false agglutination is excluded. If true autoagglutination is not evident, diagnosis is most accurately made by agglutination in a **direct antiglobulin (Coombs) test** (*q.v.*), performed by incubating washed patient

erythrocytes with appropriate dilutions of antiserum to equine IgG, IgM and complement components. A false negative Coombs test may occur immediately following a hemolytic crisis, or when corticosteroid therapy has been initiated. The **osmotic fragility test** should not be used for definitive diagnosis of AIHA, since positive results occur during other diseases that compromise erythrocyte membrane function (e.g. oxidative insult).

Horses with AIHA should have a thorough diagnostic work-up in search of neoplasia and a Coggins test for EIA (*q.v.*).

Treatment

Any current medication should be immediately discontinued in an attempt to exclude the possibility of **drug-associated AIHA**. Necessary antimicrobials are replaced by the most chemically dissimilar substitute (e.g. do not replace penicillin with ampicillin). Horses with severe AIHA require **corticosteroid therapy**. All beneficial actions of corticosteroids are unknown, but they will reduce erythrocyte clearance by the MPS and impair autoantibody production. **Dexamethasone** (0.05–0.2 mg/kg, IV or IM once daily) seems to be most effective for initial therapy of equine AIHA. If the PCV does not stabilize within 24–48 h, the dose rate of dexamethasone should be increased to twice daily. The full effect of corticosteroid therapy often requires 4–7 days and blood transfusion may be necessary in the interim. Corticosteroids may worsen a primary infectious process and cause recrudescence of viremia in horses with chronic EIA.

Once the PCV stabilizes at >0.20 L/L, the dose of dexamethasone can be decreased 10% every 24–48 h while carefully monitoring for relapse. When the dose of necessary dexamethasone is ≤ 0.04 mg/kg daily, therapy can safely be given orally. Corticosteroids should be tapered as soon as possible to the lowest necessary dose and given on alternate days for 1 wk before discontinuation. Dexamethasone can be discontinued when the PCV remains stable during therapy with 0.01 mg/kg q 24–48 h. Prednisolone or prednisone can be used in lieu of dexamethasone (approximately seven times greater dose given q 12 h); however, these are erratically absorbed after oral administration.

Horses that fail to respond to corticosteroids may be treated concomitantly with oral **azathioprine** at a dose of 2 mg/kg/day. Positive results are anecdotal. Blood transfusions are avoided unless absolutely necessary, since the transfused cells are often rapidly lysed by circulating antibodies. When anemia is life threatening, Oxyglobin therapy may be preferable (*q.v.*).

Prognosis and prevention

Some cases of AIHA require treatment for several weeks then recover; horses that require constant corticosteroid therapy are often found to have incurable underlying disease (e.g. lymphosarcoma, *q.v.*).

Equine infectious anemia

Equine infectious anemia (EIA) (*q.v.*) is a multisystemic retroviral disease of Equidae, characterized by **immune-mediated hemolytic anemia**. Horses of all types are affected, but the disease is most prevalent in the southeastern

USA. Because of its importance, EIA will be briefly considered separately from other causes of AIHA.

Clinical signs and laboratory findings

Three forms of clinical disease have been described: acute, subacute to chronic, and chronic inapparent. Clinical signs of acute EIA occur 7–30 days after first exposure to the virus and include fever, depression, anorexia and mucosal petechial hemorrhages. Anemia is not seen at this stage. Horses that have been infected for more than 30 days show the more classic clinical signs of EIA, which include anemia, icterus, edema of the limbs and ventral abdomen, intermittent fever spikes and weight loss. Less common clinical signs are colic, ataxia, abortion and infertility. Deaths usually occur during this subacute to chronic form of the disease.

Most horses recover, but experience **unpredictable periodic flare-ups** of clinical disease. Severe environmental or management stresses and treatment with corticosteroids are known to **induce recrudescence** of EIA. A large number of EIA-infected horses do not show clinical signs. Although only detected by serology, these animals remain **virus carriers** and are a potential source of infection for other horses.

During acute EIA, **thrombocytopenia** is the first and most consistent laboratory finding. **Leukopenia** is often present with mild lymphocytosis and monocytosis. During the subacute to chronic stages of disease, the PCV and RBC count are reduced, with other laboratory indications of hemolysis. The Coombs test is often positive. Hypergammaglobulinemia, increased liver enzymes and proteinuria may develop. Chronic inapparent carriers and chronically infected horses between clinical flare-ups are hematologically normal.

Etiology and pathogenesis

The causative agent of EIA is a high molecular weight, non-oncogenic lentivirus of the retrovirus family. There is wide genetic variation of the antigenic properties of the viral envelope and there is drift, which interferes with development of protective immunity. Viremia is maintained persistently in infected horses, despite a detectable immune response.

The EIA virus is usually transmitted by **blood** from affected horses, although other body secretions could serve as source of infection. **Natural transmission** occurs through the interrupted feeding of horse flies (*Tabanus* spp.) and deer flies (*Chrysops* spp.). Horses showing clinical signs of EIA have a higher viremia and are much more likely to transmit disease than are inapparent carriers. In utero transmission of the EIA virus is possible.

The EIA virus multiplies in macrophages throughout the body and elaborates viral proteins that stimulate humoral and cell-mediated immune responses. Acute disease is associated with **massive virus replication** and destruction of macrophages. The incubation period before clinical signs is usually 1–3 wk, but may be as long as 3 mo. A detectable serologic response is generally attained 2–6 wk after infection and positive serology persists indefinitely.

Signs of subacute-chronic EIA result from virus-induced immunologically mediated tissue damage. Immune complex attachment to erythrocytes via the viral hemagglutinin produces hemolysis. Resultant anemia is worsened by

decreased bone marrow erythropoiesis. Periodic disease flare-ups are due to the immune response to viral antigenic drift.

Diagnosis

The **Coggins test** (*q.v.*), an agar gel immunodiffusion procedure that detects serum antibodies against the EIA virus, is the “gold standard” for confirmation of the disease. Newer ELISA based assays are more sensitive, but have lower specificity. The Coggins test may be falsely negative during acute EIA and false positives occur in foals that have absorbed colostrum from infected dams. Both drawbacks can be overcome by repeated testing.

Treatment

No treatment eliminates EIA virus from the body. **Supportive care** may aid clinical recovery; however, the horse is subject to other clinical episodes of EIA and remains a source of infection.

Prognosis

The prognosis for cure of EIA is poor. Even a horse with inapparent EIA may eventually develop the subacute form. Due to its potential to infect other horses, any horse with a positive Coggins test should be humanely destroyed, unless it can be strictly separated from all other Equidae. Before new horses are introduced to a herd, they should be seronegative for EIA on two tests, separated by 30 days.

OXIDANT-INDUCED HEMOLYTIC ANEMIA

The ingestion of some oxidizing agents causes hemoglobin denaturation by disulfide bond formation between sulfhydryl groups. **Oxidized hemoglobin** subsequently precipitates onto erythrocyte membranes as small aggregates termed **Heinz bodies**. Erythrocytes containing Heinz bodies are more prone to osmotic lysis and are readily removed by the MPS. Certain oxidants transform hemoglobin iron from the ferrous to the ferric state (methemoglobin), which does not transport oxygen. The administration of **phenothiazine** and the ingestion of **onions** or **wilted red maple leaves** have been associated with Heinz body hemolytic anemia (HBHA) in horses. There is generally a history of relevant exposure.

Clinical signs and laboratory findings

Clinical signs of depression, weakness, anorexia, tachycardia and tachypnea are typical. Affected horses are generally icteric. Red maple leaf toxicosis causes brownish discoloration of mucous membranes due to methemoglobinemia. Oliguria and pigmenturia (*q.v.*) are common.

In addition to the reduced PCV and RBC count, hematology often shows increased MCH due to hemoglobinemia. Heinz bodies may appear in blood smears as pale bleb-like projections from erythrocyte membranes; however, they are best visualized with **new methylene blue** stain. Urine is usually positive for blood and protein, plasma creatinine is often elevated and there is

indirect hyperbilirubinemia. Horses with red maple leaf toxicosis may also have brownish discoloration of blood and urine by methemoglobin.

Etiology and pathogenesis

An oxidant metabolite of **phenothiazine** (phenothiazine disulfide) causes HBHA in horses given toxic doses and those with an idiosyncratic sensitivity to the drug. Phenothiazine toxicosis is very uncommon due to its low rate of current usage, however horses with access to ruminant supplements or salt-blocks that contain phenothiazine are at risk. Wild or domestic **onions**, which contain the oxidant allyl propyl disulfide, can cause HBHA but the amount of onions required is rarely voluntarily ingested by horses. Diagnosis is based on the distinct onion odor of breath, urine and feces.

The most common cause of HBHA in horses is **red maple leaf toxicosis**. Horses in the eastern USA grazing areas inhabited by red maple trees (*Acer rubrum*) during the summer and autumn are affected. The syndrome can be reproduced by administration of dried, but not viable, red maple leaves. Affected horses develop marked methemoglobinemia in addition to other signs of acute hemolytic anemia. **Neurologic signs** due to CNS hypoxia and death are common.

Exogenous oxidants produce disease by overwhelming the natural erythrocyte reducing system that protects hemoglobin from the oxygen it carries. Intra-erythrocytic reductive capacity is relatively poor in horses. It is not clear why an oxidant will induce HBHA, methemoglobinemia or both. Both oxidative insults are additive in terms of reduced oxygenation of the tissues, and clinical signs of red maple toxicosis are typically more severe than would be suggested by the erythron data. Hemoglobinuria subsequent to IV hemolysis may cause acute renal failure, due to pigment-induced hemodynamic renal ischemia. Associated **renal pathology** may be the limiting factor for recovery in some cases of HBHA.

Diagnosis

The diagnosis of HBHA is based upon history of oxidant exposure, typical clinical signs and the presence of Heinz bodies in the peripheral blood. Heinz bodies are most easily identified on a wet-mount blood film, prepared by mixing one drop of new methylene blue stain with one drop of blood on a glass slide, topped with a cover slip. Heinz bodies appear as bluish-green, refractile granules located near the red cell margin. Chocolate-brown and brownish mucous membranes strongly suggest red maple leaf toxicosis.

Treatment

The horse should be removed from access to the oxidant and housed to minimize stress and exercise. Mineral oil and activated charcoal via nasogastric tube may be helpful if an acute case is identified. The PCV and clinical signs must be monitored closely for development of life-threatening anemia. IV therapy with **isotonic balanced crystalloid solutions** (80–100 mL/kg/24 h) is paramount to ensure hydration and minimize pigment nephrosis. Methylene blue or other reductive therapy is relatively ineffective in horses and may even enhance Heinz body formation. Purified bovine hemoglobin (Oxyglobin) may provide temporary oxygenation of the blood in an acute hemolytic crisis.

Prognosis is determined by the amount of oxidant ingested and its innate activity. Red maple leaf toxicosis carries a poor prognosis, especially when methemoglobinuria is present. Prevention is based on limiting access.

PARASITE-INDUCED HEMOLYTIC ANEMIA

Babesiosis (equine **piroplasmosis** *q.v.*) is the only intra-erythrocytic parasitic disease of horses. It is widely distributed throughout tropical and subtropical areas and to a lesser extent in temperate regions, corresponding to the habitat of natural tick vectors. Affected horses generally have recently traveled to endemic areas, which include parts of Florida, Texas, Mexico, Cuba, Central and South America, and eastern and southern Europe, Asia, Africa, the Middle East and Russia.

Clinical signs and laboratory findings

Clinical disease generally develops 5–28 days after susceptible horses are placed in an endemic area. Signs include fever, depression, anorexia, weakness, ataxia, labored breathing, chemosis, mucosal petechial hemorrhages, icterus and hemoglobinuria. Death may occur within 48 h or intermittent fever and anemia may persist for months. Horses raised in endemic areas often carry *Babesia* without showing signs.

Laboratory data are consistent with hemolytic anemia. Parasitized erythrocytes may be seen on **blood smears** during the **febrile period** but are often absent in the hemolytic crisis. *Babesia* appear as pyriform bodies in groups of two to four with their pointed ends meeting at an acute angle. Intravascular hemolysis and pigment nephropathy may ensue.

Etiology and pathogenesis

Horses are susceptible to infection with the protozoa *Babesia caballi* and *B. equi* (phylum Apicom). Only *B. caballi* is diagnosed in the USA. Natural transmission of *Babesia* spp. occurs via **ticks**, although they may be transmitted mechanically. *Dermacentor nitens*, a tick permanently established in areas where the temperature remains above 16°C (60°F), is the primary vector for *B. caballi*, which can be passed transovarially through tick generations. *B. equi* is only transmitted horizontally (trans-stadially) by species of *Dermacentor*, *Hyalomma* and *Rhipicephalus*. Intrauterine infection can occur.

Babesia spp. multiply and develop within **host erythrocytes**. Most parasitized erythrocytes are removed via the MPS; however, IV hemolysis can occur. Clinical disease associated with *B. equi* infection is much **more severe** than that caused by *B. caballi* and the mortality rate is higher. Horses that survive clinical babesiosis remain **inapparent carriers** unless treated. Foals born in endemic areas are believed to experience subclinical infection as maternal immunity is waning and develop strong active immunity dependent upon the constant presence of the organism (**premunit**). **Stress**, such as transportation or competition, can induce clinical disease in carrier horses.

Diagnosis

Definitive diagnosis of babesiosis relies upon blood smear demonstration of parasitized erythrocytes or positive serology. However, since brief parasitemia

precedes hemolysis, **diagnosis is best made serologically**. Antibodies to *Babesia* spp. are detectable within 14 days of infection. **The indirect fluorescent antibody test** can differentiate between *B. equi* and *B. caballi*. **Polymerase chain reaction (PCR) tests** are available in some areas, but not totally validated. Appropriate authorities should be contacted prior to collection of samples for diagnosis. Samples must be sent under secure conditions to authorized labs, since *B. equi* has been implicated in human disease.

Treatment

Imidocarb dipropionate depresses parasitemia and usually eradicates *B. caballi* infection (2.2 mg/kg q 24 h \times 2). *B. equi* is much more resistant, and imidocarb therapy (4 mg/kg q 72 h \times 4) is only 50–60% effective in eliminating infection, particularly of eastern European origin. Imidocarb is a toxic drug and should be used with care. It may cause colic, hypersalivation, diarrhea and/or death. Donkeys often die if given high-dose imidocarb. Supportive care should include rest, IV fluids and NSAIDs. Ketoconazole and clotrimazole have in vitro activity against *Babesia* and may have future therapeutic value.

Prognosis

The prognosis for *B. caballi* infection is fair to good with imidocarb treatment. Prognosis for *B. equi* infection is variable. Disease transmission can be minimized by tick control and sanitary veterinary practices. Identified carrier horses in non-endemic areas should be quarantined until they are effectively treated.

MICROANGIOPATHIC HEMOLYSIS

Thrombosis and/or fibrinoid change within the lumen of small blood vessels can cause damage and lysis of erythrocytes. This microangiopathic hemolytic disease is a characteristic of chronic **disseminated intravascular coagulation** (DIC) and has been reported in horses. Usually hemolysis is mild and any anemia is due to blood loss.

Fulminant intravascular hemolysis has been reported in horses with **terminal liver failure** and DIC. Pathogenic alterations in red cell membrane lipoproteins and metabolism have been suggested in the pathogenesis.

ANEMIA DUE TO INADEQUATE ERYTHROPOIESIS

When the rate of erythropoiesis is inadequate to replenish aged erythrocytes, anemia ensues. This non-regenerative anemia can be caused by:

1. Deficiency of substances essential for erythrocyte production
2. Diseases that interfere with erythropoiesis
3. Conditions that damage normal bone marrow elements.

Anemia solely due to inadequate erythropoiesis develops slowly because equine erythrocytes have a long lifespan. Depressed erythropoiesis associated with blood loss or hemolysis produces a life-threatening anemia. Definitive classification of anemia as non-regenerative requires **bone marrow evaluation** (*q.v.*).

Iron deficiency anemia

Iron deficiency anemia is extremely rare in horses and only develops when the rate of iron loss from the body exceeds the absorption of iron from the diet. Milk is particularly low, while soil and legumes are high in iron. Iron deficiency is usually associated with chronic external blood loss.

Clinical signs and laboratory findings

Clinical signs of iron deficiency do not differ from those of chronic blood loss. Serum iron and percentage saturation of transferrin decrease while the total iron binding capacity increases. Hypoproteinemia is common. Iron deficiency eventually induces **microcytic hypochromic anemia**.

Etiology and pathogenesis

Ulcerative gastrointestinal lesions, such as those induced by NSAID toxicosis and neoplasia (*q.v.*), result in chronic external blood loss. Iron deficiency anemia is particularly prevalent in horses with **gastric squamous cell carcinoma** (*q.v.*). Iron deficiency results in an erythrocyte maturation arrest in the bone marrow. Late rubricytes awaiting hemoglobin synthesis may undergo cell division, but they produce erythrocytes that are smaller than normal and deficient in hemoglobin with a shortened lifespan.

Diagnosis

Serum concentrations of **ferritin**, an intracellular iron storage protein, <45 ng/mL are suggestive of iron deficiency in horses. The presence of bone marrow iron specifically eliminates iron deficiency as the cause for anemia.

Treatment

Therapy should be aimed at identification and correction of the primary disease. Parenteral iron solutions can cause **anaphylactoid reactions** (*q.v.*), thus only oral iron supplementation is safe.

Prognosis

The prognosis depends upon the cause of chronic blood loss. Iron deficiency anemia is reversible.

Anemia of inflammatory disease

Anemia of inflammatory disease (AID) is the **most common anemia** in horses. Clinical signs are usually ascribed to the primary disease process. Hematology reveals a mild non-responsive anemia (PCV 0.23–0.20 L/L) with neutrophilic leukocytosis, hyperfibrinogenemia and/or hypergammaglobulinemia. Serum iron is usually decreased and serum ferritin is increased.

Pneumonia, pleuritis, peritonitis, internal abscesses and neoplasia (*q.v.*) are the most common underlying disorders. The AID develops because the **bone marrow** fails to compensate for a modest decrease in circulating erythrocyte

lifespan. Impaired erythropoiesis is due to altered iron metabolism and sequestration by cells of the MPS. Interleukin 1, tumor necrosis factor and other cytokines released in the “acute phase” response to infection may have a role in inhibition of erythropoiesis.

The presence of **non-responsive anemia** in the face of clinical and laboratory evidence of chronic disease is generally suggestive of AID. Therapeutic efforts should be aimed at the **underlying disease**, which determines prognosis.

Anemia associated with renal disease

A defective marrow response to erythropoietin in combination with reduced erythrocyte longevity accounts for the anemia of renal disease. Therapy must be aimed at the renal disease (*q.v.*); prognosis is poor.

Myelophthistic anemia

Myelophthistic anemia is due to destruction of the normal marrow habitat by neoplastic or inflammatory tissue. The net result is **pancytopenia**. Because of the shorter half-life of granulocytes and platelets, bleeding and infections generally precede anemia, which is exemplified by lethargy, anorexia and mucosal pallor. Hematology reveals severe neutropenia and thrombocytopenia in addition to non-responsive anemia.

Myelophthistic anemia has been described in horses with several types of **myeloid neoplasia** (*q.v.*), wherein a marrow-derived blood cell proliferates at the expense of all others. Myelophthistic disease could also result from metastasis of neoplasia to the bone marrow, although this is exceedingly rare in horses. Diagnosis is confirmed by documenting the proliferation of atypical cells by **bone marrow examination**. Occasionally, abnormal cells are found in the peripheral blood. Blood transfusions are only palliative and hematopoietic neoplasia is considered fatal in horses.

Bone marrow aplasia

Bone marrow aplasia (**aplastic anemia**) is caused by failure of stem cells to differentiate because of intrinsic damage or due to interruption of their interactions with supporting cells that constitute the microenvironment. The net result is marrow hypoplasia associated with pancytopenia. Aplastic anemia is very uncommon in horses and generally is an acquired disorder. Rare cases have been associated with phenylbutazone.

Clinical signs and laboratory findings

The clinical features of aplastic anemia are similar to those accompanying myelophthistic disease. **Hemorrhagic diathesis** secondary to thrombocytopenia (e.g. epistaxis, mucosal petechial hemorrhages, or prolonged hemorrhage following injections) is often the first indication of disease. Neutropenia causes increased susceptibility to infections and intermittent fever, weight loss and exercise intolerance ensue. Neutropenia, monocytopenia and

thrombocytopenia occur first, followed by severe anemia. Blood loss often hastens the development of anemia and some cases may have a positive Coombs test. **Absolute lymphopenia** is not uncommon.

Etiology and pathogenesis

The cause for marrow aplasia cannot be proven in most instances. A diverse array of chemicals, drugs, ionizing radiation, viral infections, bacterial toxins and immune-mediated diseases have been implicated. Regardless of the exact cause, pluripotent stem cells (*q.v.*) fail to differentiate in aplastic anemia. Immunologic rejection of stem cells probably plays a role.

Diagnosis

The diagnosis of aplastic anemia is based upon **peripheral pancytopenia** and **fatty bone marrow** with essentially empty stroma. Because sternal bone marrow aspirates are frequently contaminated by peripheral blood, a **core marrow biopsy** (*q.v.*) from the rib or ileal wing should be examined histologically. Benign lymphoid nodules may create confusion with lymphosarcoma (*q.v.*). Biopsies from at least two sites are necessary to substantiate definitively marrow failure.

Treatment

Treatment includes removing the horse from any possible causative drugs, chemicals or environmental toxins and providing supportive care until spontaneous remission occurs. Early, **intense broad-spectrum antimicrobial therapy** should be instituted.

Immunosuppressive drugs or myelostimulatory androgens have produced discouraging results in humans with marrow aplasia and are largely unproven in horses. The treatment of choice for human aplastic anemia is bone marrow transplantation, which is an unlikely treatment option in horses. Blood or platelet transfusions only provide temporary relief. Use of human erythropoietin may ultimately cause red cell aplasia in horses, since it causes the production of antibodies that cross-react with the equine erythropoietin.

Prognosis

Too few horses with aplastic anemia have been studied to give a clear indication of prognosis.

ERYTHROCYTOSIS (POLYCYTHEMIA)

Erythrocytosis is defined as an elevation of PCV and RBC count above those considered normal. Relative erythrocytosis is common in horses, whereas absolute erythrocytosis is exceptionally rare.

Relative erythrocytosis describes a relative increase in the PCV and RBC count, and is usually due to a reduction in plasma volume (**dehydration**). Relative erythrocytosis also accompanies splenic contraction, which induces a

red cell mass at the upper end of normal, combined with a low normal plasma volume. Clinical evidence of dehydration such as **tacky mucous membranes** and **reduced skin pliability** suggests dehydration (*q.v.*). Endotoxemia or other forms of shock (*q.v.*) may be manifested by tachycardia, cool extremities and mucosal congestion or pallor.

Relative erythrocytosis is definitely diagnosed by resolution of the condition following **IV fluid replacement**. Therapy is aimed at fluid administration necessary to maintain hydration and treatment of the primary disease process.

Absolute erythrocytosis refers to an increased circulating RBC mass without change in plasma volume. Irrespective of etiology, absolute erythrocytosis causes a number of clinical manifestations due to expanded blood volume and increased blood viscosity. These include “**muddy**” **hyperemia of mucous membranes**, lethargy and weight loss subsequent to decreased cardiac output, hemorrhagic diathesis and/or an increase in thrombotic complications.

PRIMARY ERYTHROCYTOSIS

Autonomous proliferation of erythroid progenitors rarely occurs. This may be a single cell disorder or a component of **polycythemia vera** (*q.v.*), in which there is also abnormal proliferation of myeloid cells and megakaryocytes. The diagnosis of primary erythrocytosis is based on demonstration of increased erythrocyte mass without excessive erythropoietin (Ep) production. Affected patients have erythrocytosis that is not responsive to IV fluid therapy.

Therapy of primary erythrocytosis includes **phlebotomy** to keep the PCV ≤ 0.50 L/L. **Hydroxyurea** causes reversible bone marrow suppression and has been used successfully in people and dogs with primary erythrocytosis but there is no experience with its use in horses. Prognosis for cure is poor.

SECONDARY ERYTHROCYTOSIS

Increased concentrations of Ep or erythropoietin-like compounds result in secondary erythrocytosis.

Physiologically appropriate erythrocytosis, the most common form of absolute erythrocytosis, is due to **chronic tissue hypoxia**. Residence at **high altitude** (above 2200 m) and some **congenital heart defects** cause a compensatory increase in plasma Ep in horses. Diminished atmospheric oxygen tension produces an inadequate driving force for tissue oxygenation and horses may develop an increased erythrocyte mass. Congenital cardiac disorders, such as **tetralogy of Fallot** (*q.v.*), that produce right to left shunting of blood away from the lungs cause absolute erythrocytosis.

Physiologically appropriate erythrocytosis can be diagnosed by documenting low arterial pO_2 . Oxygen delivery is impaired when the PCV > 0.60 L/L and at this point phlebotomy (*q.v.*) is indicated. The optimal PCV for patients residing at high altitudes or those with right to left cardiac shunts can only be determined by trial and error.

Physiologically inappropriate erythrocytosis is due to the autonomous elaboration of Ep. Neoplasia of the liver or kidney and non-malignant renal disorders (*q.v.*) may induce Ep production. Erythrocytosis may rarely accompany chronic hepatic disease in horses.

ALTERATIONS IN WHITE BLOOD CELL NUMBERS

Leukocytosis or leukopenia in horses is almost always subsequent to changes in the total neutrophil count. Leukocytosis may be attributed to pathologic or physiologic causes, but **leukopenia is always considered pathologic**.

NEUTROPHILIA

Neutrophilia often occurs with a normal WBC count. **Physiologic neutrophilia** accompanies exercise, excitation, transport or other stress that induces catecholamine or corticosteroid release, which causes temporary mobilization of the marginal neutrophil pool. Catecholamines also induce lymphocytosis while corticosteroids cause lymphopenia. The circulating cells are mature, with normal morphology, and there is no other hematologic evidence of inflammation.

Pathologic neutrophilia results from inflammatory disease, and bacterial infection is the most common cause. Acutely after infection, there may be an increased number of immature neutrophils (usually bands) in the blood, which is termed a “**left shift**”. Neutrophilia is most common as a bacterial infection is being localized, especially in concert with abscess formation (*q.v.*). **Rebound neutrophilia** often follows endotoxin-induced neutropenia (*q.v.*) and is generally a good prognostic sign. Once an infection is localized or chronic, left shift is rare, and horses often show only mild, mature neutrophilia with normal total WBC count. Less common causes for pathologic neutrophilia include tissue destruction by neoplasia, severe injury or surgery, parasitic or mycotic infections and autoimmune diseases (*q.v.*). An increased number of circulating abnormal neutrophils is a feature of granulocytic leukemia (Box 9.1).

Neutrophil morphology can help determine the cause for neutrophilia (or neutropenia) or indicate disease in a horse with a normal leukocyte count. Bacterial infections, particularly those caused by Gram-negative organisms, result in cytoplasmic and nuclear alterations in developing neutrophils. These “toxic changes” are reflected in the peripheral blood by neutrophil cytoplasmic basophilia, foaminess, vacuolation, purple “toxic” granules and bluish **Dohle bodies**. Rarely, bizarre giant forms occur. Inflammation subsequent to other

insults is not associated with neutrophil “toxic” changes. The neutrophils in granulocytic leukemia show cytologic criteria for neoplasia.

NEUTROPENIA

As opposed to neutrophilia, **neutropenia is always pathologic** and reflects underlying disease. The most common cause for neutropenia in horses is endotoxemia (*q.v.*). This may accompany Gram-negative bacterial infections, which are particularly prominent in neonates, or gastrointestinal disorders, especially colitis (*q.v.*).

Endotoxin acutely causes neutrophils to marginate along the walls of small capillaries, particularly in the lung. For neutrophil numbers to return to normal, at least partial resolution of endotoxemia and release of new neutrophils from the bone marrow are required. Left shift is very common during acute sepsis/endotoxemia. If the numbers of immature neutrophils in the blood exceed the number of mature neutrophils, the left shift is said to be **degenerative**. This is a poor prognostic sign that indicates the presence of overwhelming endotoxemia and/or depletion of bone marrow neutrophil reserves. Endotoxemia results in neutrophil toxic changes, the degree of which reflects the severity of endotoxemia.

Viral diseases and **anaphylaxis** (*q.v.*) may also cause neutropenia (Box 9.2). Rarely, neutropenia is due to a reduction in bone marrow precursors, subsequent to myelophthistic disease or aplastic anemia (*q.v.*).

LYMPHOCYTOSIS

Physiologic leukocytosis due to catecholamine release during excitement or exercise causes lymphocytosis as well as neutrophilia in young horses. Lymphocytosis is uncommon in horses >2 yr old, but may rarely accompany chronic viral infections or autoimmune disease. Lymphocytic leukemia is very rare in horses.

LYMPHOPENIA

Lymphopenia accompanies any pathologic state that induces endogenous glucocorticoid release and the **exogenous administration of corticosteroids**.

| ■ Acute metritis | |

Causes of lymphopenia include acute viral infection, endotoxemia, severe bacterial infection, septicemia, immunodeficiency and malnutrition (*q.v.*). Persistent lymphopenia indicates a poor prognosis.

EOSINOPHILIA

Eosinophilia is uncommon in horses. Although it is usually caused by tissue **parasite migration** (*q.v.*) or **allergy** (*q.v.*), the latter cannot be excluded by absence of eosinophilia. Systemic neoplasia and chronic granulomatous disease processes have rarely been associated with eosinophilia. A multisystemic eosinophilic syndrome has been described in horses, characterized by weight loss, diarrhea and rare respiratory signs. The cause is unknown and long-term prognosis is poor.

HEMATOPOIETIC NEOPLASIA

The most common internal malignant neoplasia of horses is lymphosarcoma (*q.v.*). Although the disease arises from the hematopoietic system, peripheral blood evidence of equine lymphosarcoma is exceedingly rare. Other forms of hematopoietic neoplasia are uncommon in horses.

LYMPHOSARCOMA

Four anatomic forms of lymphosarcoma have been described in horses (generalized, intestinal, mediastinal, cutaneous), however the forms substantially overlap clinically and pathologically. Lymphosarcoma has been documented in horses of both sexes ranging from birth to 25 yr old, but most affected are 5–10 yr old. Lymphosarcoma is reported in 2–5% of horses that are necropsied.

Clinical signs and laboratory findings

Clinical manifestations are highly variable depending upon organ involvement and duration of disease. The most common clinical signs of lymphosarcoma are chronic weight loss, ventral edema and regional lymphadenopathy. Peripheral lymphadenopathy is not consistently present. Thoracic cavity involvement may cause tachypnea, dyspnea, coughing and pleural effusion. In addition to weight loss, intestinal lymphosarcoma may cause colic or diarrhea. Subcutaneous lymphosarcoma nodules have been reported in horses, with or without internal organ involvement. Localized tumors may result in dysphagia, nasal discharge, chemosis, ataxia and jugular venous distension. Splenic enlargement, internal lymphadenopathy or abdominal masses may be rectally palpated. Signs may occur acutely and intermittent fever is not uncommon.

Laboratory findings are highly variable. **Non-regenerative anemia** (*q.v.*) and **hyperfibrinogenemia** are common. Lymphocytic leukemia with peripheral lymphocytosis is rare, but **atypical neoplastic lymphocytes** may be found in the peripheral blood in approximately 30% of cases. The total plasma protein varies, but the albumin–globulin ratio is often reduced. Polyclonal gammopathy is common, and monoclonal gammopathy associated with serum hyperviscosity and a hemorrhagic diathesis has been described.

Coombs positive immune-mediated hemolytic anemia and/or thrombocytopenia may occur. Hypercalcemia is rare in association with pseudohyperparathyroidism.

Etiology and pathogenesis

Clinical signs and laboratory changes are generally due to infiltration and loss of normal organ function, physical obstruction by tumor masses, and/or excessive generation of tumor cell products. Some neoplastic lymphocytes are of T cell lineage and may have immunosuppressive effects. Other neoplastic lymphocytes arise from auto-reactive B cell clones and produce antibodies responsible for gammopathies and/or immune-mediated cytopenias. Neoplastic proliferation of natural killer cells was described in one case. Extensive intestinal infiltration produces malabsorption, which contributes to hypoalbuminemia and weight loss.

Diagnosis

Lymphosarcoma is diagnosed by demonstration of **neoplastic lymphocytes** in affected tissue. Histologic examination of a tumor mass or affected lymph node is the most reliable method, and **excisional biopsies** (*q.v.*) are optimal. Unless tissues are accessible for biopsy, ante mortem diagnosis is difficult. Definitive diagnosis is only rarely possible on a peripheral blood smear, but may be made by cytologic evaluation of bone marrow, pleural effusion or peritoneal fluid. Radiography and/or ultrasonography may be useful to locate, and perhaps enable biopsies of, masses in the thorax or abdomen. Often, lymphosarcoma must be diagnosed by laparotomy or post mortem examination.

Neoplastic lymphocytes usually appear as large lymphoid cells with a variable nuclear-cytoplasmic ratio, multiple nucleoli, nuclear chromatin clumping, cytoplasmic basophilia and vacuolation. Mitotic figures and/or binucleate cells may be seen. The cytologic diagnosis of lymphosarcoma requires experience, since normal “reactive” lymphocytes and mesothelial cells resemble well-differentiated neoplastic cells. **Histologic destruction** of normal tissue architecture by lymphoid cells aids the diagnosis.

Treatment

Transient improvement in **systemic lymphosarcoma** has occurred following use of cytotoxic drugs (*q.v.*), immunostimulants (*q.v.*) and/or corticosteroids; however, long-term response is poor and debilitation ultimately occurs. The localized cutaneous form of lymphosarcoma may respond to corticosteroids but often recurs in a more pathogenic form when treatment is stopped.

Prognosis

The prognosis for lymphosarcoma is grave. Most horses die or are destroyed for humane reasons within 6 mo of the onset of signs (except for the cutaneous form where the horse can survive for years).

PLASMA CELL MYELOMA

Plasma cell myeloma (**multiple myeloma**), a systemic proliferation of neoplastic plasma cells, is very rare in horses. Reported clinical signs include

weight loss, weakness, recurrent fever, ventral edema, hemorrhages, lameness and ataxia. Renal failure and infections are not uncommon, but osteolysis as seen in humans and dogs does not consistently occur.

Laboratory findings include anemia and hyperproteinemia with monoclonal gammopathy. Hypercalcemia, azotemia and/or light-chain proteinuria (**Bence Jones proteins**) are variable. Criteria for diagnosis include **bone marrow or soft tissue plasmacytosis**, evidence of invasiveness, and the presence of monoclonal gammopathy or light-chain proteinuria. Definitive differentiation from lymphosarcoma (*q.v.*) may be difficult in some cases.

MYELOID NEOPLASIA

Myeloid neoplasia is characterized by the unregulated proliferation of a bone marrow-derived blood cell line. Forms of myeloid neoplasia described in horses include:

1. Granulocytic leukemia
2. Myelomonocytic leukemia
3. Monocytic leukemia
4. Eosinophilic myeloproliferative disorder.

There appears to be no age predilection. Predominant clinical signs include depression, weight loss, and those described for myelophthisic and aplastic anemias (*q.v.*). Affected horses are anemic and have thrombocytopenia. The total WBC count may be elevated, normal or reduced, but abnormal leukocytes have been invariably found in the peripheral blood. Abnormal leukocytes predominate in **bone marrow aspirates**. Treatment with cytotoxic agents has been unsuccessful.

HEMOSTATIC DYSFUNCTION

Disorders of hemostasis (**coagulopathies**) are characterized by hemorrhagic diathesis of variable severity and/or thrombosis. The latter is manifested as organ failure or edema of tissue proximal to the obstruction.

THROMBOCYTOPENIA

A **reduced number of circulating platelets** may be due to reduced platelet lifespan, platelet sequestration, or failure of megakaryocyte maturation within the bone marrow. The spleen normally stores platelets, but hypersplenism does not appear to cause thrombocytopenia in horses. Platelet production failure is usually caused by **myelophthisic disease** or **aplastic anemia** (*q.v.*), both of which are rare. The most common cause of thrombocytopenia is reduced lifespan of circulating platelets. Over-utilization is generally a component of a more extensive coagulopathy such as **disseminated intravascular coagulation** (*q.v.*). Idiopathic thrombocytopenia is probably due to **immune-mediated platelet destruction**.

Profound thrombocytopenia in a horse with minimal evidence of hemorrhage should be re-evaluated. Improper blood collection, inadequate volume of anticoagulant or platelet clumping in EDTA can cause **spuriously low** platelet counts. **EDTA-induced platelet clumping** is more common in patients with

prolonged severe illness. If **pseudothrombocytopenia** (*q.v.*) is suspected, the platelet count should be determined on a blood sample anticoagulated with 3.8% **sodium citrate**. If the citrated sample has a significantly higher platelet count than blood collected in EDTA, true thrombocytopenia is unlikely.

Idiopathic thrombocytopenia

Thrombocytopenia without other recognizable evidence of hemostatic dysfunction characterizes idiopathic thrombocytopenia (ITP). Any horse may be affected, although ITP seems to be more prevalent in young adult Thoroughbreds.

Clinical signs and laboratory findings

Petechial hemorrhages on mucous membranes, the nictitans and/or sclerae are characteristic. Epistaxis, hyphema, occult melena, hematuria, bleeding from injections or wounds and hematomas following minor trauma may occur. Other signs are referable to the presence of any underlying disease.

Laboratory findings include severe thrombocytopenia ($\leq 40\,000/\mu\text{L}$), prolonged bleeding time and abnormal clot retraction. The prothrombin time (PT), activated partial thromboplastin time (APTT) and thrombin time (TT) are normal. Serum concentrations of fibrin or fibrinogen degradation products (FDP) may be mildly increased. If the condition is chronic, anemia and hypoproteinemia may occur.

Etiology and pathogenesis

The clinical course and therapeutic response of ITP in horses suggests a similarity to immune-mediated thrombocytopenia in humans and dogs, where **surface antibodies cause phagocytic destruction of platelets** by the MPS. The platelet-associated immunoglobulin (Ig) in **primary ITP** is usually complement-fixing IgG. The mean half-life of circulating platelets and the platelet count are inversely proportional to the quantity of platelet-associated IgG and/or complement components. The spleen seems to be the major site of platelet phagocytosis. The bleeding diathesis posed by thrombocytopenia is caused by insufficiency of numerous hemostatic functions (*q.v.*).

Megakaryocyte numbers generally increase as a compensatory response to ITP, but autoantibodies may cause decreased platelet production by megakaryocyte destruction and/or prevention of newly formed platelets from entering the circulation. The potential mechanisms for autoantibody production in ITP are similar to those described for AIHA (*q.v.*). **Secondary ITP** results from non-specific binding of immune complexes to the platelet surface. Thrombocytopenia has been reported in horses secondary to EIA, lymphosarcoma and AIHA (*q.v.*).

Drugs implicated in the pathogenesis include phenylbutazone, aspirin, heparin, quinidine, penicillin, erythromycin, sulfonamides, tetracycline and gold salts. **Drug-induced ITP**, except that due to gold therapy, generally abates within days after the offending agent is discontinued.

Diagnosis

Clinical evidence of **small blood vessel hemorrhage** and **severe thrombocytopenia** in a horse with normal coagulation times (PT, APTT) and neutrophil

count are presumptive evidence of ITP. **Response to corticosteroids** (see below) adds support to the diagnosis. Definitive diagnosis of immune-mediated thrombocytopenia requires demonstration of increased platelet-associated Ig, currently not commercially available. Any suspicion of myelophthisis (*q.v.*) can be ruled out by bone marrow examination.

Treatment

The rationale of initial treatment for ITP is very similar to that described for AIHA. Any medication should be stopped or replaced by the chemically most dissimilar substitute. In the unlikely event of life-threatening hemorrhage, a **transfusion** (*q.v.*) of fresh whole blood (8–16 mL/kg BW), platelet-rich plasma or platelet concentrate should be administered.

Horses with suspected ITP generally respond favorably to corticosteroids. In addition to their effects on the immune response and MPS clearance, corticosteroids improve capillary integrity and increase thrombocytopoiesis. **Dexamethasone** (0.05–0.2 mg/kg IM or IV s.i.d.) usually causes an increased platelet count within five days, although full benefit may not be evident for 1–3 wk. Once the platelet count is $> 100\,000/\mu\text{L}$, the dosage of dexamethasone can be decreased by 0.01 mg/kg daily while monitoring for a relapse. Prednisolone (initial dose 1 mg/kg IM q 12 h) may be used in lieu of dexamethasone, however it often is not as effective. Corticosteroids should be continued until the platelet count has been normal for at least five days. If glucocorticoid administration proves necessary beyond 2 wk, then alternate morning low dose therapy (0.01 mg/kg dexamethasone) should be continued for 10 more days.

Alternate methods for treating ITP in horses are largely unproven. **Splenectomy** to remove the major site of platelet destruction is successful in some humans and dogs with ITP. Post-splenectomy sepsis is a major risk of this procedure. The cytotoxic drug, **vincristine** (0.01–0.025 mg/kg IV q 7 days), combined with glucocorticoids, has been successfully used to treat horses with ITP refractory to corticosteroids alone. There are no data regarding the effect of azathioprine and cyclophosphamide in equine ITP. Due to their potential to induce severe bone marrow suppression, cytotoxic drugs should be used with extreme caution, and only in horses that are non-responsive to corticosteroids for at least 10 days.

Prognosis

Most horses with ITP recover within 3–4 wk if treated appropriately. This suggests that many cases are secondary, although the initiating cause is rarely found. Chronic, recurrent ITP, requiring prolonged corticosteroid therapy, has been reported in horses. Horses with EIA or underlying neoplasia obviously have a poor prognosis.

CLOTTING FACTOR DEFICIENCY

Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) is a form of hemostatic dysfunction that occurs in horses with **severe underlying disease processes**.

DIC is a pathologic activation of coagulation that causes microvasculature clotting and may lead to hemorrhage subsequent to procoagulant consumption and/or the action of fibrinolytic by-products. Disease processes that cause DIC in horses include gastrointestinal disorders that induce colic (particularly enteritis/colitis), localized and/or systemic sepsis, systemic neoplasia and hemolytic anemia (*q.v.*).

Clinical signs and laboratory findings

Due to its heterogeneous and dynamic nature, the clinical manifestations of DIC vary from diffuse thrombosis and ischemic organ failure to severe hemorrhagic diathesis. In horses, DIC is more a thrombotic disorder than one causing massive hemorrhage. **Thrombosis of peripheral veins** tends to be a prominent manifestation of equine DIC. Sometimes a **jugular vein** will undergo **complete thrombosis** within hours of a routine blood sampling procedure.

Other clinical manifestations of thrombosis depend upon the organ involved. **Renal hypoperfusion** (*q.v.*) and subsequent failure produces signs of anorexia, depression, gastrointestinal ileus and oliguria/polyuria. **Gastrointestinal microthrombosis** may induce colic, complicating the clinical picture in horses with primary gastrointestinal disease. **Digital ischemia** frequently accompanies DIC in horses and may play a key role in development of acute laminitis (*q.v.*). Pulmonary microthrombosis may rarely cause tachypnea and hypoxemia. Microangiopathic hemolysis, hemoglobinemia and hemoglobinuria are rare in horses with DIC.

Depending upon the rate of DIC, horses develop a tendency for hemorrhage characterized by petechial or ecchymotic hemorrhages on mucous membranes/sclerae and bleeding following venepuncture or minor trauma. Spontaneous epistaxis, hyphema and melena occur less commonly. Life-threatening hemorrhage is rare in horses with DIC, unless there is initiating trauma (e.g. nasogastric intubation).

Numerous tests of hemostasis may be abnormal during DIC. Increased consumption causes reduced plasma concentrations of platelets, some coagulation factors, fibrinolytic proteins, anticoagulants and antifibrinolytic proteins with a secondary increase in FDP. Laboratory changes of DIC may include thrombocytopenia; prolonged PT, APTT and TT; reduced plasma concentrations of fibrinogen, factor V, factor VIII, AT-III, plasminogen and α_2 -antiplasmin (AP); and increased serum concentrations of FDP and soluble fibrin monomer. None of these tests is always sensitive, or specific for DIC, but one consistent feature of DIC is the presence of **multiple hemostatic abnormalities**. Serial analyses of hemostatic data should reveal reduced platelet numbers and a trend toward prolongation of the PT, APTT and/or TT.

Etiology and pathogenesis

Disease processes that trigger DIC generate excessive procoagulant activity and/or cause abnormal surfaces to contact blood. The nature and intensity of the procoagulant force, the concentration of natural coagulation inhibitors, and the functional capacity of the MPS play vital roles in determining whether an individual develops DIC. Gastrointestinal diseases that cause **colic** and **bacterial sepsis** are the most common disorders associated with

DIC in horses. In both, endotoxins, the lipopolysaccharide (LPS) portion of Gram-negative bacterial cell walls, gain access to the blood and initiate severe morbidity and mortality.

The equine gastrointestinal tract normally contains a large quantity of luminal endotoxins, only a small amount of which are absorbed into the portal blood and then removed by the liver. **Intestinal ischemia** or edema induced by strangulating obstruction, thromboembolic infarction and severe colitis (*q.v.*) allows luminal endotoxins to be absorbed at a rate which overcomes Kupffer cell clearance capacity, with resultant endotoxemia. Gram-negative sepsis, which is particularly common in equine neonates, causes endotoxemia and is a frequent initiator of DIC.

Endotoxins have numerous procoagulant effects. Endotoxins directly activate factor XII, can cause endothelial cell damage and TF release, stimulate platelets to release TXA₂ and induce granulocytes and macrophages to release platelet-activating factor (PAF). Most importantly, endotoxins stimulate macrophages to produce a procoagulant activity (PCA) that functions identical to TF. Other LPS-induced macrophage products, particularly interleukin (IL-1) and tumor necrosis factor (TNF), amplify these procoagulant actions. Endothelial cells, perturbed by LPS, IL-1 and/or TNF, do not express sufficient thrombomodulin, causing the anticoagulant actions of AT-III and activated protein C (APC) to be reduced. Finally, endotoxemia inhibits fibrinolysis by increased plasma concentrations of plasminogen activator inhibitors (PAI), and downregulation of protein C.

Other mechanisms may also trigger DIC during sepsis. **Circulating antigen-antibody** complexes can disrupt endothelium as well as directly activate factor XII. Inflammatory destruction of tissue may result in TF release and/or PCA production by activated leukocytes. The final common path of any triggering mechanism for DIC involves generation of **excess thrombin and plasmin**. Anticoagulants (AT-III and protein C) may become depleted during DIC. **Fibrinopeptides A and B**, liberated during fibrin formation, induce vasoconstriction that compounds hypoperfusion. Polymerized fibrin entraps platelets and damages red cells. Microangiopathic hemolysis provides ADP and phospholipid (PL) to continue the process of DIC.

Thrombin formation is linked to the systemic generation of plasmin, primarily via tPA release from underperfused tissues. The resultant FDP predispose to hemorrhage by interfering with thrombin activity, fibrin monomer polymerization and platelet function. Paradoxically, combined clotting factor consumption and fibrinolysis potentiate bleeding at the same time that disseminated thromboses occur. Tissue-fixed macrophages of the spleen and liver normally remove activated clotting factors and FDP from the circulation, and plasma concentrations are increased only when the formation rate exceeds the clearance ability of the MPS. **Shock** or diseases associated with excessive tissue debris (e.g. sepsis, metastatic neoplasia) will reduce the function of the MPS and predispose to DIC.

Diagnosis

Numerous tests of hemostatic function may be abnormal, but no one test consistently or specifically indicates the presence of DIC. Laboratory criteria for

the diagnosis of DIC must always be interpreted in the light of the patient's **underlying disease**. The diagnosis of DIC is made by clinical signs in specific disease settings and laboratory data only provide support.

The combination of **thrombocytopenia** with **prolongation of the PT** and/or **APTT** (*q.v.*) strongly suggests the presence of DIC in horses. Thrombocytopenia may also occur with ITP, bone marrow aplasia or myelophthisic disease (*q.v.*); however, these latter conditions are not associated with other abnormalities of hemostatic function (e.g. PT, APTT). The PT is a crude measure of the extrinsic and common coagulation pathways and the APTT assesses function of the intrinsic and common pathways. Clotting times are not sensitive and only become prolonged when the tested factors are ≤ 30 –50% normal, i.e. late in the genesis of coagulopathy. Thus, thrombocytopenia alone may occur early in DIC.

Adult horses with DIC uncommonly develop hypofibrinogenemia. Because infection, endotoxemia and/or inflammation generally initiate coagulopathy in horses, the **acute-phase hepatic response** to increase fibrinogen synthesis probably compensates for consumptive loss. Serum FDP concentration ≥ 40 $\mu\text{g/mL}$ usually indicates DIC, but the absence of FDP does not rule it out. Early in DIC, there often is MPS compensation and/or degradation of FDP to undetectable forms. Severe inflammation, localized intravascular coagulation or other hemorrhagic disorders, like ITP, can increase serum FDP, but the concentrations rarely exceed 40 $\mu\text{g/mL}$.

Treatment

Treatment of DIC is controversial and the only widely accepted modalities are treatment of the primary disorder with general supportive measures to combat shock and maintain tissue perfusion. **IV fluids** help to reduce organ dysfunction caused by microvascular thrombosis. Septic conditions require appropriate antimicrobial therapy. Necrotic tissue, purulent exudate and non-viable bowel should be removed whenever possible. **Flunixin meglumine** (0.25 mg/kg IV q 8h) reduces eicosanoid generation and may be useful for endotoxemia. **Corticosteroids are not indicated** since they reduce the phagocytic action of the MPS and potentiate the vasoconstrictor effects of catecholamines.

Life-threatening hemorrhage is an indication for fresh plasma administration (15–30 mL/kg) to replace utilized coagulant, anticoagulant and/or fibrinolytic proteins. Concomitant **heparin administration** (*q.v.*) may help to prevent further thromboses, although the appropriate dose and rate in horses are unknown.

Controlled studies have not been performed in horses, but experience suggests that **aggressive therapy of the primary disease** is the most effective treatment for DIC.

Prognosis

The prognosis for DIC depends upon the severity of the primary disease process and how effectively the latter is treated. Mild DIC associated with gastrointestinal-induced endotoxemia generally resolves; however, debilitating sequelae such as laminitis or renal failure (*q.v.*) may ensue. Once blood incoagulability predominates, the prognosis for DIC is grave.

Warfarin toxicosis

Warfarin, a coumarin derivative anticoagulant, has been used therapeutically in some horses to treat navicular disease (*q.v.*) but is still used widely in some countries as a rodenticide in grain stores and yards to which horses may have access.

Clinical signs and laboratory findings

Coagulopathy is usually manifested by **mucosal ecchymotic hemorrhages**, hematomas, epistaxis and/or prolonged bleeding from minor trauma. Petechial hemorrhages do not occur. The earliest laboratory indication of warfarin toxicosis is **prolongation of the PT**. As the disease progresses, **APTT becomes prolonged**. Horses may develop **blood loss anemia** and **hypoproteinemia**.

Etiology and pathogenesis

Therapeutic amounts of warfarin may become toxic by a **cumulative effect** if there is **concurrent use of highly protein-bound drugs** such as phenylbutazone, etc., and/or there is a dietary alteration with **reduced vitamin K intake**. Warfarin antagonizes the enzyme responsible for regeneration of active vitamin K, which is necessary for liver production of the clotting factors II, VII, IX and X. Factors VII, IX, X and II have increasingly greater half-lives and depletion of factor VII causes prolongation of the PT within 36 h of toxicosis. Over the next 2–3 days, factors II, IX and X become deficient. Warfarin is **rapidly absorbed** from the gastrointestinal tract, then highly bound to plasma proteins. This protein-bound portion of warfarin acts as a reservoir for the free active drug.

Hypoalbuminemia, or the use of other protein-bound compounds such as **phenylbutazone** and chloral hydrate, can **enhance the toxicity of warfarin** by allowing a greater proportion of circulating unbound form. Rapid withdrawal of drugs that induce hepatic microsomal enzyme metabolism (e.g. **rifampicin**, **chloramphenicol**) may **potentiate warfarin toxicosis** since its metabolism is enhanced by these drugs. Finally, hepatic dysfunction or reduced content of dietary vitamin K (e.g. by feeding good to poor quality roughage) can precipitate warfarin toxicosis.

Diagnosis

Warfarin toxicosis is diagnosed by history of exposure, hemorrhagic diathesis without petechiae and prolonged PT/APTT with no other hemostatic abnormalities. Occasionally, hemorrhage precedes abnormal laboratory data by up to 24 h.

Treatment

Warfarin access must be discontinued. **Vitamin K₁** (1 mg/kg SC) should be administered every 6 h until clinical signs have abated and the PT is normal for at least two days. Treatment may be necessary for several days due to continued gastrointestinal absorption of warfarin and time required for clotting

factor production. Vitamin K₃ has poor therapeutic benefit and may induce nephrotoxicosis. Life-threatening hemorrhage can be controlled by **transfusion of plasma** (4–20 mL/kg), which must be fresh to ensure active coagulation factors. Life-threatening anemia can be treated with whole blood transfusion (*q.v.*).

Prognosis

Prevention is based on limiting access of horses to rodenticides and carefully monitoring the therapeutic use of warfarin. Other drugs (particularly **phenylbutazone** and other highly plasma protein bound COX-2 inhibitors) should be limited during warfarin therapy. Initially, the PT is monitored daily and the dose of warfarin adjusted as needed to achieve <2-fold increase.

During **warfarin therapy**, e.g. for navicular syndrome (*q.v.*), the PT should be checked at least twice weekly and more often if there is a change in diet, concurrent disease or other medication.

Congenital coagulation disorders

Selected deficiencies of factor VIII (hemophilia A), factors IX and XI, prekallikrein and the contact phase of intrinsic coagulation have been reported in horses. By far the most common congenital coagulopathy is **hemophilia A**. This sex-linked recessive **heritable** condition has been reported in Thoroughbreds, Standardbreds and Quarter Horses. Only **homozygous males** are clinically affected.

Clinical signs and laboratory findings

Clinical signs of excessive hemorrhage are usually manifested within the first few weeks of life. SC and/or IM hematomas and joint swellings due to **hemarthroses** are the most common complaints. Affected joints are not hot or painful to palpation but foals may have a **stiff gait**. Hemorrhage into body cavities may cause colic, depression and/or dyspnea. There is increased tendency to bleed following minor trauma and surgical procedures. Petechial hemorrhages are noticeably absent and epistaxis is rare. The only abnormal hemostatic test is **prolonged APTT**.

Etiology and pathogenesis

Hemophilia A is inherited as a sex-linked recessive trait and affected horses are unable to form functional factor VIII. Procoagulant factor VIII (factor VIII:C) generally circulates in a complex with a high molecular weight protein called **von Willebrand factor (vWF)**, part of which is immunologically active and termed factor VIII-related antigen (VIII:RA). The synthesis and secretion of factor VIII:C is decreased in patients with hemophilia A. Plasma and endothelial concentration of vWF are normal and plasma VIII:RA may even be increased. Deficiency of factor VIII:C compromises intrinsic coagulation. The severity of the resultant hemorrhagic diathesis is inversely correlated with the plasma concentration of factor VIII:C. Severe, moderate and mild hemophilic bleeding is associated with factor VIII:C activities of <1% of normal, between 1% and 5%, and between 5% and 20%, respectively.

Diagnosis

Horses with hemophilia A have APTT prolonged at least twice normal while other hemostatic tests are normal. The APTT can be corrected by **mixing patient plasma 1:1 with normal horse plasma**. Definitive diagnosis of hemophilia A is based on a specific assay for factor VIII activity that is <20% of normal. Carrier mares generally have factor VIII:C between 30% and 60% of normal. Since factor VIII:C >50% of normal is necessary to prevent hemorrhage after surgery or major trauma, some carrier mares may be at risk of bleeding.

Treatment

The most effective treatment for hemophilia is **transfusion** with fresh plasma. The half-life of transfused factor VIII:C is only 8–13 h, necessitating daily transfusions in severely affected patients. The use of **desmopressin** (1-deamino-8-D-arginine-vasopressin), or **DDAVP**, has not been explored in horses. Affected horses should be rested in a safe enclosure such that the chances of trauma are minimized.

Prognosis

The long-term prognosis for hemophilia A is poor. There is no cure, and therapy is only palliative. Most affected foals die or are destroyed because of **progressive debilitation** by 6 mo of age, although a mildly affected Thoroughbred was described at 3 yr of age.

Removal of **carrier mares** from the breeding population is the basis for prevention of affected foals. Definitive diagnosis of hemophilia A in a colt documents the mare as a carrier. Factor VIII:C may be elevated from the last trimester through 60 days post partum, thus carrier mares may have normal concentration at this time.

THROMBOPHLEBITIS

Inflammation of a vein associated with its thrombosis is termed thrombophlebitis. The mere presence of a thrombus initiates phlebitis. **Septic thrombophlebitis** occurs when there is bacterial or fungal infection of the thrombus and adjacent vessel wall. Although there are many factors that predispose to thrombophlebitis, alteration of normal hemostasis is necessary in the pathogenesis.

Clinical signs and laboratory findings

Often the initial sign is congestion and edema of tissues normally drained by the thrombosed vessel. Because **jugular thrombophlebitis** is most common in horses, head edema and hyperemia of the oral and nasal mucosae are prominent (*q.v.*). The thrombosed vessel feels like a firm, **cord-like structure**. Heat, pain, perivascular swelling, neck stiffness, fever and draining exudates strongly suggest sepsis. The development of collateral circulation from the affected tissue (usually face) is manifested as **numerous superficial small arborizing vessels**. Neutrophilia and hyperfibrinogenemia may accompany septic thrombophlebitis.

Etiology and pathogenesis

Causative factors of thrombophlebitis include stasis of normal blood flow, injury to the vessel wall and a hypercoagulable state. **Vessel wall injury** probably has a major role in the pathogenesis, since severe or septic thrombophlebitis most frequently involves vessels that have been catheterized, have undergone multiple venepunctures and/or been infused with irritant solutions. Most cases of thrombophlebitis result from a combination of vessel wall trauma and a hypercoagulable state. This increased tendency for the formation and maintenance of fibrin is inherent in the pathogenesis of thrombophlebitis, as well as DIC.

As discussed for DIC, thrombophlebitis most commonly accompanies endotoxin-mediated disease processes in horses, especially gastrointestinal diseases that cause colic (*q.v.*). **Endotoxin** is thrombogenic in numerous ways, as discussed under DIC. Insufficient anticoagulant mechanisms can also predispose to thrombosis, and severe protein-losing disease processes may be attended by thrombophlebitis. In horses, **hypoproteinemia** often attends NSAID toxicosis, salmonellosis and other causes of acute toxic colitis, infiltrative bowel diseases such as granulomatous enteritis and lymphosarcoma, and chronic glomerulonephritis (*q.v.*).

Diagnosis

Thrombophlebitis of the jugular or other peripheral veins can usually be diagnosed by clinical signs alone. Ultrasonography may allow detection of an occult thrombosis that is altering venous flow. Cavitation (hypoechoic area) suggests **sepsis**. Clinical diagnosis of deep vein thrombosis is usually not possible and there are no definitive laboratory tests. Definitive diagnosis of septic thrombophlebitis relies on isolation of a **pathogen** from the thrombus or peripheral blood. Positive culture of an appropriately removed catheter tip (to prevent skin contamination) may be confirmatory.

Treatment

Non-septic thrombophlebitis generally resolves with time and supportive care to reduce inflammation and improve blood supply to the area. At the first sign of thrombophlebitis, any catheter should be **aseptically removed and cultured**. Needle puncture of the involved vein is contraindicated. **Hydrotherapy** of the affected area and **topical dimethyl sulfoxide** (50%) may be useful.

Septic thrombophlebitis necessitates systemic antimicrobial therapy. The choice of drugs may be directed by the results of culture from a catheter tip, exudate or blood. Since the latter is usually not possible, **broad-spectrum antimicrobial** therapy should be continued for at least 10 days or until there is clinical and laboratory evidence of sepsis resolution. Persistent perivascular pain, intermittent fever and leukocytosis may be indications for surgery to drain an abscess or remove a section of the involved vein.

Client education and prevention

The prognosis for thrombophlebitis is determined by the location and extent of involvement of the vein, presence of sepsis and the underlying disease

process. Non-septic thrombophlebitis generally resolves quickly with appropriate supportive care. Mild, localized cases of septic thrombophlebitis generally respond to conservative therapy with antimicrobials, although there is a minor risk of **thromboembolism** to the heart and lungs. Other life-threatening sequelae include bacterial septicemia and external hemorrhage due to vessel wall necrosis. Persistent morbidity associated with thrombophlebitis warrants surgical intervention, which carries a fair prognosis. Horses with severe endotoxemia generally have a poor prognosis.

Effective treatment of the underlying disorder is the most effective way to minimize the contribution of hypercoagulability to thrombophlebitis. Proper catheter care is paramount in reducing the incidence of thrombophlebitis (Box 9.3). **Repeated needle puncture** of large veins should be avoided in patients with hypercoagulability. Small samples may be taken by 25 G needle from a facial vein; large samples should be aseptically removed from a catheter.

VASCULITIS

Vasculitis is a general term referring to inflammation of blood vessels; it may be primary or secondary to some underlying disease. Vasculitis in horses generally develops as a **hypersensitivity reaction** to an infectious, toxic or neoplastic process. Hypersensitivity vasculitis is characterized by predominant involvement of small blood vessels in the skin. The most common inflammatory pattern is **leukocytoclasia**, defined by the presence of neutrophilic nuclear debris in and around the involved vessels, with necrosis and fibrinoid changes.

Clinical signs and laboratory findings

Vasculitis is characterized by well-demarcated areas of **cutaneous edema** involving any portion of the body. The distal extremities and ventral body wall are most commonly affected. The edema is often hot and painful and affected horses are depressed and reluctant to move. Hyperemia, petechiae with or without ecchymotic hemorrhages and ulcerations, are commonly present on mucous membranes of the mouth, nose, vulva, etc. Other signs are variable and may reflect edema, hemorrhage and infarction in other systems. Lameness, colic, diarrhea, dyspnea and/or ataxia rarely occur. Secondary complications such as laminitis, thrombophlebitis and localized infections are common.

Laboratory findings may reflect chronic inflammation (e.g. neutrophilia, mild anemia, hyperglobulinemia and hyperfibrinogenemia). The platelet count is generally normal. With renal involvement, creatinine may be elevated and urinalysis may reveal hematuria and/or proteinuria.

Etiology and pathogenesis

The antigenic stimulus of **hypersensitivity vasculitis** is usually a microbe, drug, toxin or foreign protein. The deposition of circulating immune complexes is widely accepted as the major event in the pathogenesis of vasculitis. Deposited immune complexes activate complement with resultant formation of potent chemotactic factors. Infiltrating neutrophils release lysosomal and other cytoplasmic enzymes that directly damage vessel walls. Vessel wall leakage and luminal compromise result in edema, hemorrhage, thrombosis

Box 9.3 Proper intravenous catheter use**Insertion**

- Aseptic technique (surgical scrub and sterile gloves)
- Subcutaneous tunnel prior to vein entry optimal
- Smallest bore catheter that is practical
- Least thrombogenic catheter material
- Secure to skin (sutures)
- Cover with aseptic bandage, if possible

Use

- Aseptic technique for all injections
- Sterile solutions only
- Change injection lines every 24 h
- Flush with heparinized (10 IU/mL) saline solution every 6 h

Maintenance

- Change every 72 h if not tunneled
- Catheterize another vein
- Remove at first evidence of swelling, heat, pain or exudate at site
- Culture tip of suspect catheters

and ischemia in supplied tissues. Vascular dysfunction characterized by vasoconstriction and platelet aggregation further contributes to **tissue ischemia**.

Factors that determine which individuals develop hypersensitivity vasculitis remain undefined. Genetic and acquired alterations of immunoregulatory mechanisms that result in reduced immune complex clearance by the MPS are likely to be important. Physical factors such as blood flow turbulence, hydrostatic pressure and previous endothelial damage are likely to determine the size, type and location of blood vessels involved. Increased hydrostatic pressure in affected postcapillary venules results in a propensity for lesion formation in the skin of dependent body portions.

Diagnosis

Definitive diagnosis of vasculitis is based on typical histologic changes in involved vessels. Full thickness **punch skin biopsies** (>6 mm in diameter) from an affected area should be preserved in 10% formalin. **Michel's transport medium** is used for samples to detect immune complexes by immunofluorescence. Multiple biopsies from various sites are optimal since histologic lesions and/or immune complexes are patchily distributed; however, there is increased risk of cellulitis and/or exuberant granulation tissue (*q.v.*) on the distal limbs. Often the diagnosis of vasculitis must be made on clinical grounds and response to therapy.

Specific equine vasculitic syndromes

Equine purpura hemorrhagica (EPH) is believed to be an allergic response to streptococci or equine influenza virus (*q.v.*). This vascular syndrome typically

occurs 2–4 wk after infection by *Streptococcus equi* (strangles) (*q.v.*). Exposure of a **previously sensitized horse** to infected horses may also precipitate EPH. Rarely EPH may follow infections with *Strep. zooepidemicus* or influenza. Immune complexes containing IgA and a protein of *Strep. equi* have been demonstrated in the blood vessels of horses with EPH. Serum IgA titers to *Strep. equi* are higher in horses with EPH, but titers of IgG are curiously decreased. The significance of these findings remains unclear because EPH is difficult to reproduce experimentally.

Classical signs of EPH include **mucosal petechial hemorrhages** and **demarkated areas of edema** on the limbs, ventral abdomen, head and trunk. Edema of other tissues may cause dysphagia, dyspnea, colic, lameness or renal disease. Hematology generally reflects **chronic inflammation**. Moderate anemia (PCV 0.20–0.25 L/L) may develop due to fluid shifts or shortened erythrocyte lifespan. Tentative diagnosis of EPH is based on history and clinical signs. **Leukocytoclastic venulitis** in the dermis and subcutaneous tissue of a skin biopsy supports the diagnosis. Although most horses with EPH respond to therapy (see below), some cases are refractory. Deaths are usually secondary to laminitis (*q.v.*) or septic complications.

Equine viral arteritis (EVA) is caused by an RNA virus of the genus *Arterivirus*. There are numerous strains of EVA virus (*q.v.*) with variable pathogenicity. Infection classically occurs via inhalation of aerosol secretions from an affected horse, but **venereal transmission** may play a significant role in EVA dissemination.

Clinical disease of variable severity or an inapparent infection may follow EVA exposure. Clinical signs, after an incubation period of 2–13 (mean 7) days, may include fever, depression, anorexia, periorbital and palpebral edema, conjunctivitis, ocular and nasal discharge, edema of the legs and ventral abdomen and/or respiratory distress. Pregnant mares infected during the last trimester generally abort 5–30 days after the febrile response and they may not show other clinical signs. The fetus is usually autolyzed.

Definitive diagnosis of EVA (*q.v.*) requires **viral isolation** or **seroconversion**. The EVA virus may be isolated from nasopharyngeal and conjunctival swabs, citrated blood early in the course of the disease, and semen or placental and fetal fluids. Immunochemistry and PCR may replace virus isolation. A 4-fold increase in serum antibody titer to EVA virus in two samples collected 10–14 days apart is considered evidence of infection. Affected horses usually recover with supportive care within 3 wk. Infected stallions can remain **persistent carriers/shedders** of the EVA virus in semen. Infection by EVA can be prevented by use of a modified live vaccine at least 3 wk prior to exposure.

Infection with the **equine infectious anemia (EIA)** virus (*q.v.*) may cause **necrotizing vasculitis** of the skin or other organs. Classical signs include fever, icterus, mucosal petechiae, ventral edema, anemia and weight loss. Diagnosis of EIA is confirmed by an agar gel immunodiffusion (Coggins) test for serum antibodies to the EIA virus. Horses remain viremic.

Infection by the rickettsial agent *Anaplasma phagocytophila* (*q.v.*) may cause a vasculitic syndrome. Although the disease originally termed **equine ehrlichiosis** usually occurs in northern California, individual cases have been reported in other states and countries. Its distribution overlaps that of the tick reservoir, *Ixodes pacificus*. Horses over 3 yr of age are more severely affected

and signs include fever, depression, anorexia, mucosal petechial hemorrhages, icterus, ventral limb edema, weakness, ataxia and/or reluctance to move. Hematology often reveals mild to moderate leukopenia, thrombocytopenia and anemia. *A. phagocytophila*, which infects granulocytes, is antigenically distinct from *Neorickettsia risticii*, the etiologic agent for **Potomac horse fever** (*q.v.*). Infection confers immunity for up to 2yr that is not associated with a carrier state. Diagnosis is based on serology and active cases have a 4-fold rise in titer over 4wk. Affected horses generally recover within 2wk with supportive care alone, but **oxytetracycline** (7 mg/kg IV s.i.d. for 5 days) usually causes a prompt remission of clinical signs within 1–2 days.

Horses may develop **idiopathic vasculitic syndromes** with uncharacterized pathogenesis and unpredictable clinical course. Clinical signs often resemble EPH (*q.v.*) but may include intermittent fever, weight loss, alopecia, hyperkeratosis and hypopigmentation of the skin.

Treatment

Therapy of vasculitis is aimed at **reducing any known antigenic stimulus**, reducing vessel wall inflammation, normalizing the immune response and providing supportive care. **Hydrotherapy** and **pressure wraps** help to reduce limb edema. Horses that become unwilling or unable to drink require **fluids** IV or via nasogastric tube. Horses with dyspnea secondary to upper respiratory tract edema require tracheostomy. Phenylbutazone, flunixin meglumine or other NSAIDs **reduce vascular inflammation** and provide analgesia. The incidence or severity of cellulitis (*q.v.*) and other septic sequelae may be minimized by **antimicrobials**.

No treatment effectively eliminates the viruses of EVA or EIA from the body. Oxytetracycline therapy is indicated to considerably shorten the clinical course of ehrlichiosis (*q.v.*). Horses thought to have **EPH** should receive **penicillin** (22 000 IU/kg procaine benzylpenicillin G IM q 12h or potassium benzylpenicillin G IV q 6h) for at least 2wk although the sensitizing infection has usually resolved by the time there are signs of EPH. **Idiopathic vasculitis** can be difficult to treat because the antigenic stimulus remains undefined and may not be easily eliminated. Any drug used at the time when signs occur should be discontinued. Underlying infection or neoplasia should be sought.

The use of **corticosteroid therapy** for the treatment of hypersensitivity vasculitis is controversial, however horses with EPH or idiopathic vasculitis usually respond favorably to corticosteroids. Whether the main effect of the latter is anti-inflammatory or immunosuppressive is unknown. The dose and rate of dexamethasone (0.05–0.2 mg/kg IV or IM q 12–24h) necessary to effect reduction in edema should be given. Prednisolone (0.5–1 mg/kg IM q 12h) is often not as effective as dexamethasone. Once edema starts to resolve, the corticosteroid dose can be gradually reduced (by 10–15%, q 24–48h) while the horse is monitored carefully for any signs of relapse. Horses with EPH may require corticosteroid therapy for up to 6wk before edema permanently resolves. Intermittent disease flare-ups, which require increasing the corticosteroid dose above a previously efficacious level, may occur. Oral prednisolone and prednisone are not recommended since they are erratically absorbed. **Antimicrobials are indicated** throughout the period of systemic corticosteroid administration.

Prognosis

The prognosis of vasculitis depends upon the cause. With early aggressive therapy most horses recover from EPH within 4 wk although numerous sequelae may prolong the convalescence. **Dermal infarction** often leads to skin sloughing followed by exuberant granulation tissue in the distal limbs.

BLOOD AND PLASMA THERAPY

Whole blood administration should be used only as a temporary life-saving procedure to improve oxygen delivery to the tissues during anemia. Crossmatch compatible equine erythrocytes are lost from circulation within 4 days of administration and the increased cellular debris that must be processed by the MPS may immunocompromise the patient. **Blood transfusion** blunts renal production of erythropoietin, thus impeding a bone marrow response that is highly important for ultimate recovery from anemia. If compatible whole blood is not available, bovine polymerized hemoglobin (Oxyglobin) may be used (*q.v.*) but the beneficial effects likely wane after 24–48 h.

Plasma may be administered to provide immunoglobulins, hemostatic factors, enzymes and transport proteins, as well as to maintain vascular oncotic pressure. Diseases that may benefit from plasma therapy include failure of passive transfer in foals, protein-losing enteropathy or nephropathy, DIC or other coagulopathies (*q.v.*). Horses with total plasma protein ≤ 4 g/dL and hemoconcentration and/or associated peripheral edema, and all those with a total plasma protein ≤ 3 g/dL, warrant a plasma transfusion.

DONOR SELECTION AND MANAGEMENT

Blood donor selection by **compatibility testing** is recommended to prevent fatal transfusion reactions as well as to maximize in vivo survival of transfused erythrocytes. Compatibility testing to identify the presence of antibodies to allogeneic erythrocytes (alloantibodies) in the donor or recipient is complicated by the high degree of **equine blood group polymorphism** (*q.v.*). Although a completely compatible donor is a near impossibility, testing can help to avert severe transfusion reactions by identification of existing alloantibodies.

The most immunogenic of equine alloantigens, Aa of the A system and Qa of the Q system, are highly prevalent among light horse breeds. Transfusion of blood containing these alloantigens to horses that lack them results in a high titer of alloantibodies that mediate severe hemolysis upon subsequent exposure. Horses can also become sensitized by previous pregnancy or therapy with erythrocyte-contaminated blood components (e.g. plasma).

The **saline agglutination crossmatch** is performed by incubating washed erythrocytes from donor (major) and recipient (minor) with serum from the other, followed by gross and microscopic examination for clumping. Hemolysins, which comprise many equine alloantibodies, are not detected by the routine crossmatch and are reliably diagnosed by adding absorbed rabbit serum to provide complement to the reaction mixture. Special handling and storage of rabbit serum limits hemolysin testing to specialized hematology laboratories.

In an emergency, the **agglutination crossmatch** is recommended but test results may not always predict a serious transfusion reaction. The first transfusion is generally well tolerated because natural equine alloantibodies are rare and weakly reactive. In a life-threatening situation, a horse <3 yr old with no history of blood or plasma therapy is the best potential donor. Alloantibodies to incompatible alloantigens may develop within days, making subsequent transfusions from the same or a different donor hazardous.

Horses that lack alloantigens Aa and Qa as well as serum alloantibodies are the best blood or plasma donors. Such horses can be identified by sending serum and blood, anticoagulated with acid citrate dextrose (ACD) solution, from a number of potential donors to a laboratory experienced in equine blood typing. Suitable donors are most easily found among Quarter Horses and Standardbreds. Multiparous mares should not be considered. Identified donors should be **retested annually** or after any major illness to ensure lack of serum alloantibodies.

For **plasma donor selection**, only alloantibodies to recipient erythrocytes (minor crossmatch) must be considered. Although the best donor would lack all erythrocyte alloantibodies, donors lacking antibodies for Aa and Qa are usually adequate. Plasma harvested without centrifugation is usually contaminated with erythrocytes in a quantity sufficient for recipient sensitization. Thus, plasma donors would optimally lack alloantigens Aa and Qa.

BLOOD COLLECTION

Blood (9 parts) should be aseptically collected into sterile bottles or bags containing ACD solution (1 part). The ACD solution can be made by mixing 11 g dextrose, 9.9 g sodium citrate and 3.3 g citric acid, qs ad 300 mL with distilled water, then autoclaved. Adult horses can donate 8–10 L of blood (20–25% of blood volume) every 30 days. This amount is more than needed for a foal and is usually therapeutic for severe anemia in the adult. Blood for transfusion should be used immediately or stored upright in a refrigerator (4°C) for less than 24 h.

PLASMA PREPARATION

Plasma can be produced by collecting the liquid portion of whole blood that has been centrifuged or allowed to sit at room temperature for 1–2 h. This manual technique is simple but carries the risks of bacterial contamination and recipient sensitization. Cell-free sterile plasma is optimally produced by **plasmapheresis** wherein whole blood is withdrawn and separated into its component parts (plasma, erythrocytes, granulocytes, platelets), plasma is collected, and the remaining blood components are returned to the donor. There are many sources of commercially available frozen plasma from donors that lack Aa and Qa alloantigens and serum alloantibodies. Immunoglobulins are preserved for at least a year in frozen plasma, but hemostatic proteins deteriorate.

BLOOD COMPONENTS

Concentrates of specific equine plasma components could provide more focused therapy in certain situations, but as yet are unavailable. Plasma components

that are useful in the human include concentrated immunoglobulins, cryoprecipitate, purified fibronectin, and the anticoagulant proteins AT III and protein C.

Centrifugation apheresis allows collection of granulocyte, platelet and/or erythrocyte concentrates. Granulocyte transfusion may improve survival in neonatal foal septicemia. Platelets and erythrocytes would be useful in treatment of life-threatening thrombocytopenia or anemia (*q.v.*).

TRANSFUSION TECHNIQUE

Blood products should be **warmed to 37°C in a water bath**, then administered IV through a **blood filter**. Vital signs of the recipient are recorded prior to transfusion, then 0.1 mL blood or plasma per kg body weight should be administered over 10 min. If attitude and vital signs do not change, the transfusion is continued at a rate of 5–20 mL/kg/h. In the absence of hypovolemia, slower flow rates are optimal to prevent volume overload and to allow detection of delayed adverse reactions prior to excessive blood delivery. **The transfusion should be stopped immediately if the recipient shows any change in demeanor** (see below).

The necessary dose of whole blood for a severely anemic horse can only be estimated. In most instances, replacing 20–40% of the calculated loss is sufficient to maintain life until the bone marrow responds. A drop in the PCV from 36% to 12% in a 500 kg horse (total blood volume is 8% BW or 40 L blood) would represent loss of about 27 L of blood, thus 6–8 L of blood should be therapeutic. A rule of thumb for plasma therapy is that IV infusion of 7 L of plasma containing protein at 7 g/dL in a 500 kg horse raises the TPP by approximately 1 g/dL.

POTENTIAL COMPLICATIONS

Signs of a “**transfusion reaction**” include restlessness, tachypnea, dyspnea, tachycardia, piloerection, sweating, defecation and muscle fasciculations. Hemolysis or anaphylaxis is mediated by recipient antibodies to donor blood components.

Improperly obtained, handled or administered blood components may cause endotoxemia and/or complement activation. Rarely, citrate in the ACD solution may result in **hypocalcemia**.

At the first sign of a problem, the transfusion should be stopped immediately and replaced by **isotonic crystalloid solution**. **Flunixin meglumine** (1.1 mg/kg IV) may be indicated and **calcium gluconate** should be given if hypocalcemia is identified. Collapse or profound dyspnea should be treated with **epinephrine** (adrenaline) (0.01–0.02 mL/kg of 1:1000 solution IM). Another blood or plasma donor should be identified unless the adverse reaction is known not to be immunologically mediated.

INTRODUCTION

Diseases of the gastrointestinal and digestive system are among the most common problems affecting horses. Mortality and treatment costs exceed those associated with other systems. Gastrointestinal and digestive system diseases cause dysphagia, colic, endotoxic shock, weight loss, diarrhea and liver failure (icterus, hepatoencephalopathy, photosensitization).

DISEASES OF THE ESOPHAGUS

ESOPHAGEAL IMPACTION

Etiology and pathogenesis

Obstruction or “**choke**” is the most common of the esophageal disorders in the horse. Common predisposing factors include feed changes, poor dentition, trauma, inadequate water intake, foreign bodies, and ingestion of dry, coarse feed items (dry grains, ears of corn and pelleted feeds). **Gluttonous horses** that rapidly eat feed without proper mastication or ingest bedding also are at risk of developing esophageal impaction. The lodging of dry material in the esophagus may initiate impaction formation.

Irritation of the esophageal mucosa and esophageal distension may cause **esophageal spasm**, thereby worsening esophageal impaction. Long-standing impaction can result in ulceration and necrosis of the esophageal wall. **Ulceration** of the esophageal wall can lead to esophageal spasm leading to recurrence of impaction. Severe necrosis can result in **perforation**.

Clinical findings and diagnosis

The horse with a physical obstruction of the esophagus may exhibit dysphagia, coughing and nasal regurgitation of food material, water and saliva from the mouth and nostrils. The horse may make repeated attempts at ingestion followed by extension of the head and neck to facilitate swallowing. This is often accompanied by **odynophagia** (painful swallowing), head-tossing and other signs of agitation and frustration.

The time from ingestion to the onset of clinical signs is dependent on the location of the obstruction within the esophagus and can vary from

immediately after ingestion to 10–12 s following ingestion. After an initial excitatory period, forced attempts at swallowing become less frequent, and distress and frustration are replaced by depression, anorexia, electrolyte imbalances and dehydration. Intermittent signs of obstruction may indicate a more complex underlying disease and justify further diagnostic evaluation. **Aspiration pneumonia** (*q.v.*) is a frequent complication of esophageal obstruction.

Diagnosis of esophageal obstruction often is based on clinical signs. Esophageal obstruction can be confirmed by attempting to pass a **nasogastric tube**, which cannot be passed beyond the site of obstruction. Palpation of the neck may reveal enlargement of the cervical esophagus. Crepitation and diffuse cervical enlargement may denote **cellulitis** (*q.v.*) resulting from perforation of the esophageal wall. Thoracic auscultation and ultrasound should be performed to ascertain and monitor the development of aspiration pneumonia.

Transtracheal aspiration (*q.v.*) provides a sample for cytology and bacterial culture as an aid in determining the identity and antimicrobial sensitivity of the bacterial organisms causing pneumonia. Gram-positive cocci (especially *Streptococcus* spp.), Gram-negative enteric bacteria (*Escherichia coli*, *Proteus* spp., *Klebsiella* spp. and *Pseudomonas* spp.) and anaerobic bacteria are all common. **Aspiration pneumonia** (*q.v.*) sometimes results in severe consolidation, abscessation or pleuritis, which can best be evaluated with thoracic radiography and ultrasonography.

Horses with esophageal obstruction that recurs or does not resolve after conservative therapy should be evaluated for esophageal foreign body, ulceration, stricture, diverticulum and megaesophagus (*q.v.*).

Endoscopy and radiography are helpful for definitive diagnosis. The endoscope length must be 200 cm to examine the entire esophagus. A flexible endoscope with insufflation and irrigation capabilities is necessary for a thorough and complete examination. Endoscopic examination is best performed by fully inserting the endoscope into the insufflated esophagus and then slowly withdrawing it. Ulceration, stricture, diverticulum or dilatation may be seen. With the esophagus relaxed, normal longitudinal mucosal folds should be seen. The mucosa should be white to pale pink in color. Insufflation causes flattening of these folds and permits evaluation of luminal diameter. **Transverse folds** can be iatrogenically produced by moving the endoscope aborally and should not be mistaken for mural lesions.

Survey radiographs may reveal the presence of a feed impaction or foreign body. Radiography performed within 24–48 h after relieving the obstruction may reveal **dilatation of the esophagus** in the area of the obstruction, visible as air contrast. **Barium**, given orally as a paste (85% with 120 mL water), or as a liquid (72% with 420 mL water) under pressure via a nasogastric tube, will delineate the longitudinal mucosal folds and localize the obstruction. Escape of barium into the surrounding tissues indicates **rupture** of the esophagus.

Liquid barium (480 mL) followed by air (480 mL) provides a double contrast study and is best for evaluation of the mucosal lesions, such as circumferential mucosal ulcers secondary to feed impactions. Swallowing during contrast studies may produce radiographic artifacts that mimic an esophageal stricture. **Xylazine** (0.25–1.1 mg/kg IV) and **butorphanol** (0.02–0.08 mg/kg IV)

or **detomidine** (0.01–0.02 mg/kg IV) given 5 min before the study helps to eliminate this artifact by suppressing the swallow reflex.

Manometric techniques to evaluate esophageal dysfunction are routinely used in human medicine and have been developed for use in horses. The availability and technical difficulty of this procedure, however, has limited its use in equine practice.

Treatment and prognosis

Prompt therapy is vital to successful management of esophageal impactions. Feed impactions become **more inspissated** over time, thereby making removal more difficult and complications more likely. Impactions present for only a few hours can sometimes be relieved by sedating the animal with **xylazine** (0.25–1.1 mg/kg IV) and **butorphanol** (0.02–0.08 mg/kg IV) or **detomidine** (0.01–0.02 mg/kg IV) to reduce swallowing, thereby decreasing the frequency of contractions of the esophagus. Access to food and water should be prevented.

Nasal intubation with **gentle warm water lavage** under xylazine sedation is successful in relieving most simple impactions. If gentle lavage fails, a cuffed nasogastric tube may be placed in the sedated animal thereby allowing the lavage to be performed under moderate pressure without reflux of fluid back into the pharynx. External massage may increase the efficacy of lavage. If this is unsuccessful, the animal should be muzzled to prevent food or water intake and administered **balanced, isotonic IV fluids**. After softening the impaction by rehydration of the patient, sedation and lavage should be repeated. Excessively aggressive lavage can result in severe aspiration or esophageal damage and/or perforation. Attempting to remove the impaction by applying pressure with a nasogastric tube often lodges the impaction in the narrower, more distal esophagus or causes perforation of the esophagus.

Relaxation of the esophagus would facilitate removal of the obstruction by preventing **esophageal spasm**. Detomidine, xylazine, butorphanol and guaifenesin only slightly reduce the strength of contractions of the esophagus but these sedatives do reduce the **frequency of contractions** of the esophagus by reducing the attempts to swallow. **Oxytocin** (0.11–0.22 IU/kg IM) and **acepromazine** (0.04–0.06 mg/kg IV) have a slight effect on the strength of contraction of the esophagus, thereby minimally reducing the impact of spasm.

Because these medications lack a pronounced effect on esophageal contraction, general anesthesia and intubation with a **cuffed endotracheal tube** may be necessary in cases that are refractory to standing warm water lavage. This technique reduces the likelihood of aspiration, provides more esophageal muscular relaxation, and reduces the chance of perforation.

Following relief, **feed should be withheld** for at least 24 h to allow esophageal function to return to normal. After 24–48 h, frequent interval, small volume, soft, moist mashes (alfalfa pellets or complete feed) and/or grass should be fed for 1–7 days. Feeding of hay and other dry feeds **should not be resumed** until it is felt that the esophagus has healed and returned to normal function. In some cases, endoscopic examination is needed to assess resolution of **secondary esophageal damage**. Horses should not be allowed to ingest bedding or other foreign material. Fresh water should be available at all times and electrolyte abnormalities corrected with oral or IV solutions.

Broad-spectrum antimicrobial therapy should be instituted for at least 7 days for **aspiration pneumonia** (*q.v.*). Long-term antimicrobial therapy is necessary in cases in which significant lung damage due to aspiration has occurred. Any underlying problems (e.g. management and dentition) should be corrected.

Impactions that do not respond to conservative therapy should be definitively identified, localized and relieved by **surgical intervention**. Either extraluminal massage or longitudinal esophagotomy may be performed. The goals of surgery are to relieve the obstruction and to return the esophagus to near normal size and function with minimal contamination and stricture formation at the surgical site. This requires strict asepsis and meticulous surgical technique. **Longitudinal esophagotomy** with primary closure of the incision results in minimal complications when performed in a region of normal esophagus. This procedure has a favorable prognosis for first intention healing and is preferred over manipulations that may induce further esophageal trauma. Postoperative therapy includes **withholding of feed and water** for 48–72 h with IV fluid therapy to correct electrolyte and acid–base abnormalities. Broad-spectrum antimicrobial drugs should be administered perioperatively if esophagotomy is performed or if there is a risk of **aspiration pneumonia** (*q.v.*). Beginning 48 h after surgery, frequent interval, small volume, soft, moist mashes should be fed for 7–10 days.

Impactions of short duration that are properly managed have a **good prognosis**. Reimpaction with premature ingestion of coarse feed and aspiration pneumonia (*q.v.*) are the most common complications. Impactions of long duration (≥ 24 h) are accompanied by damage to the esophageal wall and more severe aspiration and have a more guarded prognosis. Esophageal impactions requiring surgery have a **guarded prognosis**. Stricture formation, fistula formation, incisional dehiscence and descending cellulitis with resulting pleuritis are all possible complications, which occur with a higher incidence when the esophageal wall is compromised. Esophageal impactions leading to perforation have a grave prognosis.

ESOPHAGEAL FOREIGN BODY

Etiology and pathogenesis

Ears of corn, pieces of wood, wire, and medication boluses can all become lodged within the esophagus. These result in trauma to the mucosa and distension of the esophageal wall. Prolonged distension of the esophagus can lead to **mucosal necrosis and tearing of the muscular layer**, which may progress to perforation. The presence of the foreign body, swelling of the wall, and accumulation of feed material lead to obstruction of the esophageal lumen (*q.v.*).

Clinical findings and diagnosis

Clinical findings are similar to those found with impactions (*q.v.*). If the foreign body is located within the cervical esophagus it may be externally palpable, however **extreme caution** should be used during palpation to prevent further trauma to the wall. When there is **perforation** of the esophagus,

diffuse cervical cellulitis and abscessation are readily apparent (*q.v.*). Diagnosis usually is made by radiography and/or endoscopy.

Treatment and prognosis

If a secondary impaction is present, it must be relieved before attempting to remove a foreign body. Non-surgical methods for removal include **endoscopically guided retrieval** or pushing the object into the stomach by use of a **nasogastric tube**. Because the risk of esophageal trauma and perforation with these techniques is great, surgery is preferred.

Longitudinal esophagotomy with primary closure results in minimal complications when performed in a region of normal esophagus. Postoperative therapy includes withholding of feed and water for 48–72 h with IV fluid therapy to correct electrolyte and acid-base abnormalities. Broad-spectrum antimicrobial drugs should be administered. Following the initial postoperative period, frequent interval, small volume, soft, moist mashes should be fed for 7–10 days.

ESOPHAGEAL STRICTURE

Etiology and pathogenesis

Narrowing of the esophageal lumen due to stricture formation is usually present as an annular lesion and may be classified into three types:

1. **Mural lesions** that involve the adventitia and muscularis
2. **Esophageal rings** or webs that only involve the mucosa
3. **Annular stenosis** that involves all the layers of the esophageal wall.

Strictures usually result from **circumferential damage** to the esophagus, which heals with fibrous tissue. Impactions of **extended duration** with resultant circumferential mucosal irritation and ulceration, esophageal trauma resulting from attempts at relieving an obstruction, and surgical correction of previous annular lesions (*q.v.*) are common forms of trauma leading to stricture. Gastrointestinal disease resulting in **secondary reflux esophagitis** (*q.v.*) may result in stricture formation. Severe external cervical trauma occasionally will cause esophageal damage that heals with a stricture.

Clinical findings and diagnosis

The clinical signs associated with esophageal stricture are caused by **secondary feed impaction** at the proximal aspect of the constricted segment. Thus the clinical presentation of stricture is similar to that of esophageal obstruction. Endoscopic examination after removal of the secondary feed impaction will generally reveal the stricture. Maximal reduction in esophageal lumen size occurs up to 30 days after esophageal trauma or surgery; therefore, follow-up examination may be necessary. If the impaction is corrected without detection of the stricture, recurrent obstruction is likely.

Stricture formation usually impedes the passage of a **nasogastric tube** into the stomach and may be identified endoscopically or by positive pressure contrast radiography. Swallowing during contrast studies may produce **radiographic artifacts** that mimic an esophageal stricture. IV xylazine, given 5 min

prior to examination, suppresses the swallow reflex and reduces this swallowing artifact.

Treatment and prognosis

Conservative management of stricture formation is directed at **dilating the stenotic segment** of esophagus and is most successful in early cases. Post-surgical strictures and those following circumferential mucosal ulceration may be dilated by feeding **small quantities of a low bulk** diet over a period of several months. Grass and mashes made of complete feed or alfalfa pellets are satisfactory diets. Concurrent non-steroidal anti-inflammatory drug (NSAID) therapy, phenylbutazone (2.2–4.4 mg/kg b.i.d. PO or IV), may be helpful. Following circumferential esophageal ulceration, maximal reduction in luminal diameter occurs at approximately 30 days post obstruction but this returns to normal by 60 days from the original insult. Therefore, if possible, it is important to **postpone surgical intervention** for at least 60 days, to assess maximal luminal diameter and corresponding clinical response to conservative therapy. **Bougienage** (passing a cylinder into a passage) has also been used in the management of equine esophageal stricture.

Chronic strictures (≥ 60 days in duration) have a mature cicatrix that is usually unresponsive to conservative attempts at dilatation. These may be corrected by esophagomyotomy, partial or complete resection and anastomosis, or a patch graft (*q.v.*) using the sternocephalicus or brachiocephalicus muscle.

Mural strictures respond well to **esophagomyotomy** and have the best prognosis for recovery without re-stricture. In this procedure the esophagus is incised longitudinally through the stricture to the level of the mucosa. The myotomy is not closed but the surrounding tissues are apposed.

Longitudinal esophagomyotomy and mucosal resection are used to relieve strictures caused by mucosal rings or webs and annular cicatricial lesions involving all layers of the wall. In cases of extensive stricture formation where the mucosa cannot be closed, regeneration of the mucosa will occur within the muscularis and adventitia. This procedure is indicated when myotomy fails to correct the stricture, since it carries a greater risk of re-stricture than myotomy alone.

The diameter of the esophageal lumen may also be increased in cases of extensive stricture and annular stenosis through use of a **patch graft** utilizing the **sternocephalicus or brachiocephalicus muscle**. Under general anesthesia, the surgical procedure begins by approaching the esophagus via the ventral midline or laterally. After nasogastric intubation, a longitudinal incision is initially made through the muscularis from a point 3 cm distal to and extending 3 cm proximal to the stricture. The incision is then extended through the submucosa and mucosa. The caudal portion of the muscle belly of the brachiocephalicus or sternocephalicus is mobilized by blunt dissection. The muscle should maintain its proximal and distal attachments and should be freely movable as to not exert tension on the closure with movement of the neck. Routine closure with suction drains is performed, and extraoral alimentation is preferred for 10 days. Indwelling nasogastric tubes will only stimulate salivation and increase the incidence of fistula formation.

Complete resection and anastomosis of the esophagus should be reserved for cases of rupture in which the muscularis is severely compromised.

Placement of an **esophagostomy tube** distal to the lesion for extraoral alimentation greatly facilitates healing and minimizes incisional complications. An indwelling nasogastric tube is not recommended due to stimulation of saliva formation, thus increasing the incidence of fistula formation.

The prognosis for correction of esophageal strictures is guarded. Conservative management of early strictures is sometimes successful. However, surgical management of chronic strictures often is complicated by re-stricture, fistula formation, incisional dehiscence and descending cellulitis with resulting pleuritis (*q.v.*). Surgical procedures and diseases of the esophagus in the cervical area may also result in **laryngeal hemiplegia** (*q.v.*) because of the close proximity of the recurrent laryngeal nerves.

ESOPHAGEAL DIVERTICULUM

Etiology and pathogenesis

Diverticula of the esophagus are a rare cause of dysfunction. They are usually acquired lesions and may be classified into two types. A **traction or true diverticulum** results from **periesophageal fibrosis**, causing an outward tenting of all the layers of the esophageal wall. These commonly develop at a site of an esophagotomy or traumatic wound of the esophagus that is allowed to heal by second intention. They may also occur at a surgical or traumatic site where leakage of saliva has induced inflammation or abscess formation.

A **pulsion or false diverticulum** results from protrusion of mucosa and submucosa through a defect in the muscular layers of the esophageal wall. Pulsion diverticula may result from fluctuations in intraluminal pressure and damage of esophageal musculature by impacted feed material. In the horse **external trauma** is the most common cause of diverticula.

Clinical findings and diagnosis

Diverticula of the esophagus should be suspected when enlargement of the cervical area and dysphagia are present, yet **a nasogastric tube can be passed** into the stomach without difficulty. **Positive contrast radiography** confirms the diagnosis. During barium swallow esophograms, **traction diverticula** are spherical and have a wide area of communication with the esophagus. **Pulsion diverticula** are flask shaped and have a narrow area of communication with the esophagus. Positive pressure contrast studies that distend the esophageal lumen and outline the opening of the diverticula may assist in differentiation between the two types. Endoscopy is also useful in localizing the lesion and determining the size of the opening of the evagination.

Traction diverticula, even when large, produce minimal clinical signs and rarely require treatment. Pulsion diverticula, however, tend to enlarge progressively, thereby increasing the possibility of esophageal obstruction and rupture.

Treatment and prognosis

Diverticulectomy should be performed when the mucosal sac is very large and the communication with the esophagus is narrow. Pulsion diverticula may be repaired surgically by either diverticulectomy with resection of the

mucosal–submucosal sac followed by reconstruction of the mucosa, submucosa and muscularis, or inversion of the mucosal–submucosal sac with reconstruction of the muscularis.

Mucosal inversion is the preferred procedure for most cases because it minimizes the risk of postoperative complications such as dehiscence or leakage, infection, fistula formation and postoperative re-obstruction. Soft, moist feed mash should be fed for 4–6 days following surgery and treatment with antimicrobial drugs is indicated when contamination is encountered during surgery. Prognosis is dependent on the type, size and duration of the diverticulum. If the esophageal lumen is not invaded and the integrity of the esophageal wall is intact, the overall prognosis for recovery is good.

INTRAMURAL CYST

Etiology and pathogenesis

Esophageal mural cysts are a rare cause of dysphagia and are usually located between the mucosa–submucosa and muscularis of the esophageal wall. They are often lined with stratified squamous epithelium and filled with keratinaceous material (epithelial inclusion cysts). These cysts are most commonly seen in young horses and are believed to be a **developmental anomaly**.

Clinical findings and diagnosis

Dysphagia, regurgitation and a palpable soft tissue mass in the cervical area are clinical signs usually associated with mural cysts. Failure of or resistance to complete passage of a nasogastric tube is also a common finding. Contrast radiography demonstrating a mural filling defect, ultrasonography and endoscopy often provide a definitive diagnosis.

Treatment and prognosis

Surgical repair is accomplished through enucleation of the cyst with inversion or resection of redundant mucosa. A longitudinal esophagomyotomy is performed with meticulous dissection of the intact cyst away from the esophageal wall without perforation of the mucosa. The redundant mucosa is then treated by inversion, preferably, or by diverticulectomy if the mucosal sac is too large to invert. Prognosis for recovery is good if the cyst can be resected en bloc and the mucosa is not invaded.

ESOPHAGITIS

Etiology and pathogenesis

Esophagitis may be caused by ingested irritants (e.g. topical irritant medications or blisters, blister beetles or cantharidin toxicity), prolonged use of a nasogastric tube, or reflux of gastric or gastroduodenal contents (*q.v.*). NSAID therapy can lead to esophageal ulceration. The result can be **inflammation, erosion and ulceration** of the esophageal mucosa. Chronic inflammation produces pain and may decrease esophageal motility. In severe cases, megaesophagus can result.

Lower esophageal and gastric inflammation may reduce the tone of the lower esophageal sphincter, thereby causing or perpetuating inflammation of

the lower esophagus. **Reflux esophagitis** most often occurs in foals with gastric paresis or gastric outlet obstruction caused by gastric ulceration. Duodenogastric reflux may occur in horses with duodenitis/proximal jejunitis or small intestinal obstruction.

Clinical findings and diagnosis

Esophageal inflammation causes **pain**, which is usually manifest as anorexia, stretching the neck, odynophagia (*q.v.*) and ptyalism (excessive salivation). These signs may be most obvious when the animal is attempting to eat. Dysphagia may result if esophageal motility is affected. The diagnosis can be made via **endoscopic examination** by revealing a hyperemic, edematous, eroded or ulcerated esophageal mucosa.

Treatment and prognosis

Exposure to the caustic agent should be removed and the esophagus allowed to rest. Slurries made of pelleted feed and grass should be fed frequently in small amounts. The animal should not be allowed to eat coarse roughage. Reflux esophagitis should be treated with the proton pump antagonist, **omeprazole** (4.4 mg/kg PO), or H₂-receptor antagonists such as **cimetidine** (20 mg/kg PO t.i.d. or 4.4 mg/kg IV q.i.d.) and **ranitidine** (6 mg/kg PO or IV b.i.d.) to decrease gastric acid production.

Metoclopramide (0.02–0.1 mg/kg SC q 4–12 h) and **bethanechol** (0.03 mg/kg SC or 0.4 mg/kg PO q 6–8 h) increase the tone of the lower esophageal sphincter and distal esophageal and gastric motility and, therefore, may be useful in foals with gastric paresis and reflux esophagitis. Metoclopramide and bethanechol should not be used in animals with **gastric outflow obstruction**. Metoclopramide sometimes causes neurologic side effects. The prognosis with esophagitis is usually good. In the case of some **ingested toxins** (e.g. cantharidin), the resulting systemic disease is of greater consequence than the esophagitis. The prognosis is poor if severe megaesophagus (*q.v.*) develops.

MEGAESOPHAGUS

Etiology and pathogenesis

Megaesophagus is **esophageal dilatation** resulting in accumulation of food material and fluid within the esophageal lumen. Megaesophagus can be idiopathic or secondary to numerous primary disease processes. **Congenital idiopathic megaesophagus** has been reported in a few weanling foals. **Secondary megaesophagus** most often results from reflux esophagitis and chronic esophageal obstruction, such as that caused by vascular ring anomalies, lymphosarcoma involving cervical or mediastinal lymph nodes, or abscessation (*q.v.*).

Neuromuscular diseases may disrupt esophageal motility and cause chronic dilatation and ineffectual esophageal contraction. Dysphagia associated with esophageal disease has been reported in horses with botulism, equine protozoal myeloencephalitis, equine herpesvirus, and damage to the vagus nerve from trauma, neoplasia and lymphadenopathy (*q.v.*).

Clinical findings and diagnosis

Clinical signs of megaesophagus include **nasal reflux** of food and water. **Aspiration pneumonia** (*q.v.*) is a common sequel and, therefore, fever, coughing and dyspnea are often present. In cases of secondary megaesophagus, signs of the primary disease process (e.g. weakness, ataxia, etc.) are common.

Esophageal dilatation can be demonstrated by **contrast radiography** and **endoscopy**. Dilatation and accumulation of contrast material on sequential radiographs confirm the presence of impaired esophageal clearance. On esophagoscopy, dilatation, absence of peristaltic waves, and pooling of feed or fluid are observed. In cases of esophageal obstruction or esophagitis, the primary lesion may be observed via contrast radiography and esophagoscopy. A thorough neurologic examination and CSF analysis are indicated if megaesophagus is suspected to be a complication of a **primary neurologic disease** (*q.v.*).

Treatment and prognosis

In **secondary megaesophagus**, therapy for the obstruction, esophagitis, neurologic disease or neuromuscular disease should be instituted. There is no specific therapy for idiopathic megaesophagus; however, **metoclopramide** (0.02–0.1 mg/kg SC q 4–12 h) and **bethanechol** (0.03 mg/kg SC or 0.4 mg/kg PO q 6–8 h) may be used to improve distal esophageal peristalsis. Because aspiration causes mixed bacterial contamination of the lung, broad-spectrum antimicrobial coverage is necessary. **Dietary management** is necessary to prevent further pulmonary soilage and to maintain nutrition and hydration. If the resulting dysphagia is severe and prolonged, parenteral or enteral feeding will be necessary. If the dysphagia is incomplete, a **slurry** of pelleted feed or grass may be fed.

The prognosis depends upon the severity and cause of the dilatation. The prognosis for return of esophageal function is poor if the dilatation is severe and long-standing. Cases in which nasal reflux of food material and **pulmonary soilage** can be avoided by proper dietary management have a better prognosis. The prognosis in secondary megaesophagus depends upon the prognosis associated with the primary disease process. In foals with congenital megaesophagus, function may return to normal as the foal matures.

ESOPHAGEAL NEOPLASIA

Etiology and pathogenesis

Neoplastic diseases of the esophagus are rare. **Squamous cell carcinoma** (*q.v.*) is the most common and may extend from its origin in the squamous epithelium of the stomach. Other reported neoplasms of the equine esophagus include fibromas and melanomas. Clinical signs result from **esophageal obstruction** (*q.v.*).

Clinical findings and diagnosis

Clinical signs reflect esophageal **pain** and/or obstruction and include anorexia, stretching the neck, odynophagia, ptyalism and dysphagia. Diagnosis is based on endoscopy, radiography and biopsy. Endoscopy will reveal a **nodular mass**, which may be ulcerated. Double contrast radiography

may reveal an ulcerated mass. Ultrasound examination from the left cranial abdomen may reveal a mass in the wall of the stomach. **Multiple biopsies** should be obtained via endoscopy. Small biopsies of the mass surface obtained via endoscopy most often reveal surface necrosis and bacterial contamination. Attempts should be made to obtain samples of tissue deep to the surface. The stomach should also be examined. Double contrast radiography may reveal an ulcerated mass.

Treatment and prognosis

There is no treatment for horses with esophageal neoplasia.

DISEASES OF THE STOMACH

GASTRIC ULCERATION

Etiology and pathogenesis

The specific etiology of gastric ulceration in horses is unknown. Gastric acid hypersecretion, disturbances of gastric mucosal blood flow, impaired production of prostaglandin (PG) E or the gastric mucus/bicarbonate layer, and gastric emptying disorders are potentially involved in the initiation of gastric ulceration. Furthermore, after ulceration occurs, gastric acid **prevents healing** of the gastric mucosa. Other disease processes (e.g. foal diarrhea and neonatal sepsis), **stressful conditions** (e.g. horses in show and race training) and medication (e.g. NSAIDs [*q.v.*]) are factors commonly associated with a higher incidence of ulceration.

Modern management practices in which horses are stall confined and eating high energy feeds intermittently (e.g. twice daily) rather than grazing continuously on roughage are major factors in development of gastroduodenal ulceration.

Clinical signs and diagnosis

Clinical signs in **foals** with gastric ulcers depend upon the region of the stomach involved. In most foals with gastric ulcers, lesions are distributed throughout the squamous mucosa. These foals may be **asymptomatic** or exhibit poor growth, rough haircoat, a “pot belly” appearance, bruxism, salivation, colic, dorsal recumbency and, sometimes, diarrhea. Lesions can occasionally result in hemorrhage that rarely is associated with anemia or hypoproteinemia. Healing of antral or pyloric lesions can lead to pyloric stricture and obstruction (*q.v.*).

Gastric ulcer syndrome (GUS) also occurs in yearlings and mature horses with an overall prevalence of approximately 10%. Studies have found **squamous ulceration** in 70–100% of racehorses and around 60% of other performance horses. Ulceration of the **glandular mucosa** of the stomach occurs in 60% of horses in a hospital setting. Clinical signs in mature horses classically include **anorexia** and **chronic intermittent colic** of varying severity. Vague clinical signs include **poor performance** or failure to perform to expectations, decreased body condition, poor-quality haircoat and decreased concentrate

consumption. Colic signs in some horses with gastric ulceration are post prandial. Many horses with endoscopic evidence of disease may appear to be clinically normal.

Gastroduodenal ulceration is diagnosed by observation of typical clinical signs, endoscopic findings and response to therapy. A presumptive diagnosis of gastric ulceration can be made when typical clinical signs are observed, other causes of these signs are ruled out, and a response to administration of agents used to treat gastroduodenal ulceration is observed.

Confirmation of the presence of gastroduodenal ulceration is only made by **endoscopic examination**. Lesions occur predominantly in the squamous mucosa adjacent to the margo plicatus. Lesions at the cardia are common and require retroflexion of the endoscope to be observed. In foals >1 mo of age and horses, fasting and sedation will facilitate this procedure. In some neonatal foals, the stomach can be examined with a 100 cm endoscope; however, in older foals a 200 cm endoscope is needed. A 200 cm endoscope is required for examination of the duodenum in foals up to 6 mo of age. Examination of the duodenum in older animals requires a 300 cm endoscope.

Treatment and prognosis

The therapeutic strategy for gastric ulceration is reduction of gastric acid secretion, thereby allowing healing of the damaged mucosa, by use of proton pump antagonists (**omeprazole** 4 mg/kg daily) or H₂-receptor antagonists (**cimetidine** 20 mg/kg PO t.i.d. or 4.4 mg/kg IV q.i.d.; **ranitidine** 6.6 mg/kg PO or IV b.i.d.). Appetite, signs of colic and diarrhea should begin to improve within 48 h of therapy, which should be continued for approximately 28 days.

Because many cases require therapy of longer duration, assessment of ulcer healing via endoscopic examination is useful for determining the duration of therapy. Recurrence has been documented after endoscopic confirmation of healing in some horses. **Maintenance therapy** (omeprazole 2–4 mg/kg daily) has been used in some cases to prevent recurrence of gastric ulceration. A recent study of performance horses revealed that the occurrence and recurrence of gastric ulceration was the same with a lower dose of omeprazole (1 mg/kg/day) as that in horses treated with omeprazole at 2 mg/kg/day. Studies to document the overall impact of preventative therapy on the incidence of gastric ulceration have not been performed.

Other drugs may be useful in combination with H₂-receptor antagonists. **Sucralfate** (2–4 g PO q.i.d.) has been used in combination with H₂-receptor antagonists for treatment of gastric ulcers in horses. Sucralfate promotes synthesis of PGE, stimulates mucus secretion and protects ulcerated mucosa during healing. PGE inhibits gastric acid secretion and promotes mucosal blood flow, mucus production and mucosal cell division. **PGE analogues** have been effective therapy for gastric ulcers in humans but have not been used clinically in horses due to expense. **Antacids** have limited efficacy in treatment of gastric ulcers in horses due to the large doses (200 mL/500 kg BW) required.

The prognosis with gastric ulceration is good if appropriate therapy is continued for an adequate period of time and if complications do not develop. On the other hand, animals with **duodenal ulceration** are less responsive to therapy and more likely to develop complications. Complications that may result from gastroduodenal ulceration include gastroesophageal reflux,

megaesophagus with aspiration pneumonia, gastric paresis, pyloric or duodenal stricture, gastric or duodenal perforation, and ascending cholangitis and hepatitis (*q.v.*).

GASTRITIS

Etiology and pathogenesis

Gastritis occurs secondary to the reflux of duodenal contents from the pylorus to the stomach. The gastric inflammation probably results from exposure to bile acids and gastric acid. **Intestinal reflux** results from either small intestinal obstruction or ileus (*q.v.*).

Clinical findings and diagnosis

Clinical findings result from small intestinal obstruction or ileus and, therefore, include signs of abdominal pain, nasogastric reflux, and rectal palpation of distended small intestine. If an endoscopic examination is performed, the inflamed, eroded and/or ulcerated gastric mucosa will be seen.

Treatment and prognosis

The gastritis will resolve after the cause of the small intestinal obstruction and ileus is removed. It is necessary to frequently **remove fluid** accumulating in the stomach via nasogastric intubation to prevent excessive gastric distension and rupture. The prognosis depends upon the disease causing the small intestinal obstruction.

GASTRIC IMPACTION

Etiology and pathogenesis

Although gastric impaction is not a common disease in horses it is occasionally diagnosed as a cause of colic (*q.v.*). The cause is unknown but may be associated with ingestion of **coarse roughage** and **inadequate water** intake.

Clinical findings and diagnosis

Gastric impaction causes anorexia and varying degrees of abdominal pain. Rectal examination is normal. Diagnosis can be made when endoscopic examination or laparotomy reveals a large volume of desiccated ingesta in the stomach. Mild cases probably respond to therapy without definitive diagnosis.

Treatment and prognosis

Nasogastric lavage with small amounts of water (1–2 L; as described to reflux a horse) and **IV balanced polyionic fluids** (such as acetated Ringer's; 50–100 mL/kg/day) are recommended to hydrate the impacted ingesta, thereby facilitating passage. However, if surgery is attempted due to the severity of the clinical signs, the impaction may be removed by injecting 4 L sterile saline solution into the stomach and massaging the impaction. Postoperative care includes lavaging the stomach to remove remnants of the impaction. Severe gastric impaction can result in **gastric rupture** (*q.v.*) with

medical or surgical therapy, although the prognosis improves if treated early, before severe desiccation and distension occur.

GASTRIC NEOPLASIA

Etiology and pathogenesis

Neoplastic diseases of the equine stomach, including squamous cell carcinoma, lymphosarcoma, mesothelioma and gastric adenocarcinoma (*q.v.*), occur infrequently. **Squamous cell carcinoma**, originating in the gastric squamous epithelium, is by far the most common. These tumors may metastasize, cause gastrointestinal bleeding or obstruct the cardia.

Clinical findings and diagnosis

Gastric squamous cell carcinoma occurs most frequently in older horses. Presenting signs often include **weight loss**. Horses may develop **intermittent colic** due to obstruction of the cardia or metastasis to other abdominal organs. Colic occurring immediately after eating is especially common. Obstruction of the cardia can result in megaesophagus (*q.v.*) and/or nasal regurgitation of food. Horses with thoracic metastasis often develop thoracic effusion, which may cause tachypnea (*q.v.*). Melena, anemia and hypoproteinemia may occur in horses with gastrointestinal bleeding. Occasionally squamous cell carcinoma causes gastric rupture (*q.v.*) and peritonitis (*q.v.*). Diagnosis can be made by cytologic examination of peritoneal fluid in horses with abdominal metastasis.

Treatment and prognosis

There is no treatment for horses with gastric neoplasia.

PYLORIC HYPERTROPHY

Etiology and pathogenesis

The cause of muscular hypertrophy of the pylorus is unknown. Although this is a rare cause of colic, it has been diagnosed in a few young horses.

Clinical findings and diagnosis

Horses with pyloric hypertrophy present with signs of abdominal pain and nasogastric reflux. Rectal examination does not reveal intestinal distension. Hypochloridemic metabolic alkalosis may result from reflux of gastric fluid. Both chronic intermittent and acute abdominal pain occur in horses with pyloric hypertrophy.

Treatment and prognosis

Pyloric hypertrophy has been successfully treated via **pyloromyotomy**, **Weinberg modified Heineke—Mikulicz pyloroplasty** and a **side-to-side gastroduodenostomy**. These surgical techniques are not routine, and the small number of cases makes determination of the long-term prognosis difficult. IV therapy with 0.9% saline solution should precede surgery in animals with hypochloridemic metabolic alkalosis.

DISEASES OF THE SMALL INTESTINE CAUSING COLIC

INTRODUCTION

Approximately 34% of all colic cases at referral institutions involve small intestine diseases.

Abnormalities of the equine small intestine may be broadly classified as either **physical** or **functional** obstructions. **Non-strangulating physical obstructions** may be caused by either intraluminal masses or reduction of the lumen by intramural thickening or extramural compression. **Strangulating obstructions** can follow incarceration of intestine through internal or external hernias, intussusception, or a greater than 180° twist of a segment of intestine on its own mesentery.

Functional obstruction, referred to as adynamic or **paralytic ileus**, may be either idiopathic in origin, result from **inflammatory disease** (e.g. duodenitis and proximal jejunitis [*q.v.*]), or result from **serosal irritation** due to surgical manipulation. The majority of cases of small intestinal colic (58–80%) are caused by **strangulating lesions** and the remainder by simple and functional obstructions. The ileum is involved in 41–46% of all small intestinal obstructions.

Intestinal obstruction prevents the aboral movement of gastrointestinal contents, thereby resulting in **distension** of the intestine. As the distension increases, venous drainage from the intestinal wall is impaired and the mucosa becomes congested and edematous. If the obstruction persists for a prolonged period of time, significant compromise of intestinal vascular integrity may result in mucosal ischemia. **Shock** (*q.v.*) will develop with prolonged ileus due to decreased oral intake and accumulation of fluid in the intestinal lumen. With progressive distension, **gastric rupture** (*q.v.*) may occur.

In strangulating obstructions, the above events are combined with rapid tissue hypoxia and ischemia of the affected segment leading to necrosis and transmural leakage of endotoxin. **Cardiovascular deterioration** rapidly follows transperitoneal absorption of endotoxin resulting in hypovolemia and endotoxic shock (*q.v.*). For these reasons it is important that small intestinal lesions are identified early in the disease process, based on a thorough history and physical examination.

Abdominal pain, small intestinal **distension** (identified by transrectal palpation and abdominal ultrasound examination), **nasogastric reflux** and decreased or **absent borborygmi** are common clinical signs in patients with small intestinal disease. The expression of abdominal pain can depend on the temperament of the horse, the degree of restraint, administration of sedatives or analgesics, and mental attitude. Reduced or absent borborygmi may be encountered with obstruction developing at any site in the gastrointestinal tract. Ultrasonographic examination can also be used to assess the presence or absence of intestinal motility in individual segments of bowel. **Strangulating obstructions** usually cause severely distended, turgid small intestine.

With both non-strangulating and functional obstructions, mild to moderate **distension of small intestine** commonly is present. The severity of small intestinal distension can be assessed via rectal examination and ultrasonographic examination of the abdomen. In cases of ileal impaction, ileocecal and jejunojejunal intussusception, and inguinal hernias, transrectal palpation may

Table 10.1 Analgesics for control of acute abdominal pain

Analgesic	Dosage	Efficacy
Flunixin meglumine	0.25–1.1 mg/kg IV or IM	Excellent
Detomidine hydrochloride	0.01–0.04 mg/kg IV or IM	Excellent
Xylazine hydrochloride	0.2–1.1 mg/kg IV or IM ¹	Good
Butorphanol tartrate	0.02–0.08 mg/kg IV or IM ²	Good
Ketoprofen	1.1–2.2 mg/kg IV	Good
Dipyrone	10 mg/kg IV or IM	Poor
Phenylbutazone	2.2–4.4 mg/kg IV	Poor

¹ Repeated administration may compromise colonic motility.

² IV administration may cause excitement if used alone. Often combined with xylazine or detomidine.

reveal the specific etiology of the obstruction. Small intestinal distension may also occur with large intestinal obstruction or displacement, causing secondary extraluminal compression of the small intestine.

Therapy for small intestinal lesions includes controlling pain, maintenance of cardiovascular and metabolic status, and establishing a patent and functional intestine. Pain control is accomplished by **gastric decompression** via a nasogastric tube and administration of visceral and centrally acting analgesics (Table 10.1). Maintenance and support of cardiovascular and metabolic status is achieved by IV administration of balanced, isotonic fluids. In most cases of physical obstruction, **ventral midline exploratory celiotomy** is necessary for identification and correction of the inciting lesion.

NON-STRANGULATING OBSTRUCTIONS

Non-strangulating obstructions cause partial or complete luminal obstruction without significant compromise of the vascular integrity of the intestine. These may be classified as intraluminal or extraluminal obstructions. **Intraluminal obstructions** include ascarid impactions, feed impactions, ileal hypertrophy and neoplasia (*q.v.*). **Extraluminal** causes of intestinal obstruction include intra-abdominal masses, adhesions and abscesses (*q.v.*).

Ascarid impaction

Etiology and pathogenesis

Heavy ascarid (*Parascaris equorum*) infestation (*q.v.*) can lead to intraluminal obstruction in foals, weanlings and yearlings (median age of 5 mo, range of 4–24 mo). The affected animals usually have a poor parasite control program leading to heavy infestation with ascarids. **Ascarid impactions** commonly follow use of **high efficacy anthelmintics** such as ivermectin, which inhibit neuromuscular transmission, thereby paralyzing the ascarid. Intussusception, peritonitis and intestinal rupture (*q.v.*) are possible sequels to ascarid impaction. Foals usually develop immunity to the parasite by 6 mo to 1 yr of age and, therefore, ascarid impactions are uncommon in adult horses.

Clinical findings and diagnosis

Clinical signs are dependent on the duration and degree of small intestinal obstruction and may include unthriftiness, poor haircoat and mild to severe

abdominal pain. **Nasogastric reflux** is usually present and may contain ascarids. Transrectal examination reveals multiple loops of distended small bowel. The diagnosis is based on signalment, history conducive of heavy ascarid infestation and clinical signs consistent with small intestinal obstruction.

Treatment and prognosis

Partial obstruction of the intestine with ascarids may be treated medically with **intestinal lubricants** (e.g. mineral oil), **analgesics** (e.g. flunixin meglumine and/or xylazine \pm butorphanol tartrate; see Table 10.1), **balanced polyionic IV fluids** (acetated Ringer's; 50–60 mL/kg/day) and **low efficacy anthelmintics** (e.g. fenbendazole 5 mg/kg PO) to prevent further impaction. If obstruction is complete or if medical therapy is unsuccessful, **surgical intervention** is necessary to relieve the obstruction. **Multiple enterotomies** may be necessary to remove the obstruction. Mortality rates can be as high as 92%, with peritonitis and adhesions accounting for most deaths.

Ileal impaction

Etiology and pathogenesis

The most common site for intraluminal **feed impactions** of the small intestine is the ileum; however, impactions of the jejunum and duodenum have been reported. The incidence of the disease appears to vary with geographic location, being most common in Europe and the southeastern USA. Mares and Arabians are over-represented in ileal impactions.

The etiology of **ileal impactions** is unknown. An association with feeding fine, high roughage forage, such as coastal Bermuda hay, during the fall/autumn season has been suggested. It is possible that feed material accumulates in the ileum producing an obstruction. **Spasmodic contractions** of the ileum and absorption of water from the lumen worsen the impaction over time. Ileal hypertrophy, mesenteric vascular thrombotic disease, tapeworm infestation (*Anoplocephala perfoliata*) and ascarid impaction (*Parascaris equorum*) (*q.v.*) are less common causes of ileal impaction.

Clinical findings and diagnosis

Clinical signs associated with ileal impaction are variable and depend on the duration of the impaction. Most often the condition occurs in adult horses. Immediately following the impaction, the horse demonstrates signs of moderate to severe **abdominal pain** due to focal intestinal distension and spasmodic contraction around the impaction. Animals usually respond transiently to analgesic therapy.

Early in the disease course, transrectal palpation may reveal a 5–8 cm diameter, firm and smooth-surfaced viscus originating at the cecal base and coursing from right of midline obliquely downward and to the left of midline. Normal borborygmal sounds are usually auscultated. Nasogastric reflux may be absent in these early stages.

During the 8–10 h following the initial episode of colic, small intestinal and gastric distension develops due to the prevention of aboral flow of intestinal contents, thereby resulting in recurrence of signs of pain. **Dehydration and**

depression develop. Nasogastric reflux eventually develops and gastric decompression often provides temporary analgesia. **Borborygmal sounds** become diminished or absent. Transrectal examination reveals multiple loops of moderate to severely distended small intestine. The impaction is often **not palpable** at this time because of displacement and concealment by other loops of distended small intestine.

Hemogram, electrolytes, blood gases and abdominocentesis are usually within normal limits. However, hemoconcentration and elevated peritoneal fluid protein followed by elevated peritoneal nucleated cell count may be observed in long-standing disease.

Treatment and prognosis

Initial therapy of horses with ileal impaction is supportive and should include **gastric decompression**, **balanced polyionic IV fluids** (e.g. acetated Ringer's; 50–100 mL/kg/day), **analgesics** (e.g. flunixin meglumine; see Table 10.1) and intensive monitoring.

Occasionally, the impaction may resolve with medical therapy, however **surgical therapy** usually is necessary. If colic signs persist, ventral midline exploratory celiotomy with reduction of the obstruction by manual extraluminal massage provides the best prognosis for complete recovery. Mixing of the impaction with distal jejunal fluid or direct infusion of the impaction with sterile saline solution or carboxymethylcellulose will facilitate reduction of the impaction. When marked mural edema and congestion are present, evacuation of the ileal contents through a jejunal enterotomy will facilitate reduction of the impaction without excessive manipulation of the bowel.

If resection and anastomosis or bypass (ileocecostomy or jejunocecostomy) is required to relieve the obstruction, the prognosis for survival is reduced.

Ileal hypertrophy

Etiology and pathogenesis

Muscular hypertrophy of the distal ileum may produce narrowing of and partial obstruction of the intestinal lumen. Primary or idiopathic hypertrophy of the muscularis externa and muscularis mucosae is thought to be the result of either **autonomic imbalances** that produce **uncontrollable peristalsis** or a response to neurogenic stenosis of the ileocecal valve. Secondary muscular hypertrophy may result from mucosal damage or strongyle larval migration (*q.v.*). The transition from normal to abnormal bowel is gradual and the hypertrophy occurs in both the circular and longitudinal layers of the muscularis.

Clinical findings and diagnosis

Partial obstruction of the small intestine may produce **chronic weight loss**, lethargy and intermittent signs of mild to moderate abdominal pain. The horse may experience intermittent signs of colic for weeks to months, and in some cases years. Sequential colic episodes often increase in severity. **Transrectal palpation** during these episodes reveals multiple loops of distended small intestine. Complete obstruction produces persistent, moderate to severe abdominal pain that is only temporarily responsive to analgesics.

Definitive diagnosis of partial or complete obstruction is made at surgery or post mortem examination.

Treatment and prognosis

Partial obstruction may respond to medical therapy (see ileal impaction, *q.v.*) but recur at a later time. Surgical correction is performed via ventral midline exploratory celiotomy. Longitudinal ileal myotomy, ileocecostomy or jejunocecostomy may be performed to relieve or bypass the obstruction created by ileal hypertrophy. If no chronic distension of the small bowel has occurred, the prognosis for survival is good.

Intra-abdominal adhesions

Etiology and pathogenesis

Peritoneal adhesions form in response to either peritoneal inflammation or the presence of foreign material in the abdominal cavity. Adhesions may be initiated by peritonitis, ischemic necrosis, bacterial infection, parasite larval migration or surgical manipulation (*q.v.*). Traumatic tissue handling, peritoneal contamination, tissue dehydration, hemorrhage, improper surgical technique and postoperative ileus **all predispose** to adhesion formation.

Intra-abdominal adhesions may be present without altering intestinal function or may cause intestinal obstruction by distortion, stricture or direct compression of the intestinal lumen. **Fibrous adhesions** also form a potential internal hernial orifice or predispose to volvulus. Postoperative adhesions may be formed in 5–7 days and cause clinical signs within 14 days. Most clinical signs associated with intra-abdominal adhesion formation become apparent within 4–8 wk postoperatively.

Clinical findings and diagnosis

Small intestinal adhesions may be present without causing clinical signs. However, following abdominal surgery or peritonitis, a small percentage (22%) of horses later develop recurrent episodes of moderate to severe **abdominal pain** due to adhesions. Clinical and laboratory findings are similar to those described above for horses with ileal impaction (*q.v.*). If adhesions are associated with an active peritonitis, depression, pyrexia, leukocytosis, and elevated peritoneal protein fluid concentration and nucleated cell count may be present. Transrectal palpation reveals **small intestinal distension** and in rare cases adhesions may be palpable. Diagnosis is usually made by history and surgical or post mortem examination findings.

Treatment and prognosis

Every effort should be made to minimize adhesion formation at the time of original insult or surgery. NSAIDs, heparin, carboxymethylcellulose and other pharmacologic agents have been used to minimize adhesion formation, however no drug has been shown unequivocally to prevent their formation without causing other deleterious effects.

In cases that are at a high risk of developing postoperative intra-abdominal adhesions, **sterile carboxymethylcellulose** (1–2L) may be placed into the

abdomen before closing. In cases where a resection and anastomosis is performed, a bioresorbable hyaluronate–carboxymethylcellulose membrane may be applied over the surgical site to prevent adhesion formation. **Sodium heparin** (intra-abdominal instillation of 40–80 IU/kg in 1 L of 0.9% NaCl) may be added to this regimen, if postoperative hemorrhage is not anticipated to be a problem. Non-traumatic, aseptic, proper surgical technique, constant tissue irrigation and **fastidious hemostasis** should be employed to minimize post-operative complications secondary to adhesion formation.

Surgical intervention includes adhesiolysis and resection and anastomosis of the affected segment of bowel to re-establish luminal patency. Adhesiolysis can also be performed via laparoscopy within 10 days following initial surgery. The prognosis is guarded at best, due to a high incidence of recurrence. Less than 20% of repeat celiotomy cases survive long term.

Neoplasia

Etiology and pathogenesis

With the exception of **lipomas** (*q.v.*), obstruction of the small intestine caused by intra-abdominal neoplasia is rare. Other neoplasms that have been reported to cause small intestinal obstruction by infiltration and stenosis include squamous cell carcinoma, lymphosarcoma, adenocarcinoma, leiomyoma, leiomyosarcoma, ganglioneuroma and fibroma (*q.v.*).

Clinical findings and diagnosis

Clinical signs associated with intra-abdominal neoplasia may include weight loss, fever, anorexia, mild abdominal pain, diarrhea and dependent edema. An intra-abdominal mass may be palpable on transrectal examination. Abdominocentesis may yield neoplastic cells, however multiple attempts and cytospin of samples are often necessary.

Treatment and prognosis

Surgical exploratory or post mortem examination is often necessary to obtain a definitive diagnosis. Prognosis for intra-abdominal neoplasia is **poor** due to local infiltration and metastasis. Focal benign neoplasms may respond favorably to surgical resection, but these are not a common occurrence in the horse abdomen.

STRANGULATING OBSTRUCTIONS

Strangulating obstructions cause **complete luminal obstruction** combined with significant compromise of the vascular integrity of the intestine. **Vascular occlusion** can be either exclusively **venous**, resulting in hemorrhagic strangulation, or **arterial and venous**, resulting in ischemic strangulation.

The hypoxia and ischemia that develop rapidly lead to **necrosis** of the involved segment of intestine. As a result, physical deterioration from hypovolemic and endotoxic shock occurs rapidly in horses with strangulating lesions. Equine small intestinal strangulating obstructions include small intestinal volvulus, lipomas, intussusception and herniation (*q.v.*).

In patients with **small intestinal strangulating obstruction**, therapy is aimed at controlling pain, maintaining cardiovascular and metabolic status, and establishing a patent and functional intestine. Pain control is accomplished by gastric decompression via a nasogastric tube and administration of visceral and centrally acting analgesics (see Table 10.1). Maintenance and support of cardiovascular and metabolic status is achieved by IV administration of **balanced, isotonic fluids**.

Surgical exploration via ventral midline celiotomy is necessary for identification and correction of the lesion. The prognosis is dependent on the duration of illness and amount of intestine affected. With early detection and rapid treatment the prognosis is good. In cases of prolonged duration or cases requiring resection of greater than 60–70% of the small intestine, the prognosis is poor.

Volvulus

Etiology and pathogenesis

A volvulus is the **rotation** of a segment of intestine around the long axis of its mesentery. Although most cases are not accompanied by predisposing lesions, adhesions, infarctions, intestinal incarcerations, pedunculated lipomas and mesodiverticular bands (*q.v.*) can predispose to volvulus. Abrupt dietary changes and verminous arteritis have also been incriminated. The length and segment of the intestine involved is variable, but the ileum is frequently involved due to its fixed attachment at the ileocecal junction.

Clinical findings and diagnosis

Horses presenting with a strangulating obstruction of the small intestine usually exhibit an **acute onset** of progressive, moderate to severe, continuous pain that may initially be responsive to analgesics. However, the effectiveness of analgesics rapidly declines as the disease progresses. There is **rapid, progressive cardiovascular deterioration** indicated by poor peripheral perfusion (hyperemic or cyanotic mucous membranes with a prolonged capillary refill time, and a rapid, weak pulse). Hypovolemia and hemoconcentration develop much more rapidly than in cases of simple obstruction. Hypoproteinemia may develop due to losses of protein via damaged vasculature and mucosa in the ischemic segments.

Nasogastric reflux is often present but, in contrast to simple obstructions, decompression may not provide analgesia. Transrectal examination usually reveals moderate to severe small intestinal distension, and mild tension on the mesentery may elicit a painful response. However, the lack of palpable small intestinal distension does not rule out the possibility of a strangulating lesion, as the distended intestine may be beyond the reach of the examiner.

Abdominocentesis may yield normal or serosanguineous fluid with elevated peritoneal protein concentration (≥ 3.0 g/dL) and nucleated cell count ($\geq 10\,000$ cells/ μ L). The devitalized section of intestine may be isolated from the peritoneal cavity (e.g. within the omental bursa) and the peritoneal fluid analysis may not accurately reflect the degree of intestinal change.

Treatment and prognosis

The strangulated intestine is identified and exteriorized via **ventral midline celiotomy**. The direction of rotation of the segment involved may be determined by palpation of the mesentery at surgery. After correction of the volvulus, intestinal viability should be evaluated and resection and anastomosis performed if deemed necessary by the surgeon. At least 20–30 cm of normal bowel should be included at each end of the resected segment to ensure adequate vascularity at the site of anastomosis.

Surgical management of small intestinal volvulus must be accompanied by **aggressive supportive medical therapy**. Pre- and postoperative management of horses that retain sufficient viability of the small intestine, or those in which resection and anastomosis are successfully performed, includes **nasogastric decompression** as needed, antimicrobial drugs (e.g. **potassium benzylpenicillin** 22 000 IU/kg IV q.i.d. and **gentamicin sulfate** 6.6 mg/kg IV s.i.d.; and **metronidazole** 15–25 mg/kg t.i.d. per rectum), and treatments for endotoxemia (*q.v.*). **Balanced polyionic IV fluid therapy** is needed in volumes (75–100 mL/kg/day) to correct dehydration, to replace fluids lost in nasogastric reflux, and to support venous return during cardiovascular shock. Administration of IV hypertonic saline (1–2 L of 7% NaCl/450 kg BW) will improve cardiovascular function for several hours.

In horses with severe (<4 g/dL) hypoproteinemia, administration of **colloidal solutions** is necessary to maintain oncotic pressure for adequate circulation volume. Fresh or thawed frozen **plasma** (6–10 L/450 kg BW) is ideal to restore oncotic pressure and provide functional proteins beneficial for clotting, immunity and modulation of the systemic inflammatory process. Alternatively, administration of **synthetic solutions** (hetastarch 6%, 5–10 mL/kg) may result in adequate transient volume expansion.

Horses with ischemic damage to intestinal segments generally absorb large amounts of endotoxin, thereby causing further cardiovascular deterioration. Treatment to dampen the systemic inflammatory response associated with endotoxemia is frequently beneficial. Choice of treatment options is based on severity of disease, renal function and hydration status.

The most important strategy in management of endotoxemia is aggressive management of the primary disease process (e.g. **rapid removal of devitalized segments**). Available are **immune sera and plasma** collected from donors inoculated with portions of endotoxin molecules derived from Gram-negative bacteria. The resulting antibodies may bind circulating endotoxin and render it inactive; however, results of experimental studies are not definitive. **Polymyxin B** is an aminoglycoside antibiotic that binds and neutralizes endotoxin and decreases the systemic effects of endotoxemia when administered at 2000 IU/kg slow IV t.i.d. Side effects include nephrotoxicity and neurotoxicity; patients therefore should be monitored closely, especially during use of other nephrotoxic medications, azotemia and dehydration. Treatment of endotoxemia also involves inhibition of mediator synthesis.

Non-steroidal anti-inflammatory drugs (especially **flunixin meglumine** 0.25 mg/kg t.i.d. or 1 mg/kg b.i.d. IV or IM) are most often employed for this purpose. **Pentoxifylline** (8 mg/kg PO t.i.d.) **combined with flunixin meglumine** may be slightly more beneficial than flunixin meglumine alone.

Inactivation of oxygen-derived radicals is sometimes attempted with **dimethyl sulfoxide** (DMSO 0.1–1 g/kg/day IV as a 10% solution).

Because **laminitis** (*q.v.*) is a common complication associated with all inflammatory and ischemic disease in horses, frog supports are recommended preventatively in these patients. Digital pulses and signs of lameness should be monitored closely.

Antimicrobial therapy is needed for treatment of the **peritonitis** (*q.v.*) that commonly accompanies ischemic intestinal disease and celiotomy with intestinal resection. **Broad-spectrum therapy** is essential: those drugs commonly employed include penicillin (procaine benzylpenicillin 22 000–44 000 IU/kg IM b.i.d. or potassium benzylpenicillin 22 000–44 000 IU/kg IV q.i.d.), gentamicin (6.6 mg/kg IV s.i.d.) and metronidazole (15–25 mg/kg PO or per rectum t.i.d.).

Postoperative ileus is a common complication of intestinal ischemia and resection in horses. Consequences include prolongation of hospitalization and fatalities. This is best minimized by adherence to good surgical techniques and supportive therapy. Motility-enhancing drugs have been advocated but information regarding dosages and efficacy of these medications in horses is variable. For postoperative ileus associated with small intestinal lesions, **2% lidocaine** (loading dose of 1.3 mg/kg IV followed by continuous infusion of 0.05 mg/kg/min) is commonly selected. Other prokinetics include **erythromycin lactobionate** (2.2 mg/kg in 1 L of saline IV q.i.d. or b.i.d.), **metoclopramide** (0.04 mg/kg/h continuous IV infusion), and **cisapride** (0.1 mg/kg IV or IM t.i.d.). For large intestinal lesions, **neostigmine** is often used at 0.0044 mg/kg SC or IV repeated q 2–4 h. If there is no response and abdominal pain is not noted, the amount can be increased by 2 mg increments to a total of 10 mg per treatment. Postoperative ileus involving the cecum is most frequently treated with **erythromycin lactobionate** (*q.v.*).

The effect of **lidocaine** on intestinal function is thought to result from blockade of inhibitory sympathetic and parasympathetic reflexes, anti-inflammatory properties, inhibition of free radical formation, reduced circulating catecholamine concentrations and direct stimulation of smooth muscle. Systemic administration of lidocaine is also thought to significantly attenuate the perception of pain by depressing the spiking activity amplitude and conduction time of both myelinated A and unmyelinated C fibers.

Erythromycin is thought to promote intestinal motility by initiating the migrating motor complex via motilin receptors. **Metoclopramide** promotes the release of acetylcholine from post-synaptic cholinergic neurons via activation of 5-hydroxytryptamine receptors, antagonizes the inhibitory influence of dopamine on intestinal smooth muscle, and blocks the α_2 -adrenergic receptors. **Cisapride** selectively enhances the release of acetylcholine from post-ganglionic neurons in the myenteric plexus via stimulation of serotonergic receptors and antagonism of dopaminergic receptors. **Neostigmine** enhances large colon motility by inhibiting cholinesterase activity, thereby prolonging the presence of acetylcholine in the neuromuscular junction.

The proposed causes of ileus are complex and involve a combination of factors such as neural dysfunction, electrolyte disturbances, intestinal edema and local and regional ischemia with reperfusion injury. Thus the most effective therapy is likely a **combination of agents** that act by different or

complementary mechanisms. Most clinicians change medications if no response is obtained within 72 h.

The prognosis is dependent on the duration of illness and amount of intestine involved in the volvulus. With early detection and rapid treatment the prognosis is good. In patients with **long-standing strangulation**, postoperative peritonitis, ileus and adhesion formation are common. There is a high incidence of postoperative malabsorption and weight loss when resection of >60–70% of the small intestine is required, and euthanasia should be considered in these cases.

Pedunculated lipoma

Etiology and pathogenesis

Pedunculated lipomas are a common cause of **small intestinal strangulation** or obstruction in horses >15 yr of age. In a recent study, the mean age of horses with strangulating lipoma was 19.2 yr. Ponies, Arabians and Quarter Horses appear to be predisposed to lipoma formation. **Multiple lipomas** usually attach to the mesentery by a fibrovascular stalk of variable length. They are often incidental findings during exploratory surgery or necropsy, but these suspended masses have the potential to incarcerate a segment of small intestine and produce obstruction or, more commonly, strangulation (*q.v.*).

Clinical findings and diagnosis

Pedunculated lipomas should be suspected in horses >15 yr of age that demonstrate signs consistent with **small intestinal obstruction**. Strangulation obstruction by lipomas is characterized by acute, persistent abdominal **pain**, hemoconcentration and decreased borborygmal sounds. Nasogastric reflux usually is present, but may be absent early in the disease. Multiple loops of small intestine are evident on transrectal examination and elevations in peritoneal fluid protein concentration and nucleated cell count reflect the degree of **intestinal necrosis**.

Treatment and prognosis

Surgical correction involves abdominal exploration via ventral midline celiotomy, ligation and transection of the pedicle and lipoma, and resection and anastomosis of the affected segment of bowel. The ileum and jejunum are the most commonly affected segments of the small intestine. To minimize recurrence, **multiple lipomas**, even if not involved with the lesion, should be removed. The prognosis is favorable with early diagnosis and prompt treatment. Pre- and postoperative supportive therapies (see volvulus, *q.v.*) are necessary. If devitalized bowel cannot be safely resected or if peritonitis has progressed the prognosis is poor.

Herniation

Herniation of the small intestine may be classified as internal or external hernias. **Internal hernias** occur within the abdominal cavity and do not contain a hernial sac. Displacement of the small intestine through the epiploic foramen,

cecocolic fold, mesenteric defects, and rents in the gastrosplenic and broad ligaments are examples of such lesions. Mesodiverticular bands and Meckel's diverticulum are two congenital abnormalities that are also included in this category.

External hernias extend beyond the limits of the abdominal cavity and include inguinal, umbilical (including strangulating parietal hernias), ventral abdominal and diaphragmatic hernias.

Epiploic foramen herniation

Etiology and pathogenesis

The epiploic foramen is a **potential opening** approximately 4–6 cm in length that separates the omental bursa from the peritoneal cavity.

At one time, aged horses were thought to be predisposed to epiploic foramen entrapment due to enlargement of this space by atrophy of the right caudate lobe of the liver. In a recent study, no correlation was found between occurrence and age of affected horses. The average age for horses with epiploic foramen was 9.6 yr in that study. Herniation through the foramen may occur as a left to right or, less commonly, a right to left displacement when the horse is in dorsal recumbency.

Clinical findings and diagnosis

Clinical signs of **epiploic foramen herniation** are usually similar to those of horses with volvulus (*q.v.*). However, many horses may exhibit only mild signs of pain, and have no nasogastric reflux or palpable intestinal distension. In these horses, **peritoneal fluid analysis** (*q.v.*), which usually yields serosanguineous fluid with elevated protein concentration and nucleated cell count, is the most useful diagnostic test in determining the severity of the lesion and the need for surgical intervention. **Sequestration of the abnormal bowel in the omental bursa** may limit the impact of the incarcerated bowel on the peritoneal fluid and rectal examination findings.

Treatment and prognosis

Surgical exploration is often needed to confirm the diagnosis, at which time **decompression of the bowel** and careful manual dilatation of the foramen and reduction of the hernia can be performed. Decompression can be achieved with a **jejunotomy** and removal of luminal contents prior to reduction to minimize the amount of dilatation necessary to correct the hernia. Excessive trauma during dilatation of the foramen can result in fatal rupture of the caudal vena cava or portal vein.

After reduction of the herniation, **intestinal viability** should be evaluated and resection and anastomosis performed if necessary. Pre- and postoperative supportive therapies (see volvulus, *q.v.*) are necessary. Prognosis for surgical correction is dependent on the duration of illness and amount of intestine requiring resection, but is considered poor due to the difficulty encountered in reduction of the hernia.

Cecocolic fold herniation

Etiology and pathogenesis

The proximal aspect of the cecocolic fold can be a site for herniation and entrapment of the small intestine, most commonly the ileum and distal jejunum. The cecocolic fold attaches the lateral teniae of the cecum and the lateral free teniae of the right ventral colon. The exact etiology of this condition is unknown, but one hypothesis is that pressure from the small intestine on the cecocolic fold may cause hernia formation leading to intestinal strangulation.

Clinical findings and diagnosis

Clinical signs of cecocolic fold herniation are usually similar to those of strangulating obstruction (*q.v.*). Rectal examination commonly reveals small intestinal distension. Nasogastric intubation usually results in moderate reflux depending on the duration of the obstruction. In these horses, peritoneal fluid analysis (*q.v.*), which usually yields serosanguineous fluid with elevated protein concentration and nucleated cell count, is a useful diagnostic test in determining the severity of the lesion and the need for surgical intervention.

Treatment and prognosis

Surgical exploration is often needed to confirm the diagnosis, at which time decompression of the bowel and careful manual dilatation of the cecocolic fold defect and reduction of the hernia can be performed. After reduction of the herniation, **intestinal viability** should be evaluated and resection and anastomosis (jejunocecostomy) performed if necessary. Pre- and postoperative supportive therapies (see *volvulus, q.v.*) are necessary. The cecocolic fold defect is not closed primarily, and the defect is not reported to predispose affected horses to recurrence of this or other strangulating lesions. Prognosis for surgical correction is dependent on the duration of illness and amount of intestine requiring resection, similar to other strangulating small intestinal lesions.

Mesenteric defects

Etiology and pathogenesis

Defects or rents in the mesentery, gastrosplenic or broad ligaments, mesodeferens and greater omentum provide a potential site for intestinal incarceration or strangulation (*q.v.*). Mesenteric defects most often occur in the small intestinal mesentery, and less commonly in the large and small colon mesentery. Defects most commonly are acquired as a result of either severe **blunt abdominal trauma** or surgical manipulation of the bowel and mesentery. A segment of intestine passes through the defect and becomes incarcerated or strangulated.

Mesodiverticular bands, congenital remnants of a vitelline artery and its associated mesentery, extend from one side of the mesentery to the antimesenteric border of the jejunum. These normally atrophy during the first trimester of pregnancy. Failure of the band to atrophy results in formation of a **triangulated mesenteric sac**. A loop of intestine may become incarcerated in the sac, thereby leading to mesenteric rupture with resulting herniation and strangulation. **Meckel's diverticulum** is a remnant of the vitelline duct that

forms a blind extension from the antimesenteric surface of the distal jejunum or ileum. Occasionally, a fibrous band will persist from the apex of Meckel's diverticulum to the umbilicus, forming the vitelloumbilical band. Small intestine can become entangled and strangulate around this band.

Clinical findings and diagnosis

Clinical signs are similar to those described for horses with other strangulating obstructions (*q.v.*). Acute onset of severe abdominal pain, positive nasogastric reflux, evidence of small intestinal distension on transrectal examination and rapid systemic deterioration are often present. **Abdominocentesis** may yield normal or serosanguineous fluid with elevated protein concentration and nucleated cell count. Severity of the signs is dependent on the location, duration and extent of the lesion. Exploratory celiotomy is necessary for definitive diagnosis.

Treatment and prognosis

Surgical correction includes reduction of the hernia with resection and anastomosis of devitalized bowel. Pre- and postoperative supportive therapies (see volvulus, *q.v.*) are necessary. The **hernial ring** often requires **manual dilatation** to reduce the hernia. The mesenteric rent or tear should always be closed. A defect near the root of the mesentery is extremely difficult to close because of limited exposure. Care should be taken not to suture the mesenteric vasculature during repair.

Gastrosplenic ligament incarceration

Etiology and pathogenesis

Incarceration of the small intestine through the **gastrosplenic ligament** is relatively uncommon. The ligament attaches the left aspect of the greater curvature of the stomach to the hilus of the spleen and continues ventrally with the greater omentum. Defects in the ligament are usually acquired as a result of **trauma**. The distal jejunum and ileum are most often involved in the incarceration with herniation occurring in a caudal to cranial direction. The intestine becomes situated craniolateral to the spleen and lateral to the stomach.

Clinical findings and diagnosis

Clinical signs are similar to those described for horses with strangulating obstruction (*q.v.*). Acute onset of severe abdominal pain, positive nasogastric reflux, evidence of small intestinal distension on transrectal examination and rapid systemic deterioration are often present. Distended small intestine may not be palpable early in the disease process due to the cranial location in the abdomen. **Abdominocentesis** may yield normal or serosanguineous fluid with elevated protein concentration and nucleated cell count. Severity of the signs is dependent on the location, duration and extent of the lesion. Ventral midline celiotomy is often necessary for definitive diagnosis.

Treatment and prognosis

Surgical correction utilizes ventral midline exploratory celiotomy and gentle traction on the involved segment of bowel to reduce the hernia. Pre- and

postoperative supportive therapies (see volvulus, *q.v.*) are necessary. Since the ligament is relatively avascular, digital enlargement of the rent facilitates reduction with minimal risk of serious hemorrhage. No attempt is made to close the defect in the ligament due to inadequate surgical exposure and friability of the tissue.

Inguinal hernia

Etiology and pathogenesis

Acquired inguinal hernias in stallions are often associated with breeding or other strenuous exercise and almost always cause acute onset of severe abdominal pain. Sudden increases in intra-abdominal pressure or an enlarged internal inguinal ring may be predisposing factors. Inguinal hernias usually occur unilaterally and occur more frequently in Standardbreds, Saddlebreds and Tennessee Walking Horses than in other breeds. Inguinal herniation and evisceration may also be a complication to castration.

Congenital inguinal hernias in foals usually close spontaneously as the foal matures and rarely cause intestinal problems. However, **scrotal herniation** may require surgical correction when the bowel ruptures through the parietal tunic and **migrates subcutaneously**.

Clinical findings and diagnosis

Acquired inguinal and scrotal herniations in the stallion almost invariably produce acute intestinal obstruction (*q.v.*) that requires **immediate surgical intervention**. Incarcerated bowel becomes strangulated in several hours and hypovolemic and endotoxic shock (*q.v.*) rapidly cause **systemic deterioration**.

The hernia is usually indirect and unilateral with the incarcerated intestinal segment descending through the vaginal ring and contained within the tunica vaginalis. Affected horses demonstrate a rapid onset of moderate to severe abdominal **pain**. Palpation of the scrotum usually reveals a **firm, swollen, cool testicle** on the affected side. Early in the disease process, scrotal swelling may not be obvious. The loop of herniated small bowel may be palpable per rectum descending into the inguinal canal. With increasing duration of herniation the signs of typical strangulating obstruction, such as tachycardia, dehydration, endotoxemia and rapidly **progressive cardiovascular deterioration**, develop.

Abdominocentesis usually yields fluid with elevated protein concentration and nucleated cell count. Direct hernias with rupture of the vaginal tunic in newborn foals may cause mild pain and depression, local edema and subsequent abscessation. These are usually not reducible and are treated as surgical emergencies.

Treatment and prognosis

Correction requires ventral midline and inguinal incisions to achieve adequate surgical exposure and reduction. Reduction with resection and anastomosis of the affected bowel, unilateral castration and inguinal herniorrhaphy are usually required.

Inguinal herniation in colts may be contained in the vaginal tunic or may rupture through the tunic and lie subcutaneously. Those within the vaginal tunic may be manually reduced and usually spontaneously correct, but those that

rupture through the tunic require surgical repair via inguinal and scrotal incisions. Pre- and **postoperative supportive therapies** (see volvulus, *q.v.*) are necessary.

Prognosis for recovery is good if reduction and repair are performed within a few hours of herniation, before strangulation. The prognosis worsens with increasing duration before correction. The prognosis for breeding soundness is good if only one testicle is involved.

Diaphragmatic hernia

Etiology and pathogenesis

Diaphragmatic hernia may be **congenital** or **acquired** and is a rare cause of abdominal pain in horses. These hernias most often result from strenuous exercise, a hard fall, striking a stationary object while running, being struck by a large object, or parturition/dystocia (*q.v.*).

Clinical findings and diagnosis

Clinical signs associated with **diaphragmatic hernia** include abdominal pain, tachypnea and dyspnea. The severity of signs is dependent on the size of the hernial opening and degree of visceral herniation. Although the presence of viscera within the thoracic cavity may decrease the audibility of breath sounds and cause dullness during percussion, auscultation and percussion of the thorax does not always reveal abnormalities. Radiography and ultrasound may be diagnostic, demonstrating fluid- or ingesta-filled loops of intestine in the thorax. Because increases in pleural fluid protein and cell count may reflect the presence of devitalized intestine in the thoracic cavity, thoracocentesis may be a useful diagnostic aid. An exploratory celiotomy is often necessary for a definitive diagnosis.

Treatment and prognosis

Closure of the defect is accomplished by direct suturing or placement of a synthetic mesh over the defect. Diaphragmatic hernias located ventrally are accessible via a ventral midline celiotomy. With a dorsal hernia, the incision is extended 15 cm laterally in a paracostal fashion for adequate exposure. Prognosis for surgical repair is poor due to inadequate surgical exposure and a high incidence of postoperative complications such as septic pleuritis, implant failure and hernia recurrence.

Intussusception

Etiology and pathogenesis

Small intestinal intussusception usually occurs in younger horses and involves invagination of a segment of bowel (intussusceptum) and its mesentery into the lumen of an adjacent distal segment of bowel (intussusciptens). Continued peristalsis progressively draws more bowel and its mesentery into the intussusception, thereby causing **venous congestion, edema and, eventually, infarction and necrosis** of the involved segment. **Complete small intestinal obstruction** and **strangulation** usually results.

Intussusception results from alterations in intestinal motility. Enteritis, abrupt dietary changes, heavy ascarid (*Parascaris equorum*) or tapeworm (*Anoplocephala*

perfoliata) infestation (*q.v.*), anthelmintic treatment and intestinal anastomosis (*q.v.*) have all been implicated as inciting factors. In most cases, however, **no inciting factor** is identified. Jejunojejunal and jejunoileal intussusceptions are most common in foals. Ileocecal intussusceptions are most common in adults.

Clinical findings and diagnosis

Jejunal and ileocecal intussusceptions usually cause acute, moderate to severe abdominal pain. Clinical signs vary with the degree and duration of the condition. Most commonly, intussusception leads to **complete intestinal obstruction** and strangulation of the intussusceptum, causing an **acute onset** of **persistent abdominal pain**. Nasogastric reflux develops and progressive dehydration and hypovolemia rapidly ensue. Transrectal examination reveals loops of distended small intestine and occasionally the intussusception may be palpated. With an ileocecal intussusception, a turgid segment of bowel may be palpable within the cecum. Ultrasonographic findings of the involved bowel are usually described as a “**bull's-eye**” appearance with a segment of bowel within another segment.

Elevated peritoneal protein concentration and nucleated cell count reflect devitalization of the affected bowel. Peritoneal fluid analysis, however, may not accurately reflect the degree of intestinal compromise due to isolation of the devitalized intussusceptum within the intussusciptens.

Cases of **chronic ileocecal intussusception** have been described in which long-term, partial obstruction causes intermittent or continual abdominal pain, weight loss, poor general physical condition and varying degrees of anorexia and depression. This may continue for weeks to months but eventually leads to an acute episode of severe abdominal pain corresponding to complete obstruction of the intestine.

Treatment and prognosis

Surgical correction includes manual reduction of the intussusception and resection and anastomosis of the affected intestine (end-to-end jejunal anastomosis, ileocecostomy or jejunocecostomy). Some intussusceptions cannot be reduced due to the length of bowel involved, venous congestion and edema, and thus require total resection and anastomosis. Even if the intestinal segment appears viable, resection and anastomosis should be strongly considered due to the possibility of mucosal necrosis, serosal inflammation and postoperative adhesion formation. Pre- and postoperative supportive therapies (see *volvulus, q.v.*) are necessary.

The prognosis after early diagnosis and surgical repair of jejunal, ileal or ileocecal intussusception is good. If the intussusception is advanced and irreducible, the prognosis is fair to poor due to the likelihood of ileus, peritonitis and postoperative complications.

INFLAMMATORY AND/OR ISCHEMIC DISEASES

Duodenitis/proximal jejunitis

Etiology and pathogenesis

Duodenitis/proximal jejunitis is a distinct syndrome characterized by transmural inflammation, edema and hemorrhage in the duodenum and proximal

jejunum. The small intestinal mucosa and sometimes the small intestinal contents are a **red or red-brown color**. The stomach and proximal small intestine are moderately distended with fluid, whereas the distal jejunum and ileum are usually flaccid. Histologic lesions include hyperemia and edema of the mucosa and submucosa, villus epithelial degeneration and sloughing, neutrophil infiltration, hemorrhages in the muscular layer and fibrinopurulent exudation on the serosa. The cause of this extensive intestinal damage is unknown. *Clostridium perfringens* (*q.v.*) is one suspected etiologic agent.

The clinically relevant events that result from the intestinal damage are proximal small intestinal distension and nasogastric reflux, dehydration, and hypovolemic and endotoxic shock. The primary cause of the intestinal distension and reflux is probably accelerated transmucosal movement of fluid. The resulting inflammation and distension may alter intestinal motility resulting in **adynamic ileus**.

Clinical findings and diagnosis

Clinical signs include acute abdominal pain, **copious amounts of nasogastric reflux** (10–20 L; often red-brown colored fluid), rectal examination finding of moderate to severe small intestinal distension, absent borborygmal sounds, tachycardia, dehydration, slight increase in body temperature (38.6–39.1°C), hyperemic mucous membranes and prolonged capillary refill time. Although the abdominal pain usually abates after gastric decompression, the animal remains severely depressed.

Clinical laboratory findings include an increased packed cell volume (PCV) and total plasma protein (hemoconcentration), elevated creatinine concentration (pre-renal or renal azotemia), elevated peritoneal fluid protein concentration, mild to moderate elevation of peritoneal white blood cell (WBC) count (5000–15 000 cells/ μ L), hyponatremia, hypokalemia, hypochloremia and sometimes metabolic acidosis (poor perfusion). Complete blood count may reveal a normal, increased (neutrophilia due to inflammation) or decreased (neutropenia and left shift due to endotoxemia and consumption) WBC count. Definitive diagnosis can only be made via gross examination of the duodenum and proximal jejunum at surgery or post mortem. **Laminitis** (*q.v.*) is a common complication.

The clinical findings overlap with strangulating obstruction and non-strangulating obstruction (*q.v.*). Therefore, cases with colic, small intestinal distension and nasogastric reflux present a diagnostic challenge to the clinician. After initiation of nasogastric decompression, the abdominal pain usually abates and is replaced by depression in patients with duodenitis/proximal jejunitis. On the other hand, severe or progressive abdominal pain and serosanguineous abdominal fluid should be considered signs of strangulating or non-strangulating obstruction.

Treatment and prognosis

There is no specific treatment other than aggressive supportive therapy. Because voluminous gastrointestinal reflux is produced consistently for 3–7 days, periodic **gastric decompression (approximately every 2 h)** is necessary to prevent distension potentially leading to pain and rupture. Food and oral

medication should be withheld until small intestinal function returns. Because **clostridial infection** is one suspected etiology, treatment with **penicillin** (potassium benzylpenicillin 22 000–44 000 IU/kg IV q 6 h) is recommended. Surgery should be avoided.

Management of horses with duodenitis and jejunitis includes nasogastric decompression as needed, IV fluids, antimicrobial drugs and treatments for endotoxemia (*q.v.*). IV crystalloid therapy (e.g. acetated Ringer's solution 50–100 mL/kg/day) is needed in volumes to correct dehydration, to replace fluids lost in nasogastric reflux, and to support venous return during cardiovascular shock. Blood gases and serum electrolyte concentrations should be monitored and IV solutions altered as needed to correct deficiencies. Administration of **IV hypertonic saline** (1–2 L of 7% NaCl/450 kg BW) will improve cardiovascular function for several hours.

In horses with severe (<4 g/dL) hypoproteinemia, administration of **colloidal solutions** is necessary to maintain oncotic pressure for adequate circulation volume. Fresh or thawed frozen **plasma** (6–10 L/450 kg BW) is ideal to restore oncotic pressure and provide functional proteins beneficial for clotting, immunity and modulation of the systemic inflammatory process. Alternatively, administration of synthetic solutions (**hetastarch** 6%, 5–10 mL/kg) may result in adequate transient volume expansion.

Horses with ischemic damage to intestinal segments generally absorb large amounts of endotoxin, thereby causing further **cardiovascular deterioration**. Treatment to dampen the systemic inflammatory response associated with endotoxemia is frequently beneficial. Choice of treatment options is based on severity of disease, renal function and hydration status.

The most important strategy in management of endotoxemia is **aggressive management of the primary disease** process. Available are **immune sera** and plasma collected from donors inoculated with portions of endotoxin molecules derived from Gram-negative bacteria. The resulting antibodies may bind circulating endotoxin and render it inactive; however, results of experimental studies are not definitive. **Polymyxin B** is an aminoglycoside antibiotic that binds and neutralizes endotoxin and decreases the systemic effects of endotoxemia when administered at 2000 IU/kg t.i.d. Side effects include nephrotoxicity and neurotoxicity, and patients should be monitored closely accordingly, especially during use of other nephrotoxic medications, azotemia and dehydration.

Treatment of endotoxemia also involves inhibition of mediator synthesis. NSAIDs (especially **flunixin meglumine** 0.25 mg/kg t.i.d. or 1 mg/kg b.i.d. IV or IM) are most often employed for this purpose. **Pentoxifylline** (8 mg/kg PO t.i.d.) **combined with flunixin meglumine** may be slightly more beneficial than flunixin meglumine alone. Inactivation of oxygen-derived radicals is sometimes attempted with **dimethyl sulfoxide** (DMSO 0.1–1 g/kg/day IV as a 10% solution).

Because **laminitis** (*q.v.*) is a common complication associated with all inflammatory and ischemic disease in horses, **frog supports** are recommended preventatively in these patients. Digital pulses and signs of lameness should be monitored closely. Blood gases and serum electrolytes should be monitored and the IV solution adjusted to correct deficiencies. Moreover, as clostridial infection (*q.v.*) is one suspected etiology, treatment with penicillin

(potassium benzylpenicillin 22 000–44 000 IU/kg IV q 6 h) is recommended. Surgery should be avoided in these horses.

After the nasogastric reflux has decreased to 1–2 L over a 4 h period, small amounts of water can be offered. If the water is tolerated without recurrence of colic, small amounts of mash and grass can be fed frequently. Coarse roughage should be avoided for 48 h. Overly aggressive feeding can lead to distension of the small intestine, ileus and recurrence of colic and nasogastric reflux.

In patients with prolonged (≥ 7 –10 days) nasogastric reflux, parenteral nutrition may be necessary to provide nutritional support until the reflux resolves. **Parenteral nutrition** is administered IV and must provide a source of dextrose, lipids, amino acids and multivitamins.

Also in long-standing cases, surgery can be considered to augment medical therapy. Two approaches have been used. A standing right flank laparotomy may be used for exposure of the duodenum and cecal base to create a stoma between the duodenum and cecal base using a side-to-side anastomosis. This stoma may act as a shunt for fluid to decompress the small intestine. The stoma usually spontaneously closes. More often, a ventral midline celiotomy offers better exposure of the abdomen for examination and shunt formation. A side-to-side anastomosis can be formed between the diseased jejunum (as far proximal as can be easily exteriorized) and a segment of normal distal jejunum.

With appropriate management, the intestinal disease resolves in 95% of cases. Losses result from laminitis and intra-abdominal adhesions (*q.v.*). Without appropriate gastric decompression, death can result from **gastric rupture** (*q.v.*). Spontaneous nasogastric reflux, which leads to aspiration pneumonia, occurs in a very small percentage of horses with fluid distension of the stomach.

Non-strangulating infarction

Etiology and pathogenesis

Non-strangulating infarction describes infarction (**necrosis due to loss of blood supply**) of the intestine without a constricting or compressive lesion.

Post mortem examination of most horses with **intestinal infarction** reveals **thrombus formation** at the cranial mesenteric artery consistent with damage by migration of fourth and fifth stages of *Strongylus vulgaris* larvae (*q.v.*). However, thorough examination of the peripheral mesenteric vessels of these horses rarely reveals occlusive arterial lesions. It has been postulated, therefore, that infarction is most likely the result of **hypoxia** induced by **vasospasm**.

A large number of non-fatal cases of colic also have been attributed to infarction or ischemia due to **verminous arteritis** (*q.v.*). These can only be tentatively diagnosed because there are no specific clinical findings diagnostic of this condition.

Clinical findings and diagnosis

A **poor parasite control program** may predispose horses to develop non-strangulating ischemia and/or infarction. However, the disease also occurs in horses that are regularly treated with anthelmintics. The severity of the clinical

signs is variable, ranging from depression to moderately severe abdominal pain. Heart rate and respiratory rate may remain normal or may increase. Hyperemic mucous membranes may be present suggesting endotoxemia (*q.v.*). Body temperature may be normal or elevated due to either endotoxemia or the inflammation caused by migrating parasites. Rectal examination often is normal but may reveal distended small intestine, and pain, fremitus or thickening may be evident upon palpation of the mesenteric root.

Auscultation of the abdomen may reveal increased, normal or decreased borborygmal sounds. **Gastric reflux** may be present due to functional obstruction of the involved segment. PCV, total plasma protein and creatinine may increase due to dehydration. The peripheral blood may reveal decreased (neutropenia with a left shift due to endotoxemia), normal or increased WBC count (neutrophilia due to inflammation). Total protein may be increased due to the chronic inflammation caused by parasitism or decreased as a result of protein loss through damaged intestinal mucosa. Abdominal fluid may be normal or have tremendous elevation in protein content (≥ 3.0 mg/dL) and WBC count (up to 200 000 cells/ μ L).

Treatment and prognosis

Supportive therapies (see duodenitis and proximal jejunitis, *q.v.*) as discussed above are necessary. If nasogastric reflux occurs, careful attention should be given to maintain **gastric decompression**. Broad-spectrum antimicrobial drugs (e.g. potassium benzylpenicillin G 22 000–44 000 IU/kg IV q 6 h and gentamicin sulfate 6.6 mg/kg IV once q 24 h, and metronidazole 15–25 mg/kg t.i.d. PO or per rectum) are recommended if peritonitis is present. Pre- and post-operative supportive therapies (see volvulus, *q.v.*) are necessary. Large dosages of aspirin (20 mg/kg daily PO) and heparin (40–100 IU/kg q 8 h SC or IM) have been suggested to reverse the process of thrombosis; however, these are not routinely used.

Surgery should be considered in patients that deteriorate despite medical therapy. The prognosis is poor for patients with intestinal infarction requiring surgery for intestinal resection. Extensive peritonitis (*q.v.*) may have already developed. Ischemia not obvious at the time of surgery may later progress to infarction. Ileus and adhesions (*q.v.*) are common postoperative complications. Large intestinal involvement may be too extensive for resection to be practical. However, identification and resection of involved segments of either small or large intestine sometimes is performed successfully.

DISEASES OF THE LARGE INTESTINE CAUSING COLIC

INTRODUCTION

Abnormalities of the equine large intestine may be broadly classified as either physical or functional obstructions. Simple **physical obstructions** may be caused by intraluminal masses, large colon displacements or compression by extramural masses. Strangulating obstructions can follow intussusception (*q.v.*) or a **twist** $>180^\circ$ of a segment of intestine on its longitudinal axis. **Functional obstruction**, commonly called **adynamic or paralytic ileus**, may

be related to dietary and management factors (tympany), non-strangulating infarction, peritonitis or colitis (*q.v.*).

Intestinal obstruction prevents the aboral movement of ingesta, gastro-intestinal secretions and gas, resulting in **distension** of the intestine. As the distension increases, **venous drainage is impaired** and the mucosa becomes congested and edematous. If the obstruction persists for a prolonged period of time, significant compromise of intestinal vascular integrity may result in **mucosal ischemia**. **Hypovolemia** can result from decreased oral intake and accumulation of fluid in the intestinal lumen. In strangulating obstructions, ischemia of the affected segment leads to **necrosis** and transmural leakage of **bacteria and endotoxin**. Therefore, it is important that large intestinal lesions are identified early in the disease process.

Therapy for large intestinal lesions includes control of pain, maintenance of cardiovascular and metabolic status, and establishing a patent and functional intestine. Pain control is accomplished by **gastric decompression** (*q.v.*) via a nasogastric tube and administration of visceral and centrally acting analgesics (see Table 10.1). Maintenance and support of cardiovascular and metabolic status is achieved by IV administration of balanced, **isotonic fluids** (e.g. acetated Ringer's; 50–60 mL/kg/day). Most cases of impaction and tympany respond to medical therapy. Ventral midline exploratory celiotomy is necessary for identification and correction of displacements, strangulating lesions, impaction and **enterolith** (*q.v.*) removal.

NON-STRANGULATING OBSTRUCTIONS

Non-strangulating obstructions cause partial or complete luminal obstruction without significant compromise of the vascular integrity of the intestine. Intraluminal obstructions include cecum or colon impaction, enteroliths and neoplasia (*q.v.*). Extraluminal causes of obstructions include large colon displacements and adhesions (*q.v.*).

Impaction

Impaction involves accumulation and dehydration of ingesta within the intestinal lumen. Numerous factors may predispose to impaction, including **poor dentition**, ingestion of **coarse roughage**, **parasitic infestation** and **inadequate fluid intake**. In addition, **stress** associated with transportation or intense exercise may lead to hypomotility, inadequate water intake or excessive fluid losses through sweating.

Obstruction of the colon by adhesions or displacement may result in impaction. Many cases of impaction of the large and small colon are associated with positive *Salmonella* spp. (*q.v.*) fecal culture. Therefore, inflammatory conditions of the bowel may also predispose to colon impactions. In many cases of impaction, predisposing conditions are not identified.

Cecal impaction

Etiology and pathogenesis

In addition to the above predisposing factors, **cecal impaction** also occurs as a complication of other diseases, especially those associated with endotoxemia,

surgery or pain, such as septic metritis, septic arthritis, fractures and corneal diseases (*q.v.*). If the pain associated with these conditions is not controlled, the sympathetic component of the autonomic nervous system is upregulated, leading to a decrease in normal gastrointestinal motility. Other poorly defined causes of cecal dysfunction may play a role.

Clinical findings and diagnosis

Clinical findings include anorexia, decreased fecal passage and mild to severe abdominal pain. Heart rate varies with the degree of pain. Mucous membranes are usually pink, but may be tacky due to dehydration. There is usually no nasogastric reflux except when severe impaction results in ileus of the small intestine. PCV, plasma protein and creatinine may be elevated due to dehydration. In severe long-standing cases, damage to the cecal wall may result in transudation of protein. This can progress to **cecal perforation** leading to **peritonitis** (*q.v.*). In these cases, the peritoneal fluid protein content and/or WBC count may be increased.

Diagnosis is based upon finding cecal impaction on **transrectal examination**. The ventral cecal tenia will be taut and may be displaced ventral and medial. An excessive quantity of dry ingesta is palpable in the body and sometimes in the base of the cecum. The cecal base may be filled with moderate amounts of gas. The cecal distension may cause the dorsal and medial cecal teniae to be palpable. The left colon and small colon are usually empty.

Treatment and prognosis

Mild to moderately severe impactions of the cecum almost always respond favorably to medical therapy. All food should be withheld, but access to water may be allowed if there is no nasogastric reflux.

Large volumes of fluid (three times daily maintenance requirements) should be administered PO and IV to hydrate the impaction. Horses that do not develop nasogastric reflux usually respond to administration of **6 L of fluid (per 500 kg horse) q 2 h** via an indwelling nasogastric tube. Mild impactions require less aggressive fluid administration (one to two times maintenance requirements). **Laxative therapy** facilitates hydration of impacted ingesta: **docusate sodium** (10–20 mg/kg up to two doses 48 h apart), **magnesium sulfate** (450 g/500 kg BW) or **psyllium hydrophilic mucilloid** (400 g/500 kg BW q 6–12 h until the impaction resolves) can be used. **Mineral oil** can be administered to facilitate passage after the impaction begins to resolve; however, it is not useful to penetrate and hydrate the impacted mass.

After resolution of the impaction, feeding should be resumed **slowly** to avoid immediate recurrence. Grass, pellets softened to a mash with water, and bran mashes are preferable for the first 24–48 h. After this, feeding of hay and grain can be resumed slowly. Horses that have cecal dysfunction may experience recurrence despite these precautions.

The method of choice for treatment of severe cecal impactions has not been determined. Many horses with severe impactions respond to the aggressive fluid and laxative therapy outlined above. However, severe cecal impactions sometimes result in **cecal perforation** (*q.v.*).

Surgical management of cecal impactions should be considered in cases where the horse has intractable pain, the impaction is excessively large, medical therapy is unsuccessful, or peritoneal fluid analysis or transrectal examination indicates intestinal degeneration. A number of **surgical options** are described and include extraluminal massage, typhlotomy and evacuation, partial or complete typhlectomy, cecocolic anastomosis and ileocolic anastomosis. The surgical approach for these procedures is ventral midline celiotomy. Massage of the impaction with or without transmural injection of fluid may facilitate the passage of ingesta from the cecum and has the advantage that an enterotomy is not performed. **Typhlotomy** may be performed between the lateral and ventral cecal teniae, near the cecal apex, for evacuation of ingesta by use of a warm water hose. Extreme care must be taken during exteriorization of the impacted cecum to avoid **cecal rupture**. It is often difficult to fully exteriorize the cecal apex and, therefore, contamination at the enterotomy site may be excessive.

Cecocolic anastomosis may be created between the dorsal and lateral cecal teniae and the lateral and medial non-mesenteric teniae of the right ventral colon. Mild postoperative abdominal pain associated with gaseous distension of the cecum has been reported with this procedure. This may be due to inability of gas to exit through the cecocolic anastomosis or accumulation of reflux gas from the right ventral colon.

Jejunocolic or ileocolic anastomosis to bypass the cecum and redirect ingesta to the right ventral colon appears to be superior to cecocolic anastomosis. In this procedure the proximal ileum or distal jejunum is transected and the distal stump oversewn. An end-to-side or side-to-side anastomosis is then created between the ileum or jejunum and right ventral colon between the medial non-mesenteric tenia and the medial mesocolic tenia. Apparently, maintenance of a functional cecocolic orifice prevents reflux of gas from the right ventral colon into the cecum. If the procedure is done without terminating the ileum, continued passage of ingesta into the cecum may lead to recurrence of the impaction.

Complete typhlectomy and ileocolic anastomosis has been described but infrequently performed for management of cecal impaction. This surgical technique requires positioning in left lateral recumbency with a right lateral paralumbar fossa approach and resection of the eighteenth rib.

Prognosis for mild to moderate cecal impactions is good. Severe cecal impactions may result in death as a result of perforation. Severe cecal impactions may require surgical therapy, which can be complicated by adhesions or peritonitis. The prognosis with severe impactions is guarded.

Large colon impaction

Etiology and pathogenesis

Large colon impactions occur at three sites of the large colon: the **pelvic flexure**, **right dorsal colon** and **transverse colon**. These also are sites of origin of retropulsive contractions (those propagated in an oral direction), which retain ingesta for microbial digestion. These normal contractile patterns may contribute to worsening of impactions.

Clinical findings and diagnosis

Clinical findings include anorexia, decreased fecal passage and mild to severe abdominal pain. Initially the abdominal pain is mild and intermittent, but signs gradually worsen. Heart rate varies with the degree of pain. Mucous membranes are usually pink, but may be tacky due to dehydration or hyperemic due to endotoxemia when the colonic mucosa is compromised. There is usually no nasogastric reflux except when severe impaction results in ileus of the small intestine or compression of loops of small intestine. PCV, plasma protein and creatinine may be elevated due to dehydration.

Transrectal examination will reveal impacted ingesta and varying degrees of distension of the pelvic flexure and ventral colon. In severe cases, the impaction can involve the dorsal colon. The distension commonly pushes the colon to the **right side** of the abdomen and into the pelvic canal. Impactions in the right dorsal and transverse colon are usually beyond the reach of the veterinarian performing transrectal examination, but secondary tympany is usually palpated.

In severe long-standing cases, distension of the colonic wall may result in **transudation of protein**. This can progress to bowel necrosis leading to peritonitis, increasing the peritoneal fluid protein content and WBC count. Severe and unrelenting abdominal pain, systemic signs of toxemia (hyperemic or cyanotic mucous membranes), tachycardia and tachypnea often become apparent with the development of bowel degeneration and peritonitis.

Treatment and prognosis

All food should be withheld to prevent continued accumulation of impacted ingesta, but access to water may be allowed if there is no nasogastric reflux. Very mild impactions respond to administration of water and mineral oil via nasogastric tube. Fluid and laxative therapy for moderate to severe colon impactions is similar to that discussed for cecal impactions.

If medical management of large colon impaction is unsuccessful, **surgical intervention** is necessary to relieve the obstruction and re-establish normal gastrointestinal transit. The decision for surgery is based on unrelenting abdominal pain, failure of medical therapy, transrectal examination findings indicating concurrent large intestinal displacement, systemic cardiovascular deterioration, or changes in peritoneal fluid characteristics indicating intestinal degeneration. A ventral midline celiotomy is performed and thorough exploration of the abdomen performed to reveal the extent of the impaction and if a concurrent colon displacement exists. The pelvic flexure is located, and colon carefully exteriorized and placed on a colon tray. An enterotomy is performed at the pelvic flexure and, with the aid of a warm water hose, ingesta is evacuated from the colon. Systematic abdominal exploration is then performed to determine possible concurrent abnormalities.

The prognosis for medical management of mild to moderate large colon impaction is good. Prognosis for surgical correction of severe large colon impaction is good unless there is **necrosis of the intestinal wall** or colonic devitalization results in intestinal rupture during exteriorization of the colons.

Sand impaction

Etiology and pathogenesis

Horses may ingest sand while grazing or eating hay from the ground. Horses on closely grazed pastures in areas with a sandy soil are at greatest risk. The ingested sand settles to the bottom of the **large colon** where it may accumulate in large quantities and cause obstruction.

Clinical findings and diagnosis

The clinical signs are similar to those caused by large colon impaction (*q.v.*). As the sand accumulates, it may cause mild intermittent abdominal pain. In some cases, the signs of pain are acute. The sand may be felt with the fingers during **transrectal examination** and can be **detected in the feces** by placing in a container and adding water. The ingesta will float in the water and be washed away; sand will settle to the bottom of the container. The shifting of sand in the colon may be **audible**, said by some to sound like “*sand on a beach*”, during abdominal auscultation.

The impaction will be palpable via transrectal examination in either the pelvic flexure or cecum. Impactions in the right dorsal or transverse colon occur less commonly and usually are out of the reach of the examiner. The sand may act as an irritant and cause **diarrhea**. Degeneration and necrosis of the bowel can occur under the weight of the sand and lead to endotoxemia and peritonitis. Abdominal radiographs have been used to identify sand accumulation in the large colon and may be beneficial in monitoring resolution of the sand impaction with medical therapy.

Treatment and prognosis

Horses with sand impaction sometimes respond to administration of fluids and laxatives as for large colon impaction. **Psyllium hydrophilic mucilloid** is a laxative used for removal of sand and should be administered at 400 g/500 kg BW q 6 h until the impaction resolves. Psyllium therapy should then be continued at 400 g/500 kg BW daily for 3 wk to remove the majority of the sand from the colon. However, thorough removal of sand from the colon cannot be confirmed, and a recent study suggests the use of psyllium hydrophilic mucilloid may not be beneficial in removing sand from the colon.

Surgery may be necessary in horses that exhibit **unrelenting pain**, develop peritoneal fluid changes indicating bowel degeneration or fail to respond to medical therapy. The sand must be removed via a **pelvic flexure enterotomy**. Postoperative complications include peritonitis and adhesion formation. Furthermore, the sand can cause **extensive damage** to the colon wall leading to postoperative ileus, endotoxemia, colitis or bowel degeneration, thereby causing peritonitis. Therefore, although the prognosis is usually good for horses with mild sand impactions, horses with severe sand impactions and damage to the colonic wall have a poor prognosis.

Owners that keep horses in **sandy environments** should be taught **preventative management**. Pastures should be managed so that grass is thick and not overgrazed. Hay should be supplemented when needed, but **not fed off the ground**. Although these management techniques are the most effective way to prevent sand impaction, anecdotally it is suggested that psyllium

therapy can be used as an adjunct to remove sand from the colon before impaction develops. Effective preventative dosages have not been determined, but 400 g/500 kg BW daily for 3 wk has been used. Many horses will eat this in their grain ration if it is divided into several feedings. Flavored or soluble forms of psyllium are more expensive but may be better tolerated. This therapy can be repeated every 4–12 mo depending upon the amount of sand exposure.

Small colon impaction and foreign bodies

Etiology and pathogenesis

The inciting factors for **large colon impaction** (*q.v.*) can also lead to small colon impaction. Small colon impaction can also occur without predisposing factors. Many cases of uncomplicated small colon impaction are associated with salmonellosis (*q.v.*). **Intraluminal obstruction** with inspissated feces (fecalith), concretions of plant material (phytobezoar), hair (trichobezoar), or a combination (phytotrichobezoar) also occurs (*q.v.*).

Foreign body obstruction of the small colon is caused by ingestion of fibrous non-digestible material such as nylon fibers from lead ropes, halters, hay nets, twine, synthetic fencing material, blankets, or pieces of rubber, carpet and feed sacks. The foreign material often becomes coated with mineral precipitate, increasing the size and diameter of the mass. The foreign body may be present in the colon for months before causing an obstruction. Animals <3 yr of age, because of their curious nature, seem to be at a higher risk.

Clinical findings and diagnosis

Clinical signs of small colon impaction and foreign body include abdominal discomfort and straining to defecate. Bilateral abdominal distension and nasogastric reflux develop as complete obstruction leads to distension of the proximal large colon with gas and ingesta. Decreased fluid intake leads to dehydration. **Transrectal examination** may reveal distended, ingesta-filled small colon in the caudal abdomen. Small colon impactions may be diagnosed rectally in approximately 87% of the cases. A **foreign body** may be palpable in the small colon. However, the limited mobility of the small colon, increased tension on the mesentery, and secondary large colon distension often hinder transrectal examination.

In long-standing cases, **pressure necrosis** of the mucosa leads to endotoxemia (*q.v.*), thereby causing fever, depression and hyperemic mucous membranes. This can progress to bowel rupture, thereby causing **lethal peritonitis** and shock. Peritoneal fluid remains normal except in cases of protracted duration, in which increases in protein concentration and nucleated cell count reflect intestinal necrosis. Endotoxemia due to bowel necrosis or concurrent salmonellosis may cause neutropenia and a degenerative left shift.

Treatment and prognosis

Medical therapy is often successful in the treatment of small colon impaction and includes IV and oral fluids, **oral laxatives** (psyllium hydrophilic mucilloid, 0.25–0.5 kg/500 kg horse in 4–8 L per nasogastric tube; docusate sodium,

120–240 mL of 5% solution in 2–4 L per 500 kg horse once daily for 2 days; and magnesium sulfate, 1 g/kg in 4–8 L of water once daily for 2 days) and **intestinal lubricants** (mineral oil; 1 L q 24–48 h). Mild, gravity flow, warm water enemas have been used, but should be avoided when there is marked colonic distension or rectal mucosal edema. Surgical intervention should be considered when there is systemic deterioration, nasogastric reflux, uncontrollable pain, severe abdominal distension, evidence of intestinal degeneration on peritoneal fluid examination, and/or lack of response to medical therapy.

Ventral midline celiotomy is the preferred surgical approach for manipulation of the small colon near the transverse colon or rectum. The preferred technique for removal of small colon impactions is to administer a gentle warm water enema by introduction of a lubricated nasogastric tube through the rectum. The surgeon then guides the tube through the small colon to the site of impaction. Alternatively, the impacted mass may be injected with fluid and massaged to encourage dissolution. The wall of the colon is often very **edematous and friable** and extreme care must be used in manipulating the bowel to avoid seromuscular tears or colonic rupture.

Severe impactions and foreign bodies require an **enterotomy** to relieve the obstruction. The area of the obstruction should be exteriorized and isolated from the abdominal incision and packed off with moist towels. The incision is most often made through the antimesenteric tenia. If possible, the incision should be made in an area of normal colon to minimize postoperative healing complications. This is often not possible due to the immobility of the impaction or foreign body within the colon. A pelvic flexure enterotomy (*q.v.*) and evacuation of the ascending colon is also performed to minimize the amount of ingesta passing the enterotomy site in the immediate postoperative period, thereby reducing the incidence of recurrence.

The prognosis for **small colon impaction** is good providing there is no intestinal devitalization and a small colon enterotomy is not performed. If a small colon enterotomy is performed, the prognosis is slightly worse. High small colon mural collagenase activity, poor blood supply, high bacterial counts, and firm, formed feces all contribute to a high incidence of enterotomy incisional complications that may lead to peritonitis.

Enteroliths

Etiology and pathogenesis

Enteroliths are concretions composed of magnesium ammonium phosphate salts (“**struvite**”) that form slowly around a **nidus** such as a small metallic object or stone. Enteroliths may be single or multiple and usually do not cause a clinical problem until they become **lodged in the transverse or small colon**. Smaller enteroliths may be passed rectally with no associated clinical problems.

The specific geographic distribution of this condition has led to speculation that undetermined constituents in water and soil of these locations may be inciting factors in the disease. **Enterolithiasis** is most frequently seen in middle-aged horses, with Arabians, Morgans, Saddlebreds and miniature horses being somewhat over-represented. A large percentage of affected horses are on an **alfalfa diet** with a high magnesium and protein content. One

hypothesis in the pathogenesis of enterolithiasis is the increase in dietary magnesium increasing intraluminal pH, thereby favoring struvite formation.

Clinical findings and diagnosis

Affected horses may present with decreased fecal passage, colic, and weight loss. Incomplete obstruction may allow passage of soft mucus-covered feces, mineral oil and gas and lead to recurrent episodes of mild colic, making the diagnosis difficult.

If the enterolith is firmly encompassed by colonic mucosa, the obstruction is complete and gas and ingesta accumulate proximal to the obstruction. This manifests as **severe acute abdominal pain**, tachycardia, abdominal distension, and sometimes nasogastric reflux. Transrectal examination most often reveals moderate to severe distension of the large colon and cecum. Abdominal radiography may be helpful in the detection of enteroliths. Peritoneal fluid usually remains normal unless pressure necrosis of the bowel wall develops around the enterolith, when there may be an increased protein concentration and nucleated cell count.

A presumptive diagnosis is made by history, geographic location and physical examination findings. Abdominal radiography and/or exploratory laparotomy are used to confirm the presence of an enterolith.

Treatment and prognosis

Although some enteroliths may be passed rectally, conservative therapy is usually not successful. **Surgical intervention** via a ventral midline or flank laparotomy is necessary for systematic exploration of the abdomen and identification and removal of the enterolith. Obstructing enteroliths are most often located in the transverse or small colon. If possible, the area of the obstruction should be exteriorized and isolated from the abdominal incision and packed off with moist towels.

Surgical removal of enteroliths in the proximal small colon or transverse colon must be preceded by evacuation of ingesta from the large colon through a pelvic flexure enterotomy to minimize abdominal contamination. A warm water hose is then passed per rectum to facilitate removal of the enterolith by flushing it proximally into the transverse or right dorsal colon. Small enteroliths may be flushed back to the enterotomy site and removed. Larger enteroliths may necessitate a separate enterotomy in the right dorsal colon to facilitate removal. It is extremely important to check the entire large and small colon for **additional enteroliths**. If the enterolith has a flat side or the shape of a polyhedron, there is at least one more enterolith present. Complete exploration of the remainder of the abdomen should be performed before closure.

Frequently enteroliths of the small colon must be removed via an enterotomy in the involved section of bowel because of the inability to move the enterolith. An enterotomy incision long enough for easy removal of the enterolith is made through the antimesenteric teniae of the small colon. Pelvic flexure enterotomy and evacuation of the large colon should be performed in addition to the small colon enterotomy to minimize the transit of ingesta passing the enterotomy site in the immediate postoperative period.

The short- and long-term prognosis for uncomplicated enterolith removal is good providing the horse presents in **good cardiovascular condition** without intestinal devitalization. If a small colon enterotomy is performed, the prognosis is slightly worse. Increased small colon mural collagenase activity, poor blood supply, high bacterial counts and firm, formed feces all contribute to a high incidence of small colon enterotomy incisional complications that may lead to peritonitis (*q.v.*).

Large colon displacements

The equine left ventral and dorsal colons are freely movable in the abdominal cavity, thereby allowing for intestinal displacement and torsion. The cause of displacement is not known, however alterations in colonic motility, excessive gas production, and rolling secondary to abdominal pain have been incriminated. Dietary changes, excessive concentrate intake, grazing lush pastures and parasitism may initiate colonic displacement. However, in most cases no initiating factors are identified. Rotation of the colon less than 180° does not cause vascular occlusion, but will cause partial luminal obstruction and mural edema due to lymphatic obstruction.

Right dorsal displacement of the colon

Etiology and pathogenesis

Right dorsal displacement of the colon involves displacement of the left large colon to the right of the cecum, between the cecum and the right abdominal wall. Most commonly, the pelvic flexure migrates to the right, traversing the pelvic inlet cranial to the base of the cecum, and comes to rest at the sternum. Less commonly the pelvic flexure migrates from its normal position directly to the right, caudal to the base of the cecum, and again comes to rest at the sternum. Both of these displacements may be complicated by variable degrees of **volvulus** (*q.v.*).

Clinical findings and diagnosis

Clinical signs associated with colon displacement include abdominal pain and abdominal distension. The degree of clinical signs depends upon the duration and amount of colonic distension. Signs usually develop more rapidly and are more severe than with impaction because of tension on the mesentery and greater colon distension. The displacement often results in pressure on the duodenum, thereby resulting in **nasogastric reflux**. Peritoneal fluid usually remains normal in the early stages of displacement; however, in cases of long duration, increases in peritoneal protein concentration and nucleated cell count reflect compromise of the intestinal wall.

Transrectal palpation reveals mild to severe gas distension of the cecum or colon with large colon teniae often palpable lateral to the cecum or horizontally traversing the pelvic inlet. If the small intestine is secondarily obstructed, several loops of moderately distended small intestine may also be palpable. Following **gastric decompression** and rectal flatulence the horse may exhibit less pain, only to demonstrate recurrent moderate to severe pain when feeding is resumed.

Treatment and prognosis

Correction of right dorsal displacement requires **surgical intervention**. Exposure is best achieved through a ventral midline celiotomy. The pelvic flexure is located and the colons exteriorized. Decompression is often necessary to facilitate exteriorization and correction. The colon is examined for concurrent torsion and the colon is placed back into the abdomen in its proper anatomic position. Effective reduction is ascertained by being able to exteriorize the colon normally and visualize the entire cecocolic fold. Enterotomy is not necessary unless the colon is severely distended with ingesta. Prognosis for complete recovery is good. There is a low occurrence of complications such as adhesions and laminitis (*q.v.*) associated with right dorsal displacement.

If recurrence is a problem, colopexy or large colon resection should be discussed. **Colopexy** may be performed via ventral midline celiotomy or laparoscopically. However, these two procedures are not benign due to the potential postoperative complications, including dehiscence of the colopexy site, catastrophic rupture of the left ventral colon, fistulous tracts associated with sutures entering the lumen of the colon, and severe abdominal adhesions.

Left dorsal displacement of the colon

Etiology and pathogenesis

Left dorsal displacement of the colon involves displacement of variable portions of the left large colon to a position between the dorsal abdominal wall and the nephrosplenic ligament. The colon may pass through the **nephrosplenic space** from a cranial or caudal direction, or it may migrate dorsally when lateral to the spleen. The exact cause of this displacement is not known, but some horses that suffer from the condition have an excessively large nephrosplenic space.

Clinical findings and diagnosis

Clinical signs are similar to those found in horses with right dorsal displacement (*q.v.*). Initially, only a **partial obstruction** exists, thereby resulting in mild pain. However, ingesta and gas accumulate in the region of the pelvic flexure, thereby increasing the distension and the severity of the pain. In some cases obstruction of small intestine by the distended colon will result in **nasogastric reflux**.

Long-standing cases will develop **dehydration**. Peritoneal fluid usually remains normal in the early stages of displacement; however, in cases of longer duration, increases in peritoneal protein concentration and nucleated cell count reflect intestinal devitalization. **Transrectal palpation** reveals mild to severe gas distension of the cecum or colon with large colon teniae often palpable coursing cranial and to the left, over the nephrosplenic space.

The horse may demonstrate signs of discomfort when the nephrosplenic region is palpated. The spleen may be rotated caudally, away from the left body wall due to ventral tension on the nephrosplenic ligament. Transabdominal ultrasound examination of the nephrosplenic space is reported to be a valuable aid in the diagnosis of nephrosplenic entrapment of the colon.

Treatment and prognosis

Non-surgical correction of left dorsal displacement of the colon is often successful in cases in which an early and accurate diagnosis has been made. The first method involves administering the sympathomimetic drug **phenylephrine IV** (20 mg diluted in a 1 L balanced electrolyte solution) to **contract the spleen** and then **jog the horse** to release the entrapment.

The second technique requires **anesthesia** with the horse positioned in right lateral recumbency. **Phenylephrine** is administered prior to induction of general anesthesia to contract the spleen. Hobbles are placed on the hindlimbs and the horse is lifted into dorsal recumbency. As the hindlimbs are lifted to elevate the hind end of the horse off the ground, the abdomen is **vigorously balloted**. This allows the large colon to fall cranial and to the right. The horse is then rolled 360° back to right lateral recumbency, and allowed to recover.

Transrectal palpation to assess the position of the colon may be performed with the horse in lateral recumbency or after recovery. If the procedure is unsuccessful it may be repeated one or two more times. This procedure should not be performed when there is **severe colonic distension** or evidence of **intestinal devitalization**, due to the increased risk of intestinal rupture resulting in fatal peritonitis. The procedure is 70–90% successful in patients with a stable cardiovascular status without severe colonic distension or devitalization. Worsening or recurrence of the displacement, iatrogenic colonic or cecal torsion, and intestinal rupture are potential complications that must be considered before performing this procedure.

When non-surgical treatment is unsuccessful, surgery is necessary. Ventral midline celiotomy reveals the left colons to be located dorsal to the spleen with the pelvic flexure approximating its normal position or slightly flexed cranial or to the right. The entire colon should be located before exteriorizing the pelvic flexure to prevent excessive tension on the ligament. Correction is achieved by pushing the spleen medially and elevating the colon ventrally, lateral to the spleen.

Decompression may be required to assist reduction. Once the colon is free from the nephrosplenic space the pelvic flexure may be exteriorized and the colon placed in its normal position, medial to the spleen. A bruise may be evident on the serosal surface of the colon where it rested on the ligament. Ingesta should be manually redistributed within the colon, however enterotomy and evacuation of ingesta is seldom required. If the colon wall is not compromised, prognosis for complete recovery is good. If recurrence is a problem, colopexy, large colon resection and nephrosplenic space ablation could be discussed. Nephrosplenic space ablation is not associated with complications in athletic horses, unlike colopexy.

Displacements of the pelvic flexure and/or left colon

Etiology and pathogenesis

The most common displacement is **cranial flexion of the left colon** that causes the pelvic flexure to come to lie by the sternum. Displacement and entrapment of the pelvic flexure through a rent in the gastrosplenic ligament, diaphragm, or intra-abdominal mesoductus deferens have also been reported.

Clinical findings and diagnosis

Clinical signs associated with these lesions are similar to those found in horses with right and left dorsal displacement (*q.v.*). The pelvic flexure often cannot be located by transrectal examination.

Treatment and prognosis

Surgery is required for correction of the displacement and repair of the defect. Rents that are impossible to close due to inadequate surgical exposure must be left unrepaired in the hope that displacement will not recur. Diaphragmatic defects should be repaired because recurrence is probable with associated cardiovascular compromise. Prognosis is good if the rent can be closed and the intestine is not devitalized.

STRANGULATING OBSTRUCTIONS

Strangulating obstructions cause **complete luminal obstruction** combined with significant **compromise of the vascular integrity** of the intestine. Vascular occlusion can be either exclusively venous, resulting in hemorrhagic strangulation, or arterial and venous, resulting in ischemic strangulation. Hypoxia and ischemia cause **necrosis** of the involved segment of intestine, thereby leading to hypovolemic and endotoxic **shock**. Equine large intestinal strangulating obstructions include large intestinal torsion, intussusception and incarceration through mesenteric defects (*q.v.*).

Torsion of the large colon

Etiology and pathogenesis

Torsion of the large colon is one of the most **severe and rapidly fatal** abdominal conditions occurring in horses. The condition consists of rotation of the ventral and dorsal colons around their long axis at the origin of the large colon including the cecum, just distal to the cecum in the right colon, or in the middle of the colons. Viewing the horse in dorsal recumbency, the colon usually twists in a counter-clockwise direction with respect to the base of the cecum. The large colon and cecum can also rotate together about the vertical axis of the mesentery (*volvulus, q.v.*).

Rotations of 360° cause the colon to come to lie in an apparently normal position with the mesenteric root completely strangulated. After 4 h of ischemia resulting from vascular occlusion, the colonic mucosa becomes **completely necrotic**, with marked submucosal edema and hemorrhage. By 5 h there is hemorrhage, edema and necrosis at all levels of the bowel wall, often resulting in **intestinal rupture** (*q.v.*). These **time lines** do not always correlate well with clinical findings. The severity of the intestinal compromise may be substantially worse compared with the duration of colic signs.

The exact cause of colonic torsion is not known. **Hypomotility** secondary to dietary changes, electrolyte imbalances and stress may predispose to excessive gas accumulation and floating of the larger ventral colon lateral and dorsal to the smaller dorsal colon, thereby initiating twisting. There is a higher incidence of colon torsion in periparturient brood mares.

Clinical findings and diagnosis

Colon torsions cause an **acute onset** of severe, unrelenting abdominal pain that is either only mildly responsive to analgesic therapy or totally refractory. Both xylazine and detomidine alone or in combination with butorphanol may offer temporary relief. Tachycardia, tachypnea and blanched or congested mucous membranes are usually present. As distension progresses, respiratory function is impaired, resulting in **respiratory acidosis**. Serosanguineous peritoneal fluid with increased protein concentration and nucleated cell count reflects intestinal ischemia and necrosis. Transrectal palpation reveals severe colonic distension sometimes accompanied by mural and mesenteric thickening secondary to edema formation. Teniae may be palpable traversing the abdomen, however the severity of the distension often prevents complete transrectal examination.

Treatment and prognosis

Successful treatment requires an **early diagnosis** and expedient surgical correction. **Decompression** is often necessary to exteriorize the colon. The colon should be placed on a colon tray and an enterotomy performed at the pelvic flexure to evacuate the large colon. This removes endotoxin that can be potentially absorbed following detorsion, prevents further distension during manipulation of the bowel, and facilitates correction. The colonic mucosa should be evaluated during this procedure to assess the degree of **ischemic necrosis**. The direction of the torsion should be determined by palpation at the base of the cecum, and the exteriorized colon rotated in the opposite direction until the cecocolic ligament is visible, running from the lateral cecal tenia to the lateral tenia of the right ventral colon. The affected bowel typically appears blue gray initially and then becomes red to black.

Following correction, the color of the serosal surface of the colon usually improves; however, evaluation of mucosal integrity as well as of the intestinal circulation with fluorescein dye, ultrasound Doppler, tissue oximetry and frozen tissue biopsy can be performed to further assess intestinal viability.

Postoperative treatment of horses that retain sufficient viability of the colon should include **aggressive support therapies** (see volvulus, *q.v.*). If viable cells remain in the mucosal crypts, the epithelium should regenerate within 48–72 h. These horses usually remain endotoxic and pass dark hemorrhagic stools during this time. In some cases, the absorptive function of the colon is lost and diarrhea and protein loss develop. This may resolve after several weeks or be permanent.

If the affected colon is non-viable, colon resection or euthanasia are the only alternatives. Resection involves creating a 15–20 cm side-to-side anastomosis between the remaining viable juxtaparietal (lateral) aspects of the dorsal and ventral colons and resecting the non-viable dorsal and ventral colons. This may be performed by hand suturing techniques or with intestinal stapling equipment. The staple anastomosis minimizes surgical time and contamination at the surgical field, and is therefore recommended if the colonic wall is not excessively edematous. An end-to-end anastomosis has also been described 10–12 cm distal to the cecocolic fold between the dorsal and ventral colons. Approximately 95% of the large colon may be resected, but future colonic function may be compromised.

Colonic torsion recurs in approximately 20–30% of cases. **Colopexy** techniques, in which the lateral tenia of the left colon or the lateral teniae of both the left and right colons are sutured to the abdominal wall, have been used by some surgeons to reduce the incidence of recurrence. Release of the adhesion, suture failure and colonic tearing are potential complications that have been reported. Controlled studies have not been performed to determine the efficacy and safety of these procedures. Elective **colon resection** may also be performed to minimize recurrence.

Prognosis for recovery following colonic torsion is dependent on the interval between diagnosis and surgical correction. Irreversible intestinal ischemia and necrosis rapidly progress to hypovolemic, endotoxic shock and peritonitis. Therefore, the prognosis is poor unless surgery is performed within 2–3 h of the onset of clinical signs. The prognosis is also associated with the length of intestine resected. If >50% of the colon is removed the prognosis is guarded.

Cecocecal and cecocolic intussusception

Etiology and pathogenesis

Cecocecal and cecocolic intussusception are rare causes of intestinal obstruction in horses and result from **invagination** of the **apex of the cecum** into the base of the cecum, or a continuation of the invagination through the cecocolic orifice into the right ventral colon. Ultimately, the **entire cecum** may invaginate into the colon and become strangulated. The exact etiology of these intussusceptions is not known; however, conditions causing aberrant intestinal motility, such as parasitism (most commonly, *Anoplocephala perfoliata*, *q.v.*), changes in diet, impaction, intramural lesions, and motility altering drugs may predispose to the condition. Cecocolic intussusception appears to occur most frequently in horses <3 yr of age and Standardbreds are over-represented.

Clinical findings and diagnosis

Horses with **strangulating intussusception** may exhibit signs of acute, severe abdominal **pain**. In cases of chronic non-strangulating intussusception clinical signs include intermittent mild to moderate abdominal pain associated with depression, weight loss and scant, soft feces. The intussusception may be palpable per rectum as a large mass in the right caudal abdomen. The cecum may be distended and palpable in cases of cecocecal intussusception, but is not palpable with cecocolic intussusception. If the ileum is involved in the intussusception, distended small intestine may be palpable. The intussusception may have a “**bulls-eye**” appearance on ultrasonographic examination of the right lower quadrant of the abdomen.

Inflammation and edema of the invaginated cecum cause increased peritoneal fluid protein concentration and nucleated cell count. These changes, however, are often not evident until late in the disease because the affected tissue is sequestered from the abdominal cavity by normal cecum or colon. Failure to respond to medical therapy often leads to surgical exploration, at which time a definitive diagnosis is made.

Treatment and prognosis

Treatment involves **surgical correction** through a ventral midline celiotomy. If the apex of the cecum cannot be located and there is a firm mass palpable in the cecal base and/or the right ventral colon, a cecocecal or cecocolic intussusception should be suspected. The distal ileum and ileocecal orifice are usually involved, and tracing of the ileum into the intussusception confirms the diagnosis.

Attempts to reduce the intussusception are often unsuccessful due to marked mural edema and adhesions that may form between the serosal surfaces. However, if reduction is successfully accomplished and the viability of the cecum is questionable, a **partial typhlectomy** should be performed. If external reduction is not possible, reduction and resection of the devitalized segment of cecum may be performed via an enterotomy in the right ventral colon. If only the apex of the cecum is involved and external reduction is possible, the prognosis is good.

If reduction necessitates an enterotomy, or the entire cecum is involved in the intussusception, the prognosis depends on intestinal viability and degree of contamination at the surgical site, thereby causing peritonitis. A retrospective study on cecocolic intussusceptions suggested that even cases with a partial typhlectomy via a right ventral colon enterotomy with minimal intra-operative contamination should have a good prognosis. Successful management requires aggressive pre- and postoperative supportive therapies (see volvulus, *q.v.*).

Colocolic intussusception

Etiology and pathogenesis

Colocolic intussusception is a rare cause of intestinal obstruction in horses. The left ventral, pelvic flexure or left dorsal colons are most frequently involved. The exact etiology of **colocolic intussusception** is unknown; however, aberrant intestinal motility secondary to parasitism, changes in diet, impaction, intramural lesions and motility altering drugs may initiate intussusception. Colocolic intussusception appears to occur most frequently in **younger horses**.

Clinical findings and diagnosis

Initially, clinical signs include periods of mild to moderate **abdominal pain**. As the disease progresses, the pain becomes more persistent and is only mildly responsive to analgesics. Tachycardia, dehydration and depressed borborygmals sounds gradually develop. Nasogastric reflux may also be present. **Transrectal examination** may reveal a firm viscus within the large colon but, more commonly, distension of the large colon with gas and ingesta is the only abnormal finding. Increases in peritoneal fluid protein concentration and nucleated cell count reflect intestinal compromise, however these changes are often not evident until late in the disease due to sequestration of the affected tissue within the intussusceptum. **Progressive abdominal distension** and persistence of abdominal pain support the diagnosis of large bowel obstruction and the need for surgical exploration.

Treatment and prognosis

Treatment involves **ventral midline celiotomy** with decompression and exteriorization of the ascending colon. Manual reduction of the intussusception is

attempted and may be successful. If reduction is not possible or the intestine is devitalized, colon resection and anastomosis is indicated. If the colon is not markedly edematous, surgical stapling equipment may be used for the resection and anastomosis to minimize surgical time and contamination. End-to-end or side-to-side anastomosis may be performed depending on the location of the intussusceptum and the preference of the surgeon. The prognosis following manual reduction and surgical resection is fair. If resection and anastomosis is performed, successful outcome is dependent on the amount of intestine resected and the degree of peritoneal contamination.

Small colon strangulation

Etiology and pathogenesis

Strangulation of the small colon may occur when a segment of the small colon becomes entrapped in either an internal or external **hernia** (*q.v.*) or incarcerated by **pedunculated lipomas** (*q.v.*). Potential sites of **internal herniation** include the omentum, mesentery of the small or large intestine, and tears in the broad ligament of the uterus, gastrosplenic ligament, uterus or vagina. Potential sites of **external herniation** include the inguinal ring and umbilicus. Small colon volvulus (*q.v.*) is a rare cause of obstruction and strangulation that is usually associated with intra-abdominal adhesions.

Clinical findings and diagnosis

Small colon strangulation presents as acute, severe abdominal **pain** with alterations in cardiovascular and hydration status dependent on the duration of the strangulation. Nasogastric reflux may develop as the disease progresses. Fecal production is reduced or absent and complete transrectal examination is not possible due to small colon distension and tension on the mesentery. Distended loops of small colon are usually palpable, and the caudal mesenteric root may be palpable and extremely taut. The exact site of the strangulation is not discernible, and **exploratory celiotomy** is often necessary for definitive diagnosis.

Treatment and prognosis

Treatment involves ventral midline celiotomy to locate the site of entrapment or volvulus. The hernia is reduced or volvulus corrected and, when possible, defects in the mesentery, omentum or broad ligament are repaired. The viability of the involved small colon is assessed and resection of the affected segment and end-to-end anastomosis of normal colon performed.

FUNCTIONAL OBSTRUCTIONS

Primary cecal and colonic tympany

Etiology and pathogenesis

Cecal and colonic tympany may result either from primary causes or secondary to cecal impaction and large or small colon obstruction. Although the exact etiology is unknown, **primary tympany** may result from **rapid bacterial**

fermentation and gas production and/or impaired motility. Some predisposing factors include abrupt dietary changes and feeding of readily digestible foodstuffs such as grain, lush grass and clover (*q.v.*). It also has been suggested that parasitism may alter motility, leading to gas distension.

Clinical findings and diagnosis

The severity of the abdominal pain associated with cecal tympany depends upon the degree of cecal distension and the presence of a primary disease. In most cases of **primary cecal tympany**, there is mild distension causing mild intermittent abdominal pain. However, in cases of **cecal tympany secondary to physical obstruction**, there is severe distension and abdominal pain. In these latter cases, the horse may develop abdominal distension, greatest in the right paralumbar fossa, and dyspnea due to thoracic compression. The heart rate will be mildly elevated during episodes of pain in mild cases and persistently elevated (up to 90 bpm) in more severe cases. Mucous membranes are pink, but may be tacky due to dehydration. Borborygmal sounds are usually audible, but may be decreased to absent during bouts of abdominal pain.

Percussion of the abdomen reveals areas of gaseous distension. There usually is no nasogastric reflux. **Transrectal examination** usually reveals gas distension of the cecum; however, in severe cases, the ventral tenia of the cecum feels very taut as it courses from the right dorsal quadrant to the left ventral quadrant and the medial and dorsal teniae may be palpable.

In cases of cecal tympany **secondary to physical obstruction** of the colon, distension and/or displacement of the large colon may be evident on transrectal examination. There are usually no remarkable laboratory changes. Clinical examination often may not reveal differences between horses with primary cecal tympany and those with cecal tympany secondary to colonic obstruction.

Treatment and prognosis

Mild to moderate cases often respond to **analgesic drugs** (see Table 10.1). Administration of **mineral oil** (4 L to a 500 kg horse) may decrease fermentation and retard gas production. Mineral oil should not be administered to horses with nasogastric reflux. Cases in which cecal or colonic distension is secondary to a more distal obstruction usually require **exploratory celiotomy**. Cases of **colonic tympany** in which increases in heart rate, alterations in mucous membrane color, and recurrence of pain after analgesic administration are noted may have a more serious condition and should be carefully examined and monitored.

In cases of **severe cecal distension** with risk of cecal rupture, cecal trocarization for decompression may be necessary. Because of the risk of causing **severe peritonitis** due to contamination and laceration of the cecal wall, this procedure should be performed with care. The paralumbar fossa should be clipped, aseptically prepared, and blocked with a subcutaneous bleb of 2% lidocaine. A 14 or 16 G 15 cm needle or catheter should be used. Many equine cecal or bovine trocars are **too large** and will leave a large puncture in the cecal wall that does not seal after withdrawal. After the gas is removed, an antimicrobial agent may be flushed through the catheter just before it is

withdrawn to avoid leaving cecal contents in the peritoneum or abdominal wall. Even when the procedure is performed aseptically, trocarization will result in **peritonitis**, which usually resolves without consequence, but occasionally is severe with secondary abscessation. Therefore, **systemic broad-spectrum antimicrobial therapy** is indicated.

Non-strangulating infarction

Etiology and pathogenesis

Non-strangulating infarction describes **infarction** (*q.v.*) of the intestine without a constricting or compressive lesion. It has been postulated that such infarction is most likely induced by **vasospasm** associated with **verminous arteritis** (*q.v.*). Although lesions occur in both the small and large intestine, lesions of the cecum and colon are most common.

Clinical findings and diagnosis

A **poor parasite control program** may predispose horses to develop non-strangulating ischemia and/or infarction. However, the disease also occurs in horses that are regularly treated with anthelmintics. The severity of the clinical signs is variable, ranging from depression to severe abdominal pain. Heart rate and respiratory rate may remain normal or may increase. Hyperemic mucous membranes may be present suggesting endotoxemia (*q.v.*). Body temperature may be elevated due to either endotoxemia or the inflammation caused by migrating parasites. Lesions of the cecum and large intestine may cause mild or moderate cecal or colonic **tympany** (*q.v.*). Pain, fremitus or thickening may be evident upon palpation of the mesenteric root. Auscultation of the abdomen may reveal increased, normal or decreased borborygmal sounds. PCV, total plasma protein and creatinine may increase due to dehydration.

The peripheral blood may reveal decreased (neutropenia with a left shift), normal or increased WBC count. Total protein may be increased due to the chronic inflammation caused by parasitism or decreased as a result of protein loss through damaged intestinal mucosa. Abdominal fluid may be normal or have tremendous elevation in protein content (≥ 3.0 mg/dL) and WBC count (up to 200 000 cells/ μ L).

Treatment and prognosis

Balanced polyionic IV fluids (e.g. acetated Ringer's; 50–100 mL/kg/day) are an important part of therapy to correct dehydration and encourage reperfusion of the involved intestinal segments. If nasogastric reflux is obtained, careful attention should be given to maintain gastric decompression. **Broad-spectrum antimicrobials** (e.g. potassium benzylpenicillin G 22 000–44 000 mg/kg IV q 6 h and gentamicin sulfate 6.6 mg/kg IV q 24 h) should be administered if peritonitis (*q.v.*) is present. **Flunixin meglumine** (0.25 mg/kg q 8 h) may reduce thromboxane production, which causes or contributes to **mesenteric vasoconstriction**. **Dimethyl sulfoxide** (10 mg/kg q 8 h) diluted to a 10% solution in a balanced electrolyte solution and administered IV may help decrease some of the superoxide radical damage that occurs during reperfusion. Large dosages of aspirin (20 mg/kg PO daily) and heparin (40–100 IU/kg PO q 8 h) have been suggested to prevent thrombogenesis, however these are not routinely used.

Surgery should be considered in patients that deteriorate despite medical therapy. However, the prognosis is poor for patients with intestinal infarction requiring surgical resection. Extensive peritonitis may have already developed. Ischemia not obvious at the time of surgery may later progress to infarction. Ileus and adhesions (*q.v.*) are common postoperative complications. Large intestinal involvement may be too extensive for resection to be practical. However, identification and resection of involved segments of either small or large intestine is sometimes performed successfully.

LARGE COLON DISEASES CAUSING PERITONITIS

CECAL PERFORATION

Etiology and pathogenesis

The site of **cecal perforation** is usually the medial or caudal surface of the base. Excessive tension on the wall of the cecum as a result of **severe impaction** (*q.v.*) is the most common cause. Perforation of the cecum has also been associated with **late gestation** and **parturition**, but the pathogenesis of perforation in these animals is unknown. It has also been suggested that tape-worm infestation (*q.v.*) can cause perforation.

Clinical findings and diagnosis

Horses with cecal perforation usually have progressive signs of **cardiovascular shock** (*q.v.*) due to peritonitis. The rate of progression depends upon the rate of contamination of the peritoneal cavity. Transrectal examination may reveal enlargement of the cecum. However, after leakage of cecal contents into the peritoneal cavity, the distension may be reduced. **Emphysema** (*q.v.*) or roughening of the serosa at the base of the cecum may be palpable. The peritoneal fluid usually reveals an increased WBC count and protein content. Degenerative white cells and bacteria may also be present, depending upon the degree of leakage and the degree to which the resulting inflammation has sealed the perforation.

Treatment and prognosis

Therapy includes antimicrobials and supportive therapies (see duodenitis and proximal jejunitis, *q.v.*), which may result in temporary improvement of clinical signs. However, after fecal contamination of the peritoneal cavity has occurred, **death from shock** is imminent. Ventral midline celiotomy or a right flank laparotomy with resection of the eighteenth rib can be performed to repair the tear or remove the cecum and perform a bypass procedure. Open peritoneal lavage should also be performed. However, surgical correction after perforation is usually unsuccessful because the peritonitis continues to progress and the tear often cannot be completely exposed.

RECTAL TEARS

Etiology and pathogenesis

Rectal tears are most often **iatrogenic**, occurring during transrectal palpation for evaluation of the reproductive or gastrointestinal system. Other less

common causes include breeding accidents, pelvic fractures, dystocia, external trauma, perforation during enema administration and spontaneous rupture secondary to thromboembolism (*q.v.*). The rectum is the terminal 25–30 cm of the gastrointestinal tract, extending from the pelvic inlet to the anus. The peritoneum attaches 15–20 cm proximal to the anus, and therefore the proximal rectum is within the peritoneal cavity.

Most tears occur **dorsally**, between the 10 and 2 o'clock positions, in or near the site of **mesenteric attachment**. Those that occur more than 15–20 cm proximal to the anus are at a level beyond the peritoneal reflection and therefore at risk of extending into the peritoneal cavity.

Rectal tears are classified as grades I to IV according to the anatomic structures involved and **depth of mural perforation**. Grade I tears involve only the mucosa, or mucosa and submucosa. In grade II tears, only the muscular layers are separated and this results in a mucosal–submucosal diverticulum that rarely progresses to rupture. Grade IIIA tears involve perforation of the mucosa, submucosa and muscular layers, leaving the serosa as the only barrier between the peritoneal or pelvic cavity and the rectal lumen. Grade IIIB are similar to type A, but the tear is located dorsally so that only the mesorectum is left as the only barrier remaining. Both IIIA and B tears frequently progress to grade IV tears, in which all layers of the rectal wall are perforated, causing a communication between the peritoneal or pelvic cavity and the rectal lumen.

Although more common with inexperienced examiners, rectal tears may occur at all levels of experience. There appears to be a higher incidence of rectal tears in **Arabian** stallions and geldings. Regardless of the etiology, rectal tears should be considered an **emergency** and evaluated immediately to determine the degree of perforation in order to implement necessary supportive and therapeutic measures.

Clinical findings and diagnosis

In most cases the veterinarian is not aware that the tear has occurred until the arm is withdrawn and **fresh blood** is seen on the sleeve. The location of the blood on the sleeve may help indicate the depth at which the tear has occurred. A sudden release of rectal wall tension may be experienced during the tear, but is usually assumed to be a passage of a peristaltic contraction. The most common site of rectal tears is on the dorsal aspect approximately 15–55 cm from the anus.

Clinical signs will vary with the type of tear that is present. Horses with grade I and grade II tears rarely have any clinical signs associated with the tear. Horses with grade II tears may present for **rectal impaction or straining during defecation** at a later date. The diverticulum is identified during manual removal of feces from the rectum. Horses with grade III tears will develop fecal impaction within the **retroperitoneal space** of the pelvic cavity. Although there is no direct communication with the peritoneal cavity, **diffusion of bacteria and endotoxin** into the retroperitoneal cavity may cause ileus (*q.v.*), abdominal pain and increases in peritoneal fluid protein concentration and nucleated cell count.

The severity of clinical signs that follow is dependent on the degree of tissue involvement and the proximity of the lesion to the peritoneal cavity. If tissue dissection is extensive, the vascular supply to the mesocolon may be

damaged, leading to **infarction** (*q.v.*) of the affected segment of small colon and signs consistent with obstruction and strangulation (*q.v.*). If gross contamination of the peritoneal cavity occurs with grade IV tears, mild to severe abdominal pain is evident and endotoxemia (*q.v.*) and circulatory shock rapidly ensue. **Abdominocentesis** yields turbid fluid containing degenerative neutrophils, plant material and bacteria.

Diagnosis of rectal tears can be confirmed by careful digital examination of the rectum with a bare hand or visualization with a vaginal speculum or flexible endoscope. Tranquilization with **xylazine** (0.66 mg/kg IV) or acepromazine (0.06 mg/kg IV) and **caudal epidural anesthesia** (xylazine 0.017 mg/kg in 10 mL saline solution or 7–10 mL 2% mepivacaine in the first intercoccygeal space) greatly facilitates examination. The antimuscarinic **propantheline bromide** (0.014 mg/kg IV) can be used to induce **relaxation of the rectal wall**, and an **enema of 2% lidocaine hydrochloride** (30 mL mixed with **warm water**) will help desensitize the rectum. Fecal material is carefully removed and the tear is located. Once identified, the tear must be assessed for position, size, depth of penetration, and distance from the anus.

Treatment and prognosis

Medical therapy, including **stool softeners**, a **laxative diet**, **tetanus toxoid**, **IV broad-spectrum antimicrobial drugs** (e.g. metronidazole 15–25 mg/kg PO *q.i.d.*, potassium benzylpenicillin G 22 000–44 000 mg/kg IV *q 6 h* and gentamicin sulfate 6.6 mg/kg IV *q 24 h*), and **flunixin** meglumine (see Table 10.1), should be initiated immediately for all rectal tears.

Supportive therapy for **shock** (see duodenitis and proximal jejunitis, *q.v.*) is necessary in some cases. **Mineral oil** (1 L PO) is the stool softener most commonly employed. Lush green pasture with controlled exercise is probably the best diet. Pelleted feeds may be used if green pasture is not available.

Small grade I or II tears usually heal spontaneously but should be monitored closely for 4–6 days and treated medically. Larger grade II tears should be treated with **manual evacuation of feces from the tear** in addition to medical therapy. With manual evacuation, care must be taken to prevent enlargement of the tear.

More severe grade II–IV tears are considered emergencies and should be transported to a **surgical referral** facility immediately. Following epidural anesthesia, the rectum should be gently packed proximal to the tear with cotton soaked in a non-irritating disinfectant such as dilute povidone-iodine. This will minimize contamination of the tear and peritoneum with fecal material during transport.

When possible, tears may be hand sutured through the rectum in standing or lateral recumbency or by ventral midline celiotomy. Transrectal suturing techniques may be performed by one-handed blind palpation and suturing, or with the aid of an expandable wire rectal speculum and specialized long surgical instruments. Stay sutures may be used to retract the tear into view. These transrectal techniques are often frustrating and difficult and carry the risk of making the tear worse or causing further tissue trauma. The success of these techniques depends on the skill and experience of the surgeon, temperament and condition of the horse, mobility of the rectum, and location of the tear. Hourly manual evacuation has also been reported to be successful in

treating grade II–III rectal tears with adjunctive stool softeners and appropriate medical therapy.

A **rectal liner** can also be used to protect the tear from contamination during healing. A ventral midline celiotomy is performed and the large colon evacuated through a pelvic flexure enterotomy. A small colon enterotomy is then performed and a rigid plastic ring with a rectal liner attached is sutured in the lumen of the colon proximal to the tear. These sutures are placed in a manner to cause necrosis and sloughing of that portion of the bowel. The colon segments oral and aboral are sutured together over the ring, resulting in an anastomosis once the inner portion of bowel sloughs. The rectal tear heals before the inner portion sloughs. Fecal material passes into the ring and through the liner, which exits outside the anal sphincter. Difficulty of passage of fecal material through the ring and premature sloughing of the ring are reported problems of this technique.

In grade III or IV tears, a temporary diverting **colostomy** may be performed to avoid continual contamination at the perforation site and allow the tear to heal by secondary intention. Either a loop or end-on technique is performed through a left flank laparotomy. Closure of the colostomy can be a very difficult and time-consuming procedure and is best done as early as possible (2–5 wk after the initial surgery). The end-on technique produces fewer adhesions, but results in atrophy of the distal segment causing a large discrepancy in luminal diameter between the proximal and distal segments, thereby making anastomosis more difficult. The loop colostomy prevents this problem but does allow some fecal material to pass the colostomy site, thereby serving as a source for continual contamination at the tear. This is minimized by careful placement of the loop colostomy to ensure that the proximal segment of bowel is dependent.

The **prognosis for grade I and II tears is good** with early detection and immediate and proper therapy. Grade III tears have a fair to guarded prognosis and grade IV tears have a grave prognosis. Complications associated with rectal tears and surgical repair include breakdown of the suture line, peritonitis, pelvic abscess formation, impactions, prolapse of the colon (colostomy) and laminitis (*q.v.*). If fecal contamination of the peritoneal cavity is generalized, fatal peritonitis (*q.v.*) or extensive intra-abdominal adhesion formation leads to the demise of the animal.

GASTROINTESTINAL DISEASES CAUSING CHRONIC WEIGHT LOSS

INTRODUCTION

Chronic weight loss is a relatively common complaint among horses presented to the equine practitioner. While the etiologies of chronic weight loss can be numerous and varied (Box 10.1), the majority of cases are caused by one of a much smaller group of diseases. With the exception of decreased feed intake and malnutrition, gastrointestinal diseases are among the most common causes of chronic weight loss.

Clinical evaluation of a horse with chronic weight loss requires consideration of the potential underlying mechanisms. **Decreased feed intake** or malnutrition may result from inadequate feed intake, feeding poor quality

Box 10.1 Differential diagnosis of chronic weight loss in the horse**Conditions resulting in decreased feed intake or malnutrition**

- Inadequate diet
- Dental and jaw abnormalities
- Oral and pharyngeal abnormalities
- Esophageal abnormalities
- Any disease causing anorexia

Conditions resulting in increased nutrient loss

- Urinary loss of nutrients
 - Pituitary dysfunction
 - Renal disease
- Gastrointestinal loss of nutrients
 - Parasitism
 - Granulomatous, eosinophilic, lymphocytic and basophilic enteritis
 - Squamous cell carcinoma
 - Lymphosarcoma
 - Non-steroidal anti-inflammatory drug toxicity

Conditions resulting in maldigestion/malabsorption

- Maldigestion
 - Liver disease
- Malabsorption
 - Intestinal resection
 - Congestive heart failure
 - Parasitism
 - Granulomatous, eosinophilic, lymphocytic and basophilic enteritis
 - Sand-induced enteritis
 - Lymphosarcoma
 - Salmonellosis
 - Abdominal abscessation
 - Partial chronic bowel obstruction

Conditions resulting in increased energy requirements

- Abdominal abscessation
- Parasitism
- Recurrent airway obstruction
- Equine infectious anemia
- Equine viral arteritis
- Peritonitis
- Endocarditis/pleuritis
- Renal disease
- Neoplasia

foods, a failure to separate animals adequately at feeding time (thereby resulting in inadequate intake by non-dominant horses), poor dentition, oral and pharyngeal abnormalities, other causes of painful mastication and swallowing, and diseases causing anorexia.

Nutrient losses can occur in a number of conditions. For example, several diseases can cause significant loss of protein and/or glucose through the kidney or gastrointestinal tract.

Many diseases cause weight loss by impairing nutrient absorption. **Malabsorption** (*q.v.*) is a condition resulting from the impaired digestion and absorption of dietary components. It can result from structural or functional abnormalities of the large or small intestine, pancreas, liver or biliary tract. **Chronic diarrhea** due to large bowel malabsorption of water and electrolytes may or may not occur in horses with small intestinal malabsorption. **Large intestinal malabsorption** (*q.v.*) may result either from osmotic imbalances secondary to the passage of malabsorbed carbohydrates into the large intestine or from structural damage to the large intestine. Diseases causing malabsorption include disruption of the intestinal mucosa, intestinal inflammation and/or infiltration, lymphatic obstruction, abnormalities of the intestinal circulation (e.g. heart failure) and abnormalities of intestinal motility. Furthermore, impaired nutrient digestion and absorption can result from **chronic liver disease** (*q.v.*).

Increased energy demand not compensated by nutrient intake will result in weight loss. **Anxiety** or **increased exercise** may not be compensated by increases in feed ration. Chronic infection and **neoplasia** are common causes of increased energy utilization. Recurrent airway obstruction (RAO) (*q.v.*) can result in energy depletion through increased respiratory effort.

Several mechanisms may be involved in some causes of weight loss. For example, parasite infestation may result in both increased energy loss through **fecal protein exudation** and decreased absorption through damage to the intestinal absorptive surface.

DIAGNOSIS OF CHRONIC WEIGHT LOSS

History is a vital element in the diagnostic protocol for chronic weight loss. The owner should be questioned closely about the presence of additional localizing signs such as diarrhea, abdominal pain, pyrexia, exercise intolerance, coughing, dyspnea, dysphagia and polyuria (*q.v.*). If possible, the weight loss should be **quantified**. Because intermittent elevations of body temperature may be noted with some chronic infections, body temperature should be monitored periodically (e.g. twice daily). Owners can be instructed in the use of a “weigh tape” (*q.v.*) to provide a rough estimate of weight change.

Parasite control and feeding management practices should be evaluated. Knowledge of the frequency and type of anthelmintic treatment for all horses on the farm and number of horses pastured together is needed. The amount (by weight) and nature of feed consumed per day should be defined. Information about the location of feeding (group or individual) should be sought, pasture should be examined for quality, and the feed should be assessed for signs of spoilage. Analysis of the specific crude energy and protein content of the hay is useful to estimate quality.

A **complete physical examination** with close attention to the oral cavity should be made. The horse should be observed while eating for difficulty in prehension, mastication or swallowing. The presence of dyspnea, coughing, tachycardia, icterus, oral abnormalities or dysphagia may signal the presence

of respiratory, cardiovascular, liver or oropharyngeal diseases (*q.v.*) causing weight loss. If any question arises regarding quality or quantity of feeding, feed analysis is essential, and nutrient intake (*q.v.*) should be compared to estimated requirements for the individual.

Laboratory analyses should include fecal examination for parasites and blood, a complete blood count, serum chemistry (creatinine, total protein, albumin, liver enzymes, bilirubin, glucose and serum electrolytes), plasma fibrinogen concentration and urinalysis. Chronic anemia (*q.v.*) may be the result of chronic disease or diseases of the hemolymphatic system (*q.v.*) causing weight loss. Leukocytosis, neutrophilia, leukopenia, neutropenia, hyperfibrinogenemia, decreased plasma protein to fibrinogen ratio (≤ 10), or normal hematology and serum chemistry may be noted in horses with **chronic inflammatory diseases**. Elevated serum and urinary glucose concentrations may suggest an **endocrine abnormality** (*q.v.*). Elevated serum creatinine concentration, isosthenuria and proteinuria may be suggestive of **renal disease** (*q.v.*). Hypoalbuminemia may be associated with malnutrition, liver disease, renal disease or protein-losing enteropathy.

After it is determined that the horse has easy access to adequate nutrients and there is no historical, physical or laboratory evidence of diseases of other body systems, a thorough examination of the **gastrointestinal tract** is indicated. History of either intermittent abdominal pain or diarrhea is supportive of gastrointestinal disease; however, weight loss due to gastrointestinal diseases is frequently not accompanied by any other signs. For example, diseases causing **small intestinal malabsorption** can result in significant weight loss (e.g. **granulomatous enteritis**, *q.v.*). However, water absorption in the large colon, and therefore fecal character, are frequently normal in horses with small intestinal malabsorption.

Carbohydrate absorption tests should be used when intestinal malabsorption is suspected. The **glucose** and **D-xylose absorption tests** are the most widely used in horses (Box 10.2). The D-xylose absorption test is more expensive to perform due to the higher cost of xylose. However, because the results of glucose absorption tests are affected by endogenous factors (e.g. insulin and glucocorticoids), xylose absorption tests provide a more accurate indicator of small intestinal malabsorption. Both glucose and D-xylose absorption

Box 10.2 Oral glucose and D-xylose absorption test protocols

1. Fast the horse for 18–24 h
2. Administer a 10% solution of glucose or D-xylose via nasogastric tube at a rate of 1 g/kg BW
3. For the glucose assay, blood is collected in sodium fluoride tubes; for D-xylose, blood is collected in heparinized tubes
4. Blood samples are taken at 0, 30, 60, 90, 120, 150, 180, 210, and 240 min post administration
5. Peak concentration (D-xylose 20–25 mg/dL) occurs at 60–120 min post administration and is normally double the resting concentration
6. Concentration should return to normal at 6 h

tests are affected by delayed gastric emptying and increased intestinal transit time. Therefore, horses with abnormal results should be retested to eliminate the effects of these influences.

CHRONIC WEIGHT LOSS

Granulomatous, eosinophilic, lymphocytic and basophilic enteritis

Etiology and pathogenesis

These conditions are marked by a granulomatous, eosinophilic, basophilic or lymphocytic infiltration in the gut wall, with diffuse and patchy infiltrates and distinct granulomas composed of epithelioid, lymphoid and occasional giant cells and macrophages. Lymphoid hyperplasia, perilymphatic and transmural inflammation, lymphangiectasia, villous atrophy, mucosal ulceration, fibrosis, crypt abscesses and serosal fibrosis (*q.v.*) are often present. **Small intestinal lesions** are most common, thereby resulting in enteric protein loss and carbohydrate malabsorption. Protein loss may result from active protein secretion by mucosal cells, exudation through inflamed and ulcerated mucosa, disordered mucosal cell metabolism and rupture of dilated mucosal lymph vessels.

As the disease progresses, lesions develop in the large intestine **disrupting fluid absorption** and causing **diarrhea**. The etiology of these conditions is unknown but they are more prevalent in Standardbreds <5 yr of age than in other breeds. Rare cases of enterocolitis have been associated with infectious agents (e.g. *Histoplasma* and *Mycobacterium paratuberculosis*, *q.v.*).

Clinical findings and diagnosis

Chronic weight loss is the most common clinical sign associated with granulomatous, eosinophilic, basophilic and lymphocytic enteritis (*q.v.*). Appetite remains normal. Peripheral edema and diarrhea may be seen, especially in later stages of the disease. Anemia, hypoproteinemia and hypoalbuminemia are common laboratory findings. Small intestinal lesions result in malabsorption of glucose and xylose, while large bowel lesions cause diarrhea.

Hypoproteinemia in the absence of proteinuria, liver disease or malnutrition implicates the intestine as the site of protein loss. Demonstration of xylose and glucose malabsorption provides further support for the presence of an inflammatory or infiltrative disorder of the small intestine. A presumptive diagnosis can be made by ruling out other causes of malabsorption (see Box 10.1). Definitive diagnosis can only be made by **histologic examination** of intestinal sections obtained via **laparoscopy**, exploratory laparotomy or post mortem examination.

Treatment and prognosis

There is no effective treatment for these diseases. Reported treatments include administration of anthelmintic drugs, anabolic steroids, antibiotics, clioquinol, sulfasalazine and methylsulfonylmethane without efficacy. These medications may transiently alter **fecal consistency** without correcting weight loss. Temporary improvement has sometimes been associated with prolonged administration of corticosteroids. However, the weight loss and

hypoproteinemia eventually result in severe debilitation necessitating euthanasia.

Intestinal neoplasia

Etiology and pathogenesis

A number of intestinal neoplasms have been reported in the horse although the general incidence is $\leq 0.1\%$. Of the recognized intestinal neoplasms, **lymphosarcoma** (*q.v.*) is most common and affects horses of all ages. Other organ systems in addition to the gastrointestinal tract may be affected by lymphosarcoma. Other relatively common neoplasms of the equine gastrointestinal tract include gastric squamous cell carcinoma and adenocarcinoma (*q.v.*).

In horses with **intestinal lymphosarcoma**, infiltration of the intestinal wall by tumor cells can result in protein exudation and carbohydrate malabsorption. Chronic weight loss also results from increased energy requirements for tumor growth ("**cancer cachexia**"). **Gastric squamous cell carcinoma** and **adenocarcinoma** can also result in obstruction.

Clinical findings and diagnosis

Chronic weight loss is the most common early clinical sign. More specific signs vary with the location and type of tumor. Additional features may include **dysphagia** (gastric squamous cell carcinoma), acute abdominal pain, chronic abdominal pain secondary to adhesion formation, or chronic diarrhea secondary to neoplastic infiltration of the colonic wall.

As with other intestinal inflammatory or infiltrative diseases, **laboratory evaluation** may reflect intestinal protein loss (hypoproteinemia or hypoalbuminemia) and xylose and glucose malabsorption. Inflammatory responses to the tumor can also cause hyperproteinemia or hypergammaglobulinemia. Definitive diagnosis can occasionally be based on the cytologic evaluation of peritoneal fluid. With **multicentric disease**, peripheral lymph node biopsy or pleural fluid cytology may be diagnostic. Abdominal ultrasound occasionally reveals masses accessible by percutaneous biopsy. If this is unrewarding, histologic examination of intestinal tissues obtained at laparoscopy, exploratory laparotomy or post mortem may be required to provide a definitive diagnosis.

Treatment and prognosis

There is no effective treatment and euthanasia is eventually necessary due to severe debilitation.

Parasitism

Etiology and pathogenesis

Parasitic disease is the **most common cause of weight loss** in the horse (see also page 95). However, the frequency of disease has decreased with availability of newer anthelmintics. A range of deleterious effects may be ascribed to each type of parasitic infestation. Specific pathogenesis will depend on host, environment and parasite factors. Stress, immune suppression or concurrent diseases will all predispose to an increased severity of infection. Furthermore,

an intense inflammatory response to parasites may increase the severity of the intestinal lesions. As a result of the **complex interaction** of these factors, horses managed in the same environment and with identical anthelmintic therapy rarely demonstrate similar clinical signs due to parasitism.

Parasite transmission (*q.v.*) is determined by a number of factors. Heavily populated pastures with warm, moist environmental conditions promote environmental contamination, development of eggs into infective larvae, and ingestion of larvae. Parasite eggs are generally very hardy and survive for several years on pasture. Infective larvae survive for 6–10 wk in warm, moist conditions. They are relatively resistant to cold temperatures, but are rapidly destroyed by heat and desiccation.

Strongylus vulgaris (*q.v.*) larvae may cause a severe inflammatory reaction in the submucosa of the small intestine, cecum and ventral colon during their migration to the **ileocecocolic artery**. Lesions caused by the larvae in the mesenteric arteries may cause **bowel ischemia** and damage the adjacent mesenteric plexus. Gut motility and autonomic control may be disturbed. Ischemia may progress to infarction with mucosal necrosis and thus **malabsorption**. Extensive infarction can lead to **necrosis** of the entire bowel wall. Adult strongyles feed by digesting mucosal plugs in the glandular mucosa of the large intestine. This results in **ulceration**, which may extend into the muscularis and adjacent blood vessels. Absorptive and digestive functions are therefore impaired causing a malabsorptive, maldigestive weight loss. Protein exudation into the intestinal lumen infrequently occurs in horses with intestinal ulceration due to parasitism.

There has been an increased awareness of disease caused by **small strongyles (cyathostomes *q.v.*)** as a result of decreased incidence of disease due to large strongyles and increased prevalence of benzimidazole-resistant cyathostomes. Adult cyathostomes cause weight loss by causing intestinal wall inflammation and ulceration. In their larval stages, these parasites can migrate and become encapsulated in the mucosa of the large colon and cecum. These cysts damage the submucosal glands and generate an inflammatory infiltrate of neutrophils, fibroblasts and eosinophils. The fibrinous enteritis resulting from mucosal disruption also causes malabsorption and maldigestion.

Clinical signs and diagnosis

Acute clinical disease can be seen with large and small strongyle infestation. **Massive, sudden exposure** to infective larvae can result in a syndrome characterized by fever, endotoxemia, inappetence, lethargy, colic and weight loss due to massive intestinal ulceration and inflammation and/or intestinal infarction.

More commonly, subacute infestations result in chronic weight loss. Concurrent signs sometimes include dullness, poor haircoat, diarrhea and mild intermittent colic. Infestations with large and small strongyles may cause acute severe colitis or chronic weight loss due to **maldigestion/malabsorption** with or without diarrhea.

History is important in the diagnosis of parasite infestations. A horse that is presented for chronic weight loss, coming from a **crowded pasture** and with a poor or **unreliable deworming history**, should be considered at high risk for parasitic disease. Observation of the other members of the group with other

manifestations of parasite infestation may support such a suspicion. However, because there is individual variation in sensitivity to parasite infestation, disease may be restricted to one horse in a population. Weight loss due to parasitism can also occur in horses on a seemingly adequate parasite control program. **Ova counts** from fecal samples obtained from several horses in the same pasture can be used to help assess the adequacy of parasite control.

Clinicopathologic examination may reveal anemia, hyperglobulinemia, hypoalbuminemia and hypo- or hyperproteinemia. Horses do not commonly develop eosinophilia due to parasitism. Examination of feces may reveal a high ova count consistent with inadequate parasite control. However, if the disease is due to larval stages of *Strongylus vulgaris* or cyathostomes, fecal examination for ova can be negative. Peritoneal fluid may be normal or reflect mild inflammation with or without increased numbers of eosinophils.

Treatment and prognosis

The symptomatic animal should be treated with larvicidal dosages of anthelmintics (*q.v.*). Some clinicians prefer treatment with a non-larvicidal anthelmintic 2–3 days before larvicidal therapy. If severe bowel inflammation secondary to rapid parasite death is of concern, treatment with NSAIDs (e.g. **flunixin** meglumine at 0.25–1.1 mg/kg) at the time of anthelmintic administration may be warranted. **Larvicidal alternatives** include: **ivermectin** 200 µg/kg PO (single dose); **moxidectin** 400 µg/kg PO single dose; **fenbendazole** 50 mg/kg PO q 24 h for 3 days or 10 mg/kg PO q 24 h for 5 days. If improvement is not noticed in approximately 4 wk, larvicidal anthelmintic therapy should be repeated.

After larvicidal therapy, the **parasite control program** should be evaluated and improved if necessary. The frequency and type of anthelmintic treatments are important factors in a parasite control program. Commonly used anthelmintics are listed in Table 10.2. Slow rotational programs involve changing the class of anthelmintic on a yearly basis, while fast rotational programs use more frequent anthelmintic changes. **Conflicting results** have been reported as to which rotational strategy is more likely to minimize the development of resistance.

Each horse in a group should be treated **on the same day**. The **frequency** of anthelmintic therapy should be based on stocking rate, climate and pasture management. **Long-term evaluation** of a parasite control program is most easily obtained by monitoring fecal egg counts among herd members. Herd average fecal egg counts should be kept to <200 eggs per gram (EPG) at all times. Anthelmintic efficacy may be monitored by performing pre- and post-treatment fecal egg counts. A 90% decrease in EPG should be obtained for at least 3 wk post treatment.

Other parasite control measures include **rotation** to an uncontaminated pasture after anthelmintic treatment and **manure removal**, chain harrowing, or **cross grazing** of contaminated pastures with other species (e.g. cattle or sheep).

Abdominal abscessation

Etiology and pathogenesis

The diagnosis of chronic weight loss caused by **abdominal abscessation** is often difficult due to the insidious and non-specific nature of the disease.

Table 10.2 Dosage, safety and efficacy of commonly used equine anthelmintics

	Dosage (mg/kg)	Larvicidal	Worms affected
Non-benzimidazoles			
Ivermectin	0.2	Yes	<i>Parascaris equorum</i> , large strongyles, cyathostomes, bots, <i>Oxyuris equi</i>
Moxidectin	0.4	Yes	<i>Parascaris equorum</i> , large strongyles, cyathostomes, bots, <i>Oxyuris equi</i>
Pyrantel pamoate	6.6	No	<i>Parascaris equorum</i> , large strongyles, cyathostomes, <i>Oxyuris equi</i>
Pyrantel pamoate	13–20	No	<i>Parascaris equorum</i> , large strongyles, cyathostomes, <i>Oxyuris equi</i> , tapeworms ¹
Pyrantel tartrate	2.5 daily	No	<i>Parascaris equorum</i> , large strongyles, cyathostomes, <i>Oxyuris equi</i>
Praziquantel	1.5	No	Tapeworms
Ivermectin w/praziquantel	0.2 1.5	Yes	<i>Parascaris equorum</i> , strongyles, cyathostomes, bots, <i>Oxyuris equi</i> , tapeworms
Moxidectin w/praziquantel	0.4 2.5	Yes	<i>Parascaris equorum</i> , strongyles, cyathostomes, bots, <i>Oxyuris equi</i> , tapeworms
Benzimidazoles			
Fenbendazole	5–10	No	<i>Parascaris equorum</i> , large strongyles, cyathostomes, <i>Oxyuris equi</i>
Fenbendazole	10 s.i.d. × 5	Yes	<i>Parascaris equorum</i> , large strongyles, cyathostomes, <i>Oxyuris equi</i>
Fenbendazole	50 s.i.d. × 3	Yes	<i>Parascaris equorum</i> , large strongyles, cyathostomes, <i>Oxyuris equi</i>
Oxfendazole	10	No	<i>Parascaris equorum</i> , large strongyles, cyathostomes, <i>Oxyuris equi</i>
Oxibendazole	10–15	No	<i>Parascaris equorum</i> , large strongyles, cyathostomes, <i>Oxyuris equi</i>
Mebendazole	8.8	No	<i>Parascaris equorum</i> , large strongyles, cyathostomes, <i>Oxyuris equi</i>
Probenzimidazoles			
Febantel	6	No	<i>Parascaris equorum</i> , large strongyles, cyathostomes, <i>Oxyuris equi</i>

¹ Commonly recommended for tapeworms but quantitative assessment of efficacy not available.

Intra-abdominal abscesses may result from **dissemination of bacteria via the bloodstream or lymphatic system**, thereby resulting in abscessation of mesenteric lymph nodes. **Perforation of the intestine** (e.g. by a foreign body) or **penetration of the abdominal wall** may also result in local peritonitis and abscess formation. Specific etiologies include *Streptococcus equi equi*, *Strep. equi zooepidemicus*, *Rhodococcus equi* (foals), Gram-negative enteric bacteria (e.g. *Escherichia coli*, *Klebsiella* spp.) and anaerobic bacteria (*q.v.*).

Weight loss in horses with abdominal abscesses may result from several causes. Metabolic rate, and thus energy requirement, is increased as the body attempts to **resolve the infection**. Obstruction of the **mesenteric venous vasculature** may result in intestinal vascular congestion, and thus **malabsorption**. Compression of the intestine or adhesion formation may result in partial

or complete obstruction. Recurrent abdominal pain may result in inappetence. Recurrent fever may also cause depression and anorexia.

Clinical findings and diagnosis

Mesenteric abscessation may result in chronic weight loss, intermittent or low-grade fever, depression and inappetence. If the lesion results in partial or complete intestinal stricture, mild recurrent or severe acute colic may be seen. Colic may also result from a large abscess in the mesentery or secondary to peritonitis. Heart and respiratory rates may be increased.

Weight loss with an **intermittent fever** is consistent with abdominal abscessation. Hematologic abnormalities may include mild anemia, neutrophilia or neutropenia with a left shift, and elevated plasma fibrinogen concentration. Total plasma protein concentration is often elevated, with increased globulins and decreased albumin. Peritoneal fluid may be normal in the case of a walled-off abscess, however more commonly the fluid is cloudy with an increased nucleated cell count and protein concentration. Occasionally, intracellular bacteria are seen on cytologic examination of the peritoneal fluid. **Abdominal fluid should be cultured**, although the findings are often negative. The abscess may be palpable via rectal examination but may be out of the reach. Ultrasonographic evaluation may also be helpful.

Treatment and prognosis

Long-term treatment (for weeks to months) with an appropriate antimicrobial drug is usually necessary. If a positive culture is obtained, treatment should be based on antimicrobial sensitivity testing. *Streptococcus equi equi* and *Strep. equi zooepidemicus* are generally susceptible to penicillin. **Procaine benzylpenicillin** (22 000–44 000 IU/kg IM b.i.d.) or **potassium benzylpenicillin** (22 000–44 000 IU/kg IV q.i.d.) is commonly used. *Streptococcus* spp. are often sensitive to **erythromycin** (25 mg/kg PO t.i.d. or q.i.d.), but commonly resistant to potentiated sulfonamides. The combination of **clarithromycin** (7.5 mg/kg PO b.i.d.) and **rifampicin** (5 mg/kg PO b.i.d.) is the treatment of choice for abscessation due to *Rhodococcus equi*.

If the specific etiology is unknown, broad-spectrum antimicrobial therapy is indicated (potassium benzylpenicillin 22 000–44 000 IU/kg IV q 6 h or procaine benzylpenicillin G 22 000–44 000 IU/kg q 12 h with gentamicin 6.6 mg/kg once daily IV or IM and metronidazole 15 mg/kg q 8 h PO or 20 mg/kg per rectum q 8 h). Anti-inflammatory drugs such as **phenylbutazone** (4–8 mg/kg/day IV or PO) or **flunixin** meglumine (1.1 mg/kg/day IV, PO or IM) may be used to reduce fever and inappetence.

Response to therapy may be monitored by evaluating shrinking of the abscess by rectal examination or ultrasonography. Resolution or improvement of peritonitis, fever, colic and abnormal serum protein and fibrinogen is also evidence of response to therapy.

The prognosis with prolonged antimicrobial therapy is fair to good, provided there is no intestinal obstruction (*q.v.*). **Intestinal obstruction** can, however, occur during healing due to adhesion formation. In cases of abscessation with significant bowel obstruction, the prognosis is very poor. **Surgical exploration** may be indicated. The abscesses and affected bowel should be resected

if possible. If resection is not feasible, **marsupialization** of the abscess may permit flushing and drainage. An obstructed bowel that cannot be resected may be surgically bypassed, however there is risk of re-obstruction due to adhesion formation.

Sand-induced enterocolitis

Etiology and pathogenesis

Chronic weight loss can result from accumulation of **geosediment** in the colon.

Clinical findings and diagnosis

Chronic weight loss due to **sand** usually is accompanied by **diarrhea**. Rectal examination can reveal **soft stools** and **sand in the rectum**, however the presence of sand is not always obvious. The remaining physical examination and laboratory findings are usually normal. Diagnosis is made by evaluation of the environment, presence of diarrhea, absence of evidence of other diseases causing weight loss, and response to treatment for sand accumulation.

Treatment and prognosis

Specific treatment is psyllium **hydrophilic mucilloid** (see sand impaction, *q.v.*).

Non-steroidal anti-inflammatory drug toxicity

Etiology and pathogenesis

Mucosal ulcerations of the gingiva, hard palate, tongue, stomach, small intestine and large intestine can result from non-steroidal anti-inflammatory drug (NSAID) toxicity (see also Chapter 4, page 267). Right dorsal colitis also sometimes occurs in horses with NSAID toxicity. Although **high dosages of phenylbutazone** and other NSAIDs for several days are required experimentally in normal horses, mucosal ulceration has developed in clinical cases given standard dosage regimens. This implies that **clinical compromise** increases the susceptibility of horses to the adverse effects of NSAIDs. Bacterial invasion of the submucosa after damage to the mucosal barrier may be important in the pathogenesis of the ulcerative lesions. **Mucosal ulceration** allows exudation of protein into the intestinal lumen and absorption of bacterial endotoxin into the systemic circulation.

Clinical findings and diagnosis

Clinical signs include chronic weight loss, intermittent colic, diarrhea, anorexia and depression. Some horses with NSAID toxicity develop ulceration of the **gingival mucosa**. Hypoproteinemia may result in dependent edema. Hypoproteinemia due to hypoalbuminemia and hypoglobulinemia is the most consistent laboratory finding. Proteinuria (due to renal papillary necrosis) and neutropenia with a left shift (due to endotoxemia) are inconsistent laboratory findings in horses with NSAID toxicity. Peritonitis (*q.v.*) occurs rarely in horses with NSAID toxicity and results in increased concentration of WBCs and protein in peritoneal fluid. Diagnosis is based on a **history of NSAID administration** in horses with consistent clinical and laboratory findings.

Treatment and prognosis

NSAID therapy should be **withdrawn** whenever possible. There is no specific therapy for horses with NSAID-induced intestinal ulceration. **Proton pump antagonists** (**omeprazole** 4 mg/kg PO s.i.d.) or histamine receptor antagonists (**cimetidine** 4.4–6.6 mg/kg IV q.i.d. or 20 mg/kg PO t.i.d. or **ranitidine** 6.6 mg/kg IV or PO b.i.d.) and local protectants (**sucralfate** 20 mg/kg PO q.i.d.) may accelerate the healing of **gastric ulcers** (*q.v.*) due to NSAID toxicity. These medications provide minimal benefit to horses with colonic ulceration or right dorsal colitis.

The cornerstone of therapy is **reduction of stress**, correction of fluid and protein deficits (see supportive therapy in duodenitis and proximal jejunitis, *q.v.*) and feeding a low residue diet provided in an all pelleted ration with minimum of 25% fiber content. Hay and corn based diets should be specifically avoided. Transfusion with **plasma** (3–10 L) may help offset the effects of hypoproteinemia. This is usually not necessary until the plasma protein decreases <4 g/dL, however clinical signs and the rapidity of protein loss aid the clinician in choosing the patient that will benefit from plasma transfusion.

Treatment with appropriate dosages of **antimicrobials** may hasten resolution of right dorsal colitis and healing of colonic ulceration; antimicrobials also are indicated if abdominocentesis reflects peritonitis. The more commonly used antimicrobials include **potentiated sulfonamides** (15 mg/kg IV or PO b.i.d.), chloramphenicol (50 mg/kg PO q.i.d.), cephalosporins (25 mg/kg IV or PO q.i.d.), and gentamicin (2.2 mg/kg IV or IM t.i.d.) and amikacin (6.6 mg/kg IV or IM t.i.d.) combined with either **procaine benzylpenicillin** (22 000–44 000 IU/kg IM b.i.d.) or **potassium benzylpenicillin** (22 000–44 000 IU/kg IV q.i.d.).

Exploratory celiotomy may be necessary in horses with recurrent abdominal pain due to right dorsal colitis to rule out other causes of abdominal pain. Surgical treatment via resection of the right dorsal colon has been performed successfully in several cases, however the number of cases is not sufficient to conclude whether medical or surgical therapy is best.

Horses with recurrent abdominal pain due to right dorsal colitis have a guarded to poor prognosis. The prognosis is fair to guarded in horses with ulceration.

Salmonellosis

Salmonellosis (*q.v.*) rarely causes chronic weight loss in horses, except as a complication of acute salmonellosis. Chronic damage to the intestinal tract can result in malabsorption and protein-losing enteropathy, thereby causing weight loss, hypoproteinemia and diarrhea.

GASTROINTESTINAL DISEASES CAUSING ACUTE DIARRHEA

SALMONELLOSIS

Etiology and pathogenesis

Infection with *Salmonella* spp. (*q.v.*) is the most common cause of **acute toxic colitis**, an **inflammatory disease of the large colon** characterized by clinical

signs of endotoxemia (*q.v.*). The environment becomes contaminated as a result of **fecal shedding** of the bacteria by symptomatic or asymptomatic animals, including horses, rodents, birds, dogs, cats and goats. Salmonellae can survive in the environment for months to years and are not killed by freezing. Drying and exposure to sunlight will kill the organism.

Horses often become infected with *Salmonella* spp. without developing clinical signs and frequently shed organisms for weeks to months after infection. Conflicting evidence exists over whether a **chronic carrier state** with persistent tissue infection occurs in horses. The frequency of fecal shedding of salmonellae by horses in the general population is 0.8–17%. Upon infection with salmonellae, the dose, virulence and host immunity all interplay to determine whether clinical signs develop. **Stressors** associated with salmonellosis include transportation, antimicrobial treatment, surgery, colic and stable management changes.

After ingestion, organisms establish themselves on the intestinal villous surface and then invade the mucosa of the lower small intestine, cecum and large colon. **Virulence factors** that may be associated with *Salmonella* spp. include endotoxin, enterotoxin and cytotoxin. The resultant local inflammatory response leads to the production of prostaglandins, leukotrienes, bradykinins and oxygen radicals. **Diarrhea** is most likely due to a combination of motility changes, increased secretion and malabsorption. Clinical signs of shock (tachycardia, hyperemic and/or cyanotic mucous membranes, depression, weakness) result from hypovolemia and endotoxemia. Endotoxemia (*q.v.*) also causes fever and changes in the leukogram (neutropenia and left shift).

Clinical findings and diagnosis

Clinical signs of salmonellosis include fever, tachycardia, hyperemic and/or cyanotic mucous membranes, partial to complete anorexia, moderate to severe depression, various degrees of abdominal pain, increased or decreased borborygmal sounds and diarrhea. Initial signs usually include fever, depression, anorexia and, sometimes, abdominal pain and distension.

Careful **rectal examination** may reveal soft feces in the rectum with more fluid ingesta in the large colon. Occasionally the rectum will feel edematous. Diarrhea begins 1–7 days after these initial signs. After the onset of diarrhea, any abdominal distension and pain usually resolves. The duration of the diarrhea may vary from one day to several weeks. Hypoproteinemia may result in edema in the legs, ventral abdomen, throat, intestine and lungs.

Laboratory findings include leukopenia with neutropenia (degenerative left shift may or may not be present) and sometimes lymphopenia. This may be followed by rebound leukocytosis with WBC counts up to 28 000 cells/ μ L. Gastrointestinal losses of electrolytes, anorexia and intake of large quantities of fresh water often lead to hyponatremia, hypochloremia, hypokalemia and metabolic acidosis. Because large colon secretion of fluid and electrolytes may begin before the onset of diarrhea, these serum electrolyte abnormalities can occur without diarrhea. However, serum electrolytes are variable and must be monitored so that fluid therapy can be adjusted appropriately. Azotemia (*q.v.*) may be present and is usually pre-renal (urine specific gravity ≥ 1.020 without increased blood, protein or abnormal sediment). However, renal azotemia can

result from tubular necrosis due to hypovolemia and endotoxemia. Hypoproteinemia is common as a result of protein-losing enteropathy.

Horses with severe endotoxic shock due to **colitis** may develop laboratory and clinical evidence of **disseminated intravascular coagulation** (thrombocytopenia, prolonged clotting times, increased fibrinogen degradation products and evidence of hemorrhage or thrombosis). **Abdominocentesis** may be normal or consistent with a transudate due to bowel inflammation. In rare cases, the integrity of the intestinal wall is compromised resulting in bacterial leakage into the peritoneal cavity and exudative peritonitis.

A presumptive diagnosis of **acute toxic colitis** can usually be made based on physical and laboratory findings. Culture of *Salmonella* spp. from the feces, rectal mucosa biopsy, or from tissues collected at necropsy of animals with clinical signs of colitis results in a diagnosis of salmonellosis. The best fecal sample is 10–30 g of feces collected either before profuse watery diarrhea develops or during the recovery period when the feces become more formed. It often takes up to **five cultures** before the organism is recovered. The mucosal sample can be placed in 5 mL 0.9% saline solution or enrichment medium before transferring to a laboratory.

If the animal dies or is euthanatized, samples of ileum, cecum, large colon and mesenteric lymph nodes should be submitted for culture. Testing of fecal samples with polymerase chain reaction (PCR) is also commonly employed, possibly providing increased sensitivity. The specificity and rate of false positives of PCR for clinical diagnosis of salmonellosis are difficult to assess.

In some cases, it is difficult to distinguish the early stages of acute toxic colitis from other causes of colic. Careful rectal examination, resolution of the abdominal pain and the onset of **profuse watery diarrhea** aid in making a diagnosis.

Treatment and prognosis

The cornerstone of therapy is **correction of fluid deficits**, acid-base imbalances and electrolyte disturbances while the gut is healing. Fluid therapy is aimed toward correcting deficiencies and meeting ongoing losses. Not all cases will require IV therapy; however, if oral intake is not sufficient, IV supplementation will be necessary. In horses with severe profuse watery diarrhea, treatment with **IV volumes exceeding 100 L/24 h** may be necessary. The serum electrolytes and bicarbonate equivalent should be evaluated so that the oral and IV therapy will be specific to the individual metabolic disturbances. IV fluid administration is usually necessary if azotemia is present.

Fresh water and water containing electrolytes should be offered. **Specific electrolytes** added to the drinking water can be tailored according to the serum electrolyte analysis. Oral isotonic saline contains 9 g sodium chloride per liter of water and isotonic sodium bicarbonate contains 12.5 g sodium bicarbonate per liter of water. Because hypokalemia is common, these solutions should be supplemented with potassium. However, supplementation with potassium >1.5–2 g/L water decreases palatability. Fifty grams of glucose can be added to each liter of water to increase palatability and absorption of electrolytes. Either potassium chloride (30 g/4 L water/454 kg BW) or sodium bicarbonate (50 g/4 L water/454 kg BW) can be given by stomach tube twice daily to aid in correction of acidosis and hypokalemia. Correction

of acidosis can lead to **hypokalemia**, and therefore it is almost always necessary to supplement with potassium (1.5–3 g/L) when administering sodium bicarbonate. Serial evaluation of PCV and plasma proteins will help determine the adequacy of fluid therapy.

The indications for **antimicrobial therapy** during salmonellosis are controversial. Treatment with appropriate dosages of antimicrobials that demonstrate in vitro efficacy against *Salmonella* spp. does not seem to hasten recovery from diarrhea or the gastrointestinal disease. Antimicrobials are sometimes used as prophylaxis during severe leukopenia and IV catheterization to prevent septic complications associated with *Salmonella* spp. or other enteric bacteria. Antimicrobials are indicated if abdominocentesis reflects **peritonitis**. The rebound leukocytosis that may occur during the recovery phase should not be taken as an indication for antimicrobial therapy.

Because bacteremia occurs more frequently in **foals**, prophylactic antimicrobial therapy is almost always indicated in animals <9 mo of age.

The more commonly used antimicrobials include **trimethoprim—sulfonamide** (22 mg/kg IV or PO q 12 h), chloramphenicol (50 mg/kg PO q 6 h), cephalosporins (25 mg/kg IV or PO q 6 h), and gentamicin (6.6 mg/kg IV s.i.d.) and amikacin (20 mg/kg IV s.i.d.) combined with penicillin. Whenever possible, antimicrobial selection should be based upon **culture and sensitivity** of the *Salmonella* spp.

The main **contraindication for antimicrobial administration** is destruction of the normal intestinal flora, thereby allowing proliferation of the *Salmonella* spp. Therefore, antimicrobials to which *Salmonella* spp. are frequently resistant and that remain in the intestinal tract in high concentrations (e.g. **tetracyclines** and **neomycin**) are contraindicated.

Oral astringents and protectants such as **bismuth subsalicylate**, **activated charcoal** or **kaolin** products may be helpful. **Bismuth subsalicylate** can be given at the rate of 2–4 L/500 kg BW by nasogastric tube three to four times daily. If no improvement in the character of the stool is seen within 72 h, its use can be discontinued. **Activated charcoal** may act by adsorbing toxins, but seems less effective than bismuth subsalicylate. Kaolin products can have the appearance of improving the character of the stool, however they **do not decrease** the water content of the stool or decrease water losses. **Ditrioctahedral smectite** (1.36 kg [3 lb]/500 kg BW loading dose followed by 1 g/500 kg BW q.i.d.) is an organomineral that absorbs endotoxins, exotoxins and organic vapors and appears effective in reducing symptoms of equine salmonellosis.

Supportive therapy is of the utmost importance in the management of acute diarrheal disease. In horses with severe (<4 g/dL) hypoproteinemia, administration of **colloidal solutions** is necessary to maintain oncotic pressure for adequate circulation volume. Fresh or thawed frozen **plasma** (6–10 L/450 kg BW) is ideal to restore oncotic pressure and provide functional proteins beneficial for clotting, immunity and modulation of the systemic inflammatory process. Alternatively, administration of synthetic solutions (**hetastarch** 6%, 5–10 mL/kg) may result in adequate transient volume expansion. There are anecdotal reports of increased death rate among foals after administration of some hyperimmune plasma preparations.

Horses with **ischemic damage** to intestinal segments generally absorb large amounts of endotoxin, thereby causing further **cardiovascular**

deterioration. Treatment to dampen the systemic inflammatory response associated with endotoxemia is frequently beneficial. Choice of treatment options is based on severity of disease, renal function and hydration status. The most important strategy in management of endotoxemia is aggressive management of the primary disease process.

Also available are **immune sera and plasma** collected from donors inoculated with portions of endotoxin molecules derived from Gram-negative bacteria. The resulting antibodies may bind circulating endotoxin and render it inactive; however, results of experimental studies are not definitive.

Polymyxin B is an aminoglycoside antibiotic that binds and neutralizes endotoxin and decreases the systemic effects of endotoxemia when administered at 1000–5000 IU/kg t.i.d. Side effects include nephrotoxicity and neurotoxicity. Patients should be monitored closely, especially during use of other nephrotoxic medications, azotemia and dehydration. Treatment of endotoxemia also involves inhibition of mediator synthesis. NSAIDs are most often employed for this purpose. **Flunixin meglumine** (0.25 mg/kg IV or IM q 8 h) may help by decreasing the production of thromboxanes and prostacyclins from arachidonic acid, thereby preventing some of the metabolic, cardiovascular and pulmonary effects of endotoxin. Furthermore, if these products of arachidonic acid contribute to the pathogenesis of laminitis, flunixin may help to reduce the incidence of this side effect in horses with salmonellosis. Higher dosages of flunixin meglumine (up to 1.1 mg/kg IV or IM q 12 h) may be needed to provide analgesia to horses with abdominal pain. Administration of flunixin to hypovolemic horses or at excessive dosages may decrease synthesis of protective prostaglandins, thereby contributing to intestinal ulceration, protein loss and renal disease. **Pentoxifylline** (8 mg/kg PO t.i.d.) **combined with flunixin meglumine** may be slightly more beneficial than flunixin meglumine alone. Inactivation of oxygen-derived radicals is sometimes attempted with dimethyl sulfoxide (DMSO 0.1–1 g/kg/day IV as a 10% solution).

Because **laminitis** (*q.v.*) is a common complication associated with all inflammatory and ischemic disease in horses, **frog supports** are recommended preventatively in these patients. Digital pulses and signs of lameness should be monitored closely.

The prognosis for *Salmonella*-induced colitis is **extremely variable**. Horses that continue to be alert and responsive with fair to good appetites tend to have a good prognosis. Clearly if a horse is presented with a PCV $\geq 55\%$ the prognosis is guarded and if $\geq 60\%$ the prognosis is poor. Horses with purple mucous membranes, severe tachycardia (≥ 110 bpm) and renal azotemia also have a guarded to poor prognosis. The occurrence of thrombophlebitis (*q.v.*), whether septic or sterile, can also reduce the prognosis as fluid administration becomes difficult. The presence of exudative peritonitis is a reflection of severe compromise to the bowel wall indicating a poor to grave prognosis.

Horses that develop profuse diarrhea followed by scant or absent stool production, abdominal distension and pain have a poor prognosis. These horses often have irreversible intestinal ileus and pooling of fluid within the intestinal lumen that progresses to death or necessitates euthanasia.

POTOMAC HORSE FEVER (*EHRlichia COLITIS*, EQUINE MONOCYTIC EHRlichIOSIS)

Etiology and pathogenesis

Neorickettsia risticii (previously *Ehrlichia risticii*) (*q.v.*) is a rickettsial organism responsible for an **acute enterotyphlocolitis**. This disease should be considered as a differential diagnosis in any case of acute toxic colitis in an area enzootic for *N. risticii*. The disease tends to occur mostly in the summer months in 43 of the United States, Canada, France, Italy, Venezuela, India and Australia. This rickettsia has been detected in several species of snails and aquatic insects (e.g. mayflies and caddis flies) and disease has been produced by feeding infected flies.

The pathogenesis is unknown. Once the organism gains access to the host, it is believed that infection of macrophages and peripheral blood monocytes occurs followed by **colonization** of the colonic and small intestinal epithelial cells and colonic mast cells.

Clinical findings and diagnosis

Clinical and laboratory findings of Potomac horse fever (*q.v.*) are indistinguishable from those found with other causes of **acute toxic colitis** in the horse (see salmonellosis, *q.v.*). Clinical signs include fever, complete or partial anorexia, and mild to severe depression. The fever may precede other clinical signs by 2–7 days. Most horses will exhibit depression with hyperemic and/or cyanotic mucous membranes. Approximately 50% of horses will exhibit some degree of abdominal pain, decreased borborygmi, and mild to moderate abdominal distension. **Diarrhea** occurs in 60–70% of the cases and varies in consistency and volume. Rectal examination may be normal or may reveal some degree of gas and fluid accumulation in the cecum and large colon. **Laminitis** (*q.v.*) can be a complication of Potomac horse fever.

Unfortunately, there is no quick method of definitively diagnosing Potomac horse fever, but the disease should be suspected in horses with clinical signs consistent with acute toxic enterocolitis in **endemic areas**. The most commonly used diagnostic test is paired serum indirect fluorescent antibody titers taken 7–10 days apart. A dramatic (4-fold) increase or decrease in the titer is consistent with a diagnosis of Potomac horse fever. Several problems with testing make diagnosis challenging. Paired serology does not allow diagnosis before initiation of therapy. A single high titer indicates previous exposure to *N. risticii* that may or may not be related to the current disease. Many horses will seroconvert by the time clinical signs become apparent. Previous vaccination for Potomac horse fever will also cause positive titer.

Treatment and prognosis

As with salmonellosis, the chief therapeutic goal in cases of Potomac horse fever is to **maintain adequate hydration** and correct any acid-base or electrolyte abnormalities. The use of an NSAID (e.g. **flunixin** meglumine at 0.25 mg/kg IV or IM q 8h) and **bismuth subsalicylate** (2–4 L/500 kg BW) is recommended. Guidelines for plasma administration are the same as those discussed for salmonellosis (*q.v.*). Pre-renal and renal azotemia must be treated via fluid therapy. Antimicrobial therapy (oxytetracycline 6.6 mg/kg

q 24h for 5 days) reduces the severity of the disease and results in a more rapid return of appetite. Resolution of diarrhea after antimicrobial therapy may lag behind improvement of other clinical signs. Occasionally, clinical signs recur after oxytetracycline therapy has been discontinued, necessitating therapy for another 5–7 days.

If improvement is not noted within 12–36 h, another etiology should be suspected.

If **oxytetracycline** is administered during the incubation period, the onset of clinical signs is delayed but not prevented. The occurrence of laminitis (*q.v.*) does not seem to be affected by treatment with oxytetracycline. Oxytetracycline administration will not prevent the development of antibody titer. Most *Salmonella* spp. are **resistant** to oxytetracycline. Furthermore, high concentrations of oxytetracycline are present within the intestinal lumen after parenteral administration as a result of enterohepatic circulation. This results in significant disruption of the intestinal flora, and therefore administration of oxytetracycline may worsen **salmonellosis** (*q.v.*). It is recommended, therefore, that oxytetracycline therapy should be restricted to those cases of enterocolitis in which the epidemiology is consistent with Potomac horse fever.

The prognosis varies from good to grave depending upon the severity of clinical signs and laboratory changes. In general, horses that remain alert with an appetite and those treated with oxytetracycline before the onset of the diarrhea have a fairly good prognosis. The occurrence of renal azotemia, laminitis and abdominal distension with cessation of diarrhea worsens the prognosis. A PCV ≥ 55 –60% at the onset of therapy is a reflection of poor tissue perfusion and is associated with a poor prognosis. Any horse with a PCV ≥ 60 % has a grave prognosis.

PARASITIC COLITIS

Etiology and pathogenesis

The adults and larvae of the common nematodes of the cecum and large colon, *Strongylus* spp. and *Cyathostoma* spp. (*q.v.*), may cause **acute diarrhea**. Although the exact mechanism for the colitis is unknown, it appears to result from either the inflammation in the bowel wall caused by **larval migration**, damage caused by feeding of **adult parasites** or local intramural **thromboembolism** resulting in local ischemia and/or infarcts or peritonitis (*q.v.*).

Clinical findings and diagnosis

Most commonly, parasitic enterocolitis causes **chronic weight loss** and/or **diarrhea**. In cases of heavy pasture contamination, a horse may ingest large numbers of larvae resulting in severe acute inflammation and diarrhea. Several clinical syndromes then may result:

1. Sudden onset of profuse watery diarrhea accompanied by hypovolemic or endotoxemic shock
2. Sudden onset of profuse watery diarrhea that persists for weeks to months thereby causing weight loss
3. Alternating bouts of watery diarrhea and cow-like manure that lead to weight loss.

All can be accompanied by fever, variable degrees of abdominal pain or colic, and variable appetite. The mucous membranes can be pale from blood loss anemia, icteric from anorexia, or hyperemic due to endotoxemia. Laboratory analysis can reveal neutropenia due to endotoxemia (*q.v.*). Eosinophilia is not a consistent finding in horses with parasitism. Occasionally there will be an increase in the number of neutrophils or eosinophils in the peritoneal fluid, however the absence of eosinophilic transudation does not rule out parasitic colitis. Hypoproteinemia and hypoalbuminemia may be present. Azotemia may result from hypovolemia. Horses with diarrhea due to parasitic colitis may develop hyponatremia, hypokalemia, hypochloridemia or metabolic acidosis.

The clinical diagnosis is largely speculative based on history (poor parasite control program or overpopulated pastures) and exclusion of the other causes of acute diarrhea. **Rectal examination** may indicate thickening of the cranial mesenteric artery, however this is a subjective finding. Serum protein electrophoresis may reveal an increase in the concentration of β_2 -globulin due to inflammation but this is not specific for parasitism. Fecal worm egg counts are unreliable in the diagnosis of parasitic colitis, because the inflammation may be due to prepatent stages. The finding of eosinophils or cyathostome larvae in rectal biopsy samples taken with a uterine biopsy instrument is supportive of parasitic colitis, however the rectal wall is rarely involved in this disease.

Treatment and prognosis

Larvicidal anthelmintic therapy with several different anthelmintics has proven effective:

1. Fenbendazole at 10 mg/kg daily on 5 consecutive days
2. Fenbendazole at 50 mg/kg daily on 2 consecutive days
3. Oxfendazole at 10 mg/kg daily for 2 days
4. Ivermectin at 200 μ g/kg for one treatment; and moxidectin 400 μ g/kg for one treatment.

Prognosis is good provided the animal is not too debilitated at the time therapy begins. Several weeks to months may be required to regain body condition, normal serum protein concentration and optimum athletic performance.

ANTIMICROBIAL-ASSOCIATED DIARRHEA

Etiology and pathogenesis

Colitis may occur secondary to the use of **any antimicrobial**: those commonly incriminated include tetracycline, erythromycin, lincomycin, tylosin, potentiated sulfonamides, penicillin and ampicillin.

The antimicrobials may act to **alter the normal bacterial population**, thereby disrupting the critical intraluminal environment essential for normal digestion, absorption and secretion of fluid and nutrients, and maintenance of healthy epithelial cells. For example, these antimicrobials may depress volatile fatty acid absorption, which secondarily depresses sodium absorption and acidifies the colonic contents. Furthermore, removal of the normal bacterial flora may lead to **acute toxic colitis** caused by *Salmonella* (*q.v.*) and other pathogenic bacteria.

If a horse has a depressed appetite, the chance of these antimicrobials inducing diarrhea may be higher. The enterohepatic circulation of tetracycline, erythromycin, lincomycin and tylosin may increase enteric concentrations of these antimicrobials, making diarrhea more likely.

Clinical findings and diagnosis

Clinical signs and laboratory findings are as outlined for the other causes of **acute diarrhea** (*q.v.*).

Treatment and prognosis

The suspect drug should be discontinued and the use of any antimicrobial should be selected using sound medical judgment. Treatment and prognosis are as for salmonellosis (*q.v.*).

BLISTER BEETLE TOXICOSIS

Etiology and pathogenesis

Cantharidin-containing beetles belonging to the family Meloidae are responsible for the toxicosis. The **striped blister beetle** is the most common cause of toxicosis in the eastern USA; however, others (e.g. the black blister beetle) have also been identified as causes of toxicosis. **Cantharidin toxicosis** (*q.v.*) occurs when dead blister beetles that are killed in the harvesting of alfalfa are ingested. In the southeastern USA, toxicosis is uncommonly associated with harvesting of non-legume grasses.

After absorption, cantharidin induces **acantholysis** and **vesicle formation**, thereby disrupting cellular oxidative metabolism and leading to **cell death**. In addition, the normal transport systems for nutrients, water and electrolytes across the intestinal mucosa and renal tubules and collecting ducts are disrupted. Permeability changes and inflammation of the intestinal mucosa result in protein losses. Although the pathogenesis is unknown, **hypocalcemia** and **hypomagnesemia** occur commonly with blister beetle toxicosis.

Clinical findings and diagnosis

The severity of the clinical signs is proportional to the amount of toxin ingested. Common signs include abdominal pain, anorexia, depression, sweating, diarrhea and **frequent attempts at urination**. Some horses submerge their muzzles in **water** or frequently drink small amounts of water. Mucous membranes may be reddened with a prolonged capillary refill time. More variable signs include synchronous diaphragmatic flutter and a stiff, stilted gait (due to hypocalcemia), gingival and oral erosions, increased salivation and nasogastric reflux. Severe cases may progress to **shock** and death. Macroscopic hematuria and hematochezia sometimes occur. Azotemia may be pre-renal due to dehydration or renal due to toxin-induced tubular necrosis.

Laboratory abnormalities include hemoconcentration, neutropenia or neutrophilia, hypocalcemia, hypomagnesemia and azotemia. Serum protein concentration is usually normal to increased early in the disease, but hypoproteinemia develops later due to intestinal protein loss. Urinalysis often reveals dilute urine (specific gravity 1.008) and microscopic hematuria.

Peritoneal fluid analysis demonstrates an increased protein concentration. Acidosis or normal acid-base status may be present.

The clinical signs and **persistent hypocalcemia and hypomagnesemia** are suggestive of cantharidin toxicosis. Diagnosis is based upon finding blister beetles in the hay, feed or feed manger and toxin in stomach contents or urine. The optimum sample for toxicology is 500 mL of urine collected in the first 2 days of disease.

Treatment and prognosis

No specific antidote is available, therefore therapy is largely supportive (see salmonellosis, *q.v.*). **Fluid therapy** is essential to correct dehydration and promote diuresis to increase cantharidin excretion and treat azotemia. **Acetated isotonic balanced polyionic fluids** administered IV are preferred. The rate of fluid administration depends upon the amount that the horse drinks voluntarily and the amount of fluid losses in diarrhea or reflux. Maintenance fluid requirements for adult horses are approximately 50 mL/kg/day, and fluid losses can occur at the rate of 0.5 mL/lb/h (0.5 mL/450 g/h) to as high as 2 mL/lb/h (2 mL/450 g/h).

Severe hypoproteinemia may require colloidal support with administration of **plasma** (6–10 L/450 kg BW) or **hetastarch** (6%, 5–10 mL/kg). **Mineral oil** (2–4 quarts [1.9–3.8 L]/500 kg BW) may be administered via nasogastric tube to decrease absorption of the toxin and to help evacuate the intestinal contents, if nasogastric reflux is absent. Medication should not be given via nasogastric tube to animals with nasogastric reflux. NSAIDs should be used to control abdominal pain, however large dosages of these drugs may contribute to renal tubular and gastrointestinal disease.

Calcium (23% calcium gluconate) should be supplemented into the crystalloid fluid solution for slow IV infusion (2–4 mg/kg/h). Severe hypocalcemia sometimes requires treatment with calcium gluconate 23% at 6 mg/kg/h. Magnesium (magnesium sulfate or magnesium chloride) can be supplemented into the crystalloid solutions at a rate of 4–10 mg/kg/h. Serum or plasma calcium and magnesium concentration should be monitored during supplementation.

The prognosis is poor with a mortality rate near 60%. Therapy must be early and aggressive.

ARSENIC TOXICOSIS

Etiology and pathogenesis

The most common source of **arsenic** used to be fluids formerly used for the control of ectoparasites on farm animals. Poisoning may occur when horses accidentally gain access to **recently sprayed** areas or are fed grass clippings from lawns treated within 6 mo with **arsenical herbicides**. Wood preservatives containing arsenic may be a cause of poisoning when applied to fencing. Ashes from burned lumber or fence posts treated with arsenic compounds may be a cause of poisoning because of the **palatable salty** taste.

The clinical signs and pathology of arsenic toxicosis (*q.v.*) are due to the inactivation of sulfhydryl groups in tissue enzymes, thereby causing **necrosis**

of tissues rich in oxidative metabolism (e.g. gastrointestinal mucosa, neural tissue and renal tubular epithelium).

Clinical findings and diagnosis

Affected horses show signs of abdominal pain, watery diarrhea that may contain blood, depression, weakness and/or ataxia, and hyperemic mucous membranes. The heart rate is increased with a weakened pulse. Arsenic toxicity can result in polyuric or anuric renal failure. Azotemia, hypoproteinemia, hyponatremia, hypokalemia and hypochloremia are all possible laboratory findings with arsenic toxicity.

The attending veterinarian should be suspicious of arsenic toxicity in cases of **acute colitis** when the animal either has a history of exposure to arsenic, concurrent neurologic signs or bloody diarrhea. Diagnosis is made by finding high concentrations of arsenic in body fluids or tissues. Urine concentrations exceeding 16 mg/mL and liver and kidney concentrations >10–15 mg/kg are compatible with a diagnosis of arsenic toxicity.

Treatment and prognosis

Oral protectants such as mineral oil are suggested as well as oral sodium thiosulfate (20–30 g in 300–500 mL water). **Dimercaprol** is a specific antidote, although its use is frequently unsuccessful. Supportive therapy is as discussed for other causes of colitis. Mortality approaches 100% for cases of arsenic toxicosis.

MONENSIN TOXICOSIS

Etiology and pathogenesis

The use of monensin in the horse is contraindicated. Toxicosis occurs when feed containing this antimicrobial is inadvertently fed to horses. **Ionophores** disrupt membrane transport systems in the horse.

Clinical findings and diagnosis

Clinical signs resulting from altered gastrointestinal function include variable levels of abdominal pain and diarrhea. Diagnosis is based upon compatible clinical signs, history of possible exposure to cattle feed, and identification of the ionophore in the feed.

Treatment and prognosis

There is no specific antidote to the ionophores, and therefore therapy is supportive (see salmonellosis, *q.v.*). The prognosis is poor.

CLOSTRIDIUM PERFRINGENS TYPE A

Etiology and pathogenesis

Large numbers of *Clostridium perfringens* type A (*q.v.*) in the cecum and colon have been associated with **acute toxic colitis**. *C. perfringens* type A has been hypothesized to be a cause of what used to be called **colitis X**. Stress, dietary

factors (e.g. feed containing high protein and low cellulose) and antimicrobial therapy may predispose to overgrowth of *C. perfringens* type A. The disease has been reproduced experimentally by oral inoculation of bacterial culture and by administration of exotoxin IV. The cause of the diarrhea is probably the local release of mediators of inflammation and bacterial exotoxin.

Clinical findings and diagnosis

Clinical signs are similar to those associated with salmonellosis (*q.v.*) including depression, inappetence, fever, tachycardia, hyperemic and/or cyanotic mucous membranes and diarrhea. Abdominal pain and sweating are sometimes seen. Horses frequently die within 24 h. **Common complications** include laminitis and phlebitis (*q.v.*). Laboratory analysis may reveal leukopenia, hyponatremia, hypochloremia, hypokalemia, metabolic acidosis and azotemia (renal or pre-renal). PCV is increased and serum protein concentration is elevated or decreased depending on the degree of hemoconcentration and colonic protein loss. Evidence for **disseminated intravascular coagulation** (*q.v.*) may be present in rare cases.

Because *C. perfringens* can be cultured from feces of **healthy horses**, definitive diagnosis requires assay of clostridial exotoxin from intestinal contents obtained during post mortem examination. The assay is not readily available. Presumptive diagnosis is often made by culturing at least 10^3 colony-forming units of *C. perfringens* per gram of feces. However, other causes of diarrhea and colitis may result in **clostridial overgrowth**.

Treatment and prognosis

Therapy is largely supportive as described for horses with salmonellosis (*q.v.*). Type A antitoxin is not readily available. Without therapy the mortality rate approaches 100% and the mortality rate with intensive therapy is still very high.

CLOSTRIDIUM DIFFICILE

Etiology and pathogenesis

Clostridium difficile also inhabits the intestinal tract of normal horses, but increased numbers with enterotoxin production can lead to **enterocolitis**. The conditions resulting in clostridial growth and enterotoxin production are not understood but dietary changes, other intestinal diseases (e.g. colic) and antimicrobial use appear to be factors involved in the development of *C. difficile* diarrhea. *C. difficile* produces toxins A and B which induce an intestinal inflammatory response and fluid secretion leading to diarrhea.

Clinical findings and diagnosis

Clinical findings are similar to those associated with salmonellosis (*q.v.*) including depression, inappetence, fever, tachycardia, hyperemic and/or cyanotic mucous membranes and diarrhea. The clinical course may be peracute; however, it is also common to see a milder, more prolonged clinical course with *C. difficile*.

As for *C. perfringens* (*q.v.*), diagnosis is based on culture of organism from feces and identification of toxins. Bacterial culture of *C. difficile* may be difficult and may be an insensitive test. Diagnosis of disease due to *C. difficile* from culture depends on the ability to induce toxin production within the isolate. Due to availability and sensitivity, the preferred test for diagnosis of *C. difficile* is detection of toxins A and B in feces by use of a commercial ELISA test. PCR methods have also been developed for detection of the genes for toxins A and B.

Treatment and prognosis

Therapy is largely supportive as described for horses with salmonellosis (*q.v.*). The preferred treatment is metronidazole (15–25 mg/kg q 8 h PO or per rectum) and is effective in most cases. Metronidazole-resistant *C. difficile* appears to be rare in horses.

GRAIN OVERLOAD

Etiology and pathogenesis

The consumption of **readily fermentable carbohydrates** causes **colitis** (*q.v.*). Some starches are poorly digested in the small intestine of the horse. For example, 90% of oat starch is digested in the small intestine and only 30% of corn. The highly fermentable starch is then fermented in the cecum and large colon by *Lactobacillus* to form **lactic acid** in place of volatile fatty acids. This reduces the pH and increases the osmolality of colonic contents, thereby damaging the mucosal cells. Death of the Gram-negative bacteria results in release of **endotoxins** to interact with epithelial cells to initiate an inflammatory process and to be absorbed across the damaged mucosa causing endotoxemia. Changes in the concentration of volatile fatty acids in the colonic contents alter colonic motility. The osmotic changes, mucosal necrosis and inflammation, endotoxemia and altered motility result in diarrhea.

Clinical findings and diagnosis

The clinical signs vary with the quantity of fermentable feed ingested. The most common signs to be noted are variable degrees of **abdominal pain** and **diarrhea**. In more severe cases, hyperemic and/or cyanotic mucous membranes, fever or subnormal temperature resulting from shock, sweating and tachycardia develop. Laboratory findings include leukopenia resulting from endotoxemia, increased PCV and total plasma protein due to dehydration, metabolic acidosis resulting from shock and hypoperfusion, and renal or pre-renal azotemia. **Laminitis** (*q.v.*) is a common complication. Diagnosis is based on physical examination and laboratory findings and history of exposure to quantities of concentrate, lush pasture or legume to which the horse is not accustomed.

Treatment and prognosis

Therapy is most rewarding when administered before the onset of clinical signs. **Mineral oil** (2–4 L/500 kg BW) is administered to decrease fermentation and to facilitate evacuation of colonic contents. **Fluid therapy** and other

supportive therapies are recommended (see salmonellosis, *q.v.*). **Frog supports** should be applied due to the high incidence of laminitis. The prognosis is guarded to poor due to the common occurrence of laminitis in cases of grain overload.

LIVER DISEASE IN HORSES

Hepatic disease, as determined by **increased liver enzymes** and **histopathologic changes in a liver biopsy**, is common in horses. The liver has **enormous reserve capacity** and **regenerative ability**, and disease does not result in insufficient function until 70% or more of the organ has been damaged.

Common causes of liver failure in horses and foals include pyrrolizidine alkaloid toxicosis, acute hepatitis and Tyzzer's disease (*q.v.*). Liver disease (and occasionally liver failure) sporadically is caused by mycotoxicosis, chronic active hepatitis, hepatic lipidosis, cholelithiasis, ferrous fumarate ingestion, hepatic neoplasia, hepatic abscessation, portosystemic shunts, perinatal equine herpesvirus 1, kleingrass intoxication, strangulating obstruction of the large colon, hypoxemia, septicemia and endotoxemia (*q.v.*).

CLINICAL FINDINGS AND DIAGNOSIS

Symptoms of liver failure can arise from an acute massive hepatic insult, or when chronic loss of hepatocytes and fibrotic infiltration reaches a critical threshold. The most common clinical signs of liver failure in horses are **icterus, neurologic abnormalities, anorexia, weight loss and photodermatitis**. Less common signs include colic, coagulopathy, pruritus and diarrhea.

Icterus (jaundice) is caused by accumulation of bilirubin within the blood (total bilirubin concentration of 3.5 mg/dL or greater) and tissues. Because conjugated bilirubin produces a more intense discoloration, icterus is most readily observed in association with cholestatic disorders.

Neurologic abnormalities (hepatoencephalopathy) arise from altered neurotransmission in the CNS. The severity of the clinical signs corresponds with the degree of hepatic insufficiency. Mildly affected horses may show subtle behavioral changes (*q.v.*). More severely affected horses exhibit varying degrees of mental depression, aggressive or violent behavior, head-pressing, circling, aimless propulsion and pronounced yawning. Other symptoms include mild proprioceptive deficits, dysphagia and inspiratory dyspnea caused by flaccid paralysis of the larynx and pharynx. Advanced cases of hepatoencephalopathy exhibit coma and terminal seizure activity.

The etiology of the neurologic dysfunction in hepatic insufficiency is only partially understood. Neurotoxic compounds that are produced in the gut and normally removed by the liver accumulate in the bloodstream and ultimately in the CNS. Examples of **neurotoxins** include ammonia, short-chain fatty acids, mercaptans and γ -aminobutyric acid. Neuroexcitatory transmission is further compromised by failure of the liver to remove aromatic amino acids (phenylalanine, tyrosine and tryptophan) from the systemic circulation. As a result, the ratio of aromatic to branched chain amino acids in the blood and CNS increases. Moderate to severe **hypoglycemia** secondary to impaired

gluconeogenesis can also contribute to signs of neurologic dysfunction (*q.v.*). Correction of hypoglycemia causes remission of neurologic signs in some cases of hepatoencephalopathy.

Horses with chronic hepatic insufficiency often present with **weight loss** (*q.v.*), which in some cases may be the only presenting complaint. Most horses with weight loss have a history of partial to complete anorexia for several weeks or more before examination.

Photodermatitis (*q.v.*) occurs fairly frequently in horses with liver failure. Crusty, erythematous lesions develop in unpigmented sparsely haired areas of the body such as the face (especially the muzzle) and the distal extremities as a result of **phylloerythrin accumulation** in the superficial layers of the skin. Phylloerythrin is a photodynamic by-product of chlorophyll digestion that is produced by microbes in the gastrointestinal tract. Normally it is removed from portal circulation by the liver and excreted in bile. Failure of the excretory mechanism allows phylloerythrin to enter the systemic circulation and become deposited in the skin. When phylloerythrin in the skin absorbs UV light, free radicals are generated that produce **cellular destruction**. Unpigmented skin is more vulnerable because it absorbs UV light more efficiently.

Hepatocellular swelling and obstruction of the biliary tract can cause signs of abdominal pain. For this reason, **hepatobiliary disease** should be an etiologic consideration for colic (*q.v.*), particularly if symptoms are recurrent and accompanied by icterus, fever and weight loss. Palpation of the abdomen caudal to the last rib on the right side may elicit a painful response in these cases.

The liver is the major site for synthesis of circulating hemostatic proteins. As a result, some horses with severe hepatic insufficiency manifest **increased bleeding tendencies**, particularly following trauma (venipuncture, nasogastric intubation, etc.). Spontaneous hemorrhage in the lungs and gastrointestinal tract is observed less frequently. Clotting factor VII has the shortest half-life, so prolongation of the prothrombin time may precede prolongation of the activated partial thromboplastin time in progressive cases of liver failure. Because absorption of fat-soluble vitamins is dependent on the presence of bile acids in the intestinal lumen, cholestasis can lead to increased bleeding tendencies by causing **vitamin K deficiency** (*q.v.*). Clotting factors (II, VII, IX and X) need vitamin K to complete hepatic modification into active clotting factors.

Pruritus, diarrhea and terminal hemolysis are infrequent manifestations of liver failure in horses. **Pruritus** arises from accumulation of bile salts within the skin. Causes of **diarrhea** include portal hypertension, hypoalbuminemia, maldigestion due to bile acid deficiency, and altered gastrointestinal microflora.

Hepatic integrity can be assessed through a variety of tests that reflect hepatocellular injury, cholestasis and reduced functional mass. In addition, the morphology of the liver can be assessed by ultrasonography and microscopic evaluation of a liver biopsy. Table 10.3 lists approximate normal ranges for liver diagnostic tests.

Enzymes normally confined within the cytosol are released into extracellular fluid following hepatocellular necrosis. The magnitude of the increase in serum enzyme concentration correlates directly with the magnitude of the injury, but not with the reversibility of the lesion. Cytosolic enzymes are most likely to be elevated in acute disorders when active cellular destruction is

Table 10.3 Diagnostic tests for equine liver disease

Test and reference range	Interpretation of results	Sample handling
Sorbitol dehydrogenase (SDH) 1–8 U/L	Increase indicates active hepatocellular necrosis (liver specific)	Serum sample. Refrigerate immediately and analyze within 12 h
Aspartate aminotransferase (AST)	Increase indicates active hepatocellular or muscle damage	Serum sample. Stable for several days at room temperature and for 1 wk in refrigerator
Gamma glutamyltransferase (GGT) 8–28 U/L	Increase indicates hepatobiliary disease (especially cholestasis; liver specific)	Serum sample. Stable for several days at room temperature and for 1 wk in refrigerator
Alkaline phosphatase (ALP)	Increase indicates hepatobiliary disease (especially cholestasis). Also elevated by bone growth and remodeling and intestinal epithelial damage	Serum sample. Stable for several days at room temperature and for 1 wk in refrigerator
Bilirubin Total: 0.2–2.0 mg/dL Conjugate: 0.0–0.4 mg/dL Total bile acid <10 μ mol/L	Total bilirubin increased by hepatobiliary disorders, hemolysis and fasting >20 μ mol/L consistent with hepatobiliary disease	Serum sample. Stable for several days. Keep sample out of direct sunlight Serum or plasma
Blood ammonia 13–108 μ g/dL	Increase indicates hepatic insufficiency or portosystemic shunting	Heparinized blood is collected and immediately placed on ice. Separate plasma from cells within 30 min and analyze within 1 h

occurring. In chronic liver disease and biliary tract disorders, concentrations of these enzymes may be normal or only slightly increased.

Clinically useful tests for hepatocellular necrosis in equine practice include **sorbitol (iditol) dehydrogenase** and **serum aspartate aminotransferase** (formally serum glutamic oxaloacetic transaminase). Sorbitol dehydrogenase (SDH) has the advantage of being a **liver-specific test**. SDH has a relatively short serum half-life (12 h), and returns to normal within 4–5 days after an acute hepatic insult. For this reason, it is useful for monitoring improvement following hepatic injury. Its major disadvantage is its poor stability in serum, particularly at room temperature. Analysis should be performed as soon as possible and within 12 h on a refrigerated (4°C) sample to obtain reliable results. Aspartate aminotransferase (AST) is more stable in serum, but is less liver specific. Elevations are noted in serum following muscle damage (cardiac and skeletal) and hemolysis. Foals, weanlings and yearlings have higher serum concentrations of AST than adults.

Gamma glutamyltransferase (GGT) and **alkaline phosphatase (ALP)** are clinically useful markers of **cholestasis**. Both enzymes are synthesized in increased quantities in response to hepatobiliary disorders. Intrahepatic cholestasis due to blockage of canaliculi by hepatocyte swelling commonly leads to increases in GGT in horses with hepatocellular disorders. Serum GGT concentration is elevated primarily by increased hepatocellular production

whereas serum ALP may reflect increased production by liver, bone, placenta and intestinal epithelium. As a result, serum GGT is more specific for liver disease than serum ALP. Because the reference range for GGT is much narrower than ALP, serum GGT results are easier to interpret. GGT is elevated in most cases of acute and chronic liver disease and is a good screening enzyme for liver disorders. Serum GGT has a long half-life, and may stay elevated for weeks after clinical signs and other laboratory findings are improving.

Some drugs (e.g. **corticosteroids**) secondarily cause transient elevations of serum concentrations of liver enzymes. These cases can be differentiated by history and by restoration of normal enzyme concentrations over time. **Persistent elevations** of liver enzymes in horses should be evaluated by other bile acids, liver ultrasound, and liver biopsy. Foals have higher serum concentrations of GGT and ALP than adults. Levels progressively decline and approximate adult concentrations by 3 mo of age.

Hepatic functional capacity is evaluated in various ways. The **serum bilirubin** concentration and **total bile acid concentration** reflect the liver's ability to remove endogenous anions from the blood, whereas the **sulfobromophthalein (BSP) clearance** test (*q.v.*) evaluates the liver's ability to remove exogenous anions from circulation. Blood glucose concentration, serum albumin concentration, clotting profile, serum urea nitrogen concentration and blood ammonia concentration also are useful indices of liver function.

Hyperbilirubinemia occurs most frequently in acute hepatic failure and biliary obstruction. **Total bilirubin concentration** may be normal or only slightly increased in cases of chronic liver failure. Horses with hepatic insufficiency characterized by impaired biliary excretion develop hyperbilirubinemia secondary to regurgitation of conjugated (direct reading) bilirubin from bile canaliculi into the bloodstream. Unconjugated (indirect reading) bilirubin increases in the blood due to impaired uptake and conjugation. In contrast to other species, horses with liver failure or obstruction of the bile duct develop relatively modest increases in the serum concentration of conjugated bilirubin.

Even with **complete obstruction of the common bile duct**, the conjugated fraction rarely exceeds 50% of the total. A conjugated (direct) bilirubin concentration of 25–50% of the total bilirubin concentration is indicative of significant cholestasis. Although an increase in the conjugated fraction is a useful parameter, a normal concentration does not rule out hepatic insufficiency in horses. Other causes of hyperbilirubinemia include fasting and hemolysis. The total bilirubin concentration can exceed 10.0 mg/dL in horses with normal hepatic function after 48 h of fasting. The increase is due to elevation of unconjugated bilirubin, and conjugated bilirubin remains normal during fasting.

The presence of **urobilinogen** in urine indicates that the bile duct is patent. If the common bile duct is completely obstructed, urobilinogen will not be detected on urine reagent strips. Urobilinogen concentration in urine is increased by **hemolysis** and **hepatic disease**. Conjugated bilirubin is normally absent from the urine, but it can be detected in some cases of hepatobiliary disease because regurgitated conjugated bilirubin is freely filtered by the kidney.

The urine can be screened in the **field** for the presence of conjugated bilirubin by **shaking fresh urine** until it foams. Normal urine creates a **white foam** whereas urine that contains conjugated bilirubin makes a **yellowish-green foam**.

Total serum bile acid determination is a relatively new clinical tool and is becoming more available on a commercial basis. Bile acids are produced by the liver from cholesterol and excreted in bile conjugated to either glycine or taurine. Approximately 86% of equine bile acids are conjugated to taurine. The bile acids are actively absorbed in the ileum and removed from portal circulation by the liver; only small quantities of bile acids reach systemic circulation. Normal horses have total serum bile acid concentrations of $<10 \mu\text{mol/L}$. Elevations $>20 \mu\text{mol/L}$ are highly associated with hepatic insufficiency, obstruction of the biliary tract and portosystemic shunting.

Bile acids are excreted into and absorbed from the gastrointestinal tract at a fairly constant rate in horses; total bile acid concentration can be measured at any point regardless of feeding time. Assays that only measure bile acids conjugated to glycine are not as useful in equine practice as assays that measure total bile acids because the glycine conjugates account for only 14% of the total in horses.

The clearance rate of **sulfobromophthalein (BSP)** dye from the bloodstream assesses the liver's ability to remove anions from circulation. The dye is injected IV at 2.2 mg/kg , and heparinized blood samples are collected at 6, 9, 12 and 15 min. The dye is very irritating, and perivascular injection should be avoided. The amount of dye cleared per unit time is reported as the half-life ($t_{1/2}$) for disappearance. Normal horses have a $t_{1/2}$ for BSP of 2.0–3.7 min. Because BSP dye is rarely available and measurement of serum concentrations of total bile acids provide a sensitive and specific test of liver function, BSP clearance is rarely assessed in horses.

Evaluation of other blood parameters can provide supportive evidence of hepatic insufficiency. Blood glucose can be normal, increased or decreased in horses with liver failure. **Hypoglycemia** is attributed to impaired gluconeogenesis and anorexia. **Hyperglycemia** may be observed post-prandially in horses with liver failure that are still eating.

In advanced cases of liver failure, inadequate protein synthesis can result in **hypoalbuminemia**. Because the half-life of albumin is >100 days, albumin concentration is usually normal in acute cases of hepatic insufficiency. Impaired production of proteins also can result in hemostatic abnormalities. When clotting factors reach plasma concentrations of $<30\%$ of normal, prolongation of fibrin endpoint tests such as the prothrombin time and activated partial thromboplastin time is observed. **Hypergammaglobulinemia** commonly occurs in patients with liver disease; gut toxins normally removed from portal circulation by the highly phagocytic Kupffer cells enter the systemic circulation and stimulate lymphocytic antibody production.

Because the failing liver is unable to convert ammonia to urea, the **serum urea nitrogen** concentration can be reduced and the plasma ammonia concentration elevated. Plasma ammonia determination is impractical for most field situations, however, because the heparinized sample must be chilled immediately, the plasma separated from cells within 30 min, and analysis performed within an hour of collection to prevent false increases.

Ultrasonography of the liver provides useful non-invasive information concerning the size of the liver and may detect soft tissue masses, choleliths, parenchymal changes and dilated bile ducts. It is important to realize, however, that a normal scan does not conclusively rule out the presence of liver

disease. Normally the liver has a homogeneous parenchyma with an echogenicity similar to or slightly greater than the renal cortex but less than the spleen. The liver can be imaged on the right side along the ventral lung margin from the 6th–15th intercostal space. Age-related atrophy of the right side of the liver may prevent visualization on this side. The liver can be viewed on the left side below the costochondral arch from the 8th–10th intercostal space; however, in some horses imaging from the left side is obscured by the spleen and colon. A 3.0 or 5.0 MHz scanner (linear or sector) is suitable for examination.

Microscopic examination of a **liver biopsy** can yield important etiologic and prognostic information. Since biopsy is not a benign procedure, its use should be reserved for patients with elevated liver enzymes in association with clinical signs of liver failure and/or abnormal liver function tests, and for horses with persistent, unexplained elevations in liver enzymes. Abnormal liver enzymes arising from secondary hepatic insults generally return to normal once the primary disease process resolves. Liver biopsy is most informative in disease processes that cause uniformly dispersed lesions.

Liver biopsy can be performed under **field conditions**. **Hemorrhage** is the major complication, and a **clotting profile** (*q.v.*) and **platelet count** should be assessed prior to biopsy to ensure hemostatic capabilities are adequate. Because of the potential for abdominal and thoracic contamination, a liver biopsy should not be performed in cases of suspected liver abscessation.

Liver biopsy is performed on the horse's **right side** through the 13th or 14th intercostal space at the height of a line drawn from the point of the shoulder to the tuber coxae. The site is clipped, surgically prepared and infiltrated with 2% lidocaine. Using sterile technique, a small stab incision is made through the skin with a number 15 scalpel blade, and a notch-cutting biopsy needle (Tru-Cut, Travenol, Deerfield, IL, USA) is then inserted in a slightly ventral direction. The needle passes through the caudal aspect of the thorax and the diaphragm, then into liver parenchyma.

Ultrasonography facilitates selective needle placement, and is especially helpful when the liver is small. In horses with decreased colonic filling due to anorexia and a large window of liver against the abdominal wall, ultrasound guided transabdominal liver biopsy can be safely performed without puncturing the colon. Some discomfort can be expected as the needle passes through the pleura and peritoneum, so the horse should be restrained to minimize the risk of injury. After the biopsy is obtained, the sample is placed in formalin and submitted for histopathology. Another sample can be placed in transport medium for culture and sensitivity. Hepatic lesions and their significance are described in Table 10.4.

The creatinine concentration, electrolyte, acid-base and hydration status should also be carefully assessed, since other abnormalities often arise in horses with liver failure. In addition, a complete blood count and serum fibrinogen concentration should be evaluated for evidence of inflammatory changes. These findings will help guide appropriate supportive therapy.

TREATMENT AND PROGNOSIS

When treating horses with liver failure, the goal is to provide **supportive care** while the liver regenerates to the point that function is restored. Treatment is

Table 10.4 Histology of hepatic lesions

Lesions	Causes	Clinical significance	Liver enzymes
Randomly dispersed focal areas of necrosis	Secondary to bacterial septicemia, salmonellosis, endotoxemia, EHV-1	Rarely associated with signs of liver failure	SDH, AST increased; GGT often increased
Centrilobular lesions	Hypoxic injury secondary to cardiac insufficiency, severe anemia, shock, monensin toxicity	Rarely associated with signs of liver failure	SDH, AST increased; GGT often increased
Acute massive necrosis	Acute, hepatic necrosis (Theiler's), aflatoxin, carbon tetrachloride, ferrous salts,	Clinical signs of hepatic insufficiency when >70% of functional mass affected	SDH, AST increased; GGT, ALP increased
Diffuse hepatic lipidosis	Negative energy balance, azotemia, and endotoxemia	Rarely associated with signs of liver failure in horses. Severely affected ponies can develop hepatic failure	SDH, AST increased; GGT, ALP sometimes increased
Focal hepatic lesions	Abscesses, neoplasia	Rarely associated with signs of hepatic failure	SDH, AST variable; GGT, ALP variable
Cholelithiasis (cholangiohepatitis)	Ascending bacterial infection, obstructed bile flow	Causes intermittent colic, inappetence, fever. Clinical signs of hepatic insufficiency when >70% of functional mass affected	SDH, AST variable; GGT, ALP disproportionately increased; conjugated bilirubin increased
Portal venous systemic shunts	Congenital or acquired (secondary to chronic fibrosis)	Clinical signs of hepatic insufficiency when >70% of functional mass affected	SDH, AST, GGT, ALP, normal; increased ammonia
Chronic progressive primary liver disease	Pyrrolizidine alkaloid toxicosis, aflatoxins, chronic active hepatitis	Clinical signs of hepatic insufficiency when >70% of functional mass affected	SDH, AST increased initially but can decline as disease progress; GGT, ALP increased

ALP, alkaline phosphatase; AST, aspartate aminotransferase; GGT, gamma glutamyltransferase; SDH, sorbitol dehydrogenase.

most successful in horses with **acute hepatic failure** because there is greater potential for hepatocyte renewal. The initial aim in patient management is to correct hydration, acid-base and electrolyte abnormalities. Acidosis should be corrected gradually, and overcorrection avoided. Alkalemia favors movement of ammonia into the CNS, thereby precipitating or worsening hepatoencephalopathy. Horses improve with **glucose administration** even if they are not hypoglycemic on presentation.

If hypoglycemia is detected, administer **10% glucose IV** to establish normoglycemia, then maintain therapy with 5% glucose at a rate of 2 mL/kg/h for the initial 24 h of hospitalization. The blood glucose should be monitored and the rate adjusted to maintain blood glucose between 80 and 110 mg/dL. Fluids containing balanced electrolyte solutions and glucose (**half-strength**

lactated Ringer's solution and **2.5% dextrose**) can be used at 4 mL/kg/h to provide fluid, electrolytes and glucose for maintenance.

Horses with signs of **hepatoencephalopathy** (*q.v.*) can be uncontrollable or abnormally agitated; sedation may be necessary. Small dosages of **xylazine** (0.2–0.5 mg/kg IV), chloral hydrate (50 mg/kg IV as a 5% solution) or detomidine (0.005–0.007 mg/kg IV) work well in these instances. Care should be taken when using sedatives since hepatic metabolism of the drugs will probably be impaired.

When signs of hepatoencephalopathy are noted, steps should be taken to reduce absorption of toxic metabolites from the gut. **Mineral oil** is a safe, cost-effective laxative, and can be administered by nasogastric tube at a rate of 2–4 L/500 kg horse s.i.d. Intubation should be conducted carefully since **impaired hemostasis** may result in prolonged bleeding after trauma. Other therapeutic modalities include oral administration of **lactulose syrup** (0.3 mL/kg q.i.d.) or **neomycin liquid** (50–100 mg/kg q.i.d.). Lactulose is digested by colonic bacteria into small organic acids that reduce luminal pH and create an osmotic diarrhea. Lactulose has been documented to decrease ammonia production without causing diarrhea. Neomycin decreases microbial production of toxic metabolites, but its negative impact on normal flora increases the risk for salmonellosis (*q.v.*), thus limiting its clinical usefulness.

Dietary management (*q.v.*) is an important therapeutic consideration. Frequent administration of small quantities of a diet low in protein and high in carbohydrates is recommended. Dietary restriction of protein decreases the amount of protein available for production of neurotoxic substances. **Legume hays should be avoided** and only **grass or oat hay** fed to horses with liver failure. An example of a useful maintenance diet for horses with compromised livers that are still eating is a mixture of one part cracked corn and two parts beet pulp in molasses. Sorghum, oat hay or grass hay can be used instead of beet pulp. Feed 2.5 kg/100 kg/day split into 4–6 meals.

Anorectic horses can be supplemented a gruel containing oral formulations of branched chain amino acids (24 g leucine, 18 g isoleucine, 18 g valine per day). Administer vitamin B₁ and folic acid parenterally on a weekly basis. Horses should be allowed to graze, but kept out of intense sunlight to avoid **photosensitization** (*q.v.*). Partial parenteral nutrition and treatment with IV preparations of branched chain amino acids is rarely utilized due to economics.

The prognosis for liver failure depends largely on the **regenerative capabilities** of the liver. Extensive fibrosis and impaired hepatocellular division warrant a poor to guarded prognosis.

INDIVIDUAL CAUSES OF LIVER FAILURE

Pyrrolizidine alkaloid toxicity

Etiology and pathogenesis

Pyrrolizidine alkaloid (*q.v.*) toxicity is a common cause of liver failure in horses. Although acute liver failure is occasionally noted, chronic liver failure is the most common presentation. Prolonged ingestion of small amounts of **toxic plants** generally precedes onset of clinical signs by weeks to months. More than 150 plants worldwide contain pyrrolizidine alkaloids toxic to grazing

animals. Most of them belong to the genera *Amsinckia*, *Crotalaria*, *Echium*, *Heliotropium*, *Senecio* and *Trichodesma*. Horses ingest the plants when forage is poor. **The plants retain their toxicity after drying**, and horses can be poisoned by contaminated hay and pelleted hay cubes.

Clinical findings and diagnosis

Gradual weight loss and decreased interest in food is noted by some owners for several weeks prior to development of hepatoencephalopathy, mild icterus and photodermatitis. **Inspiratory dyspnea** associated with hepatoencephalopathy is reported as a primary presenting complaint in some animals with pyrrolizidine-induced chronic liver failure.

The GGT, ALP, SDH, AST and serum bile acid concentration are generally increased. In long-standing cases SDH and AST may be normal or only slightly elevated. Histopathologic changes characteristic of **pyrrolizidine alkaloid toxicosis** are portal necrosis and fibrosis, biliary hyperplasia and megalocytosis. Pyrroles produced by hepatic metabolism of pyrrolizidine alkaloids produce an anti-mitotic effect by cross-linking DNA; megalocytes develop because hepatocytes cannot divide properly.

Ingestion of **kleingrass** (*Panicum coloratum*) sporadically causes **chronic hepatitis** in horses, characterized by bridging fibrosis, biliary hyperplasia, cholestasis and multifocal areas of necrosis. The absence of megalocytosis differentiates this plant toxicity from pyrrolizidine toxicosis.

Treatment and prognosis

Prognosis for advanced cases of chronic liver failure is poor, and most cases die within several weeks after clinical signs become apparent. Acute or mildly affected cases are more likely to respond to supportive therapy. Long-term prognosis depends on the ability of the liver to regenerate to a functional point, and the prevention of further hepatic insults.

Acute hepatitis

Etiology and pathogenesis

Acute hepatitis (**Theiler's disease, serum sickness**) is a common cause of liver failure in adult horses. Symptoms of acute liver failure can appear 1–2 mo after receiving an equine origin serum-derived product such as **tetanus antitoxin**. In some farm outbreaks, however, there is no history of horses receiving serum-derived biologicals. The seasonality and large number of animals affected during these outbreaks have prompted speculation that an infectious agent spread by **hematophagous insects** or direct contact may be involved.

Clinical findings and diagnosis

Horses with acute hepatitis typically exhibit intense **icterus**, signs of **hepatoencephalopathy** and **photodermatitis**. Laboratory findings include hyperbilirubinemia, elevated cytosolic leakage enzymes (SDH, AST), induced enzymes (GGT, ALP) and elevated bile acid. Marked diffuse hepatocellular necrosis, varying degrees of bile duct proliferation and inflammatory cellular

infiltration in the portal area are noted histologically. Grossly, the liver is either swollen or smaller than normal.

Treatment and prognosis

Supportive therapy is warranted in acute hepatitis, as most cases have a fair prognosis for survival. Most cases either die or recover within a week after the onset of clinical signs.

Tyzzer's disease

Etiology and pathogenesis

Tyzzer's disease is a sporadic and highly fatal disease of foals 9–45 days of age caused by *Clostridium piliformis* (*q.v.*). The bacterium is probably shed in the feces of clinically normal horses. Ingested bacteria gain access to the portal circulation and subsequently the liver of susceptible foals.

Clinical findings and diagnosis

The infection produces a **fulminant septicemia**, and death occurs 2–48 h after signs appear. Affected foals exhibit depression, fever, hypoglycemia, tachycardia and diarrhea. In more protracted cases, icterus may be observed. Terminally, foals become recumbent, hypothermic and comatose. An ante mortem diagnosis is difficult to achieve because signs are non-specific and the course of the disease peracute. Polymerase chain reaction has been used to identify the bacterial antigen in biopsy specimens of exotic animals. Many foals with Tyzzer's disease are **found dead**, and the diagnosis is made on post mortem examination of the liver. Necrotizing lesions are noted in the liver parenchyma, particularly in periportal regions. Necrotic areas are surrounded by a neutrophilic response, and bacteria are readily observed along the periphery of lesions with silver stains.

Treatment and prognosis

Treatment with broad-spectrum antibiotics such as a combination of **potassium benzylpenicillin** (44 000 IU/kg IV q.i.d.) and an **aminoglycoside** (e.g. gentamicin 6.6 mg/kg IV or IM s.i.d.) should be initiated promptly. Supportive therapy with **IV fluid** therapy (e.g. acetated Ringer's solution at 4–8 mg/kg/h) and an **NSAID** (flunixin meglumine 0.5–0.75 mg/kg IV s.i.d.) is also recommended to treat shock. The prognosis is grave.

Mycotoxicosis

Etiology and pathogenesis

Aflatoxins (*q.v.*) are the most common mycotoxins associated with liver disease (and occasionally liver failure) in horses and other domestic livestock. Aflatoxins are fungal metabolites produced by *Aspergillus flavus* and *A. parasiticus*. **Fumonisin**, a mycotoxin produced by *Fusarium moniliforme*, is associated with the development of **leukoencephalomalacia** (*q.v.*) and **hepatitis** in horses. Damaged **corn kernels** that are stored in a moist, warm environment provide optimal growth conditions for *A. flavus* and *F. moniliforme*.

Clinical findings and diagnosis

The signs depend on the dosage of mycotoxin ingested over time. Consumption of **large quantities** of aflatoxins or fumonisin can cause depression, neurologic signs (circling, head-pressing, blindness and ataxia), anorexia and death within 5 days (or more) of exposure. Hypoglycemia, elevated liver enzymes and abnormal liver function tests may be noted. Chronic low-grade exposure to aflatoxins is associated with immunosuppression, ill thrift and increased liver enzymes. The effect of chronic exposure to low levels of fumonisin is unknown.

Post mortem hepatic changes suggestive of **aflatoxicosis** and **fumonisin toxicosis** include fatty degeneration, biliary hyperplasia, periportal fibrosis and hepatocellular necrosis. Other changes associated with acute fatal aflatoxicosis in horse are encephalomalacia of the cerebrum, myocardial degeneration and fatty degeneration of the kidney. Liquefactive necrosis of the cerebral hemispheres (leukoencephalomalacia) is a prominent finding in horses poisoned by fumonisin ingestion.

Mycotoxigenesis should be considered whenever more than one horse in a group demonstrates symptoms shortly after consumption of **feed recently introduced** to the group. The feed should be withdrawn and analyzed for mycotoxins. Although there are no safe levels of aflatoxins in feeds, levels >20 ppb are considered unsafe for consumption by people, dairy cattle and young animals. In several natural outbreaks of acute aflatoxicosis in horses, feedstuffs containing >400 ppb were being consumed at 0.5 mg/kg/day for 5 days or more prior to death. Levels of 72 ppm fumonisin have been measured in association with an outbreak of leukoencephalomalacia in horses.

Treatment and prognosis

Prognosis for advanced cases of chronic liver failure is poor, and most cases die within several weeks after clinical signs become apparent. Acute or mildly affected cases are more likely to respond to supportive therapy. Long-term prognosis depends on the ability of the liver to regenerate to a functional point, and the prevention of further hepatic insults.

Iron toxicity

Etiology and pathogenesis

Iron intoxication is an uncommon cause of hepatitis in adult horses and foals. Neonates are particularly susceptible to toxicosis prior to ingestion of colostrum. Ingestion of a single dose of an oral inoculant containing ferrous fumarate shortly after birth caused hepatitis and death in foals by 2–5 days of life; the product associated with the syndrome was removed from the market in 1983 and no subsequent cases occurred.

Consumption of vitamin supplements containing **ferrous fumarate** has been associated on several occasions with the development of hepatitis in adult horses. Normal daily iron intake for adult horses is 40 ppm. Iron is absorbed from the intestinal tract, and surplus iron is stored in high concentration in body tissues, particularly the liver and spleen. Ferrous iron is more soluble than ferric iron, and therefore more readily absorbed. If accumulation of iron within tissues becomes excessive, toxicosis can occur. The time to onset

of clinical signs is influenced by the daily dosage, the presence of underlying hepatic disease, and the antioxidant capacity of the liver. Vitamin E and selenium are important cofactors in the glutathione peroxidase antioxidant mechanism. If vitamin E or selenium concentrations are reduced, the liver is more vulnerable to damage.

Clinical signs and diagnosis

Icterus, hepatoencephalopathy and coagulopathy characterize iron toxicosis. Cholestasis and hepatic necrosis elevate the serum GGT and SDH concentrations, respectively. Serum bilirubin and plasma ammonia concentrations are typically elevated, and lymphopenia is noted on the hemogram. Clotting profile abnormalities (*q.v.*) include thrombocytopenia, prolongation of the prothrombin time and activated partial thromboplastin time, and increased fibrin degradation products. Serum iron concentration exceeds the normal equine reference range (73–140 µg/mL).

Histopathologic lesions consistent with iron toxicosis are periportal proliferation of bile ductules, necrosis and fibrosis of periportal and periductule hepatocytes, and infiltration of affected areas by a mixture of inflammatory cells. Lymphoid necrosis, particularly in the spleen, is a prominent finding.

Treatment and prognosis

Treatment consists of discontinuing iron supplementation and providing supportive care for liver failure. **Chelation therapy** with **ethylenediaminetetraacetic acid (EDTA)** or **desferrioxamine** has been used successfully in people and small animals with iron intoxication. As a rule, chelation therapy is reserved for patients whose total body iron stores exceed five times the upper limit of the reference range. Prognosis for foals and horses with iron intoxication is guarded. Most foals with hepatic failure caused by ferrous fumarate ingestion in the early 1980s did not recover.

Cholelithiasis

Etiology and pathogenesis

Cholelithiasis is defined as the presence of **calculi** (choleliths) in the hepatobiliary system, usually accompanied by biliary inflammation and infection. It is uncertain whether the association between cholangiohepatitis and cholelith formation is one of cause and effect. The isolation of **enteric bacteria** and anaerobes from equine cases suggests ascending infection from the proximal small intestine.

Equine **choleliths** are predominantly calcium bilirubinate and calcium phosphate, which are associated with ascending biliary infection in man. The calculi vary in size and are most often multiple. **Hepatolithiasis** refers to cholelithiasis of the intrahepatic biliary tracts, whereas **choledocholithiasis** refers to calculi in the common bile duct.

The cause of cholelithiasis is unknown, but **biliary stasis**, ascending Gram-negative bacterial infections and alteration in biliary composition are likely contributors to calculus formation. Furthermore, **ascaris ova** (*q.v.*) may serve as nuclei for formation of calculi in the biliary tract.

Clinical findings and diagnosis

Cholelithiasis occurs most commonly in middle-aged horses (5–18 yr of age). Symptoms of biliary obstruction include icterus, fever, anorexia and abdominal pain. Clinical signs may be intermittent, and chronic cases generally develop weight loss. Hepatoencephalopathy and photosensitization develop in a small percentage of cases.

Marked elevation of induced cholestatic enzymes (GGT, ALP) and mild to moderate elevation of cytosolic enzymes (SDH, AST) characterize biliary tract obstructive disorders. Conjugated bilirubin concentration is often >25% of the total bilirubin concentration. Bilirubin can often be detected in the urine, and urinary urobilinogen is often undetectable. Total serum bile acids are generally increased. Inflammatory changes such as a neutrophilic leukocytosis with a left shift, hyperproteinemia and hyperfibrinogenemia are noted frequently in the leukogram. The prothrombin time and activated partial thromboplastin time may be prolonged if biliary obstruction is chronic enough to interfere with clotting factor synthesis.

Ultrasonography is an important adjunct diagnostic tool. Visualization of well-defined hyperechoic masses with acoustic shadows within dilated bile ducts confirms the diagnosis. However, not all choleliths are easily seen with ultrasonography so failure to observe them does not preclude a diagnosis of cholelithiasis. Other ultrasonographic findings highly supportive of a diagnosis of obstructive biliary disorders include hepatomegaly, increased echogenicity of liver parenchyma and bile duct dilatation.

A **liver biopsy** (*q.v.*) is necessary to help determine long-term prognosis, particularly when surgery is being contemplated. The biopsy typically reveals varying degrees of periportal and intralobular fibrosis, bile duct proliferation and foci of hepatocellular necrosis with infiltration of polymorphonuclear cells. A culture and sensitivity can be performed on a biopsy sample. Mixed populations of Gram-negative bacteria (*E. coli*) and anaerobes (*Clostridium* spp., *Bacillus* spp. and *Peptostreptococcus* spp.) (*q.v.*) are commonly isolated from the hepatic biopsies of horses with cholelithiasis.

Treatment and prognosis

The prognosis for horses with **symptomatic cholelithiasis** is guarded to poor. Conservative medical management alone is often unsuccessful and surgical management is associated with many risk factors. Supportive therapy, as described in the section covering treatment of horses with liver failure (*q.v.*), should be initiated along with broad-spectrum **antimicrobial therapy** for the accompanying cholangitis. Broad-spectrum antimicrobial therapy can be initiated with potassium benzylpenicillin (22 000–44 000 IU/kg IV q.i.d.) and gentamicin (6.6 mg/kg IV s.i.d.) and further therapy should be adjusted based on culture and sensitivity of liver biopsy and response. Antimicrobial therapy should be continued for several weeks to months until GGT concentrations in serum are normal.

Surgery is an option for horses with calculi in the common bile duct that do not have extensive fibrosis on liver biopsy. If the cholelith cannot be gently massaged into the duodenum, then gentle digital pressure should be applied to crush the concretion (**choledocholithotripsy**). The fragments can then be flushed into the duodenum with saline solution.

If these methods are unsuccessful, **choledochotomy** can be attempted. This procedure is risky, however, because the common bile duct is deep in the abdomen and difficult to isolate surgically. **Iatrogenic contamination** of the peritoneal cavity with bile results in life-threatening chemical and bacterial peritonitis. This complication, as well as failure to remove all calculi, warrants a guarded prognosis. Horses should be treated with appropriate antimicrobials. Broad-spectrum antimicrobial therapy can be initiated with potassium benzylpenicillin (22 000–44 000 IU/kg IV q.i.d.) and gentamicin (6.6 mg/kg IV s.i.d.) and further therapy should be adjusted based on culture and sensitivity of liver biopsy and response. Antimicrobial therapy should be continued for several weeks to months until GGT concentrations in serum are normal for treatment of cholangiohepatitis.

Chronic active hepatitis

Etiology and pathogenesis

Chronic active hepatitis (CAH) in horses is a chronic, progressive hepatopathy of unknown etiology. A similar syndrome in people has been linked to autoimmune disease, viral hepatitis, Wilson's disease, α_1 -antitrypsin deficiency and drug allergy. Extrahepatic signs of autoimmune disease occur in some people including dermatitis, arthritis and glomerulonephritis.

Coronary dermatitis has been observed in some horses with CAH and could be a manifestation of autoimmune disease (*q.v.*); however, this has not been confirmed by immunohistologic staining. Viral hepatitis, Wilson's disease and α_1 -antitrypsin deficiency have not been documented in horses. Therefore, immune mediated disease is commonly incriminated as a cause of CAH in horses. Although idiosyncratic drug hypersensitivity has been reported in a few cases in horses, this is not a consistent finding in horses with CAH.

In addition, CAH may result from **chronic cholangitis** in horses. Suppurative inflammation is documented histologically in some cases accompanied by culture of a coliform organism (*q.v.*) from biopsy samples. These horses often respond to antimicrobial treatment.

Clinical findings and diagnosis

Clinical signs of CAH are intermittent and insidious with minimal manifestation of illness until severe liver pathology and failure ensue. Signs of progressive liver failure include exercise intolerance, partial anorexia, **icterus** and fever.

Horses with CAH frequently have mild elevations of SDH and AST with more dramatic increases of GGT. Serum bile acid and bilirubin are normal until 70% of the liver is involved leading to liver failure. Total protein is generally elevated. Immunodiagnostics including antinuclear antibody titer and anti-immunoglobulin staining of skin lesions rarely confirm an autoimmune phenomenon.

Diagnosis is based on histologic lesions obtained from **liver biopsy** (*q.v.*) in the face of significant laboratory findings and, sometimes, clinical signs. The definitive diagnosis of CAH depends on the presence of periportal hepatocellular necrosis obscuring and distorting the limiting plate. This causes bridging necrosis, leading to fibrosis and cirrhosis. Mononuclear cells are the predominant

infiltrate; however, neutrophils predominate if **cholangiohepatitis** is the etiology and may be accompanied by biliary hyperplasia.

Treatment and prognosis

Supportive therapy is paramount in the treatment of CAH. Specific therapy depends on the histopathologic findings. If the liver biopsy reveals predominantly mononuclear cells, including plasma cells suggestive of an immune etiology, **corticosteroids** may be helpful. Treatment is commonly initiated with dexamethasone 0.05–0.1 mg/kg/day PO for 7 days followed by a gradual reduction in dose over 30 days. Additional treatment with prednisolone (1 mg/kg/day PO) for several weeks may be necessary.

When the liver biopsy contains large numbers of neutrophils supporting **cholangiohepatitis** or when **culture of liver biopsy is positive**, antimicrobial therapy instead of corticosteroids is indicated. Broad-spectrum antimicrobial therapy can be initiated with potassium benzylpenicillin (22 000–44 000 IU/kg IV q.i.d.) and gentamicin (6.6 mg/kg IV s.i.d.) and further therapy should be adjusted based on culture and sensitivity of liver biopsy and response. **Antimicrobial therapy** should be continued for several weeks to months until GGT concentrations in serum are normal for treatment of cholangiohepatitis. If GGT concentrations do not return to normal after 6 wk and liver biopsy reveals mononuclear CAH with resolution of the suppurative disease, corticosteroid therapy should be considered.

The duration of the disease greatly affects the prognosis in horses with CAH. **Hepatic cirrhosis** warrants a grave prognosis.

Other biliary tract disorders

Fibrotic obstruction of the common bile duct can occur in foals secondary to healing of duodenal ulcers. **Cholangiohepatitis** can result from ascension of enteric bacteria up the common bile duct; it generally occurs in association with **cholelithiasis** (*q.v.*) but occasionally occurs as a distinct disease. **Congenital atresia** of the common bile duct has been described in one foal.

Hepatic abscessation

Hepatic abscessation occasionally develops in horses. Bacteria gain access to the liver **hematogenously** through the portal vein, hepatic artery, the umbilical vein (neonates) and by ascending up the common bile duct from the bowel lumen. ***Clostridium spp.*** (*q.v.*) and enteric bacteria are the most common isolates. Non-specific symptoms include fever, intermittent signs of low-grade abdominal pain, and weight loss. Ultrasonography may identify a hypoechoic mass in the hepatobiliary tract. Biopsy of the abscess is not recommended because it can cause iatrogenic bacterial peritonitis and pleuritis. Treatment consists of supportive care and administration of long-term broad-spectrum antibiotics. The prognosis is guarded.

Hepatic neoplasia

Hepatic carcinoma, diffuse hepatic lymphosarcoma and biliary tract carcinomas (*q.v.*) have been sporadically identified in horses. Although neoplasias

arise more commonly in older horses, hepatic carcinomas have been reported in yearlings and young adults. Signs of liver failure arise if over 60–70% of the liver parenchyma is damaged, or if the neoplasia obstructs the common bile duct. Prognosis for horses with hepatobiliary neoplasia is extremely poor.

Portosystemic shunts

Etiology and pathogenesis

Portosystemic shunts are uncommon in horses. **Congenital vascular anomalies** involving shunts between the portal circulation and the caudal vena cava and the azygos vein have been described in horses under a year of age. Failure of portal blood to circulate through the liver in a normal fashion results in liver atrophy.

Clinical findings and diagnosis

Affected horses manifest symptoms of **intermittent neurologic disease** (hepatoencephalopathy) (*q.v.*) and stunted growth. Consistent laboratory findings include increased total bile acids and elevated plasma ammonia concentration. The blood urea nitrogen (BUN), glucose, clotting profile and albumin concentration findings are more variable. Liver enzymes are within normal ranges or only mildly elevated. Ultrasonography may reveal an undersized liver. Microscopically, hepatocytes are smaller than normal, especially in the centrilobular areas. **Mesenteric portography** is recommended for congenital cases in which surgical correction is being considered in order to determine the number and locations of shunts.

Treatment and prognosis

Surgical correction of a single shunt should theoretically be possible, based on success in people and small animals. However, reports of attempted surgeries in large animals are lacking. Most cases described in the literature were definitively diagnosed by post mortem examination.

PERITONITIS

ETIOLOGY AND PATHOGENESIS

Peritonitis is **inflammation of the mesothelial lining of the peritoneal cavity**. Types of peritonitis can be characterized according to onset (peracute, acute, chronic), region affected (diffuse, localized) and presence of bacteria (septic, non-septic).

Causes of **septic peritonitis** include gastrointestinal perforation, gastrointestinal inflammation or infarction with transmural migration of bacteria, abdominal abscessation, septicemia, omphalophlebitis, uterine perforation, surgical complications, enterocentesis, complications associated with castration, and penetrating abdominal wounds (*q.v.*).

Causes of **non-septic peritonitis** include gastrointestinal inflammation without transmural migration of bacteria, hemoperitoneum, neoplasia, urinary

tract perforation or rupture, cholelithiasis, abdominocentesis, and abdominal surgery (*q.v.*). Parasite larval migration, verminous arteritis and systemic diseases such as equine influenza, equine viral arteritis, equine infectious anemia and African horse sickness (*q.v.*) can also cause peritonitis.

Peritoneal inflammation results in release of inflammatory mediators, increases in vascular and peritoneal permeability, vasodilatation, chemotaxis of inflammatory cells, fibrin deposition on the peritoneal surface, and disruption of gastrointestinal motility. **Bacterial toxins** within the peritoneal cavity easily enter the systemic circulation causing endotoxemia (*q.v.*). Hypovolemia may result from leakage of fluid into the peritoneal cavity.

CLINICAL SIGNS AND DIAGNOSIS

Peracute septic peritonitis can result in hyperemic or cyanotic mucous membranes, tachycardia, weakness, depression, tachypnea, weak peripheral pulse, nasogastric reflux, colic and rapid deterioration to death. Rectal examination may reveal emphysema or roughening of the serosa. **Acute peritonitis** often causes reluctance to move and splinting of the abdomen due to parietal pain. Tachycardia, tachypnea, sweating, pawing, kicking at the abdomen and other signs of abdominal pain may be present. In severe cases, nasogastric reflux and clinical signs of shock may be present.

Horses with **localized peritonitis** often present with intermittent fever, weight loss, depression and anorexia. If present, abdominal pain is low grade. Heart rate and respiratory rate are normal or slightly increased. Decreased water intake may result in dehydration.

Laboratory findings may include increased PCV due to dehydration and reduced total protein due to leakage of large quantities of protein into the peritoneal cavity. When the duration of peritoneal inflammation is >48 h, hyperfibrinogenemia often occurs. The acute inflammatory process and/or endotoxemia associated with peritonitis often result in neutropenia and a left shift. **Metabolic acidosis** may occur in horses with shock.

The diagnosis of peritonitis is confirmed with **peritoneal fluid analysis**. The volume of peritoneal fluid and ease of collection are variable and cannot be used as a basis for diagnosis of peritonitis. During inflammation, peritoneal fluid usually is turbid and may become either bloody or serosanguineous. Clinicopathologic examination of the fluid reveals elevation of the WBC count and total protein. **Biochemical analysis** of peritoneal fluid may be useful in detecting sepsis when cytologic examination and culture are equivocal. Peritoneal fluid pH and glucose are significantly lower (pH < 7.3 and glucose < 30 mg/dL) in horses with septic peritonitis than in horses with non-septic peritonitis and healthy horses. Differences in serum and peritoneal glucose concentration > 50 mg/dL are most predictive of septic peritonitis.

In **acute peritonitis**, either degenerative or non-degenerative neutrophils are the predominant cell type, whereas in chronic peritonitis the majority of the cells are either macrophages or neutrophils. **Degenerative neutrophils** are more likely to be present in cases of septic peritonitis or peritonitis due to tissue necrosis. In cases of septic peritonitis, cytologic evaluation of the peritoneal fluid may reveal bacteria free or phagocytosed in leukocytes. Gram stain may help to identify the types of bacteria present, thereby assisting with

antimicrobial choices. Bacterial cultures are sometimes negative in cases of septic peritonitis. Furthermore, the absence of bacteria on cytologic examination does not rule out septic peritonitis.

TREATMENT AND PROGNOSIS

Therapy involves correction of the **primary disease process**, broad-spectrum antimicrobial agents (see antimicrobial therapy below, *q.v.*) and therapy for hypovolemia and endotoxemia (see salmonellosis, *q.v.*). In some cases, abdominal surgery is necessary to correct the primary disease. Because it is often not possible to differentiate septic and non-septic peritonitis, antimicrobial therapy should be initiated whenever peritonitis is diagnosed or suspected.

It is preferable to obtain an **abdominal fluid sample** for cytology and culture before initiating antimicrobial therapy. Aerobic (*Escherichia coli*, *Streptococcus zooepidemicus*, *Strep. equi*, *Pseudomonas* spp., *Klebsiella* spp., etc.) and anaerobic bacteria are often involved in peritoneal infections; therefore, broad-spectrum antimicrobial therapy is indicated until results of culture and sensitivity are available.

IV antimicrobial therapy provides higher plasma levels and is therefore more effective in cases of acute peritonitis. **Penicillin** is effective against *Streptococcus* spp. and non- β -lactamase-producing anaerobic bacteria. Unless the presence of Gram-negative bacteria has been ruled out, penicillin should be **combined with an aminoglycoside or potentiated sulfonamide**. **Metronidazole** is often effective against β -lactamase-producing anaerobic bacteria. Chloramphenicol has efficacy against aerobic and anaerobic bacteria. However, plasma concentrations achieved with chloramphenicol administration in horses are low. Therefore, chloramphenicol is more effective for chronic therapy after penicillin and an aminoglycoside or potentiated sulfonamide have been administered in the acute stages. The minimum duration of antimicrobial therapy for peritonitis usually is 3 wk. Treatment of abdominal abscessation sometimes requires months.

Peritoneal lavage is sometimes attempted by placing 14 G catheters in each paralumbar fossa by use of aseptic techniques for infusion of large volumes (>20 L) of sterile polyionic fluid solutions. A Foley catheter (30 F) is placed in the ventral abdominal wall for drainage of lavage fluid. Successful drainage of infused fluids rarely occurs. Complications of peritoneal lavage include further introduction of bacterial organisms and adhesions.

Prognosis is at best guarded. The most common complication is **adhesion formation** leading to future **bowel obstruction**. Failure of antimicrobial cure due to resistance of bacterial organisms and failure of antimicrobial penetration can occur. Laminitis (*q.v.*) is a potential life threatening complication.

INTRODUCTION

The endocrine system comprises a complex and integrated system of glands and chemical substances (**hormones**) that function, along with the nervous system, to maintain homeostasis. Hormones have considerable influences on many of the **metabolic processes** of the body, and are involved not only in diseases that are commonly regarded as endocrine in nature, but also in such processes as growth and pregnancy, the response of the body to infection and trauma, and the development of neoplasms.

Much of the endocrine system is related developmentally, anatomically or functionally to the **nervous system**. The **hypothalamus** is part of the brain and is a most important part of the endocrine system. It controls directly the adenohypophysis (anterior pituitary gland), and indirectly (via the pituitary) several other glands, including the adrenal cortex, the gonads and the major part of the thyroid. Part of the hypothalamus extends into the neurohypophysis (posterior pituitary) to form a single anatomic and functional unit. Nuclei within the hypothalamus control the **sympathetic nervous system**, which includes the adrenal medulla.

Another group of endocrine tissues are derived embryologically from the **neural crest**, and are present as cells or clusters of cells within other organs; these include the parafollicular cells of the thyroid, the endocrine cells of the alimentary tract and the islet cells of the pancreas. Finally, there is a group of endocrine cells and tissues that is apparently **independent of the nervous system**; this includes the parathyroids, part of the adrenal cortex, and parts of other organs, tissues and blood. It is often said that the alimentary tract represents “the largest endocrine organ of the body”, and the complex endocrine and neural enteric systems have essential roles in the coordination of gut function, including motility, mucosal transport and local blood flow. The principal hormones and their sites of actions are summarized in Table 11.1.

Clinical endocrinology involves the study of how the body behaves in endocrine disorders and the application of the results to prevent, alleviate or cure endocrine disease. Unfortunately, the amounts of hormones usually present in the blood (especially the pituitary hormones) are extremely small, and the difficulty of measuring them has hindered the study of endocrine disorders. However, recent improvements in analytical techniques and in specificity and sensitivity of hormone assays have led, and continue to lead, to dramatic advances in the understanding of the normal and pathologic processes of endocrinology.

Diseases of the endocrine system often cause **dysfunction** of one or more of its parts. Hormones may be secreted in excess, causing syndromes of glandular hyperfunction, or in deficient amounts, causing syndromes of hypofunction. The overactivity or underactivity of one gland may adversely affect the function of another. Disorders may also arise because of a defect in the metabolism or breakdown of hormones, or the target tissues may become insensitive to the action of a hormone.

THE PITUITARY GLAND

INTRODUCTION

The equine pituitary gland measures approximately 2 cm × 1 cm and weighs from 1 to 3 g. The terms anterior and posterior lobes are anatomically incorrect in horses, since the **neurohypophysis** (equivalent to the posterior lobe in primates) is embedded in and lies dorsal to the **adenohypophysis** (equivalent to the anterior lobe of primates). The adenohypophysis (80–85% of the total weight of the gland) is composed of endocrine cells derived from ectoderm. The neurohypophysis (15–20% of the total weight of the gland) consists of

Table 11.1 Principal endocrine glands and hormones

	Anterior pituitary hormones	Target glands/tissues	Main hormones
Hypothalamus and dependent glands			
1. Hypothalamic nuclei secreting trophic hormones			
(a) Releasing hormones (RH)			
Growth hormone RH	GH	All tissues	—
Thyrotropin RH	TSH	Thyroid (follicular)	Thyroxine Triiodothyronine
Corticotropin RH	ACTH	Adrenal cortex	Cortisol Androgens Estrogens
Follicle stimulating hormone RH	FSH	Ovary	Estrogens
Luteinizing hormone RH	LH	Testis (tubules)	—
		Ovary	Progesterone
		Testis (Leydig cells)	Testosterone
(b) Inhibiting hormones (IH)			
Prolactin releasing IH	Prolactin	Mammary gland	—
Melanocyte stimulating IH		MSH Melanocytes	—
2. Hypothalamic nuclei related to posterior pituitary			
Antidiuretic hormone (ADH)		Renal tubes	—
Oxytocin		Uterus	—
		Mammary gland	—
3. Hypothalamic nuclei controlling sympathetic nervous system			
Adrenal medulla and sympathetic nervous tissue	Catecholamines		
Endocrine glands and tissues derived from neural crest			
Thyroid (parafollicular cells)		Calcitonin	
Alimentary tract (endocrine cells)		Gastrin Secretin Cholecystokinin Enteroglucagon Enterogastrone 5-Hydroxytryptamine	
Pancreatic islet cells		Insulin Glucagon	
Endocrine glands and tissues independent of nervous system			
Parathyroids		Parathormone	
Skin		Vitamin D	
Adrenal cortex (zona glomerulosa)		Aldosterone	
Kidney		Renin Vitamin D	
Blood		Erythropoietin Angiotensin II Kinins	
Liver		Gonadotropin Lactogen Thyrotropin Progesterone Estrogens Relaxin	
Other tissues		Histamine Prostaglandins Leukotrienes	

modified glial cells and axonal processes extending from nerve cell bodies in the supraoptic and paraventricular nuclei of the hypothalamus.

The adenohypophysis consists of three parts: the pars distalis, the pars intermedia and the pars tuberalis. Control of secretion from the pars distalis and pars tuberalis is by means of hypothalamus-derived releasing and inhibiting factors which are transported to the pituitary gland by local circulatory pathways. Control of secretion of the pars intermedia is by hypothalamus-derived neurotransmitters that are transported by axons directly into the pars intermedia.

The **pars distalis** is responsible for the secretion of numerous hormones, including growth hormone, prolactin, the gonadotropins luteinizing hormone (LH) and follicle stimulating hormone (FSH), pro-opiomelanocortin (POMC), adrenocorticotrophic hormone (ACTH), corticotropin-like intermediate lobe peptide (CLIP), β -endorphin (β -END), thyrotropin (TSH) and melanocyte stimulating hormone (MSH). The **pars intermedia** is associated primarily with the synthesis of MSH and β -END.

The **circadian rhythm** of ACTH release arises mainly from **corticotropin** in the pars distalis. Increases in plasma ACTH lead to increases in circulating **cortisol** concentration. A diurnal pattern of ACTH and cortisol release occurs, with cortisol surges lasting 1–2 h starting between 02.00 and 04.00 h, resulting in peak plasma cortisol concentrations between 06.00 and 09.00 h. Circulating cortisol is largely bound to cortisol-binding globulin and has a half-life of 2–3 h.

The **neurohypophysis** comprises the pars nervosa, infundibular stalk and the pituicytes. Oxytocin and antidiuretic hormone (ADH) (also known as arginine vasopressin, AVP) are secreted by hypothalamic neurons arising in these nuclei, and are stored in the neurohypophysis.

The most common malfunction of the equine pituitary gland is associated with functional adenomas or adenomatous hyperplasia of the pars intermedia resulting in **Cushing's disease** (*q.v.*).

DIABETES INSIPIDUS

Diabetes insipidus (*q.v.*) results from the decreased release of **antidiuretic hormone** (ADH) from the posterior pituitary (**central diabetes insipidus**) or lack of sensitivity of the kidney to actions of ADH (**nephrogenic diabetes insipidus**). The disease is most commonly associated with destruction of the posterior pituitary by compression from a tumor of the pars intermedia; however, rare cases of **idiopathic diabetes insipidus** have been recorded. The clinical signs include polydipsia and polyuria, with urine specific gravity <1.010 that fails to increase after a **water deprivation test** (*q.v.*). Serum ADH levels are low and remain unaltered by water deprivation.

Diagnosis may be achieved by using a water deprivation test and ADH response test. In the **water deprivation test**, access to all feed and water is denied and the bladder is emptied by **catheterization**. Urine specific gravity, body weight, blood urea and creatinine levels are monitored every 4 h for a maximum of 20 h. Water deprivation should be terminated if urine specific gravity rises >1.020, or if blood urea or creatinine levels increase above normal, or if there is **clinical dehydration** or a loss of more than 5% body weight.

Horses in which urine specific gravity fails to exceed 1.020 during 20 h water deprivation are deficient in, or lack sensitivity to ADH. The **ADH response test** is performed by the IM injection of 40–60 U **pitressin** (*q.v.*) following bladder evacuation and recording of urine specific gravity. Urine samples are collected 8, 12, 16 and 20 h post injection, and should exhibit maximal concentrations. Restoration of the ability to concentrate urine after ADH administration in an animal that failed to concentrate urine after water deprivation confirms **central diabetes insipidus**.

Treatment is by IM injections of **desmopressin** s.i.d. or b.i.d.; the dose must be adjusted to the individual requirements of the patient.

Failure to concentrate urine after water deprivation and ADH administration confirms **nephrogenic diabetes insipidus**, which may occur secondary to renal infection such as **pyelonephritis** (*q.v.*). This condition must be differentiated from the more common **medullary washout** that occurs in association with **psychogenic water drinking**. Animals affected by the latter condition are expected to show a normal urine concentrating response to water deprivation, although this may take the full 20 h or even slightly longer.

THE ADRENAL CORTEX

INTRODUCTION

The paired adrenal glands contain two anatomically and functionally distinct parts—the cortex and the medulla. The outer cortex, comprising 90% of the gland, surrounds the central medulla. The cortex is a zoned structure and is covered by a thin capsule, below which are isolated groups of glomerulosa cells. Most of the cortex is made up of the zona fasciculata and the zona reticularis, the latter adjoining the medulla.

The **adrenal cortex** produces three major types of steroid hormones: **mineralocorticoids**, **glucocorticoids** and **androgens**. The source of mineralocorticoids, aldosterone and in part deoxycorticosterone, is the glomerulosa cells. Aldosterone is involved in the regulation of sodium and potassium balance, and is under the control of the **renin–angiotensin system** (*q.v.*). Cortisol and the adrenal androgens (estrogens and progesterone) are derived from the fasciculata and reticularis cells. The only known important control mechanism is by means of **ACTH**. This adenohypophysis-derived hormone regulates adrenocortical growth; it also mediates the rate at which steroid biosynthesis occurs.

Cortisol and **corticosterone** are the principal glucocorticoids of horses. As with many other species, there is a **circadian rhythm** of adrenal activity, with peak secretion of glucocorticoids occurring in the morning. Levels of cortisol can be increased by **stress** (such as transport and surgery) and **exercise**. Normal term foals have a high plasma cortisol concentration and have a maximum response to exogenous ACTH during the first day of life. Premature foals have decreased adrenocortical function and the adrenal gland appears to be refractory to ACTH. Low cortisol levels have also been reported in **chronic infections**.

The most commonly recognized abnormality of the adrenal cortex in the adult horse is hyperadrenocorticalism (**Cushing's disease**, *q.v.*) secondary to pituitary **pars intermedia dysfunction**. Hypoadrenocorticalism secondary to synthetic steroid administration also occurs, but there are few well-documented cases.

ADRENAL EXHAUSTION AND THE ACTH STIMULATION TEST

Adrenal insufficiency (also known as hypoadrenocorticalism or "steroid let-down syndrome") is a poorly defined syndrome, sometimes associated with stress or poor performance syndrome (*q.v.*). Low circulating cortisol levels have been reported in **endurance ride horses** following a 100 mile (161 km) ride, but abnormal responses to ACTH have not been determined and no deficiency in cortisol levels in racehorses affected by poor performance has ever been recorded. In fact, adrenal gland hypertrophy is more commonly observed at necropsy of racehorses than adrenal atrophy.

The adrenal glands are **shock organs** and can be damaged during endotoxemia, colic and anaphylaxis (*q.v.*). **Long-term administration** of exogenous corticosteroids or anabolic steroids can also lead to adrenal insufficiency if treatment is suddenly discontinued. The steroids suppress production of **pro-opiomelanocortin** (POMC) peptides by pituitary corticotropins, and the adrenal gland atrophies due to lack of ACTH stimulation. As little as 4 mg of dexamethasone may suppress the pituitary–adrenal axis for 18–24 h.

Clinical features of adrenal insufficiency include depression, anorexia, weight loss, poor haircoat and lameness. Serum biochemistry may be normal or show variable degrees of reduced levels of sodium and chloride, hyperkalemia and hypoglycemia.

Laboratory confirmation of adrenal insufficiency depends on an abnormal response to **ACTH challenge**; this may be performed using either ACTH gel or cosyntropin (synthetic ACTH). The test should be performed early in the morning. The protocols are summarized in Box 11.1.

Treatment of adrenal insufficiency includes rest and steroid supplementation.

Box 11.1 Protocols for ACTH challenge

ACTH Gel

1. Obtain pre-challenge plasma sample for cortisol estimation
2. Administer 1 U/kg ACTH gel IM
3. Obtain plasma samples at 2 and 4 h

In the normal horse, plasma cortisol should increase by 100–200% over basal levels after stimulation.

Cosyntropin

1. Obtain pre-challenge plasma sample for cortisol estimation
2. Administer 100 IU (1 mg) cosyntropin IV
3. Obtain plasma sample at 2 h

In the normal animal, plasma cortisol should increase by 100% after challenge.

CUSHING'S DISEASE

Introduction

Cushing's disease (hyperadrenocorticalism) (*q.v.*) arises as a result of prolonged exposure to excess glucocorticoids, produced as a consequence of hyperplasia of the adrenal cortex. In the horse, this condition is almost exclusively associated with **pituitary pars intermedia dysfunction**, usually due to a functional tumor (**adenoma**).

The abnormal pituitary glands usually weigh 2–3 times the normal weight. The tumors cause varying degrees of **compression** of the pars distalis and occasionally infiltrate the neurohypophysis. Dorsal expansion of the tumor through the diaphragma sella can also lead to compression of the hypothalamus and optic chiasm, resulting in blindness and other neurologic deficits. The tumor cells have not been reported to metastasize.

Pars intermedia adenomas in horses contain markedly reduced amounts of **dopamine** (approximately 10% of normal), and it has been suggested that hyperplasia may arise as a result of loss of hypothalamic dopaminergic innervation. Currently, it is uncertain whether pituitary pars intermedia dysfunction in horses is the result of spontaneous pituitary disease (neoplasia) or the result of loss of dopaminergic innervation and thereby a primary hypothalamic disorder. If the latter mechanism is important, then there is justification for considering treating clinical cases with compounds with **dopamine agonist** action in order to limit the secretion of the active pituitary products.

Conventionally, and simplistically, it has been presumed that neoplastic pituitary glands secrete high levels of ACTH that result in hyperplasia of the adrenal cortices. However, the pathogenesis of equine Cushing's disease is more **complex**, involving alterations in metabolism of other endocrine substances derived from the pituitary gland, including β -END, MSH and CLIP.

Although there are only limited data on the incidence of equine Cushing's disease, it is recognized that the condition has a pronounced age distribution: essentially this is a disease of **aged ponies and horses**. The mean age of affected horses in a number of case series has ranged from 18 to 23 yr. The condition is very rare in horses <10 yr old, and the youngest recorded age is 7 yr.

The frequency of diagnosis of the condition has increased significantly over the past decade, but this is probably due to greater awareness and a larger population of older horses, rather than to an increasing prevalence. All breeds and types of equids (including donkeys) can be affected by Cushing's disease, but ponies and Morgan horses may be at greatest risk. There is no apparent sex predisposition to the disease.

Clinical signs

Cases of equine Cushing's disease may be presented for investigation of a fairly **diverse range** of complaints, including lethargy, dullness, weight loss, excessive thirst, chronic infections, abnormal haircoat, persistent sweating and chronic, refractory laminitis (*q.v.*). The classic clinical sign of Cushing's disease is generally considered to be **hirsutism** (a long, curly haircoat that fails to shed). Despite the characteristic appearance of "classical" **cushingoid**

ponies or horses, it is not uncommon for owners to have accepted many, or all, of these features as normal aging processes.

Most of the clinical signs of equine Cushing's disease are explicable by the presence of increased amounts of **plasma cortisol**. For example, chronic, intractable infections are consequent upon **prolonged immunosuppression**, and **laminitis** (*q.v.*) arises from the effects of endogenous cortisol on the laminae of the foot. Commonly recognized infections include skin infections, recurrent subsolar abscesses, conjunctivitis, sinusitis, gingivitis and alveolar periostitis. **Chronic insidious onset laminitis** is seen in >50% of affected horses and is a common reason for euthanasia. The precise mechanisms by which hypercortisolism results in laminitis is poorly understood, but might relate to hyperinsulinemia and decreased glucose uptake by the laminar tissues.

High levels of plasma cortisol also stimulate **protein catabolism**, resulting in loss of body weight. Typically this is most pronounced in the **epaxial and lumbar musculature** such that affected animals appear dip-backed and/or pot-bellied. Despite the weight loss, the appetite of affected animals is usually normal, or may even be increased. However, dental abnormalities (*q.v.*) are common and can lead to painful mastication and quidding; this results in reduced feed intake that can also contribute to weight loss.

Other cortisol effects, seen less consistently, include **oral ulceration** and **redistribution of fat**. Deposition of fat occurs along the crest of the neck, over the tail head, and in the sheath of male horses. Another common site of fat deposition is above the eyes, producing prominent, bulging supraorbital fat pads.

Excessive thirst, or polydipsia, with increased urine output, is present in approximately one third of animals with Cushing's disease. A number of different disease mechanisms may contribute to this **polyuria–polydipsia** (PU/PD) (*q.v.*). The enlarged pars intermedia may destroy the neurohypophysis by expansion resulting in partial neurogenic diabetes insipidus. Hypercortisolism may also result in central stimulation of thirst. In addition, PU/PD can arise through direct effects of cortisol on renal function causing increased glomerular filtration or antagonism of ADH at the collecting ducts. Cortisol also indirectly contributes to PU/PD via the osmotic diuresis effects of glucosuria, inevitable in hyperglycemic horses. The hyperglycemia of equine Cushing's disease arises from the inhibition of the action of insulin to lower plasma glucose. Thus, PU/PD in equine Cushing's disease may be a consequence of secondary diabetes insipidus (*q.v.*) and secondary diabetes mellitus (*q.v.*) within the same animal. Another possible urinary complication of Cushing's disease is urinary tract infection, which may result in dysuria (*q.v.*).

Clinically, the most distinctive feature of cases of equine Cushing's disease is the **abnormal hair growth pattern** which presents as an extremely long haircoat (hirsutism), frequently with a very curly appearance, and which is often retained for prolonged periods including into the summer months. During the first few years of the disease, the abnormal haircoat may be restricted to the lower jaw, base of neck and palmar/plantar aspects of the distal limbs. Later, **generalized hirsutism** may develop, and in some cases a dark haircoat may turn lighter in color. In some animals, the haircoat may be found to be matted and wet due to persistent sweating (**hyperhidrosis**) unrelated to exercise. The pathogenesis of hirsutism and hyperhidrosis (*q.v.*) is unclear but

it has been suggested that it may be related to elevated POMC peptides or possibly due to the physical effect of the tumor causing pressure on the adjacent hypothalamus, thereby affecting the **thermoregulatory center**.

In a small proportion of cases, other clinical effects may arise from physical expansion of the neoplastic pituitary gland such as ataxia, seizures or blindness due to pressure on the optic nerves and/or their blood supply. Although interpretation of clinical findings such as lethargy or dullness must be somewhat subjective, it is not infrequent for these cases to appear **abnormally docile**, stolid or even somnolescent. It is possible that this changed behavior arises from raised levels of β -endorphins in plasma and cerebrospinal fluid (CSF).

Other clinical signs that have been reported in horses with Cushing's disease include persistent lactation and infertility. These effects could be due to abnormal release of prolactin and gonadotropic hormones. Hypertrophic osteopathy has been reported in one pony with a pituitary adenoma. Breakdown of the suspensory apparatus and spontaneous fractures have also been described.

Diagnosis

In many instances, the clinical presentation and physical findings are virtually pathognomonic of equine Cushing's disease. However, some cases may not manifest typical signs such that the diagnosis will require confirmation. The most consistent **laboratory findings** are hyperglycemia, glucosuria, raised plasma liver enzymes, mild anemia, absolute or relative neutrophilia and lymphopenia. Neutrophils may appear hypersegmented. On occasions, blood samples will appear lipemic due to raised levels of plasma triglycerides and cholesterol.

In principle, assessment of endocrine function in equine Cushing's disease is appropriate in order to reach a definitive diagnosis, which may be particularly important prior to initiating treatment. In fact, the usefulness of **endocrine function tests** in horses is compromised to some extent by apparent **wide variation in responses** between individual animals, and a lack of studies that compare different tests or validate the results of tests with pathologic findings. The endocrine investigation is directed toward the assessment of function of the adrenal glands and the pituitary gland.

Adrenal cortical dysfunction may be assessed by the following:

1. Resting plasma levels of cortisol
2. Diurnal rhythm of plasma cortisol
3. Adrenocorticotropin stimulation test
4. Dexamethasone suppression test (DST)
5. Combined DST/ACTH stimulation test
6. Urinary corticoid-to-creatinine ratio
7. Salivary cortisol concentration.

Resting plasma levels of cortisol

Although hyperadrenocorticalism may be accompanied by elevated plasma cortisol concentration, resting plasma cortisol levels are not routinely elevated in horses with Cushing's disease. Therefore, measurement of plasma cortisol concentration alone is not a reliable diagnostic test for the disease.

Diurnal rhythm of plasma cortisol

Loss of the normal diurnal rhythm of plasma cortisol concentration has been described as a screening test for Cushing's disease. A variance of <30% between plasma cortisol concentrations measured in samples collected in the morning and the evening has been suggested to indicate loss of normal diurnal variation. There are, however, few published data to validate this test.

Adrenocorticotropin stimulation test

Administration of exogenous ACTH produces an exaggerated cortisol response in animals with adrenocortical hyperplasia. This test is commonly used to confirm hyperadrenocorticalism in other species. However, in the horse, only about 20% of animals with Cushing's disease actually have adrenocortical hyperplasia. This test is therefore considered unreliable for the diagnosis of equine Cushing's disease. It might, however, be helpful in identifying those cases with adrenocortical hyperplasia (*q.v.*), prior to treatment with drugs that inhibit cortisol secretion from the adrenal cortex.

Dexamethasone suppression test

The dexamethasone suppression test (DST) is considered to be the “**gold standard**” endocrinologic test for the diagnosis of equine Cushing's disease by many workers. There is concern, however, that the administration of dexamethasone could exacerbate or induce **laminitis** (*q.v.*) although this complication appears to be extremely rare.

Several different protocols for the DST have been proposed, and two are summarized in Box 11.2. The overnight protocol is useful as a screening test, but the standard protocol allows more detailed assessment of the degree of loss of pituitary function.

In normal horses, the plasma cortisol will fall to 1 µg/dL or less 19–24 h after the administration of dexamethasone. In affected horses, the cortisol levels show only a slight fall from basal levels.

Although the overnight DST is the most useful diagnostic test for Cushing's disease in practice, both **false positive** and **false negative results** sometimes occur. Results always need to be interpreted along with clinical and other information.

Box 11.2 Protocols for the dexamethasone suppression test

Overnight protocol

1. Obtain plasma sample for baseline cortisol between 16.00 and 18.00 h
2. Administer dexamethasone IM (40 µg/kg or 2 mg/50 kg)
3. Obtain plasma sample for cortisol estimation at 12.00 h the following day (i.e. 19 h post dexamethasone)

Standard protocol

1. Obtain plasma sample for baseline cortisol at 24.00 h
2. Administer dexamethasone IM (40 µg/kg or 2 mg/50 kg)
3. Obtain plasma samples for cortisol estimation at 08.00, 12.00, 16.00, 20.00 and 24.00 h

Combined DST/ACTH stimulation test

The protocol for this test involves collection of a resting plasma sample and IM administration of 10 mg dexamethasone. A second plasma sample is collected 3 h later, followed by IV administration of 100 IU of synthetic ACTH. A third blood sample is collected 2 h later.

The reason for performing the combined test is to **suppress endogenous cortisol** concentration in cushingoid horses to a value similar to normal horses before ACTH administration, and then to document an exaggerated response to exogenous ACTH. However, the combined DST/ACTH stimulation test is **not recommended**, since it does not allow evaluation of the rebound of cortisol seen in affected horses 24 h after dexamethasone administration. Also, adrenocortical hyperplasia is not a common feature of equine Cushing's disease.

Urinary corticoid-to-creatinine ratio

Measurement of urinary corticoids is commonly undertaken in other species and might be valuable in the assessment of equine Cushing's disease. However, few studies have investigated the value of this test. Currently, a urinary corticoid-creatinine ratio $>20 \times 10^{-6}$ is considered consistent with Cushing's disease.

Salivary cortisol concentration

Salivary cortisol concentration may be useful in the investigation of Cushing's disease, but has received only limited assessment to date.

Insulin resistance

Indirect evidence of hyperadrenocorticalism can be obtained by demonstrating **insulin resistance** on the basis of the following tests:

1. Resting serum insulin concentration
2. Glucose tolerance test
3. Failure to increase plasma insulin in response to glucose loading
4. Insulin tolerance test.

Resting serum insulin concentration

The frequency of **hyperinsulinemia** (*q.v.*) in equine Cushing's disease appears to be greater than the incidence of hyperglycemia. Increased serum insulin levels may be due to the antagonistic metabolic effects of excess circulating cortisol, or due to secretory effects of increased CLIP levels. Measurement of fasting serum insulin concentration can therefore be used as a **screening test** for Cushing's disease.

Although hyperinsulinemia ($>57 \mu\text{U/mL}$) is commonly present, it is not specific for Cushing's disease and can occur for other reasons, including **peripheral Cushing's syndrome** (excessive cortisol activity in peripheral tissues due to altered activity of 11- β -hydroxysteroid dehydrogenase, *q.v.*). The measurement of serum insulin concentration should not, therefore, be used as the sole test to confirm Cushing's disease.

Glucose tolerance test and serum insulin response to glucose challenge

The protocols for glucose tolerance tests are described in the section on diabetes mellitus (*q.v.*). Many of the limitations that affect the sensitivity and specificity of single measurement of serum insulin also affect these tests.

Insulin tolerance test

The insulin tolerance test is performed by administering 0.05 U/kg crystalline insulin IV; blood samples for glucose estimation are obtained before insulin challenge, and at 15 min, 30 min, 1 h, 2 h and 4 h post challenge. In the normal horse the plasma glucose falls by 30–45% at 15 min, 60% at 30 min, and returns to normal by 2 h. Failure to lower resting hyperglycemia by administration of exogenous insulin is expected in Cushing's disease. However, caution should be exercised when interpreting insulin tolerance test results because **pony breeds** are known to be inherently **less sensitive to insulin** and this may be further exacerbated by the presence of obesity and/or laminitis.

Pituitary gland dysfunction

Pituitary gland dysfunction is best demonstrated by:

1. Thyrotropin-releasing hormone (TRH) stimulation test
2. Combined DST/TRH stimulation test
- 3 Plasma ACTH concentration.

TRH stimulation test

Plasma samples for cortisol estimation are obtained before and 15, 30, 60, 90 and 120 min after IV administration of 1 mg TRH. Although TRH normally causes release of thyroid-stimulating hormone and prolactin, it is known that when given to animals with pituitary disorders it gives rise to elevations in plasma cortisol via release of ACTH.

In equine Cushing's disease, there is a consistent increase in plasma cortisol soon after TRH administration that is not seen in normal animals. A 30% increase in plasma cortisol concentration between 15 and 90 min after administration of TRH is considered supportive of Cushing's disease. However, interpretation of the results can be complicated if the initial basal cortisol concentration is high.

Combined DST/TRH stimulation test

The combined DST/TRH stimulation test is used to try to overcome the problem of variable initial cortisol concentration that can complicate interpretation of the TRH stimulation test. Dexamethasone (40 µg/kg) is administered 3 h before TRH to suppress cortisol concentration to similar values in both Cushing's-affected and normal horses. Cortisol concentration is measured before and 30 min after TRH administration. Horses with Cushing's disease show an increase in cortisol, whereas normal horses do not.

Plasma ACTH concentration

Horses with Cushing's disease usually have elevated amounts of ACTH in the pars intermedia and release increased amounts of ACTH into the circulation.

Measurement of plasma concentration of ACTH can therefore be helpful diagnostically. However, many of the assays currently used to measure ACTH have not been validated for equine plasma. In addition, sample handling is difficult. ACTH can be adsorbed onto glass and can be degraded by proteolytic enzymes in whole blood and plasma. Therefore, collection into plastic tubes prefilled with enzyme inhibitors, rapid separation from red blood cells, and freezing the plasma prior to shipment are recommended. The use of a laboratory that runs an assay that has been validated as specific for ACTH in equine plasma is recommended.

An alternative approach to confirming pituitary dysfunction is by measurement of plasma levels of other pituitary peptides such as β -END or MSH. However, at present, assays for these substances are not widely available in clinical practice.

Diagnostic imaging

Diagnostic imaging using computed tomography (CT) or magnetic resonance imaging (MRI) has been described in horses with Cushing's disease, but the sensitivity and specificity of the techniques are currently unknown. In view of the fact that some horses with pituitary pars intermedia dysfunction do not have gross enlargement of the pituitary gland, it seems unlikely that these imaging techniques will be useful for routine diagnosis. They may, however, become important if surgical treatment should be considered.

Definitive confirmation of equine Cushing's disease is only possible by post mortem identification of a pituitary tumor together with hyperplasia of the adrenal cortices. The tumors are usually clearly delineated white or yellow masses within the pars intermedia with variable compression of the adjacent pars distalis, hypothalamus or optic chiasm. Other pathologic features that may be present include hepatopathy, laminitis and septic foci. Very rarely, clinical signs might arise from a primary adrenal disease such as an adrenal tumor, but the strict classification of such an animal would be equine Cushing's syndrome.

Treatment

Management of cases is affected by the severity of signs and financial considerations. For example, in some animals there may be unacceptable **pain** from laminitis or marked debilitation from protracted muscle wasting such that euthanasia is the humane decision. Other cases may be managed by **supportive therapy** such as treating respiratory or skin infections, maintaining a high plane of nutrition, and hoof care for mild laminitis (*q.v.*). **Clipping** to remove long hair may be beneficial. Such conservatively managed cases may have a life of acceptable quality for several years.

Successful treatment, in terms of diminution of clinical signs, has been achieved by medication with several compounds that modify the secretion of the active peptide substances of the pituitary tumor. Drugs that have been used for this purpose include cyproheptadine, bromocriptine and pergolide. Drugs that target steroidogenesis (such as trilostane) have also been used.

Cyproheptadine

Oral **cyproheptadine**, a serotonin antagonist that also has anticholinergic and antihistaminic effects, was one of the first drugs used to treat equine Cushing's disease. Serotonin has been shown to be a potent secretagogue of ACTH in laboratory animals. The suggested dosage regimen is 0.25 mg/kg s.i.d. for 8 wk increasing to 0.50 mg/kg divided twice daily for a further 4–8 wk if no improvement is seen. Although this treatment has been reported to result in improvement in some clinical cases, the response appears to be variable and it can be difficult to separate clinical improvement due to the drug from that attributable to improved management and nutrition.

Bromocriptine mesilate

Since loss of dopaminergic innervation appears to be important in the pathogenesis of pituitary pars intermedia dysfunction, treatment with **dopaminergic agonists** is a rational approach. Beneficial effects have been obtained using oral, subcutaneous, IM or IV **bromocriptine mesilate** (5–100 mg b.i.d.), which is a dopaminergic drug. However, the bioavailability of this drug is low, and it is not readily available.

Pergolide

The **therapy of choice** is probably oral medication with the **dopamine agonist, pergolide** (0.01 mg/kg daily). Clinical improvement is generally more apparent than normalization of blood glucose concentration or endocrinologic test results. A low-dose regimen (0.002 mg/kg PO q 24 h) (1 mg/500 kg horse) appears to be effective in approximately 80% of cases.

If no improvement is noted within 4–8 wk of “low-dose” pergolide treatment, the daily dose can be increased by 0.002 mg/kg monthly up to a total dose of 0.01 mg/kg. Side effects of the drug can include anorexia, diarrhea and colic, but these are more likely at the higher dose rates. The drug is an ergot alkaloid and may have vasoconstrictive effects; this has led to concern that it might exacerbate laminitis, although this problem has not been described in clinical cases.

Concurrent administration of pergolide and cyproheptadine (0.3–0.5 mg/kg) might be beneficial in refractory cases; however, few data supporting this approach are available.

Trilostane

Trilostane is a competitive inhibitor of 3- β -hydroxysteroid dehydrogenase. This drug has been used in an attempt to block endogenous cortisol production by the adrenal gland, and has been demonstrated to reverse both the clinical signs and abnormal endocrinologic test results in one series of equine Cushing's disease cases. The recommended dose rate is 0.4–1.0 mg/kg once a day given in the feed.

These treatments are expensive and there is no regression of the pituitary neoplasia such that lifelong medication is required. Response to treatment, by improvement of clinical and laboratory findings, should be evident within about 4 wk. Nutritional supplementation and complementary therapies (such

as acupuncture, homeopathy and herbal remedies) are commonly employed. Both magnesium and chromium supplementation have been advocated.

PERIPHERAL CUSHING'S DISEASE ("EQUINE METABOLIC SYNDROME")

The term "peripheral Cushing's disease" refers to the syndrome of **mature, adult horses** that develop **laminitis in the face of obesity**. Abnormal regulation of glucocorticoids at the cellular level in the laminae of the feet may play an important role in this condition. By comparison with similar human diseases, the term "**equine metabolic disease**" is probably a more appropriate term.

Obesity results in **insulin insensitivity**, also known as insulin refractory state. Multiple metabolically active factors are secreted by adipocytes and exert their actions locally through paracrine and autocrine mechanisms, and systemically through endocrine mechanisms. These factors inhibit the action of insulin in central (hepatic) and peripheral (skeletal muscle and adipocytes) tissues. Inhibited insulin responsiveness leads to the development of **glucose intolerance**. Hyperglycemia that occurs as a result of insulin insensitivity can have a toxic effect on certain tissues, including endothelial cells, and this may play a role in the development of laminitis (*q.v.*).

Horses affected by the metabolic syndrome are usually obese and tend to be aged between 8 and 18 yr. These horses are commonly described as being "easy-keepers". Affected horses may present with signs of laminitis, or may have evidence of chronic subclinical laminitis (convex sole, divergent hoof lines, widening of the white line).

Diagnosis of equine metabolic syndrome is based on the characteristic clinical signs, ruling out other endocrinopathies with specific tests, and demonstrating **hyperinsulinemia**. Hyperinsulinemia in the presence of a normal or slightly elevated blood glucose concentration in the fasted animal supports the diagnosis of peripheral Cushing's syndrome. Serum free fatty acid levels are also commonly elevated. Glucose intolerance can be confirmed using an intravenous glucose tolerance test.

Treatment of this syndrome consists of increasing physical activity and reducing body weight by dietary modification. Although thyroid supplementation has been widely used in the management of obesity-associated laminitis, there is no evidence to support the concept that hypothyroidism occurs in this condition.

THE ADRENAL MEDULLA

INTRODUCTION

The adrenal medulla, like the sympathetic neurons, is derived from ectodermal cells of the neural crest. These chromaffin cells, so called because they stain brown with chromium salts, have a central position in the gland. The adrenal medulla secretes the **catecholamines**: noradrenaline (norepinephrine), adrenaline (epinephrine) and dopamine. Compared with other species,

relatively little is known about adrenal medullary function and dysfunction in the horse.

The biologic effects of catecholamines released into the circulation depend on the amount fixed in the tissue, which is related to its blood supply and sympathetic innervation, and also on the sensitivity of the tissue receptor binding sites. α -Adrenergic receptors cause smooth muscle contraction, for example in the skin and dilator muscles of the iris. The β -adrenergic receptors mediate smooth muscle relaxation, for example in the bronchi. Adrenaline/epinephrine acts on both α - and β -receptors, whereas noradrenaline/norepinephrine acts mainly on α -receptors.

Of the three major catecholamines, it is most appropriate to measure adrenaline/epinephrine in cases of suspected **adrenal medullary dysfunction**. However, care must be exercised in the interpretation of catecholamine data due to **physiologic variability**. Stressful conditions and acidosis or hypoxia will result in increased catecholamine levels.

CATECHOLAMINE LEVELS IN THE NEONATE

It has been suggested that premature foals have depressed adrenocortical and medullary function, but wide variations in catecholamine levels are seen in the newborn foal and these variations are probably related more to the degree of **stress at parturition** than to the maturity of the foal.

There is an inverse relationship between plasma catecholamine levels and blood pH around the time of birth, although hypoxemia appears to be more important than low blood pH in stimulating adrenal medullary secretion. The catecholamine concentrations are higher in stressed foals than in non-stressed foals. The proportions of adrenaline/epinephrine and noradrenaline/norepinephrine vary with maturity of the foal at birth; in full-term foals, adrenaline/epinephrine predominates, whereas in premature foals noradrenaline/norepinephrine predominates.

CATECHOLAMINE LEVELS IN THE ADULT

High adrenaline/epinephrine levels are expected to occur during stressful events. For example, elevated levels (4–6 ng/mL) have been recorded during second stage labor, but these subsequently fall to 1–3 ng/mL soon after delivery.

Elevated levels of plasma catecholamines (along with ACTH and cortisol) have been detected in cases of **grass sickness** (*q.v.*). These levels are higher than those seen in other cases of colic (*q.v.*), but the precise role of sympathoadrenal activation in grass sickness is unknown.

PHEOCHROMOCYTOMAS

Pheochromocytomas are **tumors of the chromaffin cells** of the adrenal medulla. A small number of cases have been reported in aged horses, usually as an incidental post mortem finding. The tumors may be functional (i.e. they secrete excessive quantities of catecholamines) or non-functional. **Functional pheochromocytomas** result in increased catecholamine production which in turn produces varied clinical effects including anxiety, sweating, trembling, ileus, tachycardia, tachypnea and mydriasis (with intact pupillary light

reflex). **Compromised renal function** and acidosis, resulting from the vasoconstrictive action of noradrenaline/norepinephrine, may also result. Myocardial degeneration secondary to hypertension and cardiovascular collapse are common terminal events in human patients.

A few cases of functional pheochromocytomas have been recorded in horses. Most of these have had **non-responsive colic** as the predominant presenting clinical sign. The signs are generally acute and rapidly progressive, and may be confused with those seen in other more common acute conditions including intestinal obstruction, rhabdomyolysis, acute laminitis and impending colitis (*q.v.*). One horse had no other sign except chronic, watery diarrhea. Increased hematocrit and a “stress leukogram” may be identified. Azotemia, metabolic acidosis, hyperglycemia and hyperkalemia are the most consistent clinicopathologic findings.

Documentation of high serum concentrations of catecholamines or their metabolites in urine is difficult to achieve because of the labile nature of these substances and technical difficulties involved with their measurement.

Attempted treatment of pheochromocytomas in the horse has not been recorded; adrenalectomy might be attempted, but surgical access and the risk of fatal arrhythmias would make this treatment extremely difficult.

THE OVARY AND REPRODUCTIVE HORMONES IN THE MARE

INTRODUCTION

The ovaries (*q.v.*) of the mare are bean-shaped organs of variable size that contain the female gametes. The ovary is an intraperitoneal structure that is attached to the body wall by a fold of peritoneum. The ovarian stroma is composed of spindle-shaped cells and intercellular substance with the stroma forming a tough capsule that encloses the ovary except at the ovulation fossa.

The **immature ovary** contains many thousands of primordial follicles, each containing a primordial germ cell (oogonium). Some of the oogonia develop into primary oocytes that undergo the first stage of meiosis, but they do not complete meiosis until after puberty when the follicle is mature. Most of the primary follicles degenerate and only a small percentage will reach maturity and release their ova.

Follicle development involves a change of the epithelial cells surrounding the oocyte from flat to stratified columnar, an increase in the size of the oocyte, and the accumulation of fluid in a cavity lined by the follicular cells. The stroma around the follicle also becomes organized into a membrane (theca). The mature follicle bursts at the ovulation fossa and discharges its contents toward the **Fallopian tube**. Hemorrhage occurs in the center of the collapsed follicle, and the clot is invaded with follicular or granulosa cells, which, together with the thecal cells, form the **corpus luteum**.

Some 75–80% of mares demonstrate **seasonal polyestrous behavior**, whereas 20–25% demonstrate estrous cycles all year round. The distinct seasonal effects on the estrous cycle can be categorized as:

1. The ovulatory phase: the period from first ovulation in the spring until the last ovulation in the autumn

2. Anestrus: the period of ovarian inactivity during winter
3. The transitional phase: the period of irregular or prolonged estrus receptivity in early spring or late autumn.

THE ESTROUS CYCLE

Estrus (*q.v.*) is the period of sexual receptivity. Estrus in the mare lasts on average for **5–7 days** with ovulation occurring 24–48 h before the end of estrus. The cycle is, however, highly variable. Growth of the pre-ovulatory follicle is controlled by the pituitary gonadotropins, **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**.

Plasma concentrations of FSH peak twice during the cycle at 10–11 day intervals. FSH secretion is stimulated by increased day length and suppressed by **inhibin** secreted by developing follicles. The second FSH peak, which occurs during mid to late diestrus, stimulates growth and development of the pre-ovulatory follicle. The final growth and maturation of the pre-ovulatory follicle is associated with the increase in plasma concentrations of LH in early estrus. At this time most of the remaining follicles become atretic and regress. It is thought that this process of follicular selection may occur due to the production of inhibin or inhibin-like substances by the dominant follicle, which will decrease pituitary release of FSH. However, in some cases other large follicles that are present at the time of ovulation may ovulate either within 24 h or later in diestrus.

Estrous behavior (*q.v.*) is stimulated by the high circulating concentrations of estradiol-17 β from the pre-ovulatory follicle. The **estradiol peak**, which occurs approximately 2 days prior to ovulation, is thought to contribute to the final maturation of the pre-ovulatory follicle by stimulating further LH release. LH reaches its maximum level at, or shortly after, the time of ovulation and concentrations then decrease slowly over the next 5 days. The first peak of FSH also occurs near the end of estrus and coincides with the LH peak.

Development of the **corpus luteum** (*q.v.*) starts immediately after ovulation. Elevated concentrations of **plasma progesterone** are detected within 24 h and estrous behavior ceases. Plasma concentrations of progesterone peak after approximately 6 days and then plateau. Plasma LH levels are low between days 6 and 15 after ovulation because of the negative feedback action of progesterone on the hypothalamus, causing suppression of gonadotropin-releasing hormone (GnRH).

At day 14 or 15 of diestrus the corpus luteum undergoes **luteolysis** in response to release of **prostaglandin (PG) F_{2 α}** from the endometrium. Luteolysis results in a rapid decline in plasma progesterone concentrations. This decrease in circulating progesterone removes negative feedback on the pituitary and hypothalamus, plasma concentrations of LH increase, and the mare returns to estrus.

SYNCHRONIZATION OF ESTRUS

Prostaglandins

Mares are responsive to the luteolytic effect of PGF_{2 α} over only about 30% of the estrous cycle, therefore prostaglandins are **relatively ineffective** at synchronizing estrus in mares. In practice it has been found that two injections of PGF_{2 α} at

an interval of 14–15 days are optimal for synchronization in the mare. Approximately 90% of mares will show heat by 6 days after the second injection.

Progestogens

Progestogens (*q.v.*) (e.g. 0.044 mg/kg **altrenogest** daily PO) may be administered to mares for a period of 15 days (i.e. slightly longer than the normal lifespan of the corpus luteum). Estrus will be delayed until after the end of treatment. Most mares demonstrate signs of estrus within 1–5 days following the last treatment. However, progestogens do not suppress FSH secretion and therefore follicular development and even ovulation may occur during treatment. Thus PGF_{2α} should be administered at the end of progestogen therapy to lyse any corpora lutea that may be present.

Improved control over the cycle can be obtained by using **estradiol** together with **progestogens** because estradiol suppresses release of FSH in the mare. It also seems that progestogens plus estrogens cause greater inhibition of LH than progestogens alone. Progesterone and estradiol are usually given for 10 days (e.g. progesterone in oil 150 mg/day IM, and 17-β-estradiol 10 mg/day IM) and PGF_{2α} is administered at the end of treatment. Follicles predictably ovulate 8–10 days later. Administration of **human chorionic gonadotropin** when the pre-ovulatory follicle reaches 35 mm further improves synchronization by inducing ovulation 36–48 h later.

PREGNANCY

In pregnant mares (*q.v.*), the early conceptus inhibits the release of PGF_{2α} from the endometrium and the primary corpus luteum persists. Numerous follicles develop on the ovaries during the first 3 mo of pregnancy. It is thought that this follicular activity is a result of the continuation of maternal FSH release at 10 day intervals. Progesterone concentrations reach a peak around Day 25 of pregnancy then decrease until Days 40–50, when progesterone again rises to a peak between Days 80 and 90.

The rise in progesterone between Day 40 and Day 90 is associated with the formation of **secondary corpora lutea** on the ovaries. These structures form from ovulation or luteinization of follicles as a result of the luteotropic effect of **equine chorionic gonadotropin** (eCG) produced by the endometrial cups, formed by the invasion of the endometrium by chorionic girdle cells of the trophoblast. Endometrial cup formation begins at Day 25. Detectable concentrations of eCG are present in plasma by Day 40 of gestation. Peak concentrations are reached between Days 55 and 65 and then concentrations decline and are undetectable by Day 150. After regression of the endometrial cups, concentrations of progesterone decrease and remain low between 150 and 300 days of gestation. During the last month of gestation, concentrations of progesterone increase until parturition.

The **placenta** (*q.v.*) starts to secrete progestogens, progesterone and progesterone metabolites around Day 50 and is the sole source of progestogens after the corpora lutea have regressed. Between Days 35 and 40, circulating concentrations of conjugated estrogens increase. A second major increase occurs around Days 70–80 and concentrations finally peak between Days 210 and 240

of gestation. The maternal ovaries appear to be the main source of conjugated estrogens before Day 70. After Day 70, the placenta synthesizes estrogens using steroid precursors provided by the fetal gonads. From Day 200, concentrations of conjugated estrogens decline.

The placenta is also the primary source of **relaxin**. Relaxin is first detected in plasma around Day 70 and increases to initial peak concentrations between 150 and 180 days. After 240 days, relaxin increases progressively until parturition. In the mare, relaxin appears to work with progesterone in maintaining pregnancy and preventing spontaneous uterine contractions. Relaxin levels return to baseline after expulsion of the fetal membranes.

High maternal concentrations of **oxytocin** trigger the rapid increase in concentrations of $\text{PGF}_{2\alpha}$ that are present at parturition. These high concentrations of oxytocin and $\text{PGF}_{2\alpha}$ may then provide the hormonal stimuli for the powerful uterine contractions that occur during second stage labor.

Hormonal diagnosis of pregnancy

Equine chorionic gonadotropin

Tests are accurate between Days 45 and 100 of pregnancy. A limitation of this test is that eCG is a product of the endometrial cups and therefore is secreted even though fetal death could have occurred.

Estrone sulfate

Slight elevations can be measured after Day 40 but large increases occur after Day 60–70. High circulating concentrations are present only in pregnant mares with normal fetal development.

HORMONAL PROBLEMS OF MARES

Absence of estrus

Four clinical syndromes can result in failure of the mare to manifest estrus: silent estrus, prolonged diestrus, granulosa cell tumors and seasonal anestrus (*q.v.*).

Silent estrus

Mares will occasionally fail to show estrus if there is an unusually short period between luteolysis and ovulation. This can arise if a **large follicle** present at the end of diestrus ovulates shortly after luteolysis.

If $\text{PGF}_{2\alpha}$ has been administered to induce luteolysis, ovulation may occur so soon after treatment that the formation of the new corpus luteum masks lysis of the original corpus luteum and can lead to the clinical impression that luteolysis has failed. It is important therefore to **examine follicle development** on the ovaries at the time of $\text{PGF}_{2\alpha}$ treatment. Rarely, mares with normal luteal and follicular phases will also fail to show estrus.

Prolonged diestrus

Prolonged diestrus (*q.v.*) can occur in bred and unbred mares and is caused by failure of luteal regression at the normal time in non-pregnant mares. Up to

25% of cycles may be affected and luteal function may persist for 2 mo or more. It is believed that the endometrium of these mares may fail to release $\text{PGF}_{2\alpha}$ although in most cases no uterine pathology has been specifically implicated.

In mares with severe **chronic endometrial degeneration** and **pyometra** (*q.v.*), the endometrium is unable to produce adequate concentrations of $\text{PGF}_{2\alpha}$ and the corpus luteum persists. However, probably the most common cause of prolonged diestrus is the occurrence of a **diestrus ovulation** on Day 9–14. When $\text{PGF}_{2\alpha}$ is released by the endometrium (Day 14 diestrus) the developing corpus luteum is <5 days old and is unresponsive to lysis by $\text{PGF}_{2\alpha}$. This newly formed corpus luteum will persist for another 14 days.

Another cause of prolonged diestrus is **early embryonic death** (*q.v.*). The presence of a conceptus within the uterus will inhibit release of $\text{PGF}_{2\alpha}$, even if the embryo is lost a few days later, and results in prolongation of the lifespan of the corpus luteum.

Diagnosis is based on history and the stimulatory effect of progesterone on the tone of the uterus and cervix. The condition is treated by IM administration of $\text{PGF}_{2\alpha}$. The mare will return to estrus in 3–4 days.

Granulosa cell tumor

Granulosa cell tumor (*q.v.*) is the most common **ovarian neoplasm** in the mare. One of the first palpable changes is an enlarged ovary with loss of the ovulation fossa. Steroid hormones and/or inhibin produced by the tumor have an inhibitory feedback on the hypothalamus and pituitary. The opposite ovary regresses and is typically palpable as hard, small and inactive. One of the behavioral manifestations of a granulosa cell tumor may be **anestrus**. Alternatively, affected mares may exhibit continuous estrus or masculine behavior.

Granulosa cell tumors are diagnosed by history, behavior, rectal palpation, ultrasonography and hormone analysis. Affected mares that show masculine behavior may have elevated plasma testosterone concentrations (>40–100 pg/mL). However, elevated plasma testosterone levels are present in only about 50% of affected mares. Elevated concentrations of inhibin (>1 pg/mL) are commonly present. Mares demonstrating persistent signs of estrus may have elevated concentrations of plasma estrogen.

Granulosa cell tumors (*q.v.*) are usually benign and **surgical removal** of the affected ovary usually allows the other one to resume normal cyclical activity and restores fertility. Rare cases of bilateral granulosa cell tumors have been described.

Seasonal anestrus

It is thought that during the winter there is a **decrease in secretion** of gonadotropin-releasing hormone (GnRH). As day length increases, GnRH release rises, resulting in increased concentrations of circulating FSH and stimulation of follicular development. Final follicular development and ovulation do not occur until estrogen production is high enough to cause feedback on the hypothalamus and pituitary resulting in LH release. This transitional period may last for 2 mo. A number of treatments have been reported to hasten the onset of cyclical activity:

1. **Progestogens** such as **altrenogest** (0.044 mg/kg) administered orally for 10 days will induce ovulation 7–13 days later. This treatment works best when

follicles of at least 20 mm in diameter are present on the ovaries. It is likely that treatment with progestogens primes behavioral centers in the CNS and allows substantial release of LH when they are withdrawn. It is possible that a combination of progesterone and estrogen promotes the onset of cyclicity more efficiently than progestogens alone, because estradiol enhances the FSH response to GnRH in anestrus mares.

2. **Artificial lighting:** 16 h light per day are required to speed up the cycle. The light may be provided by one 200 W incandescent lamp or two 40 W fluorescent tubes per average 3.7 m × 3.7 m loose box. Ovulation is stimulated 8–10 wk after the onset of treatment.
3. **GnRH:** A synthetic GnRH agonist (**deslorelin**) can be administered as a subcutaneous pellet to advance the first ovulation of the year by approximately 18 days. A single implant placed every other day for up to 6–8 doses may be needed.

To aid in diagnosis of the cause of **estrus failure** blood samples can be collected on five occasions at 5-day intervals and assayed for **progesterone concentrations**. During a normal cycle, progesterone concentrations will be low in two of the samples and high in three of the samples. In **persistent diestrus** progesterone concentrations may be high in all five, and during seasonal anestrus progesterone concentrations will be consistently low.

Excessive signs of estrus

Intermittent or **continuous estrus** is most common in mares during the transitional period. It is probably caused by estrogens secreted by successive waves of developing ovarian follicles in the absence of ovulation. After the first ovulation of spring, cyclicity tends to continue normally. Administration of **progesterone** (*q.v.*) tends to hasten the onset of cyclical activity.

Oral or injectable progestogens are also commonly used to suppress estrus in mares during **performance events**. Altrenogest is now permitted by the Fédération Equestre Internationale (FEI) (*q.v.*) under its Veterinary Regulations but can only be given to mares at the manufacturer's recommended dose and on completion of the appropriate form.

A **granulosa cell tumor** (*q.v.*) of the ovary can cause signs of excessive estrus or **nymphomania** due to production of **estradiol** by the tumor. During seasonal anestrus mares may exhibit sexual receptivity. In general, exhibition of estrus behavior in the mare appears to be more dependent on the absence of the suppressive effects of progesterone than on the presence of high concentrations of estrogen.

Male-type behavior

Granulosa cell tumors can present with a history of male-type behavior. In these cases plasma concentrations of **testosterone** (*q.v.*) are generally elevated. Removal of the tumor results in reversion to normal sexual behavior. Approximately 5% of mares exhibit aggressive behavior between 4 and 6 mo of gestation. This behavior is thought to result from the effects of androgens produced by the feto-placental unit.

Progesterone deficiency in pregnant mares

Oral progestogens are now commonly used to support pregnancies in mares that are believed to have **deficient luteal function**. However, it is likely that premature luteolysis is usually the result of premature release of level $\text{PGF}_{2\alpha}$ rather than inadequate luteal function. Mares can maintain pregnancy with circulating concentrations of progesterone $<2\text{ ng/mL}$.

It has been reported that **stress** from acute clinical conditions such as colic (*q.v.*) may precipitate abortion in mares with marginal placental production of progestogens and it may be advisable to administer progestogens (11–44 mg **altrenogest** PO s.i.d.) to these mares. However, it should also be considered that mares with marginal progestogen production may also suffer from other signs of abnormal placental function such as poor gas and nutrient exchange. During early pregnancy (≤ 55 days) endotoxemia (*q.v.*) can cause an immediate release of $\text{PGF}_{2\alpha}$, which can lyse ovarian corpora lutea. Pregnancy loss can be avoided by treating these mares with progestogens.

THE TESTIS AND REPRODUCTIVE HORMONES IN THE STALLION

INTRODUCTION

During sexual maturity, the testis (*q.v.*) performs two distinct but related functions: spermatogenesis and androgen production. **Spermatogenesis** takes place in the seminiferous tubules, which are abundantly coiled and constitute 95% of the testis volume. The Leydig (interstitial) cells occur in clumps between the seminiferous tubules and are involved in **androgen production**.

REPRODUCTIVE HORMONES IN THE STALLION

The Leydig cells of the testis produce **testosterone** under the influence of LH from the anterior pituitary gland. The testosterone is delivered to both the local testicular environment and the systemic circulation. High concentrations of testosterone are necessary for maintenance of **spermatogenesis** in the stallion. FSH stimulates Sertoli cells in their role in germ cell development and in production of **inhibin, androgen-binding protein and activin**.

Inhibin and activin feed back negatively on the hypothalamus and pituitary to inhibit and promote, respectively, FSH release. **Androgen-binding protein** binds to both dihydrotestosterone and testosterone, and provides a high concentration of both of these hormones locally around the germ cells.

FSH and LH secretion is stimulated by GnRH (released by the hypothalamus) and is inhibited by estradiol and testosterone. Increasing day length has a positive influence on secretion of gonadotropins. Because of increased circulating gonadotropin concentrations, testosterone concentrations also increase in spring. The stallion testes also secrete high concentrations of estrone sulfate. However, circulating concentrations of estrogen are not influenced by season and are constant throughout the year.

There appears to be little correlation between circulating concentrations of testosterone and **fertility in stallions**. Some stallions with **low libido** (*q.v.*)

have low concentrations of LH in plasma. However, some stallions with vigorous libido and good seminal characteristics may also have low LH concentrations. Preliminary data suggest that GnRH treatment may be beneficial in some cases of infertility in stallions.

CRYPTORCHIDISM

Approximately 50% of supposedly castrated horses presented with male behavior are **cryptorchids** (*q.v.*) and the ability to differentiate between castrates and cryptorchids is therefore important.

In horses <2–3 yr of age, and in donkeys of any age, a **human chorionic gonadotropin (hCG) stimulation test** is recommended for diagnosis. In older horses, a single blood sample for estrone sulfate estimation is adequate. The hCG stimulation test is performed by administering an IV dose of 6000–10 000 IU hCG to the animal; concentrations of testosterone are measured in paired serum samples collected before and 60 min after administration of hCG. In cryptorchids, basal testosterone concentrations are usually >100 pg/mL and the level will increase up to 3- or 4-fold, but geldings have low basal levels (<40 pg/mL) that do not respond to hCG treatment. It has been reported that doubtful results are recorded in 11% of cases.

Estrone sulfate determination is helpful in horses >2–3 yr of age. Cryptorchids have concentrations >400 pg/mL, compared with <100 pg/mL in geldings. This assay has been reported to produce doubtful results in only 2% of cases when performed in horses that are at least 3 yr old. In younger animals, the hCG stimulation test should be used.

THE THYROID GLAND

INTRODUCTION

The thyroid gland is found on the ventral aspect of the neck, loosely attached to the anterior trachea. It consists of a pair of lobes situated on each side of the trachea adjacent to the larynx. These lobes are connected by an isthmus running over the ventral surface of the trachea. The isthmus is a narrow structure and may only be represented by a fibrous band.

The major function of the thyroid gland is the production of **thyroid hormones**. Thyroid hormone secretion is dependent on adequate blood concentrations of **thyroid-stimulating hormone (TSH)** (thyrotropin) and **iodine**. Follicular cells take up iodide from the circulation for incorporation into **thyroglobulin**. This is subsequently broken down by lysosomal enzymes to **tri-iodothyronine (T3)** and **thyroxine (T4)**, which are stored in the colloid of the follicles prior to release into the circulation. The majority of circulating thyroid hormone is bound to blood constituents including thyroid hormone-binding protein and albumin. Unbound (“free”) hormone is biologically active.

Thyroid hormones exert effects on almost all body tissues so that manifestations of thyroid dysfunction are **extremely varied**. Central nervous tissues, including the hypothalamus, monitor blood concentrations of thyroid

hormones, particularly T4. Low thyroid hormone concentration elicits a rise in thyrotropin releasing hormone (TRH) secretion by the hypothalamus. This stimulates release of TSH from the adenohypophysis.

Thyroid disease in the horse is rare but may be divided into a number of conditions.

GOITER

Dietary iodine is essential for the production and release of thyroid hormones. In conditions of too much or too little dietary iodine, retention of thyroxine leads to **gross enlargement** of the thyroid gland (goiter). Clinically, goiter due to **excess iodine** is more common and is usually associated with the use of **iodine-rich feed supplements** (especially seaweed-derived preparations). It is easily corrected by reducing the dietary intake. **Neonatal goiter** has been associated with feeding of **seaweed supplements** to the pregnant mare.

Goiter caused by lack of iodine is rare due to the widespread use of iodized salt in commercial feeds and feed supplements. It may occur with the ingestion of goitrogenic substances, especially *Brassica* (*q.v.*).

Goiter in either form is most commonly seen in neonates and has been associated with stillbirth, the birth of weak foals, and foals with forelimb contracture.

HYPOTHYROIDISM

Hypothyroidism has only been recently recognized in the horse with the availability of thyroid hormone assays and the use of thyroid function tests. Clinical signs are varied since thyroid hormones exert widespread effects on body tissues. Old and young horses are most commonly affected. Clinical syndromes in the foal include prematurity, poorly ossified or malformed carpal and tarsal bones, forelimb contracture, ruptured common digital extensor tendons, mandibular prognathism and angular limb deformities (*q.v.*). In the adult horse clinical signs may include dullness, bradycardia, myxedema, agalactia, exercise intolerance and variable appetite. Other reported signs include myopathy in racing animals, and cutaneous signs, particularly alopecia.

Hypothyroidism may be defined as primary, secondary or tertiary. **Primary hypothyroidism** refers to a disease of the thyroid gland itself. **Secondary hypothyroidism** results from reduced secretion of TSH from the adenohypophysis. **Tertiary hypothyroidism** results from inadequate TRH release from the hypothalamus.

Although there are no documented cases of primary hypothyroidism resulting from iodine deficiency in adult horses, this could potentially cause goiter and hypothyroidism. Likewise, immune-mediated thyroiditis has not been definitively diagnosed in the horse. Most cases of primary hypothyroidism are idiopathic. These cases are rare.

Diagnosis of hypothyroidism is based on **dynamic function tests**. Thyroid hormone assays should be performed at a **specialized endocrine laboratory** and the patient needs to be maintained free of all medication for at least 10 days prior to the test. Baseline levels of serum T3 and T4 are measured and then repeated following the administration of **TSH**. A protocol for the TSH

Table 11.2 Expected responses to TSH stimulation test using IV bovine TSH administered IM in normal horses

Time	T3	T4
Baseline	See laboratory normals (0.09 ± 0.02 µg/100 mL)	See laboratory normal (1.8 ± 0.8 µg/100 mL)
3 h	3–5 × baseline	1–2 × baseline
6 h	1–3 × baseline	2 × baseline

stimulation test, together with expected normal responses, is shown in Table 11.2. In primary hypothyroidism a reduced response of T3 and T4 is expected.

If persistently low resting levels of T3 and T4 are found despite a normal TSH stimulation test result, then a **TRH stimulation test** may be used to confirm a state of secondary hypothyroidism, i.e. due to underlying pituitary dysfunction. Where exogenous (bovine) TSH is not commercially available, the routine diagnosis of hypothyroidism will depend on measurement of serum T3 and T4 levels, and the TRH stimulation test. The TRH stimulation test is performed by administering IV 1 mg TRH and collecting blood samples after 2 and 4 h. In normal healthy horses, T3 and T4 concentrations are twice that of baseline after 2 and 4 h respectively. The test can be used to demonstrate hypothyroidism due to abnormal hypothalamus–pituitary–thyroid axis function.

Treatment for primary hypothyroidism involves replacement therapy with oral **levothyroxine sodium** at 10–20 mg/day or iodinated casein at 5 g/day. T4 levels should be monitored 1 wk after treatment commences and the dose adjusted to maintain the T4 level within the normal range.

Low thyroid hormone levels can also occur as a result of suppression of TSH formation and/or TRH-induced TSH release. Causes include **phenylbutazone therapy**, high energy diets, high protein diets, glucocorticoid administration, etc. Phenylbutazone (*q.v.*) is highly protein bound, and it displaces thyroid hormone from carrier proteins. The increased amount of free hormone exerts a negative effect on the thyroid hormone feedback pathway and inhibits the hypothalamus–pituitary–thyroid axis.

SICK EUTHYROID SYNDROME

Sick euthyroid syndrome is recognized in other species, and probably also occurs in the horse. It is characterized by low thyroid hormone levels associated with severe non-thyroid disease. It is believed to be a protective function to preserve calories in catabolic states.

HYPERTHYROIDISM

There are very few well-documented reports of equine hyperthyroidism. Clinical signs include thyroid gland enlargement, tachycardia and arrhythmias, emaciation despite normal appetite, restlessness and excitement. The **diagnosis** is based on the clinical signs and elevated resting levels of T3 and T4.

Treatment is aimed at limiting thyroid hormone synthesis with “thyrostatics” such as **carbimazole**. However, dosage rates of such drugs for use in

the horse have not been evaluated. Thyroidectomy has been used in the past for the treatment of bizarre behavioral problems thought to be associated with hyperthyroidism, but the results were unreliable and now the technique is widely considered unethical.

NEOPLASIA

Thyroid **adenomas** represent the most common form of thyroid disease in the older horse. Only one lobe of the gland is usually affected and presents as a non-painful, progressive swelling on the ventral aspect of the anterior neck. Typically, the adenoma is **non-functional** so there are no associated clinical signs. Occasionally, bizarre signs have been reported in conjunction with a thyroid adenoma and these have resolved following surgical excision. Removal of the affected lobe may be justified on grounds of a space-occupying lesion or suspicion of a thyroid carcinoma. Percutaneous needle biopsy (*q.v.*) of a thyroid swelling will allow differentiation between a carcinoma and an adenoma.

Thyroid carcinomas are rare. Like adenomas they usually present solely as swellings in the thyroid area although other clinical signs have been reported. Signs of coughing, anorexia and depression have been seen, and thoracic and abdominal metastases may be found at post mortem examination. One case had reduced exercise tolerance, which returned to normal following surgical treatment. Both follicular and medullary carcinomas have been identified histologically.

THE PANCREAS

INTRODUCTION

The pancreas is a compound racemose gland that has important exocrine and endocrine functions. Up to a million islets of Langerhans are present in the organ, but these account for only approximately 2% of its total weight. Two major cell types are present in the islet tissue: α cells are responsible for the secretion of **gastrin** and **glucagon**, and β cells are the source of **insulin**.

Insulin is synthesized in the endoplasmic reticulum of the β cell as a single chain polymer, **pro-insulin**, from which the two-chain structure is split off by a trypsin-like enzyme. The rates of pro-insulin and insulin synthesis are highly dependent on **blood glucose** concentration; other factors that stimulate pancreatic insulin release include amino acids, glucagon, enterohumoral factors, growth hormone, corticotropin and vagal stimulation. The major effect of insulin is to **increase the utilization of glucose** by most body tissues. This is achieved by increasing the transportation of glucose across the cell membrane and stimulating lipogenesis. Fasting insulin concentration is usually between <5 and $20 \mu\text{IU/mL}$.

DIABETES MELLITUS

Diabetes mellitus has been considered a rare disorder in the horse. The word diabetes generally is associated with a failure of insulin production and the

resulting abnormalities that develop in the control of carbohydrate, protein and lipid metabolism. Therefore diabetes mellitus for a long time was associated with hypoinsulinemia and hyperglycemia. In fact diabetes mellitus is an **extremely complex syndrome** that consists of a number of different disorders.

The National Diabetes Data Group has classified human diabetes into groups to address both the clinical and subclinical stages of the onset of this disorder. These are:

1. Insulin dependent
2. Non-insulin dependent
3. Secondary diabetes
4. Gestational diabetes
5. Impaired glucose tolerance.

Similar groups have also been identified in horses and ponies, and it is appropriate to adopt a similar classification system here.

Insulin-dependent diabetes

Insulin-dependent diabetes is associated with failure to produce or release insulin. This form of diabetes is very rare in the horse and no cases of juvenile-onset insulin-dependent diabetes have been reported. Adult horses and ponies have been noted to develop insulin-dependent diabetes following destruction of the pancreas. In several of these reports the migration of *Strongylus equinus* and *S. edentatus* parasites (*q.v.*) was the apparent cause of the pancreatitis.

The **clinical signs** noted in insulin-dependent diabetes mellitus include weight loss, depression, polyuria and polydipsia. Clinical pathologic abnormalities include hyperglycemia, glucosuria and hypertriglyceridemia. In addition, horses with migrating parasites may have increased eosinophil counts in the leukogram and be hyperglobulinemic.

The **diagnosis** of insulin-dependent diabetes can be confirmed by performing either an oral or IV **glucose tolerance test** (*q.v.*).

Once significant damage to the pancreas occurs with the destruction of the islets of Langerhans, the only available **treatment** is administration of **parenteral insulin**. The insulin dosage should be established by monitoring the response to small doses initially and then gradually adjusting the dosage. In one report of diabetes associated with pancreatitis in a pony, protamine zinc insulin (0.5–1.0 U/kg) was more effective than regular insulin in decreasing the hyperglycemia.

Secondary diabetes

The most common form of diabetes in the horse is secondary diabetes. Secondary diabetes has been reported following **hyperadrenocorticalism** and in association with **granulosa cell tumors** (*q.v.*). Theoretically, it could also occur in association with growth hormone excess and pheochromocytomas (*q.v.*), but neither association has been cited in the literature.

Hyperadrenocorticalism is a common endocrine disorder of older horses resulting from the excessive production of adrenocorticotrophic hormone from a pituitary adenoma (*q.v.*). The increased production of cortisol inhibits the function of insulin, leading to insulin resistance and hyperinsulinemia. This is accompanied by hyperglycemia from increased hepatic glucose production and decreased glucose utilization by the peripheral tissues. The mechanisms for impaired glucose tolerance and hyperinsulinemia have not been determined but may result from direct stimulation of pancreatic β cells or a post-receptor defect involving the insulin target receptors. Hyperadrenocorticalism is most readily diagnosed by performing a **dexamethasone suppression test** (*q.v.*).

Non-insulin-dependent diabetes (see peripheral Cushing's disease *q.v.*)

Recently an additional group of pony diabetics has been identified. These ponies are classified as non-insulin-dependent diabetics and are generally **obese** (Table 11.3). Similar findings have been noted in human patients with non-insulin-dependent diabetes, where 80% are obese. These ponies show no abnormal physical or clinical pathologic changes other than being obese. There appears to be a progressive decline in insulin sensitivity associated with increased body condition. Ponies therefore initially show **impaired glucose tolerance** (Table 11.3, group 2) and then develop hyperinsulinemia and hyperglycemia (group 3).

Affected ponies tend to have **increased fasting insulin concentrations** and following the administration of oral glucose become hyperinsulinemic and hyperglycemic. It has been suggested that affected ponies may be susceptible to the development of laminitis (*q.v.*) and the hyperlipemia syndrome (*q.v.*) but it is not determined what roles the hyperinsulinemia and hyperglycemia play. Human patients suffering from non-insulin-dependent diabetes may

Table 11.3 Classification of pony diabetics based on insulin and glucose data following oral glucose administration

develop insulin-dependent diabetes following β cell exhaustion. A similar progression in the severity of this disorder has not been noted in ponies.

Ponies with non-insulin-dependent diabetes will show improved insulin sensitivity on feeding a maintenance diet alone or in association with a mild exercise program.

Gestational diabetes

Pregnancy in the mare is a **diabetogenic stress**. During pregnancy, mares may develop hyperinsulinemia, enhanced β cell sensitivity to endogenous and exogenous glucose, increased degradation of insulin, insulin resistance and exaggerated responses to fasting and feeding. These adaptive glucose and insulin changes during pregnancy aim to protect the rapidly growing foal in the final trimester.

Glucose tolerance tests

If a horse or pony is suspected of suffering from diabetes mellitus then either an oral or an IV glucose tolerance test can be performed. The **oral glucose tolerance test** is performed after withholding feed for 16 h and then administering glucose at a dosage of 1 g/kg as a 20% solution by stomach tube. Blood samples are collected for glucose and insulin determination at times 0, 30, 60, 90, 120, 150, 180 and 210 min. Following oral glucose administration normal ponies will tend to double their glucose concentrations between 90 and 120 min then quickly decrease both the insulin and glucose concentrations.

The **IV glucose tolerance test** is performed by administering 0.5 g/kg of glucose IV as a bolus (e.g. 40%) and collecting samples at times 0, 15, 30, 45, 60, 120, 180 and 240 min for glucose and insulin estimations. Insulin-resistant ponies fail to decrease the glucose concentration even with very high insulin concentrations, while insulin-dependent diabetics will have high glucose concentrations with little increase in insulin concentration.

THE PARATHYROIDS AND CALCIUM METABOLISM

INTRODUCTION

The anatomic position of the parathyroid glands is quite variable. One pair is usually embedded in the thyroid glands, while a second pair may be located from the area of the thyroid gland to 15 cm cranial to the first rib.

Calcium metabolism is under the control of a variety of hormones. The most important of these are **parathyroid hormone (parathormone, PTH)** and **vitamin D**, which act on the intestine, bone and kidney. In this way, serum calcium concentration is maintained within closely defined limits. The major stimulus for PTH secretion is hypocalcemia. PTH acts predominantly on the kidneys to increase calcium resorption in the tubule, although calcium resorption in bone is also increased by PTH. It also acts on the renal tubule to decrease phosphorus resorption.

Cholecalciferol (vitamin D₃) is formed predominantly in the skin and is metabolized in the liver and kidney to form the active metabolite 1,25-hydroxy-vitamin D, which facilitates calcium absorption in the small intestine. It is also essential for bone formation, but when present in excess stimulates bone resorption and causes hypercalcemia.

Calcitonin is produced by the parafollicular C cells of the thyroid gland. Its actions are the opposite of PTH, since it inhibits bone resorption and lowers serum calcium.

Serum calcium is present in three forms: ionized, protein-bound and complexed calcium. **Ionized calcium** is the physiologically active form and accounts for nearly half of the total calcium. **Protein-bound calcium** is complexed predominantly to albumin, and alterations in serum proteins will result in changes in the concentrations of protein-bound calcium. Since most measurements of serum calcium only give an estimate of total serum calcium, these values must always be interpreted in conjunction with simultaneous measurement of serum proteins.

HYPERCALCEMIA

Hypercalcemia has been associated with renal disease, neoplasia, vitamin D toxicity and hyperparathyroidism.

Chronic renal failure

Some horses with chronic renal failure (*q.v.*) develop hypercalcemia and hypophosphatemia. The horse relies on renal excretion to eliminate excessive quantities of calcium absorbed from the intestine; chronic renal disease therefore may result in failure of this mechanism.

Ectopic or pseudo-hyperparathyroidism

Hypercalcemia is a relatively common complication of malignancy in humans, but has been identified only rarely in the horse. The tumors most commonly associated with hypercalcemia in the horse are **lymphosarcoma**, **gastric squamous cell carcinoma** and **mesothelioma** (*q.v.*). The hypercalcemia in these cases is thought to result from the secretion of tumor-derived humoral factors, and the syndrome is referred to clinically as ectopic or pseudo-hyperparathyroidism.

The precise nature of the humoral factors causing hypercalcemia is uncertain, but in most cases it appears that it is not PTH. Prostaglandins and osteoclastic activating factor have been implicated in some cases, but other factors are probably important as well. Soft tissue mineralization (especially of the heart and major blood vessels) and hypercalcemic nephropathy have been identified in some cases.

No attempted treatment of this condition in the horse has been recorded, although in other species surgical removal of the tumor mass has been shown to reverse the hypercalcemia.

Hypervitaminosis D

Iatrogenic hypervitaminosis D may result from **overdoses of vitamin supplements** or ingestion of toxic plants with vitamin D activity. Hypercalcemia, hyperphosphatemia and soft tissue mineralization have been recorded in such cases. Treatment consists of removal of the source of excessive vitamin D.

Primary hyperparathyroidism

Primary hyperparathyroidism is very uncommon in the horse and is a clinical condition produced by the inappropriate overproduction of PTH. The precise cause for the autonomous PTH overproduction is often undetermined, even in humans. Persistent hypercalcemia and hypophosphatemia result, and the diagnosis is achieved by detection of a high PTH concentration. A radioimmunoassay for C-terminal PTH has been validated for use in the horse. The clinical features of primary hyperparathyroidism in the horse appear vague, but include intermittent lameness and recumbency.

Nutritional secondary hyperparathyroidism

Nutritional secondary hyperparathyroidism, also known as “**big head**” and “**miller’s disease**” (*q.v.*), occurs in horses fed rations containing an **excess of phosphorus relative to calcium**. The disease is seen most commonly in young horses, or occasionally in pregnant mares.

Shifting-leg lameness is a common initial sign and is caused by focal periosteal avulsion, detached or torn ligaments, or subepiphyseal microfractures. The **laminae durae surrounding the teeth may become resorbed**, resulting in difficult and painful mastication, and bilateral symmetrical facial swellings occur.

The ingestion of excessive phosphorus causes hyperphosphatemia and secondary hypocalcemia. This is the stimulus for PTH secretion, which returns the serum calcium levels back to normal. **Parathyroid gland hypertrophy** may result in long-standing cases. The **diagnosis** is made on the basis of the clinical signs and is supported by feed analysis. Radiographic evidence of loss of the laminae durae is also helpful. Serum calcium levels are usually in the low–normal range. The fractional renal excretion of phosphorus is increased.

Treatment consists of correcting the dietary imbalance and supplementing the diet with calcium (e.g. limestone flour).

INTRODUCTION

The upper urinary tract comprises the kidney and the ureters. The kidneys are responsible for the fine-tuning of the water and electrolyte balances, and the amount of water ingested or produced metabolically can have a significant effect on urine production. The ureters conduct the urine to the bladder in a

pulsatile fashion with muscular contractions delivering accumulated urine from the renal pelvis to the bladder up to 6–10 times per minute.

The bladder and urethra make up the lower urinary tract. The bladder stores urine and the urethra conducts it out of the body.

Normal horses produce between 5 and 15 mL urine per kg body weight per day but this varies with **food type** and the extent of loss of water from the gut, the respiratory tract and skin. Even during extreme dehydration urine will be produced at approximately 2.5 mL/kg/day.

Renal disease affects the whole body but the common clinical features of equine urinary tract disease are non-specific. From a clinical perspective urinary tract disease is manifest by:

1. Weight loss
2. Abnormal urination (volume or character)
3. Pigmenturia.

Related non-specific systemic signs include anorexia, depression, ventral edema, oral ulceration and colic.

Normal horses pass urine freely after posturing appropriately, and the ability to **posture correctly** has an important role in the ability and willingness of the horse to urinate. If the horse cannot (for pain or physical reasons) posture correctly an impression of urinary tract disease may be displayed.

For the most part, **weight loss** is an indicator of renal disease while bladder and urethral problems are associated with abnormal urination.

NORMAL MICTURITION

The normal equine bladder can accommodate 4–4.5 L of urine. Horses usually urinate four to six times daily and, depending on size, will produce between 3 and 15 L of urine. The volume and composition of normal urine changes frequently in response to external influences such as water consumption, dietary composition, ambient temperature, exercise and natural diurnal variations.

Box 12.1 Definitions of urologic terms

Polydipsia: Increased water intake/thirst beyond normal volume

Polyuria: Abnormally increased urine production/volume of urination

Strangury: Difficulty with urination (usually with straining and, possibly, pain)

Pollakiuria: Frequent urination (not necessarily associated with increased volume)

Anuria: Absence of urine production

Oliguria: Production of reduced volume of urine

Isosthenuria: Urine that has similar osmolarity to serum

Hyposthenuria: Urine that is more dilute than serum

Azotemia: Pathologically increased blood concentrations of urea nitrogen and creatinine (and other non-protein nitrogen) in blood

Uremia: The complex of clinical and pathologic effects of high concentrations of urea on tissues within the body (azotemia)

Pigmenturia: Abnormal coloration of freshly voided urine

Incontinence: Inability to retain urine in the bladder

Bladder function is governed by sympathetic, parasympathetic and somatic nerves. Throughout filling, afferent (sensory) neurons induce increased sympathetic activity, which inhibits detrusor contraction. Passive outflow of urine from the urinary bladder is prevented by muscular tone in the neck of the bladder and the proximal urethra. Bladder distension triggers micturition by coordinated contraction of the bladder detrusor muscle, which generates intravascular (bladder) pressure, and simultaneous relaxation of the bladder and urethral “sphincters”. Higher centers in the motor cortex, midbrain and medulla can both inhibit and facilitate contraction by over-riding the automatic local functions. In this way urination can be consciously delayed.

The diagnosis of urinary tract disease presents a **clinical challenge** because many of the most serious signs are subtle. As a result, cases are often presented with advanced disease. Differentiating between **pre-renal** (decreased renal perfusion), **renal** (renal damage or compromise) and **post-renal** (obstructive lower urinary tract disease or uroperitoneum) disease is a cornerstone of renal medicine.

GENERAL PRINCIPLES OF THE DIAGNOSIS OF URINARY TRACT DISEASE

Urinary tract disease presents with a variety of clinical signs that relate to the etiology, the extent of renal compromise and the organs that are affected secondarily. Thus, difficulty with or **pain during urination** can be a sign of an obstructive or inflammatory condition in the lower urinary tract (usually the bladder or the urethra). Polydipsia or oliguric renal failure results in little pain but there are significant alterations in urine production. The volume and quality of urine produced may be the only outward evidence of severe renal disease. **Advanced renal failure** with azotemia and uremia has profound effects on almost all the body organs. Additionally, central nervous signs, anemia, weight loss, oral and intestinal ulceration, are all possible.

Obvious difficulty with urination (**dysuria**) or **variations in the color and character of urine** are often the signs that owners will notice. In contrast, because the early signs of renal or lower urinary tract compromise are often subtle, owners may not notice any problem until the condition is advanced.

A **thorough clinical investigation** is essential in every case of suspected urinary tract disease; the urinary tract should not be overlooked when investigating a variety of other apparently unrelated clinical signs such as **colic** and **weight loss** (*q.v.*) and must be carefully assessed in every case of suspected urinary tract disease.

The clinical investigation of urinary tract disease relies heavily on **urinalysis** and biochemical tests, but subtle (or sometimes more obvious) clinical indicators of disease do exist; the role of the clinician is to identify these and assess their combined importance.

The limitations to clinical examination mean that there is an increased reliance upon other diagnostic aids. Urinary tract endoscopy (including ureteroscopy) and percutaneous and transrectal ultrasonography, in particular, have significantly improved the prospects of a definitive diagnosis. In adult horses, useful physical examination is limited to **rectal palpation**. The procedure is indicated in all cases of suspected urinary tract disease.

RECTAL PALPATION

The value of rectal palpation for urinary tract disease depends upon the relative sizes of the operator and the horse and operator experience. In the case of foals, rectal examination is not feasible but in some cases the bladder can be palpated abdominally.

It is usually only possible to assess the size, texture and outline of the caudal pole of the **left kidney**. The right kidney is best regarded as non-palpable. The size, wall thickness and texture of the **urinary bladder** can be appreciated and sometimes abnormal content or masses can be felt. The **texture** of the bladder can be a major diagnostic aid. In some cases repeated examinations will need to be made to establish variations in function during the normal cycle of filling and emptying.

Unless they are enlarged or inflamed (or both) the **ureters** are not usually identifiable. It may be more rewarding to palpate the distal regions of the ureters of a mare per vaginam. If the ureters can be felt easily, they can be taken to be abnormal. In any case, the **trigone of the bladder** should always be palpated. In mares it may be possible to palpate the vesicoureteral opening directly via the urethra and then it may be feasible to pass a catheter directly into the ureters.

ENDOSCOPY

Cystoscopy is a simple procedure in mares, although it is sometimes difficult to maintain insufflation. Male horses require a longer thinner endoscope (<1 cm diameter, >1 m long). **Videoendoscopy** is very helpful but suction apparatus is essential.

Saline distension of the bladder during endoscopy in both male and female is recommended because, in contrast with air insufflation, there is little or no iatrogenic superficial inflammation. Urine samples should be taken **before insufflation** or distension to avoid artifactual results.

Ureteroscopy and visualization of the renal pelvis is possible with a suitably sized instrument. It is then possible to **sample urine** from each kidney independently. This procedure does, however, carry risks of introducing infection from the lower tract.

Endoscopic biopsy of pathologic lesions is possible but the biopsy instruments are usually too small to obtain meaningful specimens.

ULTRASONOGRAPHY

Ultrasonography is feasible even in large horses, with a suitably configured high power machine (2.5–5.0 MHz). A sector array is required because of the relatively narrow window between the ribs. The right kidney is located behind the dorsal aspects of ribs 12–14, intimately related to the liver, while the left is more caudal and may be visualized from the last rib space or even from the most anterior dorsal aspect of the sublumbar fossa close to the top of the spleen. The size and shape of the kidneys can be estimated reasonably accurately.

Color-flow Doppler can be used to measure blood flow in the renal arteries and veins and in some cases within the substance of the kidney.

Ultrasonography is an essential aid to safe **percutaneous renal biopsy** (*q.v.*).

RENAL BIOPSY

Renal biopsy is a useful technique and can provide a definitive diagnosis in many cases, especially in diffuse renal disease. However, the procedure carries **significant risks** including **perirenal hematoma** and heavy (possibly fatal) **hemorrhage**, and is only justified if histopathology is likely to have a significant influence on subsequent therapy. Biopsy specimens examined by light microscopy may appear normal despite clinicopathologic evidence of severe dysfunction and so the value of biopsy is not always worth the risks. Experience is invaluable in minimizing the problems and meticulous procedural technique will limit the number of biopsies required and the associated risks.

Ultrasound guidance is essential and enables a specific site to be biopsied safely. Biopsy of the right kidney via the 17th intercostal space is the preferred procedure and is diagnostically useful provided that a **diffuse bilateral condition such as chronic active glomerulonephritis is present**. The left kidney is less simple and usually can only be sampled by crossing the spleen first. In some cases the biopsy instrument can be guided past the spleen directly into the left kidney.

Automatic or spring-loaded biopsy instruments and adequate restraint (stocks and sedation) are important considerations. The clinician must ensure familiarity with the specific biopsy instruments to be used.

The procedure is best performed under standing sedation using a suitable chute or stocks and an IV combination of an α_2 -adrenoreceptor agonist drug (such as romifidine 0.07 mg/kg, or detomidine 0.03 mg/kg) with an opioid such as butorphanol (0.05–0.1 mg/kg). The procedure should be performed after aseptic preparation of the skin at the chosen site and immediately prior to biopsy an ultrasound check should be made. In some circumstances it may be possible to guide the biopsy instrument using simultaneous ultrasound examination. In all cases biopsy must avoid the renal hilus. Preferred sites are at the caudal pole of the kidney although the location of focal lesions will have a significant influence on the technique and direction of biopsy.

Two biopsies should be obtained: one fixed in 10% formalin solution for histopathology and a frozen one for bacteriology, immunofluorescence testing and electron microscopy.

RADIOGRAPHY

Radiography has limited diagnostic value in examining the urinary system of adult horses, even when contrast studies are used, but in foals the procedure can be helpful. Diagnosis of bladder and ureteral problems in foals can sometimes be confirmed directly but single or double contrast studies can give added information. Inflation of the foal's bladder with 200–250 mL air provides a negative contrast that will possibly identify some pathologic changes in the bladder wall (such as defects in the wall). Positive contrast materials based on iodine (such as **iohexol**) can be infused directly into the bladder via a urethral catheter but can also be infused IV to provide a positive contrast excretory urogram. Positive contrast IV excretory pyelography is performed by injecting an appropriate volume (1 mL/kg iohexol) IV. All these techniques are usually performed in the standing foal.

IV pyelography/excretory urograms can be performed in adult horses and are used mainly to identify ectopic ureters. Suitable contrast medium (e.g.

iohexol) is administered by slow IV injection (at a rate of 1 mL/kg body weight) via a jugular catheter. The first radiographs are taken at 3 min and then sequential views are taken at 2 min intervals thereafter for 6–10 min. By this stage the contrast should be clearly visible in the renal pelvis and passing down the ureters. An ectopic ureter will be seen to discharge into an abnormal site (e.g. the anterior vagina) whereas in the normal ureter(s) the contrast will accumulate in the bladder and be clearly visible. The technique has limitations of size and facilities to take diagnostic lateral radiographs. Combinations of positive and negative contrast can be helpful also but these can be logistically more difficult.

SCINTIGRAPHY

Soft tissue phase gamma scintigraphy and urinary clearance of a radionuclide provide a new and exciting diagnostic mode in some specialized centers. The IV administration of **technetium 99m** results in rapid delivery of the radiopharmaceutical into the urine, and imaging with a high-resolution gamma camera can identify the individual kidneys and ureters within minutes of injection. Delivery to the bladder (or ectopic location of a ureter) can be detected. Similarly a poorly perfused kidney may have little gamma activity when compared to the contralateral normal kidney or when compared with normal kidneys in the event of a bilateral vascular problem. Tumors and sites of inflammation may be detected by prolonged retention of radionuclide in an affected kidney. During orthopedic scintigraphy the delivery of the radionuclide to the bladder can be a significant complication.

HEMATOLOGY AND BIOCHEMISTRY

The hemogram provides non-specific information in cases of **renal failure**. Increases in hematocrit indicate **dehydration**, and in chronic disease a **non-regenerative anemia** is expected. **Leukocytosis** may accompany inflammation of the upper urinary tract and an elevated **plasma fibrinogen** concentration is usually indicative of **septic inflammation**.

Serum creatinine is widely used as an indicator of renal disease while **blood urea** is somewhat less useful. **In combination** these two metabolites can provide significant information but the concentrations of any blood metabolite must be considered along with the **hydration status** of the patient.

Creatinine is a metabolite derived from muscle function that is selectively excreted by the renal tubules after being freely filtered into the urine and is then concentrated in the urine. Dietary protein has no material effect on the production of creatinine. Creatinine is estimated directly from serum or urine and the ratio of blood creatinine to urinary creatinine is usually taken as a measure of renal perfusion or more specifically glomerular filtration rate (GFR, *q.v.*).

Urea excretion is completely passive and the high urinary concentration is achieved directly as a result of medullary hypertonicity in the loop of Henle. Therefore, although high dietary protein results in a corresponding increase in urea excretion, low protein diets do not reduce the “work” of the kidney. Urea is measured from serum or plasma and is a routine laboratory procedure.

Azotemia is a laboratory-derived term used when there are increased blood concentrations of urea and creatinine (and other non-protein nitrogen)

in blood. The term **uremia** (uremic syndrome) is used to describe the widespread effects of high concentrations of urea (azotemia) on body tissues. There is a poor correlation between the severity of uremia and the laboratory-derived concentrations of urea and creatinine. The extent of azotemia is usually highest with renal and post-renal azotemia but the best approach is probably achieved by comparing the blood and urinary creatinine and urea concentrations:

1. A urine to blood creatinine ratio $>50:1$ (reflecting concentrated urine) would be expected in **pre-renal azotemia**.
2. Urine to blood creatinine ratios $<37:1$ probably indicate **renal disease**.
3. A high urinary specific gravity (>1.035) is usually present in pre-renal azotemia.
4. Dilute urine in the face of dehydration is consistent with a diagnosis of renal disease.

Repeat estimation of urea and creatinine at 24–72 h intervals over the initial period of treatment is probably the most useful practical indicator of the nature and prognosis of the condition.

Dietary intake and gastrointestinal function, hydration, acid-base balance, GFR, urinary volumes and the type of renal lesion govern plasma electrolyte concentrations. It is seldom possible to define a state that is invariably consistent with renal failure.

Since the kidneys are the main sites of **potassium excretion**, anuria or oliguria is likely to be associated with **hyperkalemia**, but progressive tubular damage may then lead to hypokalemia.

Oliguria and anuria may cause increased plasma concentrations of sodium and chloride, but progressive tubular damage will be associated with their loss and plasma concentrations may reflect this. If tubular damage is associated with polyuria, then plasma concentrations of sodium and chloride may be within reference ranges (*q.v.*) as a result of dehydration. Renal dysfunction may be associated with hypercalcemia and hypophosphatemia.

Renal failure also causes a shift in the **acid-base balance**. Failure of alkali reserve regulation by tubular cells leads to a state of **metabolic acidosis** (*q.v.*); this may cause an increase in respiratory rate and depth (**Kussmaul's respiratory pattern**).

Indirect biochemical indicators of renal disease include anemia (*q.v.*), hypoalbuminemia and hypercalcemia.

Anemia is a common secondary sign of advanced renal failure, arising from the combination of failure of renal erythropoietin production (reduced production of erythrocytes) and direct bone marrow suppression arising from uremia.

Hypoalbuminemia arises from protein loss in the urine.

Pathologic failure of the normally dominant calcium excretion of the equine kidney results in a clear urine (free of the normal calcium carbonate crystals) with calcium retention. Calcium excretion in horses is the dominant feature but the extent depends largely on **dietary calcium** content. Complete absence of calcium carbonate crystals in normal alkaline urine can therefore be physiologic or pathologic. Hypercalcemia can be a helpful diagnostic feature of advanced renal failure, but there are other conditions, including paraneoplastic pseudoparathyroidism (*q.v.*), that result in a similar finding.

URINALYSIS

Visual inspection

Urine should be visually inspected as soon as it is collected; normal horse urine may change color to red or brown after standing due to the presence of an oxidizing agent known as pyrocatechin. Owners observing discolored urine collected on concrete floors or in snow sometimes mistake this as abnormal.

Tables 12.1 and 12.2 list the chemical and sedimentary characteristics of normal urine and the changes associated with disease. It is important to make the distinction between physiologic and pathologic changes in color. **Normal horse urine** varies from pale yellow to almost colorless. The yellow coloration is due to a normal pigment (urochrome) and its intensity can vary in proportion to the specific gravity. Water deprivation results in the excretion of concentrated urine with a higher specific gravity and more intense color. Physiologic dilution of urine can occur with **psychogenic polydipsia** (*q.v.*) and with **excessive fluid therapy**.

Table 12.1 Chemical characteristics of normal equine urine and changes associated with disease

Parameter	Normal range	Disease
pH	7.0–9.0	Acidity associated with metabolic acidosis (e.g. renal failure)
Protein	Usually <100 mg%	Severe proteinuria associated with glomerular lesions. Raised in inflammatory lesions of urinary tract
Glucose	None	Present when hyperglycemia exceeds threshold (Cushing's disease, diabetes mellitus, stress). Presence without hyperglycemia indicates tubular dysfunction
Ketones	None	Ketosis rare—suggests nutritional stress/protein catabolism
Bilirubin	None	Present in hemolysis or obstructive jaundice
Hemoglobinuria	None	Present in intravascular hemolysis (serum appears hemolyzed)
Myoglobinuria	None	Present in rhabdomyolysis (serum appears clear)

Table 12.2 Sedimentary characteristics of normal equine urine and changes associated with disease

Parameter	Normal content	Disease
Hematuria	None	Hematuria reflects inflammation, trauma, neoplasia or coagulopathy in urinary tract. Trace associated with catheterization
Leukocytes	None	Large numbers associated with inflammation of tract (pyuria)
Transitional	Few	Large numbers reflect inflammation, trauma, neoplasia
Bacteria	None	Moderate to heavy Gram smears/cultures reflect pyelonephritis or cystitis
Crystals	Usually calcium carbonate; occasional triple phosphate; occasional calcium oxalate	Large numbers of triple phosphate indicate infection of tract. Large numbers of calcium oxalate are abnormal, but of uncertain significance
Casts	No cellular casts. Occasional hyaline (mucoprotein) casts	Cellular casts reflect tubular damage in association with protein exudation or leakage

The three most common alterations of urine color from the normal pale yellow color are listed in Box 12.2.

Pathologic red to brown discoloration of urine (pigmenturia) may be a result of one of the following:

1. Hematuria (whole blood in urine)
2. Hemoglobinuria (hemoglobin in urine)
3. Myoglobinuria
4. Certain drugs (e.g. phenothiazine, rifampicin and the diagnostic compound bromsulfophthalein).

Red discoloration is usually due to either hematuria or hemoglobinuria (*q.v.*). Brown discoloration of urine is generally due to myoglobinuria (*q.v.*).

Clinical distinction between myoglobinuria and hemoglobinuria can be difficult and usually relies upon electrophoretic or spectrophotometric analysis. Hemoglobin usually derives from **plasma** and so a comparison to plasma can sometimes be helpful. Myoglobin has a lower molecular weight and lower capacity to bind to protein than hemoglobin and so is usually cleared rapidly by the kidney without any discoloration of the plasma.

Alterations in appearance

Apart from foals, normal horses seldom void water-clear urine. Normal urine is characteristically **turbid and mucinous** for two reasons:

1. Mucous glands within the ureters and renal pelvis result in the characteristic **appearance and texture** of equine urine. Mucus secretion is thought to be an evolutionary adaptation to the presence of the rough/irritant calcium carbonate crystals in the urine.

Box 12.2 Common alterations of urine color

Colorless urine

Diseases that result in polydipsia and polyuria (*q.v.*) frequently result in the production of dilute urine that may be water clear. The principal causes and laboratory features of polydipsia/polyuria are summarized in Table 12.4.

Dark yellow urine

Concentrated urine is produced in the face of dehydration (either a result of pathologic or physiologic relative water loss) or in acute oliguric renal failure (*q.v.*). The most common cause of oliguria in the horse is dehydration associated with such conditions as diarrhea and colic (*q.v.*) in which concentrated urine with a deep amber color and high specific gravity may be produced.

Red to brown urine

Urine does not normally contain erythrocytes and it should not have any red discoloration. Samples collected by catheter may have a few erythrocytes; some of these may lyse and so the sample may be red and have an erythrocyte button after centrifugation. Prolonged storage or exposure to air often gives urine a red-brown color (*q.v.*).

2. On normal diets, urine is often saturated with **calcium carbonate**, which precipitates spontaneously and gravitates to the floor while urine is held within the bladder. A sample obtained at the onset of urination may be much less turbid than one passed at the end of the stream. Therefore, naturally voided urine and urine collected by catheter frequently appears to vary in its turbidity depending on the part of the bladder being drained at the time. Thick sediment is obtained from the floor while the supernatant is almost clear. Sediment will usually be noted if the container is left undisturbed for a short time.

Normal horse urine will **foam on agitation** due to the natural protein content.

Routine urinalysis

Routine urinalysis includes the measurement of specific gravity, pH, protein, glucose, bilirubin, urobilinogen and ketones. Usually these are all performed with a single dipstick and results as a rule are clinically reliable. Microscopic examination of urine sediment after centrifugation is a very useful technique but is often complicated by large amounts of calcium carbonate.

Specific gravity

Urine specific gravity (SG) (or, more correctly, its **osmolality**) is the only indicator of renal **function** in the urinalysis. Urinary specific gravity reflects the ability of the kidney to concentrate urine and is therefore a useful indicator of renal function.

1. The specific gravity of normal equine urine varies between 1.020 and 1.050.
2. Dehydration results in a more concentrated urine (SG over 1.035–1.055).
3. Pre-renal azotemia would be indicated by a high SG and elevated urea/creatinine concentrations.
4. The presence of dilute urine (SG of 1.005–1.020) in an azotemic (elevated creatinine and urea concentrations) or dehydrated horse is indicative of renal azotemia (tubular dysfunction).
5. Fluid therapy in a dehydrated pre-renal azotemia case would result in restoration of the normal concentrations of these metabolites. By contrast, a renal azotemia case would simply produce more urine of an equally dilute nature without normalization of the creatinine and urea concentrations. In acute renal failure, fluid therapy would not normally induce urination within 6 h of the initiation of fluid therapy.

On rare occasions, dilute urine may be found in a hydrated, non-azotemic horse as, for example, in diabetes insipidus (*q.v.*), psychogenic polydipsia (*q.v.*) or diseases that antagonize the action of antidiuretic hormone.

A **24 h water deprivation test** (Box 12.3, *q.v.*) may be necessary to assess renal concentrating ability. However, it is imperative that the horse is carefully monitored during the test to avoid dangerous dehydration. Where dehydration is a real or potential hazard, urine-concentrating ability can be measured following the administration of exogenous antidiuretic hormone.

It should be noted that **renal medullary washout** is due to excessive drinking in the absence of pathology and follows the loss of osmotic gradient

Box 12.3 Water deprivation test

Water deprivation tests are used to identify renal failure and to differentiate psychogenic polydipsia from neurologic (central) and nephrogenic (renal) diabetes insipidus.

These tests **must not** be performed in horses that are azotemic (*q.v.*) or show evidence of any dehydration. It is essential therefore that an **accurate body weight** is taken before embarking on the test, and accurate weighing should be available during the test procedure.

The procedure for a water deprivation test is as follows:

1. Take a routine blood sample and submit for routine hematology, total protein and albumin and urea and creatinine.
2. Weigh the horse accurately.
3. Remove water from the stable in the evening (so that the test can be performed the following morning). Sometimes feed is removed but this is not likely to affect the test materially. Concentrate and salty foods must not be given.
4. Empty the bladder by catheterization and determine urine specific gravity.
5. Weigh the horse and obtain urine and blood samples at 4–8 h intervals.
6. The test should be stopped if the horse shows an ability to concentrate urine (SG rising > 1.025) or if weight loss reaches 5% or if any overt evidence of azotemia or dehydration develops.

Interpretation of the test can be summarized as follows:

1. Normal horses show rapid urine concentration with SG rising > 1.025 .
2. Horses with psychogenic polydipsia also show normal concentration ability.
3. A low or suboptimal SG suggests diabetes insipidus or renal medullary washout (see text).
4. If urine does not concentrate at 24 h to SG > 1.025 , an extended modified (partial water deprivation test is advisable) (see text).

within the renal tubules. In this case it is possibly better to perform a **partial water deprivation test**. The partial water deprivation test is performed by restricting water intake to 40–45 mL/kg/day for several days; water should be offered in small volumes frequently through the day. This will usually restore the gradient, the urine SG will rise to > 1.025 and the associated polydipsia will usually resolve. An increase in SG > 1.025 suggests **psychogenic polydipsia** (*q.v.*) while failure to concentrate > 1.025 suggests diabetes insipidus (*q.v.*).

pH

Horse urine is usually **alkaline** (pH 7.0–9.0). Attempts to acidify urine (to assist dissolution of calculi or treat bacterial infections of the lower urinary tract) traditionally relied upon dietary administration of ammonium chloride or sodium acid phosphate (sodium dihydrogen phosphate). **Neither method is well tolerated and neither is effective.**

Acidic urine can be established by alteration of the acid-base balance of the diet (**dietary cation–anion balance/DCAB**). It is calculated using the equation:

$$\text{DCAB (mEq/kg dry matter)} = [\text{Na} + \text{K}] - [\text{Cl}]$$

Acidification results because of the ion exchange that takes place in the kidney and gastrointestinal tract. A diet with a high DCAB value (300+) increases body pH, while one with a low DCAB (<100) reduces body pH. **A low DCAB diet** is generally high in Cl^- ions. High Cl^- causes a release of bicarbonate ions into the gastrointestinal tract and urine. This leads to a drop in body pH. On the other hand, **a high DCAB diet** is high in Na^+ and particular K^+ ions. High cation intakes increase intestinal loss of H^+ and increase absorption of Na^+ and K^+ leading to an increase in body pH. Low dietary DCAB, i.e. diets that are anionic or acidic, cause a **metabolic acidosis** (*q.v.*), which in turn reduces the pH of blood and urine. If the horse is producing acidic urine, the normal sediment of calcium carbonate crystals may not form. Low DCAB rations also increase urinary mineral loss, particularly calcium, and so the urine could become cloudier, if the urine pH did not become acidic.

Protein

Urine protein concentration in normal horses is usually <1.00 g/L and the protein to creatinine ratio should be <1:1. Although proteinuria (and more specifically **albuminuria**) is frequently used to support a diagnosis of **renal failure** (*q.v.*) or insufficiency, traces of protein are commonly detected in normal horses. This is probably due to the non-specific reaction on “dipstick” tests to alkaline urine. Furthermore, the normal protein content can be misleading.

Abnormal loss of albumin is a result of **glomerular failure** (*q.v.*). The molecules should be retained effectively and, with the exception of the normal proteinuria of young foals (*q.v.*), albuminuria is always significant.

Hemoglobin

Normal horse urine contains neither blood nor hemoglobin. Erythrocytes, free hemoglobin and myoglobin are the most common abnormal pigments in horse urine and they can often be detected visually. **Ortho-toluidine test strips** can identify invisible amounts of blood (**microhematuria**) or hemoglobin and can also differentiate between free hemoglobin (hemoglobinuria) and intact erythrocytes (hematuria) (*q.v.*).

Red cells in the urine (**hematuria**) usually derive from renal or post-renal **hemorrhage**; the latter are more common but the former are usually more profuse (*q.v.*). The red color will fall to the bottom of the sample when centrifuged or allowed to sediment if hemorrhage is present.

Free hemoglobin (**hemoglobinuria**) usually derives from **intravascular hemolysis**. Centrifugation of a truly hemoglobinuric urine specimen will result in no detectable “button” of red cells at the bottom of the tube and a **uniform redness to the spun sample**.

Combined hematuria and hemoglobinuria may be found on some occasions, such as if erythrocytes lyse in hyposthenuric urine, and so both intact cells and free hemoglobin may be detected.

Box 12.4 The Blondheim test for myoglobinuria**Stage 1**

1. Add of 1 mL urine to 3 mL of 3% sulfosalicylic acid.
2. Mix and filter or centrifuge.

If the pigment is precipitated it is a protein and therefore *may* be **myoglobin** or **hemoglobin**. If, however, the pigment is not precipitated then the pigment is not a protein and alternative explanations for pigmenturia must be sought.

Stage 2

3. To 5 mL of urine add 2.8 g ammonium sulfate and dissolve by mixing. This brings the urine to 80% saturation.
4. Filter or centrifuge the mixture.

If the filtrate displays an abnormal color, myoglobin is present. If only the normal urine color is present in the supernatant then the precipitated pigment is hemoglobin.

It is important to realize that erythrocytes may hemolyze if the urine sample is either stood for any length of time or if the sample is agitated roughly. Careful collection, prompt cooling of the sample and timely analysis are, therefore, recommended. Collection of free-flow samples during micturition can give a misleading result and so it is sometimes helpful to obtain the **whole urine production** or **sequential samples** so that analysis can provide useful information. Catheterization of the bladder of mares or geldings is practical but again the sample so obtained may be misleading. In general it is wise to collect several samples unless a diagnosis can be established definitively from a single one.

A positive “hemoglobin” test may also arise if myoglobin is present, but it cannot identify myoglobin specifically. Differentiation between myoglobin and hemoglobin can be made using spectrophotometric methods and/or the **ammonium sulfate precipitation test** (Blondheim test*, Box 12.4) (*q.v.*). Unfortunately this test has largely been ignored but it is a simple and practical way of separating out the two major causes of pigmenturia.

The Blondheim test is applicable to freshly voided urine or to properly preserved urine. Urine can be preserved for the test by adjusting the pH to 7.0–7.5 (this actually approximates to normal urine but not necessarily to urine from horses with acidosis) and then refrigerated at 4°C. Urine preserved in this way can be tested for up to 2 mo or more despite a moderate degree of bacterial contamination.

Glucose

Urine glucose tests are extremely sensitive and care must be taken when collecting urine into non-medical receptacles in case there is residual sugar in the container or its cap. **No glucose is present in normal urine.**

* Blondheim, S.H., Margoliash, E., Shafir, E. (1958) A simple test for myohemoglobinuria (myoglobinuria), *Journal of the American Medical Association* 167: 453–454.

A positive glucose test reflects either a **reduction in tubular resorption** (often termed “a reduction in renal threshold”) or an **abnormal blood glucose concentration** (often expressed as “exceeding the renal threshold”). **Diabetes mellitus** (*q.v.*) is extremely rare in horses but **glycosuria** is a common feature of **equine Cushing’s disease** (*q.v.*); lesser concentrations may simply reflect **renal failure**.

Urine sediment

Microscopic examination of the **centrifuged sediment** in the laboratory is rewarding. Normal sediment usually has a large amount of calcium carbonate crystals. Abnormal crystals include calcium oxalate and calcium phosphate. Urine sediment from normal horses may occasionally contain **hyaline casts that appear as slightly refractile tubular structures**, especially if the horse is undertaking strenuous work, but granular/protein, erythrocytic and fatty tubular casts are abnormal. These are denser and have a better defined form than the rather amorphous hyaline casts. A small number of leukocytes and bacteria may be observed in normal horses, especially in naturally voided samples from mares.

Delays in examination, especially at room temperature, usually cause artifactual degeneration in cells and allow bacterial proliferation. Usually, however, specific cell types can be identified. Samples should be collected fresh so far as is possible and should be collected into a sterile container. The sample should be stored in a refrigerator at 4°C until analysis can be performed. Urinary infection is usually indicated by high numbers of neutrophil leukocytes in urine but this does not indicate specifically if the origin is renal, ureteral or the bladder. It can be difficult to differentiate contaminant (incidental) bacteria from pathogens in samples that have been stored for more than 12 h even if they have been refrigerated. Where cytology only is required, a drop or two of 10% formalin solution can be added to the urine to maintain cell structure. This, however, will clearly completely negate any attempt at culture.

Erythrocytes and ghost cells will be seen in cases of hematuria (*q.v.*) even if a degree of hemolysis has occurred in the urinary tract or after collection of the sample. Grossly abnormal cells, including neoplastic and extensive sheets of transitional or cuboidal epithelial cells, indicate severe abnormality.

URINARY ENZYMES

Gamma glutamyltransferase (GGT) is found in the liver, pancreas and luminal brush border of the proximal tubular cells. This enzyme is not excreted by glomerular filtration, so when it is detected in **urine** it is strongly indicative of **tubular damage**. Because it appears before azotemia develops, it is a sensitive indicator of early (acute) renal tubular disease such as **acute tubular necrosis** (*q.v.*).

Urinary GGT concentrations are conventionally expressed as a ratio to urinary creatinine concentrations to compensate for variations in urine flow rate at the time of sampling:

$$\frac{\text{GGT (IU/L)}}{\text{UCr (}\mu\text{mol/L)}}$$

Horses with **renal compromise** have values ≥ 25 but urinary GGT values fall once the acute insult has ceased, despite persistent tubular dysfunction. The value of this assay in progressive or chronic renal failure is therefore doubtful.

GLOMERULAR FILTRATION RATE

In health the **glomerular filtration rate (GFR)** remains remarkably constant due to the intrarenal regulatory mechanisms; the net urinary excretion of an electrolyte is governed by GFR and the efficiency of tubular resorption. GFR can be measured by several methods including clearances of endogenous creatinine or exogenous inulin, or radionuclide (^{99m}Tc -DTPA) or plasma disappearance of sodium sulfanilate, phenolsulfonphthalein or radiolabeled compounds. Certain drugs such as the **potentiated sulfonamides** reduce tubular secretion of creatinine and so may induce a rise in serum creatinine and a fall in measured clearance.

Creatinine is excreted by filtration alone and its rate of excretion therefore provides a good indicator of the GFR, even during renal dysfunction. The only practical method of measuring (estimating) the GFR in horses with normal or near normal renal function is through measurement of the creatinine clearance. Urea is not a useful parameter to use to calculate GFR.

The normal GFR of horses is between 1.6 and 2.0 mL/min/kg and this must be reduced by 60–75% to result in a detectable increase in serum urea and creatinine concentrations. Measurement of the circulating concentrations of creatine and urea are relatively insensitive indicators of renal function because they change relatively slowly with time.

A pathologic reduction in intrarenal blood flow, glomerular damage or loss, or obstruction to the free flow of ultrafiltrate along the renal tubular system causes the GFR to fall, and with it the ability of the kidney to eliminate waste material and to regulate the volume and composition of body fluid will decline. This is manifest as a rise in blood urea and creatinine concentrations and a reduction in the measured GFR.

There is no convenient method of collecting total urine voided by ambulatory foals or mares, but urine output can be collected in male horses by placing a urine collection device around the abdomen. When monitoring urine output in critically ill foals and mares is desired, it can be accomplished by use of an indwelling **Foley catheter** and **urine collection bag** (closed system). The risk of ascending infection can be reduced by placing a one-way valve (such as the cut off finger of a surgical glove) over the end of the catheter to prevent aspiration of air and bacteria.

FRACTIONAL ELECTROLYTE EXCRETION

Creatinine clearance is a useful standard against which the clearance of an electrolyte may be compared in health or disease. The **fractional excretion (FE) of an electrolyte** is defined as the per cent ratio of its clearance to the clearance of endogenous creatinine. In normal homeostatic balance, FE values vary with dietary and water intake variations, but usually fall within a

Table 12.3 Fractional excretion ratios of the major electrolytes as calculated from the serum and urinary creatinine

Electrolyte	Sodium	Potassium	Calcium	Inorganic phosphate	Chloride
FE ratio (%)	0.01–1.00	15–75	2.0–3.0	0.04–1.19	<4

definable range. With a loss of tubular resorption the excretion of an electrolyte is often increased and its FE rises above the normal range. The FE is derived as follows:

$$\frac{\text{urinary concentration of electrolyte (uE)}}{\text{plasma concentration of electrolyte (pE)}} \times \text{urine flow rate/min} \times 100\%$$

divided by

$$\frac{\text{urinary concentration of creatinine (uCr)}}{\text{plasma concentration of creatinine (pCr)}} \times \text{urine flow rate/min}$$

which can be simplified to:

$$\text{FE} = \frac{\text{uE}}{\text{pE}} \times \frac{\text{pCr}}{\text{uCr}} \times 100\%$$

The FE of an electrolyte is therefore calculated from urinary and plasma concentrations of the electrolyte and creatinine. The FE ranges for healthy horses are shown in Table 12.3.

In general terms, a persistent increase in the FE of one or more electrolytes (frequently sodium and phosphorus) is suggestive of **tubular dysfunction** but there are a number of caveats to the interpretation of results of FE calculations:

1. Clearance is influenced by dietary, hydration and endocrine factors.
2. In health, urinary concentrations of electrolytes and their rates of excretion vary between horses and within the same individual through the day.
3. Measurements in horses receiving IV fluids will be spurious, and electrolytes trapped in urinary crystals (calcium and occasionally phosphorus) are not measurable.

DISORDERS OF THE EQUINE URINARY TRACT

URINARY FUNCTION IN NEONATAL FOALS

Special considerations of renal function in the foal

The fetal urinary tract is immature and has limited control of fluid and electrolyte balance and removal of nitrogenous waste products; the fetus relies heavily (but not exclusively) on the placenta.

Normal colt foals will void a normal stream of urine within 4 h of birth while the first urination of filly foals is often delayed up to 6 h. This has implications

for the detection of **patency of the urinary tract** (*q.v.*). Mature renal function is not achieved for several weeks after birth. Foals often have a **transient proteinuria** for the first 2–3 days as a result of filtration of small molecular weight proteins absorbed with colostral protein. The high dietary fluid intake results in **acidic urine** of **low specific gravity** (1.001–1.004), low osmolarity and high volume (148 mL/kg/day, i.e. up to 6–7 L/day). A few epithelial cells and calcium oxalate crystals may be present in normal foal urine. However, the presence of erythrocytes, leukocytes, casts, hemoglobin or myoglobin in foal urine is **always abnormal**.

Serum creatinine elevations in neonatal foals
